- **Macrotrabecular variant of hepatoblastoma:** Tumor is composed of >10 cells thick plates arranged in trabecular fashion.
- **Small cell (undifferentiated) variant of hepatoblastoma:** Tumor has more primitive histology with predominance of small to medium-sized cells arranged in loose clusters.
- **Epithelial–mesenchymal variant of hepatoblastoma:** Tumor consists of teratoid features, comprising of spindle or oval cells with osteoid, cartilage or other sarcomatoid characteristics. It is worth mentioning that there is absence of portal tracts in hepatoblastoma. The tumor cells show pleomorphism and mitoses in comparison to minimal pleomorphism and low mitotic figures. Histology of hepatoblastoma is shown in Fig. 21.88.

Immunohistochemistry Technique

Hepatoblastoma shows positivity of α-fetoproteins (AFP), Hep Par 1, human chorionic gonadotropin (hCG), cytokeratin, carcinoembryonic antigen (CEA), glycipan 3, epithelial membrane antigen and vimentin.

Markers	Expression
α-Antitrypsin	Positive
AFP	Positive
Hep Par 1	Positive
hCG	Positive
Cytokeratin	Positive
CEA	Positive
Glycipan 3	Positive
EMA	Positive
Vimentin	Positive
Arginase	Positive

Prognostic Factors

Prognosis of hepatoblastoma is better than the hepatocellular carcinoma. The α-fetoprotein (AFP) levels are commonly elevated. When AFP is not raised at diagnosis, the prognosis is poor.

Patient with <1 year of age, histologic variants, i.e. macrotrabecular and small cell types of hepatoblastoma are associated with poor prognosis.

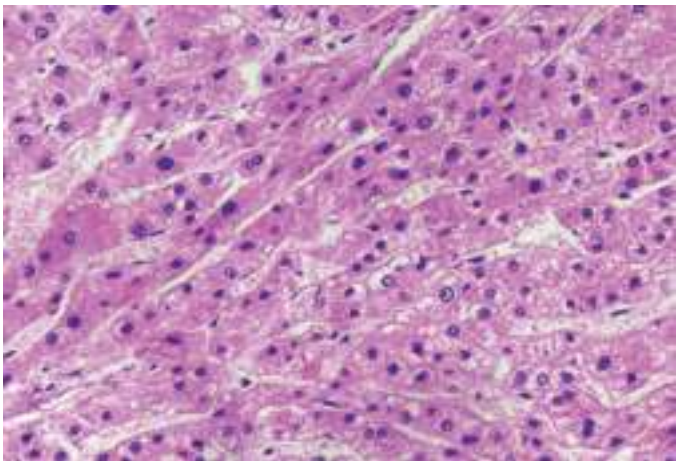

Fig. 21.88: Hepatoblastoma. Tumor is composed of polygonal cells with central round nuclei and prominent nucleoli. The 2–3 cells thick plates are arranged in sheets, trabeculae and solid groups. There may be foci of hematopoiesis (400X).

Children with fetal variant have better prognosis with survival for an average of 9 years. Complete surgical resection remains key treatment for achieving long-term survival.

HEPATIC ANGIOSARCOMA

Hepatic angiosarcoma is a rare malignant vascular tumor of liver. It most often occurs in adults. It may also affect children.

Risk Factors

Predisposing factors for development of hepatic angiosarcoma include macronodular cirrhosis, hemochromatosis and prolonged exposure to drugs, e.g. thorotrast, polyvinyl chloride (PVC), arsenic and androgens.

Clinical Features

Patient with hepatic angiosarcoma presents with abdominal distension and discomfort, weight loss and fatigue. Presence of jaundice, ascites and hepatomegaly is usually associated with advanced disease.

Surgical Pathology: Hepatic Angiosarcoma

Light Microscopy

- Hepatic angiosarcoma tumor is composed of anastomosing vascular channels lined by atypical and proliferative active endothelial cells.
- Tumor may vary from well differentiated to poorly differentiated anaplastic lesions.

Immunohistochemistry Technique

Tumor cells express positivity for immunohistochemical markers factor VIII related antigen, CD31, CD34, p53 and vimentin.

Markers	Expression
▪ Factor VIII related antigen (F VIII R:Ag)	▪ Positive (100%)
▪ CD31	▪ Positive (100%)
▪ CD34	▪ Positive (100%)
▪ p53	▪ Positive (100%)
▪ Vimentin	▪ Positive (100%)

Differential Diagnosis

Hepatic angiosarcoma should be differentiated from Kaposi sarcoma on immunohistochemistry. Tumor cells of Kaposi sarcoma show positivity for human herpesvirus 8 (HHV-8) and BCL-2.

Prognosis

Hepatic angiosarcoma metastasizes to regional lymph nodes, lungs, bones and other regions. Mortality is high in these patients.

HEPATIC EPITHELIOID HEMANGIOENDOTHELIOMA

Hepatic epithelioid hemangioendothelioma is a low-grade malignant vascular tumor, which arises from small blood vessel. It may rarely present as an intravascular neoplasm. Various sites are skin, deep soft tissue, bone, lung and liver. It affects children and adults.

Clinical Features

Patient presents with vascular thrombosis and painful lump in superficial or deep soft tissue. Patient with bone lesion presents with asymptomatic osteolytic lesion. Involvement of lung and liver by tumor may be asymptomatic.

Surgical Pathology: Epithelioid Hemangioendothelioma

Gross Morphology

Epithelioid hemangioendothelioma neoplasm excised from superficial and deep soft tissue is white, firm and sometimes calcified. Lesion from lung may show thrombosed blood vessel lesion.

Light Microscopy

- Epithelioid hemangioendothelioma is composed small uniform epithelioid to bland spindled neoplastic cells without mitoses, arranged in nests, cords and single-file arrays. These neoplastic cells are embedded in dense myxochondroid or myxohyaline matrix. Necrotic debris, hyaline collagen and thrombosed material may be demonstrated within the blood vessel (Fig. 21.89A).
- Approximately 30% of epithelioid hemangioendothelioma shows anaplastic features, i.e. high nuclear grade, numerous mitoses and necrosis with aggressive clinical course referred as malignant or high-grade epithelioid hemangioendothelioma.

Immunohistochemistry Technique

Hepatic epithelioid hemangioendothelioma shows positivity for CD31, CD34, FLI-1, vWF and low molecular weight cytokeratins (25%). Epithelioid hemangioendothelioma shows positivity for CD34 (Fig. 21.89B and C).

Markers	Expression
▪ CD31	▪ Positive
▪ CD34	▪ Positive
▪ FLI-1	▪ Positive
▪ vWF	▪ Positive
▪ Cytokeratins (LMW)	▪ Positive (25%)

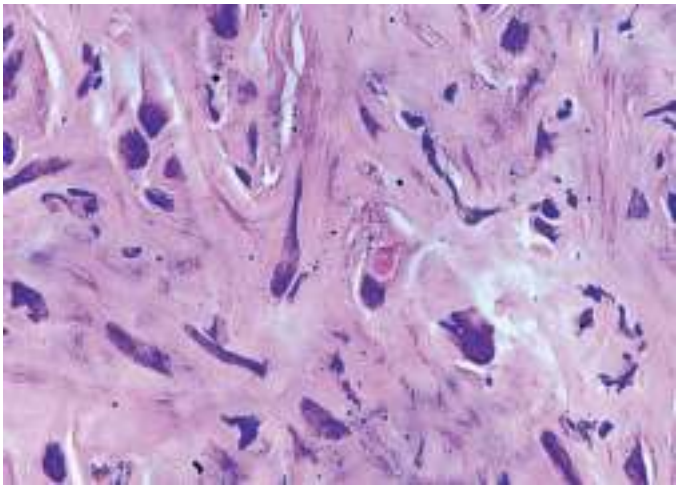

Fig. 21.89A: Hepatic epithelioid hemangioendothelioma. It is composed of small uniform epithelioid to bland spindled neoplastic cells without mitoses, arranged in nests, cords and single-file arrays. Tumor cells are embedded in dense myxochondroid or myxohyaline matrix. Necrotic debris, hyaline collagen and thrombosed material may be demonstrated within the blood vessel (400X).

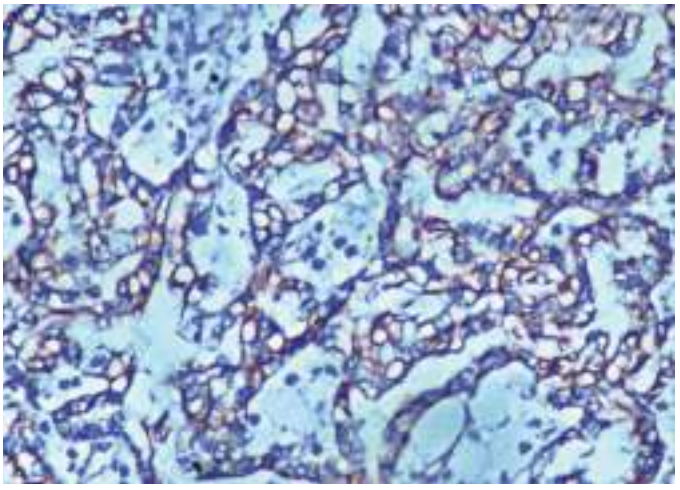

Fig. 21.89B: Hepatic epithelioid hemangioendothelioma. It shows positivity for CD34 (100X).

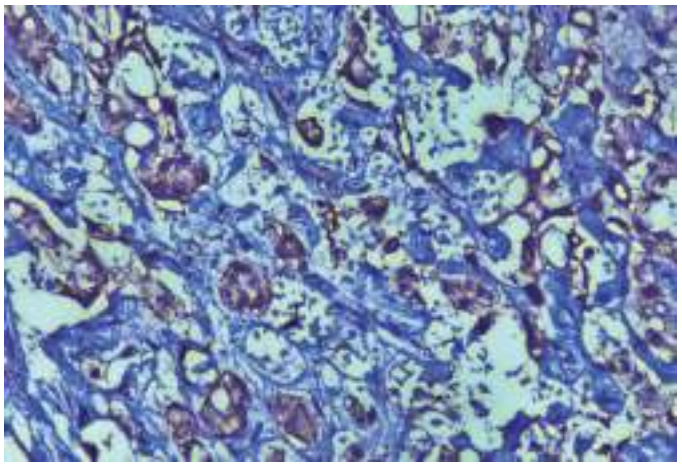

Fig. 21.89C: Hepatic epithelioid hemangioendothelioma. It shows positivity for CD34 (400X).

Differential Diagnosis

Hepatic epithelioid hemangioendothelioma should be differentiated from epithelioid hemangioma, epithelioid angiosarcoma, and metastatic carcinoma especially lobular carcinoma of breast. Distinguishing features of hepatic epithelioid hemangioendothelioma and metastatic adenocarcinoma are given in Table 21.89.

Prognosis and Treatment

Hepatic epithelioid hemangioendothelioma is treated by wide surgical excision. Adjuvant radiotherapy may be in selected cases. Hepatic epithelioid hemangioendothelioma should be treated by liver transplantation. It may metastasize to distant sites in 17% of cases with poor prognosis. Classic low-grade and high-grade epithelioid hemangioendothelioma have risk of local recurrence and distant metastasis. Death occurs due to hepatocellular failure.

METASTATIC TUMORS (LIVER METASTASES)

Despite all the foregoing material, hepatic metastatic malignancies are commonest. Such metastases may be present in 40% of adults with malignant disease elsewhere.

- Metastatic deposits are visible on the capsular surface of the liver. These deposits show multiple nodules of variable sizes with central depression as a result of tumor necrosis.
- Liver metastases arising from epithelial, mesenchymal and round cell tumors are shown in Fig. 21.90.

Immunohistochemistry technique in malignant tumors metastasizing to liver is given in Table 21.90. Gross and histologic features of primary and secondary malignancies of the liver are given in Table 21.91.

MODE OF METASTASES TO LIVER

- **Direct spread:** Liver may be involved by direct spread from malignant neoplasms in the vicinity such as pancreas, extrahepatic bile duct, stomach and gallbladder.

Table 21.89 Distinguishing features of hepatic epithelioid hemangioendothelioma and metastatic adenocarcinoma

Features	Hepatic Epithelioid Hemangioendothelioma	Metastatic Adenocarcinoma
Clinical features		
Patient age	Mean 40 years	Mean 60 years
Gross morphology		
Underlying liver disease	Absent	Absent
Unicentric or monocentric	▪ Multiple or solitary ▪ Well-circumscribed tumor	▪ Multiple > solitary lesions ▪ Ill-defined
Histologic features		
Gland formation	Absent	Present
Tumor cell morphology	Epithelioid morphology	Epithelioid morphology
Cytoplasmic vacuoles	Necrotic debris, hyaline collagen and thrombosed material within the blood vessel	Intracytoplasmic lumina containing mucin
Nuclear features	Mild to moderate atypia	Severe atypia
Mitoses	Occasional mitosis	Frequent mitoses
Stroma of tumor	Myxoid or hyalinized stroma	Desmoplastic stroma
Vascular invasion	Multicentric invasion in large veins	Lymphovascular invasion around portal tracts

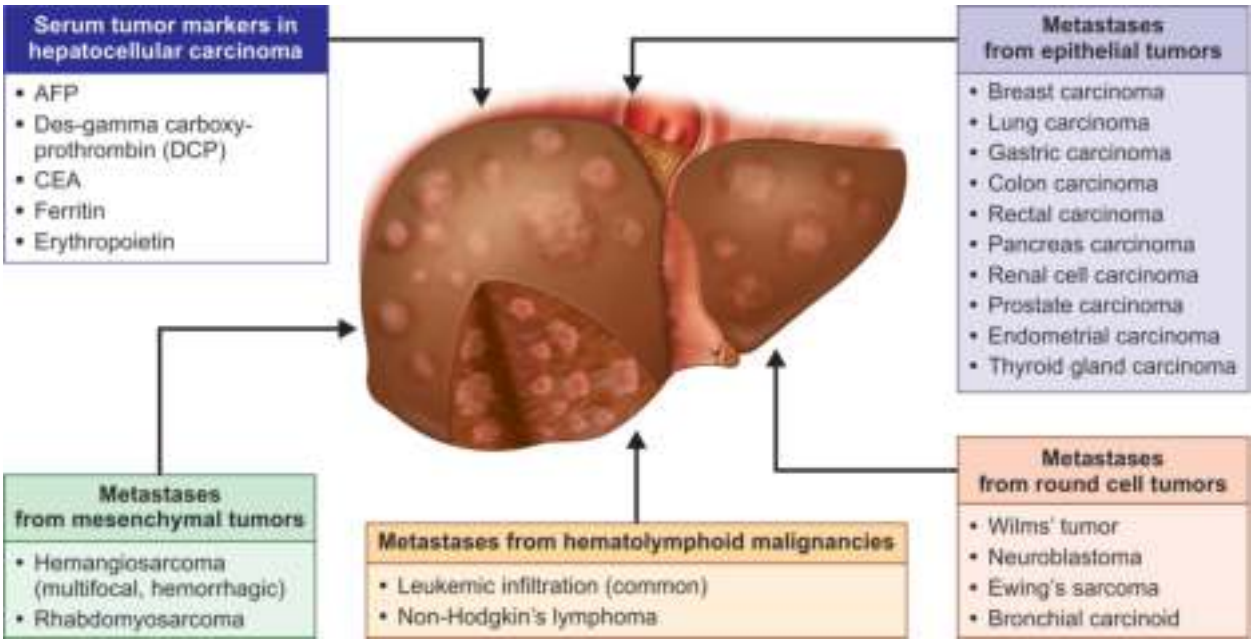

Fig. 21.90: Liver metastases from epithelial, mesenchymal and round cell tumors.

Table 21.90 Immunohistochemistry technique in malignant tumors metastasizing to liver

Tumor	Immunohistochemical Markers
Liver metastases from epithelial tumors	
Breast carcinoma	ER, PR, HER2/neu, CK7, GCDFP-15 (gross cystic disease fluid protein 15) and mammoglobulin, Ki-67, eK5, NY-BR1, E-cadherin
Lung carcinoma	EMA, CK7 and TTF-1
Gastric carcinoma	Cytokeratin, EMA and CEA
Colorectal carcinoma	CK20, CDX2, CEA and β-catenin
Pancreas carcinoma	Vimentin, α_1-antitrypsin and α_1-antichymotrypsin
Renal cell carcinoma	Coexpression of cytokeratin and vimentin
Prostate carcinoma	Prostate-specific antigen (PSA), prostate-specific alkaline phosphatase (PSAP), NXK31, prostein and p63
Endometrium carcinoma type 1	ER, PR and PTEN
Thyroid gland carcinoma	TTF-1, thyroglobulin, CA 125 and cell surface glycoprotein
Liver metastases from lymphoid cell malignancies	
NHL B cell (common)	CD10, CD19 and CD20
NHL T cell (common)	CD3
Leukemias* (common)	Cytochemistry, flow cytometry and cytogenetics
Liver metastases from mesenchymal tumors	
Rhabdomyosarcoma	Desmin, myogenin, myoglobin, MyoD1 and vimentin
Metastases from round cell tumors	
Wilm's tumor	WT1 and WT2
Neuroblastoma	Nonspecific enolase (NSE), neurofilament, chromogranin, synaptophysin
Ewing sarcoma	CD99 (MIC2 specific marker), vimentin and NSE
Bronchial carcinoid tumor	NSE, chromogranin, synaptophysin and cytokeratin

**Hemangiosarcomas (multifocal, hemorrhagic) may also metastasize to liver.*

Table 21.91 Gross and histologic features of primary and secondary malignancies of the liver

Gross and Histologic Features	Conventional Hepatocellular Carcinoma	Metastatic Adenocarcinoma	Metastatic Melanoma	Metastatic Endocrine Tumor
Gross morphology				
Tumor number	Solitary > multiple	Multiple > solitary	Multiple	Multiple
Background liver morphology	Cirrhotic background	Unremarkable	Unremarkable	Unremarkable
Histologic features				
Architecture	Neoplastic cells arranged in trabecular, acinar, pseudo-glandular architecture with mitoses, bile in neoplastic cells	Neoplastic cells form glandular structures with mucin in lumen and cytoplasm	Neoplastic cells arranged in sheets and nests	Neoplastic cells arranged in trabecular and forming glandular structures
Quality of stroma of tumor	Absent or minimal stroma, fibrous in fibrolamellar variant	Desmoplastic stroma	Minimal stroma	Hyalinized stroma
Cytomorphological features	Uniform neoplastic cells resembling hepatocytes; pleomorphism in high-grade tumor	Neoplastic cells pleo-morphic and signet ring cells	Neoplastic cells with eosinophilic cytoplasm containing melanin, eccentric nuclei with macronucleoli	Neoplastic round cells with eosinophilic cytoplasm and stippled chromatin
Mitoses	Easily demonstrated	Easily demonstrated	Easily demonstrated	Rare

- **Hematogenous route:** Most common malignancies metastasizing to liver in adults include colon, lung, breast, kidney, stomach and malignant melanoma. Metastases confined to liver are more probable in association with tumors drained by portal vein. Blood-borne spread from colorectal carcinoma is most often seen in the liver. Multiple metastases in liver are shown in Fig. 21.91. Solitary liver metastasis is shown in Fig. 21.92.

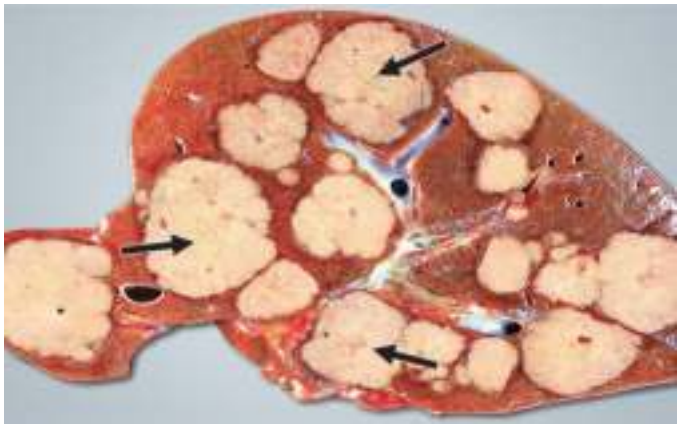

Fig. 21.91: Multiple metastases in liver. Note the numerous mass lesions that are of variable size. Some of the larger ones demonstrate central necrosis. The masses are metastases to the liver. The obstruction from such masses generally elevates alkaline phosphatase, but not all bile ducts are obstructed, so hyperbilirubinemia is typically not present. Also, the transaminases are usually not greatly elevated (arrows).

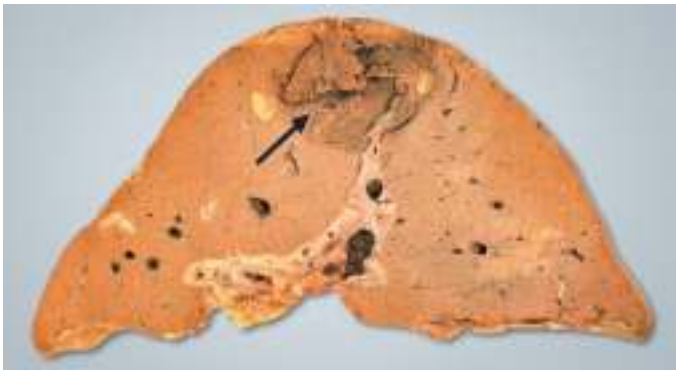

Fig. 21.92: Solitary metastasis in liver (arrow).

CLINICAL FEATURES

Patient presents with massive hepatomegaly with nodules at the free edges, jaundice at a later stage as a result of massive liver involvement and obstruction of major hepatic ducts. There is unexplained increase in the serum concentration of alkaline phosphatase.

IMAGING TECHNIQUE

Tumors metastasizing to liver are most often multiple, however solitary metastatic deposit can be demonstrated by imaging technique. Computed tomographic (CT) scan with contrast of the abdomen in transverse view demonstrates metastases in liver (Fig. 21.93).

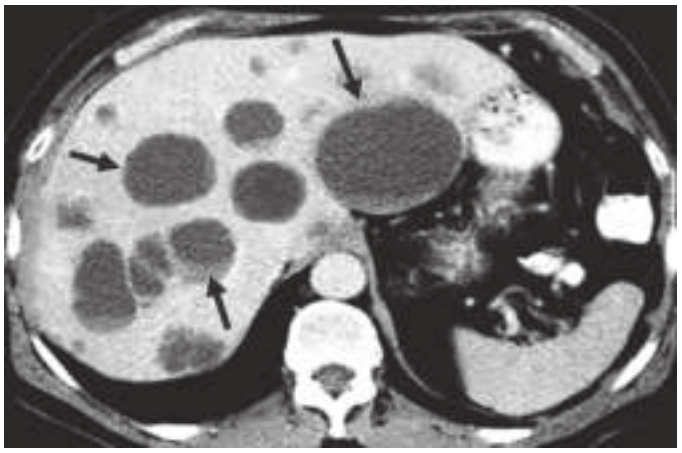

Fig. 21.93: Computed tomographic (CT) scan with contrast of the abdomen in transverse view demonstrates multiple mass lesions representing metastases from a colonic adenocarcinoma. A normal spleen appears at the lower right in the image (on the patient's left) (arrows).

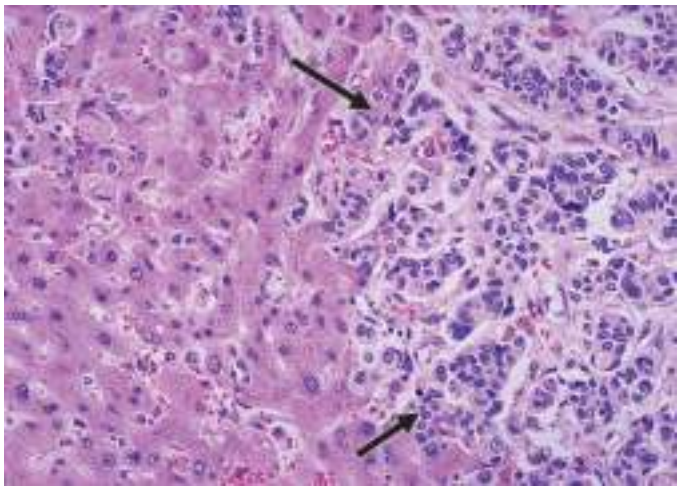

Fig. 21.94: Liver metastases from breast carcinoma. Microscopically, metastatic infiltrating ductal carcinoma from breast is seen on the right, with normal liver parenchyma on the left (arrows) (400X).

Surgical Pathology: Liver Metastases

Light Microscopy

Histologic examination is done on biopsy obtained from liver metastatic deposits. Histologic examination of metastatic deposit in liver from breast carcinoma and from squamous cell carcinoma is shown in Figs 21.94 and 21.95 respectively.

PROGNOSIS

Median survival in untreated cases with liver metastases varies between 4 and 15 months. Patient with solitary liver metastasis has longer survival. Solitary metastasis in liver may be treatable by wedge resection, giving months/years symptom-free remission.

Multiple liver metastases are not resectable. These may respond to chemotherapy.

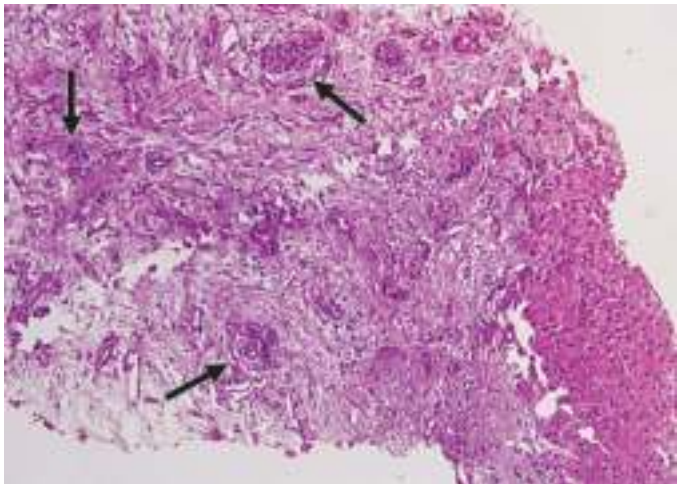

Fig. 21.95: Liver metastasis from squamous cell carcinoma (arrows) (100X).

DISORDERS OF GALLBLADDER

GALLBLADDER: OVERVIEW

ANATOMY

Gallbladder consists of fundus, body and neck, which is covered by serosa except the portion in the liver fossa which merges with liver parenchyma. It is located in the right upper quadrant, under the costal margin at the level of the 9th costal cartilage.

The extrahepatic ducts include the right and left hepatic ducts, which join to form common hepatic duct in the porta hepatis. Common hepatic duct is joined by cystic duct to form common bile duct, which form with pancreatic duct to join and open into the duodenum as the common hepatopancreatic duct guarded by a sphincter called the **sphincter of Oddi**.

HISTOLOGY

Gallbladder consists of a layer of folded columnar epithelium and lamina propria of loose connective tissue that directly rests on muscularis propria and irregularly arranged smooth muscle bundles. External surface of gallbladder is covered by layer of serosa.

PHYSIOLOGY

Bile juice is composed of **bile salts**, water (95%), bilirubin, porphyrins, vitamins, sodium taurocholate and sodium glycolate, cholesterol and phospholipids secreted by the hepatocytes passes through the hepatic ducts stored and concentrated by gallbladder.

Stimuli are received from vagus nerve, secretin, mucus, water and electrolytes for synthesis of bile juice. Bile salts are necessary for emulsification of fats as well as their absorption. Bile juice also activates lipase.

DIAGNOSTIC APPROACH

Cholecystectomy is usually performed for cholelithiasis. **Porcelain gallbladder** is uniformly firm and associated with flattened mucosal surface and submitted to rule out adenocarcinoma.

Endoscopic retrograde cholangiopancreatography (ERCP) is performed to take biopsy for stricture and overt neoplasm. Frozen section is done to evaluate bile duct margins during pancreatoduodenectomy or liver resection for bile duct adenocarcinoma.

NON-NEOPLASTIC DISORDERS

Non-neoplastic disorders of gallbladder are acute and chronic cholecystitis, cholesterolosis, mucocele, choledochal cyst and cholelithiasis.

- Chronic cholecystitis is associated with cholelithiasis in >90% of cases. Classical signs of cholecystitis result from obstruction of the cystic duct by gallbladder stones, which leads to enlarged painful gallbladder distension. Abnormal cholesterol metabolism and bile salts play an important role in the pathogenesis of gallbladder stones.
- Acute cholecystitis is most common during middle age; the chronic cholecystitis occurs most often in elderly people. Classification of cholecystitis is given in Table 21.92.

ACUTE CHOLECYSTITIS

Acute cholecystitis is characterized by full thickness edema, congestion and serosal fibrinopurulent exudate, and most often caused by pyogenic bacteria. It may also occur due to poor or absent blood flow to the gallbladder. Stone impacted in neck or cystic duct results in obstruction of bile flow into the duodenum.

Clinical Features

Patient presents with nausea, vomiting, fever, jaundice (if stone in bile duct), and leukocytosis associated with right upper quadrant and epigastric pain and tenderness. **Murphy sign** is associated with acute cholecystitis.

Table 21.92 Classification of cholecystitis

Acute Cholecystitis
Calculous cholecystitis
Acalculous cholecystitis
Emphysematous cholecystitis
Chronic Cholecystitis
Calculous cholecystitis
Calculous cholecystitis, not otherwise specified
Hyalinizing cholecystitis
Xanthogranulomatous cholecystitis
Acalculous cholecystitis
Lymphoeosinophilic cholecystitis
Eosinophilic cholecystitis
Granulomatous cholecystitis
Diffuse lymphoplasmacytic cholecystitis
Lymphocytic cholecystitis

Surgical Pathology: Acute Cholecystitis

Gross Morphology

- The gallbladder lumen is filled with fibrin, frank pus and hemorrhage, which becomes enlarged and tense. Accumulation of pus in lumen is known as **empyema gallbladder**.
- Patient may also develop gangrenous cholecystitis characterized by hemorrhage, transmural necrosis, and perforation. Serosal surface is covered with inflammatory exudates. Subserosal region exhibits bright red areas of hemorrhages to green-black discoloration.

Light Microscopy

Histopathologic examination of acute cholecystitis shows transmural edema, congestion, serous fibrinopurulent exudate composed of fibrin and polymorphonuclear cells.

Treatment

Acute cholecystitis is initially treated with intravenous fluids and antibiotics which lead to a resolution of the acute inflammation in 70–80% of patients.

Complications

Empyema gallbladder occurs due to accumulation of pus seen in 2–3% of patients with acute cholecystitis. Necrosis of gallbladder results in perforation, abscess formation and peritonitis. Complications of acute cholecystitis are shown in Fig. 21.96.

- Acute inflammation of gallbladder causes edema, vascular compromise and superadded infection resulting in empyema gallbladder (a pus-filled gallbladder).

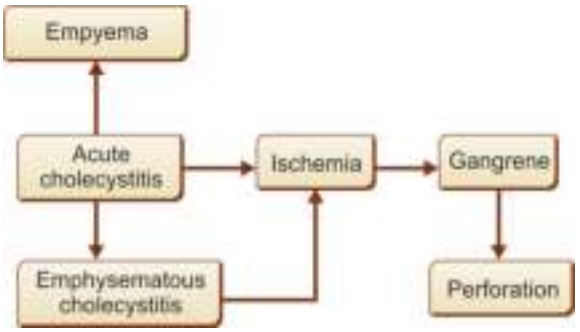

Fig. 21.96: Complications of acute cholecystitis.

- Patient usually experiences severe abdominal pain for more than 7 days.

CHRONIC CHOLECYSTITIS

Chronic cholecystitis is associated with hypertrophy of muscle bundles, fibrosis, chronic inflammatory infiltrate and formation of Rokitansky-Aschoff sinuses. Gallbladder is thickened by fibrosis, which may become rigid.

Etiology

Chronic cholecystitis may develop insidiously or after repeated episodes of acute cholecystitis. It is invariably associated with gallbladder stones.

Clinical Features

Patient may be asymptomatic or symptomatic. Patient with chronic cholecystitis may present with constant or an excruciating colicky pain. Biliary colic and jaundice occur due to obstruction of the biliary system by gallbladder stone.

Infection of static bile causes cholangitis and liver abscess. There is increased risk for development of gallbladder carcinoma in cholelithiasis.

Surgical Pathology: Chronic Cholecystitis

Gross Morphology

- Gallbladder wall is thickened by fibrosis exhibiting gray white in color. The wall is thickened from 2 mm to 1 cm depending on fibrosis.
- Mucosa may be ulcerated. Gallbladder lumen may contain stones impacted in bile (Fig. 21.97).

Light Microscopy

- Epithelium shows formation of '**Rokitansky-Aschoff sinuses**' due to herniation of the lining mucosa into the muscle layers. Rupture of Rokitansky-Aschoff sinuses may lead to '**xanthogranulomatous cholecystitis**' containing lipid-laden macrophages and giant cells mimicking clear cell carcinoma. It is prone to give rise to fistulae. Muscularis mucosa is absent.
- Muscular coat is replaced by **fibrosis**. Muscle bundles are hypertrophied. All the coats are infiltrated by **chronic inflammatory cells** composed of lymphocytes, macrophages and plasma cells. Perimuscular fibrosis is evident.
- Serous coat shows fibrosis. The wall may be markedly thickened, '**porcelain gallbladder**' occurs due to calcification. Light microscopy of chronic cholecystitis is shown in Fig. 21.98.

CHOLESTEROLOSIS (STRAWBERRY GALLBLADDER)

Cholesterolosis (strawberry gallbladder) is characterized by yellow mucosal speckled appearance known as strawberry gallbladder. Cholesterolosis has no association with serum cholesterol elevated level or atherosclerosis. Gross morphology of cholesterolosis is shown in Fig. 21.99.

Fig. 21.97: Gallbladder stones. Cut opened specimen of gallbladder shows multiple faceted white-colored stones. Wall of the gallbladder is thickened.

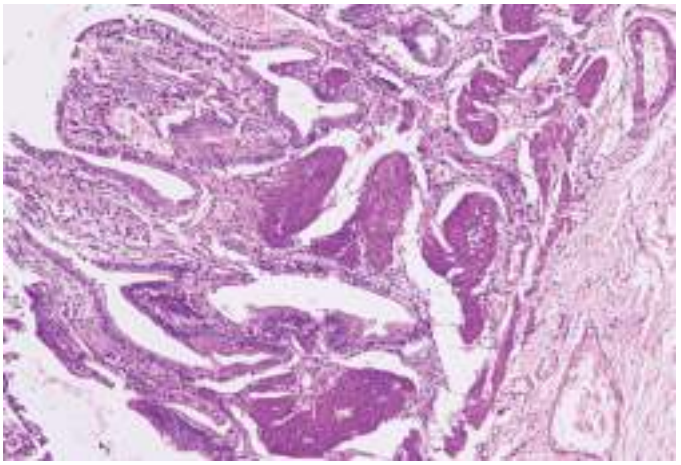

Fig. 21.98: Chronic cholecystitis. It is almost always seen in association with gallbladder stones, though precipitation of bile alone may be sufficient to produce inflammation. There may not be a history of bouts of acute cholecystitis. It shows ulceration of mucosa formation of Rokitansky-Aschoff sinuses due to herniation of the lining mucosa into the muscle layers. There is presence of perimuscular fibrosis (100X).

Fig. 21.99: Cholesterolosis (strawberry gallbladder). Mucosal surface of cut opened gallbladder shows yellow speckled appearance.

Surgical Pathology: Cholesterolosis
Gross Morphology
▪ Cut opened gallbladder specimen shows yellow, flat deposits (focal or diffuse) on mucosal surface. It may have speckled appearance. ▪ Cholesterol polyps may be observed in 20% of cholecystectomy specimens.
Light Microscopy
▪ Histologic examination of cholesterolosis shows presence of cholesterol laden macrophages in the lamina propria of the gallbladder mucosa. ▪ There is no association with inflammatory changes or presence of gallbladder stones. ▪ This finding is incidental without clinical significance (Fig. 21.100).

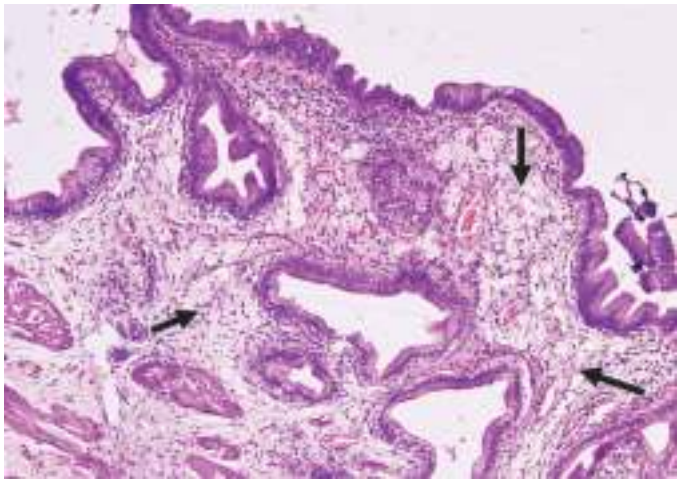

Fig. 21.100: Cholesterolosis (strawberry) gallbladder. Mucosa shows presence of cholesterol laden foamy macrophages in the lamina propria of the gallbladder mucosa (arrows).

Fig. 21.101: Mucocele of gallbladder. It is filled with mucus watery fluid.

MUCOCELE OF GALLBLADDER

Mucocele of gallbladder occurs as a result of sterile long-standing obstruction of the cystic duct by a gallbladder stone. The gallbladder is distended with clear, mucus, watery fluid resulting in flattening of mucosa and thinning of wall. There is absence of bile in gallbladder lumen and inflammatory changes in the wall. Mucocele of gallbladder is shown in Fig. 21.101.

During surgical removal, thin wall of gallbladder demands to avoid spillage of mucus into the peritoneal cavity, so that '**pseudomyxoma peritonei**' is prevented. Pseudomyxoma peritonei becomes seeded with mucus producing epithelial cells and the cavity filled with mucus.

Complications

Mucocele of gallbladder may cause cholangitis, perforation with local abscess, diffuse peritonitis, cholecyst enteric fistula and multiorgan failure.

CHOLEDOCHAL CYST

Choledochal cyst is a form of fibropolycystic disease leading to dilatation of the common bile duct assuming fusiform or spherical shape. Entire lesion should be excised and submitted for histologic examination to exclude biliary intrahepatic neoplasm.

CHOLELITHIASIS (GALLBLADDER STONE DISEASE)

Cholelithiasis is characterized by presence of cholesterol, pigment, or mixed stones in the gallbladder worldwide. It is major cause of morbidity and mortality.

- Risk factors for gallbladder cholesterol stone formation are female sex, obesity, premenopausal and age 40 (**four Fs: female, fat, forty, fertile**). Other risk factors are over age 40, female gender,

high cholesterol diet, increased lipid profile, obesity, sedentary lifestyle, alcohol, tobacco smoking and rapid weight loss.

- Gallbladder stones are usually asymptomatic, however patient may present with severe colicky pain in right upper quadrant with fatty foods, nausea, vomiting and intolerance to fatty food.
- Cholesterol gallbladder stone formation involves four processes: supersaturation of cholesterol, hypomotility of gallbladder, accelerated nucleation of cholesterol in the bile juice and increased synthesis of gel forming mucus. Excess insoluble unconjugated bilirubin precipitates around a nidus forming pigmented stones associated with hemolytic anemia and bacterial infection.
- Complications of gallbladder stones are biliary colic, cholecystitis, common bile duct obstruction, ascending cholangitis, acute pancreatitis, gallbladder stone ileus, mucocele and malignancy. High levels of serum alkaline phosphatase indicate obstructive process by gallbladder stone.
- Cholelithiasis produces histologic changes in the gallbladder mucosa such as acute cholecystitis, chronic cholecystitis, granulomatous inflammation, hyperplasia, cholesterols, dysplasia and gallbladder adenocarcinoma.

BILE JUICE: COMPOSITION

The liver synthesizes bile juice continuously, and enters the gallbladder via hepatic ducts. The gallbladder concentrates and stores it until the duodenum transmits signals to gallbladder to release bile juice into the duodenum for digestion of fat. Bile juice consists of cholesterol, bile salts, bile acids, phospholipids, proteins, bilirubin, sodium bicarbonate and water. Bile juice solutes are shown in Fig. 21.102 and Table 21.93.

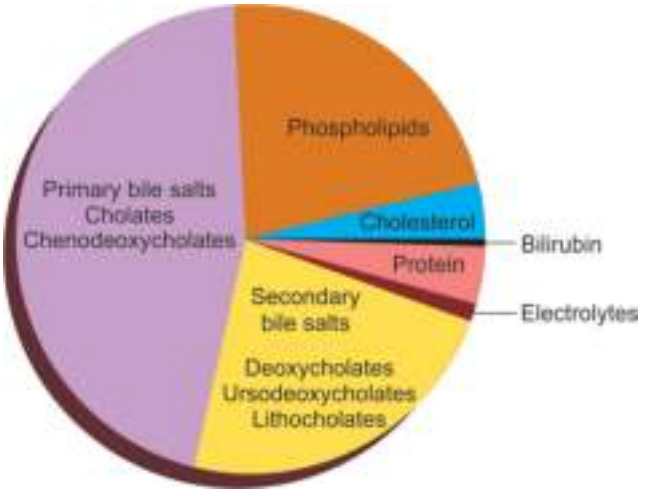

Fig. 21.102: Components of bile juice.

Table 21.93 Bile juice solutes

Bile Solute	% of Solute Present in Bile Solute
Water	97%
Bile salts (cholic acid, chenodeoxycholic acid and deoxycholic acid)	67%
Phospholipids (mainly lecithin)	22%
Protein	4.5%
Cholesterol	4%
Bilirubin (bile pigment)	0.3%
Sodium bicarbonate	Present in small fraction

- **Cholesterol:** Bile contains 4% of cholesterol, which is kept soluble by bile salts and lecithin.
- **Bile salts/acids (cholic acid/chenodeoxycholic acid):** Bile salts are derived from the catabolism of cholesterol and linked with taurine or glycine to form the bile salts. Bile salts constitute 67% of bile, which are mostly reabsorbed in terminal ileum (enterohepatic circulation).
- **Phospholipid (mainly lecithin):** It increases solubility of cholesterol.
- **Proteins:** Bile juice contains 4.5% of proteins.
- **Bilirubin:** It is a by-product of heme degradation.
- **Inorganic salt (sodium bicarbonate):** It keeps bile juice alkaline to neutralize gastric acid in duodenum.
- **Water:** Bile juice contains 97% of water.

GALLBLADDER STONES: CATEGORIES

Vast majority of gallbladder stones are classified into three categories: cholesterol stones (20% cases), pigment stones (5% cases) and mixed stones (75% cases). Depending on chemical constituents in calculus, gallbladder stones are of three types: pure stones, mixed stones and combined stones.

- **Pure gallbladder stones:** Pure gallbladder stone comprises single chemical constituent (**cholesterol** or **calcium bilirubinate** or **calcium carbonate**). Cholesterol stones occur due to disproportion between bile salts/lecithin and cholesterol allows cholesterol to precipitate out of solution and forms stones. Pigment stones occur due to excess of circulating bile pigment (e.g. hemolytic anemia).
- **Mixed gallbladder stones:** Mixed gallbladder stones account for 85% of all gallbladder stones. Most of mixed gallbladder stones are a mixture of cholesterol and calcium salts in variable proportions, which have similar pathophysiology as cholesterol stones.

  Mixed gallbladder stones are multiple and faceted external appearance owing to tight opposition with one other. On cut section, the mixed gallbladder

stones exhibit laminated appearance, which can often be visualized on radiograph due to presence of calcium salts in the stones.

- **Combined gallbladder stones:** Combined gallbladder stones are composed of mixture of salts forming a nucleus surrounded by a shell.

RISK FACTORS

Gallbladder stone disease is a multifactorial disease. Changes in composition of bile juice during synthesis in liver and absorptive ability of gallbladder epithelial lining participate in the pathogenesis of gallbladder stone (cholelithiasis). Risk factors for gallbladder stones are described as under:

- **Race:** Native Americans or Mexican Americans have the highest incidence of gallbladder stones of any specific racial groups.
- **Gender:** Women most common develop gallbladder stones than men especially during the fertile years.
- **Obesity:** Obesity, particularly abdominal or centripetal obesity, is a well-established risk factor for gallbladder stone disease. Obesity is associated with an increased activity of the rate-limiting step in cholesterol synthesis, by hepatic enzyme, 3-hydroxyl-3-methylglutaryl co-enzyme A (HMG-CoA) reductase leading to increased cholesterol synthesis in the liver, its secretion into bile juice and storage in the gallbladder.
- **Female sex hormones:** During pregnancy, female sex hormones are endogenously raised, which adversely influence hepatic bile secretion. Estrogen increases amount of cholesterol in bile and decreases gallbladder activity. These changes allow the cholesterol to crystallize in the gallbladder. Estrogen levels may be related to contraceptive pills, or hormone replacement therapy. Progesterone acts by reducing bile salts secretion and impairing gallbladder emptying leading to stasis.
- **Oral contraceptives:** Oral contraceptives with three months estrogen therapy increase the incidence of gallbladder stone disease in younger women. Estrogen augments functions of the hepatic estrogen receptor-α (ER-α). In the liver, the ER-α receptor stimulates the **SREBP-2** (**sterol regulatory element-binding protein 2**) pathway, promotes cholesterol biosynthesis and hepatic secretion of biliary cholesterol.
- **Rapid weight loss:** Low caloric diet or rapid weight loss exceeding 1.5 kg/week following bariatric surgery increases the risk for gallbladder stone formation especially during the first 6 weeks. These factors reduce gallbladder emptying, so bile becomes concentrated and cholesterol precipitates out into stones.
- **History of gallbladder stones:** People who have gallbladder stones in the past are more likely to develop gallbladder stones in future.
- **Obesity and estrogen imbalance:** Obesity and estrogen imbalance especially in women of 40 years age causes liver to synthesize bile juice that is high in cholesterol or lacking proper concentration of bile salts. When the gallbladder concentrates bile juice, inflammation may occur. Excessive reabsorption of water and bile salts makes the bile less soluble.
- **Diabetes mellitus:** Diabetics have high levels of triglycerides, which increase the risk for gallbladder stones.
- **Liver disease:** Advanced cirrhosis is a well-established risk factor for gallbladder pigmented stones. It is related to altered pigment secretion, abnormal gallbladder motility and/or increased estrogen levels.
- **Crohn's disease:** There is increased risk of development of gallbladder stones in patients with Crohn's disease. Terminal ileum is not able to transport bile acids, so these enter the colon. Biological detergents solubilize unconjugated bilirubin resulting in absorption and return to the liver. The liver then secretes excessive pigment that subsequently precipitates as gallbladder stones. Fasting in Crohn's disease or altered bacterial colonic flora may enhance the deconjugation of bilirubin, which is passively absorbed resulting in increased enterohepatic cycling of the bile pigment.
- **Cystic fibrosis:** Similar to ileal Crohn's disease, cystic fibrosis is associated with bile acid malabsorption due to its binding to undigested dietary nutrients. Gallbladder stone prevalence in cystic fibrosis is 10–30%.
- **Sickle cell disease:** In sickle cell disease, chronic RBCs hemolysis leads to excessive bilirubin excretion with the formation of black pigment stones composed of calcium bilirubinate in gallbladder.
- **Cholesterol lowering drugs:** The drugs that are designed to lower blood cholesterol help to concentrate cholesterol in the gallbladder, thus increasing the risk for forming gallbladder stones.
- **Octreotide drug:** Octreotide drug is a long-acting analogue of somatostatin that inhibits cholecystokinin release, resulting in decreased motility of gallbladder and small intestine. Bile stasis enhances synthesis of deoxycholic acid (bile acid) and cholesterol resulting in precipitation, crystallization of cholesterol and cholelithiasis.
- **Thiazide diuretics:** Thiazide diuretics may increase biliary cholesterol saturation leading to gallbladder stone formation.

PATHOGENESIS OF CHOLELITHIASIS

Bile salts, cholesterol and lecithin are present in the form of mixed micelles and vesicles in gallbladder.

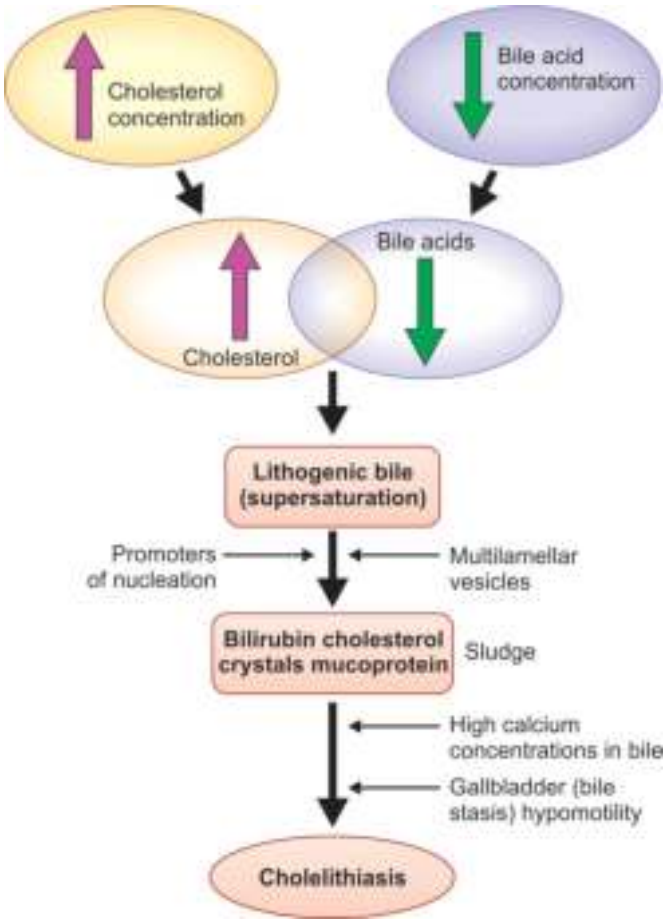

Fig. 21.103: Pathogenesis of gabladder stone formation.

Pathologic changes in gallbladder epithelium may play an important role in the process of gallbladder stone formation. Pathogenesis of gallbladder stone formation is shown in Fig. 21.103.

- **Multilamellar vesicle formation:** Supersaturation of bile juice constituents, i.e. bile salts, cholesterol and lecithin form multilamellar vesicles. The amount of cholesterol in the bile is supposed to increase with age. Hypercholesterolemia is caused by dyslipoproteinemia that results in a linear increase in cholesterol excretion into the bile juice. Cholesterol-7α-hydroxylase is the rate limiting enzyme that regulates the synthesis of bile acids from cholesterol. It is exclusively expressed in the liver. Bile acid synthesis is impared due to deficient cholesterol-7α-hydroxylase.
- **Nucleation:** Gallbladder hypomotility and **cholesterol** nucleation convert multilamellar vesicles to cholesterol monohydrate filaments, which are arranged in plates (nucleation).
- **Promotion:** Promoters, i.e. mucus hypersecretion, gallbladder hypomotility, **calcium salts** act on cholesterol monohydrate plate resulting in accretion (nucleation) and formation of cholesterol stones.

CHOLELITHIASIS: CLINICAL ASPECTS

Asymptomatic/Silent Gallbladder Stones

Most patients are unaware of gallbladder stone disease and remain asymptomatic for life. They never experience biliary pain or complications such as acute cholecystitis, cholangitis, or pancreatitis. Hence, most gallbladder stones are clinically silent, an incidental finding often discovered during abdominal ultrasound being performed for another reason.

Symptomatic Gallbladder Stone Disease

Gallbladder stones can produce a variety of symptoms depending on their anatomical site. These patients require surgical cholecystectomy. Most complications associated with cholelithiasis are related to obstruction of the biliary tree.

Additional rare complications include empyema of the gallbladder, perforation, fistula formation, bile peritonitis, and gallstone ileus. In most cases, gallbladder stones are associated with chronic cholecystitis. Natural history of gallbladder stone disease is given in Table 21.94.

Functional (Acalculous) Gallbladder Disease

Acalculous cholecystitis occurs due to gallbladder ischemia caused by sepsis with hypotension, burns, major trauma and multisystem organs failure. Other causes include diabetes mellitus and infections by cytomegalovirus in immunosuppression state.

- Biliary pain in acalculous gallbladder results from increased intraluminal pressure, as the gallbladder contracts against an obstructed sphincter of Oddi outlet. Biliary colic occurs due to lack of coordination between gallbladder contraction and sphincter of Oddi relaxation, or visceral hypersensitivity.
- A clue to its existence is impaired gallbladder emptying, reliably estimated by cholecystokinin-cholescintigraphy. Ultrasonography shows empty gallbladder lacking gallbladder stone disease.
- Patient presents with acute abdominal pain in the right upper quadrant that may radiate to the back, between the shoulders, or to the front of the chest, colic, nausea and vomiting, chill, low-grade fever,

Table 21.94 Natural history of gallbladder stone disease

Symptom	% of Patients
Asymptomatic	40%
Cholangitis	20%
Jaundice	20%
Biliary colic	15%
Pancreatitis	5%

jaundice, belching, flatulence, indigestion and light headedness.

GALLBLADDER STONES: TYPES

The causes of gallbladder stones are hypercholesterolemia, hyperbilirubinemia, and gallbladder stasis.

GALLBLADDER CHOLESTEROL STONES

Molecules involved in dissolving cholesterol in bile include water-soluble bile salts and water insoluble lecithins.

- More than 75% of gallbladder stones contain significant amount of cholesterol. Cholesterol stones are round or faceted, yellow to tan, and may be single or multiple. The stones are too large to enter the cystic duct or the common bile duct.
- Gallbladder cholesterol stones are radiolucent and not demonstrated on radiograph. But these are demonstrated by ultrasonography (Fig. 21.104).

Composition of Gallbladder Stones

- **Gallbladder cholesterol stone:** Gallbladder cholesterol stone contains 90% of cholesterol, which is most often single, large stone >2.5 cm, pale or white in color. It has soft consistency and can be cut easily. Cut surface has radiating structure made up of cholesterol crystals.
- **Gallbladder mixed stones:** Gallbladder mixed stones contain **50% of cholesterol** and rest mucoproteins, calcium and bilirubin. These are usually multiple but smaller than pure cholesterol stones measuring 0.5–2.5 in diameter. Gallbladder mixed stones account for 85% of all gallbladder stones. These exhibit characteristic faceted appearance.

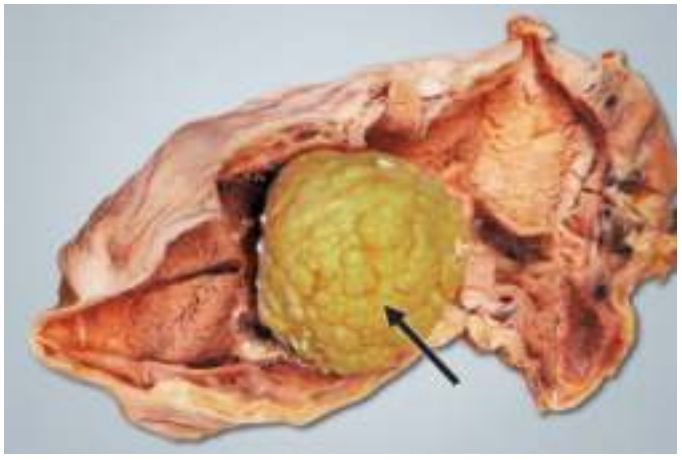

Fig. 21.104: Cholecystectomy specimen shows solitary yellow cholesterol stone (arrow). Cholesterol stone is composed mainly of undissolved cholesterol but may contain other constituents.

Predisposing Factors

During reproductive years, women are up to three times more likely to develop gallbladder cholesterol stones than men. Risk factors for gallbladder cholesterol stones include obesity, female sex, diabetes mellitus, pregnancy, estrogen therapy, hyperlipidemia, bile stasis and inborn disorders of bile acid metabolism.

In obese women, cholesterol secretion by the liver is increased. Impaired gallbladder motor function is another risk factor that leads to gallbladder stone formation. In this way, stasis permits the formation of biliary sludge, which then progresses to macroscopic stones, which are more prevalent in Americans.

Clinical Pearls: Predisposing Factors for Gallbladder Cholesterol Stones

Predisposing factors for development of gallbladder cholesterol stones are described as under:

- Advanced age
- Obesity
- Hyperlipidemia syndrome
- Female sex hormones pregnancy and oral contraceptives
- Bile stasis
- Inborn disorders of bile acid metabolism
- Diabetes mellitus

Pathogenesis

Supersaturation of cholesterol, hypomotility of gallbladder and mucins in gallbladder participate in the pathogenesis of cholesterol stones.

Clinical Pearls: Cholesterol Gallbladder Stone Formation

Cholesterol gallbladder stone formation involves four simultaneous processes as under:

- Supersaturation of cholesterol
- Hypomotility of gallbladder
- Accelerated nucleation of cholesterol in the bile juice
- Increased synthesis of gel forming mucins, e.g. MUC5AC and MUC2.

- **Supersaturation of cholesterol:** If the bile juice contains excess of cholesterol or deficient in bile acids, it becomes supersaturated with cholesterol and precipitates to form stones (lithogenic bile). Cholesterol nucleation is accelerated in bile and mucous hypersecretion in the gallbladder.
- **Gallbladder hypomotility:** Gallbladder motility is decreased in pregnancy, rapid weight loss and long term starvation. Gene polymorphisms increase the rate of cholelithiasis due to impaired gallbladder motility.
- **Mucins in gallbladder:** Mucin-glycoprotein gel is one of the most important and identified pronucleators. Secretory mucins are gel-forming and may increase bile juice viscosity.

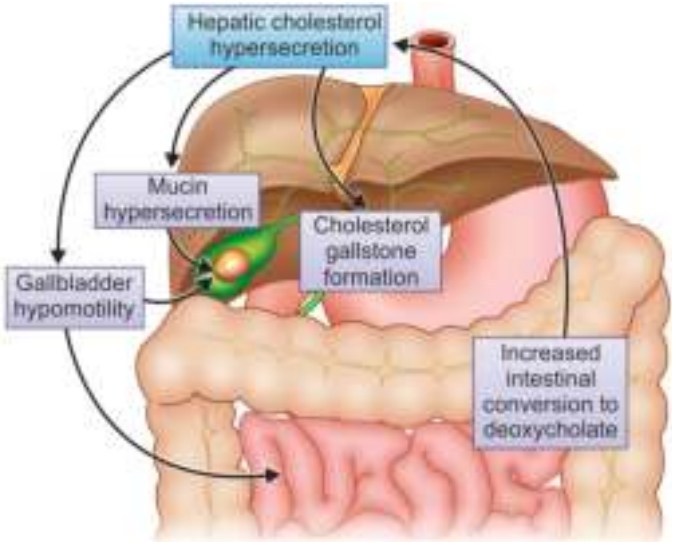

Fig. 21.105: Cholesterol stone formed by hypersecretion leading to formation of cholesterol stone.

Fig. 21.106: Pigmented gallbladder stones. Gallbladder shows multiple faceted yellow tan gallbladder stones. Stone may exit via the cystic duct or common bile duct and obstruct bile flow. It may obstruct at the ampulla of Vater and produce a pancreatitis. Biliary tract obstruction leads to jaundice with increased total and direct bilirubin in serum.

An increased expression of gel-forming mucins such as MUC5AC and MUC2 has been associated with hepatobiliary gallbladder stones, indicating a gene-gene interaction that might affect the accumulation of mucin gel and cholesterol gallstone formation. Pathophysiology of cholesterol stones is shown in Fig. 21.105.

GALLBLADDER PIGMENT STONES

Gallbladder pigment stones occur in 10% of Western population. These are more common in Asian population. Chronic intravascular hemolysis is the cause of gallbladder pigment stones. Precipitation of excess insoluble unconjugated bilirubin results in the formation of pigment stones, which are most often associated with hemolytic anemia and bacterial infection. Gallbladder pigment stones show multiple faceted yellow tan gallbladder stones are shown in Fig. 21.106.

Categories of Gallbladder Pigment Stones

Gallbladder pigment stones are classified into two main categories:

- **Gallbladder black pigment stones:** Gallbladder black pigment stones are most common and associated with hemolysis and cirrhosis. Chronic extravascular hemolytic anemia, e.g. sickle cell disease increases the synthesis of conjugated bilirubin into the bile juice. Increased concentration of bilirubin in bile juice produces formation of calcium bilirubinate resulting in formation of black pigmented gallbladder stones. These are confined to the gallbladder. Bile juice is sterile. Gallbladder pigment stones consist of large amounts of polymerized degradation product of oxidized bilirubin.
- **Gallbladder brown pigment stones:** Gallbladder brown pigment stones are formed due to bacterial contamination resulting in release of microbial β-glucuronidases, which hydrolyzes bilirubin glucuronides resulting in an increase of unconjugated bilirubin in the biliary tree that exceed its solubility. Gallbladder brown pigment stones contain large amount of calcium bilirubinate, which have soft consistency. Cut surface of brown pigment stone shows laminated appearance. These brown pigment stones are formed either in gallbladder or bile ducts. The bile is most often infected.

Predisposing Factors

There is increased frequency of gallbladder pigment stones in Crohn's disease, ileal resection or bypass, cystic fibrosis with pancreatic insufficiency and chronic hemolytic anemia. Gallbladder pigment stones are more common in Asian than Western population.

Predisposing Factors: Gallbladder Pigment Stones

Predisposing factors for development of gallbladder pigment stones are described as under:

- Chronic hemolytic syndrome
- Biliary infection
- Ileal resection or bypass
- Crohn's disease involving ileum
- Cystic fibrosis
- Pancreatic insufficiency

Table 21.95 Differences between various types of gallbladder pigment stones

Parameters	Cholesterol Stones	Black Pigment Stones	Brown Pigment Stones	Biliary Sludge (Microlithiasis)
Composition	Cholesterol (50–100%)	Calcium bilirubinate polymer	Unconjugated bilirubin, calcium soap of fatty acids, cholesterol and mucin	Pigment (calcium bilirubinate) cholesterol microcrystals and mucin
Location	Gallbladder ± common bile duct	Gallbladder ± common bile duct	Bile ducts	Gallbladder
Detection	Ultrasound	Ultrasound	Cholangiography	Abdominal or endoscopic ultrasonography
Clinical association	Family history (genetic), obesity, female sex and aging (excessive cholesterol secretion)	Increased or altered bilirubin excretion in hemolysis, cirrhosis, cystic fibrosis, Crohn's disease and advanced age (excessive bilirubin excretion)	Infection, inflammation and infestation (stasis and strictures)	Fasting total parenteral nutrition (TPN) and pregnancy

Surgical Pathology: Gallbladder Pigment Stones

Gross Morphology

- Gallbladder pigment stones are usually multiple measuring <1.5 cm in diameter found in sterile bile.
- Gallbladder pigment stones are composed of calcium salts of unconjugated bilirubin (calcium bilirubinate), mucin glycoprotein, less cholesterol monohydrate crystals.
- Gallbladder pigment stones are radiopaque in 50–75% of cases (imaging technique). Differences between various types of gallbladder pigment stones are given in Table 21.95.

GALLBLADDER STONES: COMPLICATIONS

Most common complications of cholelithiasis include severe biliary colic due to stone in cystic duct, obstructive jaundice (common bile duct obstruction), ascending cholangitis and acute pancreatitis. Less common complications are acute cholecystitis, empyema, gallbladder perforation, gallstone ileus, porcelain gallbladder, mucocele of gallbladder, squamous cell carcinoma, extension of inflammation in the biliary tree, Mirizzi's syndrome and Bouveret's syndrome.

Clinical Pearls: Gallbladder Stones—Complications

- Severe biliary colic
- Obstructive jaundice
- Ascending cholangitis
- Acute pancreatitis
- Acute cholecystitis
- Empyema gallbladder
- Gallstone ileus
- Porcelain gallbladder
- Mucocele of gallbladder
- Extending inflammation in biliary tree
- Mirizzi's syndrome
- Bouveret's syndrome
- Squamous cell carcinoma

SEVERE BILIARY COLIC

If a gallbladder stone lodges in the cystic duct, the gallbladder contracts but cannot empty. Passage of stones into the cystic duct often causes severe biliary colic. Fat entering the duodenum causes the intestinal mucosa to secrete the hormone cholecystokinin, which stimulates the gallbladder to contract and empty.

Clinical Features

Patient presents with sudden pain in right upper quadrant that may radiate to scapular region, lasts for 2–4 hours following ingestion of fatty meals, alcohol, and caffeine. Pain is accompanied by nausea and vomiting. Mild inflammatory change in the gallbladder wall can occur with biliary colic; with recurrent episodes leading to chronic cholecystitis.

OBSTRUCTIVE JAUNDICE

Lodgement of gallbladder stone in the common bile duct leads to obstructive jaundice, cholangitis, and acute pancreatitis. Patient develops conjugated hyperbilirubinemia, hypercholesterolemia and high alkaline phosphatase level. Biliary narrowing and swelling of the tissue around the stone can also cause irritation and inflammation of the common bile duct.

Clinical Features

Patient presents with yellow discoloration of skin and the eyes (sclera) and skin itch. As the condition worsens, patient develops severe abdominal pain, fever, chills nausea and vomiting.

ASCENDING CHOLANGITIS

Infection in the common bile duct from obstruction is common and serious. Ascending cholangitis results from secondary bacterial infection facilitated by obstructed bile flow as a result of stone in common bile duct.

- Patient presents with Charcot's triad of fever, jaundice and right upper abdominal pain.

- This potentially life-threatening complication requires urgent supportive care, antibiotics and drainage of the biliary tree, usually by endoscopic retrograde cholangiopancreatography (**ERCP**) with either removal of the stone or placement of a stent.

ACUTE PANCREATITIS

Stones in the lower portion of common bile duct obstructing pancreatic duct increases risk for acute pancreatitis.

- Autodigestion of the pancreas occurs by the lipase enzyme, which normally secretes into the duodenum. Autodigestion of pancreas by lipase leads to release of lipids. These lipids then form soaps, i.e. saponification with calcium leading to hypocalcemia.
- Patient presents with rapid onset of upper abdominal pain and vomiting.
- Acute pancreatitis can be a life-threatening disease and requires correction of hypovolemia, administration of antibiotics and the early consideration of endoscopic sphincterotomy via ERCP in severe cases.

ACUTE CHOLECYSTITIS

Acute cholecystitis occurs due to complete obstruction of the cystic duct by a gallbladder stone in 95% of gallbladder stone disease. Acalculous cholecystitis occurs in remainder 5% of cases.

- The most serious complication of acute cholecystitis is infection, which develops in about 20% of cases. Acute cholecystitis is extremely dangerous and life-threatening if it spreads to other parts of the body leading to septicemia and surgery is often required.
- Untreated cases of acute cholecystitis may result in formation of abscesses, gangrene and necrosis, which are encountered in elderly diabetic patients.
- Patient presents with pain abdomen lasting for several hours, nausea, vomiting, fever, chills and passage of clay colored stool. Pain occurs usually in the middle of right side of upper abdomen, which may also radiate to right shoulder or back region.
- Acute cholecystitis is diagnosed by abdominal ultrasonography, hepatobiliary scintigraphy, cholangiography and CT scan.
- Acute cholecystitis is initially treated by antibiotics and intravenous fluids resulting in resolution of acute inflammation of gallbladder in 70–80% of cases.

EMPYEMA GALLBLADDER

Acute cholecystitis in presence of bacteria in the bile juice may progress to suppurative infection of the gallbladder filled with purulent material (pus) in 2–3% of cases. This condition is referred as empyema gallbladder, which develops when the gallbladder neck is obstructed by gallbladder stone in the presence of infection, thus preventing pus draining via cystic duct.

- Necrosis of the gallbladder results in perforation, abscess formation and peritonitis.
- Patient usually experiences severe abdominal pain, which persists for more than 7 days.
- Most patients of empyema gallbladder require aggressive hydration, intravenous antibiotics and surgery within 48 to 72 hours after optimal hydration.

PERFORATED GALLBLADDER WITH PERITONITIS

An estimated 10% of acute cholecystitis results in a perforated gallbladder, and diffuse peritonitis. It is a life-threatening condition. Perforation of the gallbladder is most common in people with diabetes mellitus.

- The risk for emphysematous cholecystitis increases due to infection by gas forming bacteria (*E. coli* and *Clostridium welchii*).
- Once the gallbladder has perforated, pain may temporarily decrease, which is a dangerous and misleading sign, because peritonitis develops afterward.

GALLSTONE ILEUS

In some cases of gallbladder stone disease, gallbladder stone erodes through the gallbladder into the adjacent small bowel forming cholecystoenteric fistula.

- Gallstone enters ileum through the fistulous tract and blocks the intestine known as gallstone ileus.
- Gallbladder stone ileus can be very serious and requires immediate surgery, which primarily occurs in patients over age 65, and can sometimes be fatal.

RISK FOR SQUAMOUS CELL CARCINOMA OF GALLBLADDER

Primary squamous cell carcinoma of gallbladder is most often associated with cholelithiasis in 75% of cases. Presence of gallbladder stones increases risk of development of carcinoma by 4 to 5 folds. Elective cholecystectomy can be preventive measure for gallbladder carcinoma in some patients with chronic cholelithiasis.

- Chronic irritation of gallbladder induced by gallbladder stones leads to squamous metaplasia of columnar mucosa leading to squamous cell carcinoma (exophytic or infiltrative growth).
- Patient is most often asymptomatic until the disease has reached an advanced stage. Patient presents with weight loss, anemia, recurrent vomiting and abdominal lump.

PORCELAIN GALLBLADDER

Gallbladder is referred to as porcelain gallbladder, when their walls become calcified due to calcium deposits appears like porcelain on radiograph. Porcelain gallbladder has been associated with a high risk for primary squamous cell carcinoma of gallbladder. This condition

may develop from a chronic inflammatory reaction that may actually be responsible for the gallbladder cancer risk.

MUCOCELE OF GALLBLADDER

Gallbladder distended with mucus secondary to sterile long-standing obstruction of the cystic duct by a gallstone is known as mucocele of gallbladder. During surgical removal, thin wall of gallbladder demands to avoid spillage of mucus into the peritoneal cavity, so that '**pseudomyxoma peritonei**' is prevented. Pseudomyxoma peritonei becomes seeded with mucus-producing epithelial cells and the cavity fills with mucus.

Surgical Pathology: Mucocele of Gallbladder
Gross Morphology
Gallbladder is distended with clear, mucus and watery fluid.
Light Microscopy
▪ Accumulation of clear, mucus and watery fluid in gallbladder leads to flattening of mucosa and thinning of wall. ▪ There is absence of bile in lumen and inflammatory changes in the wall.
Differential Diagnosis
Mucocele of gallbladder may be mistaken for a mucinous carcinoma. Macarophages may resemble signet ring cells. Immunohistochemistry helps in differentiating mucocele and mucinous carcinoma of gallbladder.

Complications

Mucocele of gallbladder may cause cholangitis, perforation with local abscess, diffuse peritonitis, cholecyst enteric fistula and multiorgan failure.

EXTENDING INFLAMMATION IN BILIARY TREE

Inflammation due to cholelithiasis can progress up the biliary tree into any of the bile ducts, which causes scar tissue, fluid accumulation, cirrhosis, portal hypertension, and bleeding.

MIRIZZI'S SYNDROME

Impaction of gallbladder stones in the gallbladder neck or cystic duct (Hartmann's pouch) can lead to compression of the common hepatic duct producing jaundice, which is termed '**Mirizzi's syndrome**'. It is rare presentation of gallstone disease. It may be complicated by fistula formation (cholecystocholedochal fistula), which usually requires surgical repair.

BOUVERET'S SYNDROME

A large gallbladder stone can rarely erode through the gallbladder wall and stomach resulting in cholecystogastric fistula formation. Gallbladder stone impaction in the stomach or duodenum leads to gastric outlet obstruction; known as 'Bouveret's syndrome'.

Clinical Pearls: Pain in Right Upper Quadrant
Differential diagnosis of pain in right upper quadrant of abdomen includes gallbladder disease (and its related complications), gastritis/duodenitis, peptic ulcer disease/perforated peptic ulcer, acute pancreatitis, right lower lobe pneumonia and myocardial infarction (Table 21.96).

Table 21.96 Differential diagnosis of pain in right upper quadrant of abdomen

Pathological Entity	Clinical History	Clinical Examination	Laboratory Investigations
Biliary colic	Intermittent pain (minutes to hours) in right upper quadrant/radiating to back and right shoulder	Tenderness in right upper quadrant, afebrile and no peritonism	LFT, CRP and WBCs count normal
Acute cholecystitis	Constant pain in right upper quadrant, radiating to back and right shoulder	Tenderness in right upper quadrant, Murphy's sign and febrile	CRP and WBCs raised, LFT normal or mild elevation
Empyema	Constant pain in right upper quadrant, radiating to back or right shoulder	Tenderness in right upper quadrant, peritonism, Murphy's sign +ve, pyrexia, more septic than acute cholecystitis	WBCs and CRP raised, LFT normal or mild elevation
Obstructive jaundice	Yellow discoloration of eyes, passage of pale stool and dark urine, painless or mild pain in right upper quadrant	Jaundice, nontender right upper quadrant, no peritonism, afebrile, Murphy's sign negative	WBCs and CRP normal, LFT (serum bilirubin and alkaline phosphatase raised)
Ascending cholangitis	Beck's triad (pain in right upper quadrant, jaundice and rigors)	Jaundice, tenderness in right upper quadrant, peritonism, spiking high pyrexia, and may develop septic shock	WBCs and CRP normal, LFT (serum bilirubin and alkaline phosphatase raised)
Acute pancreatitis	Severe constant pain in upper abdominal pain, radiating to back and profuse vomiting	Tenderness in right upper abdomen or generalized peritonism and afebrile	WBCs and CRP raised, LFT normal, serum amylase raised and DIC (complication)

Clinical Pearls: Laboratory Diagnosis of Gallbladder Stone Disease

Laboratory investigations carried out in diagnosing gallbladder stone disease include complete hemogram, blood biochemistry and imaging techniques. Approximately 10% gallbladder stones are radiopaque.

Ultrasonography

Ultrasonography is the first line investigation in gallbladder stone disease for diagnosing cholelithiasis. Dilatation of biliary tree calibre suggests stone in common bile duct (normal CBD <8 mm). Thickening of wall of gallbladder suggests chronic cholecystitis.

Magnetic Resonance Cholangiopancreatography (MRCP)

MRCP is noninvasive diagnostic tool much more accurate than ultrasonography. It visualizes biliary tree accurately. It is used to look for biliary dilatation and any stones in biliary tree.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

- ERCP invasive technique has diagnostic and therapeutic utility in biliary obstruction. It visualizes biliary tree dilatation and stones in biliary tree.
- Gallbladder stones can be extracted to unobstruct the biliary tree and perform sphincterotomy. There is increased risk of development of pancreatitis and duodenal perforation.

Percutaneous Transhepatic Cholangiography (PTC)

PTC invasive technique is used to unobstruct biliary tree when ERCP has failed. It has higher complication rate than ERCP.

CT Scan

CT scan is not the first line investigation used if suspicion of gallbladder empyema, gangrene, or perforation and in acute pancreatitis.

COMMON NEOPLASMS AND PRECURSOR LESIONS OF GALLBLADDER

Benign tumors of the gallbladder are rare. The most common primary tumor of the gallbladder is adenocarcinoma, often associated with gallbladder stones.

- Carcinoma of the extrahepatic biliary ducts and the ampulla of Vater is less common than adenocarcinoma of the gallbladder. Modified WHO classification of the gallbladder and extrahepatic bile ducts is given in Table 21.97.
- Patient suffering from adenocarcinoma of gallbladder presents with progressive, relentless obstructive jaundice and palpable gallbladder.
- Tumor obstructing the common bile duct leads to an enlarged, distended gallbladder. Gallbladder adenocarcinoma is almost always adenocarcinoma.

Table 21.97 Modified WHO classification of the gallbladder and extrahepatic bile ducts

Category	Tumors
Epithelial tumors	▪ Preinvasive lesions ▪ Biliary intraepithelial neoplasms (dysplasia) (BilIN) ▪ Intracholecystic papillary-tubular neoplasm (applicable to extrahepatic bile duct), e.g. adenomas, intracystic neoplasms ▪ Mucinous cystic neoplasm ▪ Carcinomas ▪ Adenocarcinoma, pancreaticobiliary type ▪ Adenocarcinoma, intestinal type ▪ Adenocarcinoma, mucinous type ▪ Signet ring (poorly cohesive cell) carcinoma ▪ Adenosquamous carcinoma ▪ Intracholecystic papillary-tubular neoplasm with associated invasive carcinoma ▪ Squamous cell carcinoma ▪ Undifferentiated carcinoma, medullary type ▪ Undifferentiated carcinoma, sarcomatoid type ▪ Neuroendocrine neoplasms ▪ Well-differentiated neuroendocrine tumor (NET grade 1 and grade 2 carcinoid tumors) and goblet cell carcinoma ▪ High-grade neuroendocrine tumor (NET grade 3), large cell neuroendocrine carcinoma and small cell neuroendocrine carcinoma ▪ Mixed adenocarcinoma and high-grade neuroendocrine carcinoma
Mesenchymal tumors	▪ Granular cell tumor ▪ Leiomyoma ▪ Leiomyosarcoma ▪ Rhabdomyosarcoma ▪ Kaposi sarcoma
Lymphomas	Lymphomas rare
Secondary tumors	▪ Lymphomas ▪ Leukemias ▪ Multiple myeloma ▪ Mastocytosis ▪ Metastatic melanoma

GALLBLADDER ADENOMA

Gallbladder adenoma is a rare benign solitary polypoidal lesion. Small adenoma has low malignant potential. Large adenoma may harbor foci of high-grade biliary intraepithelial neoplasia 3 (BilIN3) and invasive carcinoma. Histologic examination of gallbladder adenoma shows tubular or papillary or tubulopapillary appearance.

BILIARY INTRAEPITHELIAL NEOPLASIA

Biliary intraepithelial neoplasia may be grades 1, 2 or 3. Grade 3 biliary intraepithelial neoplasia may be associated with invasive carcinoma. Therefore, thorough sampling of the cystic duct and margins of the lesion should be carried out to exclude malignancy. Cholecystectomy is curative. Grade 3 biliary intraepithelial neoplasia shows overexpression of TP53 gene.

GALLBLADDER ADENOCARCINOMA

Gallbladder adenocarcinoma can develop in obese women, cholelithiasis, porcelain gallbladder and primary sclerosing cholangitis. The prognosis patient with adenocarcinoma of gallbladder is usually poor, because tumor has often invaded and metastasized by the time tumor is discovered.

Pathology Pearls: Risk Factors for Development of Gallbladder Adenocarcinoma

- Gallbladder stones
- Porcelain gallbladder
- Choledochal cyst
- Gallbladder polyps
- Abnormality of the pancreaticobiliary duct

Pathogenesis

- Metaplasia of gallbladder mucosa occurs as a result of irritation by solitary gallbladder stone. It is widely accepted that metaplastic epithelium is more susceptible to malignant transformation.
- Low-grade dysplasia occurs in 40% and high-grade dysplasia in 16% of cases with cholelithiasis. Carcinoma *in situ* has been observed in 3.5% of cholecystectomy specimens. The great majority of *in situ* carcinoma is grossly indistinguishable from cholecystitis and can easily be overlooked on microscopic examination. Dysplasia, carcinoma *in situ* and invasive carcinoma of gallbladder have been associated with multiple gallbladder stones.

Molecular Genetic Alterations

Changes of the E-cadherin/β-catenin complex during cell to cell interactions result in the loss of cell adhesion and may account for the ability of cancer cells to metastasize.

Surgical Pathology: Gallbladder Adenocarcinoma

Gross Morphology

- The thickness of the gallbladder wall may be normal or minimally thickened.
- Mucosal induration mimics chronic cholecystitis. The mucosa may appear granular, slightly nodular or trabecular pattern in carcinoma *in situ* and invasive carcinoma. It gives support to the idea that carcinoma *in situ* grows slowly and considered a precursor lesion of invasive carcinoma of gallbladder (Fig. 21.107).

Light Microscopy

- **Well differentiated adenocarcinoma:** Tumor is composed of columnar cells forming glandular and papillary structures invading gallbladder wall.The mucosal surface shows massive ulceration and necrosis. Perineural invasion, and vascular emboli may be observed. Sometimes acidophilic secretion is demonstrated within the lumen. Histologic features of well differentiated adenocarcinoma of gallbladder are shown in Fig. 21.108.
- **Undifferentiated adenocarcinoma:** Tumor shows presence of clusters of tumor cells with numerous mitoses surrounded by sclerohyaline stroma.
- **Squamous cell carcinoma:** Cholelithiasis causing squamous metaplasia of columnar epithelium leads to squamous cell carcinoma (exophytic or infiltrative growth). It comprises islands of tumor cells with keratinization and keratin pearls. In some islands of tumor cells, partial necrosis lesions and a polymorph inflammatory reaction are observed.
- **Mucin secreting adenocarcinoma:** Tumor is composed of tumor cells arranged in glandular pattern. There is presence of abundant mucus secretion in the cells identified as signet ring cells and outside glands compressing clusters of malignant cells. Numerous tumor emboli in lymphatic channels predict unfavorable prognosis.
- **Papillary adenocarcinoma:** Tumor is composed of exuberant surface proliferation forming villous structures. The tumor cells invade the gallbladder wall. There is presence of perineural invasion by tumor cells. Lymphatic channels show presence of tumor emboli.

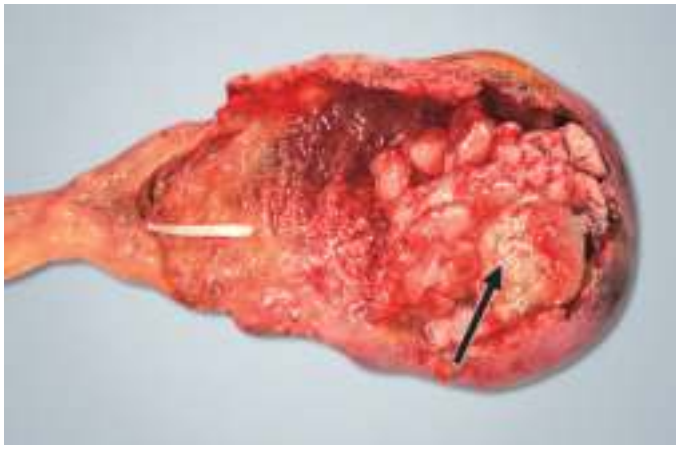

Fig. 21.107: Gallbladder adenocarcinoma. Cholecystectomy specimen shows exophytic and polypoid growth, thickened and indurated gallbladder wall. Cut surface is firm, gritty, tan-yellow to yellow-gray (arrow).

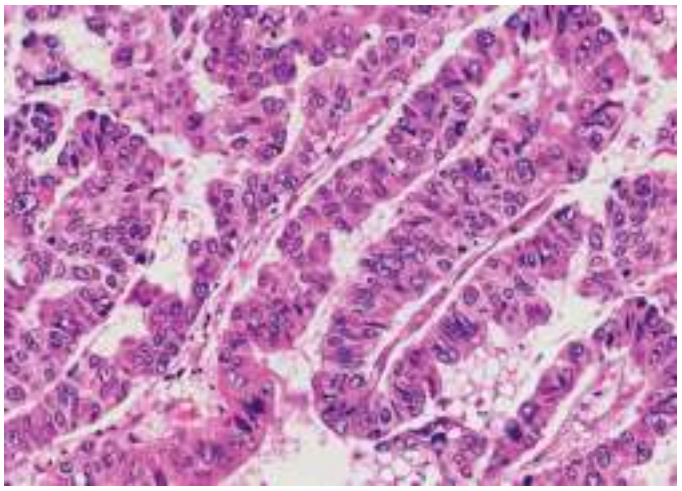

Fig. 21.108: Well-differentiated adenocarcinoma of gallbladder. Tumor is composed of columnar cells forming glandular and papillary structures. The prognosis with adenocarcinoma of the gallbladder is usually poor, because they have often invaded and metastasized by the time they are discovered (400X).

KLATSKIN TUMOR

Klatskin tumor is a slow-growing hilar cholangiocarcinoma, occurring at the confluence of the right and left hepatic ducts.

Predisposing Factors

Etiology of Klatskin tumor is not well defined, which may occur due to acute or chronic biliary tract epithelial injury, primary sclerosing cholangitis, choledochal cysts, caroli's disease and anomalous pancreaticobiliary duct junction. In South East Asia, disease may be caused by *Clonorchis sinensis* and *Opisthorchis viverrini* parasites.

Serum Tumor Markers

Levels of CA 19-9, carcinoembryonic antigen (CEA) and CA 125 are abnormally high in the blood of patients with Klatskin tumor and intrahepatic cholangiocarcinoma.

Imaging Techniques

Ultrasonography detects dilatation of the bile ducts, but more rarely the tumor itself. Magnetic resonance cholangiopancreatography (MRCP) is a good non-invasive technique to detect tumor.

BILIARY ADENOCARCINOMA

Biliary adenocarcinoma may be composed of intestinal, goblet and neuroendocrine cells. Tumor composed of intestinal goblet cells are most often CK20 and CDX2 immunoreactive.

EXTRAHEPATIC BILE DUCT ADENOCARCINOMA

Extrahepatic bile duct adenocarcinoma has been classified as perihilar or distal adenocarcinomas. Each of these entities has its own staging system. These tumors show thickening of the wall. Therefore,

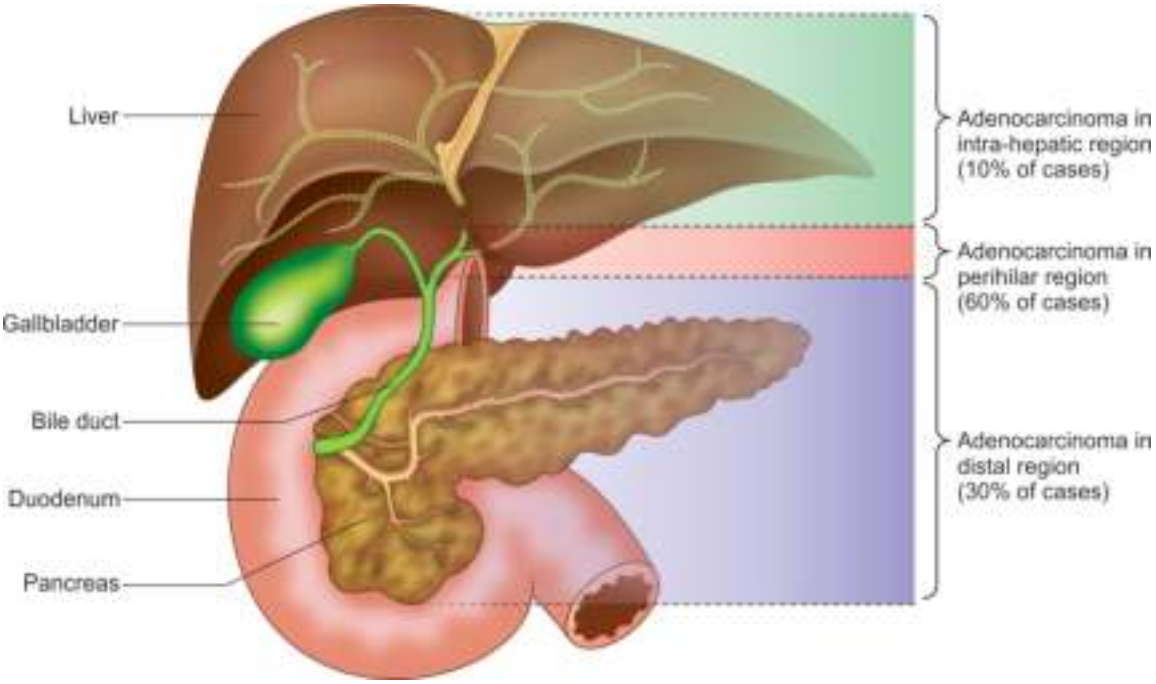

Fig. 21.109: Anatomic boundaries for classification of adenocarcinomas of extrahepatic bile ducts.

thorough sampling of the tumor is required to evaluate margins and local extension.

Perihilar Region of Adenocarcinoma

Perihilar adenocarcinoma originates proximal to cystic duct, which accounts for 60% cases of adenocarcinomas.

Distal Region of Adenocarcinoma

Distal adenocarcinoma arises between the junction of the cystic duct and common bile duct and the ampulla of Vater. It accounts for 30% of adenocarcinomas. Anatomic boundaries for classification of adenocarcinomas of extrahepatic bile ducts are shown in Fig. 21.109.

DISORDERS OF EXOCRINE PANCREAS

EXOCRINE PANCREAS: STRUCTURE

ANATOMY

Pancreas is a large gland located behind stomach and beside the duodenum or upper part of the small intestine. It measures 15–20 cm and weighs 85–120 g and consists of head, neck, body and tail. Pancreas is divided into exocrine portion (acinar and duct system) and endocrine portion (islets of Langerhans).

- The exocrine pancreas forms 85% of the pancreas.
- Exocrine pancreas has duct system. Acinar cells drain into intercalated ducts, interlobular ducts, and main pancreatic duct of Wirsung and accessory duct of Santorini.
- Pancreas receives blood supply from coeliac trunk and superior mesenteric artery. Lymphatic drainage of pancreas occurs to lymph nodes in the region of celiac trunk.
- Annular pancreas is a congenital anomaly in which head of the pancreas surrounds the second portion of the duodenum, which may associated with duodenal atresia. Infants present with feeding disorders and growth retardation.

PHYSIOLOGY

Exocrine pancreas synthesizes digestive enzymes, water, $NaHCO_3$ into the duodenum. The endocrine pancreas synthesizes its hormones (insulin, glucagon) and somatostatin into the bloodstream. In addition, the pH of the pancreatic secretions is alkaline due to very high concentration of $NaHCO_3$. Pathologic disorders of pancreas seen in clinical practice are shown in Fig. 21.110. Composition of pancreatic juice is given in Table 21.98.

PANCREATITIS: OVERVIEW

Pancreatitis is a rare disorder in which the pancreas becomes inflamed. Pancreatic damage occurs when the digestive enzymes are activated and begin attacking the pancreas. In very severe cases, pancreatitis can cause serious damage to pancreas resulting in bleeding into the gland itself, pseudocyst formation and rupture.

- Severe pancreatitis can result in damage to the other vital organs such as heart, lungs and kidneys.

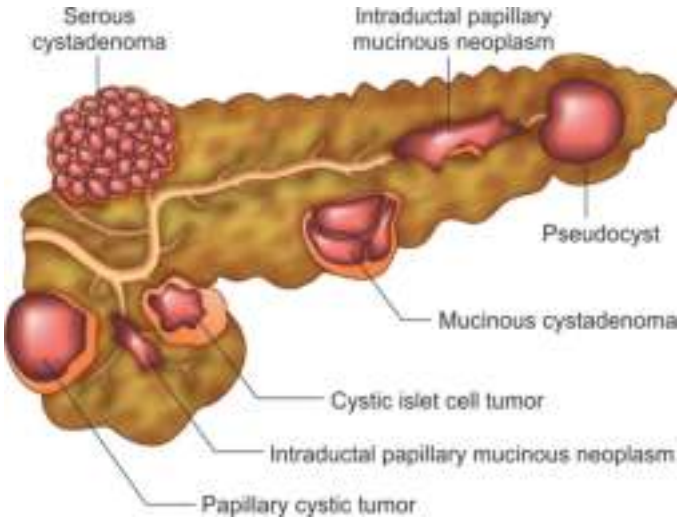

Fig. 21.110: Pathological lesions of pancreas in clinical practice.

Table 21.98 Composition of pancreatic juice

Pancreatic Juice Constituent	Comments
Amylase	Converts starch into maltose and α-dextrins
Lipase	Converts emulsified triglyceride by bile salts into fatty acids and monoglycerides
Trypsin	Enterokinase converts trypsinogen into trypsin, that converts proteins into peptides
Chymotrypsin	Trypsin also converts chymotrypsinogen into chymotrypsin, that proelastase into elastase; and converts proteins into peptides
Carboxypeptidase	Trypsin also converts procarboxypeptidase into carboxypeptidase, that converts terminal amino acid at carboxyl acid end of peptides into peptides and amino acids
Ribonuclease	Coverts ribonucleic acid into nucleotides
Nucleosidase	Converts nucleotides into nucleosides

There are two forms of pancreatitis: acute and chronic.

- Acute pancreatitis occurs suddenly and may lead to life-threatening complications. However, the 80% of patients recover.
- Chronic pancreatitis occurs as a result of long-standing damage to the pancreas in chronic alcoholic persons. Chronic pancreatitis is marked by severe pain abdomen and impairment of pancreatic functions.

- Significant proportion of patients with idiopathic acute and chronic pancreatitis have underlying genetic abnormalities. Laboratory evaluation for acute and chronic pancreatitis is given in Table 21.99.

ACUTE PANCREATITIS

Acute pancreatitis is an inflammatory disease of the exocrine pancreas that results from injury to the acinar cells. It is characterized clinically by acute abdominal pain and increased levels of **serum amylase** and **lipase**. Approximately 89% of the episodes of acute pancreatitis are mild resulting in resolution without serious morbidity. Pancreatic neoplasm may also manifest as acute pancreatitis in an occasional case.

Etiopathogenesis

Alcohol abuse (>80 g daily intake) and obstruction of common bile duct by stones are most important causes of acute pancreatitis in 80% of middle-aged persons.

- Cholelithiasis induced pancreatitis usually affects elderly women as a result of migration of gallbladder stone and subsequent pancreatic duct obstruction.
- Although cholelithiasis is the most important cause of biliary obstruction, yet biliary duct obstruction by neoplasms in periampullary region and head of the pancreas may also provoke acute pancreatitis.
- Pancreatic acinar cell injury induced by injurious agents leads to premature activation protease in pancreatic acinar cells resulting in autodigestion of pancreas.
- Pancreatic acinar cell injury occurs by autoactivation of cathepsin B, which converts cationic trypsinogen to cationic trypsin, anionic trypsinogen to anionic trypsin and mesotrypsinogen to mesotrypsin. These metabolic conversions are inhibited by SPINK1 gene. The cationic trypsin and anionic trypsin convert pro-elastase to elastase, chymotrypsinogen to chymotrypsin, pro-carboxypeptidase A1 to carboxypeptidase A1; and pro-phospholipase A2 to phospholipase A2.
- Autodigestion of pancreas is caused by various enzymes. Phospholipase and lipase cause fat necrosis of pancreas.
  - Elastase enzyme causes damage to the blood vessel resulting in hemorrhage in pancreas.
  - Protease enzyme damages pancreatic acinar cells. Thrombosis in small blood vessels occurs due to activation of coagulation system cascade and complement system.
  - The release of amylase and lipase enzymes from injured pancreas into the blood is a sensitive indicator for monitoring acute pancreatitis. Causes of acute pancreatitis are given in Table 21.100.

Pathogenesis

Genetic Predisposition

Genetic predisposition of acute pancreatitis may occur in minority of cases.

- In recurrent acute pancreatitis, genetic testing demonstrates mutations of **PRSS1** (cationic trypsinogen) gene, **SPINK1** (serine protease inhibitor Kazal type 1) gene, **CFTR** (cystic fibrosis transmembrane conductance regulator) gene and **CTRC** (chymotrypsin C) gene.
- Mutations in PRSS1, SPINK1 and CFTR have been implicated in idiopathic acute and chronic pancreatitis.
- SPINK1 gene is a serine peptidase inhibitor, Kazal type 1. The protein encoded by this gene is a trypsin inhibitor, which is synthesized from pancreatic acinar cells and secreted into the duodenum, which prevents trypsin-catalyzed premature activation of zymogens within the pancreas and the pancreatic duct. SPINK1 gene mutation is associated with hereditary pancreatitis and tropic chronic pancreatitis.

Table 21.99 Laboratory evaluation for acute and chronic pancreatitis

Disorder	Test	Expected Result
Acute pancreatitis	▪ Serum amylase ▪ Serum lipase ▪ Amylase/creatinine clearance	▪ Increased ▪ Increased ▪ Increased
Chronic pancreatitis	▪ Serum amylase ▪ Serum lipase ▪ Amylase/creatinine clearance	▪ Increased, normal or decreased ▪ Increased, normal or decreased ▪ Increased, normal or decreased

Table 21.100 Causes of acute pancreatitis

Category	Causes	
Toxic agents	▪ Alcohol abuse (>80 g daily intake) ▪ Tobacco smoke	▪ Drugs (phenacetin, valproate, thiazide, estrogen, azathioprine)
Obstruction of main pancreatic duct	▪ Cholelithiasis (45%)	▪ Pancreatic neoplasms
Genetic predisposition including hereditary pancreatitis results in recurrent acute pancreatitis	▪ PRSS1 (cationic trypsinogen gene) mutation ▪ SPINK1 (serine protease inhibitor Kazal type 1 gene) mutation	▪ CFTR (cystic fibrosis transmembrane conductance regulator gene) mutation ▪ CTRC (chymotrypsin C gene) mutation
Infectious agents	▪ Human immunodeficiency virus ▪ Mumps virus	▪ Coxsackie virus
Miscellaneous causes	▪ Traumatic injury to pancreas ▪ Hypotensive shock ▪ Post-transplantation	▪ Post-irradiation ▪ Vascular disease (atheroembolism) ▪ Tropical pancreatitis

Alcohol abuse (>80 g daily intake) and obstruction of common bile duct by stones are most important causes of acute pancreatitis in 80% of cases.

- PRSS1 (cationic trypsinogen) gene is located on chromosome 7q34, which provides instructions for making an enzyme called cationic trypsinogen. The cationic trypsinogen enzyme is synthesized in the pancreas and is transported to the small intestine, where it is cleaved to form trypsinogen. PRSS1 gene is associated with hereditary pancreatitis and idiopathic pancreatitis.

Role of Pancreatic Trypsin Role

Activation of trypsinogen to trypsin is a key event in the initiation of pancreatitis. Most investigators believe that acute pancreatitis is caused due to unregulated activation of pancreatic trypsin.

- The trypsin is responsible for autodigestion of pancreas and local inflammation. Enterokinase converts trypsinogen by proteolytic cleavage to trypsin.
- Trypsin also activates other proenzymes in a cascade-like fashion converting chymotrypsinogen into chymotrypsin, that proelastase into elastase.
- Intracellular trypsin may activate other digestive proenzymes, in spite of presence of the trypsin inhibitor SPINK1 and the trypsin-degrading enzyme chymotrypsin C.

Role of Complement System, Kinin System and Cytokines

Complement system and kinin system are also activated, which participate in pathogenesis of acute pancreatitis.

- The inflammation is further propagated by chemical mediators such as IL-1, IL-6 and IL-8 synthesized by neutrophils, macrophages and lymphocytes that reach site of inflamed pancreas.
- Inflamed pancreas shows hemorrhagic fat necrosis and deposition of calcium soaps.
- Autodigestion of the pancreas occurs by the action of various enzymes: (a) phospholipase and lipase produce fat necrosis, (b) elastase damages pancreatic blood vessels resulting in hemorrhage, (c) protease damage pancreatic acinar structures, (d) activated factor XII and complement system cause thrombus formation in the pancreatic blood vessels.
- Pancreatic acinar cell injury results in release of **amylase** and **lipase** in the peripheral blood and their elevated levels are sensitive markers for diagnosing acute pancreatitis.

Clinical Features

Patient presents with acute constant abdominal pain that radiates to the back, nausea and vomiting. Severe acute pancreatitis with retroperitoneal hemorrhage manifests pain in the periumbilical region (**Cullen sign**) and abdominal flank and bluish cutaneous lesions on abdomen. Clinical examination reveals upper abdominal tenderness, tachycardia and hypotension.

Complications

Complications of acute pancreatitis are pseudocyst formation, progression to chronic pancreatitis, diabetes mellitus and abdominal compressional syndrome. Long-term exocrine and endocrine insufficiency may occur. Destruction of islets of Langerhans may result in diabetes mellitus (Fig. 21.111).

- **Pseudocyst formation:** Pseudocyst formation is late complication of acute pancreatitis, which occurs as a result of liquefaction of pancreatic parenchyma by the action of pancreatic enzymes amylase, lipase, elastase and peptidase. Pseudocyst is lined by connective tissue filled with necrotic debris and blood. It may enlarge and obstruct the duodenum. It may become secondarily infected resulting in pancreatic abscess formation.
- **Progression to chronic pancreatitis:** Acute pancreatitis can be imposed on chronic pancreatitis.

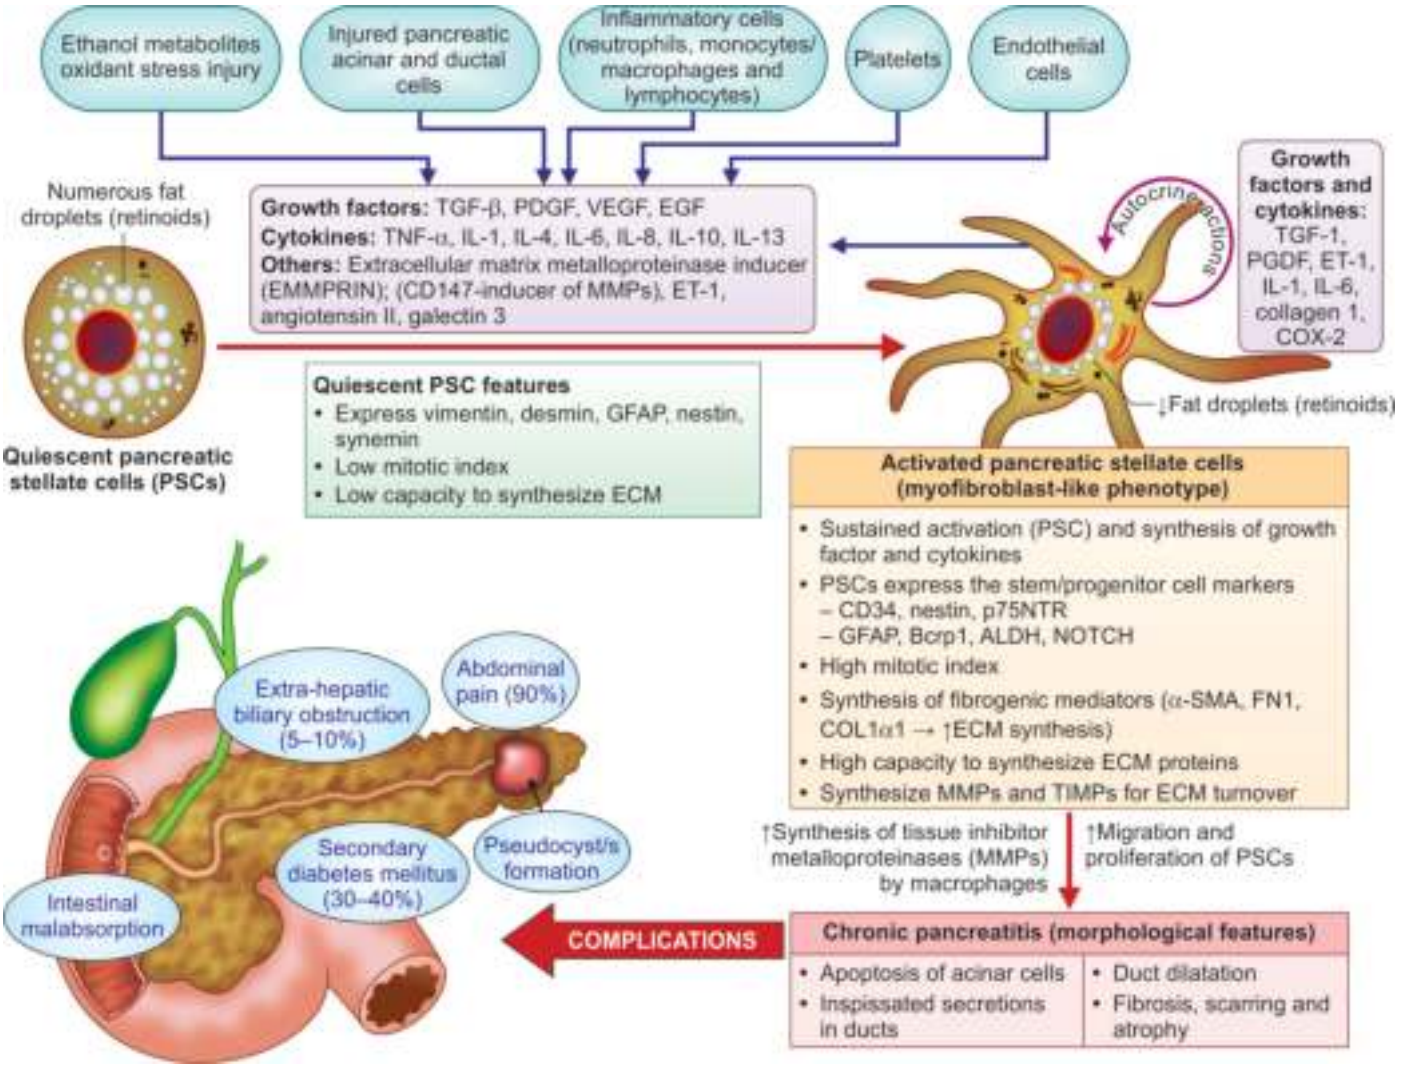

Fig. 21.111: Morphological features and clinical manifestations of chronic pancreatitis.

- **Diabetes mellitus:** Long-term exocrine and endocrine insufficiency may occur in the course of acute pancreatitis. Destruction of islets of Langerhans may result in diabetes mellitus.
- **Abdominal compartment syndrome:** Patient with acute pancreatitis may develop disseminated intravascular coagulation, mesenteric venous thrombosis, bowel infarction, acute respiratory distress syndrome, shock and acute renal failure.

Surgical Pathology: Acute Pancreatitis

- The diagnosis of acute pancreatitis is confirmed by demonstration of elevated serum amylase and lipase.
- Contrast enhanced computed tomography (CT) is performed to confirm the diagnosis of acute pancreatitis, that demonstrates local complications such as fluid collection and necrosis and score the severity of the disease.
- Atlanta classification of acute pancreatitis divides the disease into two grades: mild cases (80%) and severe cases (20%).

Gross Morphology

- The pancreas typically appears swollen and pale. With mild acute pancreatitis, multiple tiny spots of opaque white fat necrosis are observed on the surface of the pancreas.
- In severe cases of acute pancreatitis, large confluent areas of fat necrosis and hemorrhagic areas are observed.

Light Microscopy

- The histologic changes of acute pancreatitis have been demonstrated in autopsy material. In mild form of acute pancreatitis, the disease is concentrated in the interlobular septa of the pancreas. With time, the foci of fat necrosis in the interlobular septa are replaced by fibrosis.
- In more severe form of acute pancreatitis, there is diffuse fat necrosis involving the pancreatic acinar and ductal tissue accompanied by acute inflammatory cells admixed with macrophages. Pancreas shows hemorrhagic necrosis with deposition of calcium soaps. The foci of fat necrosis may liquefy to form a pseudocyst by the action of pancreatic enzymes. The pseudocyst may become infected and associated with high mortality.

Damage to the blood vessels of pancreas results in diffuse hemorrhagic pancreatitis. Well-characterized example of acute pancreatitis triggered by atheroembolism has been reported. Pathogenesis of acute pancreatitis and complications is shown in Fig. 21.112. Fat necrosis of pancreas is shown in Fig. 21.113.

Treatment

Mild form of acute pancreatitis is managed by fluid resuscitation. Severe form of acute pancreatitis requires aggressive fluid resuscitation and antibiotics. Pancreatic fat necrosis and infection are two important local complications, and the infection is responsible for high mortality. When infection is suspected, a fine needle aspiration is done to obtain material for microbiological studies.

CHRONIC PANCREATITIS

Chronic pancreatitis is a pathologic fibroinflammatory disorder of the pancreas and characterized by irreversible morphologic changes such as irregular sclerosis with destruction and permanent loss of exocrine parenchyma, which may be focal, segmental or diffuse and recurrent or persistent abdominal pain.

- Pancreatic duct system shows various degrees of dilatation and its lumen is filled with proteinaceous material and calcification.
- All types of inflammatory cells may be present in varying proportion as well as edema and focal necrosis. Islets of Langerhans may undergo destruction in the later stage resulting in development of diabetes mellitus in these patients.
- Pancreatic insufficiency results in malabsorption syndrome.
- Histologic examination remains the gold standard for diagnosis of chronic pancreatitis. However, biopsy is not feasible in these cases.
- Endoscopic retrograde cholangiopancreatography (ERCP) or biopsy may differentiate inflammatory process from ductal carcinoma of the pancreas.

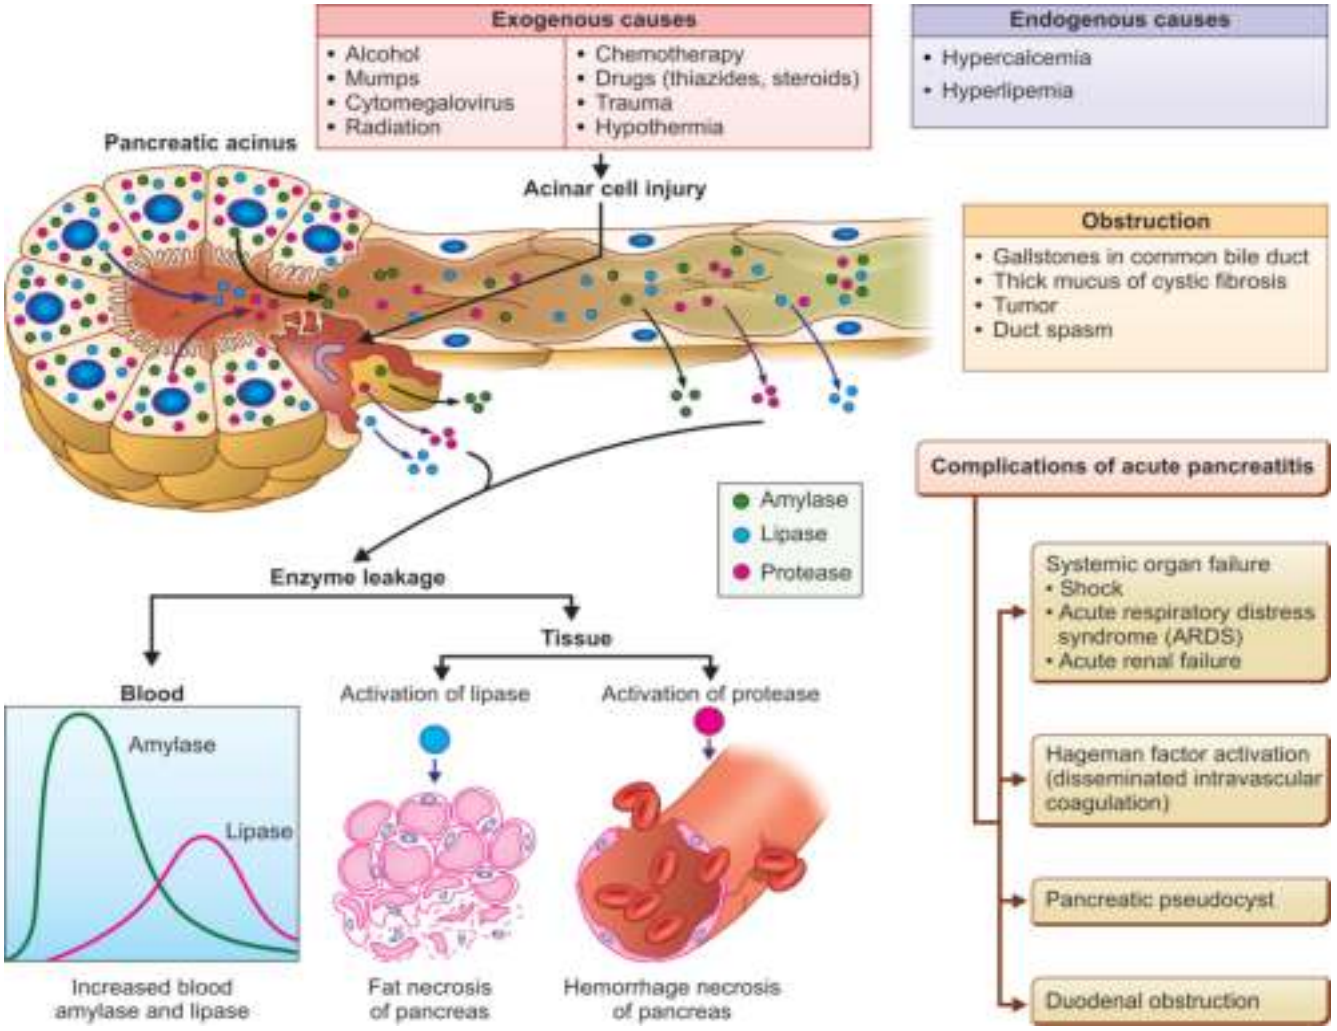

Fig. 21.112: Pathogenesis of acute pancreatitis shows causes of pancreatic injury implicated and complications.

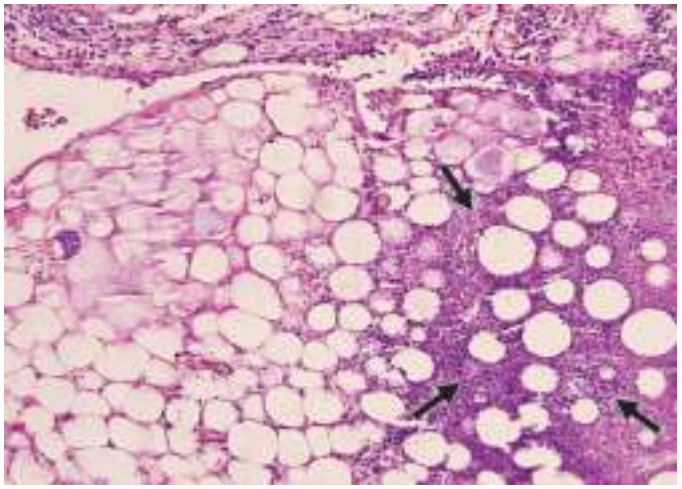

Fig. 21.113: Fat necrosis of pancreas. Microscopic examination reveals irregular islands of necrotic fat cells, which lose their outlines and become indistinct. There is presence of inflammatory cells, macrophages filled with fat and calcium deposits. Deposition of calcium around the periphery of necrotic fat cells gives a basophilic tinge (arrows) (100X).

Etiopathogenesis

In most countries, the most important cause of chronic pancreatitis is alcohol abuse in 60–70% of cases. Some cases suffer from nonalcoholic pancreatitis. Other types of chronic pancreatitis include hereditary pancreatitis, obstructive pancreatitis and pancreatitis associated with hyperparathyroidism.

- Genetic predisposition of acute pancreatitis may lead to chronic pancreatitis in minority of cases.
- In recurrent acute pancreatitis, genetic testing demonstrates mutations of PRSS1 (cationic trypsinogen) gene, SPINK1 (serine protease inhibitor Kazal type 1) gene, CFTR (cystic fibrosis transmembrane conductance regulator) gene and CTRC (chymotrypsin C) gene.
- Mutations in PRSS1, SPINK1 and CFTR have been implicated in idiopathic acute and chronic pancreatitis.
- More recently, mutation in the pancreatic secretory trypsin inhibitor (PST1; N34S located on chromosome 5) has been demonstrated in idiopathic pancreatitis in 25% of cases. Causes of chronic pancreatitis are given in Table 21.101.

Table 21.101 Causes of chronic pancreatitis

Chronic alcoholism
Cholelithiasis
Hypertriglyceridemia
Hypercalcemia
Biliary tract disease
Certain medications
Viral infection

Clinical Features

Clinical features in chronic pancreatitis are variable. Patient may present with recurrent episodic abdominal pain and steatorrhea (foul smelling stool) as a result of pancreatic insufficiency.

- Long-standing malabsorption is accompanied by nutritional deficiency such as anemia, weight loss, bleeding manifestations and osteocalcin (vitamin deficiency).
- The most common local complication of chronic pancreatitis is development of pseudocysts in 25% of cases. These pseudocysts are either retention cysts or that develop following acute exacerbation of chronic pancreatitis. Most pseudocysts regress spontaneously over time.
- Biliary strictures may occur as a complication of chronic pancreatitis.
- Another important complication of chronic pancreatitis is splenic vein thrombosis in 10% of cases. Rare complication is rupture of the main pancreatic duct.

Radiologic Findings

Plain radiograph of the abdomen may demonstrate calcification in chronic pancreatitis. The presence of calcification is best demonstrated by CT scan of the abdomen. Ductal changes are demonstrated by gold standard ERCP and magnetic resonance cholangiopancreatography.

Surgical Pathology: Chronic Pancreatitis

Gross Morphology

Gross morphologic findings in autopsy cases in chronic pancreatitis include irregular scarring, formation of pseudocysts, fat necrosis (autodigestion of pancreatic fat by enzymes) and calcification.

Light Microscopy

- Histologic findings in a case of chronic pancreatitis include presence of extensive fibrosis and inflammatory cells such as lymphocytes, plasma cells and macrophages, perivenular and obliterative thrombophlebitis.
- It is worth mentioning that ductal adenocarcinoma of the pancreas may show histologic features of obstructive pancreatitis distal to the tumor (Fig. 21.114).

AUTOIMMUNE PANCREATITIS

Autoimmune pancreatitis (AIP) is a chronic discrete mass-forming inflammatory lesion in the head of the pancreas, that may mimic pancreatic carcinoma. About 25% of pancreatic resections lack evidence of pancreatic carcinoma. Two subtypes of AIP are now recognized, type 1 and type 2.

- Type 1 AIP is also called IgG4-related disease that often affects multiple organs such as pancreas, bile

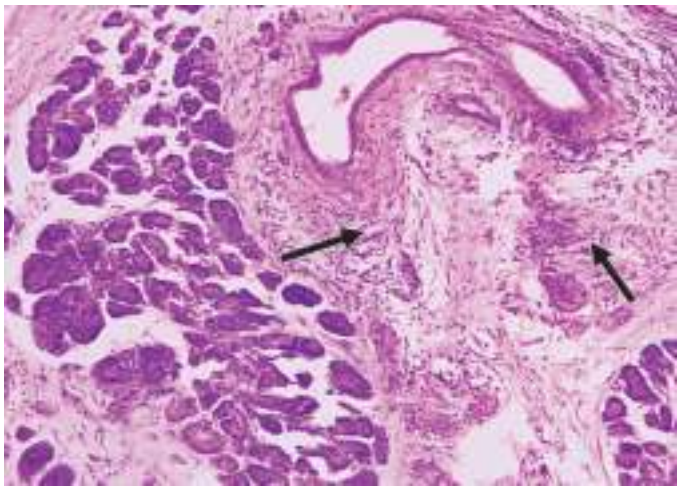

Fig. 21.114: Chronic pancreatitis. It shows infiltration by chronic inflammatory cells. Fibrosis is evident (arrows) (100X).

ducts in the liver, salivary glands, kidney and lymph nodes over age of 40 years. A major milestone in the understanding of the disease is the demonstration of elevated levels of serum IgG4.

- Type 2 AIP is idiopathic, that affects only duct system of pancreas over age of 40 years. Although 33% of persons with type 2 AIP are associated with inflammatory bowel disease.
- AIP can cause pancreatic insufficiency, diabetes mellitus and pancreatic calcification. Differences between type 1 and type 2 AIP are given in Table 21.102.

Clinical Features

Autoimmune pancreatitis is difficult to diagnose. Most patients are asymptomatic. In symptomatic patients, signs and symptoms are similar to those observed in pancreatic carcinoma.

- Patient presents with passage of dark colored urine, pale stool floating in the toilet, yellow discoloration of eyes and skin (jaundice), pain occurring in the upper or middle abdomen, nausea, vomiting, weakness, loss of appetite and weight loss.
- Most common sign of autoimmune pancreatitis in 80% of persons is jaundice as a result of blockage of bile ducts.
- Type 1 AIP responds rapidly to corticosteroid therapy, which is likely to relapse if treatment is discontinued.

Laboratory Investigations

Elevated serum IgG4 is the most robust biomarker for type 1 autoimmune pancreatitis in 80% of cases. The specificity of the test is improved when the threshold of serum IgG4 is set at 280 mg/dl (two times than the normal).

- On imaging, three patterns of AIP are recognized: diffuse (most common), focal and multifocal.
- On ERCP, following four features help in distinguishing AIP from pancreatic adenocarcinoma: (a) a long stricture involving more than one-third of the main pancreatic duct, (b) lack of upstream dilatation, (c) side branches arising from a strictured segment, and (d) the presence of multiple strictures involving the main pancreatic duct.

Surgical Pathology: Autoimmune Pancreatitis

Gross Morphology

- Autoimmune pancreatitis can involve any part of the pancreas. In the active phase, pancreas is enlarged, but in the later phase, pancreas becomes shrunken and fibrotic.
- Gross examination reveals bulky and hard in consistency. Occasionally, a discrete mass is identified, the gross appearance is indistinguishable from pancreatic carcinoma. Main duct of the pancreas is narrow.

Table 21.102 Differences between type 1 and type 2 autoimmune pancreatitis (AIP)

Parameters	Type 1 Autoimmune Pancreatitis	Type 2 Autoimmune Pancreatitis
Age group	Elderly persons during seventh decade of life	Middle aged persons during fifth decade
Sex predilection	Men > women affected	Men = women affected
Clinical presentation	Jaundice (75%) and acute pancreatitis (15%)	Jaundice (50%) and acute pancreatitis (33%)
Systemic disease	Presence of association with system disease	Absence of association with system disease
Elevated serum IgG4	80%	Uncommon
Inflammatory bowel disease	No association	16–30%
Histologic features	Periductal inflammation with one or more of the obliterative phlebitis and storiform fibrosis	Periductal inflammation with one or more of the ductal/lobular abscesses and ductal ulceration with neutrophils
Long-term outcome	Frequent relapse	No relapse

Light Microscopy

- **Type 1 AIP:** It shows periductal inflammation with one or more of the obliterative phlebitis and storiform fibrosis.
- **Type 2 AIP:** It shows periductal inflammation with one or more of the ductal/lobular abscesses and ductal ulceration with neutrophils.

Differential Diagnosis

Autoimmune pancreatitis should be differentiated from pancreatic carcinoma.

CYSTIC FIBROSIS OF PANCREAS

Cystic fibrosis is autosomal recessive disorder of exocrine glands that causes their secretions (mainly mucus, digestive enzymes, bile and sweat) to become abnormally thick and viscous. It is also known as mucoviscidosis or fibrocystic disease of pancreas. It is a lethal disease among White population.

- **Physiologic state:** Normally, transmembrane conductance regulator (CFTr) gene located on long arm of chromosome 7 codes for a membrane protein that participates in the movement of chloride and other ions across membranes.
- **Pathologic state:** Mutation of CFTr gene causes malfunction of exocrine glands results in increased viscosity of mucus and increased chloride concentration in sweat and tears. Pathologic effects in cystic fibrosis are shown in Fig. 21.115.

PATHOLOGICAL LESIONS

Cystic fibrosis affects mostly the lungs but also the pancreas, liver, kidneys and reproductive systems. Systemic manifestations of cystic fibrosis are given in Table 21.103.

- **Respiratory system:** Patient develops recurrent pulmonary infections such as chronic bronchitis, lung abscess, and bronchiectasis. *Pseudomonas aeruginosa* infection is a common cause of death in cystic fibrosis. Other respiratory system changes include development of nasal polyps and chronic sinusitis. Ultimately congestion of lung may alter the pulmonary circulation and to the possibility of right-sided heart failure.
- **Digestive system:** Newborn develops intestinal obstruction caused by thick viscous meconium is known as meconium ileus. In adults, cystic fibrosis interferes with the normal synthesis and drainage of bile juice resulting in gallbladder stones, portal hypertension, splenomegaly, or cirrhosis. Thick mucus also clogs pancreatic duct and hinders the release of pancreatic enzymes. About 90% of cystic fibrosis also develop exocrine pancreatic insufficiency. Later chronic pancreatitis causes diabetes mellitus.
- **Skin:** Cystic fibrosis affects sweat glands in the skin resulting in abnormally thick salty perspiration. There is increased risk of heat stroke and salts depletion especially in infants.
- **Reproductive system:** Almost all men with cystic fibrosis are sterile because epididymis cannot synthesize or incomplete formation of vas deferens. Women with cystic fibrosis often have normal reproductive system and can have successful pregnancies.

DIAGNOSIS AND MANAGEMENT

Sweat chloride test is an important diagnostic tool. Secretion by sweat glands of chloride and sodium is normal, but their reabsorption by sweat ducts is impaired.

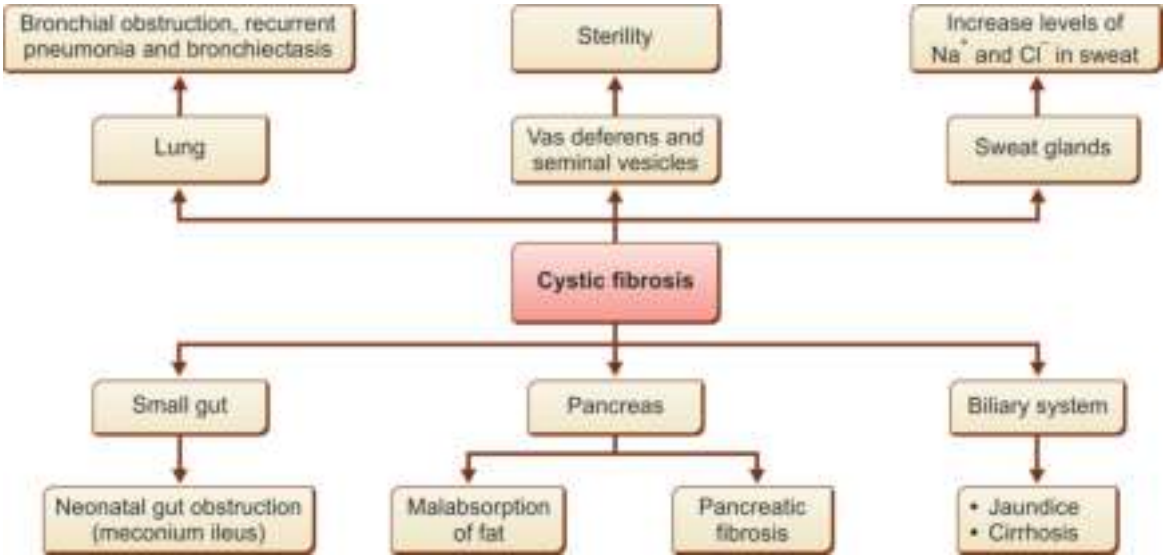

Fig. 21.115: Pathologic effects of cystic fibrosis of pancreas.

Table 21.103 Systemic manifestations of cystic fibrosis

Organs	Secondary Effects
Skin	▪ Salty sweat results in hyponatremia ▪ Acrodermatitis ▪ Dilation of eccrine and apocrine glands
Gastrointestinal lower tract	Meconium ileus resulting in obstruction, perforation, peritonitis, rectal prolapse
Pancreas	▪ Pancreatic duct obstruction causes pancreatic insufficiency (steatorrhea) ▪ Chronic pancreatitis ▪ Failure to thrive ▪ Diabetes mellitus
Liver	▪ Hepatic duct obstruction causes biliary cirrhosis resulting in esophageal varices ▪ Sclerosing cholangitis
Gallbladder	Cholecystitis
Kidney	▪ Nephrolithiasis ▪ Diabetic glomerulopathy ▪ Immune complex-mediated glomerulonephritis
Respiratory system	▪ Bronchiectasis ▪ Recurrent infections ▪ Atelectasis ▪ Allergic bronchopneumonia ▪ Aspergillosis
Heart	▪ Cor pulmonale ▪ Left ventricular fibrosis ▪ Carotid bodies enlarged
Male genital system	Male infertility (obstructive aspermia due to vas deferens atresia in 6% and male infertility in 1–2%)
Female genital system	▪ Multiple ovarian follicular cysts ▪ Cervicitis ▪ Reduced fertility
Musculoskeletal system	▪ Osteoporosis ▪ Muscle wasting ▪ Hypertrophic pulmonary arthropathy ▪ Clubbing
General manifestations	▪ Malnutrition ▪ Vitamin deficiencies (vitamin B_{12}, vitamin K*) ▪ Amyloidosis

Contd...

**Vitamin K deficiency at birth may lead to bleeding.*

- Molecular testing of CFTR gene mutation is another tool. Screening done by using immunoreactive trypsinogen (IrT) assay shows elevated levels in infants with cystic fibrosis.
- Inhalation of bronchodilators reduces resistance in respiratory airways. Inhaled mucolytic agents and saline help in dissolving mucus. Antibiotics are administered to cover infection.

EXOCRINE AND ENDOCRINE PANCREATIC TUMORS

WHO classification of pancreatic neoplasms is given in Table 21.104. Solid and cystic neoplasms of pancreas are given in Table 21.105. Characteristics of epithelial solid neoplasms of pancreas are given in Table 21.106.

Table 21.104 WHO classification of pancreatic neoplasms

Invasive Pancreatic Ductal Adenocarcinoma	
▪ Tubular (conventional) adenocarcinoma	▪ Undifferentiated carcinoma
▪ Colloid (mucinous noncystic) carcinoma	• Anaplastic (giant cell) carcinoma
▪ Medullary carcinoma	• Sarcomatoid carcinoma
▪ Adenosquamous carcinoma	• Carcinosarcoma
▪ Signet ring cell carcinoma	• Undifferentiated carcinoma with osteoclast-like giant cells
▪ Hepatoid carcinoma	▪ Mixed ductal-neuroendocrine carcinoma
Pancreatic Intraepithelial Neoplasia (PanIN)	
▪ PanIN-1A	▪ PanIN-2
▪ PanIN-1B	▪ PanIN-3
Pancreatic Serous Neoplasms	
▪ Microcystic serous cystadenoma	▪ Solid serous cystadenoma
▪ Macrocystic serous cystadenoma	▪ Serous cystadenocarcinoma

Contd...

Table 21.104 WHO classification of pancreatic neoplasms (*Contd...*)

Pancreatic Mucinous Cystic Neoplasms	
▪ Mucinous cystic neoplasm with low-grade dysplasia (mucinous cystadenoma)	▪ Mucinous cystic neoplasm with high-grade dysplasia (carcinoma *in situ*)
▪ Mucinous cystic neoplasm with intermediate dysplasia	▪ Mucinous cystic neoplasm with an associated invasive carcinoma
Pancreatic Intraductal Neoplasms	
▪ Intraductal papillary mucinous neoplasms	▪ Intraductal papillary mucinous neoplasm with an associated invasive carcinoma
▪ Intraductal papillary mucinous neoplasm with low-grade dysplasia	▪ Intraductal oncocytic papillary neoplasm
▪ Intraductal papillary mucinous neoplasm with intermediate grade dysplasia	▪ Intraductal tubulopapillary neoplasm
▪ Intraductal papillary mucinous neoplasm with high-grade dysplasia (carcinoma *in situ*)	▪ Intraductal tubulopapillary neoplasm with an associated invasive carcinoma
Pancreatic Acinar Cell Neoplasms	
▪ Acinar cell cystadenoma	▪ Mixed acinar-ductal carcinoma
▪ Acinar cell carcinoma	▪ Mixed acinar-neuroendocrine-ductal carcinoma
▪ Acinar cell cystadenocarcinoma	
Pancreatic Neuroendocrine Neoplasms	
▪ Neuroendocrine microadenoma	▪ Well differentiated PanNET, nonfunctional
▪ Well differentiated PanNET, functional	• PPoma
• Insulinoma	• Not otherwise specified
• Gastrinoma	▪ Poorly differentiated neuroendocrine carcinoma
• Glucagonoma	▪ Small cell carcinoma
• Somatostatinoma	▪ Large cell neuroendocrine carcinoma
• VIPoma	
Other pancreatic neoplasms	
▪ Pancreatoblastoma	▪ Lymphoma
▪ Solid pseudopapillary neoplasm	▪ Secondary neoplasms
▪ Mesenchymal neoplasms	

PanNET: Pancreatic neuroendocrine tumor; PPoma: Pancreatic polypeptide-secreting tumor; VIPoma: Tumor-secreting vasoactive intestinal polypeptide

Table 21.105 Solid and cystic neoplasms of pancreas

Solid Pancreatic Neoplasms	Cystic Pancreatic Neoplasms
Ductal adenocarcinoma and variants	Serous cystic neoplasms
Acinar cell carcinoma	Mucinous cystic neoplasms
Neuroendocrine neoplasms	Intraductal papillary mucinous neoplasms
Pancreatoblastoma	Solid pseudopapillary neoplasm
	Lymphoepithelial cyst

PANCREATIC ADENOCARCINOMA

Pancreatic ductal adenocarcinoma is the most common malignancy of gastrointestinal tract with high death rate. The majority of pancreatic carcinomas arise from pancreatic duct epithelium. Acinar cell carcinoma is much less common. It is most often silent before widespread dissemination occurs. Death usually results within 1 year. Pancreatic adenocarcinoma elicits an intense desmoplastic response.

Predisposing Factors

- Cigarette smoking is the most important risk factor in the development of pancreatic adenocarcinoma.
- Consumption of smoked meat and fish intake containing polycyclic hydrocarbons increases risk for pancreatic adenocarcinoma. Indirect acting chemical carcinogens associated with pancreatic cancer are given in Table 21.107.

Table 21.106 Characteristics of epithelial solid neoplasms of pancreas

Parameters	Ductal Cell Carcinoma	Acinar Cell Carcinoma	Neuroendocrine Carcinoma
Incidence	More common	Less common	Rare
Desmoplastic response	Marked	Uncommon	Absent
Molecular genetics	K-RAS, TP53, SMAD4, CDKN2A, BRCA2, TGF-β	APC/β-catenin pathway	MEN1 gene, DAXX gene, ATRX gene and mTOR pathway genes
Histologic features	Tumor cells arranged in glandular and papillary structures with mucin in the lumina	Tumor cells arranged in solid sheets, acini, nests with eosinophilic cytoplasm and prominent nuclei with nucleoli	Tumor cells arranged in nests, trabecular and gyriform patterns with uniform salt and pepper chromatin of nuclei
Histochemistry	PAS, mucicarmine positive	d-PAS positive granules	Argyrophil positive granules
Electron microscopic features	Mucigen granules	Zymogen irregular fibrillary granules	Neurosecretory granules
Immunohistochemistry	Glycoprotein markers (carcinoembryonic antigen, CA 19-9, MUC1, TAG72, DUPAN2)	Enzyme markers (chymotrypsin, trypsin, lipase)	Neuroendocrine markers (chymogranin, synaptophysin, CD56)

Table 21.107 Indirect acting chemical carcinogens associated with pancreatic cancer

Chemical Carcinogen	Examples	Associated Cancers
Polycyclic hydrocarbons	▪ Smoked meat and fish intake ▪ Cigarette smoke	▪ Pancreas carcinoma ▪ Oral carcinoma ▪ Esophagus carcinoma (middle and distal) ▪ Lung carcinoma ▪ Renal pelvis transitional cell carcinoma ▪ Urinary bladder transitional cell carcinoma

- *Schistosoma haematobium* also increases risk of pancreatic carcinoma. Parasite associated with pancreatic carcinoma is given in Table 21.108.
- Pancreatic intraepithelial neoplasia and acinar ductal hyperplasia are precursor lesions of pancreatic ductal carcinoma.
- Chronic pancreatitis, diabetes mellitus and alcoholism have been associated with an increased risk for pancreatic carcinoma. Consumption of high fat diet has also been implicated but less common.
- Several familial syndromes increasing the risk for pancreatic adenocarcinoma include Lynch syndrome, Peutz-Jeghers syndrome (STK11/LB1 gene on chromosome 19p13), hereditary pancreatitis (PRSS1 gene), familial atypical mole melanoma syndrome (p16 gene, chromosome 9p21), BRCA2 gene mutation (13q12–q13), familial pancreatic cancer syndrome and Fanconi anemia component genes.

Table 21.108 Parasite associated with pancreatic carcinoma

Parasite	Associated Tumors
Schistosoma haematobium	▪ Pancreatic carcinoma ▪ Squamous cell carcinoma of the urinary bladder

Molecular Genetic Alterations: Pancreatic Adenocarcinoma

Oncogenes, their mode of activation and associated cancers are given in Table 21.109. Tumor suppressor gene mutations associated with pancreatic carcinoma are given in Table 21.110. Genetic progression model of pancreatic carcinogenesis is shown in Fig. 21.116.

- **K-RAS signal-transducing proteins:** Point mutation of K-RAS (chromosome 12p) has been identified in pancreas (90%), colon (50%), and lung (30%).

  SMADA4 tumor suppressor gene (chromosome 18q): SMADA4 tumor suppressor gene is also known as *DPC4*. Mutation of DPC4 (deletion) has been demonstrated in 55% of pancreatic carcinoma.
- **BRCA2 gene (chromosome 13q):** BRCA2 tumor suppressor gene mutation has been associated with pancreatic carcinoma.
- **APC gene (chromosome 5p21):** Mutation of APC tumor suppressor gene (deletion and nonsense) has been demonstrated in sporadic carcinomas (colon, stomach and pancreas) and familial adenomatous polyposis developing colon carcinoma.
- **TGF-β tumor suppressor gene:** TGF-β tumor suppressor gene inhibits G1 to S phase of cell cycle. Mutation of TGF-β has been demonstrated in pancreatic carcinoma.

Table 21.109 Oncogenes, their mode of activation and associated cancers (signal-transducing proteins)

Category	Proto-oncogene	Mode of Activation	Associated Malignancies
GTP-binding (G) proteins	K-RAS	Point mutation	▪ Pancreatic carcinoma ▪ Colon carcinoma ▪ Lung carcinoma

Table 21.110 Tumor suppressor gene mutations associated with pancreatic carcinoma

Gene	Protein	Function	Familial Tumors	Sporadic Cancers
Mitogenic signaling pathway inhibitors				
APC	▪ Adenomatous polyposis protein (locus 5p21) ▪ Mutation by deletion or nonsense	APC inhibits Wnt signaling activator pathway, thus prevents nuclear transcription. It degrades catenin	Familial polyposis coli with malignant transformation	▪ Pancreatic carcinoma ▪ Colon carcinoma ▪ Gastric carcinoma ▪ Thyroid carcinoma ▪ Melanoma
SMADA2 SMADA4	SMADA2 protein SMADA4 protein	Both inhibit TGF-β signaling pathway. These repress CDK4 and MYC. These also induce expression of CDK inhibitor	Juvenile polyposis	▪ Pancreatic carcinoma (55%) ▪ Colon carcinoma
Cell cycle progression inhibitors				
CDKN2A	P16/INK4a and P14ARF	P16 inhibits CDK. P14 indirectly activates p53 tumor suppressor gene	Familial melanoma	▪ Pancreatic carcinoma ▪ Breast carcinoma ▪ Esophagus carcinoma
Angiogenesis inhibitors				
STK11	Liver kinase B1 (LKB1) or STK11	It activates AMPK family of kinases. It suppresses cell growth when cell nutrients and energy levels are low	*Peutz-Jeghers syndrome:* cancers of GIT and pancreas	Diverse carcinomas in 5–20% of cases

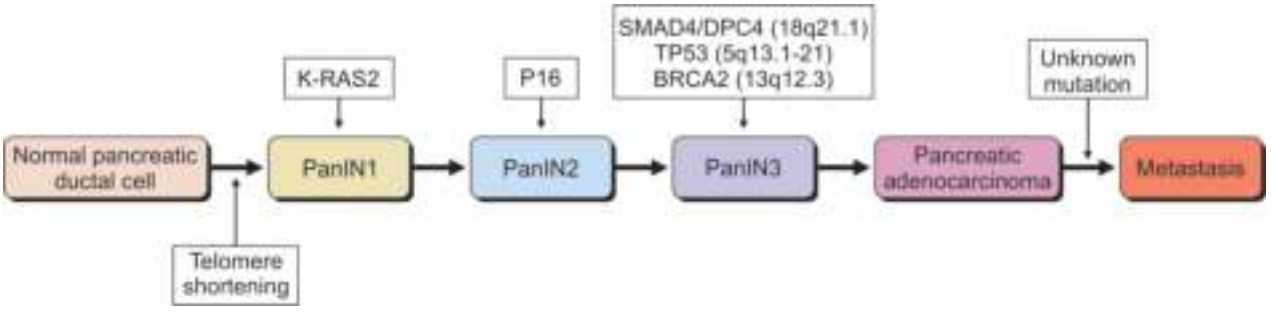

Fig. 21.116: Genetic progression model of pancreatic carcinogenesis.

Pathology Pearls: Evolution of Pancreatic Adenocarcinoma

Pancreatic carcinoma is a genetic disease of inherited or acquired gene mutations. Accumulation of multiple mutations of various genes is most important than their occurrence in a specific order. K-RAS gene mutation and alterations of tumor suppressor genes, i.e. p53, p16, SMADA4/DPC4 play important role in carcinogenesis of pancreatic carcinoma.

- **Early stage of pancreatic adenocarcinoma**: It is thought that telomerase shortening and point mutation of K-RAS (12p) oncogene is an early event in most cases of pancreatic intraductal neoplasia in >90% of cases.
- **Intermediate stage of pancreatic adenocarcinoma**: There is inactivation of the p16 tumor suppressor gene (CDKN2A on chromosome 9p) in >95% of cases.
- **Late stage of pancreatic adenocarcinoma**: Inactivation of p53, SMAD4 (DPC4 on chromosome 18q) in 55% of cases and BRCA2 (13q) tumor suppressor gene occurs in 10%. It results in invasive carcinoma. Other less common gene mutations include LKB1/STK11 (19q), MKK4 (17p) and RB1 (13q).

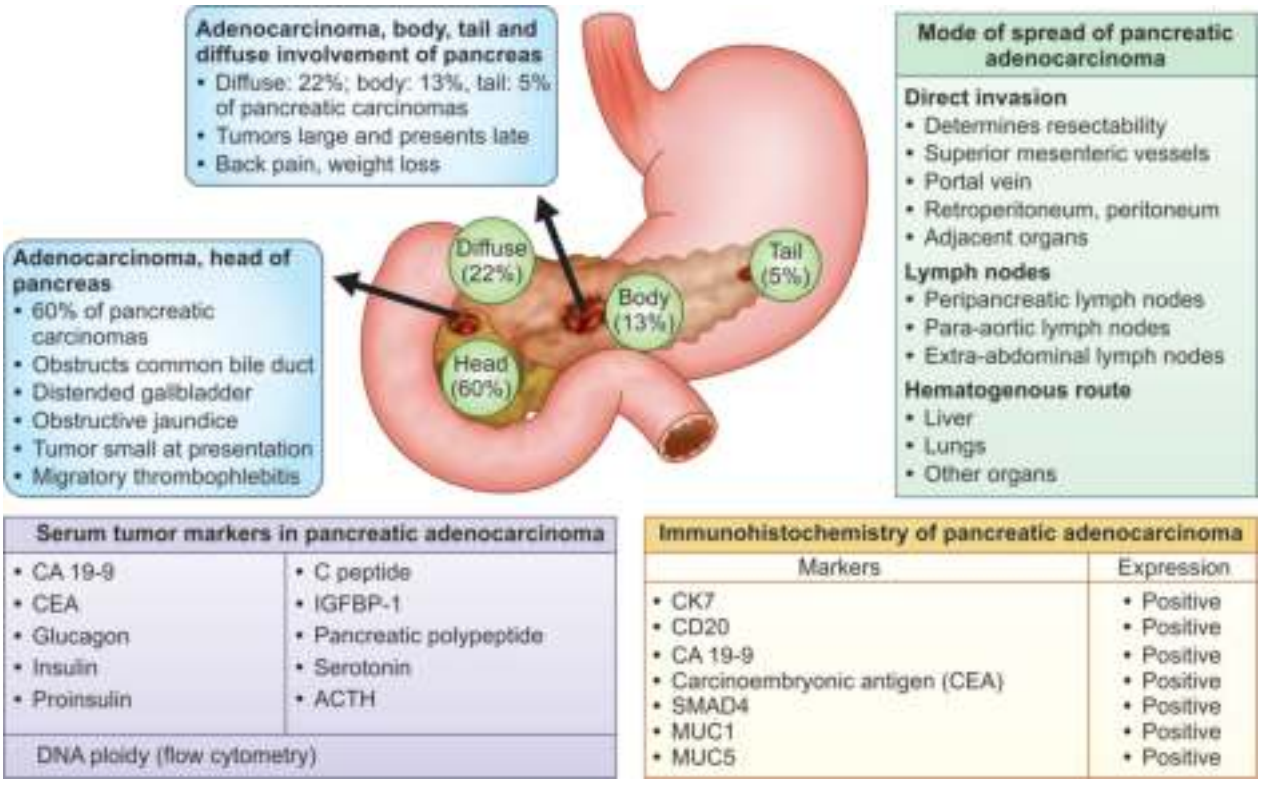

Fig. 21.117: Locations of pancreatic adenocarcinoma and clinical manifestations.

Clinical Features

Patient with pancreatic adenocarcinoma presents with abdominal dull pain constant in nature in upper abdomen radiating to the back, marked loss of weight and anorexia. Patient also mentions passage of dark-colored urine and clay-colored stool. Locations of pancreatic adenocarcinoma and clinical manifestations are shown in Fig. 21.117.

Physical Examination

Physical examination reveals loss of weight, jaundice, and distended palpable gallbladder (Courvoisier sign).

- **Migratory thrombophlebitis (Trousseau sign):** It occurs probably due to release of thrombogenic substances into the circulation (e.g. **serine proteases**) that initiate the coagulation cascade in 10% of cases.
- **Obstructive jaundice (Courvoisier sign):** Carcinoma arising in head of pancreas frequently obstructs common bile duct resulting in painless obstructive jaundice in 20% of cases. It is often accompanied by a distended, palpable gallbladder termed as Courvoisier sign in this setting.
- **Secondary diabetes mellitus:** Carcinoma involving tail of the pancreas can cause islet destruction and secondary diabetes mellitus.

Laboratory Findings

Laboratory tests are consistent with obstructive jaundice, i.e. conjugated hyperbilirubinemia with high 5′-nucleosidase (specific marker for bile duct epithelial cell injury) and alkaline phosphatase. CA19-9 tumor marker is most often elevated (normal range <37 IU/ml) in pancreatic adenocarcinoma.

Surgical Pathology: Pancreatic Adenocarcinoma

Gross Morphology

- Pancreatic adenocarcinoma occurs in various portions of pancreas: head (60%), body (15%) and tail (5%) of the gland. The tumor diffusely involves the entire gland.
- Tumor is usually hard, satellite, poorly circumscribed and gray-white in color. Gross morphology of pancreatic adenocarcinoma is shown in Fig. 21.118.

Light Microscopy

Pancreatic adenocarcinoma is most common histologic variant. Less common histologic variants include acinic cell, adenosquamous and poorly differentiated carcinoma. Morphology of pancreatic adenocarcinoma is described as under.

- Tumor is composed of pleomorphic small to bizarre cuboidal to columnar malignant cells forming abortive glandular structures or nests. Light microscopy of pancreatic adenocarcinoma is shown in Fig. 21.119. Differences between pancreatic adenocarcinoma and chronic pancreatitis are given in Table 21.111.

- Tumor is most often moderately to poorly differentiated adenocarcinoma irrespective of location of tumor in pancreas (well differentiated rare).
- Tumor cells infiltrate the wall resulting in dense stromal fibrosis.
- Perineural invasion and lymphatic invasion may be demonstrated.

Immunohistochemistry Technique

Panel of markers is used to analyze expression in pancreatic adenocarcinoma on tissue sections as given below. Panel of immunohistochemical markers applied in pancreatic tumors is given in Table 21.112.

Markers	Expression
CK-7	Positive
CK-20	Positive
CA 19-9	Positive
DPC4 (SMAD4, MADH4) tumor suppressor gene	Negative (allelic loss)
CEA	Positive
MUC1	Positive
MUC5	Positive
EMA	Negative

Mode of Spread

Pancreatic adenocarcinoma most often metastasizes to regional **lymph nodes, liver, lung, pleura, intestine** and **peritoneum**. Tumor may also metastasize to adrenal glands, bones, gallbladder, diaphragm and kidney.

CT Scan

CT scan technique highlights early detection of pancreatic adenocarcinoma, accurate staging and effective treatment of pancreatic cancer. A minimum of involvement of 15 lymph nodes has been suggested to achieve optimal staging.

Surgical Resection

Surgical excision of pancreatic adenocarcinoma is the only curative treatment option. Only 10–30% cases of pancreatic adenocarcinoma are resectable at the time of presentation with a 5-year survival rate in 18–20% of cases, and a median survival of these patients is 17–21 months. Patient with locally advanced disease has a median survival of 6–10 months.

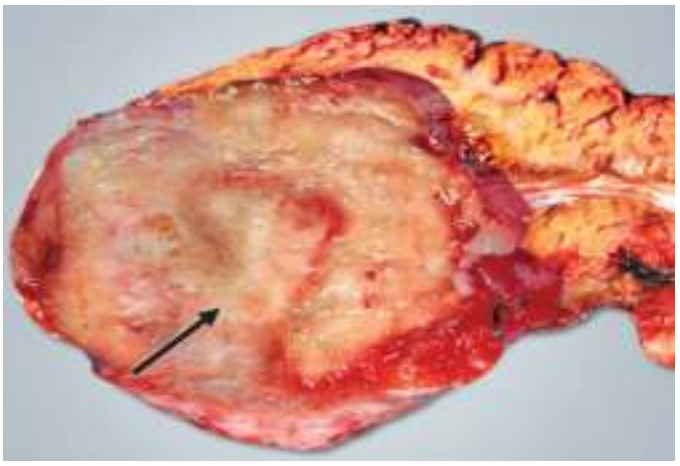

Fig. 21.118: Pancreatic adenocarcinoma. Tumor arising from head of pancreas is gray-white with areas of hemorrhage (arrow).

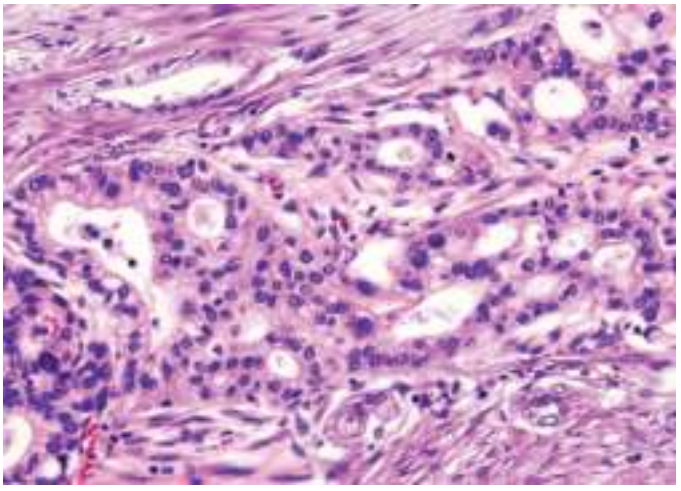

Fig. 21.119: Pancreatic adenocarcinoma. Tumor is composed of pleomorphic small to columnar malignant cells forming abortive glandular structures or nests (400X).

Table 21.111 Differences between pancreatic adenocarcinoma and chronic pancreatitis

Histologic Features	Pancreatic Adenocarcinoma	Chronic Pancreatitis
Histologic pattern	Haphazardly arranged	Lobular arrangement
Ruptured or incomplete glands	Present	Absent
Companion muscular vessel	Present	Absent
Nuclear pleomorphism	Marked in the same glands	Insignificant
Perineural invasion	Present	Absent
Invasion of blood vessels	Present	Absent
Mitoses	Frequent	Infrequent

Table 21.112 Panel of immunohistochemical markers applied in pancreatic tumors

Immunohistochemical Markers	Expression
Pancreatic adenocarcinoma	
CK-7 (cytokeratin 7)	Positive
CK-20 (cytokeratin 20)	Positive
CA 19-9	Positive
DPC4 (SMAD4, MADH4) tumor suppressor gene	Allelic loss
CEA (carcinoembryonic antigen)	Positive
MUC1	Positive
MUC5	Positive
EMA (epithelial membrane antigen)	Negative
Pancreatoblastoma (pancreatic element with ductal, acinar and neuroendocrine differentiation)	
Trypsin	Positive (acinar marker)
Chymotrypsin	Positive (acinar marker)
Lipase	Positive (acinar marker)
Cytokeratin (CK)	Positive (ductal marker)
CEA (carcinoembryonic antigen)	Positive (ductal marker)
Synaptophysin	Positive (neuroendocrine marker)
Chromogranin A	Positive (neuroendocrine marker)
NSE (neuron-specific enolase)	Positive (neuroendocrine marker)
CD56 (neuronal cell adhesion molecule—NCAM)	Positive (neuroendocrine marker)
Pancreatic endocrine neoplasm (formerly known as islet cell tumor)	
Synaptophysin	Positive (neuroendocrine marker cytoplasmic staining)
Chromogranin A	Positive (neuroendocrine marker cytoplasmic staining)
NSE (neuron-specific enolase)	Positive (neuroendocrine marker cytoplasmic staining)
CD56 (neuronal cell adhesion molecule) neuroendocrine marker	Positive (membranous staining)
Cytokeratins (AE1/AE3 and CAM 15.2 epithelial marker)	Positive (cytoplasmic staining)
Insulin hormone	Variable staining
Glucagon hormone	Variable staining
Somatostatin hormone	Variable staining
Mucinous cystic neoplasm	
ER/PR (estrogen/progesterone receptors)	Positive
Inhibin	Positive
Intraductal papillary mucinous neoplasm (IPMN)	
DPC4 intact	Positive
MUC1	Positive
MUC4	Positive
MUC2	Negative
CDX2	Negative

Contd...

Table 21.112 Panel of immunohistochemical markers applied in pancreatic tumors (*Contd...*)

Immunohistochemical Markers	Expression
Pancreatic serous cystadenoma	
CK (cytokeratin)	Positive
EMA (epithelial membrane antigen)	Positive (33%)
Inhibin	Positive
MUC6	Positive
Calponin	Positive
CD31	Positive
Factor VIII	Positive
Lymphoplasmacytic sclerosing (autoimmune) pancreatitis	
IgG4+ plasma cells infiltration	Positive (>20 per high power field)

Serum tumor markers for pancreatic adenocarcinoma include CA 19-9, carcinoembryonic antigen (CEA) glucagon, proinsulin, C-peptide, IGFBP-1, pancreatic polypeptide and serotonin.

PANCREATOBLASTOMA

Pancreatoblastoma is rare malignant pancreatic neoplasm most often affecting children up to 15 years of age.

- Most cases are sporadic, however, it may be associated with Beckwith-Wiedemann syndrome (BWS) or familial adenomatous polyposis (FAP). Patient may present with abdominal lump and pain abdomen, weight loss, diarrhea and nausea. Serum AFP, CEA and ACTH are frequently elevated.
- More than 80% of cases show loss of 11p, mutation in CTNNB1 (50–80%) and mutation in APC gene in FAP.
- Pancreatoblastoma is large (mean size 10 cm), solid and well circumscribed partially encapsulated neoplasm.
- Histologic examination of tumor reveals acinar, ductal, endocrine and squamoid differentiation. There is no cytologic atypia.
- Immunohistochemical analysis reveals tumor cells are positive, i.e. acinar cells (trypsin, chymotrypsin, lipase), neuroendocrine cells (synaptophysin, chromogranin A) and ductal cells (CK7, CK19).
- Pancreatoblastoma can be locally invasive and can metastasize to regional lymph nodes and liver at presentation.
- Prognosis is excellent if tumor is resected before it has metastasized. Overall cure rate is about 50%.

ISLET CELL TUMORS

Mitosis and tumor necrosis are most important in grading a pancreatic endocrine tumor and predicting its malignant potential.

GLUCAGONOMA

Glucagonoma is rare neuroendocrine tumor of pancreatic α cells of pancreas, which results in secondary diabetes mellitus. Patient with glucagonoma presents with necrotizing migratory erythema, mild hyperglycemia, and anemia.

INSULINOMA

Insulinoma is the most common islet cell tumor derived from β cells of pancreas. It is low-grade malignant neoplasm, which synthesizes excess of insulin resulting in hypoglycemia.

- Insulinoma synthesizes insulin by splitting of C-peptide fragment of the proinsulin molecule resulting in increased serum C-peptide level (diagnostic tool).
- Purification of commercial insulin preparations is done by splitting of C-peptide fragment of proinsulin. Hence, exogenous administration of insulin does not increase C-peptide.

Clinical Features

Insulinoma is characterized clinically by Whipple triad: episodic hypoglycemia, central nervous system dysfunction temporally related to hypoglycemia (anxiety, confusion stupor, seizures, paralysis, coma) and dramatic reversal of central nervous system symptoms by glucose administration.

GASTRINOMA

Gastrinoma is a malignant tumor derived from G cells and most often located in the pancreas. It may also occur in duodenum.

- Tumor synthesizes excess of gastrin resulting in increased serum gastrin levels.
- Gastrinoma of pancreas results in Zollinger-Ellison syndrome characterized by gastric hypersecretion of hydrochloric acid, recurrent peptic ulcer disease of the duodenum and sometimes the jejunum, and elevated levels of gastrin in blood.

STOMATOSTATINOMA

Stomatostatinoma is islet cell tumor derived from δ cells of pancreas.

- Normally, delta cells of pancreas secrete somatostatin hormone that inhibits the release of insulin by pancreas. Somatostatin also inhibits the pituitary gland to release of growth hormone. It decreases secretion, motility and absorption in the digestive tract.
- Excess synthesis of somatostatin hormone by tumor results in mild diabetes mellitus, cholelithiasis, steatorrhea, and hypochlorhydria.

VASOACTIVE INTESTINAL PEPTIDE TUMOR

Vasoactive intestinal peptide tumor is marked by secretion of vasoactive intestinal peptide (VIP).

- Vasoactive intestinal peptide stimulates adenylyl cyclase enzyme that leads to the synthesis of large amounts of cAMP. The cAMP causes increased secretion of potassium and water into the intestinal lumen.
- Patient presents with watery diarrhea (5 liters/day), hypokalemia, low levels of chloride in gastric juice (achlorhydria). These symptoms constitute pancreatic cholera.

MULTIPLE ENDOCRINE NEOPLASIA 1 (MEN 1)

Multiple endocrine neoplasia type 1 is also known as Wermer-Morrison syndrome caused by mutation of the MEN 1 tumor suppressor gene.

Wermer-Morrison syndrome comprises pituitary adenoma (acromegaly), parathyroid gland hyperplasia (hypercalcemia) or adenoma and pancreas islet cell tumors (insulinoma and gastrinoma). Gastrinoma produces Zollinger-Ellison syndrome.

CARCINOID TUMORS

Carcinoid tumors of the pancreas are rare malignant neoplasms that closely resemble intestinal carcinoids.

- When carcinoid tumors are confined to the pancreas, serotonin, bradykinin, and histamine synthesized from the tumor into venous blood, induce atypical carcinoid syndrome.
- Hepatic metastases cause the full blown carcinoid syndrome.
- Patient presents with severe facial flushing, bronchial wheezing, watery diarrhea, abdominal colic, hypotension, periorbital edema, and tearing.

METASTATIC PANCREATIC TUMORS

- Most common malignant tumors of lung, breast, thyroid gland, kidney and melanoma (skin) via hematogenous route reach the pancreas.
- Malignant tumors of stomach, duodenum, colon, kidney, lymph nodes and adrenal glands may spread to pancreas by direct extension.

Recent Advances: Liver Biopsy Specimen Handling in Surgical Pathology

Liver biopsy remains the gold standard in the diagnosis of numerous liver pathologies, which has emerged as a useful diagnostic tool to assess severity of hepatocellular damage in patients with abnormal liver functions and/or liver lesion on imaging, treatment plan, monitor response, prognosis, and function of liver transplant. The liver function tests include alanine transaminase (ALT) and aspartate transaminase (AST), alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), prothrombin time and international normalized ratio (PT–INR), serum bilirubin, total serum proteins and albumin/globulin ratio. Nearly 50% of liver biopsies are performed by radiologists by using ultrasonography, computed tomography, and magnetic resonance imaging diagnostic tools.

- **Liver biopsy techniques:** Ultrasound-guided liver biopsy specimen may be taken by using an aspiration needle (i.e. Menghini or Jamshidi) and tru-cut needle.
  - Percutaneous, ultrasound-guided liver biopsy (Menghini technique) has become a worldwide standard. Laparoscopic liver biopsy enables macroscopic inspection of the liver surface and provides more information than percutaneous liver biopsy.
  - Transjugular liver biopsy is a reasonable option for patients with severe coagulopathies or massive ascites, but it carries the risk of intraperitoneal hemorrhage while placing jugular catheter in right jugular vein, skin hematoma, pneumothorax, vena cava perforation, and cardiac arrhythmias. Liver biopsies are at least 1.5–2.5 cm in length allow for better interpretation.
- **Handling, processing, and staining of liver biopsy:** Liver biopsy specimen is fixed in 10% neutral buffered formalin, and then dehydrated and embedded in paraffin, before microtome sectioning and mounting the slides. Liver biopsy is fixed in 2% glutaraldehyde for electron microscopy. The evaluation of liver biopsy requires the use of special stains (e.g. Masson trichrome, iron, PAS with diastase, reticulin, Oil red O, Congo red, and rhodamine stain for copper) is used on

liver biopsy tissue sections other than routine hematoxylin and eosin (H&E) to highlight many important histologic features. Immunohistochemistry has diagnostic role in identification of hepatitis B surface antigen (HBsAg).

- **Hematoxylin and eosin stain:** Liver biopsy specimens are initially stained with hematoxylin and eosin (H&E). The hallmark of the lobular pattern is 'lobular disarray' with increased inflammatory cells, in which normal liver architecture undergoes disruption due to injured hepatocytes. In portal pattern, histologic features include portal/periportal inflammation with mononuclear infiltrate and fibrosis. Extension of inflammation to limiting plates is associated with interface hepatitis. In biliary pattern, distortion of the liver parenchyma is associated with inflammation within portal tracts, neutrophilic infiltrate, proliferation of bile ducts and fibrosis or cholestasis. In steatotic pattern, hepatocytes are laden with intracytoplasmic lipid (microvesicular or macrovesicular steatosis) distributed throughout the liver lobules. Steatosis associated with inflammation is known as steatohepatitis
- **Masson trichrome stain:** Masson trichrome stain is used to assess/stage fibrosis, which stains collagen fibers blue against red background of hepatocytes. It stains type 1 collagen fibers normally present in the portal tracts and blood vessel walls, but highlights reactive fibrosis due to hepatocellular injury. Masson trichrome stain highlights characteristic pattern of advanced fibrosis secondary to steatohepatitis. There is scarring around central vein, perisinusoidal fibrosis separating hepatocyte cords, formation of fibrous septum and periportal fibrosis.
- **Reticulin stain:** Reticulin stain uses silver impregnation to highlight reticulin fibers made of type 3 collagen fibers, which appear black against gray/light pink background. Reticulin stain highlights the reticular pattern in acute hepatic necrosis. The hepatocyte cords are focally expanded, band-like of reticulin collapse near central vein highlights the necrosis.
- **Perls iron stain:** Perls iron stain (prussian blue reaction) detects iron stored in the hepatocytes in the soluble form (ferritin) and insoluble form (hemosiderin). Perls iron stain highlights hemosiderin as coarse blue granules, while ferritin is seen in cytoplasmic as faint blue. Perls iron stain shows marked iron deposition in hepatocytes and Kupffer cells in the settings of primary and secondary hemochromatosis. Perls iron stain can be performed on routinely processed formalin-fixed paraffin-embedded (FFPE) liver biopsy tissue section.
- **Periodic acid–Schiff stain:** Periodic acid–Schiff (PAS) stain is useful for detection of glycogen in glycogen storage disease, but removing glycogen with diastase digestion enhances detection of undigested material such as α_1-antitrypsin globules, basement membrane, fungal organisms, and debris within macrophages.
- **Congo red stain:** Congo red stain shows bright orange positivity in areas of amyloid deposition with a characteristic apple-green birefringence under polarizing microscopy.

  - Chronic kidney disease
- Nephritic syndrome
  - Poststreptococcal glomerulonephritis
  - Alport's syndrome
  - IgA nephropathy (Berger's disease)
  - Goodpasture syndrome
  - Henoch-Schönlein purpura
  - Hemolytic uremic syndrome
- Nephrotic syndrome
  - Minimal change disease
  - Focal segmental glomerulosclerosis
  - Membranous glomerulonephritis
  - Membranoproliferative glomerulonephritis
  - Diabetic nephropathy (diffuse/nodular glomerulosclerosis)
  - Renal amyloidosis
  - Monoclonal immunoglobulin deposition disease of kidney
  - Lupus nephritis
- Rapidly progressive (crescentic) glomerulonephritis
- Chronic kidney disease
  - Chronic kidney disease: laboratory findings and clinical manifestations
  - Chronic kidney disease: medical/surgical management
- Renal biopsy evaluation and interpretation
  - Light microscopy
  - Immunofluorescence microscopy
  - Electron microscopy

TUBULAR DISEASES OF KIDNEY

- Acute tubular necrosis
  - Ischemic acute tubular necrosis
  - Nephrotoxic acute tubular necrosis
- Acute kidney disease

TUBULOINTERSTITIAL DISEASES OF KIDNEY

- Pyelonephritis
  - Acute pyelonephritis
  - Chronic pyelonephritis
  - Xanthogranulomatous pyelonephritis
  - Tubercular pyelonephritis
- Urate nephropathy
- Renal papillary necrosis
- Acute interstitial nephritis
- Light chain cast nephropathy in multiple myeloma
- Renal tubular functional disorders
  - Fanconi syndrome
  - Cystinuria
  - Hartnup disease
- Nephrocalcinosis

UROLITHIASIS

- Molecular pathogenesis of urolithiasis
  - Calcium oxalate and phosphate stones
  - Magnesium, ammonium, calcium phosphate stones (struvite stones)
  - Uric acid stones
  - Cystine stones
  - Xanthine stones
- Complications of urolithiasis
  - Hydronephrosis
  - Urinary tract infection
  - Pyonephrosis
- Laboratory diagnosis of urolithiasis
- Management of urolithiasis

VASCULAR DISEASES OF KIDNEY

- Diffuse renal cortical necrosis secondary to shock
- Renal infarction
- Sickle cell nephropathy
- Nephrosclerosis
  - Benign nephrosclerosis leads to obliteration of glomeruli
  - Malignant nephrosclerosis leads to fatal renal disease
- Thrombotic microangiopathy
- Toxemia of pregnancy involving kidneys
- Vasculitis involving kidneys

CYSTIC DISEASES OF KIDNEY

- Adult polycystic kidney disease
- Infantile polycystic kidney disease
- Solitary renal cyst

- Medullary sponge kidney
- Acquired renal cystic disease

CONGENITAL ANOMALIES OF KIDNEY

- Renal agenesis
- Multicystic renal dysplasia
- Severe congenital anomalies of kidneys and urinary tract
- Ectopic kidney
- Horseshoe kidney
- Ureter anomalies

NEOPLASTIC DISORDERS OF KIDNEY

- Nephroblastic and cystic tumors
  - Wilms' tumor (nephroblastoma)
- Renal oncocytoma
- Renal cell carcinoma
  - Clear cell renal cell carcinoma
  - Multilocular cystic renal cell carcinoma
  - Papillary (chromophil) renal cell carcinoma
  - Chromophobe renal cell carcinoma
  - Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 gene fusion
  - Collecting duct carcinoma of Bellini
  - Urothelial carcinoma of renal pelvis
- Mesenchymal tumors occurring mainly in children
  - Clear cell sarcoma of kidney
- Tumor-like lesions of kidney
  - Renal angiomyolipoma (hamartoma)

RENAL FUNCTION TESTS

- Glomerular filtration rate assessment
  - Exogenous marker of glomerular filtration rate assessment
  - Creatinine clearance
- Tubular reabsorption tests
- Blood biochemistry
  - Blood urea nitrogen
  - Serum creatinine
  - Ratio of blood urea nitrogen to serum creatinine
  - Serum cystatin C
- Novel serum, urine and tissue biomarkers
- Urine analysis

RENAL EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

EMBRYOLOGY

The main functions of the urinary system include: excretion of metabolic waste products such as urea, creatinine and uric acid, maintenance of electrolyte, water and pH balance, regulation of blood pressure, blood volume and erythropoiesis, and production of active form of vitamin D. Development of the urinary system is closely related to the development of the reproductive system, especially during the early stages of embryogenesis, where both develop from the same origin. However, urinary system develops ahead of the reproductive system. The urinary system consists of the kidneys, urinary bladder and urethra. A region of intermediate mesoderm, known as urogenital ridge, which gives rise to these structures (i.e. kidneys, urinary bladder and urethra) during embryogenesis.

DEVELOPMENT OF KIDNEYS

Urogenital ridge forms nephrogenic cord, that gives rise to the urinary system. Nephrogenic cord develops into pronephros, mesonephros and metanephros.

- Pronephros, being nonfunctional regresses completely by five weeks of gestation. Mesonephros differentiates to form mesonephric tubules and mesonephric ducts (Wolffian duct). Metanephros develops into the adult kidney.
- Metanephros located in the sacral region becomes functional at 10 weeks gestation. Ureteric bud undergoes repeated divisions to form the ureters, renal pelvis, major and minor calyces; and collecting ducts.
- The kidneys ascend from the sacral region during fetal life to vertebral levels T12–L3 in the adult. Kidneys migration is accompanied by medial rotation of kidneys by 90°. Supernumerary arteries are formed during ascent.
- A congenital developmental renal malformation occurs resulting from abnormal nephrogenesis due to inability of the ureteric bud to communicate with the metanephric blastema.
- Patients present with bilateral severe renal disease, which is characterized by maternal oligohydramnios, neonatal pulmonary and renal failure.
- Diagnosis of bilateral severe renal disease can be established on antenatal ultrasonography, which reveals small renal size, subcortical cysts, patchy contrast enhancement, architectural disarray, distorted pelvicalyceal system. It may be associated with multiple malformations. Prognosis is worst in bilateral severe renal disease.
- Kidneys are of small size to solid large size cystic and lined by dysplastic epithelium. Dysplastic renal epithelium expresses PAX2, BCL-2 and galectin 3.

DEVELOPMENT OF URINARY BLADDER AND URETHRA

Urinary bladder and urethra develop from the upper end of urogenital sinus, which is continuous with the allantois.

- Allantois becomes the median umbilical ligament (urachus). The lower end of the urogenital sinus forms the female urethra. The transitional and stratified epithelium lining the female urethra are derived from endoderm.
- The prostatic urethra, membranous urethra and proximal part of the penile urethra are also derived from endoderm. Distal part of penile urethra is derived from ectodermal glandular plate.
- The metanephric vesicles differentiate to form glomerulus, Bowman capsule, proximal convoluted tubule, loop of Henle, distal convoluted tubule and collecting ducts.
- Ureter, renal pelvis, major calyx, minor calyx and urinary bladder are lined by transitional epithelium. Collecting ducts are lined by simple cuboidal epithelium.

ANATOMY AND HISTOLOGY

The urinary system consists of the kidneys, urinary bladder and urethra. The kidneys and renal pelvises constitute upper urinary tract; the ureters, urinary bladder and urethra form lower urinary tract.

- Urine produced by nephrons within a renal pyramids empties into the orifices of the terminal collecting ducts (Bellini's ducts) into a minor calyx, major calyx and then funnel-shaped renal pelvis. The collecting system comprises renal pelvises, urinary bladder and urethra that carry urine from the kidneys to the urinary bladder and urethra for urination.
- Normal urinary tract health depends on smooth unobstructed urine. Kidneys participate in excretion of waste metabolic products, adjustment of blood pH by excretion of more or less acid, maintenance of plasma concentration of salts, regulation of blood volume, regulation of blood pressure and hematopoiesis.

KIDNEYS

Kidneys are paired bean-shaped encapsulated organs located in the abdomen (T12, L1, L2 and L3) along vertebral column in retroperitoneal region. Kidneys are invested in a layer in perinephric adipose tissue and covered anteriorly with Gerota's fascia, which is a landmark for staging renal cell malignant tumors.

- Each kidney in the human weighs 150 g. Dimensions of each kidney include: 10–12 cm vertically, 5–7 cm transversely and 3 cm in anteroposterior plane. Outer renal surface is divided into anterior surface, posterior surface, upper pole and lower pole. Medial surface of kidney is concave, deeply grooved (renal sinus) and forms renal hilum.
- Renal hilum is a slit-like space on the medial border of kidneys through with runs the ureter, branches of arteritis and veins, nerves and lymphatics.
- Renal sinus is the region on the medial aspect of the kidney that contains renal collecting system, nerves, blood vessels, lymphatics and adipose tissue and important for renal carcinomas to metastasize outside the kidney.
- Renal capsule covers the convex region of the renal cortex. Renal cortex in contact with the renal sinus lacks capsule, therefore allowing renal cancers to involve renal sinus.
- Nephron is the functional unit of the kidney. Each kidney has about one million nephrons. The number of nephrons is established during prenatal development. After birth, no new nephron can develop and a lost nephron cannot be replaced by regeneration following injury. There is gradual decrease in number of nephrons during aging process.
- Each nephron derived from the ureteric bud consists of a glomerulus, proximal tubule, loop of Henle (descending and ascending limb), distal tubule, connecting segment, and collecting duct.
- Kidneys participate in processing of blood and formation of urine. Urine produced by nephrons within a renal pyramid empties into collecting duct, which passes through a papilla into a calyceal system then renal pelvis.

Renal Histology

Kidney is composed of glomeruli, tubules, interstitial; tissue (cortex 10% and medulla 20%) and blood vessels. Disease of any one of these components affects functions of rest of components resulting in impairment of renal functions. Erythropoietin is synthesized in the cortex, while prostaglandins synthesis occurs in the medulla. Renal cortex receives 90% of blood supply. Renal medulla receives 10% of blood supply.

- Renal cortex is one centimeter beneath the renal capsule and extending down between the renal pyramids (columns of Bertini). Cortex contains 85% of nephrons (proximal and distal tubules) and lacks vasa recta.
- Beneath renal cortex, medulla is divided into outer medulla and inner medulla (papillae). At the tips of the papillae in inner medulla, the epithelium of collecting ducts transforms into urothelium. Renal medulla contains 15% of juxtamedullary nephrons and possesses vasa recta. Medulla contains loop of Henle collecting ducts.
- Efferent arterioles of juxtamedullary nephrons send straight branches and deliver isotonic blood to the renal medulla. Along with loop of Henle, these vasa recta play a crucial role in the establishment of the nephrons' countercurrent exchange system. Medulla participates in the formation of urine.

Renal Anatomy

Each kidney is composed of 8–18 lobes. Each lobe of kidney constitutes a conical medullary pyramid capped by cortical tissue. Downward extension of cortical tissue between the pyramids is called '**renal columns of Bertini**'.

- Normal renal cortex is 1.2–1.5 cm thick over the pyramids. Renal columns of Bertini are located where cortical tissue dips into the medulla between the pyramids.
- Base of pyramid is towards cortex and its papilla pointing towards renal pelvis. Comparison between renal cortex and medulla is given in Table 22.1.

Table 22.1 Comparison between renal cortex and medulla

Parameters	Renal Cortex (1.2–1.5 cm)	Renal Medulla
Blood supply	90%	10%
Number of nephrons	85%	15%
Vasa recta	Absent	Present
Nephron's portions	Glomeruli, proximal and distal convoluted tubules	Collecting ducts and loop of Henle
Interstitial tissue	10%	20–30%
Pyramids	Absent	Present
Synthesis of substances	Erythropoietin	Prostaglandins

Clinical Pearls: Papillae in Renal Pyramids

There are two types of papillae in renal pyramids: simple and compound. Schematic representation of renal simple and compound papillae is shown in Fig. 22.1.

- **Compound papillae:** Compound papillae in renal pyramids are concave shaped with valveless straight ducts located at the poles. That is the reason that hydronephrotic changes are marked in the polar regions due to presence of compound papillae resulting from obstruction to the urinary flow.
- **Simple papillae:** Rest of the pyramids contain conical simple papillae, which are obliquely placed ducts having valve-like action.

Renal Blood Supply

Renal pelvis contains renal artery, renal vein, and nerves. Renal artery arises from abdominal aorta enters kidney through the renal hilum and gives rise to segmental arteries and then branches progressively to form interlobar arteries, arcuate arteries (forming loops at the base of pyramids), traversing the renal parenchyma near the corticomedullary junction.

- Arcuate arteries give rise to interlobular arteries and subsequently efferent arterioles that course into the glomerular capillary tufts.
- Distal ends of glomerular capillaries tuft coalesce to form the afferent arterioles, which progress to a second capillary network. The peritubular capillaries surround the renal tubules.
- Renal arteries are the end arteries. Obstruction to renal artery results in renal infarction (pale/white infarct).
- Renal vein drains into interlobular veins, arcuate veins, interlobar veins, segmental veins, inferior vena cava, which opens into right heart.
- Each kidney has dual lymphatic drainage system. Major lymphatic drainage follows the vasculature

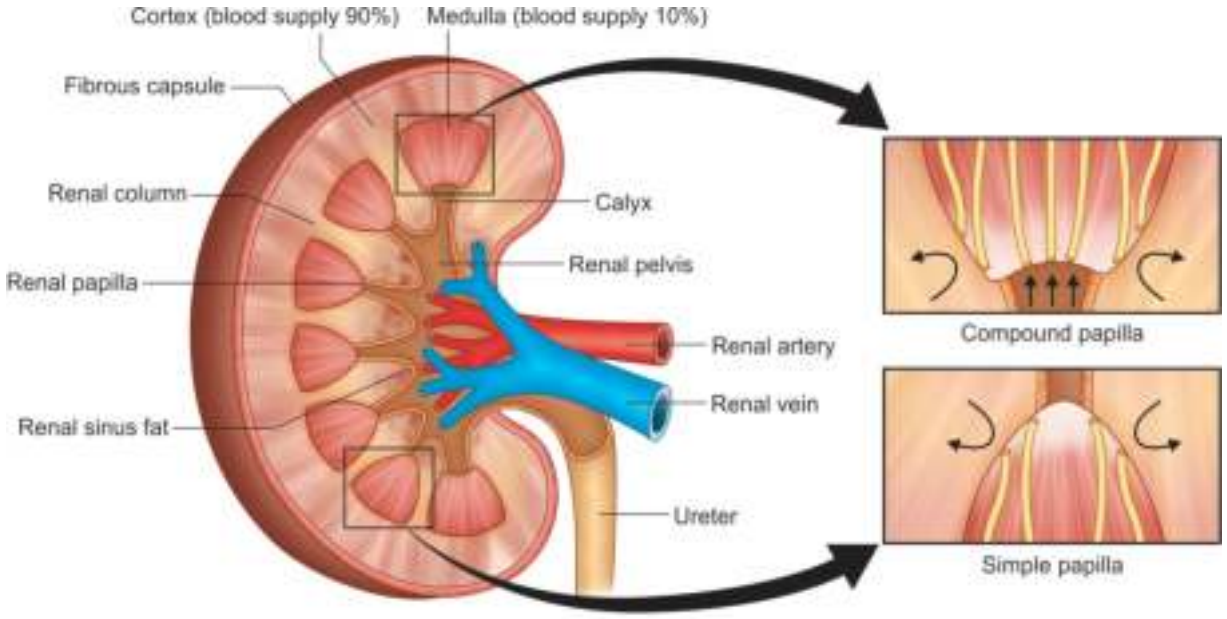

Fig. 22.1: Schematic representation of renal simple and compound papillae. Human kidney contains two types of renal papillae: simple (convex) and compound (concave) papillae. Compound papillae predominate at the polar regions of the kidney, whereas simple papillae are located at nonpolar regions. Approximately, 66% of human papillae are simple (convex) and 34% are compound and are concave (concave) papillae. Obstruction to urine flow first affect compound papillae.

from the renal parenchyma to the renal sinus and terminates in lateral para-aortic lymph nodes. Minor capsular lymphatic drainage from the superficial renal cortex courses along the renal capsule to the renal hilum to join the major lymphatic drainage.

Renal Blood Flow

Kidneys receive 25% of cardiac output: 1200 ml of blood (600 ml of plasma) per minute. The glomeruli filter 120 ml of filtrate per minute (GFR = 120 ml/minute). About 130–180 liters of glomerular filtrate is presented to the renal tubules each day, which results in production of one liter of urine per day. Renal cortex receives 90% and medulla receives 10% of arterial blood.

RENAL PELVIS

Renal pelvis is a funnel-shaped structure present at the hilum of kidney, which contains renal artery, renal vein, and nerves.

- The renal pelvis is the point where the two or three major calyces join together, which is lined by transitional epithelium.
- The renal pelvis functions as a funnel for urine flowing to the ureter. Renal pelvis is site for transitional cell carcinoma and infection.
- The size of the renal pelvis plays a major role in the grading of hydronephrosis. Transverse diameter of renal pelvis measures over 10 mm in adults.

URETERS

The ureters are tube-like structures, which carry urine from the kidneys to the urinary bladder. There are two ureters, each one is attached to each kidney.

- The upper half of each ureter is located in the abdominal region and the lower half is located in the pelvic region. The ureter is about 10–12 inches long in the average adult.
- The ureter has thick walls composed of a fibrous, a muscular, and a mucus coat, which are able to contract. Ureters are lined by transitional epithelium.
- Strong muscular contractions within calyces and renal pelvis propel the urine into the ureters. Musculature of ureter and pelvis is continuous, which allow synchronous peristaltic contractions from kidney to urinary bladder.
- Ureter disorders include duplication of ureter, ureteropelvic junction obstruction and ureterovesical junction obstruction.
- Duplication of the ureter is a congenital anomaly in which two ureters form on the same kidney. Ureteropelvic junction obstruction occurs when the connection between the kidney and ureter is blocked, preventing urine from exiting the kidney.
- Ureterovesical junction obstruction occurs between the ureter and urinary bladder. All these disorders cause obstruction to passage of urine resulting in pyelonephritis, loss of renal functions, and formation of urinary stones.
- Treatment of ureteric obstruction is possible through insertion of a catheter (a special tube), and implantation of a stent (a support to keep vessels or tubes open), or through surgery. If an infection is found, antibiotics are often prescribed.

URINARY BLADDER

The urinary bladder is a muscular sac located in the pelvis, just above and behind the pubic bone, which is lined by transitional epithelium and supplied by sacral nerves (S2, 3, 4).

- When urinary bladder is empty, it is about the size and shape of a pear. Urine produced by kidneys travels down through ureters to the urinary bladder, that stores urine, allowing urination to be infrequent and controlled. Urine is forced out of the bladder and through the urethra.
- Capacity of urinary bladder is 400–600 ml. Potential causes of urinary bladder disorders include overactive urinary bladder, urinary bladder outlet obstruction, interstitial cystitis, urinary tract infections and urinary bladder carcinoma.

URETHRA

Urethra is approximately 3 cm long in females and 20 cm in males. It is a thin fibromuscular tube at the lower opening of the urinary bladder and extends through the pelvis and urogenital diaphragms to the outside of the body, called the external urethral orifice. In males, it consists of prostatic, membranous and penile parts. Women are more prone to urinary tract infection due to short urethra. The urethra also connects to the ductus deferens in males, for the ejaculation of spermatozoa. Females only use their urethra for urination.

PHYSIOLOGY

Homeostasis is defined as a steady state for normal life's metabolic processes. The kidneys regulate the content of blood plasma to maintain the homeostasis of the internal fluid environment within normal limits. Changes in the water content in the cells beyond range may cause death. Approximately >12% of the body water loss in humans may be fatal. Human beings possess readily permeable membranes such as respiratory surfaces and oral membranes. Kidneys perform functions by filtration, reabsorption of essential metabolites, secretion and excretion of waste metabolites.

Table 22.2 Reabsorption of essential metabolites by nephron tubules

Part of Nephron	Reabsorption of Metabolites by Active Process	Reabsorption of Water by Passive Process
Proximal tubule	Na^+, K^+, Cl^-, HCO_3^-, amino acids, glucose and phosphates	Water (80%)
Loop of Henle	▪ Descending limb is only permeable to water only ▪ Ascending limb is impermeable to water, but permeable to salts. Reabsorption of Na^+, chloride, K^+, Ca^+, HCO_3^- and Mg^+	▪ Water (10%) ▪ Water (Nil %)
Distal tubule	Na^+, Cl^-, Ca^+ and Mg^+ (absorption of Na^+, Cl^-, by aldosterone)	Water (5%)
Collecting duct	Water absorption by ADH	Water (5%)

Hydrogen ions and organic acids secreted by proximal tubules enter peritubular network of blood vessels. Hydrogen ions are also secreted by distal tubule.

REABSORPTION OF ESSENTIAL METABOLITES BY TUBULES

Renal tubules absorb essential metabolites by active process such as sodium, potassium, amino acids, glucose, phosphate and bicarbonate. Water is absorbed in proximal tubules by passive process. Sodium is pumped out from tubular cell into interstitial fluid, which drives chloride ions into the interstitial fluid by passive process. Reabsorption of essential metabolites by nephron tubules are given in Table 22.2.

EXCRETION OF HARMFUL PRODUCTS

Kidneys participate in excretion of waste products such as urea, creatinine, uric acid, guanidino compounds, metabolic end products of nucleic acids, aliphatic amines, middle molecules (polypeptides). Normal range of blood urea is 20–40 mg% and serum creatinine 0.6–1.5 mg%. If the renal functions are impaired, accumulation of waste products in the body is termed '**azotemia**'. If the patient develops clinical manifestations, it is denoted as '**uremia**'.

MAINTENANCE OF ACID–BASE HEMOSTASIS

Distal tubules participate in deamination of amino acids resulting in ammonia production that enters the filtrate. Hydrogen and potassium ions also enter distal tubular filtrate in exchange of sodium ions (sodium ions moving out of filtrate). Ammonia combines with hydrogen ions to form ammonium salts.

Pathology Pearls: Urea Cycle

Blood Urea Level

- Normal blood urea is 20–40 mg% and blood urea nitrogen in 10–20 mg/dl.
- Blood urea level is increased due to prerenal causes (myocardial infarction, protein catabolism), renal diseases and post-renal causes (prostatic nodular hyperplasia).
- Blood urea level is decreased due to protein malnutrition, massive liver necrosis, pregnancy and rapid dehydration.

Liver Role in Urea Cycle

- Exogenous and endogenous amino acids reach the liver. Transamination and deamination of amino acids lead to formation of large quantity of ammonia in liver.
- Ammonia enters urea cycle leading to formation of urea 25–35 g per day in liver.
- Approximately 100 g of amino acids produce 30 g of urea. Urea synthesis is decreased in liver diseases.

Kidneys Role in Urea Cycle

Urea formed in the liver reach the kidneys and get filtered passively until it reaches the collecting ducts. Approximately 40% of urea is reabsorbed by nephrons at high rate and 60% at low rate. Most of this urea finds its way back into the descending loop of Henle. The reabsorbed urea plays important role in the maintenance of the medullary solute content.

Pathology Pearls: Creatinine Metabolism

- Creatinine is derived from high energy phosphate compound phosphocreatine, which maintains the level of ATP in muscle.
- Phosphocreatine loses its phosphate to form creatinine. Creatinine is excreted by kidneys. Small quantity of creatinine is reabsorbed by tubules.
- Plasma creatinine level depends two factors: rate of production and rate of excretion. Rate of production is related to skeletal muscle mass.
- Creatinine level is more in young persons with larger muscle mass, and low in children and elderly persons. Creatinine levels are increased in cases of reduced glomerular filtration rate.

REGULATION OF WATER AND ELECTROLYTES

Kidneys regulate water by concentrating and diluting urine and also control sodium reabsorption in the proximal and distal collecting tubules. The functioning of the kidneys is efficiently monitored and regulated by hormonal feedback mechanisms involving hypothalamus, juxtaglomerular apparatus and to a certain

extent, the heart. Renin-angiotensin-aldosterone system (RAAS), antidiuretic hormone (ADH), and atrial natriuretic factor (ANF) provide an elaborate system of checks and balances that regulate body fluid osmolarity, salt concentrations, blood pressure and blood volume. Human substances that affect renal functions are given in Table 22.3. Schematic representation of regulation of fluid and electrolytes is shown in Fig. 22.2.

Juxtaglomerular Apparatus (JGA) and Renin-Angiotensin-Aldosterone System

Renin is a central hormone enzyme in the regulation of blood pressure, electrolyte balance via renin-angiotensin-aldosterone system. Main source of renin is the juxtaglomerular cells of the juxtaglomerular apparatus (JG appratus), which release renin from stored granules in the juxtaglomerular cells.

Table 22.3 Human substances that affect renal functions

Human Substance	Source	Actions
Aldosterone	Zona glomerulosa of adrenal cortex in response to hypotension	Promotes reabsorption of sodium and water in kidneys to increase plasma volume and blood pressure
Atrial natriuretic factor (ANF)	Atrial myocardial cells in response to hypertension	Promotes excretion of sodium and water in kidneys to decrease plasma volume and blood pressure
Antidiuretic hormone (ADH)	Hypothalamus and concentrated in posterior pituitary gland in response to hypotension	Promotes water absorption from distal tubules and collecting ducts to conserve water to concentrate the urine
Renin	Kidney in response to hypotension	Renin stimulates liver to synthesize angiotensinogen
Angiotensin	Renin stimulates liver to synthesize angiotensinogen, which gets converted to angiotensin I and then angiotensin II in lungs	Angiotensin II stimulates synthesis of aldosterone by adrenal cortex, which also causes vasoconstriction and increases peripheral resistance

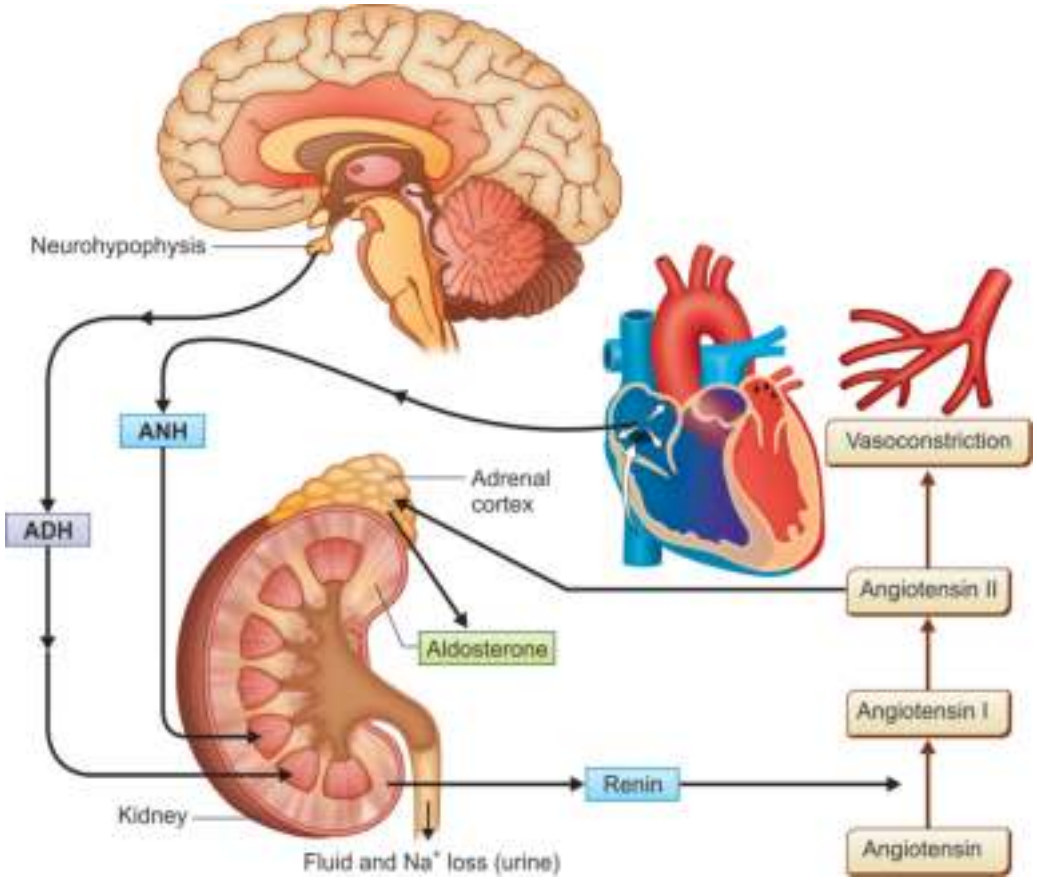

Fig. 22.2: Schematic representation of juxtaglomerular apparatus (JG apparatus). Juxtaglomerular apparatus is closely related to glomerulus, where afferent arteriole enters. JG apparatus is formed by juxtaglomerular cells in the glomerular afferent arteriole, distal convoluted tubule (macula densa, specialized epithelial cells), and nongranular lacis cells. JG apparatus regulates blood pressure and rate of glomerular filtration rate through renin-angiotensin-aldosterone system.

Juxtaglomerular Apparatus (JGA)

Juxtaglomerular apparatus is specialized structure located near the vascular pole of the glomerulus and formed by the distal convoluted tubule (macula densa), glomerular afferent arteriole and nongranular lacis cells. Schematic representation of juxtaglomerular apparatus is shown in Fig. 22.3.

- **Juxtaglomerular cells:** These are modified smooth muscle cells with granular cytoplasm present in the media of afferent arterioles. Juxtaglomerular cells synthesize renin when the blood pressure falls. Renin hormone increases blood pressure via the renin-angiotensin-aldosterone system. Lacis cells, also called extraglomerular mesangial cells, are flat and elongated cells located near the macula densa, which stores renin.
- **Macula densa:** Macula densa is a collection of specialized epithelial cells in the distal convoluted tubule, that detect sodium concentration of the filtrate in the tubular cells in response to elevated sodium. Macula densa cells trigger contraction of the afferent arteriole, reducing blood flow to the glomerulus and the glomerular filtration rate. Main function of macula densa is to regulate blood pressure and the filtration rate of glomerulus.
- **Nongranular lacis cells:** Nongranular lacis cells are present in area bounded by afferent arterioles, macula densa and glomerulus. Function of lacis cells remains unclear.

Renin-Angiotensin-Aldosterone System

- Renin secreted by juxtaglomerular apparatus (JGA) stimulates liver to synthesize angiotensinogen, which gets converted to angiotensin I, and then angiotensin II in the lungs by angiotensin converting enzyme (ACE).
- Angiotensin II is a vasoconstrictor, that increases the peripheral resistance. Angiotensin II also stimulates adrenal zona glomerulosa cells to synthesize aldosterone, which acts on distal convoluted tubule resulting in absorption of sodium and water and expansion of blood volume.
- Aldosterone acts on distal convoluted tubule and helps in absorption of Na^+ and water and completion of the feedback circuit by supporting the release of renin.
- Distal convoluted tubule helps in regulation of blood pH by the reabsorption of an important buffer bicarbonate (HCO_3^-).

Antidiuretic Hormone (ADH)

Osmoreceptors in the hypothalamus are activated by changes in blood volume, body volume and ionic concentration.

- Excess of loss of fluid from the body leads to synthesis of antidiuretic hormone (ADH) by hypothalamus via posterior pituitary gland.
- ADH circulates in blood and acts on collecting ducts to absorb water. ADH also acts on the principal cells of collecting ducts and helps absorption of water.

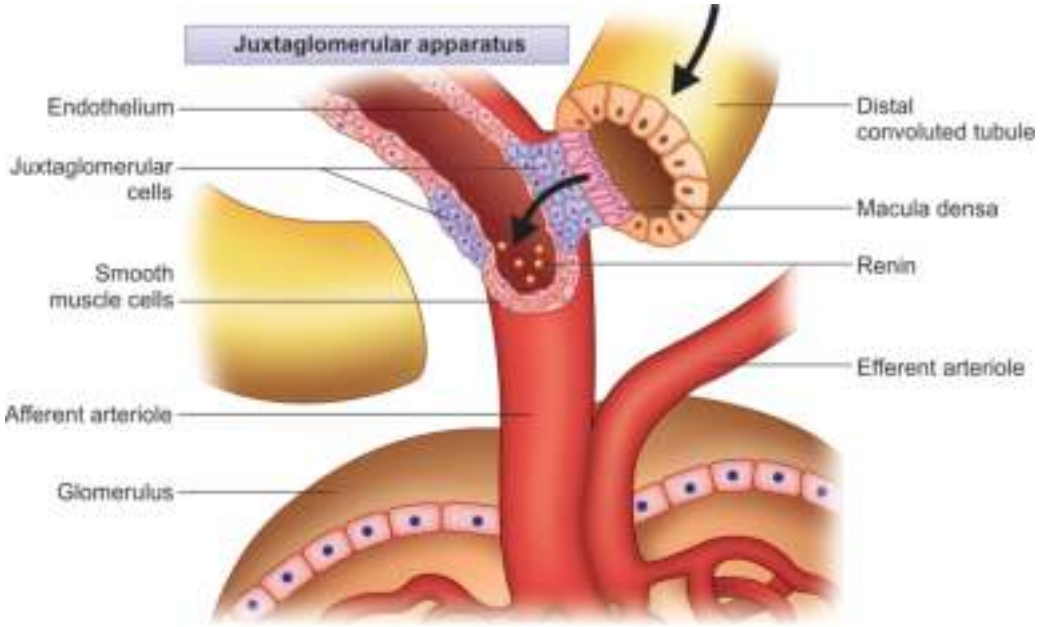

Fig. 22.3: Schematic representation of juxtaglomerular apparatus. Juxtaglomerular apparatus is closely related to glomerulus, where afferent arteriole enters. It is formed by juxtaglomerular cells in the glomerular afferent arteriole, distal convoluted tubule (macula densa, specialized epithelial cells), and nongranular lacis cells. Main function of juxtaglomerular apparatus is to regulate blood pressure and the filtration rate of glomerulus. Juxtaglomerular apparatus releases renin into the blood to raise blood pressure through renin-angiotensin-aldosterone system.

Atrial Natriuretic Factor

Atrial natriuretic factor (ANF) is a peptide hormone, which opposes the regulation by renin-angiotensin-aldosterone system (RAAS).

- The walls of both atria of the heart release atrial natriuretic factor in response to an increase in blood volume and pressure.
- Atrial natriuretic factor inhibits the release of renin from the juxtaglomerular apparatus (JGA), and thereby, inhibits NaCl reabsorption by the collecting duct and reduces aldosterone release from adrenal gland.

MAINTENANCE OF VASCULAR TONE

Kidneys play an important role in maintaining vascular tone by synthesis of angiotensin II and prostaglandins. Angiotensin II synthesized in response to renin production by juxtaglomerular cells causes vasoconstriction of peripheral afferent arterioles and efferent arterioles.

SYNTHESIS OF PRODUCTS

Erythropoietin synthesized in the endothelial cells in the peritubular capillaries (cortex) plays key role in hematopoiesis. Prostaglandins synthesized by renal medulla cause vasodilation of the afferent arterioles. Kidneys participate in the conversion of vitamin D_2 to D_3 by second hydroxylation of vitamin D.

Erythropoietin Synthesis

Erythropoietin is a glycoprotein synthesized in the endothelial cells in the peritubular capillaries of renal cortex (89–90%) and liver (<15%) in response to cellular hypoxia.

- Plasma concentration of erythropoietin is 2–25 IU/L. Erythropoietin is generally increased except in anemia of renal disease. Erythropoietin stimulates BFU-E and CFU-E to divide and mature.
- Erythropoietin increases rate of mRNA and protein (hemoglobin) synthesis. It increases rate of extrusion of nucleus from normoblasts. It stimulates early release of bone marrow reticulocytes. It decreases maturation time of normoblasts.
- Osteoclasts release enzyme alkaline phosphatase, that participates in hydrolysis of pyrophosphate and other inhibitors of calcium-phosphate crystallization, resulting in bone mineralization.

Prostaglandin Synthesis

Prostaglandin synthesis occurs in the cortex by arteries and arterioles as well as the glomerulus. Prostaglandins are important in maintaining blood flow and glomerular filtration rate (GFR) especially during enhanced vasoconstriction activity.

Calcium Homeostasis

Proximal renal tubular cells synthesize enzyme 1α-hydroxylase, that participates in conversion of vitamin D_2 (25-hydroxycholecalciferol) to vitamin D_3 (1, 25-dihydroxycholecalciferol). Vitamin D_3 is the active form of vitamin D.

- Vitamin D increases reabsorption of calcium and phosphorus by gastrointestinal tract. Vitamin D_3 along with parathormone participate in calcium absorption by distal convoluted tubules, resulting in bone mineralization. It increases the production of osteoclasts from macrophage stem cells.
- Osteoclasts release enzyme alkaline phosphatase, which participates in hydrolysis of pyrophosphate and other inhibitors of calcium phosphate crystallization, resulting in bone mineralization.

URINE FORMATION: MECHANISM

Nephrons regulate water and electrolytes, mainly sodium, in the loop of Henle, distal tubule and collecting ducts according to the body's needs. Urine is formed by glomerular filtration, tubular reabsorption, tubular secretion, and concentration of urine by the countercurrent mechanism. Schematic representation of tubular processing of the glomerular filtrate in urine formation is shown in Fig. 22.4.

Glomerular Filtration

Glomerular filtration is the first step in urine formation. Blood pressure inside the glomeruli forces water and dissolved substances into the glomerular Bowman's capsule. Blood cells and proteins remain behind in the blood.

- Glomeruli possess size and charge-dependent barriers. Glomeruli exclude all molecules ≥3.5 nm in size and negatively charged albumin with 70,000 molecular weight.
- The smaller diameter of the efferent arteriole as compared with that of afferent arteriole maintains high hydrostatic pressure. Depending on the extent of injury to the glomeruli, excretion of red blood cells and proteins in urine occurs.

Reabsorption of Essential Metabolites by Nephron

Tubular reabsorption moves essential metabolites back into the blood, while keeping waste products in the nephrons to be eliminated in the urine. Schematic representation of tubular reabsorption of essential metabolites by nephron is shown in Fig. 22.5. Schematic representation of mechanism of sodium reabsorption and potassium secretion by principal cells of the distal and collecting tubules is shown in Fig. 22.6.

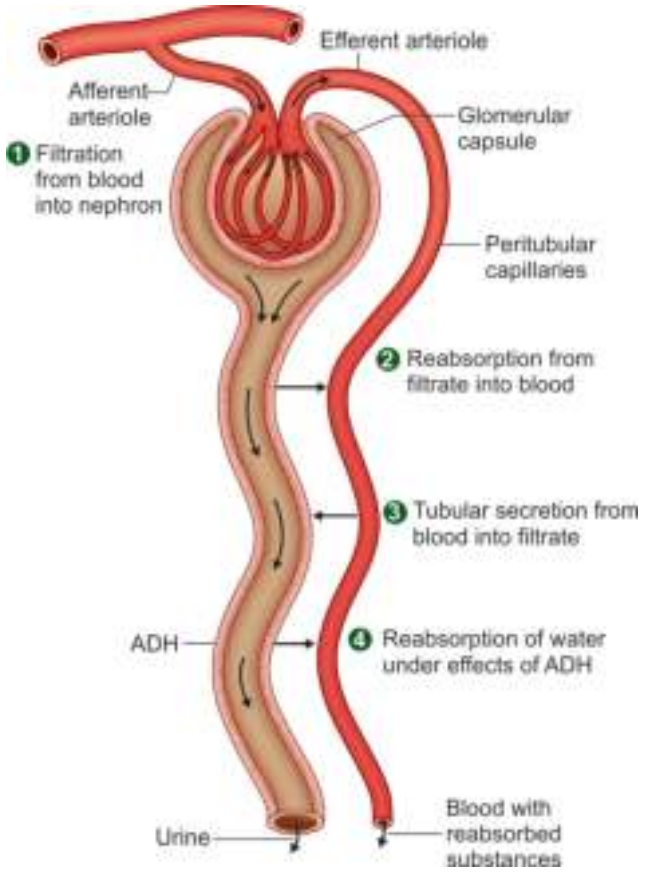

Fig. 22.4: Schematic representation of tubular processing of the glomerular filtrate and formation of urine. Normally, the tubules completely reabsorb essential substances such as glucose and amino acids from the glomerular filtrate. The tubules reabsorb variable quantity of water to adjust plasma osmolarity and secrete variable quantity of hydrogen and electrolytes to adjust plasma pH and electrolyte concentration. Toxins, urea, and creatinine are excreted into urine.

- **Proximal tubules:** Proximal tubules process the filtrate and regulate water and electrolytes. Proximal tubules contain abundant mitochondria, ATPase pump, sodium transporter proteins, aquaporins (water channels) and claudins and membrane proteins in tight junctions.
  - Proximal tubules reabsorb essential metabolites by active process such as sodium (50–55%), potassium, amino acids, glucose, phosphates (100%) and bicarbonate (80%). Water is absorbed in proximal tubules by passive process.
  - Sodium ions are pumped from tubular cell to interstitial fluid. Proximal tubules drive chloride ions into the interstitial fluid by passive process. Proximal tubules synthesize hydrogen ions, that participate in the maintenance of acid–base equilibrium.
- **Loop of Henle:** Loop of Henle participates in absorption of sodium and chloride by active process and water by passive process. Descending limb of loop of Henle is permeable to water only. Ascending limb of loop of Henle is impermeable to water but permeable to essential metabolites such as sodium, potassium, chloride, calcium, bicarbonate and magnesium. Hydrogen ions are also secreted by ascending limb of loop of Henle.
- **Distal tubules:** Distal tubules reabsorb essential metabolites such as sodium, potassium, potassium chloride, bicarbonate, calcium and magnesium, which regulate acid and base equilibrium; and maintain of fluid and electrolyte balance. Several hormones such as aldosterone and natriuretic factor affect tubular reabsorption. Both hormones have opposite action.
- **Collecting duct:** Collecting ducts are permeable to urea, but impermeable to salt. Urea diffuses out of collecting ducts and enters into interstitial fluid contributing to high osmolarity in medulla. Collecting ducts participate in absorption of water by ADH action on collecting ducts. As the urine flows through the collecting ducts, ADH increases the permeability of the collecting duct, and pushes out water from filtrate into interstitial fluid.

Tubular Secretion

Tubular secretion moves additional metabolites from the blood into the nephrons for elimination. Movement of hydrogen ions is one way by which the pH of body fluids is balanced. Distal tubules participate in deamination of amino acids resulting in ammonia production that enters the filtrate. Hydrogen and potassium ions also enter filtrate in exchange of sodium ions (sodium ions moving out of filtrate). Ammonia combines with hydrogen ions to form ammonium salts.

Countercurrent Mechanism and Urine Concentration

Human kidneys can produce nearly four times concentrated urine than the initial glomerular filtrate formed. Proximity of loop of Henle and vasa recta play an important role in production of concentrated urine by countercurrent mechanism. Fluid is flowing in opposite direction between loop of Henle and vasa recta, and thus forming countercurrent system.

- Countercurrent mechanism concentrates the urine and reduces the volume excreted. There is increasing concentration of the interstitial fluid moving from the cortex to the medulla.
- Urine concentration is regulated by means of exchange of water and electrolytes, mainly sodium, in the loop of Henle, distal tubule and collecting ducts. As urine flows through the collecting ducts, water is drawn and hypertonic interstitial fluid moving from cortex to medulla thus concentrating the urine. ADH increases the permeability of the collecting duct, and pushes out water from filtrate into interstitial fluid.

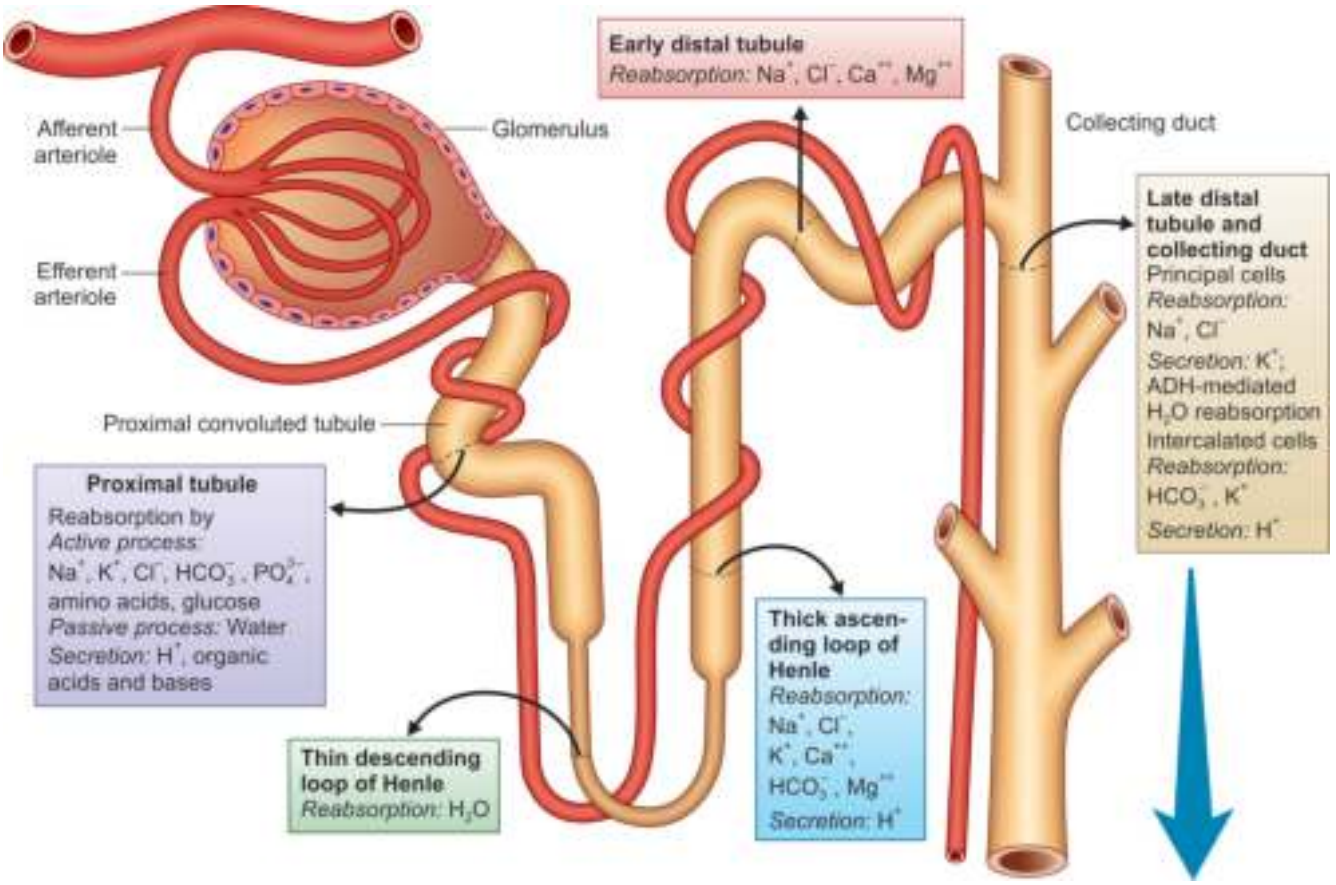

Fig. 22.5: Schematic representation of tubular reabsorption of essential metabolites by nephron. In renal physiology, tubular reabsorption is the process by which the nephron removes water and solutes from the tubular fluid and returns them to the blood circulation. Essential metabolites in the tubular fluid include water (H_2O), glucose, amino acids, Na^+ (sodium), Cl^- (chloride), HCO_3^- (bicarbonate), K^+ (potassium), Ca^{++} (calcium), and Mg^{++} (magnesium), organic acids and bases, H^+ (hydrogen), and K^+ secretion.

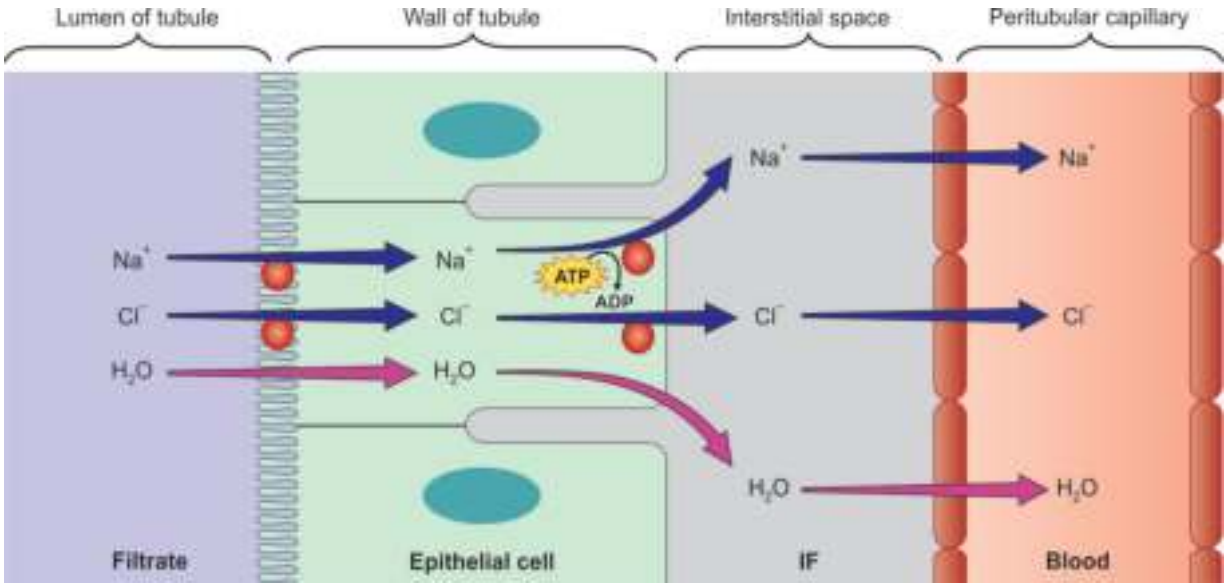

Fig. 22.6: Schematic representation of mechanism of sodium reabsorption and potassium secretion by principal cells of the late distal and collecting tubules. It is well known that sodium reabsorption and aldosterone play key roles in potassium secretion by aldosterone-sensitive principal cells of the late distal and collecting tubules of nephron. Aldosterone exerts its action by increasing the activity of the Na^+/K^+ ATPase pump that transports sodium outward through the basolateral membrane of the cell and into the blood at the same time it pumps potassium into the cell. Aldosterone also increases the permeability of the luminal membrane for potassium.

- Collecting ducts are permeable to urea, but impermeable to salt. Urea diffuses out of collecting ducts and enters into interstitial fluid contributing to high osmolarity in medulla. As the urine flows through the collecting ducts, ADH increases the permeability of the collecting duct, and pushes out water from filtrate into interstitial fluid.
- Schematic representation of concentration of urine by the countercurrent mechanism is shown in Fig. 22.7.

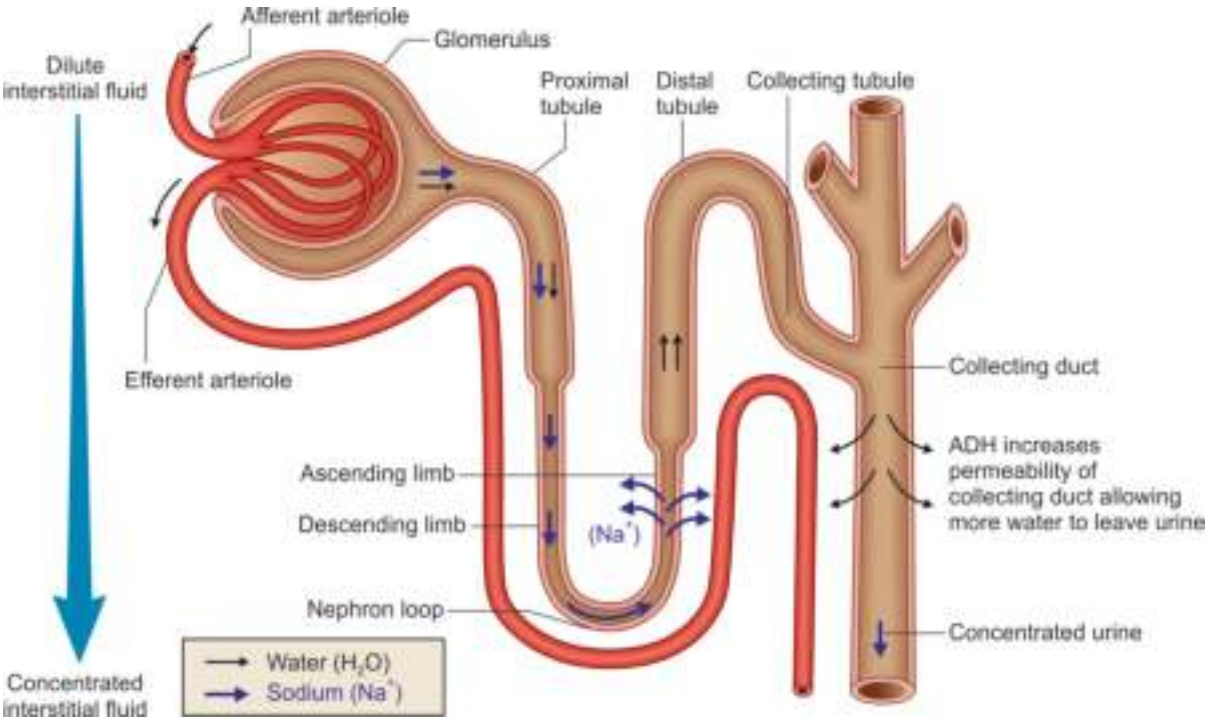

Fig. 22.7: Schematic representation of concentration of urine by the countercurrent mechanism. There are two countercurrent mechanisms in the kidneys: Loop of Henle and the vasa recta. Urine concentration is regulated by exchange of water and electrolytes mainly sodium in the loop of Henle, distal tubule and collecting duct. As urine flows through the collecting ducts, water is drawn out by the hypertonic interstitial fluid, thus concentrating the urine. Antidiuretic hormone (ADH) increases the permeability of the collecting ducts, allowing more water to leave the urine.

GLOMERULAR DISEASES OF KIDNEY

GLOMERULUS STRUCTURE

Glomerulus is composed of bunch of capillaries are lined by thin layer of fenestrated endothelial cells, and glomerular basement membrane. Capillaries are lined by thin layer of fenestrated endothelial cells being about 70–100 nm in diameter.

- The glomerular basement membrane is synthesized from the proteins synthesized by visceral cells of Bowman capsule (podocytes) and the closely apposed capillary endothelium, resulting in a double-thick layer of matrix proteins that is essential part of the glomerular blood filter.
- Glomerular basement membrane (GBM) is composed of collagen fiber types IV and V, laminin, fibronectin, proteoglycans and fibroblasts. Proteoglycans consist of glycosaminoglycans linked to protein and calcium. GMB regulates connective tissue structure permeability.
- Bowman's capsule (lined by visceral and parietal epithelial cells) and mesangial cells, size and charge on GBM determine protein filtration.
- Water, salts, glucose and other small molecules cross glomerular basement membrane from blood into Bowman's space as glomerular filtrate except red blood cells, proteins and other large molecules.
- Schematic representation of glomerulus is shown in Fig. 22.8. Schematic representation of functional parts of the glomerulus is shown in Fig. 22.9. Basic structure and function of the glomerulus is given in Table 22.4.

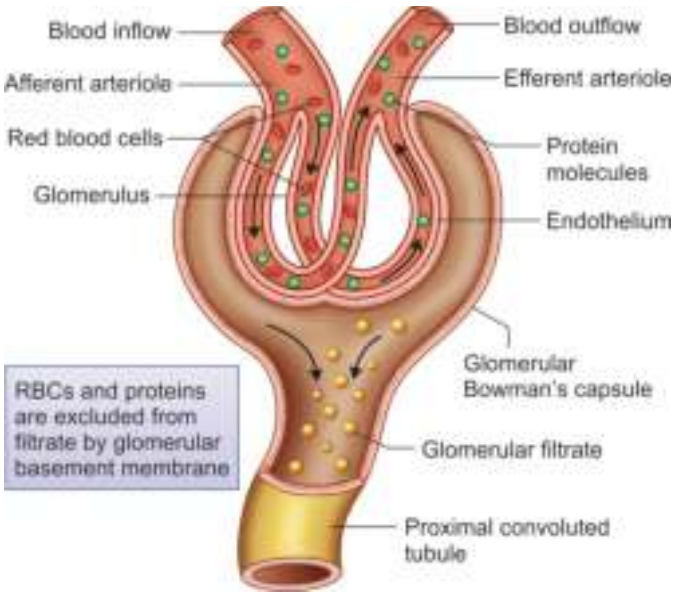

Fig. 22.8: Schematic representation of glomerulus. The glomerulus is a tuft of capillaries supported by mesangial cells and located within Bowman's capsule. Afferent and efferent arterioles are branches of renal artery. The capillaries are lined by delicate fenestrated endothelia with a central lumen. Afferent arteriole carries blood to the glomerulus, whereas efferent arteriole drains blood away from the glomerulus. Diameter of lumen of efferent arteriole is smaller than afferent arteriole, hence glomerular filtration occurs as a result of small lumen's diameter of efferent arteriole. Hydrostatic pressure in the glomerulus is >60 mm Hg. Blood flow to kidneys is 1200 ml/minute (blood plasma 600 ml/minute). Glomerular filtration is 10% of the total renal blood flow. RBCs and proteins are excluded from glomerular filtrate by GBM.

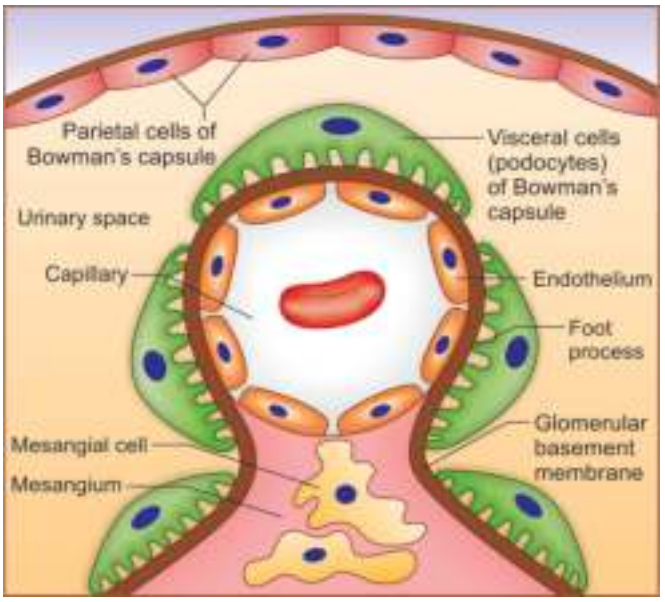

Fig. 22.9: Schematic representation of functional parts of the glomerulus. Glomerulus is the filtering unit of the kidney, which has tuft of capillaries lined by delicate fenestrated endothelia, which in contact with inner surface of glomerular basement membrane (GBM) and specialized visceral epithelial cells of Bowman's capsule. Visceral cells of the Bowman's space form the slit diaphragms between foot processes. Endothelial pores act as size-dependent barrier that excludes blood cells. GBM acts as size-dependent barrier that excludes large macromolecules. Podocytes act filtration slit diaphragm which acts as size-dependent barrier. Outer layer of the Bowman's capsule is lined by parietal epithelial cells. GBM also acts as charge-dependent barrier. Negative charge on the GBM excludes negative charged albumen in the glomerular filtrate.

Table 22.4 Basic structure and function of the glomerulus

Components	Functions
Glomerular capillary endothelial cells	
Endothelial cells lining glomerular capillaries	Exclude molecules ≥3.5 nm diameter
Glomerular basement membrane (GBM)	
GBM structure	▪ Collagen IV fibers provide strength to GBM ▪ Laminin helps in the attachment of endothelial cells and visceral cells of Bowman's capsule to the matrix ▪ Fibronectin binds to collagen fibers, heparan, and proteoglycans, fibrin, and other cells via integrin receptors. It is involved in interactions of cells with the extracellular matrix.
GBM layers	▪ Lamina rara interna is innermost layer of GBM towards glomerular capillary endothelial cells ▪ Lamina densa is middle layer of GBM ▪ Lamina rara externa is outermost layer of GBM towards visceral epithelial cells
GBM charge	Negative charge on GBM is due to polyanionic proteoglycans and anionic sialoglycoproteins exclude negative charged molecules like albumin
Bowman's capsule	
Visceral epithelial cells of Bowman's capsule	▪ Visceral epithelial cells line inner layer of Bowman's capsule form podocytes ▪ Slit pores are present between podocytes prevent filtration of large size molecules
Parietal epithelial cells of Bowman's capsule	Parietal epithelial cells lining outer layer of Bowman's capsule
Mesangial cells	
Mesangial cells present in mesangial region	Mesangial cells provide mechanical support to the glomerular capillaries and regulate glomerular filtration rate

Pathology Pearls: Components of the Glomerulus

Glomerular Capillaries

Glomerular capillaries are lined by thin layer of fenestrated endothelial cells being about 70–100 nm in diameter.

Glomerular Basement Membrane

- The glomerular basement membrane is a 250–350 nm thick ribbon-like extracellular matrix that lies between the fenestrated endothelium and podocyte foot processes, i.e. visceral layer of Bowman's capsule. The mesangium contains mesangial cells and their associated mesangial matrix. Schematic representation of glomerular basement membrane (GBM) is shown in Fig. 22.10.
- GBM consists of central electron dense layer, the lamina densa, thinner electron-lucent lamina rara interna (towards endothelial cells), and thinner electron-lucent lamina rara externa (towards visceral layer of Bowman's capsule).
- GBM is composed of collagen fiber type IV, laminin, fibronectin, proteoglycans and fibroblasts. Proteoglycans consist of glycosaminoglycans linked to protein and calcium. It regulates connective tissue structure permeability.
- There is negative charge on endothelial cells, glomerular basement membrane and visceral epithelial cells (podocytes).
- As albumin also possesses negative charge, therefore, it is repelled and not filtered in the glomerular filtrate.

Collagen IV

The major component of glomerular basement membrane is known to be type IV collagen, which provides structural strength to the capillary. It is resistant to collagenase enzymes.

Laminin

- Laminin is a cross-shaped molecule distributed along glomerular basement membrane's lamina rara interna and externa. It comprises long arm and short arm. Long arm binds heparan sulfate and short arm with globular ends to collagen. Laminin has high affinity for collagen and proteoglycans. Laminin is believed to mediate attachment of endothelium and visceral epithelium to connective tissue matrix substrates.

Fibronectin

- Fibronectin is a multifunctional glycoprotein consisting of two dimers held together by disulphide bonds. It is synthesized by fibroblasts, monocytes, endothelial cells and other cells.
- Fibronectin binds to collagen, heparan sulfate and proteoglycans, fibrin, and other cells via integrin receptors. It is involved in the interactions of cells with the extracellular matrix.

Polyanionic Proteoglycans

- Polyanionic proteoglycans comprise heparan sulfate hyaluronic acid, chondroitin, dermatan, and keratin, linked covalently to protein core.
- Heparan sulfate is present in the form of clusters in lamina densa and along lamina rara interna and externa, which retain fluid and maintain normal shape and structure of GBM.
- Proteoglycans play diverse role in regulating connective tissue, structure, charge dependent permeability barrier and modulating cell differentiation.

Anionic Sialoglycoproteins

Anionic sialoglycoproteins coat glomerular capillary endothelial cells and the visceral epithelial cells. These are responsible for charge dependent glomerular filtration barrier.

Fibroblasts

- Fibroblasts synthesize glycosaminoglycans comprising of hyaluronic acid, chondroitin, dermatan, keratin and heparan sulfate.
- Fibroblasts synthesize elastic fibers. In inflammation, elastase synthesized by bacteria, polymorphonuclear cells degrade elastic fibers resulting in formation of elastic myofibrils and elastin fibers.
- Elastin fibers are abundant amorphous substance comprising of tropoelastin (polypeptide), desmosine, iododesmosine and tropoelastin.

Bowman's Capsule

Bowman's capsule is a portion of the nephron that forms a cup-like sac surrounding the glomerulus. Bowman's capsule encloses a space called 'Bowman's space', which represents the beginning of the urinary space and is contiguous with the proximal convoluted tubule of the nephron.

Visceral Epithelial Cells of Bowman's Capsule

- Visceral epithelial cells of Bowman's capsule are primarily responsible for production of the glomerular basement membrane, which contain podocytes (foot-like processes).
- Slit pores between the podocytes 20–30 nm wide are bridged by a thin diaphragm, which serve as a distal major filtration barrier for preventing protein loss in the urine. Proteins linking podocytes include nephrin, podocin and CD2 associated proteins (CD2AP). Schematic representation of structure of kidney slit diaphragm adaptor CD2 associate protein (CD2AP) is shown in Fig. 22.11.
  - CD2AP is a multidomain scaffolding protein that has a critical role in renal function. CD2AP is expressed in glomerular podocytes at the slit diaphragm and links nephrin and podocin to phosphoinositide-3-OH kinase; this complex has cell signaling properties.
  - Nephrin and podocin are slit diaphragm proteins identified in families with congenital nephrotic syndrome.
  - Integrins span the membrane and anchor the actin cytoskeleton to the collagen type IV in the lamina rara externa of the basement membrane.
  - Effacement of podocytes seen in minimal change disease is responsible for nephrotic syndrome.

Parietal Epithelial Cells of Bowman's Capsule

Parietal epithelial cells line the Bowman's capsule. Due to increased permeability of glomeruli, fibrinogen leaks and stimulates the parietal cells, which undergo proliferation forming crescents resulting in destruction of the glomeruli, and impairment of renal functions.

Mesangial Cells

- Normally, mesangial cells are present in small number in mesangial matrix.

- Mesangial cells provide mechanical support to the glomerular capillaries.
- Mesangial cells participate in processing plasma proteins and immune complexes.
- Mesangial cells maintain glomerular basement membrane and matrix elements.
- Mesangial cells participate in modulation of glomerular filtration rate.
- Mesangial cells synthesize prostaglandins and cytokines, which participate in cell proliferation and chemotaxis of inflammatory cells.
- Mesangial cells release inflammatory mediators in IgA nephropathy.

GLOMERULAR PERMEABILITY BARRIERS

Glomeruli consist of size and charge dependent barriers, which prevent RBCs, protein, and other large molecules from leaving blood and passing into urine. Alteration in size and charge dependent barriers of glomeruli leads to leakage of proteins and red blood cells in urine.

- Glomerulopathy causes impairment of charge dependent barrier resulting in protein loss. Normally, about 300 mg of albumin is excreted in urine per 24 hours.
- Selective proteinuria reveals presence of only albumin in the urine. Nonselective proteinuria refers to loss of both albumin and globulin in urine. Glomerular permeability size and charge barriers are given in Table 22.5.

GLOMERULAR FILTRATION RATE

Kidneys receive 25% of cardiac output, i.e. 1200 ml of blood (600 ml of plasma) per minute. The normal GFR for an adult male is 90–120 ml per minute.

- Glomerular filtration occurs through endothelial cells (85%) and mesangial region (15%). Almost all of the glomerular filtrate is reabsorbed by renal tubules. Mesangial cells regulate glomerular filtration rate (GFR) and have phagocytic activity. Glomeruli participate in filtration of substances.
- Glomerular filtration is the first step in urine formation. Blood pressure inside the glomeruli forces water and dissolved substances into the glomerular Bowman's capsule. Red blood cells and proteins remain behind in the blood. The smaller

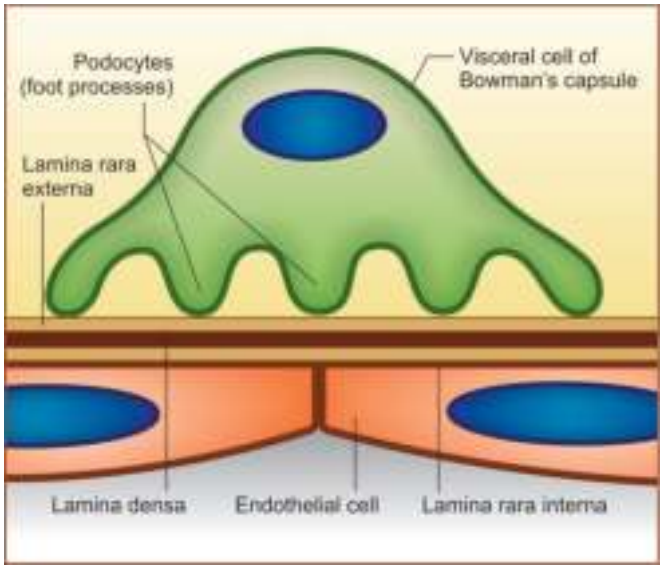

Fig. 22.10: Schematic representation of glomerular basement membrane (GBM). Glomerular basement membrane is a ribbon-like extracellular matrix that lies between the endothelium and podocyte foot processes. The mesangium contains mesangial cells and their associated matrix. GBM is composed of lamina densa (middle portion), lamina rara interna towards endothelial cells and lamina rara externa towards visceral cells of Bowman's capsule. There is a negative charge on the endothelial cells, GBM and visceral cells. These act as charge dependent barrier for negative charged albumin. Outer layer of the Bowman's capsule is lined by parietal epithelial cells.

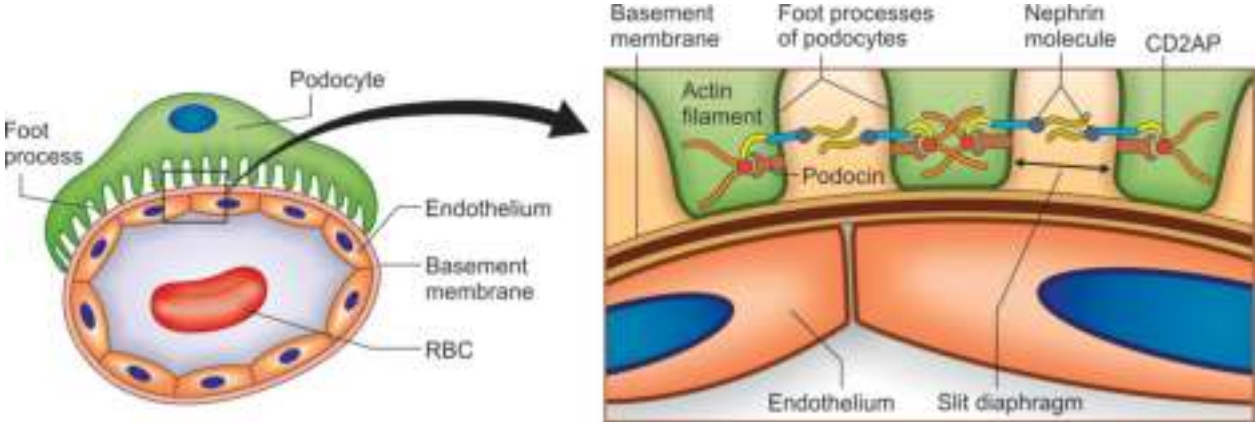

Fig. 22.11: Schematic representation of structure of kidney slit diaphragm adaptor CD2 associate protein (CD2AP). CD2-associated protein (CD2AP) is a multidomain scaffolding protein that has a critical role in renal function. Nephrin and podocin are slit-diaphragm proteins identified in families with congenital nephrotic syndrome.CD2AP is expressed in glomerular podocytes at the slit diaphragm and links nephrin and podocin to phosphoinositide 3-OH kinase; this complex has cell signaling properties.

Table 22.5 Glomerular permeability size and charge-dependent barriers

Size-dependent Glomerular Permeability Barrier
In health, the glomerular filtration size and charge dependent barriers function as a highly organized semipermeable membrane preventing the presence of the majority of proteins into the urine
Glomerular filtration size-dependent permeability barrier excludes ≥3.5 nm diameter molecules such as proteins and red blood cells
Filtration slit diaphragms are present between the podocytes of visceral epithelium of Bowman's capsule. The filtration slits are comprised of matrix proteins of glomerular basement membrane
Glomerular capillary wall and surrounding glomerular visceral epithelial cells of Bowman capsule regulate fluid movement from the glomerular capillary into Bowman's capsule space and also regulate the movement of macromolecules
Charge-dependent Glomerular Permeability Barrier
There is negative charge on the glomerular capillary endothelial cells, glomerular basement membrane and visceral epithelial podocytes of Bowman's capsule. Hence, negatively charged albumin is excluded of glomerular filtrate
Glomeruli consist of negatively charged molecules such as polyanionic glycosaminoglycans (heparan sulfate and sialoproteins), which provide negative charge on endothelial cells, glomerular basement membrane and epithelial cells
Glomeruli allow greater penetration of neutral and cationic molecules than anionic molecules of the same size. These exclude negatively charged albumin from glomerular filtrate

diameter of the efferent arteriole as compared with that of afferent arteriole maintains high hydrostatic pressure.

- Glomerular filtration rate depends upon: (a) renal blood flow, (b) hydrostatic pressure in glomeruli (normal 60 mm Hg due to smaller lumen of efferent arterioles), (c) number of functional glomeruli, (d) blood colloidal pressure (normal 25 mm Hg), and (e) back pressure in tubules (normal 15 mm Hg).
- Filtration pressure is necessary to drive fluid across the glomerular basement membrane. It is equal to the difference between the blood pressure in the glomeruli (60 mm Hg) and sum of oncotic pressure exerted by plasma proteins (27 mm Hg) and intratubular pressure (15 mm Hg). Filtration pressure = Blood pressure in the glomeruli – (oncotic pressure 27 mm Hg in glomeruli + intratubular pressure 15 mm Hg).
- Water distribution in the body is regulated by osmotic and oncotic pressure of plasma. Lower plasma oncotic pressure induces intracellular edema, while lower plasma oncotic pressure induces extracellular edema.
- Normally, renal tubules completely reabsorb from glomerular filtrate such as glucose and amino acid. Almost all of the glomerular filtrate is reabsorbed by renal tubules and returned to blood. The tubules reabsorb variable amount of water to adjust plasma osmolality and secrete variable quantity of hydrogen and electrolytes to adjust plasma pH and electrolyte concentration. Toxins, creatinine and urea pass unaltered into urine.

GLOMERULONEPHRITIS: TERMINOLOGY

Terminology used to describe morphologic lesions of kidney is given in Table 22.6. Schematic diagram of structure of distribution of glomerulonephritis disease in kidney based on glomerular involvement as shown in Fig. 22.12.

Table 22.6 Terminology used to describe morphologic lesions of kidney

Terminology	Features
Light microscopy	
Focal glomerulonephritis	▪ Involving <50% of glomeruli in both kidneys ▪ Example: Henoch-Schönlein purpura, IgA nephropathy, Goodpasture syndrome, infective endocarditis, vasculitis and connective tissue disorders
Diffuse glomerulonephritis	▪ Involving >50–100% glomeruli in both kidneys ▪ Example: Post-infectious glomerulonephritis (glomeruli are hypercellular due to proliferation of glomerular cells and leukocytic infiltration and immune complex deposits in glomeruli. It is termed as exudative/necrotizing glomerulonephritis)
Segmental glomerulonephritis	▪ Involving part of glomerular tuft ▪ Example: Diabetes mellitus (increase in extracellular matrix (hyalinization) within the mesangial region)
Global glomerulonephritis	▪ Involving whole glomerular tuft ▪ Example: Lupus nephritis (renal involvement in cases of systemic lupus erythematosus)

Contd...

Table 22.6 Terminology used to describe morphologic lesions of kidney (*Contd...*)

Terminology	Features
Membranoproliferative glomerulonephritis	Combined capillary wall thickening and mesangial or endocapillary hypercellularity
Lobular glomerulonephritis	Lobular appearance of capillary loop architecture due to endocapillary proliferation seen in membranous glomerulopathy
Diffuse glomerulosclerosis	Obliteration of capillary loop and increased mesangial matrix
Nodular glomerulosclerosis	Relatively acellular areas of mesangial matrix expansion seen in diabetic nephropathy
Crescentic glomerulonephritis	▪ Extracapillary hypercellularity other than the epithelial hyperplasia of collapsing variant of focal segmental glomerulosclerosis (FSGS) ▪ In crescentic glomerulosclerosis, inflammatory chemical mediators cause proliferation of parietal epithelial cells in Bowman's syndrome resulting in proliferation of glomerular tuft, e.g. rapidly proliferative glomerulonephritis such as Goodpasture's syndrome
Spikes and domes appearance of glomeruli	Projections of glomerular basement membrane intervening between subepithelial immune complex deposits seen in membranous glomerulopathy
Endocapillary hypercellularity	Increased cellularity internal to the glomerular basement membrane (GBM) composed of leukocytes, endothelial cells and/or mesangial cells filling up and distending capillary lumen seen in proliferative lupus nephritis
Extracapillary hypercellularity	Increased cellularity in Bowman's space, i.e. >1 layer of parietal or visceral epithelial cells on monocytes/macrophages
Fibrinoid necrosis	Destruction of glomerular cells and matrix with deposition of acidophilic fibrin-rich material
Hyaline change	Glassy acidophilic extracellular material
Sclerosis	Increased collagenous extracellular matrix that is expanding the mesangium, obliterating capillary lumens or forming adhesions to Bowman's capsule
Mesangium	Mesangium is stalk region of capillary loop with mesangial cells surrounded by matrix
Mesangial hypercellularity	Presence of 4 or more nuclei in a peripheral mesangial matrix segment
Subepithelial region	Region between glomerular basement membrane and podocytes
Subendothelial region	Region between glomerular basement membrane and endothelial cell
Tram-track appearance	Double contour of glomerular basement membrane due to deposits and/or circumferential interposition
Wire loop appearance	Thick rigid appearance of capillary loop due to massive subendothelial deposits
Activity of lesion	Treatment sensitive lesions such as extent of cellular infiltrate, crescents, necrosis and proliferation
Chronicity of renal disease	Irreversible renal lesions, i.e. extent of tubular atrophy, interstitial fibrosis, fibrous crescents, sclerosis
Immunofluorescence microscopy staining pattern	
Diffuse linear staining of GBM	Smooth continuous staining seen along capillary loops in ant-GBM antibody mediated glomerulonephritis or along tubular basement membrane in Goodpasture's syndrome
Granular lumpy bumpy deposits in glomeruli	Discontinuous flecks of staining producing granular pattern seen in membranous glomerulopathy, Poststreptococcal glomerulonephritis, IgA nephropathy and lupus nephritis
Irregular (fluffy) deposits	Irregular (fluffy) staining is seen in monoclonal light chains (AL) and amyloid associated protein (AA)
Subendothelial deposits	Immune complex deposits in subendothelial region in lupus nephritis in systemic lupus erythematosus
Subepithelial deposits	Granular lumpy bumpy (large size) immune complex deposits are demonstrated in poststreptococcal glomerulonephritis and membranous glomerulonephritis
Mesangial region deposits	Immune complex deposits (IgA1 and complement) in IgA nephropathy
Intramembranous region deposits	Immune complex deposits in membranoproliferative glomerulonephritis and lupus nephritis

Contd...

Table 22.6 Terminology used to describe morphologic lesions of kidney (*Contd...*)

Terminology	Features
Electron microscopy	
Electron dense immune complex deposits	▪ Immune complex deposits in intramembranous and subepithelial region in membranous glomerulonephritis ▪ Immune complex deposits in mesangial region in IgA nephropathy ▪ Immune complex deposits in subendothelial region in lupus nephritis
Effacement of foot processes (podocytes)	Flattening of foot processes so that cover the glomerular basement membrane with loss of slit diaphragms seen in minimal change disease
Microvillous transformation	Small extensions of visceral epithelial cells with villus-like appearance
Circumferential interposition	Extension of mesangial cell or infiltrating monocyte cytoplasm with interposition between endothelial and basement membrane, often with underlying new basement membrane formation seen in membranoproliferative glomerulonephritis
GBM thickening	Diabetic glomerulosclerosis
Collagen matrix deposit	Focal segmental glomerulosclerosis
Fibrillary deposit	Fibrils 14 nm diameter without organization seen in amyloid nephropathy

Immunofluorescence microscopy demonstrates patterns and location of immune complex deposits of IgG, IgA, IgM, complement (C1q, C3), fibrin, light chains, and albumin).

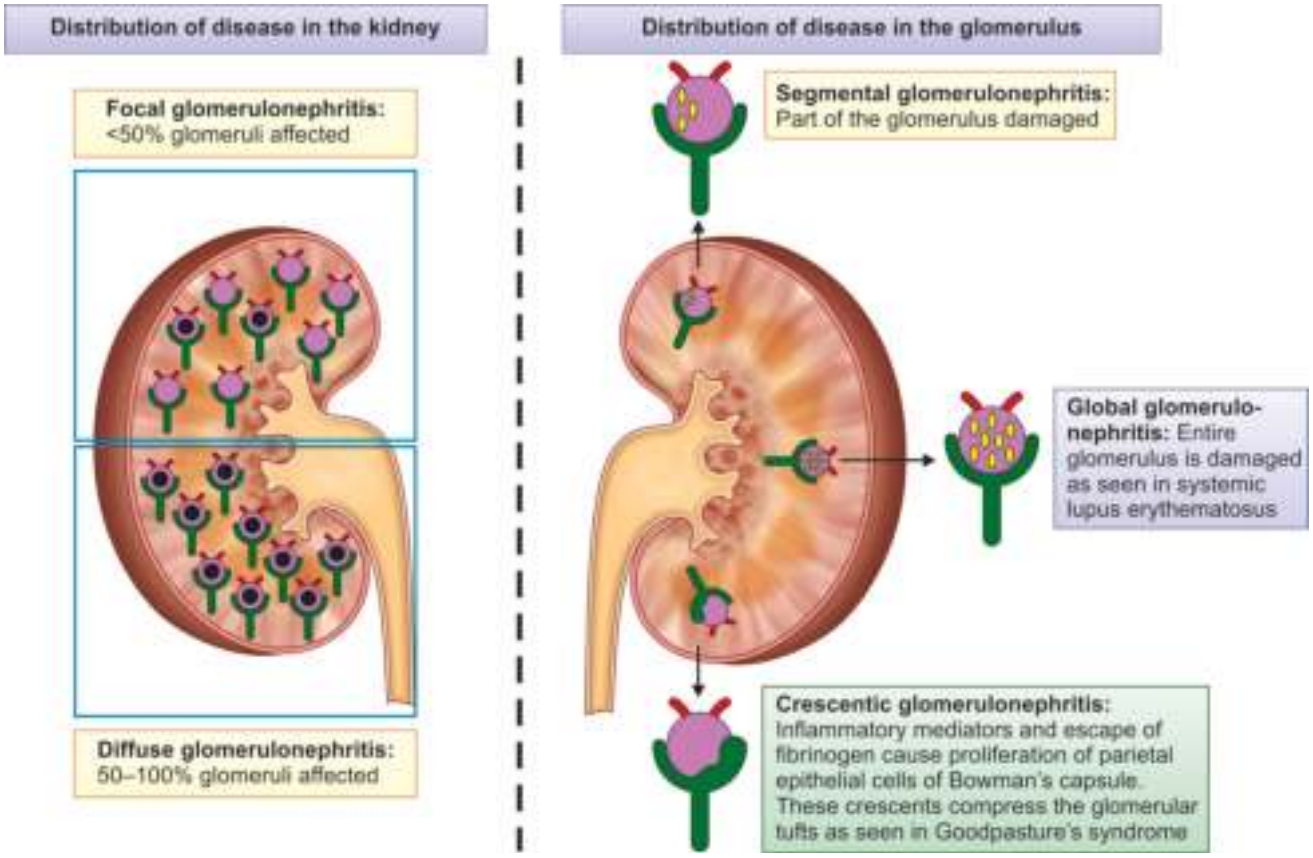

Fig. 22.12: Schematic diagram of structure of distribution of glomerulonephritis disease in kidney based on glomerular involvement. It depicts: (a) diffuse glomerulonephritis (bilateral glomeruli involvement >50–100%), (b) focal glomerulonephritis (bilateral glomeruli involvement <50%), (c) global glomerulonephritis (all the capillaries involved within glomerulus), (d) segmental glomerulosclerosis (segment of glomeruli involved with hyalinization within the mesangial region), (e) crescentic glomerulonephritis is an immune-mediated disease, which causes severe glomerular inflammation and injury, and often results in irreversible renal failure. Inflammatory mediators stimulate proliferation of parietal cells of Bowman's capsule leading to formation of crescents, which compress glomerular tufts and thus adversely affect glomerular filtration.

CLASSIFICATION OF GLOMERULONEPHRITIS BASED ON ETIOLOGY, CLINICAL PRESENTATION, APPEARANCE OF GLOMERULAR CAPILLARY TUFT AND DURATION OF DISEASE

Glomerular diseases are caused by damage to structural components of glomeruli, i.e. endothelial cells lining glomerular capillaries, glomerular basement membrane, mesangial cells, mesangial matrix and visceral epithelial cells. Visceral epithelial cells of Bowman capsule are in contact with the outer surface of the glomerular basement membrane via a series of foot processes known as podocytes. Almost all primary glomerular diseases occur due to autoimmunity. Immunologic injury to glomerular basement membrane activates complement system that attract inflammatory cells. Proteolytic enzymes released by inflammatory cells cause glomerular injury with or without interruption of the filtration barrier.

- **Classification of glomerulonephritis (GN) on the basis of etiology:** Glomerulonephritis is classified according to etiology, i.e. involvement of glomeruli either due to intrinsic cause (primary GN) or systemic disorders (secondary GN) and familial glomerulopathy. Primary glomerulonephritis is initiated by immunogenic mechanisms: (a) **antibody-mediated glomerular injury**, e.g. antibody directed against intrinsic glomerular antigen and *in situ* immune deposit, circulating antigen planted in glomeruli, and immune complex deposits, circulating immune complex deposits, or cytotoxic antibodies and (b) In secondary glomerulonephritis, T cell mediated glomerular injury. glomeruli may be damaged in the course of systemic diseases due to immune complex deposits, metabolic disorders, hematological and vascular disorders. Immune complex mediated glomerulonephritis includes systemic lupus erythematosus, Henoch-Schönlein purpura and infective endocarditis. Etiological classification of glomerular diseases is given in Table 22.7.

Table 22.7 Etiological classification of glomerular diseases

Etiology	Glomerular Diseases
Primary glomerular diseases	
Antiglomerular basement disease	▪ Goodpasture's syndrome (kidney and lung involvement) ▪ Antiglomerular basement disease without lung involvement
Proliferative glomerular diseases (immune-mediated mechanism)	▪ Diffuse proliferative glomerulonephritis ▪ Focal proliferative glomerulonephritis ▪ Membranoproliferative glomerulonephritis (MPGN) ▪ Crescentic glomerulonephritis, i.e. rapidly progressive glomerulonephritis (RPGN) ▪ Mesangial IgA nephropathy
Nonproliferative glomerulonephritis (immune-mediated mechanism)	▪ Membranous glomerulonephritis (MGN) ▪ Minimal change disease (MCD) ▪ Focal segmental glomerulosclerosis (FSGS)
Secondary glomerular diseases	
Immune-mediated glomerulopathy	▪ Lupus nephritis (glomeruli involvement in systemic lupus erythematosus) ▪ Glomerulopathy (glomeruli involvement in infective endocarditis) ▪ Glomerulopathy (glomeruli involvement in Henoch-Schönlein purpura)
Metabolic diseases induced glomerulopathy	▪ Diabetic glomerulopathy (diffuse or nodular glomerulosclerosis) ▪ Amyloid nephropathy ▪ Myeloma kidney (renal involvement in multiple myeloma)
Vascular and hematologic disorders induced glomerulopathy	▪ Polyarteritis nodosa (PAN) ▪ Microscopic polyarteritis ▪ Wegener's granulomatosis ▪ Idiopathic thrombocytopenic purpura (ITP) ▪ Disseminated intravascular coagulation (DIC)

Contd...

Table 22.7 Etiological classification of glomerular diseases (*Contd...*)

Etiology	Glomerular Diseases
Hereditary glomerular diseases	
Hereditary glomerulopathy	▪ Alport's disease ▪ Fabry's disease ▪ Thin membrane disease ▪ Nephrosialidosis ▪ Congenital nephrotic syndrome due to mutation of NPHS1 (nephrin molecules) gene and NPHS2 (podocin) gene ▪ Congenital membranoproliferative glomerulonephritis (complement factor-H, PPARγ) ▪ Focal segmental glomerulosclerosis (FSGS) due to gene mutation of ACTN4 (actinin-α) podocyte binding protein or calcium regulating TRPC6 (transient receptor potential cation channel-6)

- **Classification of GN on basis of clinical presentation:** Glomerulonephritis can also be classified on the basis of clinical presentation, which can range from heavy proteinuria ≥3.5 g/24 hours and anasarca (generalized edema), hypoalbuminemia, hyperlipidemia and lipiduria qualify for nephrotic syndrome. Nephritic syndrome is characterized by proteinuria ≤3.5 g/24 hours, hematuria, passage of smoky colored urine, hypertension and periorbital edema. The renal functions should be assessed by analyzing blood urea and serum creatinine, and urine.
- **Classification of GN according to appearance of glomerular tuft:** Glomerulonephritis is classified according to the appearance of glomerular tuft, i.e. proliferative or nonproliferative, and according to histologic patterns such as focal, diffuse, global, segmental, minimal change disease, membranous and membranoproliferative patterns.
- **Classification of GN according to duration of disease:** Glomerulonephritis is classified according to duration of renal disease such as acute, subacute and chronic.

Pathology Pearls: Causes of Nephritic and Nephrotic Syndrome

Nephritic Syndrome: Causes

- Poststreptococcal glomerulonephritis
- IgA nephropathy
- Anti-glomerular basement membrane (GBM disease), e.g. Goodpasture syndrome
- Lupus nephritis
- Idiopathic rapidly progressive (crescentic) glomerulonephritis
- Hepatitis C infection
- Polyarteritis nodosa (PAN)
- Henoch-Schönlein purpura
- Granulomatosis with angiitis
- Thin basement membrane disease
- Wegener granulomatosis
- Essential cryoglobulinemia
- Idiopathic immune complex proliferative glomerulonephritis
- Pauci-immune/antineutrophil cytoplasm antibody glomerulonephritis.

Nephrotic Syndrome: Causes

- Minimal change disease (MCD)
- Membranous glomerulonephritis (MGN)
- Membranoproliferative glomerulonephritis (MPGN) type 1 and type 2 (dense deposit disease)
- Focal segmental glomerulosclerosis
- Renal amyloidosis
- Diabetic nephropathy
- HIV associated nephropathy
- C1q nephropathy
- Hemolytic uremic syndrome
- Fibrillary glomerulonephritis
- Monoclonal immunoglobulin deposition disease
- Pre-eclampsia/eclampsia glomerulopathy
- Infections (malarial parasite, hepatitis B virus, *Treponema pallidum*)
- Drugs (penicillamine, heroin, gold, captopril)

PRIMARY GLOMERULAR DISEASES

Primary glomerular diseases are intrinsic to the kidney and mediated by immune complex mechanism. Primary glomerulonephritis is classified according to mechanism of glomerular injury.

In situ Immune Complex Mediated Glomerulonephritis

In situ immune complexes are seen in anti-GBM antibody-mediated glomerulonephritis. Antibodies circulating in blood attach to the native fixed antigen on the glomerular basement membrane (GBM).

- Antibodies can cross-react *in situ* with previously planted nonglomerular antigens such as DNA, IgG and bacterial products. Antibodies deposition shows a linear pattern of immunoglobulin deposition in GBM on immunofluorescence microscopy.
- Anti-GBM can also cross-react with the alveolar basement membrane resulting in simultaneous kidney/lung lesions as obtained in Goodpasture syndrome, characterized by rapidly progressive glomerulonephritis accompanied by pulmonary hemorrhage caused by antibodies to the glomerular and alveolar basement membranes.

Circulating Immune Complex Mediated Glomerulonephritis

Immune complexes formed elsewhere in the settings of systemic lupus erythematosus, HBV infection, *Plasmodium falciparum*, syphilis, and streptococcal infection, circulate in blood and get deposited in the glomerular basement membrane, which leads to complement system activation, leukocytes recruitment, coagulation system cascade activation and inflammation. Examples of immune-complex mediated glomerulonephritis are proliferative glomerulonephritis (focal or diffuse), membranous glomerulonephritis, membranoproliferative glomerulonephritis, focal segmental glomerulosclerosis (FSGS) and crescentic glomerulonephritis (rapidly progressive glomerulonephritis).

SECONDARY GLOMERULAR DISEASES

Glomeruli may be damaged in the course of systemic diseases caused by immune complex mediated, metabolic disorders, hematologic and vascular disorders. Immune complex mediated glomerulonephritis includes systemic lupus erythematosus, Henoch-Schönlein purpura and infective endocarditis.

- Glomerulopathy may be caused by metabolic disorders such as diabetes mellitus, renal amyloidosis and multiple myeloma.
- Glomerulopathy can be caused in settings of various hematologic and vascular disorders such as hypertension, polyarteritis nodosa, Wegener's granulomatosis, hemolytic uremic syndrome, idiopathic thrombocytopenic purpura and disseminated intravascular coagulation.

FAMILIAL GLOMERULAR DISEASES

Familial glomerular diseases include congenital nephrotic syndrome (Finnish type), Alport's syndrome, familial segmental glomerulosclerosis, familial nondiabetic end stage disease, familial membranoproliferative glomerulonephritis, Fabry's disease and nephrosialidosis. Genetic basis of familial glomerulopathy is given in Table 22.8.

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome is an autosomal recessive disorder due to mutations in NPHS1 (encoding nephrin molecules) and NPHS2 (encoding podocin). This means that each parent must pass on a copy of the defective gene in order for the child to have the disease.

- Normally, NPHS1 (encoding nephrin molecules) and NPHS2 (encoding podocin) regulate slit pores of glomerular basement membrane (GBM).
- Newborn has congenital nephrotic syndrome at birth but manifestations appear at three months of life. There is no cure for congenital nephrotic syndrome.

Alport's Syndrome

Alport's syndrome occurs due to defects in collagen IV synthesis in glomerular basement membranes in kidney,

Table 22.8 Genetic basis of familial glomerulopathy

Gene	Chromosome Location	Encoding Protein	Glomerulopathy
NPHS-1 gene	19q13	Nephrin protein (key component of the slit diaphragm) regulates glomerular filtration rate	Congenital nephrotic syndrome (Finnish type)
NPHS-2 gene	1q	Podocin protein presents in the slit diaphragm	Steroid resistant nephrotic syndrome in children or autosomal recessive focal segmental glomerulosclerosis
α-Actin 4 protein (ACTN4)	Not designated	Podocyte binding protein regulates calcium channels in podocytes	Autosomal dominant focal segmental glomerulosclerosis
TRPC6 (transient receptor potential cation channel 6) gene	Not designated	Calcium channel proteins present on podocytes regulating calcium channels	Adult-onset focal segmental glomerulosclerosis
Apolipoprotein L1 gene (APOL1)	22	Apolipoprotein	Focal segmental glomerulosclerosis and renal failure

inner ear, eye caused by mutations in COL4A3, COL4A4 and COL4A5 genes. Patient presents with hereditary nephritis, subtle nerve deafness (55%), eye disorders (15–30%, anterior lens dislocation, posterior cataracts, corneal dystrophy). It may share genetic defects and clinical features with thin glomerular basement membrane disease.

Familial Focal Segmental Glomerulosclerosis

Recently, researchers have identified a large number of families from all over the world in which two or more family members suffer from familial focal segmental glomerulosclerosis (FSGS). This is considered familial FSGS. Several genes, mainly involved in podocyte cytoskeleton regulation, have been implicated in familial forms of primary focal segmental glomerulosclerosis. Various studies identified a homozygous missense mutation in the TTC21B gene in seven families with FSGS. TRPC6 mutation causes familial focal segmental glomerulosclerosis.

Nephrosialidosis

Nephrosialidosis occurs due to deficiency of N-acetylneuraminic acid hydrolase causing nephrosialidosis. Patient progresses to end stage renal disease. Renal biopsy demonstrates histologic features of focal segmental glomerulosclerosis.

Familial Nondiabetic End Stage Renal Disease

Familial nondiabetic end stage renal disease occurs due to second hit mutation in apolipoprotein L1 (APOL1) gene in 70% of first-degree relatives of African American patients. Patients develop overt proteinuria. Serum cystatin levels are high reflecting decreased glomerular filtration rate.

Familial Membranoproliferative Glomerulonephritis

Genetic factors have been implicated in the pathogenesis of certain cases of familial membranoproliferative glomerulonephritis (MPGN).

- Genetic defects in the regulation of complement pathways appear to be at the root of many hereditary forms of MPGN. Peroxisome proliferator-activated receptor gamma (PPARγ or PPARG) gene is located on the 8p11–12 locus. Mutation in PPARγ gene causes familial membranoproliferative glomerulonephritis.
- Familial membranoproliferative glomerulonephritis (MPGN) describes a histologic lesion, characterized by mesangial hypercellularity and thickening of the glomerular capillary wall on histologic examination. It most often causes progressive chronic kidney disease, although the clinical expression is variable.

Familial Nephropathy in Fabry Disease

Fabry's disease is lysosomal storage X-linked disease due to deficiency of α-galactosidase deficiency resulting in familial glomerulopathy. Fabry's syndrome is characterized by painful extremities, red hyperkeratotic papules on skin, proteinuria, and renal failure.

CLASSIFICATION OF GLOMERULONEPHRITIS BASED ON INTEGRITY OF GLOMERULAR BASEMENT MEMBRANE AND CELLULARITY OF GLOMERULI

Glomerulonephritis is classified based on integrity of glomerular basement membrane and cellularity of glomeruli. Glomerulonephritis includes thin basement membrane disease, non-proliferative glomerulonephritis and proliferative glomerulonephritis. Classification of glomerulonephritis based on integrity of glomerular basement membrane and cellularity of glomeruli is given in Table 22.9.

Pathology Pearls: Endothelial, Epithelial and Mesangial Cell-induced Glomerulonephritis

Endothelial Cell Injury-induced Glomerulonephritis

- Postinfectious glomerulonephritis
- Mesangiocapillary glomerulonephritis
- Lupus nephritis class III and class IV
- Antiglomerular basement membrane disease
- Vasculitis and cryoglobulinemia
- Hemolytic uremic syndrome

Epithelial Cell Injury-induced Glomerulonephritis

- Membranous glomerulonephritis
- Minimal change disease
- Focal segmental (crescentic) glomerulosclerosis
- Lupus nephritis class V
- Diabetic nephropathy

Mesangial Cell-induced Glomerulonephritis

- IgA nephropathy
- IgM nephropathy
- Mesangioproliferative glomerulonephritis
- Lupus nephritis class II
- Diabetic nephropathy

THIN BASEMENT MEMBRANE DISEASE

Thin basement membrane disease (TBMD) is an autosomal dominant disorder that mainly affects glomeruli (tiny tufts of capillaries) in the kidney. Electron microscopy demonstrates thin basement membrane disease of glomeruli.

Table 22.9 Classification of glomerulonephritis based on integrity of glomerular basement membrane and cellularity of glomeruli

Glomerulonephritis	Features
Thin membrane disease	
Thin basement membrane disease	▪ Persistent hematuria ▪ Mild proteinuria ▪ Prognosis is excellent
Nonproliferative glomerulonephritis	
Minimal change disease	Effacement of visceral epithelial foot processes
Glomerulosclerosis	Obliteration of glomerular capillaries by matrix (subdivided into global and segmental sclerosis)
Focal segmental glomerulosclerosis	Thickening and wrinkling of glomerular basement membrane, mild increase in mesangial cells and lack of immune complex deposits
Nodular sclerosis	A nodular increase in mesangial matrix with patent glomerular capillary loops
Mesangial sclerosis	An increase in mesangial matrix with parent glomerular capillary loops
Membranous glomerulonephritis	Diffuse thickening of the GBM without any proliferative change
Proliferative glomerulonephritis	
Endocapillary proliferation	Increased cellularity of glomerular capillaries, due to marginating neutrophils or monocytes, or proliferation of endothelial cells of glomeruli
Extracapillary proliferation (cellular crescent)	Increased cells within Bowman's space, usually due to parietal epithelial cell proliferation extending into Bowman's capsule and infiltrating macrophages
Mesangial proliferation	Increased mesangial cellularity (>3 mesangial cells/mesangial area) with patent glomerular capillary loops
Exudative/necrotizing glomerulonephritis	Glomeruli showing infiltration by leukocytes and necrosis
Membranoproliferative glomerulonephritis	Glomerular basement membrane (GBM) thickening with proliferation of endothelial and mesangial cells of glomeruli (hypercellular glomeruli)
Crescentic glomerulonephritis (rapidly progressive glomerulonephritis)	>80% glomeruli involved with crescent formation in Bowman's capsular space around glomeruli due to proliferation of the parietal cells

- Mutations in COL4A3 and COL4A4 affecting type IV collagen of glomerular basement membrane have been demonstrated in some families.
- Patient presents with persistent hematuria and mild proteinuria but overall prognosis is excellent. Patient may develop hypertension and swelling over body.
- Renal functions are impaired. Serum creatinine is raised. Urine analysis shows proteins and red blood cells. Thin basement membrane disease is diagnosed on renal biopsy examined under electron microscope.

NONPROLIFERATIVE GLOMERULONEPHRITIS

Injured glomeruli lack increased glomerular cellularity in nonproliferative glomerulonephritis. Examples of nonproliferative glomerulonephritis are minimal change disease, focal segmental glomerulosclerosis and membranous glomerulonephritis, which are important causes of nephrotic syndrome.

PROLIFERATIVE GLOMERULONEPHRITIS

The injured glomeruli exhibit increased glomerular cellularity in proliferative glomerulonephritis, which occurs either due to proliferation of glomerular cells (endothelial cells, mesangial cells) and/or influx of inflammatory cells (neutrophils, macrophages) in glomeruli. Majority of cases of glomerulopathy over 70% belong to the group of proliferative glomerulonephritis.

- Proliferative glomerulonephritis can be categorized based on histologic appearance, e.g. diffuse proliferative glomerulonephritis, focal proliferative glomerulonephritis, exudative glomerulonephritis, membranoproliferative glomerulonephritis, crescentic glomerulonephritis, i.e. rapidly progressive glomerulonephritis (RPGN), Goodpasture syndrome and mesangial IgA nephropathy. However, it is worth mentioning that categorization is not diagnostic but rather describing a pattern glomerulopathy caused by glomerular insults.
- Proliferation of glomerular cells may be either endocapillary or extracapillary regions resulting in proliferative glomerulonephritis. More than 100 nuclei are demonstrated in affected glomeruli in diffuse or focal glomerulonephritis.
- Recent study establishes that mesangial cell proliferation in glomerulonephritis is mediated by

complement system and platelets. Mesangial cell proliferation is accompanied by increased expression genes encoding platelet-derived growth factor (PDGF) and PDGF receptor proteins resulting in an autocrine mechanism of mesangial cell proliferation.

Diffuse Proliferative Glomerulonephritis

Diffuse proliferative glomerulonephritis occurs in setting of poststreptococcal glomerulonephritis in majority of cases. Almost all the glomeruli (>50–100%) of both kidneys show pathologic change. There is diffuse global pattern of acute inflammation of glomeruli due to deposition of immune complex in glomeruli. Diffuse proliferative glomerulonephritis occurs in setting of poststreptococcal glomerulonephritis in majority of cases. Glomeruli become hypercellular due to proliferation of glomerular cells and leukocytic infiltration, which is termed as exudative/necrotizing glomerulonephritis.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) refers to pathologic change in some glomeruli (<50% of glomeruli) of both kidneys, whereas others are normal. FSGS occurs in the settings of mesangial IgA nephropathy. Goodpasture syndrome, Henoch-Schönlein purpura, infective endocarditis, vasculitis and connective tissue disorders.

Global Glomerulosclerosis

Global glomerulosclerosis is defined as glomerular impairment involving >50% of any one glomerulus manifested as scarring lesion or hyaline deposition in the glomeruli during advancing age and lupus nephritis in systemic lupus erythematosus (SLE) cases.

Segmental Glomerulosclerosis

Segmental glomerulosclerosis refers to an increase in extracellular matrix (hyalinization) within the mesangial region, involving only a segment of the glomerulus, which occurs in diabetes mellitus.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is also known as crescentic glomerulonephritis. RPGN occurs in the settings of poststreptococcal glomerulonephritis (small percentage of cases), Goodpasture's syndrome and other forms of glomerular disease. Rapidly progressive glomerulonephritis is characterized by formation of cellular crescent-shaped masses within Bowman space. Severe injury to the glomeruli results in leakage of fibrinogen and inflammatory mediators into Bowman space, that stimulate parietal epithelial cells of the Bowman capsule and thus resulting in formation of '**crescents in the glomeruli**'.

Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN) is also known as mesangiocapillary glomerulonephritis, which exhibits diffuse global pattern of glomerulonephritis with features of both proliferation of glomerular cells and thickening of glomerular basement membrane. MPGN is categorized into primary and secondary types. Primary MPGN type 1 accounts for 90% of cases and MPGN type 2 accounts for 10% of cases. Secondary MPGN is seen in the setting of systemic lupus erythematosus, infective endocarditis, malarial parasite and infected ventricular cerebrospinal shunts.

GLOMERULONEPHRITIS: MOLECULAR PATHOGENESIS

Central to the pathogenesis of glomerulonephritis is most often immune-mediated glomerular injury. Glomeruli possess three properties that make then vulnerable to immune-mediated injury: (a) glomeruli filter and trap immune complexes, (b) glomeruli contain immunologically competent cells capable of processing antigen, and (c) glomeruli have constituents like glomerular basement membrane (GBM) and mesangial cells, which can become targets to antibodies. Glomerulonephritis occurs by three mechanisms: *in situ* complex-mediated, immune complex-mediated and ANCA-mediated mechanisms.

- Soluble factors play important role in the pathogenesis of glomerulonephritis. Examples of soluble factors are cytokines, growth factors, vasoactive chemical mediators, reactive oxygen species (ROS), complement system, specific proteases, proteins in the coagulation system cascade. The soluble factors promote recruitment and activation of inflammatory cells, activation of resident glomerular cells, which directly induce glomerular injury and stimulate production of matrix proteins, which forms the basis of glomerular scarring.
- Schematic representation of pathogenesis of glomerulonephritis is shown in Fig. 22.13. Schematic representation of pathogenesis of inflammatory glomerulonephritis is shown in Fig. 22.14. Exogenous and endogenous antigens inducing glomerulonephritis is given in Table 22.10. Pathogenesis of glomerulonephritis is given in Table 22.11.

IN SITU IMMUNE COMPLEX-MEDIATED GLOMERULONEPHRITIS

In situ immune complex deposition glomerular diseases encompass a diverse group of inflammatory conditions characterized by antigen–antibody deposition and activation of complement system in the settings

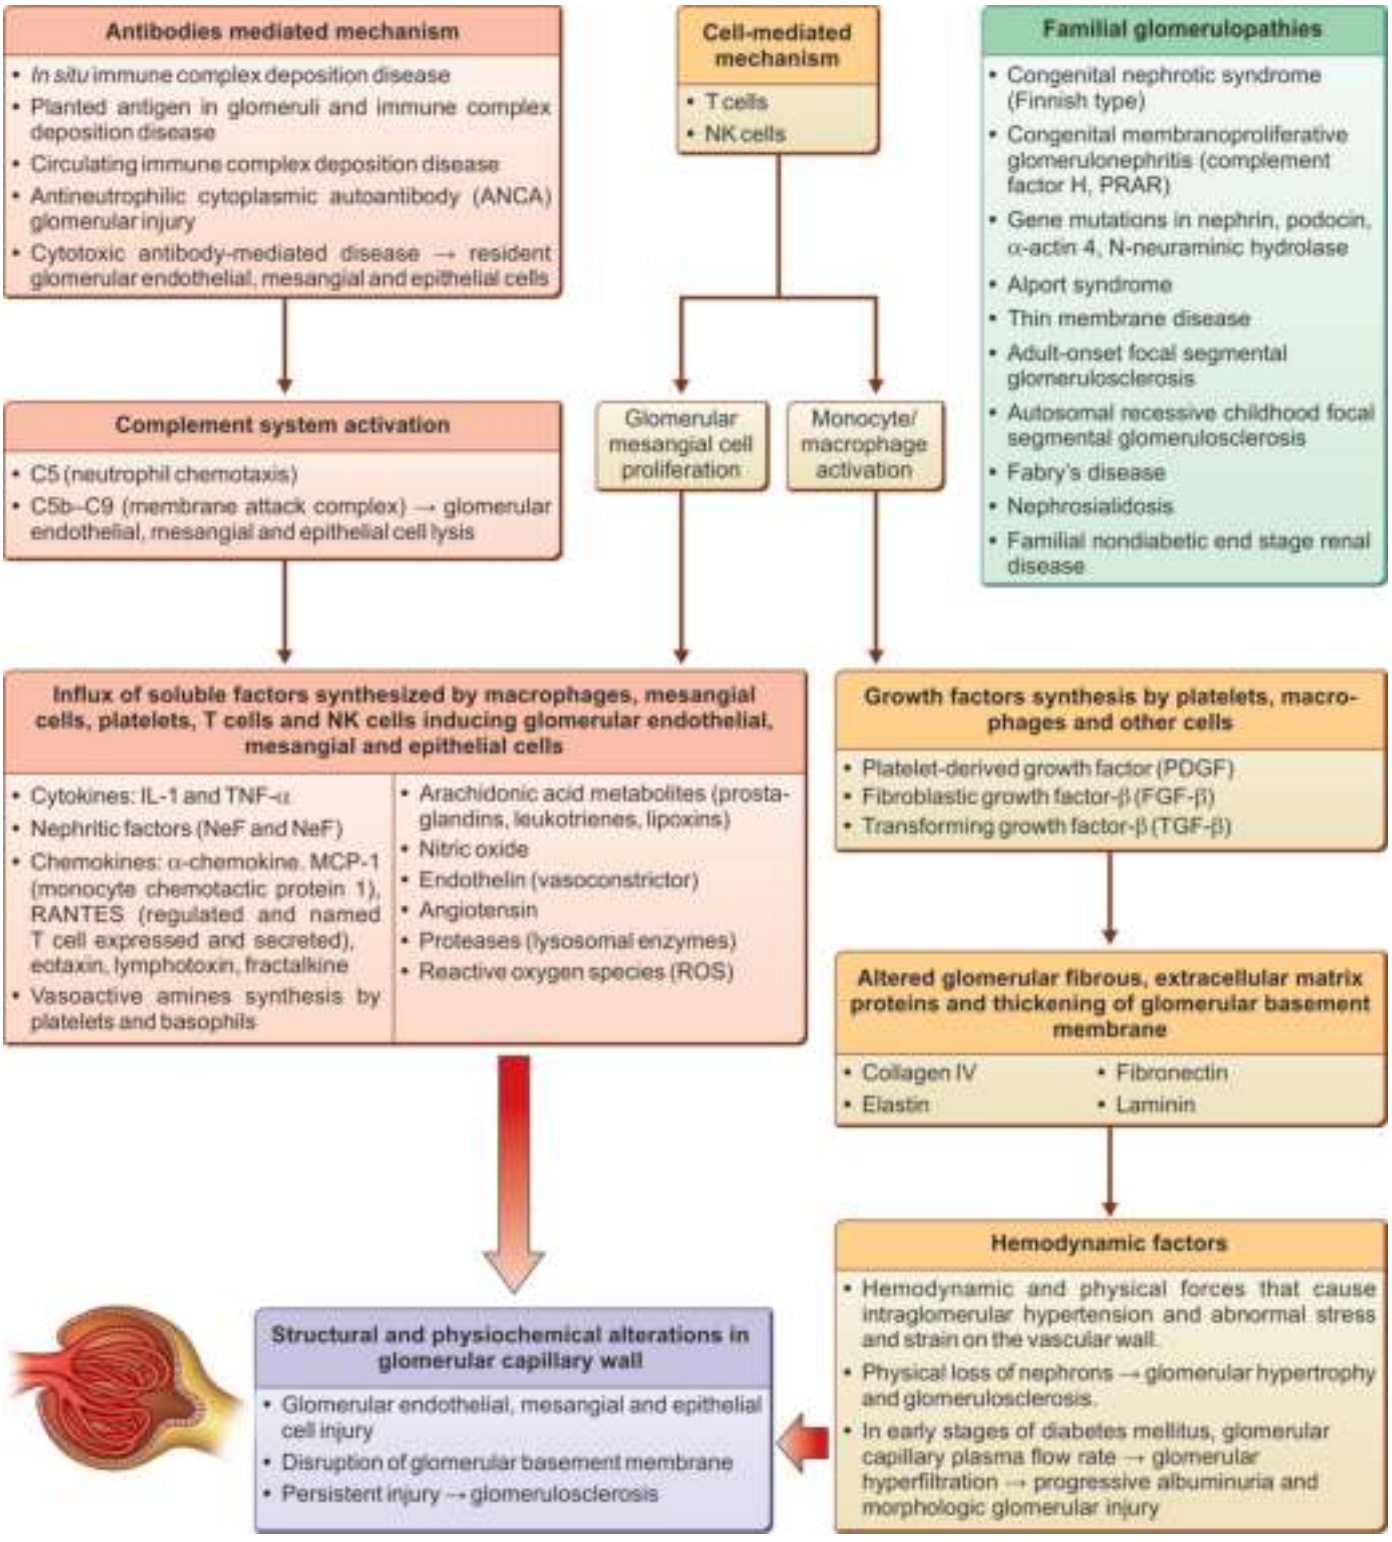

Fig. 22.13: Schematic representation of pathogenesis of glomerulonephritis

of glomerulonephritis, rheumatoid arthritis, scleroderma and Sjögren's syndrome.

- *In situ* complex-mediated glomerulonephritis is characterized by formation of antibodies against fixed intrinsic or planted antigen. *In situ* immune complex deposit formation may occur in the subendothelial, subepithelial and mesangial regions of the glomeruli.
- Type 2 hypersensitivity reaction plays an important role in the pathogenesis of *in situ* immune complex-mediated glomerulonephritis.

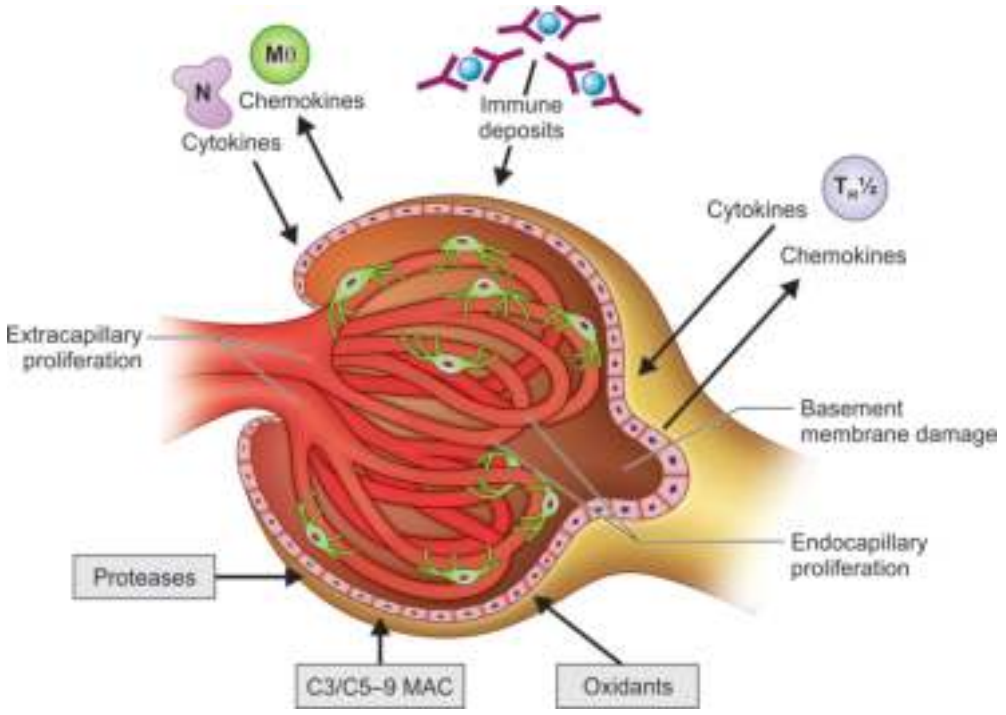

Fig. 22.14: Schematic representation of pathogenesis of inflammatory glomerulonephritis. Inflammatory is mediated by circulating inflammatory cells (neutrophils, macrophages, platelets) and/or resident glomerular mesangial cells. Neutrophil mediated injury involves local release of glomerular basement membrane (GBM) proteases or GBM halogenation induced by interaction of neutrophil-derived myeloperoxidase with H_2O_2 and a halide. Neutrophil induced glomerular injury is enhanced by platelet. Mesangial cell proliferation in glomerulitis is mediated by complement and platelets. Mesangial cell proliferation is accompanied by increased expression of platelet-derived growth factor (PDGF) receptor proteins and genes for these proteins resulting in an autocrine mechanism of cell proliferation.

Table 22.10 Exogenous and endogenous antigens inducing glomerulonephritis

Exogenous Antigens
Bacteria
Viruses (HBV, HCV)
Parasites (malarial parasite—falciparum)
Tumor antigens (colon carcinoma, lung carcinoma and lymphomas)
Drugs (heroin, gold, penicillamine)
Autoimmune disorder (systemic lupus erythematosus)
Endogenous Antigens
Goodpasture's antigen in kidney and lung
Heymann antigen: megalin antigen complex GP-330 on basal surface of visceral epithelial cells and proximal tubules

Contd...

Table 22.11 Pathogenesis of glomerulonephritis

Genetic Factors Linked to Glomerulopathy	
▪ Congenital nephrotic syndrome ▪ Gene mutations in nephrin, podocin, α-actin 4, N-neuraminic hydrolase	▪ Alport syndrome ▪ Thin basement membrane disease ▪ Familial segmental glomerulosclerosis (FSGS)
Antibody-mediated Glomerular Injury	
▪ Antibody directed against intrinsic glomerular antigen and *in situ* immune complex deposition in the glomeruli ▪ Circulated antigen planted in glomeruli and immune complex deposition in the glomeruli ▪ Circulating antigen–antibody immune complex deposition in the glomeruli	▪ Antineutrophilic cytoplasmic autoantibody-mediated glomerulonephritis with paucity of immunoglobulin staining in <2% of untreated cases ▪ Cytotoxic antibody-mediated injury to glomerular endothelial, mesangial and epithelial cells
Complement System-mediated Glomerular Injury	
▪ C5a (neutrophil chemotaxis) ▪ C5b–C9 (membrane attack complex) → glomerular cells lysis	▪ Examples: lupus nephritis, membranoproliferative glomerulonephritis type 1 and 2, and postinfectious glomerulonephritis

Contd...

Table 22.11 Pathogenesis of glomerulonephritis (*Contd...*)

Antineutrophilic Cytoplasmic Autoantibody (ANCA) Glomerulonephritis

- Cell-mediated glomerular injury
  - CD8+ cytotoxic T cells induced glomerular mesangial cell injury
  - NK cells induced glomerular injury

Influx of Circulating Inflammatory Cells

- Neutrophils
- Monocytes/macrophages
- T cells/NK cells
- Platelets
- Inflammatory cells release proteolytic lysosomal enzymes and synthesis of chemical mediators to induce glomerulopathy

Coagulation System

Glomerular endothelial injury activates clotting factors leading to formation of microthrombi and hence reduction in glomerular filtration rate (GFR)

Soluble Factors Synthesis by PMN Cells, Macrophages, Mesangial Cells, Platelets, T Cells and NK Cells

- Cytokine (IL-1 and TNF-α) and chemokines participate in recruitment of inflammatory cells at site of glomerular injury. Chemokines include α-chemokine. MCP-1 (monocyte chemotactic protein 1), RANTES (regulated and named T cell expressed and secreted), eotaxin, lymphotoxin, fractalkine
- Nephritic factors (NeF and NeF) are IgG autoantibodies are demonstrated in C3 glomerulopathy, membranoproliferative glomerulonephritis and systemic lupus erythematosus
- Proteolytic lysosomal enzymes $\rightarrow$ glomerular injury
- Vasoactive amines synthesis by platelets and basophils $\rightarrow$ increased glomerular permeability
- Eicosanoids, nitric oxide (vasodilator), endothelin synthesized by endothelial cells (vasoconstrictor), and angiotensin II regulate blood flow through the inflamed glomeruli. PGD2 promotes platelets aggregation and increases glomerular permeability
- Reactive oxygen species (ROS) act both as a signaling molecule and mediator of inflammation

Activation of Resident Glomerular Cells

- Glomerular endothelial cells
- Glomerular mesangial cells
- Glomerular epithelial cells lining Bowman space

Growth Factors Synthesis by Platelets, Macrophages and other Cells

- Platelet-derived growth factor (PDGF) $\rightarrow$ proliferation of mesangial cells
- Fibroblastic growth factor-β (FGF-β) $\rightarrow$ ECM deposition and hyalinization of glomeruli
- Transforming growth factor-β (TGF-β) $\rightarrow$ ECM deposition and hyalinization of glomeruli

Hemodynamic Factors

- Hemodynamic and physical forces that cause intraglomerular hypertension and abnormal stress and strain on the vascular wall
- Physical loss of nephrons $\rightarrow$ glomerular hypertrophy and glomerulosclerosis
- In early stages of diabetes mellitus, glomerular capillary plasma flow rate $\rightarrow$ glomerular hyperfiltration $\rightarrow$ progressive albuminuria and morphologic glomerular injury

Altered Glomerular Extracellular Matrix Proteins

- Collagen IV deposition
- Elastin
- Fibronectin
- Laminin

Circulating Antibodies against Fixed Intrinsic Normal Glomerular Tissue Antigen

Circulating antibodies are directed against fixed intrinsic normal glomerular antigens in NC1 domain of collagen type IV with linear pattern of immune deposition on immunofluorescence microscopy, and podocyte. Heymann antigen or mesangial antigen with granular pattern of immune deposition is observed on immunofluorescence microscopy.

- Antibodies (IgG) may cross-react with non-collagenous domain of type IV collagen fibers of glomerular basement membrane (GBM) COL4-A3 antigen (Goodpasture antigen) and alveolar basement membrane leading to Goodpasture syndrome.
- Over 90% of patients with anti-GBM glomerulonephritis develop Goodpasture syndrome, which is characterized by rapidly progressive (crescentic) glomerulonephritis with interstitial fibrosis, tubular atrophy and pulmonary hemorrhage. Patient develops rapidly progressive renal failure, hemoptysis and nephritic syndrome.
- Glomeruli become hypercellular with crescents in Bowman's space and influx of macrophages. Antibodies directed against the glomerular basement membrane cause rupture of GBM and extravasation

of red blood cells and inflammatory cells into the urinary space (i.e. the space between Bowman's capsule and the glomerular capillary tufts).

- Fibrinogen stimulates proliferation of parietal cells of Bowman's capsule resulting in crescents formation (crescentic glomerulonephritis). Approximately 80% of cases show presence of 'crescents' obliterating the Bowman's space. Crescentic glomerulonephritis can also occur in the settings of Wegener granulomatosis or polyarteritis nodosa.
- Renal biopsy should be considered, which has a better yield. Immunofluorescence microscopy shows diffuse linear deposition of IgG-1 and complement (C3) and fibrin along the glomerular basement membrane in >90% of cases. Serologic testing for ELISA for circulating anti-GBM antibodies should be done immediately on suspicion of the glomerulopathy. Schematic representation of pathogenesis of Goodpasture syndrome is shown in Fig. 22.15.

Nonglomerular Antigen Planted in Glomeruli and Immune Complex Deposition Glomerular Disease

Nonglomerular antigens from bacterial products, viral products (HBV, HCV), DNA, drugs (penicillamine, gold or heroin), malignant tumors of colon, lung, and *Plasmodium falciparum* are deposited in glomerular basement membrane (GBM) from the blood circulation and then circulating antibody and antigen forms immune complex, which gets deposited in the glomeruli and giving granular pattern of immune complex deposition on subepithelial region of glomeruli on immunofluorescence microscopy.

CIRCULATING IMMUNE COMPLEX-MEDIATED GLOMERULONEPHRITIS

Immune complexes formed elsewhere in the settings of systemic lupus erythematosus, HBV and HCV infection, *Plasmodium falciparum*, syphilis, and streptococcal infection, circulate in blood and get deposited in the GBM, which leads to complement activation, leukocytes recruitment, coagulation system cascade and glomerular inflammation.

- Short-lived antigen–antibody complexes are degraded by polymorphonuclear cells, monocytes, macrophages, mesangial cells and endogenous proteases. Repeated cycle of formation of antigen–antibody complexes in circulation, are trapped in the glomerular components and causing glomerular injury.

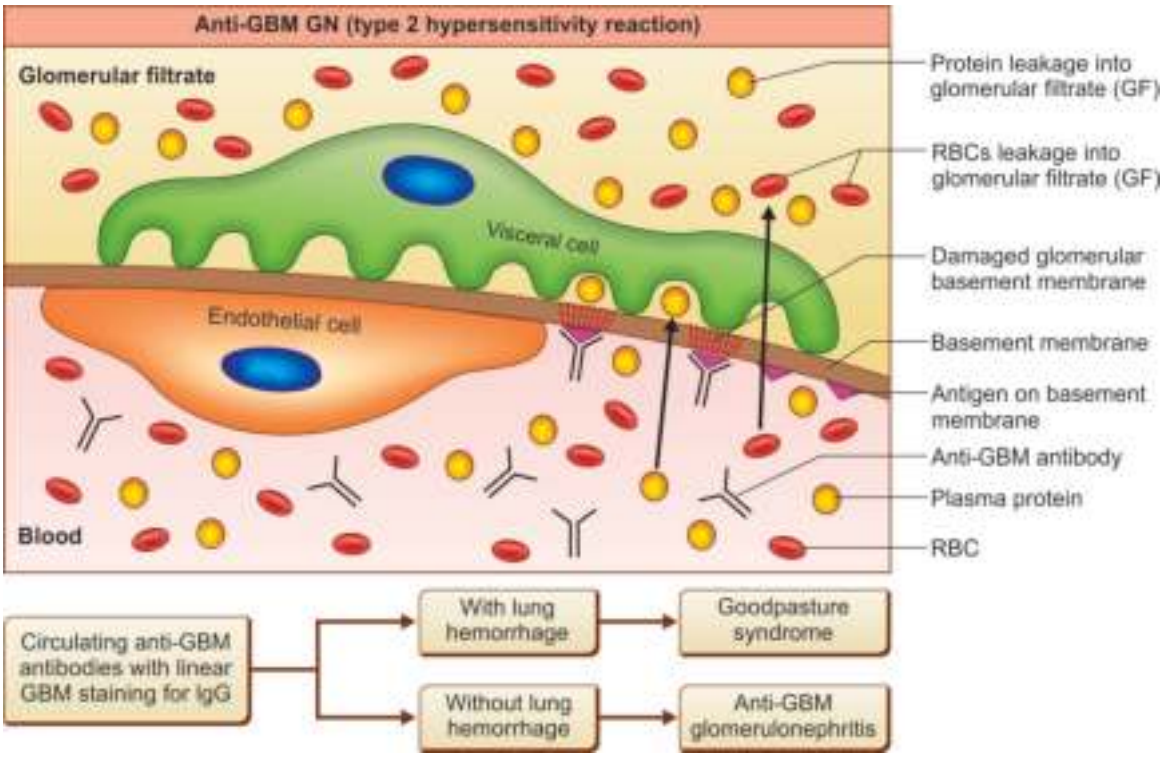

Fig. 22.15: Schematic representation of pathogenesis of Goodpasture syndrome. Goodpasture syndrome is also referred to as anti-glomerular basement membrane (anti-GBM)-mediated glomerulonephritis. Anti-glomerular basement membrane (anti-GBM) disease is a small vessel vasculitis in which circulating antibodies are directed against an antigen intrinsic to the glomerular basement membrane (GBM) and alveolar basement membrane resulting in complement activation and tissue injury. Patient develops rapidly progressive glomerulonephritis involving bilateral kidneys and/or alveolar hemorrhage. Renal biopsy should be considered, which has a better yield. Immunofluorescence shows the linear deposition of IgG-1 and complement C3 along the basement membrane. Serologic testing for enzyme-linked immunosorbent assay (ELISA) for circulating anti-GBM antibodies should be done immediately on suspicion of the disease.

- Factors influencing antigen trapped in glomeruli depend on size, electrical charge, solubility, molecular configuration and carbohydrate content of antigens.
- Antigens can be exogenous (*Plasmodium falciparum*, HBV, HCV, drugs, streptococci) or endogenous (DNA, nuclear proteins, IgA).
- Since the preformed immune complexes represent large protein aggregates that cannot pass through the GBM, they are trapped in glomeruli. Type III hypersensitivity reaction plays an important role in the immune complex-mediated glomerulonephritis.
- Immune complexes can be deposited in subendothelial region, intramembranous within glomerular basement membrane, subepithelial (between epithelial cells and GBM) and mesangial region (within).
- Examples of immune complex-mediated glomerulonephritis are given in Table 22.12. Schematic representation of immune complex-mediated glomerulonephritis is shown in Fig. 22.16.

Table 22.12 Examples of immune complex-mediated glomerulonephritis

▪ IgA nephropathy	▪ Polyarteritis nodosa
▪ Henoch-Schönlein purpura	▪ Bacterial endocarditis
▪ Lupus nephritis	▪ *Mycobacterium leprae*
▪ Poststreptococcal glomerulonephritis	▪ Hepatitis B and hepatitis C infection
▪ Membranous glomerulonephritis	▪ Malarial parasite
▪ Membranoproliferative glomerulonephritis	

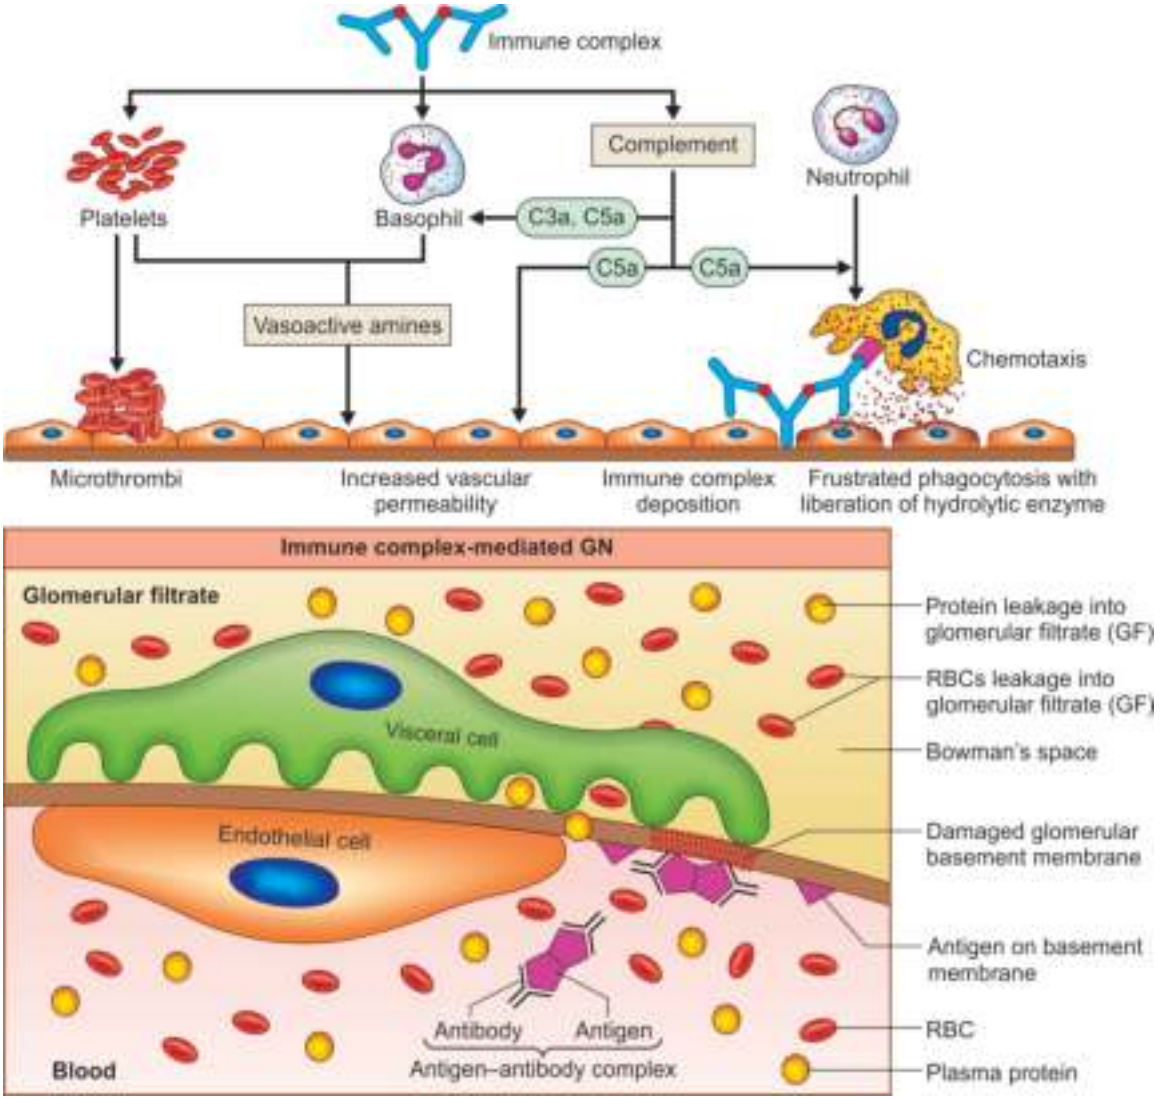

Fig. 22.16: Schematic representation of Immune complex-mediated glomerulonephritis. Immune complex-mediated proliferative glomerulonephritis is caused by the deposition of immune complexes in the glomeruli. Immune complexes activate complement system and cause tissue injury. Immune complex-mediated glomerulonephritis is characterized by proteinuria, red blood cell casts and impaired l renal functions with elevated serum creatinine and blood urea nitrogen (BUN). Renal biopsy shows granular deposits of immunoglobulin visible by immunofluorescence microscopy and electron-dense deposits visible by electron microscopy.

Pathology Pearls: Immune Complex-mediated Glomerulonephritis

Pathophysiology

- Immune complexes activate complement system. C3a and C5a increase glomerular permeability and C5a is chemotactic for neutrophils.
- Neutrophils phagocytose immune complexes. Frustrated phagocytosis by neutrophils cause to liberation of hydrolytic enzymes leading to glomerular damage.
- Platelets, basophils, complement and inflammatory cells play an important role in the pathogenesis of immune complex-mediated glomerulonephritis.
- Platelets form microthrombi resulting in decreased glomerular filtration rate. Basophils and platelets also release vasoactive amines leading to increased glomerular permeability.
- Depending on extent of glomeruli injury, patient develops clinical manifestations such as proteinuria, hematuria and uremia.
- DNA and anti-DNA complexes are formed in systemic lupus erythematosus by forming granular deposits along the glomerular basement membrane in systemic lupus erythematosus (SLE).

Location of Immune Complex Deposits in Glomeruli

- Highly anionic macromolecules are excluded by glomerular basement membrane hence trapped in subendothelial region of kidney.
- Highly cationic immunogens tend to cross subepithelial region and bind to anionic sites, DNA nucleosome and other nuclear proteins.
- Neutral charged molecules are trapped in mesangial region. Large circulating complexes are not usually nephritogenic, which are cleared by reticuloendothelial system.

CYTOTOXIC ANTIBODY-MEDIATED GLOMERULONEPHRITIS

Cytotoxic antibody-mediated glomerular injury is initiated by antigen–antibody complex formation, within the glomerulus. CD4+ helper T cells differentiate into Th2 cells and synthesize IL-4, IL-5, IL-10 and IL-13 cytokines, which activate B cells and regulate humoral immune response.

- Cytotoxic antibody-mediated glomerulonephritis is characterized by injury to resident glomerular endothelial cells, mesangial cells and epithelial cells (podocytes).
- Endothelial cells maintain glomerular perfusion, prevent leukocyte adhesion and inhibit platelet aggregation. Injured endothelial cells induce vasoconstriction, leukocytes adhesion, influx of leukocytes inducing focal/diffuse glomerulonephritis and intravascular microthrombi in glomeruli, thrombotic microangiopathies and reduction in glomerular filtration rate.
- Mesangial cells regulate glomerular filtration rate. Antibodies directed against mesangial cells result in mesangial cell proliferation or mesangiolysis. Membranoproliferative glomerulonephritis is mesangial related disease.
- Visceral epithelial cells (podocytes) prevent plasma protein filtration. Antibodies directed against visceral epithelial cells result in proteinuria. Minimal change disease and focal segmental glomerulosclerosis are examples of visceral epithelial cells related diseases.

ANTINEUTROPHILIC CYTOPLASMIC AUTOANTIBODY-MEDIATED GLOMERULONEPHRITIS

Antineutrophilic cytoplasmic autoantibody (ANCA) induces small vessel vasculitis involving capillaries, venules, and arterioles. It is characterized by complete absence or paucity of immunoglobulin staining (<2%) distinct from anti-GBM disease. Approximately 85% of active untreated cases show ANCA in the circulation.

Pathophysiology

Resting neutrophils sequestrate ANCA antigens within the primary granules. Microbes, cytokines, complement system and other inflammatory products activate neutrophils. Complement system C5a initiates priming, activation and chemotaxis of neutrophils at the site of injury.

- Activated neutrophils induce glomerular endothelial injury by release of reactive oxygen species (ROS), hydrolytic enzymes and damaged associated molecular patterns (DAMPs) within endothelial cells. Membrane attack complex (C5b, C6, C7, C8, C9) results in glomerular endothelial cell lysis.
- ANCA antigen is expressed on surface of neutrophil and released in extracellular space. Vicious cycle between neutrophil activation occurs by ANCA, NETosis, ANCA antigens exposure and further ANCA production.
- Neutrophil extracellular traps (NETs), known as NETosis, are triggered by microorganisms and endogenous stimuli such as damaged associated molecular patterns (DAMPs) and immune complexes. NETosis is unique form of cell death that is characterized by the release of decondensed chromatin and granular contents into extracellular space.
- The major clinicopathologic expression of pauci-immune and ANCA-associated glomerulonephritis and vasculitis include crescentic glomerulonephritis, ANCA glomerulonephritis without pulmonary hemorrhage, microscopic angiitis without granulomas and bronchial asthma, Wegener's granulomatosis with granulomas and polyangiitis; and without bronchial asthma and Churg-Strauss syndrome (eosinophilic granulomatosis with polyangiitis).

- Histologic examination of renal biopsy in ANCA-mediated GN shows fibrinoid necrosis and crescent formation in glomeruli. Glomerulonephritis may be accompanied by necrotizing arteritis (interlobular and vasa recta) in <10% of cases. Pathogenetic role of antineutrophilic cytoplasmic antibody-mediated glomerulonephritis and vasculitis is shown in Fig. 22.17.

T CELL-/NK CELL-MEDIATED GLOMERULAR INJURY

T cell is sensitized to endogenous or exogenous antigen present in the glomeruli recruit macrophages resulting in nonimmune complex deposition glomerulonephritis. Disease occurs through delayed type of hypersensitivity reaction initiated by CD4+ helper T cells and activating monocytes/macrophages. These cells synthesize powerful inflammatory cytokines such as IL-2, IL-12, IFN-γ and TNF-α, which induce glomerular injury. CD8+ cytotoxic T cells act by their cytotoxic ability. Examples of T cell-mediated glomerular injury include minimal change disease and focal segmental glomerulosclerosis.

COMPLEMENT SYSTEM-MEDIATED GLOMERULONEPHRITIS

Complement proteins provide an important line of defense against bacteria, fungi, and viruses. Complement system enhances the ability of antibodies, phagocytic cells to clear microbes and damaged cells, promote inflammation and attack the pathogen's cell membrane.

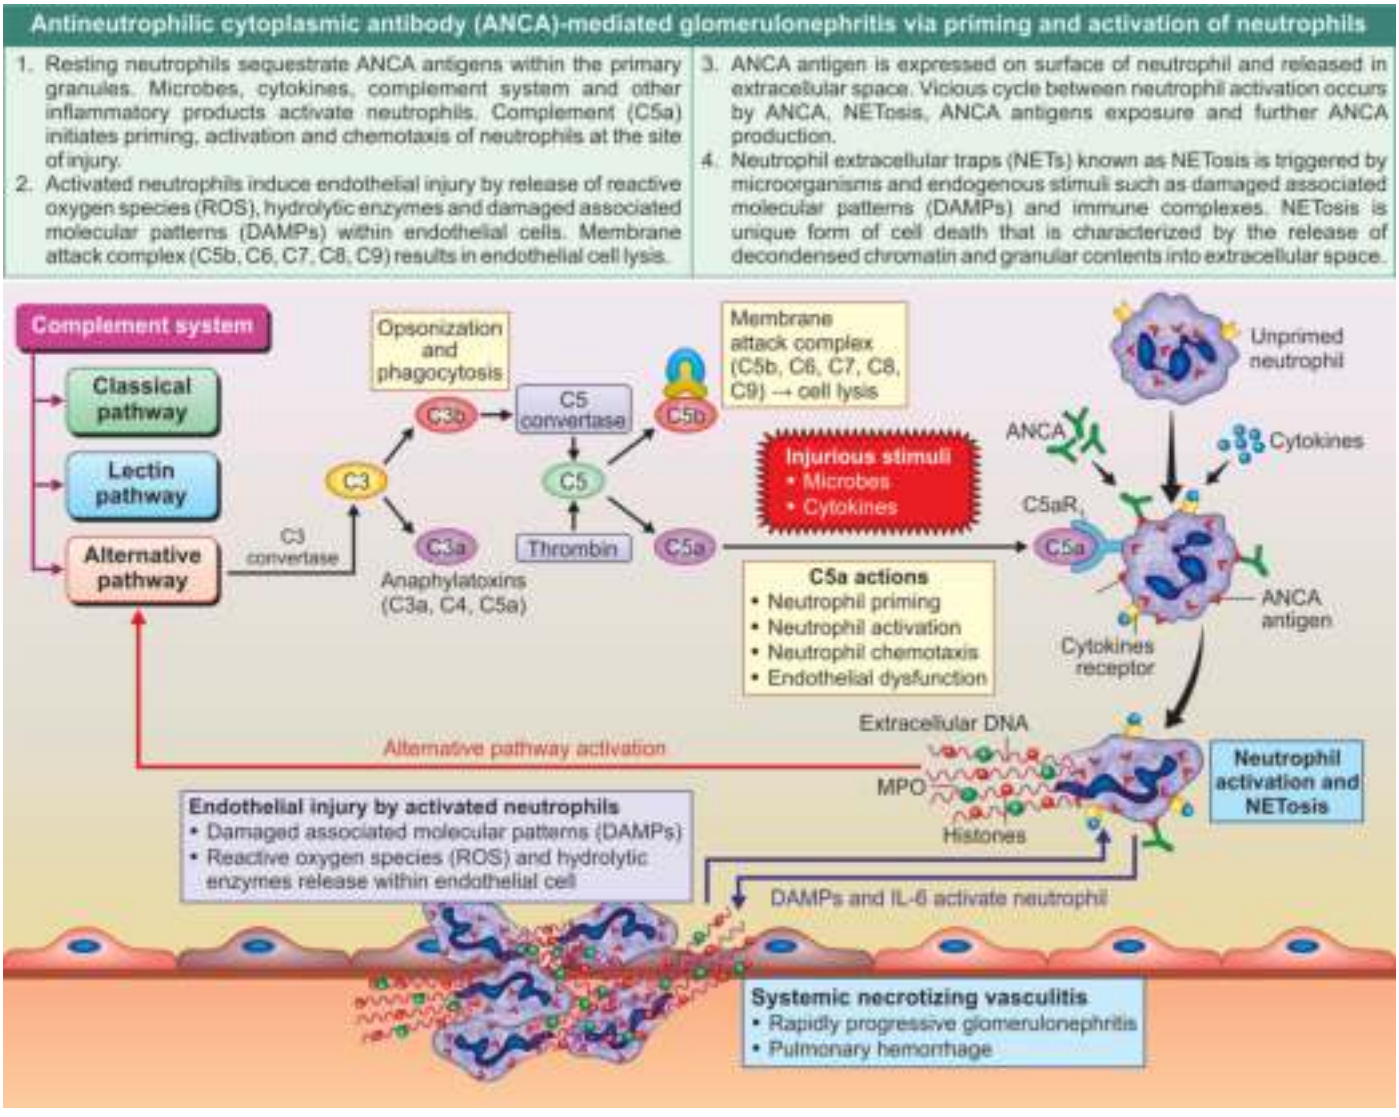

Fig. 22.17: Pathogenetic role of antineutrophilic cytoplasmic antibody-mediated glomerulonephritis and vasculitis. Antineutrophilic cytoplasmic autoantibody (ANCA) glomerulonephritis is an autoimmune disease that affects capillaries of the glomeruli due to activation of neutrophils and subsequently release inflammatory cytokines, reactive oxygen species and lytic enzymes. In addition, this excessive activation of neutrophils by ANCAs induces formation of neutrophil extracellular traps (NETs).

Complement system involves three pathways, namely classical pathway (activated by antigen–antibody, i.e. complement fixing IgG and IgM complexes, bacterial products, viruses), alternative pathway (spontaneous activation by microorganisms and IgA), and mannose-binding lectin pathway. All three pathways of complement system yield C3 convertase. Three pathways of complement system are shown in Fig. 22.18. Biological effects of complement system are given in Table 22.13.

Classical Pathway of Complement System

The classical pathway of complement system involves C1, C2 and C4, which is triggered by immune complexes (specific immune response). When antibody (IgG and IgM) binds antigen, a subtle conformational change occurs that renders the antibody molecule capable of interacting with C, which itself has subcomponents C1q, C1r and C1s. The classical pathway forms C3 convertase, C4b2a, which cleaves C3 into two fragments: (a) larger fragment C3b can covalently bind to the surface of microbial pathogens and opsonize them, and (b) small fragment C3a activates mast cells causing the release of vasoactive chemical mediators such as histamine, which increases glomerular permeability.

Alternative Pathway of Complement System

The alternative pathway of complement system is a component of the innate immune system, a natural

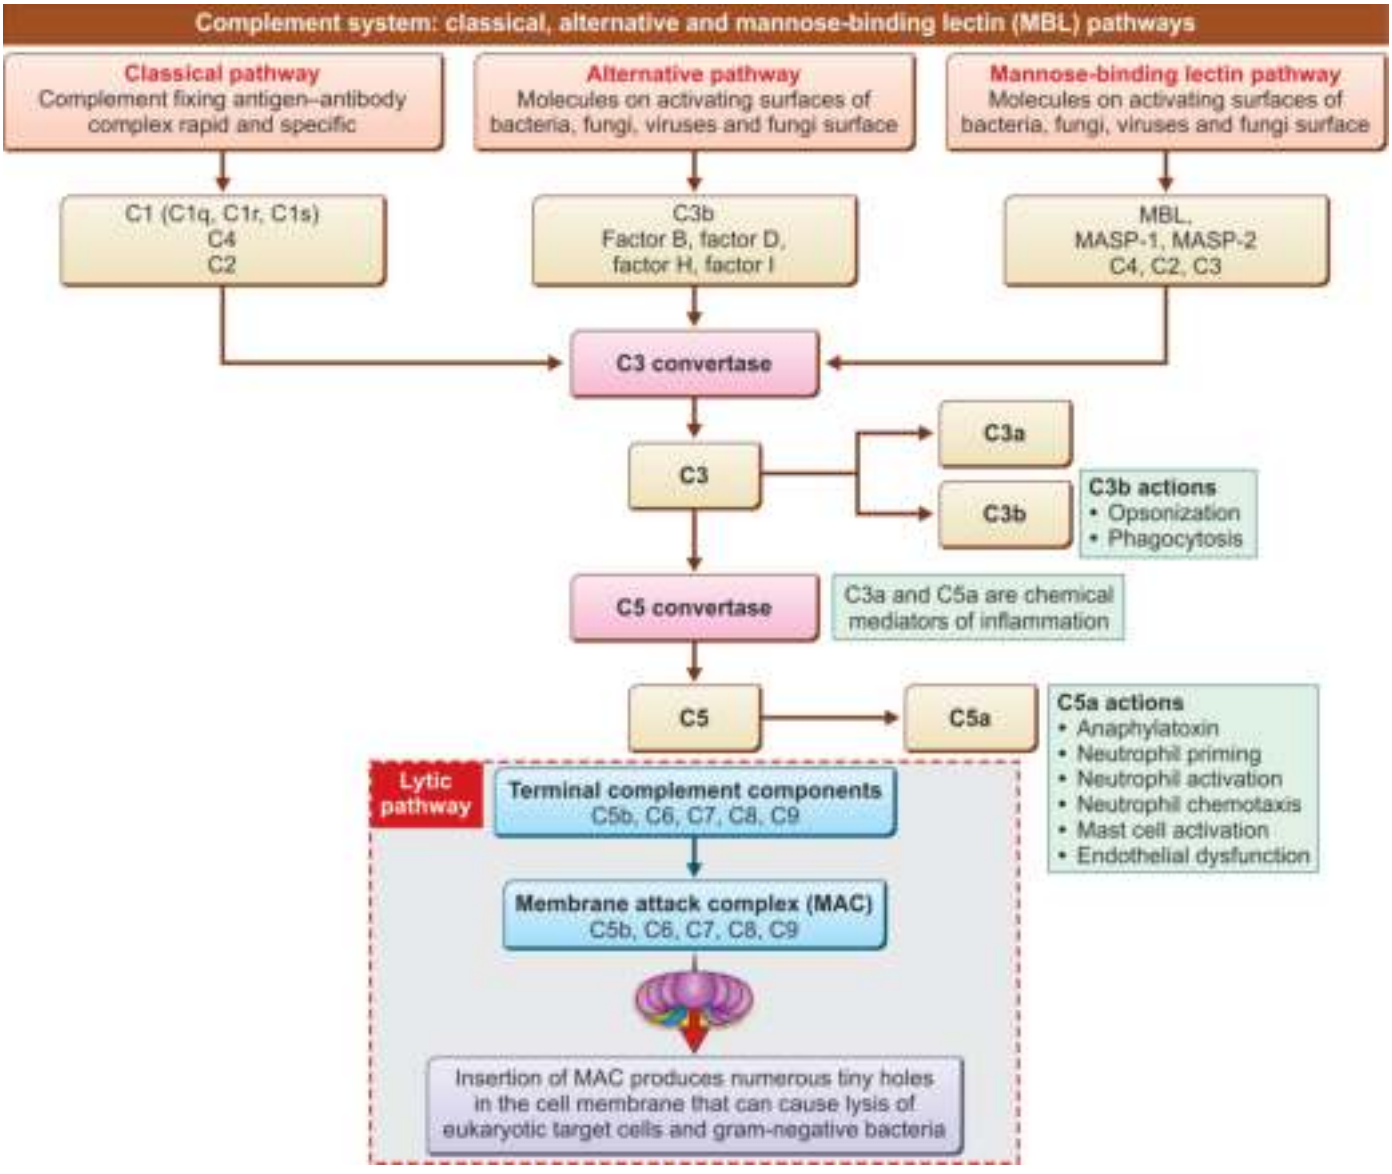

Fig. 22.18: Three pathways of complement system. Complement system involves classical, alternative and mannose-binding lectin pathways. Common aim of complement system pathways is to yield C3 convertase, which facilitates the cleavage of C3, which in turn cleaves C5 to yield C5b. C5b hence forms a complex with C6, C7, C8 and C9 to form C5b–C9, also known as the membrane attack complex (MAC) that leads to lysis of pathogen plasma membrane and target cells.

Table 22.13 Biological effects of complement system

C3a Complement Actions	
▪ Increased capillary permeability ▪ Opsonization of bacteria and chemotaxis and phagocytosis by leukocytes	▪ Contraction of smooth muscle ▪ Mast cell degranulation
C5a Complement Actions	
▪ Increased capillary permeability ▪ Chemotaxis of neutrophils	▪ Phagocytosis of bacteria by leukocytes ▪ Mast cell degranulation
C3a and C5a Complement Actions	
▪ Increased capillary permeability ▪ Contraction of smooth muscle	▪ Mast cell degranulation
C5b to C9 (Membrane Attack Complex or MAC) Complement Actions	
MAC produces hundreds of tiny holes in the bilipid layer cell membrane and results in pathogens or target cell lysis.	

defense system against infections. It is one of the three complement pathways that opsonize and kill pathogens.

- The alternative pathway of complement system is activated by IgA, bacteria, viruses, fungi, parasites, cobra venom and polysaccharide. Initiation of alternative pathway is not dependent on the presence of immune complexes. The alternative pathway involves various factors, B, D, H & I, which interact with each other, and with C3b, to form C3 convertase. C3 convertase facilitates the cleavage of C3 into C3a and C3b. Now C3b binds to C5 convertase, which in turn cleaves C5 to C5a/C5b.
- Both C3a and C5a are potent mediators of inflammation, which act by increasing glomerular permeability, contraction of smooth muscle and mast cell degranulation.
- Complement components C3a, C5a and C5, 6, 7 increase capillary permeability, attract polymorphonuclear cells and later macrophages, which cause glomerular damage by releasing proteolytic lysosomal enzymes, and by generating reactive oxygen species (ROS) and arachidonic acid metabolites. Terminal complement components C5b–C9, membrane attack complex (MAC) induces glomerular basement membrane (GBM) injury.

Mannose-binding Lectin (MBL) Pathway

The mannose-binding lectin (MBL) pathway of complement system is activated following the recognition of mannose residues and binding of pathogen-associated molecular patterns (PAMPs) on the surface of pathogen. This in turn activates MBL associated serine proteases, MASP1 and MASP2, which activate C4 and C2 to form the C3 convertase, and C3b2a.

Membrane Attack Complex Lytic Pathway

Membrane attack complex lytic pathway is initiated by the splitting of complement C5 to C5a and C5b. C5b fragment polymerizes with complement proteins C6, C7, C8 and C9 to form complex C5b–C9, also known as membrane attack complex (MAC), that produces hundreds of tiny holes in the bilipid layer of cell membrane and results in target cell lysis.

Complement System Dysregulation-related Glomerulopathy and other Disorders

Complement system has a paradoxical role in the development of lupus nephritis. Complement protein deficiencies, particularly of components of the classical pathway, are strong risk factors for the development of systemic lupus erythematosus due to defective clearance of nuclear antigens released by injured and apoptotic cells.

- C3 glomerulopathy is a recently described disorder caused by dysregulated alternative pathway activation. It is diagnosed by demonstration of C3 deposits in the glomeruli in the absence of immunoglobulin.
- Membranoproliferative glomerulonephritis type 2, also called **dense deposit disease (DDD)**, is considered a subset of C3 glomerulopathy, in which electron dense deposits are demonstrated within the glomerular basement membrane by electron microscopy. It may have a worse prognosis than C3 glomerulopathy in the absence of dense deposits.
- In immune complex-mediated glomerulonephritis, glomerular immune complexes activate the complement proteins (C1q, C4 and C3) of classical pathway. C3 fragments are demonstrated in nearly 100% of renal biopsies from patients with membranoproliferative glomerulonephritis type 1, lupus nephritis and postinfectious glomerulonephritis. Low serum C3 complement levels in patients with various renal diseases are given in Table 22.14. Normal serum C3 complement levels in various renal diseases are given in Table 22.15.

Table 22.14 Low serum C3 complement levels in patients with low various renal diseases

Glomerulonephritis	Low Serum Complement
Primary glomerulonephritis	
Poststreptococcal glomerulonephritis	90%
Membranoproliferative glomerulonephritis type 1	70%
Membranoproliferative glomerulonephritis type 2 (dense deposit disease)	80%
C3 glomerulonephritis	80%
Secondary glomerulonephritis	
Lupus nephritis III	75%
Lupus nephritis IV	90%
Lupus nephritis V	60%
Subacute bacterial endocarditis	90%
Cryoglobulinemia	90%
Hemolytic uremic syndrome	50%

Table 22.15 Normal serum C3 complement levels in various renal diseases

Glomerulonephritis	Serum Complement
Primary glomerulonephritis	
IgA nephropathy	Normal
Antiglomerular basement disease	Normal
Renal limited ANCA-associated vasculitis	Normal
Secondary glomerulonephritis	
Polyarteritis nodosa	Normal
Henoch-Schönlein purpura	Normal
Microscopic angiitis	Normal
Wegener granulomatosis with polyangiitis	Normal
Goodpasture syndrome	Normal

INFLAMMATORY CELLS INVOLVED IN GLOMERULONEPHRITIS

Neutrophils, lymphocytes, monocytes/macrophages and natural killer cells participate in the pathogenesis of glomerulonephritis. Neutrophils and macrophages synthesize proteases, reactive oxygen species (ROS), and arachidonic acid metabolites decrease glomerular filtration rate (GFR).

- Reactive oxygen species (ROS) include superoxide inion (O_2^-), hydrogen peroxide (H_2O_2), hydroxyl ions (–OH) and singlet oxygen. ROS synthesized by neutrophils and released in cells act both as a signaling molecule and chemical mediators of inflammation. ROS accumulate in the target cells, react and damage biomolecules (proteins, lipids, carbohydrates, nucleic acids) leading to oxidative damage of plasma membrane and cell death.
- On activation of macrophages, T cells and natural killer cells (NK cells) produce biologically active molecules, which participate in the pathogenesis of glomerulonephritis.

COAGULATION/FIBRINOLYSIS SYSTEM IN FIBRIN-MEDIATED GLOMERULONEPHRITIS

Recent clinical observations revealed that the fibrin deposition within glomeruli is an important pathogenetic mechanism in the series of events leading to progressive destruction of glomerular capillaries.

- Fibrin deposition can occur in any injured blood vessels and, if not rapidly dealt with fibrinolysis, and result in endothelial alterations, development of microthrombi (trapped platelets in fibrin) and organization of glomerular microthrombi leading to reduced glomerular filtration rate. It seems that glomerular capillaries are especially vulnerable to fibrin deposition. Macrophages participate in deposition of fibrin in the glomeruli.
- Plasminogen activator inhibitor 1 (PAI-1) inhibits degradation of fibrin and glomerular extracellular matrix proteins; thereby causing microthrombi formation and glomerulosclerosis.
- Resident glomerular cells and monocytes/macrophages, synthesis of proinflammatory cytokines and accumulation of inflammatory chemical mediators seem to act in concert to ensure the long-term consolidation of local inflammatory tissue injury, microthrombi (fibrin trapped platelets), organization of fibrin deposits, glomerular obliteration, reduced glomerular filtration, and progression toward irreversible glomerulosclerosis and irreversible renal failure.
- Fibrin also acts as a stimulus to form crescents in glomeruli due to proliferation of parietal cells of Bowman's capsule. Fibrin deposition is a prominent feature of rapidly progressive (crescentic) glomerulonephritis and hemolytic uremic syndrome.

PLATELET SECRETORY PRODUCTS INVOLVED IN GLOMERULONEPHRITIS

As extensively documented, platelets degranulate and release within glomeruli vasoactive, chemotactic and

mitogenic products that interact with a number of soluble chemical mediators generated by renal resident cells or inflammatory cells and contribute to amplify glomerular injury resulting in increase in glomerular permeability to proteins.

- Platelet-activating factor (PAF) and other platelet secretory products, polycationic macromolecules, platelet factor 4 and β-thromboglobulin alter glomerular permeability to proteins and enhance immune-mediated glomerular injury.

NEPHRITIC FACTORS (NE-AP AND NE-CP) INVOLVED IN GLOMERULONEPHRITIS

Normally, C3 convertase enzyme causes break down of complement proteins. While properdin opposes the action of C3 convertase.

- Nephritic factors (NeF and NeF) are IgG autoantibodies specific to C3 convertase (C42b2a or C3bBb) or C5 convertase that stabilize these enzyme complexes and prevent normal regulatory control.
- Nephritic factors (NeF and NeF), i.e. IgG autoantibodies have been mainly associated with renal diseases like C3 glomerulopathy and immune complex-mediated membranoproliferative glomerulonephritis. These IgG autoantibodies have been demonstrated in systemic lupus erythematosus.

SOLUBLE FACTORS INVOLVED IN GLOMERULONEPHRITIS

Soluble factors are synthesized by macrophages, mesangial cells, platelets, T cells and NK cells, which induce injury to glomerular endothelial, mesangial and epithelial cells. Soluble factors include cytokines (IL-1 and TNF-α), nephritic factors (NeF and NeF), chemokines, e.g. α-chemokine, MCP-1 (monocyte chemotactic protein 1), RANTES (regulated and named T cell expressed and secreted), eotaxin, lymphotoxin, fractalkine; vasoactive amines synthesis by platelets and basophils, arachidonic acid metabolites (prostaglandins, leukotrienes, lipoxins), nitric oxide (NO), endothelin, angiotensin, proteases (lysosomal enzymes) and reactive oxygen species (ROS).

Cytokines and Chemokines Involved in Glomerulonephritis

Cytokines (interleukin 1) and chemokines participate in the recruitment of inflammatory cells and their activation, which can directly contribute to the glomerular injury and glomerular permeability.

- Mesangial cells also synthesize various substances, i.e. CXC, MCP-1 and RANTES, which initiate inflammatory response in the absence of leukocytic infiltration. CXC chemokine (α-chemokine participates in activation and chemotaxis of neutrophils.
- Neutrophils liberate hydrolytic enzymes resulting in glomerular injury. MCP-1 (monocyte chemotactic protein 1) synthesized by mesangial cells attracts monocytes. RANTES (regulated and named T cell expressed and secreted) synthesized by mesangial cells attracts lymphocytes. Chemokines involved in glomerulonephritis are given in Table 22.16.

Prostaglandins, Nitric Oxide and Endothelin Mediators of Inflammation Involved in Glomerulonephritis

Prostaglandins, nitric oxide and endothelin chemical mediators act on glomerular endothelial, mesangial, and epithelial cells and may play key role in regulating the blood flow through the inflamed glomeruli.

- Nitric oxide can accumulate in high concentration and can react with oxygen-derived free radicals thereby setting up two mechanisms of cell death: oxidative injury and ATP depletion. The mitochondria can lose their membrane potential due to high concentration of nitric oxide, which can halt ATP production all together. This process can cause glomerular endothelial damage resulting in stimulation of the inflammatory response.
- PGD2 promotes platelets aggregation and causes vasodilation, and increased vascular permeability of glomeruli.

Table 22.16 Chemokines involved in glomerulonephritis

Chemokines	Examples	Actions
CXC chemokine	α-chemokine	Neutrophils activation and recruitment
CC chemokine (β-chemokine)	▪ MCP-1 (monocyte chemotactic protein 1) ▪ RANTES (regulated and named T cell expressed and secreted) ▪ Eotaxin	▪ Monocytes recruitment ▪ Lymphocytes recruitment ▪ Eosinophils and basophils recruitment
C-chemokine (γ-chemokine)	Lymphotoxin	Lymphocytes recruitment
CX3C chemokine	Fractalkine	Monocytes and T cells recruitment and strong adhesion between monocytes and T cells

Table 22.17 Role of growth factors in the pathogenesis of glomerulonephritis

Growth Factor	Source/Synthesis	Action
Platelet derived growth factor (PDGF)	▪ Macrophages ▪ Smooth muscle cells ▪ Endothelial cells ▪ Keratinocytes	Proliferation of mesangial cells
Fibroblastic growth factor-β (FGF-β)	▪ Macrophages ▪ T cells ▪ Endothelial cells ▪ Platelets	Deposition of extracellular matrix and hyalinization of glomeruli
Transforming growth factor-β (TGF-β)	▪ Macrophages ▪ T cells ▪ Endothelial cells ▪ Platelets	Deposition of extracellular matrix and hyalinization of glomeruli

- PGD_2 and PGE_2 modulate leukocytic phagocytic activity. Nitric oxide causes vasodilatation by relaxing vascular smooth muscle cells. Endothelin is potent vasoconstrictor synthesized by endothelial cells leading to decreased glomerular filtration rate (GFR).

Growth Factors Involved in Glomerulonephritis

Platelets and many other cells produce many growth factors such as platelet-derived growth factor, transforming growth factor-β (TGF-β) and fibroblast growth factor-β (FGF-β), which mediate progression of glomerulonephritis via their chemotactic activity by influx of leukocytes and their effect on extracellular matrix synthesis by resident glomerular cells.

Platelet-derived growth factor (PDGF) also causes proliferation of mesangial cells. Identification of specific platelet inhibitors or interventions specific for platelet secretory products and their target cells will be crucial for understanding the exact role of platelets and their products involved in glomerulopathy. Role of growth factors in the pathogenesis of glomerulonephritis is given in Table 22.17.

GLOMERULAR DISEASES: CLINICAL SYNDROMES

Glomerular diseases produce various clinical syndromes: asymptomatic hematuria, asymptomatic proteinuria, acute nephritic syndrome, nephrotic syndrome, rapidly progressively glomerulonephritis, chronic renal failure and end stage renal disease. Clinical syndromes of glomerular disease and underlying causative renal disease are given in Table 22.18. Progression of glomerulopathy and clinical manifestations is given in Table 22.19. Classification of primary glomerulonephritis by predominant clinical presentation is given in Table 22.20. Comparison between nephritic syndrome and nephrotic syndrome is given in Table 22.21.

- **Asymptomatic microscopic hematuria:** Asymptomatic microscopic hematuria is defined as the presence of three or more red blood cells per high power field visible in a properly collected urine specimen without evidence of infection. Idiopathic hematuria is found in 95% of cases and significant pathology on assessment in 5–10% of cases such as exercise-induced hematuria, IgA nephropathy, polyarteritis nodosa (PAN, bacterial endocarditis and Henoch-Schönlein purpura.
- **Asymptomatic proteinuria:** Asymptomatic proteinuria can be transient in many persons. It can be caused by illness with fever, dehydration, exercise, and urinary tract infections. **Orthostatic proteinuria** can also occur in urine produced in an upright position, but the same patient's urine might test negative in the supine position. Asymptomatic proteinuria can be present in the initial stage of focal segmental glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN), systemic lupus erythematosus (SLE), polyarteritis nodosa (PAN), bacterial endocarditis and Henoch-Schönlein purpura.
- **Nephritic syndrome:** Nephritic syndrome is characterized by hematuria (passage of smoky colored urine), hypertension, oliguria (urine output <400 ml/24 hours), and periorbital edema. The major underlying pathology is inflammation of the glomerulus that results in nephritic syndrome. It is often caused by immune response triggered by an infection or other disease.
- **Nephrotic syndrome:** Nephrotic syndrome is a clinical syndrome defined by massive proteinuria (≥3.5 g/24 hours) responsible for hypoproteinemia resulting with hyperlipidemia, generalized edema and various complications. Nephrotic syndrome occurs due to damage to glomeruli as a result of either structural change or deposition of excessive mesangial matrix in glomeruli in the settings of primary or secondary diseases.
- **Acute kidney disease:** Acute kidney disease occurs within a few hours/days resulting in failure to excrete waste metabolic products, concentrate urine and conserve body electrolytes in settings of prerenal, renal and postrenal etiology. Diseases other than glomerulonephritis that cause acute kidney disease include: thrombotic microangiopathy, acute tubulointerstitial nephritis, acute tubular necrosis, atheroembolization, light chain nephropathy and cortical necrosis.

Table 22.18 Clinical syndromes of glomerular disease and underlying causative renal disease

Asymptomatic Microscopic Hematuria
- Exercise-induced hematuria
- IgA nephropathy, polyarteritis nodosa (PAN)
- Bacterial endocarditis
- Henoch-Schönlein purpura

Asymptomatic Proteinuria
- Febrile illness
- Dehydration
- Exercise
- Urinary tract infection
- Initial stage of focal segmental glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN), systemic lupus erythematosus (SLE), polyarteritis nodosa (PAN), bacterial endocarditis and Henoch-Schönlein purpura

Diseases that Cause Nephritic Syndrome

Primary diseases
- Postinfectious acute diffuse proliferative glomerulonephritis
- Antiglomerular basement membrane antibody glomerulonephritis (e.g. Goodpasture syndrome)
- Rapidly progressive glomerulonephritis (RPGN)
- IgA nephropathy
- Thin basement membrane disease
- Alport syndrome

Secondary diseases
- Lupus nephritis (renal involvement in systemic lupus erythematosus)
- Polyarteritis nodosa (PAN)
- Wegener granulomatosis
- Henoch-Schönlein purpura
- Essential cryoglobulinemia
- Idiopathic immune complex proliferative glomerulonephritis
- Pauci-immune/antineutrophil cytoplasm antibody glomerulonephritis

Diseases that Cause Nephrotic Syndrome

Primary diseases
- Minimal change disease
- Membranous glomerulonephritis
- Membranoproliferative glomerulonephritis (MPGN) type 1
- Membranoproliferative glomerulonephritis type 2 (dense deposit disease)
- Focal proliferative glomerulonephritis
- Focal segmental glomerulosclerosis (FSGS)
- C1q nephropathy
- Fibrillary glomerulonephritis
- Monoclonal immunoglobulin deposition disease
- Immunotactoid glomerulopathy
- Collagenofibrotic glomerulopathy

Secondary diseases
- Immune complex mediated (e.g. systemic lupus erythematosus, Henoch-Schönlein purpura)
- Metabolic disorders (e.g. diabetic glomerulosclerosis, amyloidosis nephropathy)
- Vascular disorders (polyarteritis nodosa, Wegener granulomatosis, hemolytic uremic syndrome)
- Pre-eclampsia/eclampsia glomerulopathy
- Infections (malarial parasite, hepatitis B virus, *Treponema pallidum*)
- Drugs (penicillamine, heroin, gold, captopril)

Diseases other than Glomerulonephritis that Cause Acute Renal Failure
- Thrombotic microangiopathy
- Acute tubulointerstitial nephritis
- Acute tubular necrosis
- Atheroembolization
- Light chain cast nephropathy
- Cortical necrosis

Diseases that Cause Chronic Renal Failure
- Renal arteriolosclerosis
- Chronic sclerosis glomerulonephritis
- End stage renal disease, not otherwise specified (NOS)
- Primary and secondary diseases or disorders involving kidneys except minimal change disease and exercise-induced hematuria

Contd...

- **Chronic kidney disease:** Chronic kidney disease (chronic glomerulonephritis) is characterized by irreversible and progressive glomerular and tubulointerstitial fibrosis, ultimately resulting in reduction in the glomerular filtration rate (GFR) and retention of uremic toxic metabolic products.
  - Chronic renal failure (CRF) involves a gradual loss renal functions (estimated glomerular filtration rate <60 ml/minute/1.73 square meter for three months or more irrespective of the etiology), ultimately resulting in the need for renal transplantation or dialysis.
  - Chronic renal failure can be caused by primary and secondary renal diseases (arteriolosclerosis, chronic sclerosing glomerulonephritis, and end stage renal disease, not otherwise specified).
  - Signs and symptoms of chronic renal failure include: water retention/swelling of legs and feet, nausea, vomiting, loss of appetite, shortness of breath, insomnia, cramps, muscle twitches, oliguria/anuria, drowsiness and fatigue.

NEPHRITIC SYNDROME

Nephritic syndrome is characterized by inflammatory rupture of the glomerular capillaries with resultant red blood cells into the urinary space proteinuria (<2 g/24 hours), hypertension and mild periorbital edema.

Table 22.19 Progression of glomerulopathy disease and clinical manifestations

Disease	Mechanism	Clinical Manifestations
Nephritic syndrome	Glomerular perfusion failure (usually transient)	▪ Hematuria ▪ Oliguria (<400 ml/24 hours) ▪ Proteinuria <2 g/24 hours ▪ Periorbital edema ▪ Hypertension
Nephrotic syndrome	Glomerular permeability	▪ Massive proteinuria ≥3.5 g/24 hours ▪ Hypoproteinemia ▪ Hyperlipidemia ▪ Anasarca (generalized edema) ▪ Lipiduria
Rapidly progressive glomerulonephritis (RPGN)	Crescents formation (Bowman's capsule parietal cells proliferation) as a result of leakage of fibrinogen	Nephritic syndrome progressing to renal failure
Chronic renal failure (GFR <20% of normal)	Chronic irreversible nephron failure both glomerular and tubular failure. There is progressive parenchymal destruction	Azotemia progressing to uremia over months to years
End stage renal disease (GFR <5% of normal)	Glomeruli are markedly sclerosed, tubular atrophy with thyroidization, interstitial fibrosis and vascular thickening	Terminal stage renal disease with uremic manifestations

Table 22.20 Classification of primary glomerulonephritis by predominant clinical presentation

Primary Glomerulopathy	Nephritic Syndrome	Nephrotic Syndrome
Minimal change disease	Nil	++++
Focal segmental glomerulosclerosis	+	++++
Membranous glomerulonephritis	+	++++
IgA nephropathy	++++	++
Membranoproliferative glomerulonephritis	++	++++
Acute post-infectious glomerulonephritis	++++	+
Crescentic glomerulonephritis	++++	+

- Patient with nephritic syndrome presents with hypertension, hematuria with dysmorphic RBCs, RBC casts (<2 g/24 hours), oliguria and periorbital edema.
- Nephritic syndrome occurs due to poststreptococcal infection (most important cause in children), nonstreptococcal organisms, IgA nephropathy (most common cause in adults), Goodpasture's syndrome, systemic lupus erythematosus (diffuse proliferative type), Wegener's granulomatosis, microscopic polyarteritis, Henoch-Schönlein purpura, and essential cryoglobulinemia. Glomerular diseases commonly associated with nephritic syndrome are given in Table 22.22.

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Poststreptococcal glomerulonephritis (PSGN) is an immunologically-mediated disease following

Table 22.21 Comparison between nephritic syndrome and nephrotic syndrome

Parameters	Nephritic Syndrome	Nephrotic Syndrome
Clinical history		
Definition	History of sore throat, periorbital edema, headache and passage of smoky colored urine, proteinuria (2 g/24 hours) and low urinary output (<400 ml/24 hours)	Massive proteinuria ≥3.5 g/24 hours, markedly decreased serum proteins with reversed albumin to globulin ratio and severe generalized edema (pitting edema legs, pleural effusion, ascites)
Hypertension	Present	Less frequent
Biochemical findings		
Serum proteins (total and albumin to globulin ratio)	Total serum proteins decreased up to lesser extent Albumin : globulin ratio normal	Total serum proteins markedly decreased Albumin : globulin ratio reversed (normal albumin/globulin is 2:1)

Contd...

Table 22.21 Comparison between nephritic syndrome and nephrotic syndrome *(Contd...)*

Parameters	Nephritic Syndrome	Nephrotic Syndrome
Serum lipids	Normal	Hyperlipidemia common due to increased synthesis of lipoproteins by liver to compensate protein loss in urine
Serum complement concentration	Low	Most often normal
Urine analysis		
24 hours urine output	Oliguria (urine output <400 ml/24 hours)	Normal urine output
Color	Smoky-colored urine due to hematuria	Milky or frothy due to lipiduria
Specific gravity	Increased due to mild to moderate proteinuria	Increased due to massive proteinuria (sugar in diabetic nephropathy also increases specific gravity)
Proteinuria	<2 g/24 hours	Massive proteinuria ≥3.5 g/24 hours
Heat and acetic acid test for proteins	Positive	Positive
Sugar	Negative	Positive in diabetic nephropathy
Light microscopy	Urinary sediment shows dysmorphic RBCs and RBC casts	Urinary sediment shows hyaline casts (pus cells in diabetic pyelonephritis)
Etiology and prognosis		
Etiology	▪ Poststreptococcal glomerulonephritis ▪ Post-nonstreptococcal glomerulonephritis ▪ IgA nephropathy ▪ Goodpasture's syndrome ▪ Wegener's granulomatosis ▪ Henoch-Schönlein purpura	▪ Minimal change ▪ Membranous glomerulonephritis ▪ Membranoproliferative glomerulonephritis ▪ Focal segmental glomerulosclerosis ▪ Diabetic nephropathy ▪ Amyloid nephropathy
Prognosis	Recovery occurs in 95% cases of post-streptococcal glomerulonephritis. A few cases develop rapidly progressive glomerulonephritis	Prognosis is excellent in minimal change disease, as it responds to corticosteroid therapy. Prognosis is variable in other disorders

Table 22.22 Glomerular diseases commonly associated with nephritic syndrome

Light Microscopy	Immunofluorescence Microscopy	Electron Microscopy	Prognosis
Poststreptococcal glomerulonephritis			
Diffuse proliferative glomerulonephritis: All cells of glomeruli are increased. Glomeruli are infiltrated by neutrophils	Granular pattern: IgG, IgM, C3 (fibrin absent)	Subepithelial deposits or humps	Recovery occurs in 95% children and 60% adults. Rarely patients may develop rapidly progressive glomerulonephritis and chronic glomerulonephritis
Lupus nephritis (systemic lupus erythematosus involving kidneys)			
Diffuse proliferative glomerulonephritis: Endocapillary and/or extracapillary proliferation in 50% or more glomeruli (wire-loop lesion)	Granular pattern: IgG, C3, fibrin in mesangial and glomerular loop	Subendothelial deposits and also in mesangial region	90% patients survive at 10 years
IgA nephropathy			
Focal proliferative glomerulonephritis	Granular pattern: IgA and C3 deposition in mesangial region	Electron dense deposits in mesangial region	Patient may develop chronic renal failure and survival rate in 80–90% patients at 10 years
Rapidly progressive glomerulonephritis			
About 50% of glomeruli are compressed by crescents filling glomerular spaces	Linear pattern: IgG, C3, fibrin	Goodpasture's syndrome: No electron dense deposits	Majority (90%) progress to chronic renal failure

pharyngitis caused by nephrogenic strains of group A β-hemolytic streptococcal infections. PSGN is characterized by reduction in glomerular filtration rate (GFR) and rapid deterioration of renal functions due to an inflammatory response. PSGN most frequently occurs in children between the ages of 2 and 14 years especially boys. It may also affect adults >40 years of age and infants. PSGN affects the glomeruli and the small blood vessels of the kidneys, which returns to normal within months.

- Patient presents with nephritic syndrome usually 1 to 2 weeks after a history of sore throat, or 6 weeks after a skin infection (impetigo). When symptomatic, PSGN typically presents with features of the nephritic syndrome such as macroscopic hematuria (smoky colored urine), oliguria (<400 ml/24 hours), hypertension (reduced glomerular filtration rate and renin-angiotensin-aldosterone system activation), and facial and orbital edema especially in the morning, generalized weakness or anorexia. Less commonly presentation can mimic nephrotic syndrome with significant proteinuria.
- Diagnostic features of poststreptococcal glomerulonephritis include exudative proliferative glomerulonephritis with numerous polymorphonuclear cells infiltration on light microscopy, deposits (IgG, complement) on immunofluorescence microscopy; decreased serum complement (C3 than C4) and hump-type subepithelial deposits on electron microscopy. Schematic representation of poststreptococcal glomerulonephritis (PSGN) is shown in Fig. 22.19.

Etiology

Nephrogenic streptococci infection precedes poststreptococcal glomerulonephritis (PSGN), which initially affects skin or oropharynx.

- More recently, PSGN is associated with skin infections (impetigo after 1–2 weeks by Streptococcus β-hemolyticus group A sero M types 47, 49, 55, 2, 60 and 57) more frequently than throat infections (pharyngitis after 2–6 weeks by Streptococcus β-hemolyticus group A sero M types 1, 2, 4, 3, 25, 49 and 12).

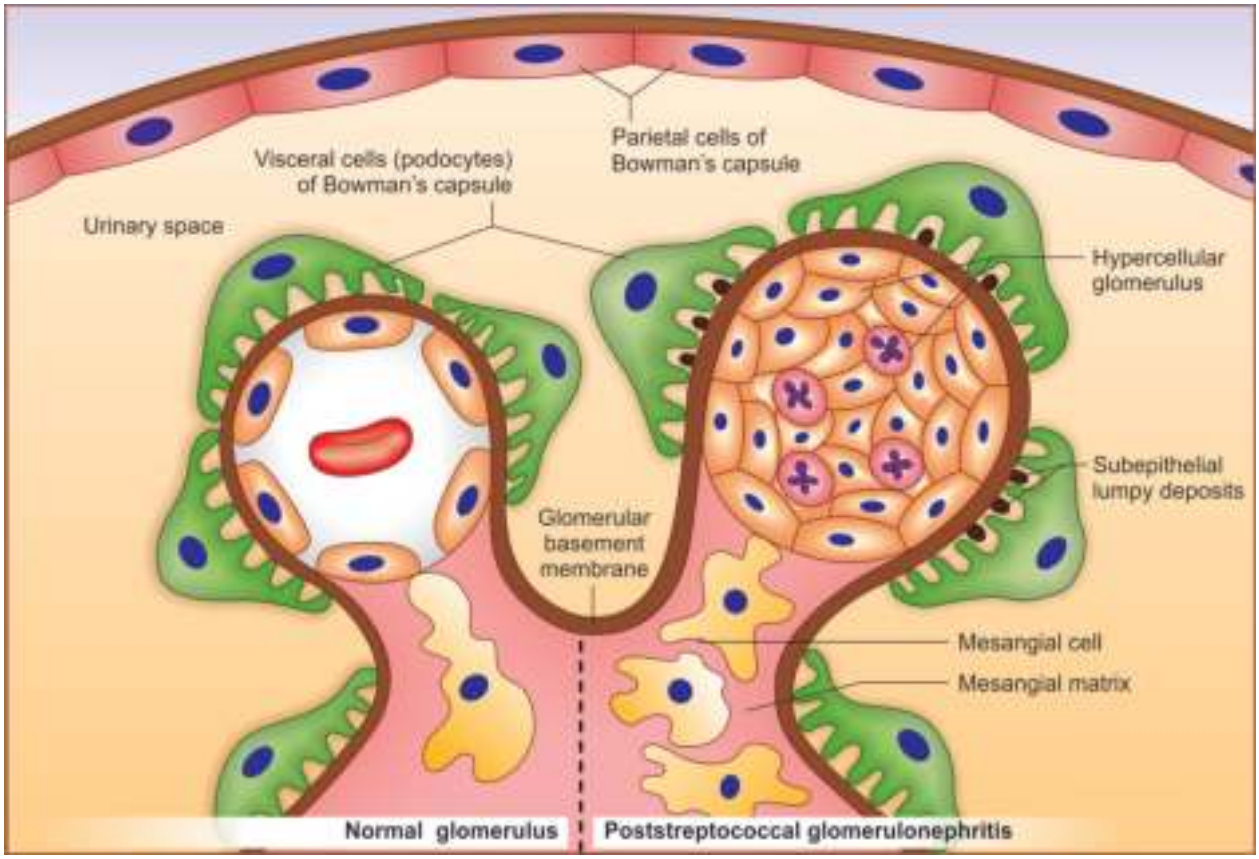

Fig. 22.19: Schematic representation of poststreptococcal glomerulonephritis (PSGN). PSGN is an immunologically-mediated disease following pharyngitis caused by nephrogenic strains of group A streptococcal infections. PSGN is characterized by rapid deterioration of renal functions due to an inflammatory response. Left half of schematic representation shows a normal glomerulus, whereas right glomerulus is hypercellular due to proliferation of glomerular endothelial cells and infiltration by neutrophils. Glomerular lumen is obliterated leading to reduction in glomerular filtration rate. Immune complexes are seen in subepithelial region.

- Rare causes of postinfectious glomerulonephritis include other bacterial or viral infections and malaria. Poor hygiene, overcrowding, and low socioeconomic status are important risk factors for streptococci outbreaks, and this explains the higher incidence of PSGN in the underdeveloped countries.
- Genetic factors are expected to predispose to the condition since almost 40% of patients with focal segmental glomerulosclerosis (FSGS) have a positive family history. There is no specific gene found to cause PSGN.

Pathophysiology

Poststreptococcal glomerulonephritis (PSGN) is an immunological disorder; representing a type 3 hypersensitivity reaction.

- The exact mechanism of pathogenesis of PSGN is not fully determined. The body responds to nephrogenic streptococcal infection by forming immune complexes containing the streptococcal antigen with a human antibody. Some authors suggest that these immune complexes reach via circulation and get deposited in renal glomeruli.
- Other authors claim that the PSGN results from an '*in situ*' formation of antigen–antibody immune complex within the renal glomeruli. This '*in situ* immune complex formation' occurs either due to a reaction against streptococci antigens deposited in the glomerular basement membrane; or according to other theories due to an antibody reaction against glomerular components that cross-react with streptococcal antigen.
- Nephritis-associated plasmin receptor (NAPlr) is released into the blood circulation and deposited on glomerular tufts resulting in plasmin related endocapillary inflammation. Antigen–antibody complex is deposited in the subepithelial region.
- Immune complex formation activates complement system pathway, which leads to the generation of additional inflammatory chemical mediators and recruitment of inflammatory cells in the glomeruli and ending in the destruction of renal glomeruli.
- Early in the course of PSGN, resident glomerular endothelial and mesangial cells undergo excessive proliferation and is accompanied by influx of polymorphonuclear cells and monocytes in glomeruli.
- Macrophages are effector cells that cause cellular proliferation of glomeruli. In addition to the streptococcal antigens, some patients may also have cryoglobulins, rheumatoid factor and antineutrophilic cytoplasmic serum antibodies in the involved glomeruli. Pathophysiology of poststreptococcal glomerulonephritis is shown in Fig. 22.20.

Clinical Features

Approximately 50% of children with PSGN remain asymptomatic. These cases are discovered as incidental finding during routine urine examination. Usually 2–5 years old child presents with history of sore throat with latent period of ≤3 weeks followed by symptoms: (a) passage of smoky-colored urine (hematuria) due to glomerular injury along with dysmorphic RBCs, (b) abrupt onset of oliguria due to reduced glomerular filtration rate (<400 ml/day urine output), (c) periorbital edema, (d) hypertension due to salt retention and increasing peripheral resistance (renin-angiotensin-aldosterone system), and (e) systemic symptoms of headache, malaise, fever, anorexia, nausea, vomiting, pallor and flank pain (due to stretching of renal capsule by inflamed hypercellular glomeruli) in 50% of cases.

- **Hematuria:** Patient presents with hematuria (often described their urine as smoky, cola colored or tea colored or rusty) due to damaged glomeruli. Frank hematuria may occur in 30–50% of cases. Urine analysis contains dysmorphic RBCs with irregular membranes due to passing through inflamed glomeruli wih immune complex deposition. Presence of RBCs cast in urinary sediment is a key finding.
- **Oliguria:** Patient presents with oliguria with urine output is <400 ml/24 hours in 30–50% of patients, which is usually indicative of severe crescentic form of renal disease (normal urine output is 600 to 2500 ml/24 hours). Inflamed glomeruli reduce glomerular filtration rate (GFR). Tubular function is intact. Oliguria is transient and improves in 7–14 days.
- **Periorbital edema (facial puffiness):** Patient develops periorbital puffiness (edema) as a result of proteinuria in nephritic range (<2 g/24 hours) and salt retention in the loose skin in periorbital area. It is most prominent in the morning hours and tends to resolve at the end of the day.
  - Activation of renin-angiotensin-aldosterone system enhances retention of sodium and water absorption resulting in increase in the hydrostatic pressure.
  - Edema may be migratory, appearing in eyelids in the morning, disappearing in the afternoon, and reappearing around the ankle in ambulatory patients by the end of the day.
  - In some cases, edema starts in the eyelids and face then lower and upper limbs and then generalized.
- **Hypertension:** Patient presents with headache due to mild to moderate hypertension. Inflamed glomeruli reduce glomerular filtration rate (GFR) and stimulate juxtaglomerular cells to synthesize renin resulting in activation of renin-angiotensin-aldosterone system.

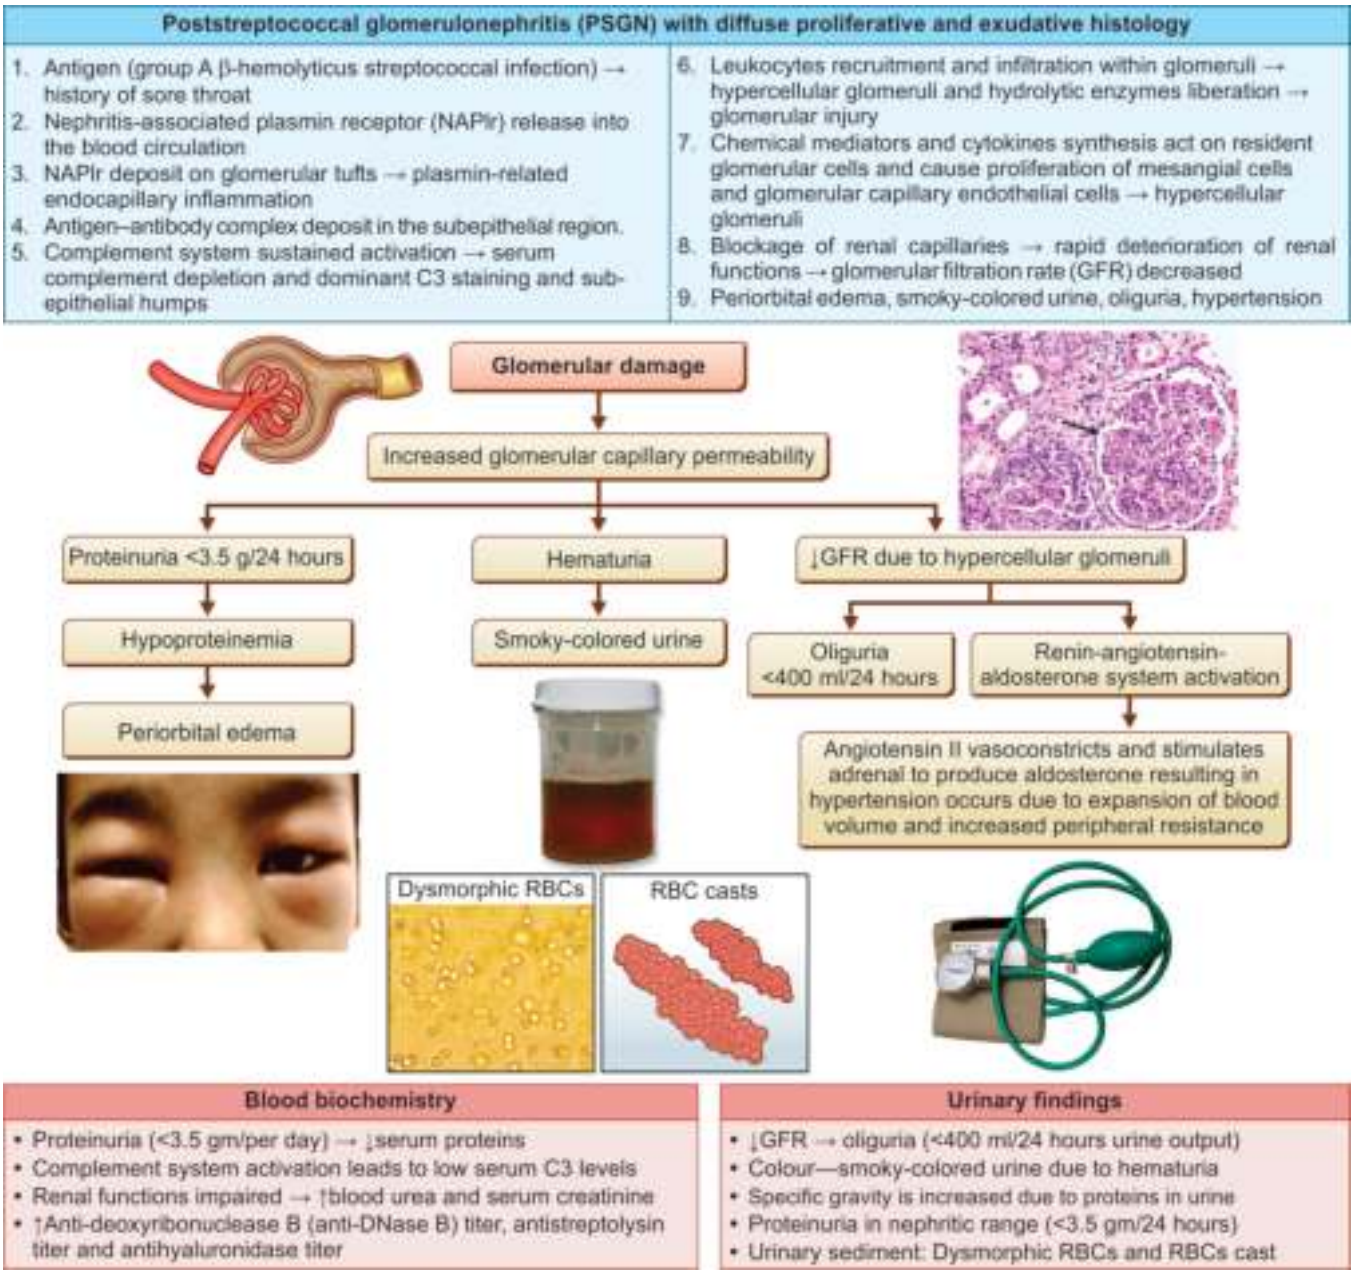

Fig. 22.20: Schematic diagram of pathophysiology of poststreptococcal glomerulonephritis (PSGN). PSGN most often affects children. Patients present with edema (often pronounced facial and orbital edema) especially in the morning, hypertension (due to decreased glomerular filtration rate and activation of renin-angiotensin-aldosterone system), proteinuria in nephritic range, macroscopic hematuria, generalized weakness or anorexia.

- Angiotensin II stimulates adrenal cortex to synthesize aldosterone, that facilitates sodium and water absorption. Angiotensin II acts as vasoconstrictor resulting in increasing peripheral resistance.
- Absorption of sodium and water and increased peripheral resistance cause hypertension. Severe cases may develop hypertensive encephalopathy and acute pulmonary edema.

- **Acute renal failure:** Patient develops acute renal failure due to glomerular injury and/or formation of microthrombi in the glomeruli. Patient may develop acute tubular obstruction due to formation of hyaline casts in the tubules.
- **Flank pain:** Patient may present with flank pain due to stretching of renal capsule by inflamed hypercellular glomeruli in 50% cases.

Imaging Techniques

Ultrasonography demonstrates enlarged kidney up to 50%. The patients may develop acute abdominal pain due to stretching of renal capsule by the enlarged kidneys. Chest radiograph may demonstrate features of heart failure.

Pathology Pearls: Poststreptococcal Glomerulonephritis (PSGN)

Renal biopsy is not recommended for diagnosing patients with PSGN and is performed only when other glomerulopathies are suspected. Renal biopsy is indicated when (a) renal functions are worsening, (b) patient has anuria, (c) there is no latent period between the acute glomerulonephritis and streptococcal infection, (d) normal serum complement level, (e) there is no rise in antistreptococcal antibodies, and (f) there is persistent hypertension.

Light Microscopy

- Hematoxylin and eosin-stained renal tissue section shows hypercellular glomeruli due to proliferation of mesangial cells; and infiltration by PMN cells and macrophages (also called 'exudative' glomerulonephritis). Mesangial cell proliferation causes widening of mesangial region.
- Glomerular endothelial cells do not proliferate but are swollen. Swelling of glomerular endothelial cells and presence of inflammatory cells obstruct capillary lumina resulting in reduction in glomerular filtration rate, and activation of renin-angiotensin-aldosterone system and hypertension. Slight mononuclear infiltrate and edema are present in the interstitium of glomeruli.
- Glomerular basement membrane is not thickened. Tubules lumina contain red blood cells, portentous material and red blood cell casts.
- Interstitial edema and inflammation may be present, indicating that the entire kidney is reacting to the immunologic injury to the glomeruli. These findings are nonspecific and can be present in other glomerulopathies. Histology of poststreptococcal glomerulonephritis (PSGN) is shown in Figs 22.21 and 22.22.

Immunofluorescence Microscopy

Immunofluorescence microscopy shows lumpy bumpy (granular) deposition of IgG, IgM, C3, and C5b–C9 in subepithelial region of peripheral glomerular loops and also in subendothelial region. However, fibrin is absent.

Electron Microscopy

On electron microscopy, large electron-dense immune deposits are most often seen on the epithelial side of basement membrane. Electron-dense immune deposits have a characteristic 'dome' shape. There may be small deposits of variable shapes in other locations.

Poststreptococcal Glomerulonephritis: Case Evaluation

Poststreptococcal glomerulonephritis (PSGN) should be suspected in all children with hypertension and heart failure, even if they do not complain of hematuria or give a history of a preceding sore throat or pyoderma. Laboratory investigations are the most useful in PSGN assessment.

- **Preceding streptococcal infection evidence:** Evidence of a preceding streptococcal infection is determined by measuring antistreptolysin O (ASO) titer, and antinicotinamide-adenine dinucleotidase (anti-NAD), which tends to rise following pharyngitis.

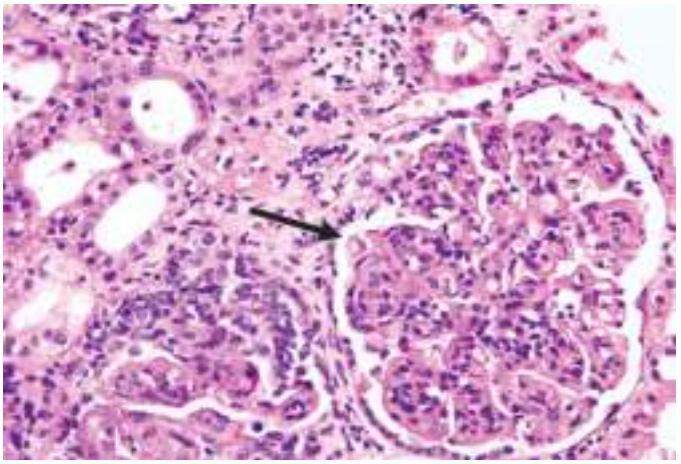

Fig. 22.21: Histology of poststreptococcal glomerulonephritis (PSGN). Hematoxylin and eosin-stained renal biopsy section shows diffuse and global thickening of glomerular basement membrane due to neutrophils and macrophages and proliferation of mesangial and endothelial cells (also called exudative glomerulonephritis). Swelling of endothelial cells and presence of inflammatory cells obstruct capillary lumina. There is sight mononuclear leukocytic infiltrate and edema in the interstitium. Tubules contain red blood cells. Immunofluorescence microscopy demonstrates hump-like structures in subepithelial region and also in subendothelial region leading to proliferation of endothelial cell and decrease in glomerular filtration rate. PSGN returns to normal within months (arrow) (400X).

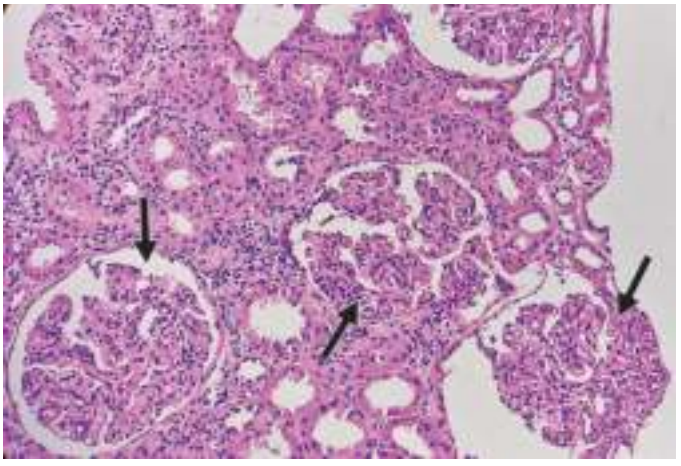

Fig. 22.22: Histology of poststreptococcal proliferative glomerulonephritis (PSGN). Hematoxylin and eosin-stained renal tissue section in PSGN shows hypercellular glomeruli (arrows) resulting from infiltration by neutrophils and macrophages and proliferation of endothelial and mesangial cells. This pattern of PSGN is called exudative glomerulonephritis. Swelling of endothelial cells and presence of inflammatory cells obstruct glomerular capillary lumina resulting in glomerular filtration reduction and activation of renin-angiotensin-aldosterone system and hypertension. Slight mononuclear infiltrate and edema are present in the interstitial tissue. Tubules contain red blood cells (400X). (*Courtesy*: Dr. Neha Kumari and Dr. Tushar Kalonia)

- Elevated serum ASO titer appears 1–3 weeks after group A β-hemolytic Streptococcal infection. It peaks at 3–5 weeks of infection. 50% of patients may show no rise in ASO titer. Height of the titer does not reflect the severity of renal diseases.
- Other antibodies such as anti-DNase B and anti-hyaluronidase are usually elevated after pharyngitis and skin infections. Antihyaluronidase titer is raised in 40% of cases. However, most sensitive is the streptozyme test; which measures the titers of all the antibodies mentioned above.

- **Serum proteins:** Serum proteins are decreased due to proteinuria (<2 g/24 hours) in poststreptococcal glomerulitis.
- **Renal function tests:** Blood urea nitrogen (BUN) and serum creatinine are elevated during the acute phase of PSGN. These values usually return to normal later. Ratio of blood urea to serum creatinine is >15. Tubular function is intact in acute phase of PSGN. In patients with heart failure, in PSGN and levels of NT-proBNP will be elevated.
- **Serum complement C3 concentration:** Serum complement levels (C3) concentration is usually low within 24 hours before the onset of hematuria due to its consumption in the inflammatory reaction. Mostly, the decrease in C3 concentration occurs before serum ASO has risen. Complement levels usually return to normal levels in 6–8 weeks unless the case is complicated.
- **Urine analysis:** Urine analysis shows oliguria (<400 ml/24 hours), smoky-colored urine (macroscopic or microscopic hematuria with dysmorphic red blood cells), mild proteinuria (<2 g/24 hours), raised specific gravity estimated by Vogal's urinometer; and RBC casts, hyaline casts and cellular casts. About 5% of children and 20% of adults have proteinuria in the nephrotic range.
- **Novel serum cystatin C and creatinine biomarkers:** Serum cystatin C and creatinine are novel biomarkers to assess glomerular filtration rate. These are upregulated in these patients.

Clinical Course

In children, prognosis is excellent in 95% of cases, who recover in 2–3 months. But 50% of glomeruli. These represent sign of severe glomerular injury.

- But <1% of cases may progress to rapidly progressive glomerulonephritis (RPGN) and chronic glomerulonephritis in 1–2%.
- Approximately 60% of adults recover from disease, but 3–5% of cases may develop rapidly progressive glomerulonephritis. With rapidly progressive glomerulonephritis (RPGN), the glomerular damage is so severe that fibrinogen leaks into Bowman's space, leading to proliferation of the parietal epithelial cells of glomeruli and formation of crescents.
- Crescents are demonstrated in >50% of glomeruli, which represent sign of severe glomerular injury. Prognosis is good in 60% of adult cases. Many adults may develop RPGN.

Treatment

Poststreptococcal glomerulonephritis (PSGN) is a self-limiting disease in most cases, and thus only symptomatic treatment is needed. Supportive treatment aims at controlling the complications of volume overload such as hypertension and edema, which are prominent during the acute phase of the disease.

- **General measures:** Patient is advised complete bed rest in the first few days. Salt and water restriction are essential to control edema.
- **Therapeutic drugs:** Patients are put on intravenous diuretic frusemide, antihypertensive drugs (angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), or calcium channel blockers (CCBs); antibiotics in case of persistent streptococcal infection; and immunosuppressive corticosteroid therapy in progressing renal failure.
- **Dialysis:** Dialysis is only performed when serum creatinine and potassium levels are critically high.
- **Throat cultures:** Throat cultures should be performed of patient and family members. All members of family should be treated with antibiotics.

ALPORT'S SYNDROME

Alport's syndrome is sex-linked disorder affecting children (M>F) described by Alport in 1927, which most often occurs in males than females.

- Alport's syndrome occurs due to defects in collagen synthesis due to mutations in COL4A3, COL4A4 and COLA5 genes encoding the α5-chain of collagen type IV, which results in interference with the assembly and architecture of collagen type IV, and causes nephritis (glomeruli proliferative and sclerosing), subtle nerve deafness (55% cases of adults) and ocular defects (15–30% of cases, anterior lens dislocation, posterior cataracts, corneal dystrophy).
- Alport's syndrome usually affects 5–20 years of age, usually males (or mosaic females). Males express the full syndrome and present with hematuria and proteinuria.
- Females are carriers, but manifest with hematuria. Rare autosomal recessive and autosomal dominant pedigree also exist, in which males and females are equally susceptible to the full Alport's syndrome.

Pathogenesis

Normally, type IV collagen fibers in glomerular basement membrane give structural strength. Mutation in COL4A3, COL4A4 and COL4A5 genes encoding the α5-chain of collagen type IV results in interference with the assembly and architecture of collagen type IV, which ultimately causes defective synthesis of glomerular basement membranes in kidneys, eye and inner ear leading to nephritis, subtle nerve deafness in adults (55%), ocular disorders in 15–30% cases (corneal dystrophy, anterior lens dislocation, posterior cataracts).

Clinical Features

Patient presents with gross or microscopic hematuria, red blood cell casts, often mild proteinuria, progressive renal failure, and hypertension later in the course of the disease. End stage renal failure occurs in second or third decade of life.

Pathology Pearls: Alport's Syndrome

Light Microscopy

- Hematoxylin and eosin-stained section of renal biopsy shows segmental proliferation of glomeruli, GBM thickening, increased mesangial matrix or mesangial cells causing mesangial widening of glomerular basement membrane, fetal type of glomeruli, and foam cells in glomeruli or tubules.
- Similar alterations may be seen in the tubular basement membrane with a distinctive basket weave appearance.
- As the disease progresses, patient develops focal segmental glomerulosclerosis, vascular sclerosis, tubular atrophy and interstitial fibrosis. Renal tubular cells acquire foamy appearance owing to the accumulation of neutral fats and mucopolysaccharides (foam cells).

Histochemistry

Segmental proliferation or sclerosis of glomeruli, increased mesangial matrix or mesangial cells are causing mesangial widening are demonstrated by Jones methenamine silver stain or periodic acid–Schiff (PAS) stain.

Immunofluorescence Microscopy

Immunofluorescence microscopy shows deposition of IgM and C3 with no definite pattern in glomeruli.

Electron Microscopy

Glomerular basement membrane shows lucency.

IGA NEPHROPATHY (BERGER'S DISEASE)

IgA nephropathy, also called Berger's disease, is a type of diffuse mesangioproliferative glomerulonephritis in adults (HLA-DR4) and children. Disease occurs due to IgA deposit in the mesangial region resulting in glomerulopathy and impaired renal functions. IgA nephropathy is often initiated by infections (bacteria and viruses) of the respiratory or gastrointestinal tracts.

- Patients present with macroscopic/microscopic hematuria (persistent/recurrent) with or without proteinuria. About 80% of cases have been associated with good prognosis. About 25–50% of cases progress to end stage disease over 20 years. Serum polymeric IgA is elevated in 30–50% of cases.
- Four processes come together to induce IgA nephropathy: (a) aberrant glycosylation of IgA1, (b) synthesis of antibodies against galactose-deficient IgA, (c) binding of the galactose-deficient IgA1 by anti-glycan/glycopeptide antibodies to form IgA immune complexes, and (d) deposition of immune complexes in the glomerular mesangial region, activation of alternative complement pathway and possibly the lectin pathway leading to glomerular injury.
- Immunofluorescence microscopy reveals IgA mesangial staining in sclerotic glomeruli.
- **Dominant IgA mesangial deposit (100%) is only defining and consistent feature of the disease.** Predominance of J chain contains IgA1 and λ light chains.
- The diagnostic feature IgA nephropathy is mesangial staining that is more intense for IgA1 and complement C3. IgA nephropathy is shown in Fig. 22.23. Pathogenesis of IgA nephropathy is shown in Fig. 22.24.

Clinical Features

IgA nephropathy is most common form of primary glomerulonephritis worldwide, which usually affects males of 10–30 years of age. Patient presents with recurrent gross or microscopic hematuria after respiratory infection without systemic disease early in life. IgA nephropathy causes slowly progressive end stage renal failure over 10 years in many persons in 30–50% of cases. Disease can recur in renal allografts in 20–50% of cases. Prognosis is poor due to prominent renal arteriolar hyalinization, older age, heavy proteinuria and hypertension.

Pathology Pearls: IgA Nephropathy

Light Microscopy

- Hematoxylin and eosin-stained renal biopsy section shows diffuse proliferation of mesangial cells, and extracellular matrix without significant involvement of capillary walls or lumina.
- Mesangial region involvement is often uneven, that resembles focal and segmental glomerulosclerosis without endocapillary or extracapillary hypercellularity. Histology of IgA nephropathy is shown in Fig. 22.25.

Immunofluorescence Microscopy

Immunofluorescence microscopy shows granular intense staining for IgA and C3 in the mesangial region of glomeruli. IgA is also demonstrated in the capillaries of dermis, lungs, liver and intestine. Immunofluorescence microscopy in IgA nephropathy is shown in Fig. 22.26.

Electron Microscopy

Electron dense deposits are demonstrated in the mesangial region of all the glomeruli.

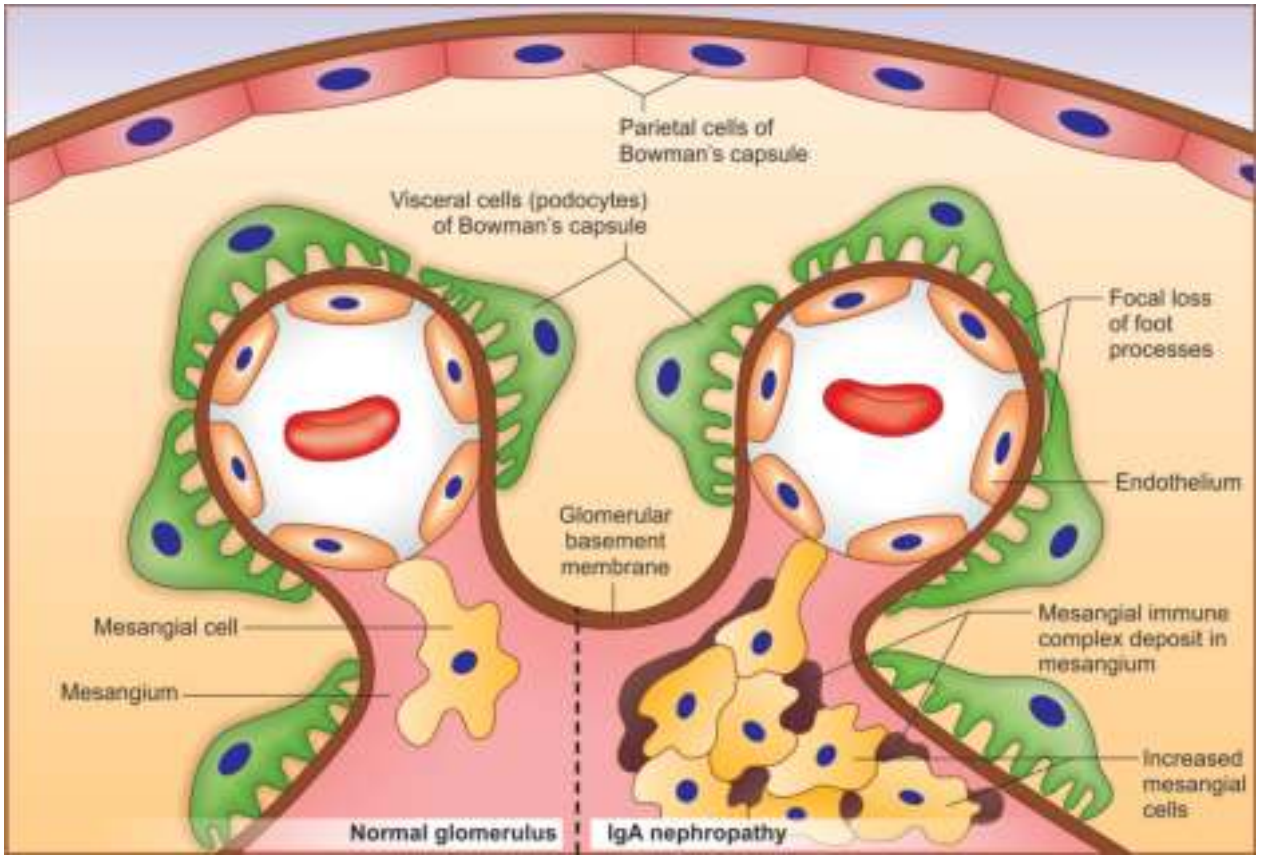

Fig. 22.23: Schematic representation of IgA nephropathy. IgA nephropathy, also called Berger's disease occurs due to IgA deposit in the mesangial region resulting in glomerulopathy and impaired renal functions. Patients present with macroscopic/microscopic hematuria with or without proteinuria. About 80% cases have good prognosis. About 25–50% cases progress to end stage disease over 20 years. Serum polymeric IgA is elevated in 30–50% of cases. Dominant IgA mesangial deposit (100%) is only defining and consistent feature of the disease.

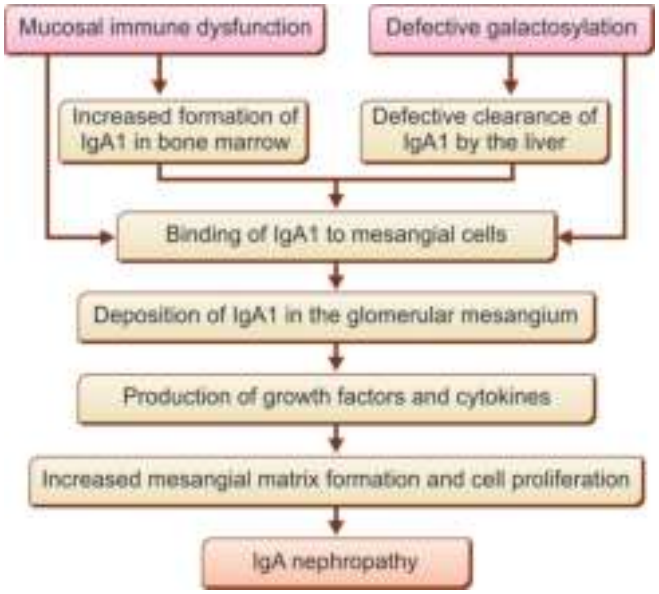

Fig. 22.24: Schematic representation of pathogenesis of IgA nephropathy. Four processes come together to induce IgA nephropathy: (a) aberrant glycosylation of IgA1, (b) synthesis of antibodies against galactose-deficient IgA, (c) binding of the galactose-deficient IgA1 by anti-glycan/glycopeptide antibodies to form immune complexes, and (d) accumulation of these complexes in the glomerular mesangium to initiate renal injury.

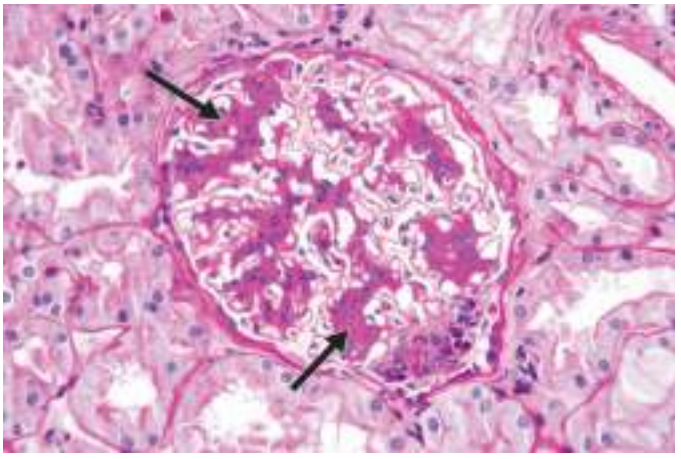

Fig. 22.25: Histology of IgA nephropathy. Confirmation of the IgA nephropathy diagnosis relies on the renal biopsy examination on histology, electron microscopy, and immunofluorescence microscopy. Hematoxylin and eosin-stained renal biopsy section of IgA nephropathy has variable presentation from minimal mesangial expansion to diffuse proliferation of mesangial cells, may have sclerosis and/or crescents resulting from IgA deposit in the mesangium (arrows). Glomeruli lacks hypercellularity in the endocapillary or extracapillary regions. Clinically the most common findings are microscopic hematuria (persistent/recurrent) and episodic macrohematuria. Blood tests might show higher levels of the waste product creatinine or the protein cystatin C (400X).

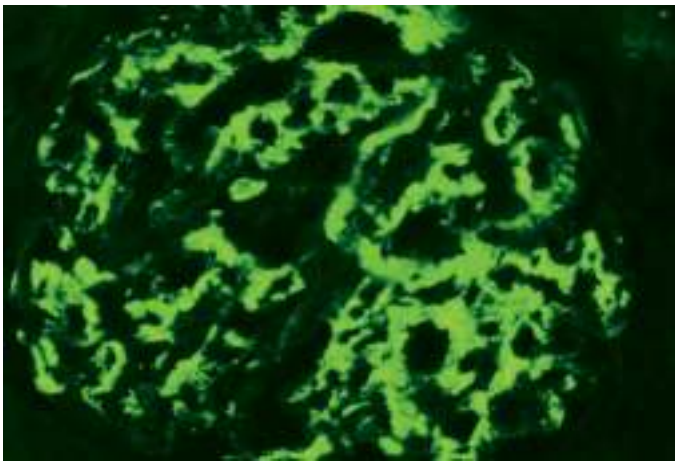

Fig. 22.26: Immunofluorescence microscopy in IgA nephropathy. Immunofluorescence microscopy reveals IgA mesangial staining in sclerotic glomeruli. Dominant IgA mesangial deposit (100%) is only defining and consistent feature of the disease. Predominance of J chain contains IgA1 and lambda light chains.

Treatment

Controlling proteinuria and blood pressure reduces impaired kidney functions in IgA nephropathy. Tonsillectomy in children improves clinicopathologic features in relatively severe form of pediatric IgA nephropathy, especially with early surgery. Patient is treated with corticosteroid therapy. Refractory cases are treated with tacrolimus (fujimycin) immunosuppressive drug.

GOODPASTURE SYNDROME

Goodpasture syndrome is an autoimmune *in situ* mediated immune complex disorder involving kidneys and lungs. Deposition of IgG in the basement membrane of glomeruli and lungs is a feature of Goodpasture's syndrome. The antibodies are formed against basement membranes of the glomeruli (noncollagenous domain of type IV collagen) and the pulmonary alveoli. Injury to glomeruli and lung leads to hematuria and hemoptysis respectively. Patient presents with dyspnea, cough, fatigue, hemoptysis, hematuria and rapidly progressive renal failure.

Pathology Pearls: Goodpasture Syndrome

Light Microscopy

- Over 90% of patients with anti-GBM glomerulonephritis develop **crescentic glomerulonephritis**.
- Antibodies directed against the glomerular basement membrane causes rupture of GBM, extravasation of blood and inflammatory cells into the urinary space, i.e. the space between Bowman's capsule and the glomerular capillary tufts.
- Fibrinogen stimulates proliferation of Bowman's capsule parietal cells resulting in crescents formation (crescentic glomerulonephritis).
- It is worth mentioning that crescentic glomerulonephritis also occurs in Wegener's granulomatosis or polyarteritis nodosa.

Immunofluorescence Microscopy

Diffuse linear immunofluorescence for IgG is seen along the glomerular basement membrane.

WEGENER'S GRANULOMATOSIS

Wegener's granulomatosis is a systemic necrotizing granulomatous vasculitis of unknown etiology, which involves blood vessels of respiratory tract such as nose, sinuses and lungs (90–95%). But renal glomeruli are involved in most cases.

- Wegener's granulomatosis mainly affects 50–60 years of age group. Males are more affected than females. Patients are usually positive for ANCA. It is probably caused due to inhalation of some infectious agents.
- Antineutrophil cytoplasmic antibodies (c-ANCA type) play pivotal role in its pathogenesis. Immune complexes are deposited in small vessels of upper and lower respiratory tract, kidneys and other organs, which cause necrotizing vasculitis, early infiltration by neutrophils, subsequent mononuclear (macrophage) cell infiltration, and fibrosis in chronic cases. Granuloma formation and giant cells in tissues are prominent histologic feature.
- Patient may also develop necrotizing glomerulonephritis, which results in acute renal failure. Cyclophosphamide plus corticosteroid is useful treatment. In untreated patients, outcome is fatal within one year.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura is the most common type of childhood immune complex-mediated renal vasculitis. The glomerular lesion is identical with that of IgA nephropathy, which may be precipitated by exogenous antigens such as drugs, foods, or infectious organisms. Henoch-Schönlein syndrome follows an upper respiratory streptococcal infection. IgA deposition occurs in blood vessels of skin often similar to IgA nephropathy.

Clinical Features

Patient presents with nephritic syndrome, skin rashes on extensor surfaces of the arms, legs, and buttocks, painful joints, and gastrointestinal tract involvement (colicky abdominal pain with melena). Most patients do well, but a few progress to end stage renal disease. In adults, a rapidly progressive (crescentic) glomerulonephritis can occur.

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is characterized by hemolytic anemia, acute renal failure (uremia), and thrombocytopenia. HUS is the most common cause of acute renal damage in children.

Etiopathogenesis

Ingestion of contaminated food with Shiga toxin strain of *Escherichia coli* is most important cause of hemolytic uremic syndrome. Toxin is injurious to glomerular endothelial cells resulting in thrombotic microangiopathy. Subendothelial electron-lucent material causes narrowing of the lumen of glomerular capillaries. Swelling of the endothelial cells also contributes to narrowing of the lumen of glomerular capillary. Patient presents with hemorrhagic diarrhea and rapidly progressive renal failure. Schematic representation of hemolytic uremic glomerulopathy is shown in Fig. 22.27.

NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by heavy proteinuria (≥3.5 g protein/24 hours), hypoalbuminemia resulting from heavy proteinuria, hyperlipidemia (compensatory synthesis of lipoproteins by liver), generalized edema resulting from decreased plasma oncotic pressure), hypercholesterolemia and lipiduria. Hematuria, hypertension or azotemia may or may not be present.

- Nephrotic syndrome occurs due to increased glomerular basement membrane permeability, permitting the urinary loss of plasma proteins, particularly low molecular weight proteins, such as albumin.
- Heavy proteinuria in nephrotic syndrome occurs due to damage to glomeruli by the following mechanisms: (a) damage to the integrity of the epithelial cells, as in minimal change disease or focal segmental glomerulosclerosis, (b) immune-complex deposition occurs within the capillary wall, as in membranous glomerulonephritis, (c) damage to the integrity of the basement membrane by excessive accumulation of abnormal membrane-like material demonstrated in diabetes mellitus, (d) deposition of extraneous substances (e.g. amyloid) occurs within the blood vessels, as in amyloid nephropathy.
- Patients excrete various essential metabolic products in the urine such as proteins, sugar, ketone bodies, immunoglobulins (recurrent infection), transferrin bound iron loss (iron deficiency anemia), antithrombin III, antiplasmin (renal vein thrombosis), thyroxine binding proteins, zinc binding proteins, and copper binding proteins.
- Urine analysis demonstrates heavy proteinuria (albumin, globulins), immunoglobulins, thyroxine binding protein, transferrin bound iron, vitamin D binding protein, zinc binding proteins, copper binding protein, antithrombin III, and antiplasmin.

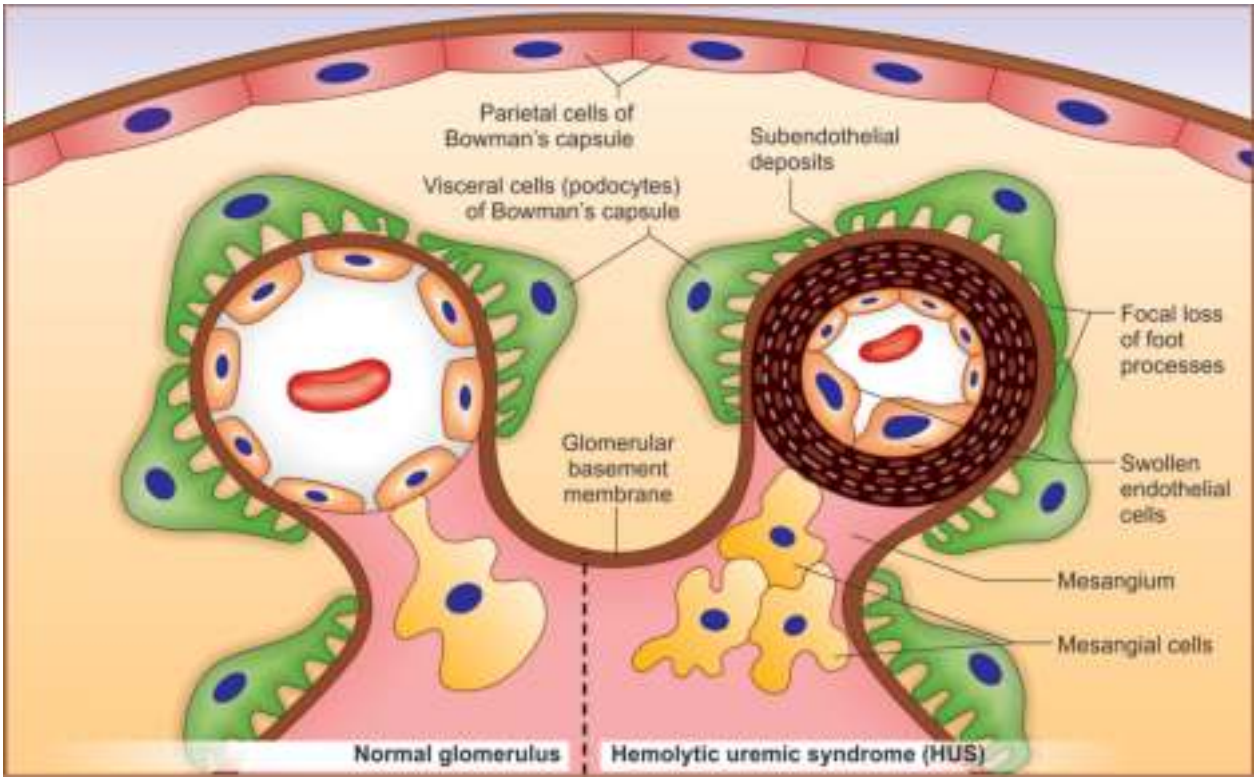

Fig. 22.27: Schematic representation of hemolytic uremic syndrome glomerulopathy. Hemolytic uremic syndrome (HUS) is characterized by progressive renal failure in children and adults that is associated with microangiopathic hemolytic anemia (nonimmune and Coombs' negative) and thrombocytopenia. Hematoxylin and eosin-stained section of renal biopsy shows capillary endothelial swelling, fibrin deposits in lumina and luminal narrowing within glomerulus. Focal loss of foot processes is present.

Light microscopy of urine reveals hyaline casts, oval fat bodies or pus cells.

- Oval fat bodies are lipid containing renal tubular epithelial cells. When urinary sediment examined under polarized light, the lipids in casts are seen as being doubly refractile or birefringent and displaying a symmetric 'Maltese cross pattern'.
- Nephrotic syndrome can be caused by primary glomerular diseases such as minimal change disease, focal segmental glomerulosclerosis, membranous glomerulonephritis membrano-proliferative glomerulonephritis, and systemic diseases (diabetes mellitus and systemic lupus erythematosus).
- Patients should be investigated by analyzing total serum proteins, albumin/globulin ratio, lipid profile, blood urea and serum creatinine, serum testing (HbsAg, HIV). Etiology of nephrotic syndrome varies in adults and children.
- Pathogenesis of nephrotic syndrome is shown in Fig. 22.28. Main causes of nephrotic syndrome in adults and children are given in Table 22.23. Glomerular diseases associated with nephrotic syndrome and its pathogenesis are given in Table 22.24.

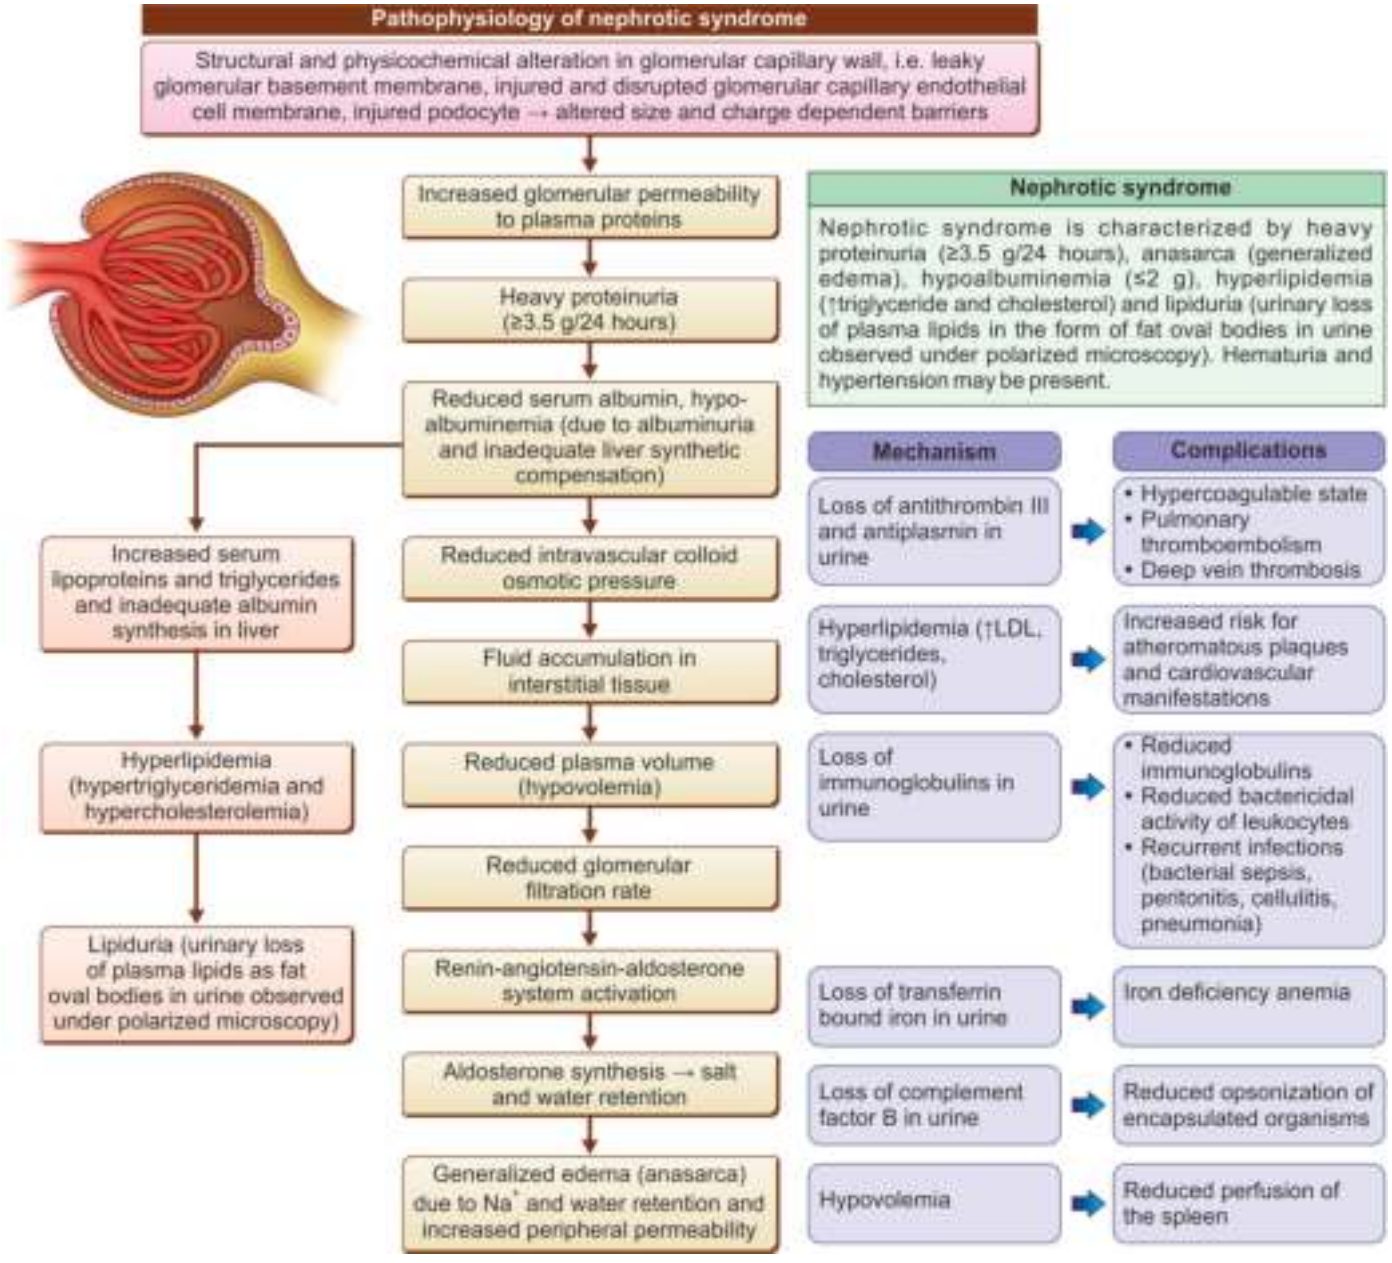

Fig. 22.28: Schematic representation of pathophysiology of nephrotic syndrome. The nephrotic syndrome is characterized by generalized edema, massive proteinuria (≥3.5 gm per day), hypoalbuminemia, hyperlipidemia and hypercholesterolemia. Hematuria, hypertension or azotemia may or may not be present. Nephrotic syndrome can be caused by primary diseases such as minimal change disease, focal segmental glomerulosclerosis, membranous glomerulonephritis; and systemic diseases (diabetes mellitus and systemic lupus erythematosus).

Table 22.23 Main causes of nephrotic syndrome in adults and children

Glomerular Diseases in Adults	Frequency (%)
Minimal change disease	10%
Membranous glomerulonephritis	20%
All forms of proliferative glomerulonephritis	15%
Focal glomerulosclerosis	10%
Membranoproliferative glomerulonephritis	5%
Diabetic nephropathy	40%
Glomerulopathy secondary to systemic disorders (amyloidosis and systemic lupus nephritis)	Relatively common

Glomerular Diseases in Children	Frequency (%)
Minimal change disease	60%
Membranous glomerulonephritis	5%
All forms of proliferative glomerulonephritis	10%
Focal glomerulosclerosis	10%
Membranoproliferative glomerulonephritis	Rare
Diabetic nephropathy	Uncommon
Glomerulopathy secondary to systemic disorders (amyloidosis and systemic lupus nephritis)	5%

Table 22.24 Glomerular diseases commonly associated with nephrotic syndrome

Light Microscopy	Immunofluorescence Microscopy	Electron Microscopy	Prognosis
Minimal change disease (MCD)			
Glomeruli appear normal (histochemistry positive for fat stains in glomeruli and tubules)	No pattern	Effacement of the podocytes of visceral layer of Bowman's capsule	Responsive to corticosteroid therapy with excellent prognosis
Membranous glomerulonephritis (MGN)			
Diffuse thickening of GBM, Jones methenamine silver stain demonstrates spikes and domes due to immune complex deposition in subepithelial region of glomeruli	Granular pattern: IgG and C3	Subepithelial deposits and fusion of podocytes of visceral layer of Bowman's capsule	Prognosis is poor as a patient progressing to end stage disease (40–50%)
Focal segmental glomerulosclerosis (FSGS)			
Detachment of epithelial cells from GBM is the hallmark of disorder	IgM and C3 in some cases	Fusion of podocytes, but no electron dense deposits	Poor prognosis as progresses to end stage disease within 10 years in 50–80% of cases
Membranoproliferative glomerulosclerosis (MPGS)			
Type 1 MPGN: Diffuse thickening of GBM (Jones silver stain shows tram-track appearance due to ingrowth of mesangial cells between endothelial cells and GBM)	Granular pattern (IgG, IgM, C3, C1q)	Electron dense deposits in subendothelial region	Prognosis is poor. About 50% of patients develop chronic renal failure within 10 years
Type 2 MPGN: Tram-track pattern not prominent with Jones silver stain	Granular pattern (IgG, IgM, C3, C1q)	Electron dense deposits within GBM	
Diabetic nephropathy (diffuse/glomerulosclerosis and Kimmelstiel Wilson disease)			
Diffuse glomerulosclerosis and nodular glomerulosclerosis	Trapping of plasma proteins	No electron dense deposits, but shows fusion of podocytes and thickening of GBM	Untreated patients progress to end stage disease
Amyloid nephropathy			
Thickening of GBM due to amyloid deposit, demonstrated by Congo red and apple green birefringence similar to color of Granny Smith apple	Nonspecific trapping of proteins	Amyloid fibrils in mesangial region, GBM and renal tubules	Renal failure is common cause of mortality
Eclampsia of pregnancy			
Glomeruli are bloodless, endothelial cells swollen	Nonspecific deposits of IgG and IgM, fibrin	Endothelial cells show vacuolation, widening of spaces between endothelial spaces	Reversible disorder after delivery of women

Contd...

Table 22.24 Glomerular diseases commonly associated with nephrotic syndrome (*Contd...*)

Light Microscopy	Immunofluorescence Microscopy	Electron Microscopy	Prognosis
Lupus nephritis (systemic lupus erythematosus)			
Type IV lupus nephritis shows endocapillary and/or extracapillary proliferation in ≥50% of glomeruli (wire-loop lesion)	Deposits in mesangial and glomerular loop	Deposits in mesangial and endothelial region	Nephrotic syndrome progresses to chronic renal failure
Type V lupus nephritis shows thickening of GBM and capillary loops; and increased cellularity of mesangial cells	Deposits in mesangial and glomerular loop	Numerous deposits in sub-epithelial region, and scattered deposits in mesangial regions	Nephrotic syndrome progresses to chronic renal failure
Alport's syndrome			
Foam cells are present in glomeruli and tubules. There is increased mesangial matrix. There is increased thickening of GBM with splitting	No definite pattern. Deposition of IgM, C3	No electron dense deposits. GBM shows lucency	End stage renal failure in second or third decade

MINIMAL CHANGE DISEASE

Minimal change disease (MCD) is glomerular disease that causes nephrotic syndrome in 70–90% of young children (peak 2–3 years with M > F) and adults (peak 80–90% with M = F) in 10–15% of cases.

- Minimal change disease in adults can also occur either primary or secondary to Hodgkin's disease (nodular sclerosis), chronic lymphocytic leukemia, or atopic allergies. Rarely familial minimal change disease occurs due to mutation in NPHS2 and dysferlin genes.
- Essential diagnostic features of minimal change disease include normal appearance of glomeruli on light and immunofluorescence microscopy, extensive effacement of foot processes (podocytes) on electron microscopy (hallmark of disease), highly selective proteinuria, mainly albuminuria and response to corticosteroid therapy in 90–95% of cases.
- Lipid accumulation is present in renal tubular cells referred to as lipoid nephrosis. Minimal change disease is also known as idiopathic nephrotic syndrome, nil disease, lipoid nephrosis and foot process disease. Urinary CD80 biomarker level is significantly elevated in MCD. Minimal change disease is shown in Fig. 22.29.

Pathophysiology

Extensive effacement of foot processes (podocytes) occurs due to epithelial injury with loss of glomerular anionic charge in minimal change disease.

- Minimal change disease is usually idiopathic in children. Secondary minimal change disease occurs due to upper respiratory viral infection, atopic allergy, altered immune response (type 4 hypersensitivity reaction with synthesis of lymphokines by T cells), immunological diseases and neoplasam, e.g. Hodgkin's disease (nodular sclerosis), non-Hodgkin's lymphoma and chronic lymphocytic leukemias in all age groups.
- Lymphokines synthesized by T cells cause ballooning of visceral epithelial cells resulting in effacement of foot processes (podocytes) and loss of charge dependent barrier of glomerular basement membrane. Loss of polyanionic proteoglycans leads to massive proteinuria (≥3.5 g/24 hours).

Clinical Features

Patient with minimal change disease presents with selective massive proteinuria ≥3.5 g/24 hours, causing hypoalbuminemia, lipiduria and severe generalized edema. Hypercholesterolemia occurs due to increased synthesis of lipoproteins by liver to compensate massive proteinuria in these cases. Patients usually do not develop hypertension, hematuria and azotemia. Adult patients can present with acute renal insufficiency.

Pathology Pearls: Minimal Change Disease

Gross Morphology

In minimal change disease, enlarged, waxy yellow cortex is observed due to lipid accumulation in proximal tubules.

Light Microscopy

Light microscopy of renal biopsy reveals normal glomeruli. Minimal change disease lacks cell proliferation in glomerular cells and alterations in glomerular basement membrane. Protein reabsorption droplets are observed in tubules. Histology of minimal change disease is shown in Fig. 22.30.

Histochemistry

Fat stains demonstrate presence of lipid in the tubules and glomeruli.

Immunofluorescence Microscopy

Immunofluorescence study is insignificant in minimal change disease. Occasionally, it shows minimal amounts of IgM in the mesangial region.

Electron Microscopy

- Electron microscopy of renal biopsy demonstrates extensive effacement of podocyte foot processes.
- Foot processes retract into cell bodies, not actually fusion occurs associated with weakening of slit pore membranes. This retraction of foot processes presumably results from extensive cell swelling and occurs in virtually all cases of proteinuria in the nephrotic range.
- Microvillous transformation of epithelial cells and cyst formation are demonstrated.

Treatment and Prognosis

Primary responders are minimal change disease patients, who have complete remission after a single course of corticosteroid therapy. Approximately 90–95% of children have complete remission after 8 weeks of steroid therapy, and 80–85% of adults will achieve complete remission after corticosteroid therapy course of 20–24 weeks.

- Immunosuppressive agents are administered in steroid resistant cases (cyclophosphamide, rituximab, abatacept). Relapses are common and often lead to corticosteroid dependence in these patients.
- Rarely, if ever, minimal change disease leads to end stage renal disease without development of focal segmental glomerulosclerosis. Adults may develop acute renal failure, and usually recover.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Focal segmental glomerulosclerosis (FSGS) is the histologic pattern of glomerulosclerosis affecting some glomeruli and only part of glomerular capillary tuft involving >50% of glomeruli and associated with nephrotic syndrome (heavy proteinuria ≥3.5 g/24 hours, hypoproteinemia, hypercholesterolemia and generalized edema) in adults (40%) and children (20%) and progressive renal failure. FSGS is more common in people over 45 years old and in men than in women.

- Glomeruli are involved without inflammation due to immune complex deposits. Glomeruli appear to adhere to Bowman's capsule. FSGS begins in cortico-medullary region.

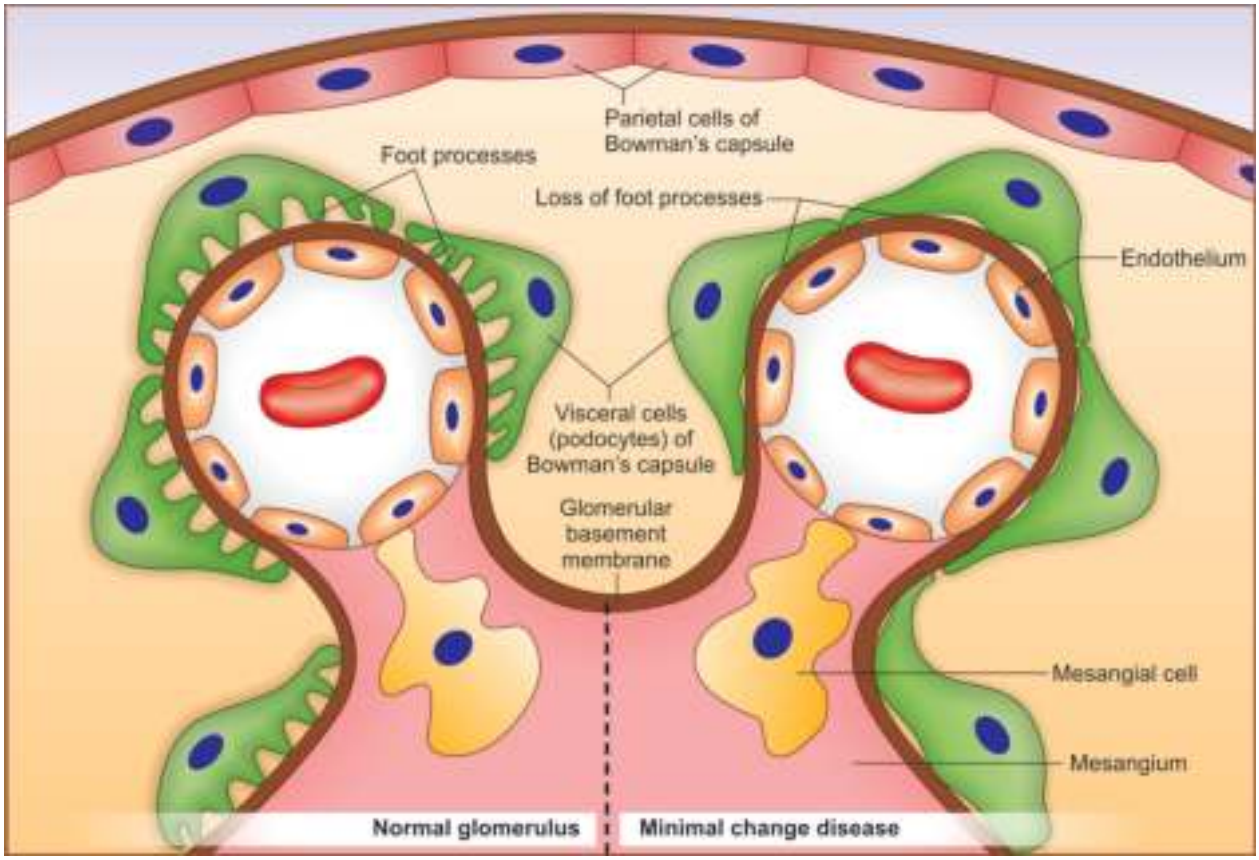

Fig. 22.29: Schematic representation of minimal change disease (MCD). Minimal change disease, also known as lipoid nephrosis or nil disease. Hematoxylin and eosin-stained renal biopsy section reveals normal glomeruli. Immunofluorescence microscopy is typically negative. Three hallmarks of minimal change disease are seen on electron microscopy: diffuse loss of podocyte foot processes of visceral epithelial cells of Bowman's capsule, vacuolation and appearance of microvilli. Patient presents with signs and symptoms of nephrotic syndrome much quicker than they would with other glomerular diseases. Nephrotic syndrome is characterized by massive proteinuria, generalized edema, hypoproteinemia, hypercholesterolemia in children but it can occur in adults. On laboratory testing, profound proteinuria, oval fat bodies may be observed.

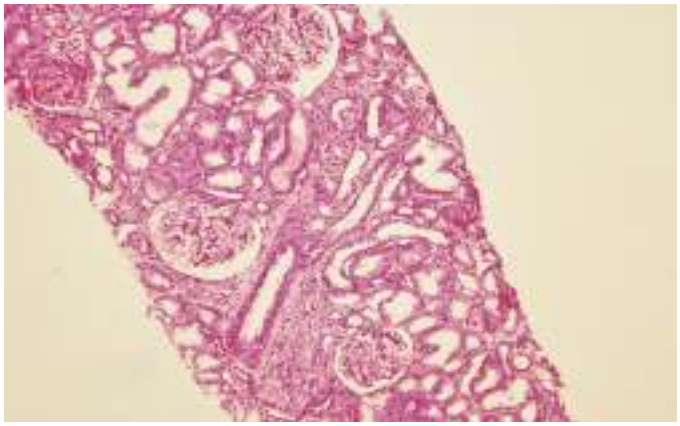

Fig. 22.30: Histology of minimal change disease. Those with minimal change disease experience the signs and symptoms of nephrotic syndrome much quicker than they would with other glomerular diseases. Hematoxylin and eosin-stained renal biopsy section reveals normal glomeruli. Immunofluorescence microscopy is typically negative. Three hallmarks of minimal change disease seen on electron microscopy: diffuse loss of podocyte foot processes of visceral epithelial cells of Bowman capsule, vacuolation and appearance of microvilli (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

- FSGS is characterized by detachment of visceral epithelial cells of Bowman capsule from glomerular basement membrane (hallmark of disease), hyalinosis, adhesions formation, segmental scarring (segmental obliteration of glomerular capillaries), involving a part of the glomerulus (segmental) at tubular pole, and some glomeruli but not all glomeruli sampled observed in H&E stained renal biopsy section. Focal tubular atrophy with interstitial fibrosis, hyaline thickening of afferent arterioles are observed.
- Other histologic features of FSGS include intramembranous hyaline deposits (PAS+, Masson's trichrome stain and Jones methenamine silver stain negative), endocapillary foam cells or lipid droplets in focal glomeruli, mild mesangial hypercellularity, that becomes hypocellular in advanced lesion. It is worth mentioning that the defining glomerular lesions in FSGS cases may not be sampled in renal needle core biopsy due to focal nature of FSGS.
- Patient can present with the clinical manifestations of nephrotic syndrome or associated with hematuria, hypertension and/or renal insufficiency.
- Tip lesion histologic variant of FSGS manifests with lower baseine serum creatinine associated with excellent response to treatment and lowest rate of progression of FSGS.

Etiology

Focal segmental glomerular sclerosis occurs due to adaptative response to several stimuli resulting in glomerular hypertension, hyperfiltration and eventual glomerular hypertrophy in the settings of diabetes mellitus, hypertension, obesity, renal aplasia, hypoplasia or dysplasia, reflux nephropathy, renal artery stenosis, cholesterol emboli, and vascular disease. On histologic examination, glomeruli are large with predominance of perihilar scarring, and partial foot process effacement.

- **Gene mutations:** Mutations in several genes encoding diaphragm proteins, cell membrane proteins, cytoskeleton proteins, mitochondrial proteins, nuclear proteins; and lysosomal proteins lead to loss of integrity of glomerular filtration barrier resulting in FSGS.
- **Circulating glomerular permeability factors/cytokines:** Primary FSGS occurs due to the presence of circulating glomerular permeability factors/cytokines such as cardiotrophin-like cytokine factor 1, apoA1b, anti-CD40 antibodies and suPAR (soluble urokinase-type plasminogen activator receptor); which cause effacement of foot processes and massive proteinuria.
- **Viruses role:** FSGS can be caused by HIV, parvovirus B19, cytomegalovirus, Epstein-Barr virus, hepatitis C virus (HCV), and Simian virus 40.
- **Nephrotoxic drugs:** FSGS can be caused by drugs such as heroin, lithium, pamidronate, interferon, mTOR inhibitors; and anabolic steroids can induce focal segmental glomerulosclerosis.

Pathogenesis

The pathogenesis of focal segmental glomerular sclerosis involves a complex interplay of several cell types including podocytes, glomerular endothelial cells, and the glomerular basement membrane resulting in massive proteinuria and subsequent development of focal sclerosing lesions.

- Podocytes are terminally differentiated cells that provide structural support to the glomerulus and are essential in maintaining an intact glomerular filtration barrier essential to prevent nephrotic range proteinuria.
- FSGS is broadly categorized into primary (idiopathic) and secondary forms, and such distinction carries both prognostic and therapeutic implications. Renal biopsy from uninvolved glomeruli sometimes leads to a misdiagnosis of FSGS.
- Patients progress to end stage renal disease in less than a year. In reflux nephropathy, reduction in renal mass causes adaptive stress on the reduced number of nephrons resulting in increased glomerular pressure and filtration and enlargement of glomeruli due to functional overwork of glomeruli.
- Possible mechanisms include T cell-mediated circulating permeability factor, TGF-β mediated cellular proliferation and mesangial matrix synthesis, and vacuolization of visceral epithelial cells (podocytes), associated with genetic mutations.

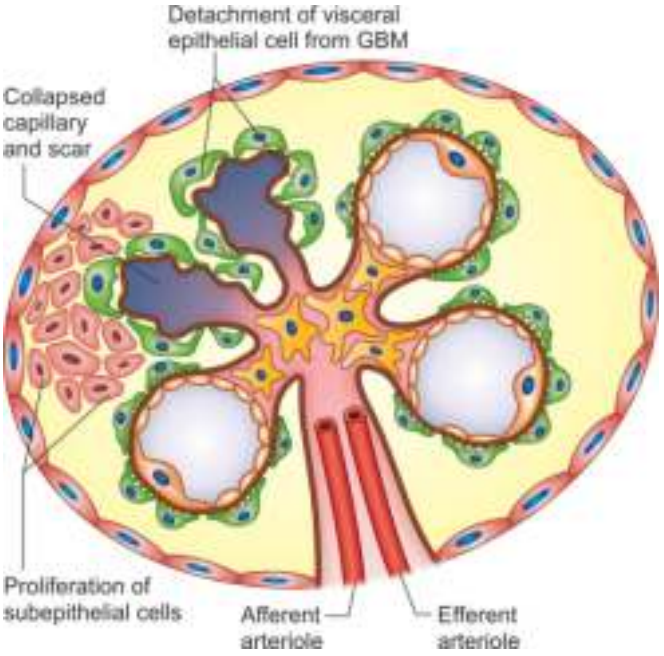

Fig. 22.31: Schematic representation of focal segmental glomerulosclerosis (FSGS). Detachment of epithelial cells from glomerular basement membrane (GBM) is hallmark of focal segmental glomerulosclerosis observed in hematoxylin and eosin-stained renal biopsy section. In FSGS, some but not all of the glomeruli (focal) are affected in one part of the glomerulus (known as a segment (segmental) with formation of scar (sclerosis) resulting in the name focal segmental glomerulosclerosis. FSGS affects both children and adults but is more common in people over 45-year-old. It occurs more often in men than in women.

Diagrammatic representation of focal segmental sclerosis is shown in Fig. 22.31.

Clinical Course

Patient presents with nephrotic syndrome in adults (30%) and children (10%) and renal insufficiency. FSGS may be associated with hematuria, and hypertension, which does not respond well to corticosteroids treatment. Approximately 60–80% of FSGS patients develop end stage renal disease (renal failure) within 10 years. Recurrence of FSGS is common after renal transplant. Approximately 60–80% of patients develop end stage renal disease (renal failure) within 10 years. Renal biopsy is essential to establish diagnosis.

Pathology Pearls: Focal Segmental Glomerulosclerosis

Light Microscopy

Hematoxylin and eosin-stained renal biopsy/tissue section in focal segmental glomerulosclerosis (FSGS), glomerulus shows foam cells in the mesangium. **Detachment of visceral epithelial cells from GBM is hallmark of disease**. Glomerular basement membrane shows thickening and wrinkling. Collapse and hyalinization of glomeruli lead to focal segmental glomerulosclerosis. Working classification of FSGS is given in Table 22.25. Histology of FSGS is shown in Figs 22.32 and 22.33.

- **FSGS perihilar variant:** The sclerosing lesion in perihilar variant is located at the vascular pole of the glomerulus and usually demonstrated in adaptive FSGS due to increased pressure in the glomerulus, which is located in close proximity to the afferent arteriole. Effacement of foot processes is mild and resulting in proteinuria in subnephrotic range and relatively normal serum albumin levels.
- **FSGS tip lesion variant:** The sclerosing lesion in tip lesion variant is located at the tubular pole of the glomerulus with effacement of foot processes, which usually affects Caucasians. Patient presents with abrupt onset of nephrotic syndrome with lower baseline serum creatinine level and lowest progressive disease, and responds well to corticosteroids treatment and associated with excellent prognosis. Histology of tip lesion variant of FSGS is shown in Fig. 22.34.
- **FSGS cellular variant:** This is the least common variant of FSGS, characterized by hypercellular glomerulus including endocapillary and glomerular epithelial cell hyperplasia. Patient presents with diffuse foot process effacement and full-blown nephrotic syndrome.
- **FSGS collapsing variant:** Focal segmental glomerulosclerosis, collapsing variant is characterized by hyperplasia and hypertrophy of podocytes (visceral glomerular epithelial cells) resulting in collapse of the glomerular tuft.
  - Focal segmental glomerulosclerosis, collapsing variant occurs in the setting of as infections (HIV, parvovirus B19, HCV, cytomegalovirus), drugs (bisphosphonates, heroin, alpha and beta interferons, anabolic steroids), vascular and metabolic disease (thrombotic microangiopathy, severe diabetic nephropathy, severe vascular and microvascular disease), genetic disorders (APOL1 high risk alleles, mitochondrial abnormalities), autoimmune disorders (post-transplant, recurrent and *de novo*).
  - Patient presents with heavy proteinuria with the lowest rate of remission, and associated with worst prognosis.
- **FSGS, not otherwise specified (NOS):** Focal segmental glomerulosclerosis, not otherwise specified is the most common subtype of FSGS and does not fit into any other morphologic forms of FSGS. It presents with a variable degree of effacement and proteinuria.

Histochemistry

Periodic acid–Schiff (PAS) stain highlights acellular, hyaline material distributed in segmental manner.

Immunofluorescence Microscopy

Glomeruli usually lack immune complex deposits. However, IgM and C3 deposits can be demonstrated in some cases of focal segmental glomerulosclerosis.

Electron Microscopy

On electron microscopy, glomeruli show fusion of podocytes but lack electron dense deposits. Retraction of foot processes of visceral epithelial cells is present.

Table 22.25 Working classification of focal segmental glomerulosclerosis (FSGS)

Working Classification of FSGS	Histologic Features	Possible Prognostic Implication
FSGS perihilar variant	Sclerosis and hyalinosis of glomeruli at vascular pole	May reflect a secondary type of FSGS
FSGS tip lesion variant	Sclerosis/adhesion of glomeruli at proximal tubule pole	Better prognosis
FSGS cellular variant	Endocapillary proliferation, often visceral hyperplasia	Early-stage lesion related to tip
FSGS collapsing variant	Collapse of glomerular tuft, visceral epithelial hyperplasia	Poor prognosis
FSGS, NOS (not otherwise specified)	Segmental sclerosis of glomeruli	Typical course

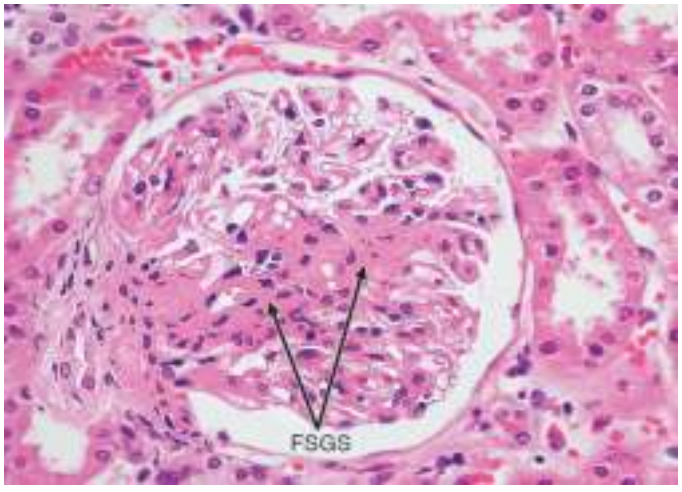

Fig. 22.32: Histology of focal segmental glomerulosclerosis (FSGS). In hematoxylin and eosin-stained renal biopsy section, FSGS appears to adhere to Bowman's capsule, which begins in corticomedullary region, intramembranous hyaline deposits (PAS+, trichrome stain and Jones methenamine silver stain negative), mesangial sclerosis in lobules, endocapillary foam cells or lipid droplets in focal glomeruli, mild mesangial hypercellularity, that becomes hypocellular in advanced lesion. Focal tubular atrophy with interstitial fibrosis, hyaline thickening of afferent arterioles. It is worth mentioning that the defining glomerular lesions may not be samples in renal needle core biopsy due to their focal nature. Hematoxylin and eosin-stained section shows sclerosis of glomerulus. Detachment of epithelial cells from glomerular basement membrane (GBM) is hallmark of disease (arrows) (400X).

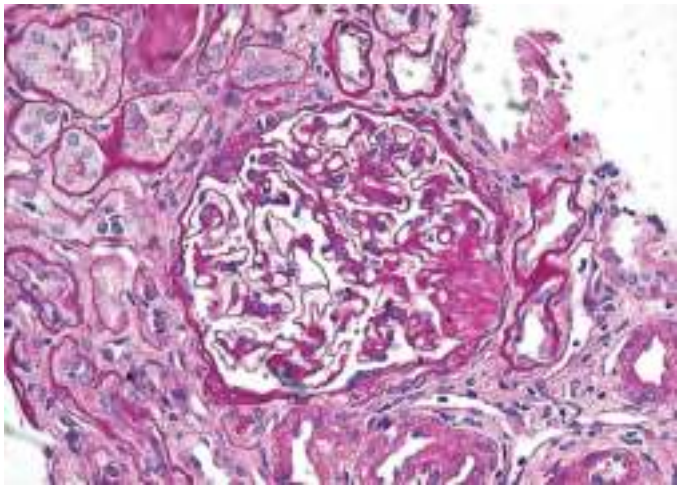

Fig. 22.33: Histology of focal segmental glomerulosclerosis (FSGS). FSGS is a histologic pattern of glomerulosclerosis affecting some glomeruli and only part of glomerular capillary tuft involving more than 50% of glomeruli and associated with heavy proteinuria ≥3.5 g/24 hours and progressive renal failure. Hematoxylin and eosin-stained renal tissue section shows focal and segmental glomerulosclerosis in lobules that appear to adhere to Bowman's capsule, which begins in the corticomedullary region. Focal tubular atrophy with interstitial fibrosis and hyalinization of afferent arterioles are present. It is worth mentioning that defining glomerular lesions may not be sampled in needle core biopsy due to focal nature of the disease (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Treatment

Glucocorticoid therapy is the first line of treatment in children and adults with focal segmental glomerulosclerosis (FSGS) for a period of 3–6 months. Patients, resistant or intolerant to corticosteroids, are treated with immunosuppressive therapy with calcineurin inhibitors such as mycophenolate mofetil, or rituximab and tacrolimus (6–12 months).

MEMBRANOUS GLOMERULONEPHRITIS

Membranous glomerulonephritis (MGN) is the most common cause of insidious onset of nephrotic syndrome in adults (30–50 years) and in children. Its etiology can be primary or secondary.

- Membranous glomerulonephritis (MGN) occurs due to deposition of immune complex (electron dense) in glomerular basement membrane but not in the mesangial region accompanying diffuse thickening of glomerular basement membrane (5–10 times of normal GBM), without mesangial sclerosis, inflammatory cells and proliferation of resident glomerular cells. Proximal convoluted tubules contain hyaline droplets reflecting protein reabsorption. Progression of the disease results in glomerular basement membrane thickening, narrow capillary lumina, mesangial sclerosis and glomerulosclerosis.
- MGN is a slowly progressive disorder affecting males than females, which shows a little response to corticosteroid therapy. Prognosis is highly variable depending on its etiology.

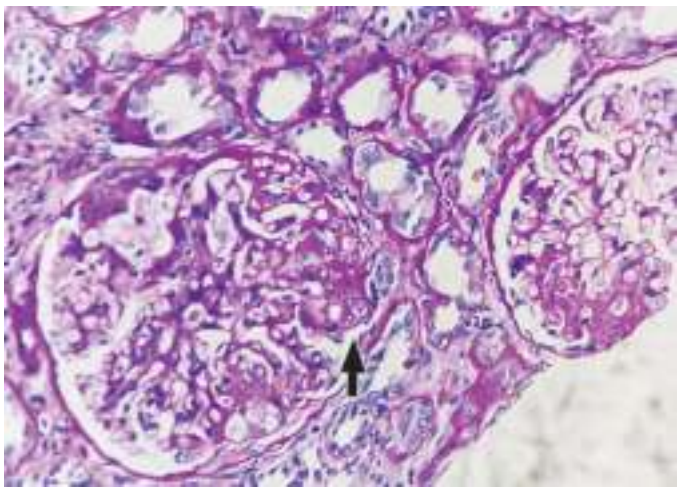

Fig. 22.34: Histology of tip lesion variant of focal segmental glomerulosclerosis (FSGS). Focal segmental glomerulosclerosis is histologically characterized by segmental sclerosis that involves a part of the glomerulus and only affects one but not all glomeruli renal biopsies. Patient with FSGS can present with the clinical manifestations of nephrotic syndrome or with hematuria, hypertension or renal insufficiency. Histologically, FSGS is classified into five variants: perihilar, tip, cellular, collapsing and not otherwise specified (NOS). Hematoxylin and eosin-stained renal tissue section examination in FSGS tip lesion shows segmental glomerulosclerosis (segmental obliteration of glomerular capillaries involving the tubular pole of glomerulus, hyalinosis, adhesions formation FSGS with tip lesion variant manifests with lower baseline serum creatinine associated with excellent response to treatment and lowest rate of progression) (400X).

- Histologic variants of membranous glomerulonephritis include MGN with crescents, MGN with antitubular basement membrane nephritis, transplant associated MGN and MGN with superimposed renal vein thrombosis.
- Renal biopsy is done to confirm the diagnosis of MGN. Immunosuppressive therapy plays a major role in the treatment of this disease.
- Jones methenamine silver-stained renal biopsy section shows characteristic black material in glomerular basement membrane that appears **'spikes' projections** around the capillary loops and '**domes**' due to immune complex deposits. Electron microscopy reveals effacement of podocytes.
- Antiphospholipase A2 receptor (PLA2R) antibodies are highly specific for the diagnosis of primary membranous glomerulonephritis.

Clinical Pearls: Membranous Glomerulonephritis

- Membranous glomerulonephritis is the most important cause of nephrotic syndrome in adults.
- Diffuse thickening of glomerular basement membrane occurs (5–10 times of normal GBM) due to *in situ* immune complexes (electron dense) in glomerular basement membrane but not in mesangial region.
- Most cases of primary membranous glomerulonephritis have PLA2R antibody positive deposits.
- Extensive subepithelial/intramembranous deposits are demonstrated by electron microscopy.
- Prognosis of MGN is highly variable depending on etiology of the disease.
- About 25% of MGN patients undergo spontaneous remission without treatment.
- Approximately 50% of patients have persistent proteinuria in nephrotic range and hematuria.
- Loss of antithrombin III and antiplasmin in urine may result in renal vein thrombosis.
- About 25% of patients develop chronic renal failure.
- Renal functions are markedly impaired.

Pathophysiology

Membranous glomerulonephritis may be primary or secondary. Membranous glomerulonephritis (MGN) may develop in the renal allograft either *de novo* or as a recurrence. These two forms of MGN may have different pathogenesis mechanisms, with different IgG subclass profiles in the immune deposits. Membranous glomerulonephritis is shown in Fig. 22.35. Etiology of membranous glomerulonephritis is given in Table 22.26.

- **Primary or idiopathic MGN:** Most cases of primary membranous glomerulonephritis are idiopathic (75% of adults and 20% of children) and are linked to HLA and caused by antibodies to renal autoantigen. Disease is considered the human model of Heymann nephritis, which in rat is produced by antibody to megalin antigen complex GP-330 on basal surface of visceral epithelial cells (megalin is homologous to LDL receptor), and brush border of epithelium of proximal convoluted tubules. Incidence of MGN is highest in teenagers and young adults.
- **Secondary MGN:** Secondary membranous glomerulonephritis is associated with immune complex deposits in glomerular basement membrane in diffuse granular fashion (usually referred to as lumpy bumpy), in the subepithelial region of glomerular basement membrane (GBM) in the setting of cancers (breast, lung, colon, melanoma and lymphomas), infectious agents (malaria, leprosy, syphilis, hepatitis B virus, filariasis, schistosomiasis), drugs (captopril, penicillamine, gold, mercury, trimethadione), and autoimmune disorders such as systemic lupus erythematosus, Hashimoto's thyroiditis (thyroglobulin), type 1 diabetes mellitus, angiofollicular lymph node hyperplasia and sarcoidosis or rarely rheumatoid arthritis. Proteinuria may occur due to glomerular injury induced by C5b–C9 membrane attack complex (MAC) in these cases.

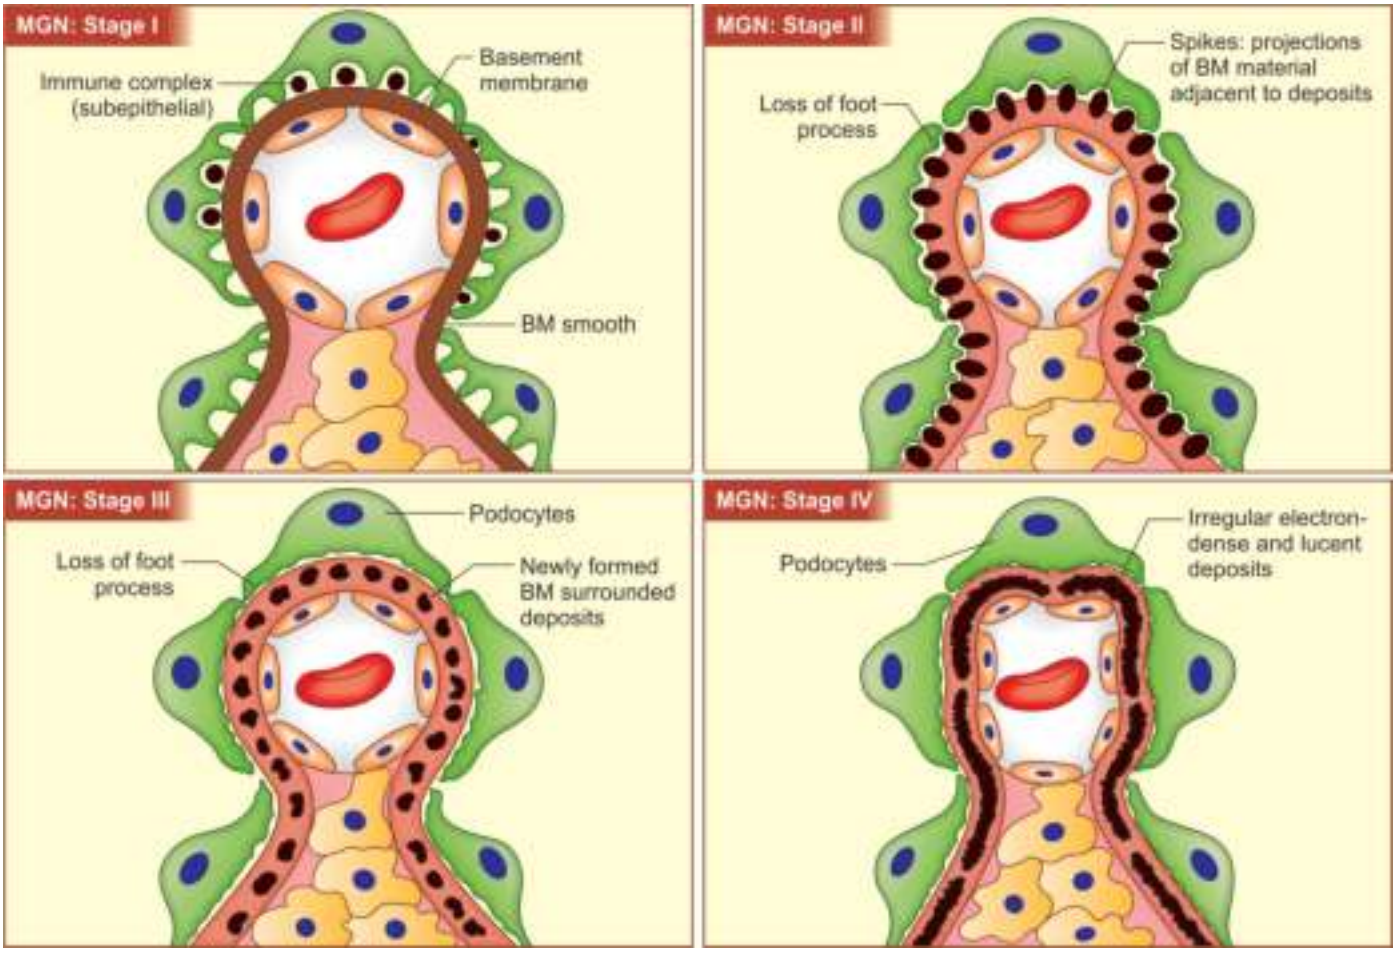

Fig. 22.35: Schematic diagram of membranous glomerulonephritis (MGN). Membranous glomerulonephritis is important cause of nephrotic syndrome. Its etiology can be primary or secondary. Disease occurs due to deposition of immune complex in subepithelial regions accompanying changes in the glomerular basement membrane. Renal biopsy is done to confirm the diagnosis. Immunosuppressive therapy plays a major role in the treatment of this disease. Electron microscopy reveals effacement of podocytes.

Table 22.26 Etiology of membranous glomerulonephritis

Categories	Examples		
Primary/idiopathic membranous glomerulonephritis (85%)			
In situ immune complex-mediated glomerulonephritis	Antibodies directed against GP-330 antigen present on brush border of epithelium of proximal convoluted tubules and visceral epithelium		
Secondary membranous glomerulonephritis (15%)			
Infectious agents	▪ Malarial parasite ▪ Mycobacterium leprae bacilli	▪ *Treponema pallidum* ▪ *Wuchereria bancrofti*	▪ *Schistosoma haematobium* ▪ Hepatitis B and C
Malignant tumor antigens	▪ Breast carcinoma ▪ Lung carcinoma	▪ Colon carcinoma ▪ Lymphoma	▪ Malignant melanoma
Drugs	▪ Gold ▪ Mercury	▪ Penicillamine ▪ Captopril	▪ Trimethadione
Autoimmune disorders	▪ Systemic lupus erythematosus (renal involvement giving pattern of membranous glomerulonephritis in 10% of cases)	▪ Hashimoto's thyroiditis ▪ Diabetes mellitus type 1	▪ Sarcoidosis ▪ Rheumatoid arthritis

Pathology Pearls: Ehrenreich and Churg Classification of Membranous Glomerulonephritis (MGN)

According to Ehrenreich and Churg classification of MGN is based on the appearance of electron-dense deposits.

- **MGN Stage 1:** MGN stage 1 shows small, sparse, electron-dense deposits on the visceral epithelial side of glomerular basement membrane (GBM).
- **MGN Stage 2:** MGN stage 2 shows larger electron-dense deposits causing glomerular basement membrane thickening along with effacement of foot processes giving characteristic '**spiles and domes**' appearance.
- **MGN Stage 3:** MGN stage 3 shows feature of stage 2 plus intramembranous coarse granular electron-dense deposits with formation of new glomerular basement membrane.
- **MGN Stage 4:** MGN stage 4 shows irregular electron-dense deposits, dissolution of electron-dense deposits. disrupted and sclerosed glomerular basement membrane.

Clinical Features

Membranous glomerulonephritis is the most common cause of nephrotic syndrome. Patient presents with insidious onset of nephrotic syndrome and occasionally hematuria and hypertension. One must rule out and treat secondary causes of MGN.

- Prognosis is variable and related to etiology such as spontaneous remission without treatment (33%). One-third of patients are stabilized with treatment.
- About 33% of patients develop persistent proteinuria, hypertension (50%), renal vein thrombosis (due to loss of antithrombin III and antiplasmin in urine) and hematuria, impairment of renal function (50%), and chronic renal failure (25%).
- Long-term prognosis of the disease may be improved by treating patients with high-dose corticosteroids and alkalinizing agents, e.g. cyclophosphamide, although associated with side effects.

Pathology Pearls: Membranous Glomerulonephritis

Light Microscopy

- Examination of hematoxylin and eosin-stained renal biopsy section reveals uniform diffuse thickening of glomerular wall without hypercellularity, without mesangial sclerosis and without inflammatory cells.
- Proximal convoluted tubules contain hyaline droplets, reflecting protein reabsorption.
- Progression of the disease leads to thickening of glomerular basement membrane, narrow capillary lumina, mesangial sclerosis and glomerulosclerosis. Histology of membranous glomerulonephritis (MGN) is shown in Figs 22.36 to 22.38. Comparison of stages of membranous glomerulonephritis by light, immunofluorescence and electron microscopy is given in Table 22.27.

Histochemistry

Jones methenamine silver stain highlights the proteinaceous basement membranes as black. It shows duplication of glomerular basement membrane with **'spikes and domes' appearance**. It results from the extension of basement membrane between and around the immune complex deposits. The spikes are basement membrane material, and the domes denoting immune complex deposits. Jones methenamine silver stain in membranous glomerulonephritis (MGN) is shown in Fig. 22.39.

Immunofluorescence Microscopy

Immunofluorescence microscopy of renal biopsy shows granular diffuse peripheral deposits of IgG or C3 also C5b–C9 or IgA or C4d outlining the glomerular capillary loops. It is a feature of immune complex-mediated glomerulonephritis.

Treatment

Clinical course of membranous glomerulonephritis makes it difficult to evaluate therapy. Patients are treated by corticosteroids, chlorambucil or cyclophosphamide chlorambucil or cyclophosphamide for six months. In case, remission is not achieved, patients may be treated by cyclosporine, adrenocorticotropic hormone, mycophenolate mofetil and rituximab. Treatment is effective on post-transplant recurrences of disease.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Membranoproliferative glomerulonephritis (MPGN) is also known as hypocomplementemic C3, lobular or mesangiocapillary glomerulonephritis.

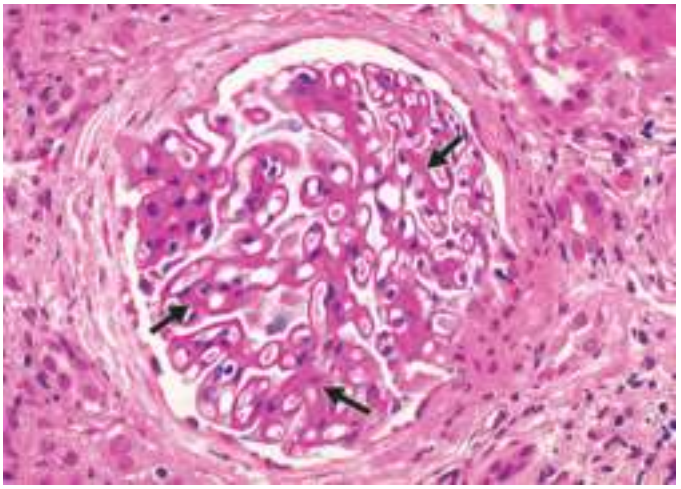

Fig. 22.36: Histology of membranous glomerulonephritis (MGN). Hematoxylin and eosin-stained renal biopsy section reveals uniform diffuse thickening of glomerular capillary walls without sclerosis and without inflammatory cells. Proximal convoluted tubules contain hyaline droplets, reflecting protein reabsorption. With progression of disease, glomerular basement membrane thickening, narrow glomerular capillary lumina, mesangial sclerosis and glomerulosclerosis (arrows) (400X).

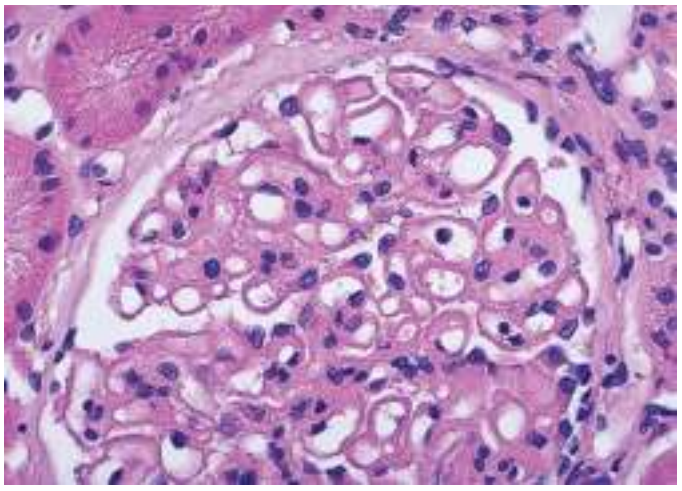

Fig. 22.37: Histology of membranous glomerulonephritis (MGN). Hematoxylin and eosin-stained renal tissue section shows uniform diffuse thickening of the glomerular capillary walls without hypercellularity and without mesangial sclerosis and without inflammatory cells. Proximal convoluted tubules contain hyaline droplets reflecting protein reabsorption. Progression of the disease results in glomerular basement thickening, narrow capillary lumina, mesangial sclerosis and glomerulosclerosis (400X).

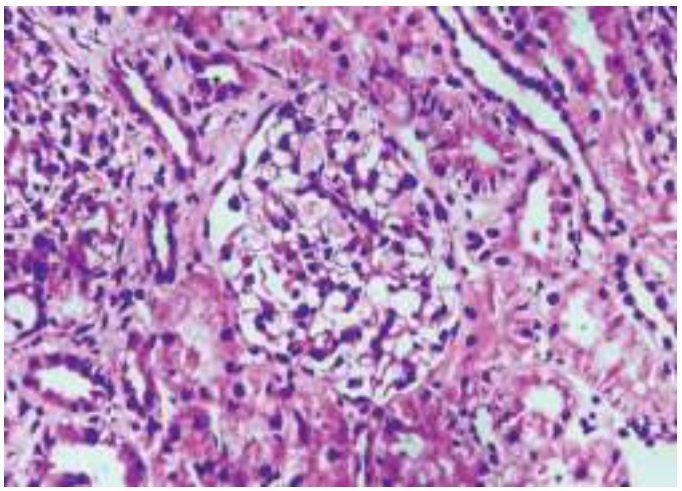

Fig. 22.38: Histology of membranous glomerulonephritis (MGN). Hematoxylin and eosin-stained renal tissue section shows diffuse thickening of the glomerular capillary walls due to *in situ* immune complexes (electron dense) in glomerular basement membrane but not in the mesangium, and without inflammatory cells. Progression of the disease results in thickening of GBM, narrow glomerular capillary lumina, mesangial sclerosis and glomerulosclerosis (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Table 22.27 Comparison of stages of membranous glomerulonephritis by light, immunofluorescence and electron microscopy

Stage of MGN	Light Microscopy	Immunofluorescence Microscopy	Electron Microscopy
Stage I	Normal or slightly thickened GBM with slight vacuolization	Fine granular IgG, C3 deposits	Scattered small subepithelial electron dense deposits, no foot process effacement or spikes
Stage II	Moderately thickened GBM with spikes and vacuolization	Moderate sized, granular IgG, C3 deposits	Diffuse effacement of foot process
Stage III	Markedly thickened GBM, residual spikes and vacuoles, chain-like appearance	Coarsely granular IgG, C3 deposits	Intramembranous deposits, spikes, new membrane formation and diffuse effacement of foot process
Stage IV	Markedly thickening of GBM with few spikes, vacuoles and glomerulosclerosis	Focal IgG, C3 deposits	Sclerotic GBM, few deposits and lacunae

- Pattern of glomerular injury in MPGN is characterized by alterations in glomerular basement membrane (thickening and duplication), proliferation of endocapillary and mesangial cells, subendothelial and mesangial deposition of immunoglobulins and possible increased mesangial matrix, variable degree of effacement of foot process, caused by persistent antigenemia or circulating immune complexes resulting in increase in mesangial matrix and exudation of inflammatory cells.
- MPGN causes nephrotic syndrome in children (rarely) and adults (5%).
- Traditional classification of MPGN is based on electron microscopy findings: (a) MPGN type 1 (subendothelial and mesangial deposits), (b) MPGN type 2 (intramembranous dense ribbon-like deposits) and (c) MPGN type 3 (subendothelial and subepithelial deposits).
- Hematoxylin and eosin-stained renal biopsy section examination shows hypercellular glomeruli that exhibit lobular appearance in type 1 and type 2 MPGN. Mesangial cells proliferation results in splitting and thickening of glomerular basement membrane, hence giving a 'double contour' of glomerular basement membrane (GBM) and/or the 'tram-track appearance', resulting from reduplication of glomerular basement membrane due to ingrowth of mesangial region demonstrated with Jones methenamine silver stain and periodic acid–Schiff (PAS) stain.

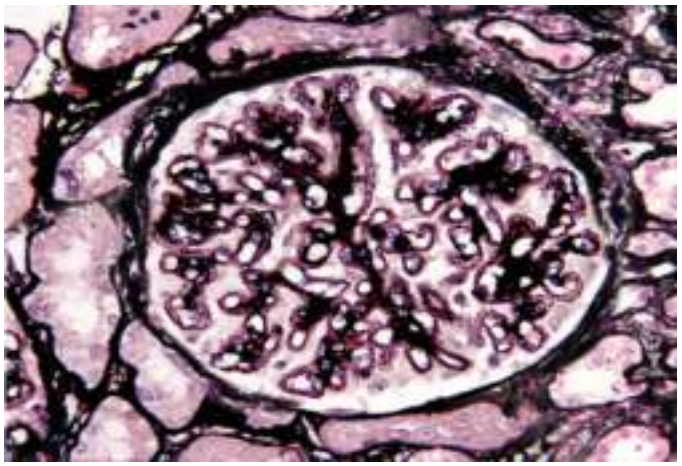

Fig. 22.39: Jones methenamine silver stain in membranous glomerulonephritis (MGN). Jones methenamine silver stained renal biopsy section shows characteristic black material in glomerular basement membrane that appears "spikes" projections around the capillary loops and 'domes' due to immune complex deposits (400X).

- C3-related membranoproliferative glomerulonephritis (MPGN)/dense deposit disease, also known as type 3 MPGN, is characterized by broad, linear, extremely electron dense deposits with C3 within glomerular basement membrane, mesangium, Bowman's capsule and tubular basement membrane, and low level of serum C3 are related to chronic activation of alternative complement system pathway resulting in the accumulation of complement components in the tissue, recruitment of leukocytes and inflammatory damage of glomeruli in hematoxylin and eosin-stained renal biopsy sections on light microscocpy.

Pathogenesis

Membranoproliferative glomerulonephritis may be caused by two mechanisms: (a) immunoglobulin mediated MPGN occurs in setting of chronic infections, autoimmune diseases, monoclonal gammopathy/dysproteinemias; (b) complement mediated MPGN occurs due to subendothelial and mesangial deposition of complement from dysregulation of alternative pathway; includes dense deposit disease (membranoproliferative glomerulonephritis type 2) and proliferative glomerulonephritis with C3 deposits; due to genetic mutations or development of autoantibodies to complement. MPGN is slowly progressive disorder with intermittent remission. It affects patients between 5 and 30 years of age and shows a little response to corticosteroid therapy.

Clinical Features

Patient initially develops nephritic syndrome slowly progressing to nephrotic syndrome and chronic renal failure; and later may develop renal vein thrombosis, hypertension, clinical manifestations of uremia and complex-mediated glomerulonephritis.

- Most patients have circulating antineutrophil cytoplasmic antibodies associated with vasculitis, i.e. Wegener granulomatosis, microscopic polyarteritis nodosa. MGPN disease occurs in three forms: type 1, type 2 and type 3.
- Comparison of types 1, 2 and 3 membranoproliferative glomerulonephritis (MPGN) is given in Table 22.28. Schematic representation of membranoproliferative glomerulonephritis type 1 and type 2 is shown in Fig. 22.40.

Pathology Pearls: Type 1 Membranoproliferative Glomerulonephritis (Type 1 MPGN)

- Type 1 MPGN constitutes 90% of cases. Patient presents with nephrotic syndrome and hypertension in 8–15 years of age.
- Disease occurs due to immune complex deposition and activation of classical and alternative complement pathways.
- About 66% of cases have persistent decrease in serum C3 due to its hypercatabolism; and reduction in total complement levels and borderline/reduced levels of C1q, C4 and properdin.
- Secondary MPGN occurs in the settings of systemic lupus erythematosus, hepatitis B, hepatitis C, HIV, malarial parasite, cytomegalovirus malarial parasite, cytomegalovirus, α_1-antitrypsin deficiency and malignancies.

Light Microscopy

- Examination of renal biopsy in type 1 classic MPGN shows marked proliferation of mesangial cells, large hypercellular glomeruli with accentuation of lobules exhibiting lobular appearance. Sometimes nodules are demonstrated in the mesangial region.
- Irregular thickening of the glomerular basement membrane occurs by interposition of mesangial cells between endothelium and glomerular basement membrane resulting in thickening of glomerular basement membrane due to ingrowth of mesangial cells..
- Neutrophils are often present. Crescents in glomeruli are demonstrated in 20% of cases. Proliferation of endothelial cells causes decrease in lumina of glomeruli resulting in decreased glomerular filtration rate. Histology of membranoproliferative glomerulonephritis (MPGN) is shown in Figs 22.41 and 22.42.

Histochemistry

Mesangial cell proliferation results in splitting and thickening of glomerular basement membrane, hence giving '**tram-track appearance**' or double contour appearance due to presence of complement, mesangial cells cytoplasm and matrix, and partly to the formation of new membrane matrix just beneath the endothelial cells demonstrated with PAS and Jones methenamine silver stain. Jones methenamine silver staining in type 1 membranoproliferative glomerulonephritis is shown in Figs 22.43 and 22.44.

Immunofluorescence Microscopy

Immunofluorescence microscopy reveals '**lumpy bumpy granular pattern**' (IgG, IgM, C3, C1q and C4) in mesangial and subendothelial regions in the new glomerular basement membrane formed. Immune complex deposits appear as spherical or ring-shaped deposits in mesangial region as well as subendothelial regions of glomeruli. Subepithelial immune deposits are composed of C3 and present in 15–20% of cases.

Electron Microscopy

Electron microscopy shows electron dense deposits in subendothelial and mesangial regions of glomeruli associated with increased mesangial matrix, mesangialization of glomerular capillary loops and fusion of foot processes.

Pathology Pearls: Type 2 Membranoproliferative Glomerulonephritis (Type 2 MPGN)

- Essential diagnostic feature of type 2 MPGN is not the membranoproliferative pattern but the presence of electron dense transformation of the glomerular basement membrane. Hence, it is also known as '**dense deposit disease**'. It accounts for 10% of cases.
- Disease may be familial or associated with partial lipodystrophy (loss of subcutaneous fat from fat and upper body).
- Disease is associated with uncontrolled activation of alternative complement system pathway. C3 nephritic factor, an autoantibody binds and stabilizes C3 convertase (C3bBb) and promotes C3 degradation resulting in very low serum C3 levels.
- There is only deposition of complement in the form of irregular ribbon-like or circular aggregates in lamina densa of glomerular basement membrane.
- Patients present with features of nephrotic syndrome than nephritic syndrome. Patients have poorer prognosis than type 1 MPGN. About 50% of patients develop renal failure over 10 years. About 80% of patients recur after renal transplant.

Light Microscopy

- Histologic features of type 2 MPGN exhibit less prominent cellular proliferation. Eosinophilic, refractile and ribbon-like thickening of glomerular basement membrane and basement membrane of Bowman capsule and tubules.
- Type 2 MPGN shows large hypercellular glomeruli with accentuation of lobules exhibiting '**lobular appearance**'. Irregular thickening of the glomerular basement membrane occurs by interposition of mesangial cells between endothelium and basement membrane.
- Mesangial cell proliferation results in splitting and thickening of glomerular basement membrane, hence giving '**tram-track appearance**' (double contour of GBM due to ingrowth of mesangial region). Histology of type 2 membranoproliferative glomerulonephritis is shown in Fig. 22.45.

Histochemistry

- Dense deposits are demonstrated by PAS and Masson's trichrome. Jones methenamine silver (JSM) stain demonstrates broad, linear, extremely electron dense deposits with C3 within basement membrane of glomeruli, tubules, Bowman's capsule, elastic lamina of blood vessels and sclerotic segments of glomeruli (glomerulosclerosis).
- Jones methenamine silver (JSM) stain in type 2 membranoproliferative glomerulonephritis (MPGN) complement related disease (C3 related glomerulopathy/dense deposit disease) is shown in Fig. 22.46.

Electron Microscopy

Electron microscopy shows electron dense deposits of immune complex within glomerular basement membrane, Bowman's capsule as long ribbon-like material.

Immunofluorescence Microscopy

Immunofluorescence microscopy shows linear or double contoured C3 and properdin (and absence of IgG, or C1q or C4) staining of glomerular basement membrane and brighter nodular or ring-like structures in mesangial region and not in dense deposits. C3 staining is also demonstrated in mesangial region, Bowman's capsule and tubular basement membranes.

Pathology Pearls: Type 3 Membranoproliferative Glomerulonephritis (Type 3 MPGN)

- Two rare morphologic subtypes of type 3 MPGN include: (a) Burkholder variant and (b) Anders variant. These are clinically similar to each other.
- Burkholder variant of type 3 MPGN has combined features of type 1 membranoproliferative glomerulonephritis and membranous glomerulonephritis. It is associated with hepatitis C and HIV coinfection.

Electron Microscopy

- Electron microscopy demonstrates subendothelial and subepithelial deposits and mesangial interposition associated with basement membrane spikes.
- Anders variant type 3 MPGN has features of hybrid of type 1 and 2 membranoproliferative glomerulonephritis.
- Electron microscopy demonstrates massive accumulation of deposits within basement membrane with membranous disruption, highlighted by Jones methenamine silver stain.

DIABETIC NEPHROPATHY

Diabetic nephropathy is a morphologic structural change in the glomeruli with mesangial matrix expansion encroaching on the glomerular capillary lumina that occurs due to long-standing hyperglycemia in diabetes mellitus. It is the most important cause of end stage renal disease in 55% of diabetic cases. Diagnostic criteria for diabetes mellitus include: fasting

Table 22.28 Comparison of types 1, 2 and 3 membranoproliferative glomerulonephritis (MPGN)

Parameter	MPGN Type 1	MPGN Type 2	MPGN Type 3
Frequency	90%	10%	Rare
Complement activation pathway	Classic pathway	Alternate pathway	Complement activation pathway absent
Immune complex deposits	IgG, IgM, C3, C1q, C4	C3 but lack IgG and C1q and C4	Nature of immune complex is unknown
Site of deposition of immune complex	Subendothelial region (most common), mesangial region and occasionally in subepithelial region of glomeruli	Electron dense deposits: C3 is deposited in the form of ribbon within lamina densa of basement membrane	Immune complex may be deposited in the subendothelial and subepithelial regions of glomeruli

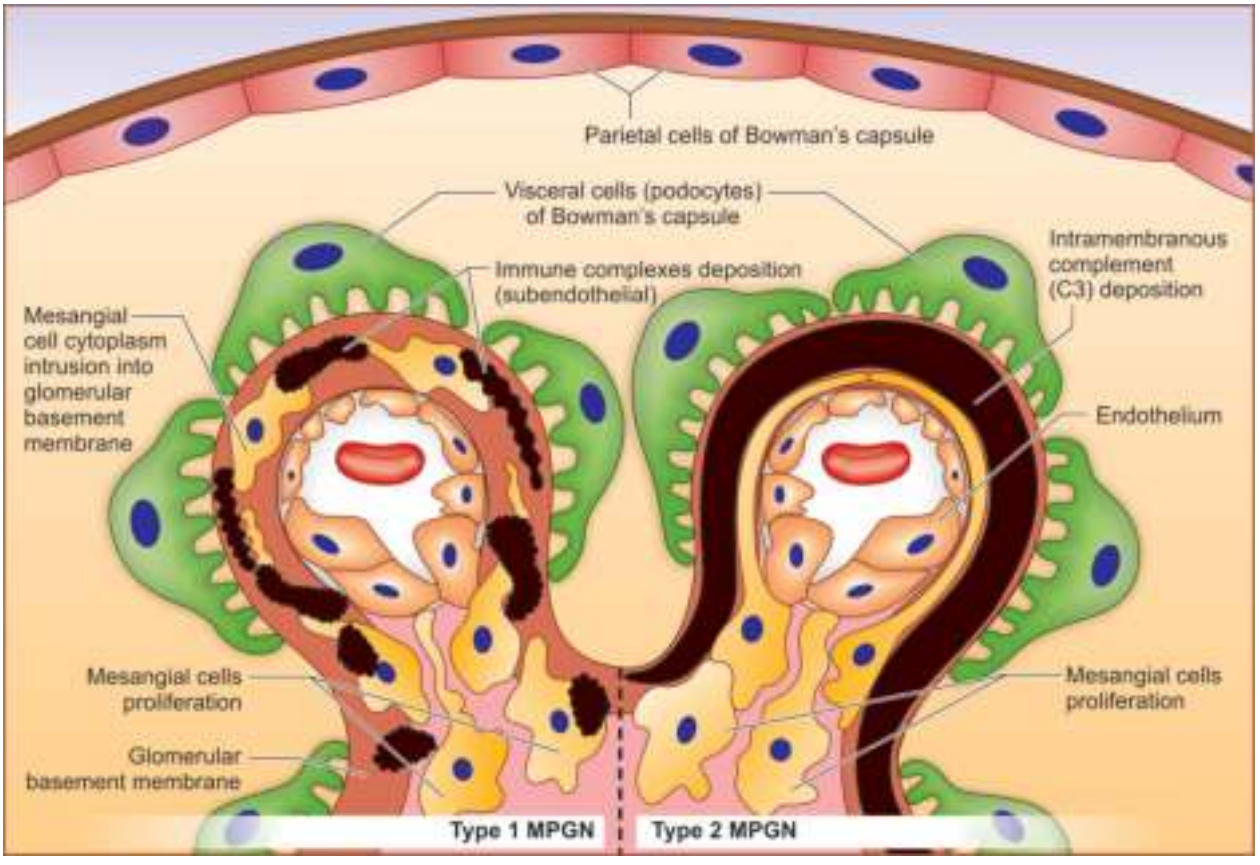

Fig. 22.40: Schematic diagram of membranoproliferative glomerulonephritis type 1 and type 2. Membranoproliferative glomerulonephritis (MPGN) is a morphologic pattern of glomerular injury, characterized by endocapillary and mesangial hypercellularity, mesangial and subendothelial deposits and duplication and thickening of glomerular basement membrane. MPGN accounts for nephrotic syndrome in children and adults. Traditional classification of MPGN 1 based on electron microscopy findings: MPGN type 1 (subendothelial and mesangial deposits), MPGN type 2 (intramembranous dense ribbon-like deposits) and MPGN type 3 (subendothelial and subepithelial deposits).

blood sugar >126 mg/dl at least on two different occasions or random blood sugar >200 mg/dl. Diffuse thickening of the glomerular basement membrane is the earliest morphologic change in diabetic patients.

- Diffuse glomerulosclerosis in diabetic glomerulopathy occurs due to accumulation of trapped proteins and synthesis of type IV collagen in extracellular matrix (ECM) encroaching on the capillary lumina. Reduced activity of mesangial matrix metalloproteinases (MMPs) is unable to degrade extracellular matrix proteins.
- Nodular glomerulosclerosis, also known as Kimmelstiel-Wilson disease, is characterized by sclerotic nodules in the peripheral region of intercapillary region of glomeruli formed due to accumulation of trapped proteins and synthesis

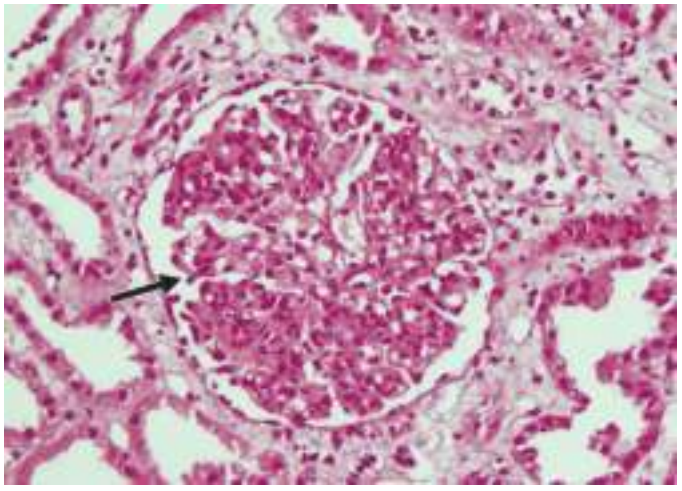

Fig. 22.41: Histology of membranoproliferative glomerulonephritis (MPGN). MPGN is a morphologic pattern of glomerular injury, characterized by endocapillary and mesangial hypercellularity, mesangial and subendothelial deposits and duplication and thickening of glomerular basement membrane. Hematoxylin and eosin-stained renal biopsy section examination shows hypercellular glomeruli that exhibit lobular appearance. Mesangial cells proliferation results in splitting and thickening of glomerular basement membrane, hence giving 'tram-track' appearance (double contour of GBM due to ingrowth of mesangial region) demonstrated with Jones methenamine silver stain (arrow) (400X).

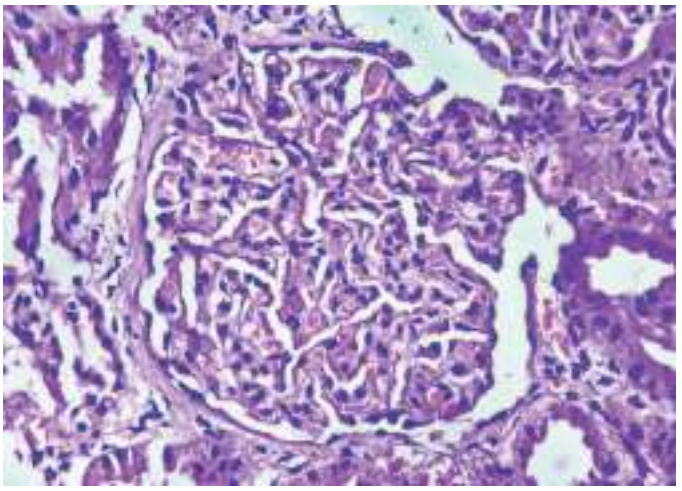

Fig. 22.42: Histology of membranoproliferative glomerulonephritis (MPGN). Hematoxylin and eosin-stained renal tissue section shows mesangial and endocapillary hypercellularity with lobular accentuation, irregular thickening of glomerular basement membrane by interposition of mesangial cells between glomerular capillary endothelium and basement membrane forming double contour/tram-track appearance as a result of immune complex deposit in subendothelial and mesangial region. Double contour of glomerular membrane/tram-track appearance can be appreciated by periodic acid–Schiff (PAS) or Jones methenamine silver stain (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

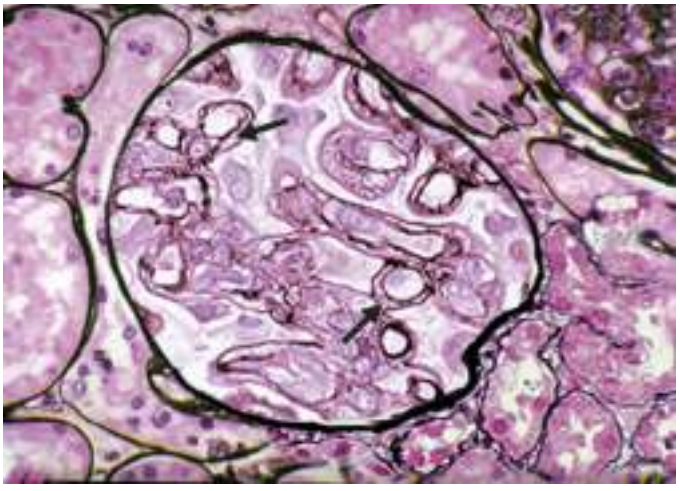

Fig. 22.43: Jones methenamine silver-stained renal biopsy section demonstrates a double contour to many glomerular basement membranes due to reduplication of glomerular basement membrane, and/or the 'tram-track appearance', resulting from reduplication of glomerular basement membrane (arrows) in type 1 membranoproliferative glomerulonephritis (MPGN) (400X). Patients present with nephrotic and/or nephrotic syndrome. Treatment of MPGN is directed at the underlying cause, when present. Idiopathic MPGN is treated by use of immunosuppressive agents.

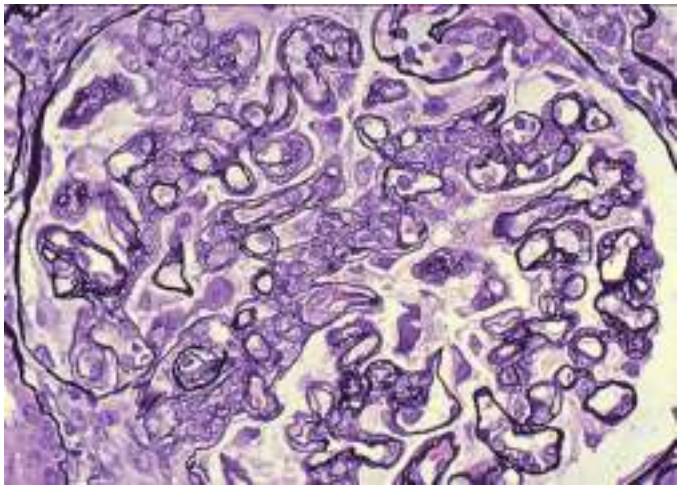

Fig. 22.44: Jones methenamine silver stain in type 1 MPGN. MPGN is characterized by subendothelial and mesangial electron dense deposits, mesangial interposition with splitting and duplication of glomerular basement membrane, possible increased mesangial matrix, variable degree of effacement of foot process. Double contour of glomerular membrane/tram-track appearance is observed by Jones methenamine silver stain (400X). (*Courtesy*: Dr. Neha Kumari and Dr. Tushar Kalonia)

of type IV collagen in mesangial matrix. Vascular hyalinosis is a common finding in nodular glomerulosclerosis. Nodules in diabetic glomerulosclerosis are periodic acid–Schiff (PAS) stain positive but negative Congo red stain.

Clinical Features

Diabetic nephropathy is a serious complication of uncontrolled diabetes mellitus that impairs renal normal functions of removing waste products and extra fluid from the body.

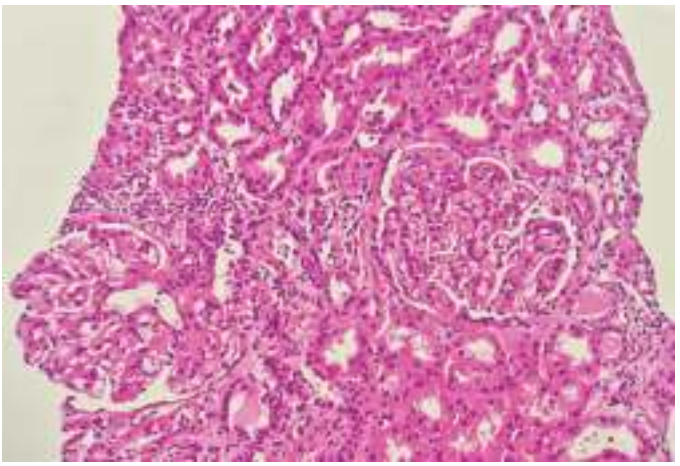

Fig. 22.45: Histology of type 2 MPGN. MPGN complement-related disease (C3-related glomerulopathy/dense deposit disease). C3-related glomerulopathy is characterized by broad, linear, extremely electron dense deposits with C3 within glomerular basement membrane, mesangium, Bowman's capsule and tubular basement membrane, and low level of serum C3-related to chronic activation of alternative complement pathway resulting in the accumulation of complement components in the tissue, recruitment of leukocytes and inflammatory damage of glomeruli. Hematoxylin and eosin-stained renal tissue section examination shows varied glomerular pathology: membranoproliferative glomerulonephritis (25–45%), mesangial proliferation (30–50%), acute exudative glomerulonephritis (10–20%) or crescentic glomerulonephritis (10–20%) (400X). (*Courtesy*: Dr. Neha Kumari and Dr. Tushar Kalonia.)

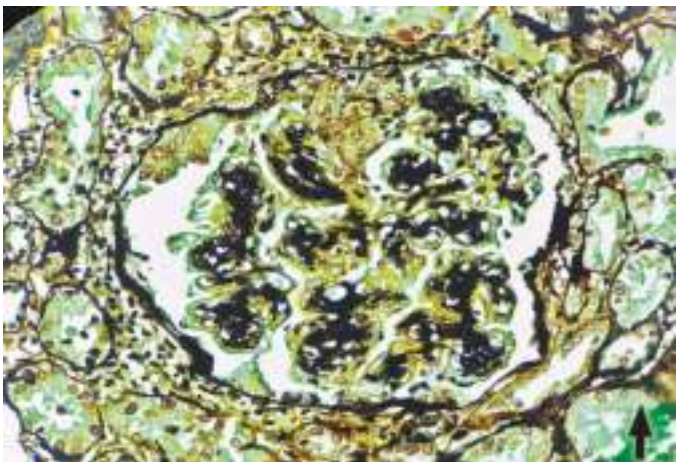

Fig. 22.46: Jones methenamine silver stain in type 2 MPGN complement-related disease (C3-related glomerulopathy/dense deposit disease). Jones methenamine silver stain highlights details of basement membrane of glomeruli, tubules, Bowman's capsule, elastic lamina of blood vessels and sclerotic segments of glomeruli (glomerulosclerosis). It delineates glomeruli within crescents and hence highlights the presence of extracapillary proliferation, also delineates mesangial regions of glomeruli which are argyrophilic (400X). (*Courtesy:* Dr. Neha Kumari and Dr.Tushar Kalonia.)

- Microalbuminuria is first sign of diabetic nephropathy; occurring after 10 years, and defined as excretion of urinary albumin >300 mg/day.
- Diabetic nephropathy manifests clinically as the nephrotic syndrome; however, it is compounded by chronic renal failure and hypertension. Retinopathy parallels nephropathy in diabetic patients.
- Diabetic nephropathy can be prevented by living healthy lifestyle and controlling diabetes mellitus and treating hypertension by captopril antagonist of angiotensin II.

Pathogenesis

Diabetic glomerulosclerosis occurs due to abnormal nonenzymatic glycosylation resulting from attachment of glucose to amino acids of serum proteins, mesangial matrix proteins and glomerular basement membrane. Mechanism of diabetic glomerulopathy is described as under.

- Glucose combines with proteins to form Schiff's base (reversible process), followed by formation of early glycosylated end products (reversible process) or (Amadori products); and then advanced glycosylated end products (irreversible process); which resist enzymatic degradation.
- Advanced glycosylated end (AGE) products induce binding of plasma proteins, i.e. immunoglobulins resulting in excessive mesangial matrix production. AGE products also bind to collagen fibers of glomerular basement membrane and tubular basement membrane, resulting in impairment of interaction.
- Other renal lesions in diabetic nephropathy are acute pyelonephritis, papillary necrosis, capsular drops

Table 22.29 Renal lesions in diabetic nephropathy

Renal Lesions	Comments
Glomerular lesions	
Diabetic glomerulosclerosis	Widening of mesangial areas occurs due to accumulation of basement-like stroma in the mesangial region, increased number of mesangial cells in 2–5 years after the onset of diabetes mellitus
Nodular glomerulosclerosis (also known as Kimmelstiel-Wilson disease)	Sclerotic nodules are formed in the peripheral region of intercapillary region of glomeruli demonstrated by PAS staining
Bowman capsule lesion	
Capsular drop	Accumulation of plasma proteins inside Bowman's capsule is known as capsular drop

Contd...

Table 22.29 Renal lesions in diabetic nephropathy (*Contd...*)

Renal Lesions	Comments
Glomerular subendothelial region lesion	
Fibrin cap	Fibrin cap is formed by plasma proteins deposition in subendothelial region
Papillary necrosis	Diabetic glomerulosclerosis leads to ischemia of papillae (papillary necrosis). Necrotic papillae may detach and pass in the urine as tissue fragments. Undetached papillae may resolve by fibrosis
Renal arterioles lesion	
Hyaline arteriosclerosis of renal arterioles	Hyaline arteriosclerosis of renal arterioles is the main cause of renal microangiopathy
Tubulointerstitial tissue lesions	
Armanni-Ebstein lesions	Deposition of glycogen in renal tubules is known as Armanni-Ebstein lesions in uncontrolled diabetes mellitus patients
Acute pyelonephritis	▪ Acute pyelonephritis occurs most frequently secondary to infection by bacteria or fungi and characterized by **pus in the tubule** and multiple grayish white areas of small microabscesses ▪ Microscopic urine analysis is the presence of white blood cell (WBC) casts

and fibrin cap. Renal lesions in diabetic nephropathy are given in Table 22.29.

Pathology Pearls: Diabetic Nephropathy

Light Microscopy

Diffuse and nodular glomerulosclerosis in diabetic nephropathy is shown in Fig. 22.47. Diffuse glomerulosclerosis in diabetes mellitus is shown in Fig. 22.48. Nodular glomerulosclerosis (Kimmelstiel-Wilson disease) in diabetes mellitus is shown in Figs 22.49 and 22.50. Benign nephrosclerosis in diabetes mellitus is shown in Fig. 22.51.

- **Diffuse glomerulosclerosis:** Diffuse glomerulonephritis parallels with widening of mesangial areas due to accumulation of basement-like stroma in the mesangial region, increased number of mesangial cells in 2–5 years after the onset of diabetes mellitus. Focal effacement of foot processes is common. Diffuse glomerulosclerosis associated with long-standing diabetes mellitus can be demonstrated by periodic acid–Schiff stain.
- **Nodular glomerulosclerosis:** Nodular glomerulosclerosis is also known as '**Kimmelstiel-Wilson disease**', which shows sclerotic nodules in the peripheral region of intercapillary region of glomeruli. Sclerotic nodules are formed in the mesangial region as a result of '**nonenzymatic glycation of proteins**' and accumulation of trapped proteins and synthesis of type IV collagen in mesangial matrix. The sclerotic nodules have a hypocellular matrix core which may be homogenous or exhibit lamellations with peripherally arranged mesangial nuclei. The sclerotic nodules vary in size that can be demonstrated by periodic acid–Schiff and silver methenamine stains. Nodular glomerulosclerosis leads to renal ischemia, tubular atrophy, interstitial fibrosis and ultimately resulting in small contracted kidneys. The remaining glomerular loops show signs of diffuse glomerulosclerosis.
- **Hyaline arteriolosclerosis:** The renal afferent and efferent arterioles may undergo hyalinization resulting in glomerular ischemia and hypertension in diabetic patients.
- **Acute pyelonephritis:** Glycosuria in diabetes mellitus predisposes to acute pyelonephritis by providing a rich medium or bacterial growth in the renal interstitial tissue. Patient presents with fever, urinary colic, and severe groin and flank pain.
- **Papillary necrosis:** Necrosis of the renal papillary tips may occur in severe cases. Renal papillary necrosis is serious complication of diabetic nephropathy. It can also be seen as a complication of chronic analgesic abuse, infectious pyelonephritis and sickle cell anemia. Necrotic papillae in the acute phases could be pale and soft or hemorrhagic. Renal papillae may become detached from cortical tissues and passed in the urine as tissue fragments. Necrotic papillae that are not detached may resolve as amorphous, fibrotic scarred tissue. Light microscopy reveals necrosis of the cellular elements of the papillae and hemorrhage and inflammatory reactions at the interface with viable areas.
- **Capsular drop:** Accumulation of plasma proteins inside Bowman's capsule is known as capsular drop.
- **Fibrin cap:** Accumulation of plasma proteins in the subendothelial region of glomeruli is known as fibrin cap.

Electron Microscopy

Electron microscopy reveals thickening of basement membrane of glomeruli and tubules, fusion of podocytes and accumulation of glycosylated basement membrane-like material in mesangial region.

RENAL AMYLOIDOSIS

Amyloidosis is characterized by deposition of abnormal extracellular fibrillar proteins in organs and tissues having an antiparallel, β-pleated sheet tertiary structure.

- Irrespective of molecular composition, amyloid always has the same characteristic histologic and ultrastructural appearance. Amyloid is resistant to enzymatic digestion, hence accumulates within tissue, interferes with function and destroys vital

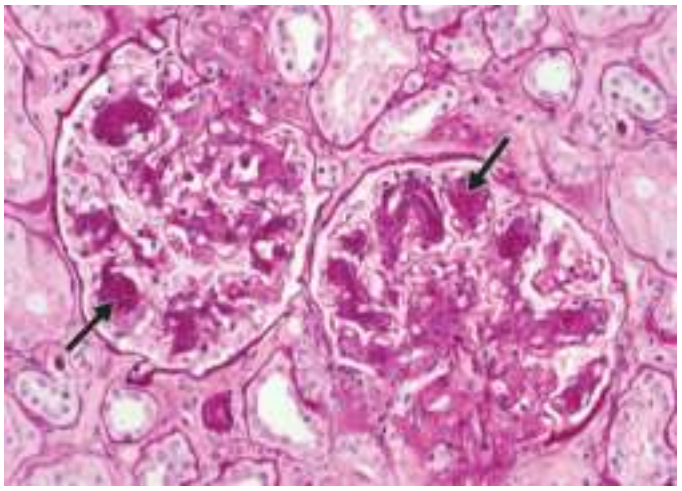

Fig. 22.47: Diffuse and nodular glomerulosclerosis in diabetic nephropathy. Hematoxylin and eosin-stained renal biopsy section shows diffuse thickening of glomerular basement membrane and tubules, expansion of mesangial matrix (diffuse/nodular or both) encroaching on the glomerular capillary lumina. In nodular glomerulosclerosis, nodules are formed due to accumulation of trapped proteins and synthesis of type 4 collagen (400X).

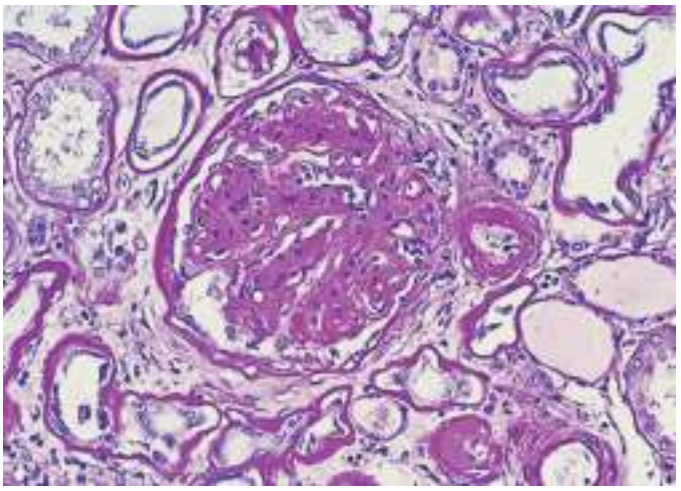

Fig. 22.48: Diffuse and nodular glomerulosclerosis in diabetes nephropathy. Hematoxylin and eosin-stained renal biopsy section shows diffuse thickening of glomerular basement membrane, increased accumulation of mesangial matrix proteins (collagen types 1, 2, and 4 and fibronectin) encroaching on the capillary lumina, and arteriolar hyalinosis. Other histologic findings can include fibrin caps, capsular drops and capillary microaneurysms (400X)

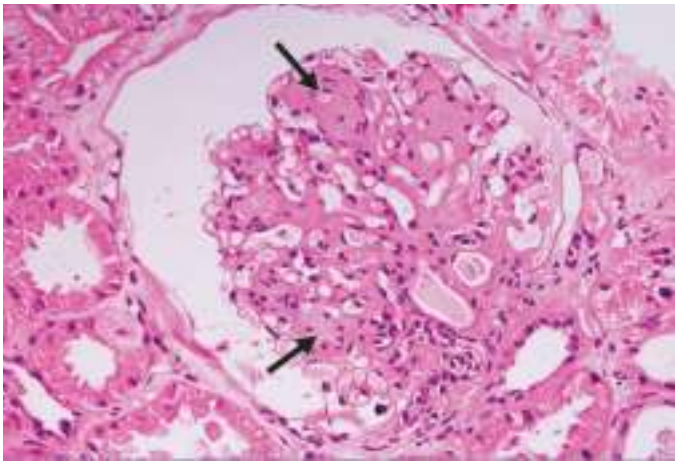

Fig. 22.49: Nodular glomerulosclerosis in diabetic nephropathy. Hematoxylin and eosin-stained renal biopsy section shows mesangial matrix expansion due to accumulation of collagen types 1, 2, and 4 and fibronectin encroaching on the capillary lumina, and arteriolar hyalinosis (400X).

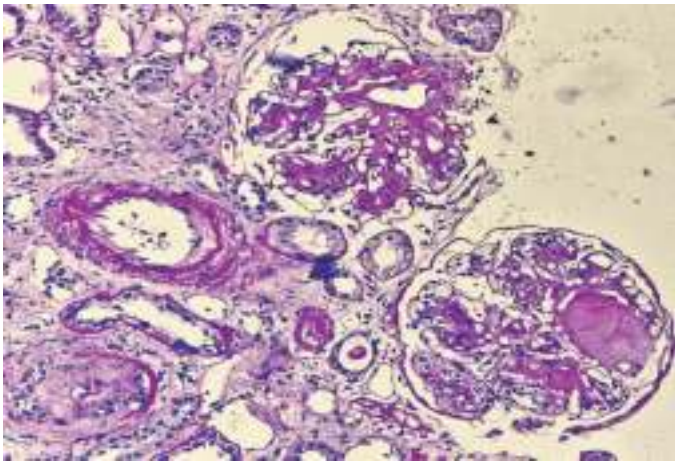

Fig. 22.50: Nodular glomerulosclerosis (Kimmelstiel-Wilson disease) in diabetes mellitus. Hematoxylin and eosin-stained renal biopsy section shows mesangial matrix expansion due to mesangial matrix proteins encroaching on the capillary lumina, and arteriolar hyalinosis (400X).

organs. Radioactive iodine labeled serum amyloid P (SAP) is used to assess amyloid deposition in nuclear medicine studies.

- Amyloid is composed of fibrillar proteins, and nonfibrillary glycoproteins (amyloid P component also called serum amyloid P [SAP], glycosaminoglycans and apolipoprotein E). Serum amyloid P component provides stability of amyloid deposits.
- Congo red stain apple-green birefringence under polarized microscopy is the most popular method for detection of amyloid material. Congo red fluorescence improves the diagnostic yield of conventional microscopy for both positive and negative cases. AA loses its Congo red-associated birefringence after oxidation in permanganate solution, whereas AL amyloid retains this feature.
- Kidneys are commonly involved in 80% cases of systemic amyloidosis. Most common clinical presentation of renal amyloidosis is nephrotic syndrome. Renal amyloidosis occurs due to deposition of amyloid material in primary (AL in multiple myeloma) and secondary amyloidosis (AA in chronic disorders). Patient develops chronic renal failure associated with fatal outcome.

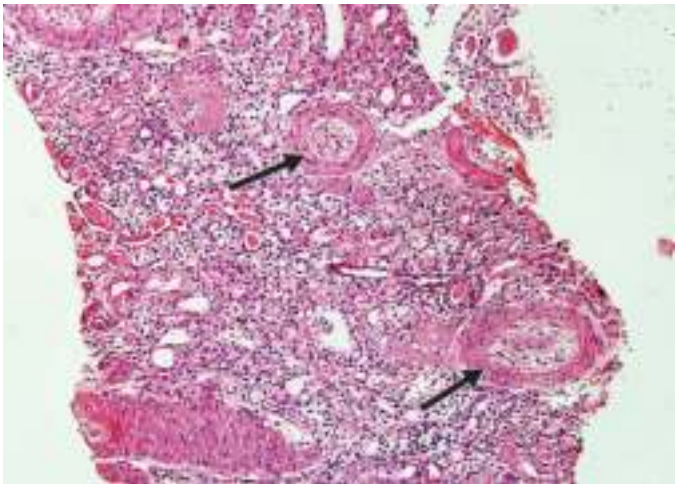

Fig. 22.51: Benign nephrosclerosis in diabetes mellitus. Benign nephrosclerosis refers to renal damage resulting from long-standing hypertension, diabetes mellitus and increasing age. Hematoxylin and eosin-stained renal biopsy section shows thickened and hyalinized arterioles and fibroelastic hyperplasia in lobular/arcuate arteries. There is presence of tubular atrophy, interstitial fibrosis, periglomerular fibrosis and glomerulosclerosis (arrows) (100X).

- In primary renal amyloidosis, κ or λ chains of immunoglobulins synthesized by clonal plasma cells are deposited initially in the mesangial matrix and then involving glomerular basement membrane (GBM). These immunoglobulins can be detected in serum or urine by electrophoresis.
- In secondary amyloidosis, amyloidosis is a well-known complication of chronic inflammatory disorder such as tuberculosis, bronchiectasis, rheumatoid arthritis, and osteomyelitis. These disorders stimulate the liver to synthesize amyloid-associated (AA) protein, an acute-phase reactant secreted by the liver. The kidneys (80%), liver, spleen, and adrenals are the most common organs involved in systemic amyloidosis. Schematic representation of renal amyloidosis is shown in Fig. 22.52.
- Hematoxylin and eosin-stained renal biopsy section in renal amyloidosis shows amorphous acellular amyloid deposit in the mesangium and extending along the inner surface of glomerular basement membrane (GBM) distorting glomerular lumina.
- Congo red stained renal biopsy section shows amyloid deposit in the mesangial region of glomeruli and blood vessels.

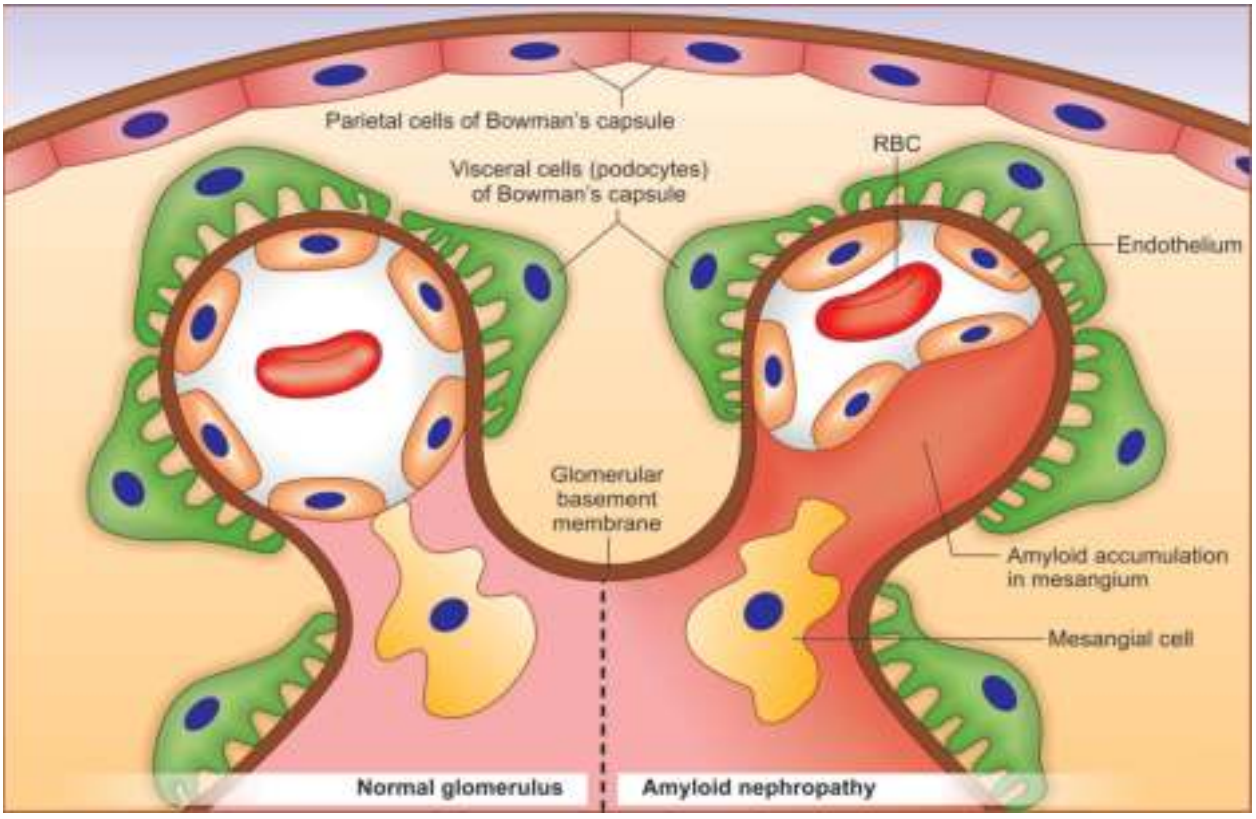

Fig. 22.52: Schematic representation of renal amyloidosis. Kidneys are most commonly affected by primary amyloidosis. Most common sign of renal amyloidosis is nephrotic syndrome. In amyloid light chain nephropathy (AL nephropathy), amyloid deposit in kidney first begins in the mesangium. Left half of schematic representation shows normal glomerulus. Right half of schematic representation shows amyloid deposit in the glomerular mesangial region.

Pathology Pearls: Renal Amyloidosis

- Amyloid refers to abnormal extracellular proteinaceous deposits in organs and tissues. Amyloid is insoluble and structurally dominated by β-pleated structure.
- Congo red stain 'apple-green birefringence' under polarized microscopy is the most popular method for detection of amyloid material.
- Congo red fluorescence improves the diagnostic yield of conventional microscopy for both positive and negative cases. Amyloid-associated (AA) loses its Congo red-associated birefringence after oxidation in permanganate solution, whereas amyloid-light chain (AL) retains this feature.

Clinical Features

Renal amyloidosis causes nephrotic syndrome in 5% of adult age group persons. Renal amyloidosis presents with nephrotic syndrome in middle-age adults, weight loss, organomegaly, monoclonal light chains in serum or urine.

- Duodenal biopsy is sensitive method for diagnosing amyloidosis in chronic kidney disease patients, and highly correlates with renal amyloidosis. About 50% of patients may have proteinuria in the nephritic range and hypertension.
- As the disease progresses, there will be renal insufficiency and chronic renal failure (small contracted kidneys) over 2–5 years.
- Renal manifestations caused by deposition of AA amyloid are clinically indistinguishable from that related to AL amyloid. Renal failure is a common cause of death in amyloidosis.

Pathology Pearls: Renal Amyloidosis

Gross Morphology

Kidney is enlarged, pale, and waxy with smooth surface with firm consistency. In advanced cases, the kidneys are contracted and shrunken due to vascular narrowing induced by deposition of amyloid. Cut section of kidneys reveals pale firm and waxy amyloid material in the renal cortex.

Light Microscopy

- Glomeruli show thickening of glomerular basement membrane. Amyloid material appears as amorphous, homogenous and eosinophilic in mesangial region, tubular basement membranes, renal vessels and interstitial tissue.
- Expansion of mesangial region obliterates the glomerular capillary loops rendering the glomerular filter leaky to plasma proteins leading to impaired renal functions.
- There is no cellular response to the amyloid deposits. The amount of amyloid in the glomeruli correlates roughly with the clinical manifestations of the disease. Histology of renal amyloidosis is shown in Fig. 22.53.

Histochemistry

- Amyloid material in glomerular mesangial matrix, glomerular and tubular basement membrane is demonstrated by Congo red staining under polarized microscopy, which reveals characteristic 'apple-green birefringence' (color of a Granny Smith apple).
- Amyloid material can also be demonstrated by various other stains, i.e. thioflavin T, thioflavin S, methyl violet, crystal violet.
- Pretreatment of tissue with potassium permanganate stained by Congo red demonstrates AL amyloid only but not AA amyloid.
- Congo red staining in renal amyloidosis is shown in Fig. 22.54. Periodic acid–Schiff (PAS): Jones methenamine silver stain in renal amyloidosis is shown in Fig. 22.55. Stains used to demonstrate amyloid material are given in Table 22.30.

Immunofluorescence Microscopy

Immunofluorescence microscopy of renal biopsy reveals non-specific trapping of proteins.

Immunohistochemistry Technique

Immunohistochemical staining for detecting SAA in secondary amyloidosis is shown in Fig. 22.56.

Electron Microscopy

Electron microscopy demonstrates fibrils 7.5–10 nm in diameter with randomly dispersed, nonbranching arrangement in mesangial and subendothelial regions of glomeruli.

MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASE OF KIDNEY

Monoclonal immunoglobulin deposition disease is characterized by excessive production and deposition

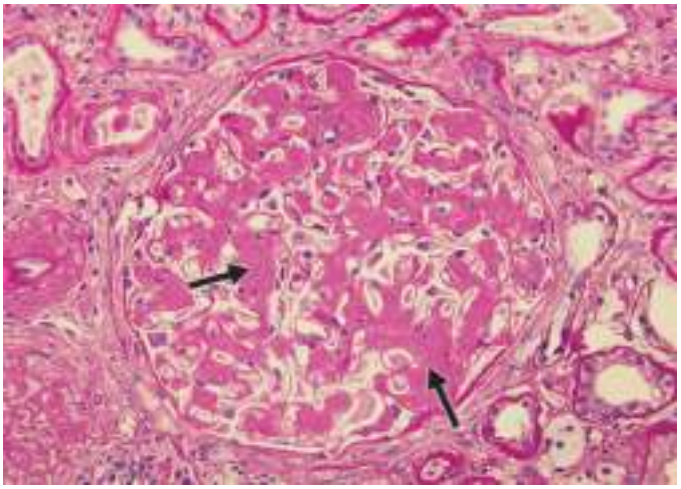

Fig. 22.53: Histology of renal amyloidosis. Hematoxylin and eosin-stained renal biopsy section shows amorphous acellular amyloid material deposit in the mesangium and extending along the inner surface of glomerular basement membrane distorting glomerular lumina (arrows) (400X).

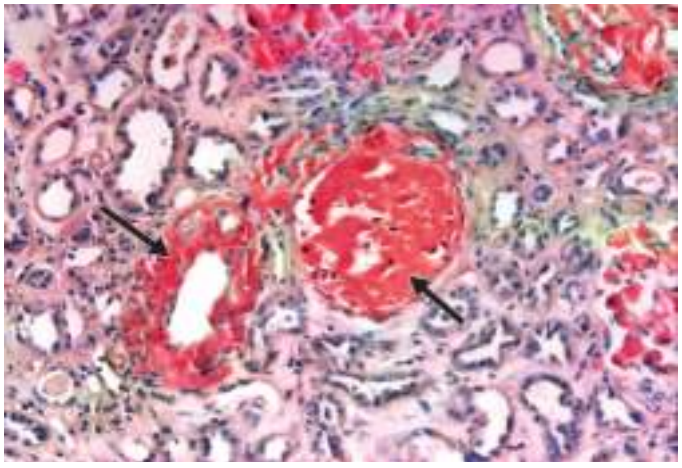

Fig. 22.54: Congo red staining in renal amyloidosis. Congo red stained renal biopsy section shows amyloid deposit in the mesangial region of glomeruli and blood vessels. It is worth mentioning that nodules in diabetic glomerulosclerosis are periodic acid–Schiff (PAS) positive but negative for Congo red stain (arrows) (400X).

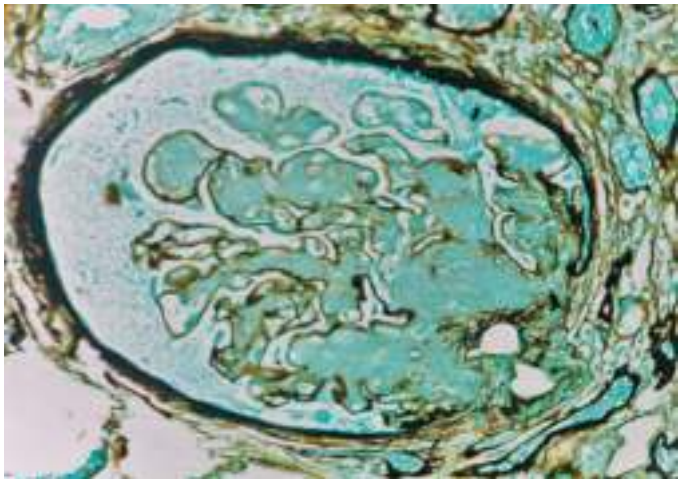

Fig. 22.55: Periodic acid–Schiff (PAS). Jones methenamine silver stain in renal amyloidosis. Jones methenamine silver stain delineates basement and connective tissue components. It is most commonly used in renal pathology to demonstrate abnormalities of the glomerular basement membrane. Glomerular basement membranes and oxidizable carbohydrates are stained black-argyrophilic. The mesangium of the glomerulus is expanded by amorphous, weakly periodic acid–Schiff positive material that produced an early nodular appearance (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Table 22.30 Stains used to demonstrate amyloid material

Amyloid Stain	Color Imparted
Congo red with light microscopy	Rose-pink
Congo red with polarizing microscopy	Apple green birefringence similar to color of Granny Smith apple
Methyl violet (metachromatic stain)	Pink
Crystal violet (metachromatic stain)	Pink
Fluorescent stains (thioflavin T, thioflavin S)	Greenish
von Gieson stain	Khaki color
Periodic acid–Schiff (PAS) stain	Magenta color

Congo red stain is commonly used to demonstrate amyloid deposits in tissue sections.

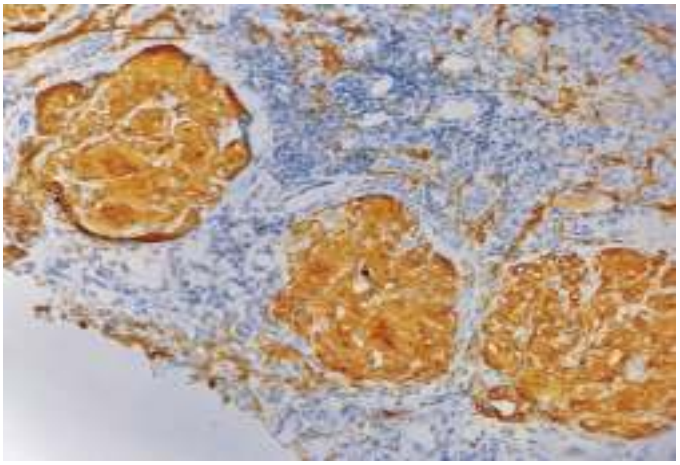

Fig. 22.56: Immunohistochemical staining for detecting SAA in secondary amyloidosis. Amyloidosis occurs when as abnormal protein, called amyloid, builds up in organs and tissues and interferes with normal function. Secondary amyloidosis (AA) is characterized by a protein called 'serum amyloid A'. This protein is produced by the body in response to chronic inflammation and infection the settings of tuberculosis and poorly controlled rheumatoid arthritis. Secondary amyloidosis (AA) commonly affects kidneys, liver and spleen. Heart involvement is extremely rare. Immunohistochemical staining is done by using antisera to 'serum AA 'on amyloid tissue in secondary amyloidosis (AA) (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

of nonamyloid immunoglobulin light chains in kidneys, liver, heart, nervous system and soft tissues in the setting of plasma cell dyscrasias.

- Monoclonal immunoglobulins are deposited in the glomerular basement membrane (GBM), tubular basement membrane, mesangium and interstitium. Periodic acid–Schiff (PAS) and Jones methenamine silver stain in renal monoclonal immunoglobulin deposition disease (MIDD) are shown in Fig. 22.57.
- Glomeruli are enlarged with (PAS) positive material in thickened capillary walls and mesangial nodules. Tubular basement is thickened and giving glassy appearance. Immunofluorescence stain shows granular κ (80%) or λ (20%) light chains along glomerular basement membrane, mesangial region, blood vessel walls and interstitium.
- MIDD subtypes include light chain (LCDD: 80% κ chain), light and heavy chain (LHCDD) and heavy chain deposition diseases (HCDD).
- Monoclonal immunoglobulin deposition disease is characterized by nodular sclerosing glomerulopathy, massive proteinuria in nephrotic range, and renal insufficiency. Some patients can develop hematuria and hypertension.

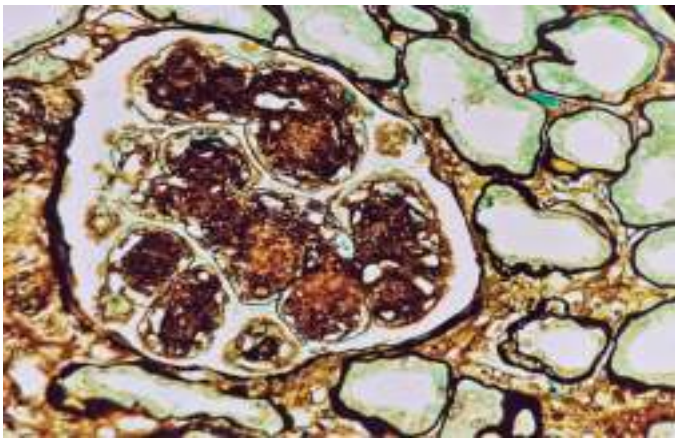

Fig. 22.57: Periodic acid–Schiff (PAS) and Jones methenamine silver stain in renal monoclonal immunoglobulin deposition disease (MIDD). Monoclonal immunoglobulins are produced by monoclonal plasma cells, which are found in the setting of plasma cell dyscrasias. Monoclonal immunoglobulins are deposited on the glomerular basement membrane, tubular basement membrane, mesangium and interstitium. The mesangial nodules are argyrophilic. The nonamyloidotic monoclonal immunoglobulin deposition disease is characterized by nodular sclerosing glomerulopathy, massive proteinuria in nephrotic range, and renal insufficiency, MIDD subtypes include light chain (LCDD: 80% κ chain), light and heavy chain (LHCDD) and heavy chain deposition diseases (HCDD) (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

LUPUS NEPHRITIS

Lupus nephritis is a common manifestation of systemic lupus erythematosus (SLE), that results in irreversible renal impairment in 60–70% cases. SLE is an autoimmune disease, that results in chronic inflammation and damage to multiple organs. SLE is diagnosed clinically and serologically with the presence of autoantibodies directed against DNA, RNA, and autologous proteins. Diagnostic criteria for systemic lupus erythematosus are given in Table 22.31.

- Many renal lesions encountered in lupus nephritis are also observed in other glomerulopathies. Hence, it is essential to provide a rational for harmonizing definitions for renal lesions irrespective of the glomerulopathy.
- In clinical practice, it is essential to obtain detailed information from the renal biopsy in paraffin-embedded sections stained by H&E stain and special histochemical stains and apply a basic format of the renal biopsy report. Renal biopsy must include approximately 10 glomeruli for evaluation.

Clinical Pearls: Diagnostic Criteria for Systemic Lupus Erythematosus

- Out of 11 diagnostic criteria for systemic lupus erythematosus (SLE), 4 are needed to confirm diagnosis.
- Eleven specific diagnostic criteria for SLE include: butterfly-shaped skin rash, raised rash patches on skin, sensitivity to light, ulcers in mouth or nose, arthritis in two or more joints plus swelling or tenderness, inflammation in the lining of heart and lungs, seizures or other neurological problems, and too much proteinuria.
- Fatigue, hair loss, antiphospholipid syndrome and elevated erythrocyte sedimentation rate are other findings in systemic lupus erythematosus, which are not part of specific diagnostic criteria.
- Hydralazine, procainamide and isoniazid drugs can produce (skin rash + joint pain + fatigue). Drug-induced lupus lesion never involves kidney and central nervous system.
- Drug-induced lupus gives anti-histone antibodies and always a positive antinuclear antibody. Complement level and anti-DS DNA are normal.
- Blood biochemistry findings include increased γ-globulin, decreased serum albumin, antinuclear test positive.
- LE cell phenomenon *in vitro* is positive (lupus cell preparation demonstrates LE cells).

Table 22.31 Diagnostic criteria for systemic lupus erythematosus

Organs	Comments
Skin manifestations and mucous membrane	Malar rash, photosensitivity rash, discoid rash and oral ulcers rash
Joints	Nonerosive arthralgia present (90%) and joint radiograph normal
Hematologic findings	Normocytic normochromic, leukopenia, thrombocytopenia, and hemolysis (any blood involvement counts as 1 criterion)
Cardiovascular system and blood findings	Libman-Sack's endocarditis (noninfective cardiac vegetations) and pericarditis
Renal manifestations	Lupus nephritis class I to class VI manifest with proteinuria in nephritic range to irreversible renal impairment in 60–70% cases
Cerebral manifestations	Behavioral change, cerebral stroke, seizures, meningitis
Serositis	Pericarditis, myocarditis, pleuritic chest pain, pneumonia pulmonary hypertension
Serology	▪ Antinuclear antibodies positive (95%) ▪ Anti-double-stranded (DS) DNA antibodies specific test (60–70%) ▪ Anti-Smith antibodies positive (10–20%) ▪ Each of serologic abnormalities counts as 1 criterion. Hence, if the person has joint pain and/or skin rash, and antinuclear antibodies and anti-double-stranded (DS) DNA antibodies, that the patient would have 4 criteria

Pathogenesis

Lupus nephritis occurs by two pathogenetic mechanisms: (a) formation of anti-DNA antibodies against planted DNA (*in situ* immune complex deposit) and trapped in the glomeruli, and (b) formation of immune complexes (DNA–anti-DNA) in circulation trapped in the glomeruli. In both mechanisms, immune complexes activate classical pathway of complement system resulting in injury to glomeruli, tubules and interstitial tissue.

- In lupus nephritis, autoantibodies are produced directed against DNA, RNA, and autologous proteins. Immune complexes are deposited in the glomeruli. Anti-double-stranded DNA antibodies may cross-react with glomerular basement membrane. Higher affinity autoantibodies may result in deposition in glomeruli.
- Cationic antibodies have a greater affinity for the anionic glomerular basement membrane. Immune complexes induce inflammatory response by the activation of the complement system and recruitment of inflammatory cells leading to injury to glomeruli, tubules and interstitial tissue.
- Glomerular thrombosis is another mechanism that plays a role of pathogenesis of lupus nephritis especially in patients with antiphospholipid syndrome and is believed to be the result of interaction between autoantibodies and negatively charged phospholipid proteins.
- Decreased serum C3 level correlates with SLE disease activity. In general, the more immune complex deposition and increased cellular proliferation, indicate poor prognosis. Renal changes are highly variable.

Clinical Features

Severity of lupus nephritis determines the clinical course. Patient presents with nephrotic syndrome but proteinuria may be in nephritic range. Approximately 90% of patients survive for 10 years. Patient develops irreversible renal impairment. Infection is the most common cause of death.

Pathology Pearls: Lupus Nephritis

Light Microscopy

Summary of pathological findings of lupus nephritis according to WHO criteria is given in Table 22.32. Activity and chronicity indices in lupus nephritis are given in Table 22.33.

- **Lupus nephritis class I:** Histologic examination shows mesangial immune complex deposits, with minimal mesangial cell hypercellularity or influx of leukocytes. Renal biopsy evaluation reveals four or more nuclei fully surrounded by mesangial matrix in the mesangial region not included the hilar region.
- **Lupus nephritis class II:** It is purely mesangial disease. Histologic examination reveals mesangial immune complex deposits and mesangial hypercellularity but without influx of leukocytes. Renal biopsy evaluation reveals four or more nuclei fully surrounded by mesangial matrix in the mesangial region not included the hilar region.
- **Lupus nephritis class III:** In lupus nephritis class III and class IV, the term endocapillary hypercellularity is used replacing endocapillary proliferation. Histologic examination shows glomeruli with segmental endocapillary hypercellularity involving <50% of glomeruli, mesangial hypercellularity, glomerular basement membrane thickening and early segmental necrosis demonstrated in Jones methenamine silver stained sections.
- **Lupus nephritis class IV:** In lupus nephritis class III and class IV, the term endocapillary hypercellularity is used replacing endocapillary proliferation.
  - Membranoproliferative glomerulonephritis is a form of endocapillary injury. Histologic examination shows subendothelial deposits, endocapillary and/or extracapillary proliferation in ≥50% of glomeruli giving '**wire-loop lesion**', and hyaline masses within glomerular capillary lumens caused by immune complex deposits (i.e. hyaline thrombi).
  - The term crescent refers to a renal lesion more than two cell layers, which consists of extracapillary hypercellularity and a variable mixture of cells. Fibrin and fibrous matrix may be demonstrated involving ≥10% of the circumference of Bowman's capsule.
  - Crescents can be cellular, fibrous and fibrocellular. Cellular crescents are composed of >75% cells and fibrin and <25% fibrous matrix. Fibrous crescents are composed of >75% fibrous matrix and <25% cells and fibrin, which are part of chronicity index. Fibrocellular crescents are composed of 25–75% cells, fibrin and the remainder fibrous matrix.
  - Fibrinoid necrosis is associated with glomerular basement membrane disruption and/or lysis of mesangial matrix, which lacks karyorrhexis. Active and chronic designations for class III/class IV lupus nephritis lesions are replaced by activity and chronicity indices in all cases.
  - Activity index includes fibrinoid necrosis as specific indicator. Segmental and global subdivisions of lupus nephritis IV have been eliminated.
- **Lupus nephritis class V:** Histologic examination demonstrates non-wire-loop lesion, membranous glomerulonephritis (thick glomerular loops), mesangial hypercellularity, influx of leukocytes, and subepithelial immune deposits in addition to subendothelial deposits.
- **Lupus nephritis class VI:** Lupus nephritis class VI lesion is rarely observed in renal biopsies. Class VI either needs to be eliminated or some fraction of globally advanced glomerulosclerosis, thickened glomerular capillary loops, tubular atrophy and interstitial fibrosis designated as the cut off between class IV and class VI.

Histochemistry

In general, the more immune complex deposition and the more cellular proliferation, the worse is the disease. Extensive immune complex deposition in the thickened glomerular loops gives so-called wire-loop appearance. Jones methenamine silver stain in wire-loop lesion in lupus nephritis is shown in Fig. 22.58.

Immunofluorescence Microscopy

Renal biopsy shows granular deposition of IgG, C3 and fibrin along glomerular basement membrane, in subendothelial and mesangial regions of glomeruli. It is indistinguishable from that of idiopathic membranous nephropathy. It is worth mentioning that subendothelial deposits are encountered in lupus nephritis and membranoproliferative glomerulonephritis.

Laboratory Findings

Decreased serum C3 level correlates with lupus nephritis activity index. Demonstration of anti-double-stranded DNA antibody is highly specific for renal disease correlating with disease activity index.

RAPIDLY PROGRESSIVE (CRESCENTIC) GLOMERULONEPHRITIS

Rapidly progressive (crescentic) glomerulonephritis (RPGN) is also known as crescentic glomerulonephritis and characterized by rapid progression to acute renal failure and end stage renal disease in 90% of cases within weeks or months. RPGN occurs due to severe glomerular injury resulting in exudation of inflammatory cells through the disrupted, segmentally necrotic glomerular basement membrane leads to the formation of crescents between the Bowman's capsule and the glomerular tuft involving >50% of glomeruli. Schematic representation of rapidly progressive (crescentic) glomerulonephritis is shown in Fig. 22.59.

Pathogenesis

Rapidly progressive (crescentic) glomerulonephritis (RPGN) is a clinical syndrome characterized by glomerular crescents involving >50% of glomeruli,

Table 22.32 Summary of pathological findings of lupus nephritis according to WHO criteria

Light Microscopy	Immunofluorescence Microscopy	Electron Microscopy	Clinical Syndromes and Prognosis
Lupus nephritis class I			
Minimal mesangial hypercellularity	Mesangial deposits	Mesangial deposits	Mild proteinuria and hematuria (asymptomatic) associated excellent prognosis
Lupus nephritis class II (25%)			
Mesangial hypercellularity increased mesangial matrix	Mesangial deposits	Mesangial deposits	Good prognosis
Lupus nephritis class III (20%)			
Focal glomerulonephritis (endocapillary hypercellularity and/or extracapillary hypercellularity in <50% of glomeruli)	Mesangial and glomerular loop deposits	Mesangial and subendothelial deposits	Mild proteinuria with or without hematuria, but normal renal functions associated with moderate prognosis
Lupus nephritis class IV (40%)			
Diffuse glomerulonephritis (endocapillary hypercellularity and/or extracapillary hypercellularity in ≥50% of glomeruli giving wire-loop lesion	Mesangial and glomerular loop deposits	Mesangial and subendothelial deposits	Nephritic syndrome, nephrotic syndrome associated with moderate to poor prognosis
Lupus nephritis class V (15%)			
Membranous glomerulonephritis (thick glomerular loops and mesangial cells hypercellularity)	Mesangial and glomerular loop deposits	Numerous subepithelial and scattered mesangial deposits	Nephrotic syndrome associated with moderate prognosis
Lupus nephritis class VI			
Advanced segmental glomerulosclerosis (>90% thickened glomerular loops, tubular atrophy and interstitial fibrosis)	Variable deposits	Variable deposits	Chronic renal failure associated with poor prognosis

Table 22.33 Activity and chronicity indices in lupus nephritis

Activity Index in Lupus Nephritis
▪ Endocapillary hypercellularity with or without leukocyte infiltration and reduction in lumen size ▪ Fibrinoid necrosis ▪ Cellular or fibrocellular crescents ▪ Subendothelial immune complex deposits identified as wire-loop lesions. Intraluminal immune aggregates (hyaline thrombi)
Chronicity Index in Lupus Nephritis
▪ Segmental/global glomerulosclerosis ▪ Fibrous adhesions ▪ Fibrous crescent

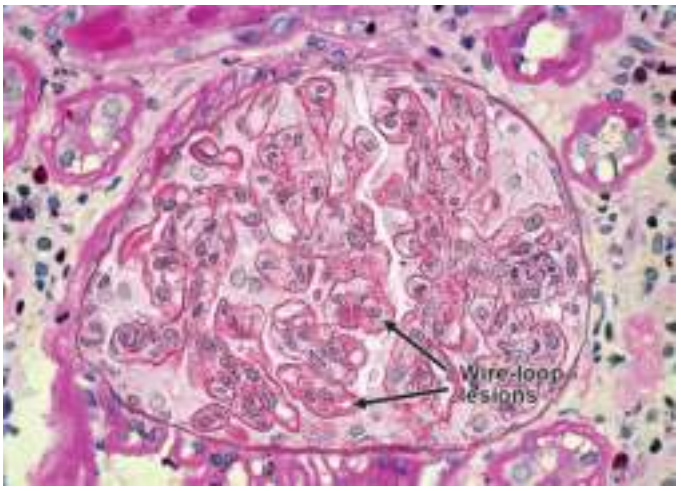

Fig. 22.58: Jones methenamine silver stain in wire-loop lesion in lupus nephritis. Jones methenamine silver stain in lupus nephritis delineates glomerular basement membrane and connective tissue components, which is most commonly used in renal biopsy to demonstrate abnormalities of the glomerular basement membrane. Glomerular basement membrane and oxidizable carbohydrates are stained black argyrophilic. Jones methenamine silver-stained renal biopsy thin about 2 μm section shows wire-loop lesion, which is one of the active lesions of lupus nephritis (arrows) (400X).

rapid decline in renal function, hematuria, proteinuria, oliguria or hypertension.

- RPGN occurs due to primary or secondary glomerulonephritis. RPGN is thought to be immune-mediated disorder, because most patients have antibodies to neutrophils (ANCA) in blood circulation.
- RPGN occurs in the settings of poststreptococcal glomerulonephritis, Goodpasture's syndrome,

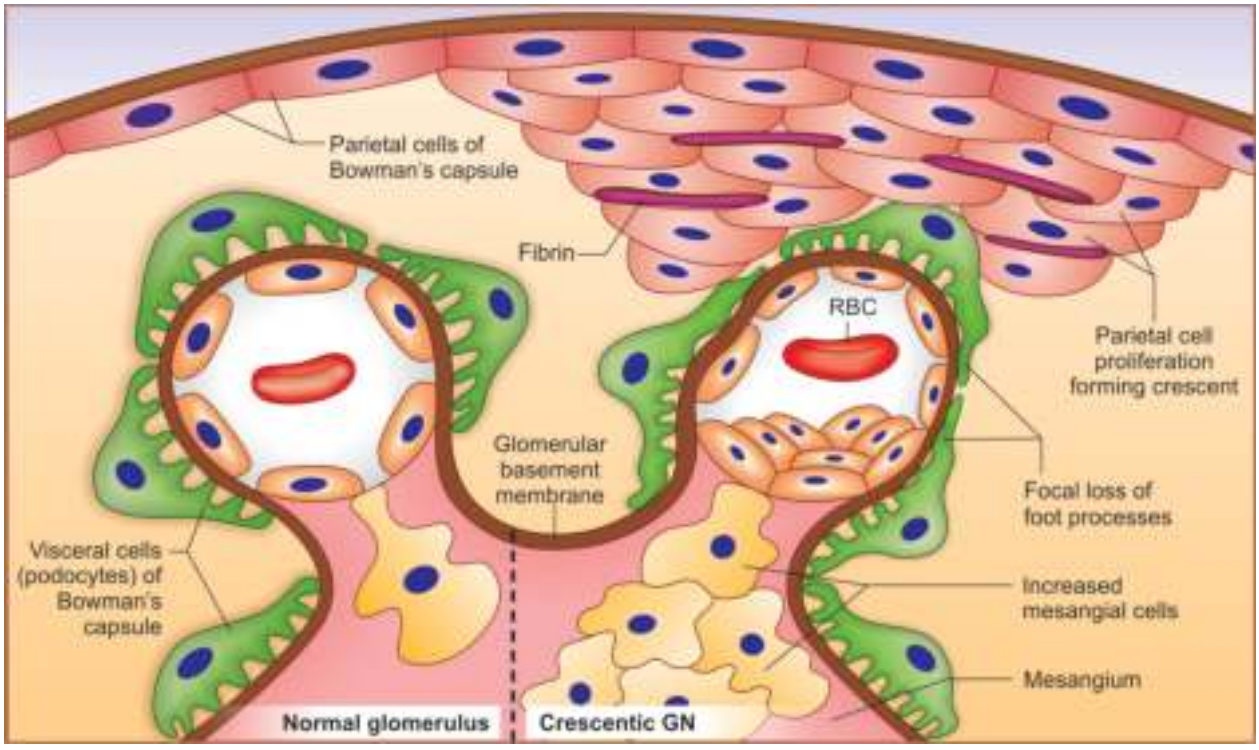

Fig. 22.59: Schematic representation of rapidly progressive (crescentic) glomerulonephritis. Rapidly progressive (crescentic) glomerulonephritis is a clinical syndrome characterized by rapid decline in renal function, hematuria, proteinuria, oliguria or hypertension. Glomerular crescents are observed in more than 50% of glomeruli. Left half of schematic representation shows normal glomerulus, whereas right half demonstrates crescent formation as a result of glomerular injury and escape of fibrin, which stimulates proliferation of parietal epithelial cells of Bowman's capsule. Crescents compress the glomerulus leading to impaired renal functions.

systemic lupus erythematosus, polyarteritis nodosa, Wegener's granulomatosis, IgA nephropathy, Henoch-Schönlein purpura and drug (penicillamine).

- Glomerular endothelial injury is a key driver of crescents formation, which causes damage and rupture of glomerular basement membrane, which triggers coagulation system cascade within Bowman's capsule space, ultimately leading to fibrin deposition. Fibrin stimulates parietal epithelial cells of Bowman's capsule to proliferate resulting in cellular crescents formation, which mount pressure and cause decline in glomerular filtration rate and thus impair renal function.
- Crescents are composed of parietal epithelial cells, macrophages and fibrin. Segmental fibrinoid necrosis of the glomerular tufts is present.

Pathology Pearls: Rapidly Progressive Glomerulonephritis (RPGN) Categories

Anti-GBM Antibody-mediated RPGN

Goodpasture's syndrome is characterized by IgG antibodies directed against noncollagenous domain of α-3 type 4 collagen in GBM and pulmonary capillaries. Patient presents with features of nephritic syndrome and hemoptysis. Immunofluorescence microscopy shows linear IgG, C3 and fibrin deposits.

Immune Complex-mediated RPGN

Immune complex-mediated RPGN may be caused by post-infectious glomerulonephritis, systemic lupus erythematosus, IgA nephropathy and Henoch-Schönlein purpura.

Pauci-immune Disease (ANCA Positive) RPGN

Most patients develop autoantibodies to neutrophils (ANCA), which activate neutrophils and cause them to adhere to endothelial cells. Neutrophils release oxygen-derived free radicals and hydrolytic enzymes resulting in glomerular endothelial cells injury.

Clinical Features

Goodpasture's syndrome begins with hemoptysis (70%) and nephritis. Rapidly progressive glomerulonephritis progresses to acute renal failure in a few weeks to months in 90% of cases. Anti-GBM antibodies are demonstrated in these patients. Plasmapheresis is useful in removing antibodies.

Surgical Pathology: Rapidly Progressive Glomerulonephritis (RPGN)

Gross Morphology

Progression of primary renal diseases and systemic disorders such as amyloidosis, diabetic nephropathy and multiple myeloma involving kidneys produce small contracted kidneys. Polyarteritis nodosa and healed infarct produce large scars in kidneys.There is loss of concentrating power of kidneys. Urine analysis shows fixed specific gravity: 1.010.

Light Microscopy

Histologic examination of renal biopsy shows glomeruli, tubules, blood vessels and interstitial tissue. Crescents are formed due to proliferation of parietal cells of Bowman's capsule, which compress glomeruli. Histology of rapidly progressive (crescentic) glomerulonephritis is shown in Figs 22.60 and 22.61.

Histochemical Stain

Jones methenamine silver (JSM) stain in rapidly progressive (crescentic) glomerulonephritis is shown in Fig. 22.62.

Immunofluorescence Microscopy

- **Linear immune complex pattern:** Linear immune complex pattern is observed in antiglomerular basement membrane disease and Goodpasture syndrome.
- **Granular immune complex pattern:** Granular immune complex pattern is demonstrated in immune complex-mediated glomerulonephritis.
- **Pauci-immune complex pattern:** Pauci-immune complex pattern is demonstrated in idiopathic crescentic glomerulonephritis.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is characterized by irreversible and progressive glomerulopathy and tubulointerstitial fibrosis, ultimately resulting in

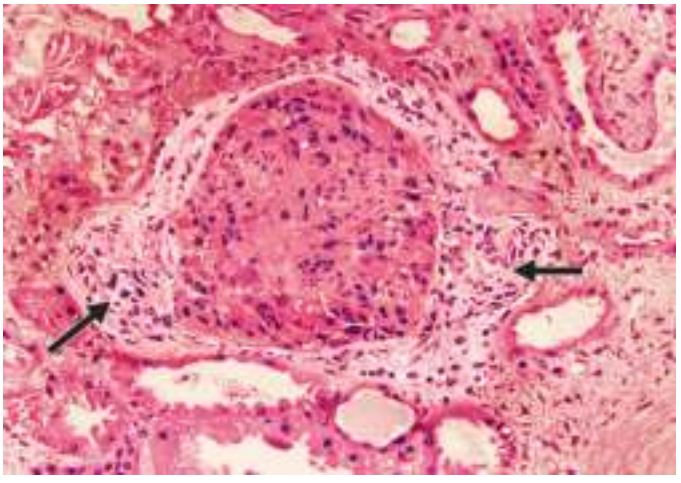

Fig. 22.60: Histology of rapidly progressive (crescentic) glomerulonephritis (RPGN). In hematoxylin and eosin-stained renal biopsy section examination, glomerular crescents are observed in more than 50% of glomeruli rapidly progressive (crescentic) glomerulonephritis. Endothelial injury is a key driver of crescents formation, which causes damage and rupture of glomerular basement membrane. This triggers coagulation cascade within Bowman's capsule space, ultimately leading to fibrin deposition. Fibrin stimulates parietal epithelial cells of Bowman's capsule to proliferate, resulting in formation of cellular crescents, which mount pressure and cause decline in glomerular filtration rate and thus impaired renal function. Arrows indicate cellular crescents (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

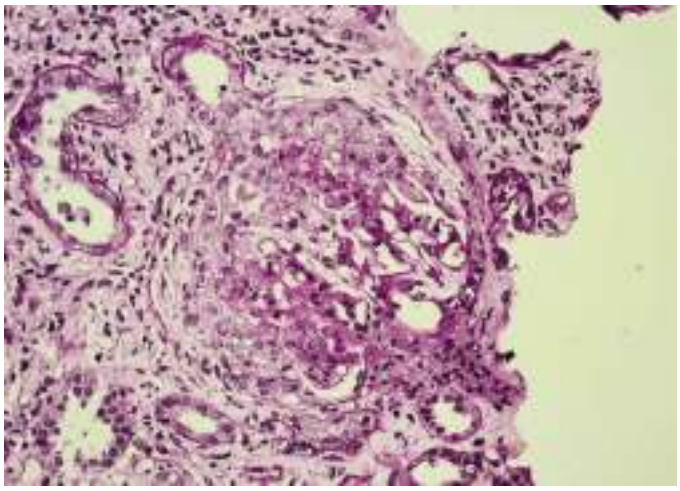

Fig. 22.61: Histology of rapidly progressive (crescentic) glomerulonephritis (RPGN). RPGN is a clinical syndrome characterized by glomerular crescents in more than 50% of glomeruli, rapid decline in renal function, hematuria, proteinuria, oliguria or hypertension. In hematoxylin and eosin-stained renal tissue section and extracapillary cellular profanation (crescents) are composed of parietal epithelial cells, macrophages and fibrin. Segmental fibrinoid necrosis of the glomerular tufts are present (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

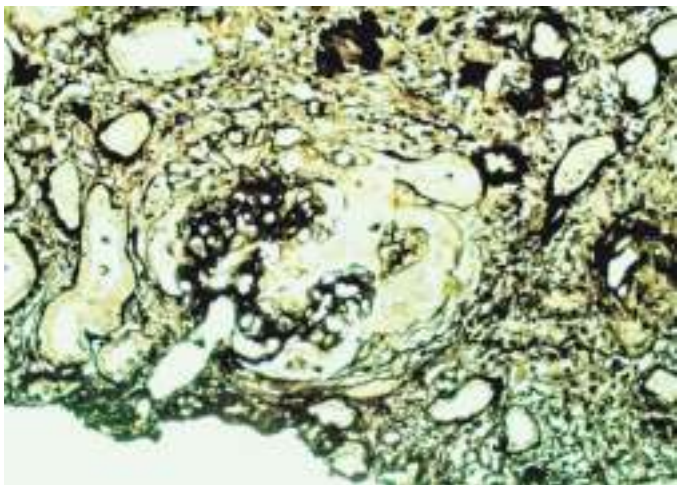

Fig. 22.62: Jones methenamine silver (JMS) stain in rapidly progressive (crescentic) glomerulonephritis (RPGN). JMS stain is a histochemical stain which highlights carbohydrates that can be oxidized to aldehydes. Aldehydes formed by oxidation of carbohydrates reduce a silver solution, causing the silver ions to bind to the carbohydrate and can be visualized. JMS stain highlights details of basement membrane of glomeruli, tubules, Bowman's capsule, elastic lamina of blood vessels and sclerotic segments of glomeruli (glomerulosclerosis). It delineates glomeruli within crescents and hence highlights the presence of extracapillary proliferation, also delineates mesangial regions of glomeruli which are argyrophilic (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

reduction in the glomerular filtration rate (GFR) and accumulation of uremic toxic products in the body.

- Progressive permanent destruction of nephrons in many kinds of kidney diseases eventually leads to chronic kidney disease (GFR <60 ml/minute per 1.73 square meters) persisting for more than three months. It is a state of progressive loss of renal functions ultimately resulting in the need for renal dialysis or renal transplantation.
- Chronic kidney disease is caused by rapidly progressive crescentic glomerulonephritis (80–90%), focal segmental glomerulosclerosis (50–80%), and membranoproliferative glomerulonephritis (50%), IgA nephropathy (30–50%), membranous glomerulonephritis (30–40%), diabetic nephropathy and rarely postinfectious glomerulonephritis (1–2%).
- Etiopathogenesis of chronic glomerulonephritis is shown in Fig. 22.63. Glomerular diseases progressing to chronic kidney disease are given in Table 22.34.

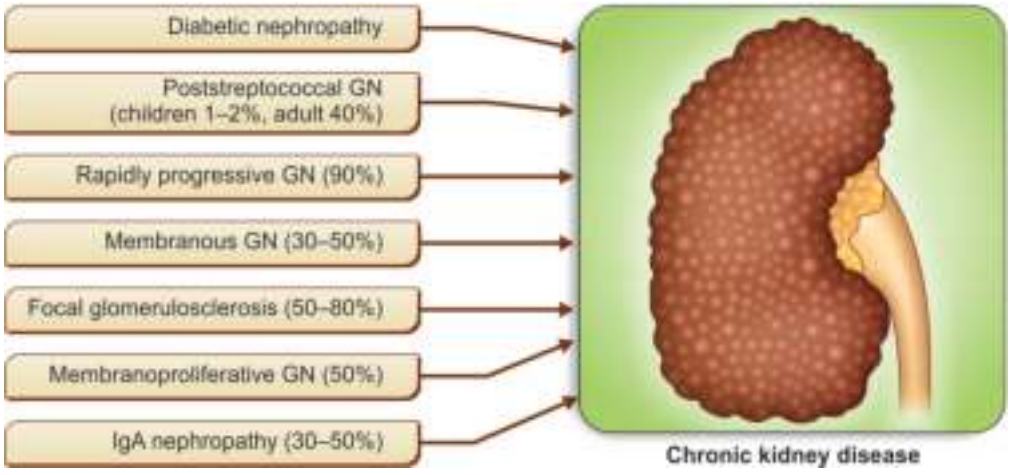

Fig. 22.63: Schematic representation of etiopathogenesis of chronic kidney disease. It is characterized by varying degrees of glomerular scarring that is always accompanied by cortical tubular atrophy, interstitial fibrosis, chronic inflammatory cells in the interstitium and arteriosclerosis. It leads to progressive renal failure. Kidneys are small contracted. External surface shows fine granularity known as 'grain leather' appearance.

Table 22.34 Glomerular diseases progressing to chronic kidney disease

Glomerular Diseases	Frequency (%)
Poststreptococcal glomerulonephritis	Children (1–2%) and adults (40%)
Rapidly progressive glomerulonephritis (RPGN)	90%
Membranous glomerulonephritis	30–50%
Focal glomerulosclerosis	50–80%
Membranoproliferative glomerulonephritis	50%
IgA nephropathy	30–50%

Glomerular filtration rate is <20% of normal in chronic glomerulonephritis.

Pathology Pearls: Chronic Kidney Disease

Gross Morphology

Bilaterally symmetrically small contracted kidneys occur due to long-standing injury to the glomeruli. External surface reveals diffuse fine granularity giving 'grain leather appearance'. Cut surface shows thinning of cortex. Peripelvic fat appears to be grossly increased, because of reduced renal parenchyma.

Light Microscopy

- **Glomeruli:** Hyaline obliteration of glomeruli transforms glomeruli into acellular eosinophilic masses (PAS+). Hyaline represents a combination of trapped plasma proteins, increased mesangial matrix, basement membrane-like material and collagen fibers.
- **Blood vessels:** Small- and medium-sized renal blood vessels are involved. Arteriosclerosis and arteriolosclerosis may be conspicuous as a result of accompanying hypertension.
- **Tubules:** These show dilation, atrophy, and loss of renal tubules. When the atrophic tubules contain eosinophilic proteinaceous casts, the resultant similarity in appearance to thyroid follicles is referred to as 'thyroidization' of tubules.
- **Interstitial tissue:** Kidneys show marked interstitial fibrosis with mononuclear cell infiltration.
- **Mesangial region:** There is increased mesangial matrix. Histology of chronic kidney disease is shown in Fig. 22.64.

CHRONIC KIDNEY DISEASE: LABORATORY FINDINGS AND CLINICAL MANIFESTATIONS

Most common laboratory findings in patients with chronic kidney disease include increased blood urea nitrogen and serum creatinine. There is disturbance of sodium, potassium, calcium, and phosphate and glucose metabolism. Acidosis is present. These patients need frequent hemodialysis.

- Urinalysis demonstrates isosthenuria fixed specific gravity due to loss of concentration and dilution functions of tubules, proteinuria, presence of waxy and broadcasts. Proteinuria diminishes due to obliteration of glomeruli.
- Azotemia refers to accumulation of waste products in blood, i.e. BUN, creatinine, urates, guanidino compounds, metabolic end products of nucleic acids, aliphatic amines, middle molecules (polypeptides) and parathormone. Parathormone is toxic to cells that augments contraction.
- Uremia is a set of clinical and laboratory findings encountered in patients with end stage kidney disease due to increased concentration of waste products in blood. Key laboratory features reflect inadequate excretion of metabolic products and minerals. Most patients are hypertensive and sometimes the dominant clinical manifestations are cerebral or cardiovascular accidents. Chronic renal disease is usually progressive.
- End stage renal disease has diminished glomerular filtration rate (GFR) <5% of normal range. The microscopic appearance of the end stage kidney is similar regardless of cause, that is why a renal biopsy in a patient with chronic renal failure yields a little useful information. The glomeruli are sclerosed. Tubules are often dilated and filled with pink casts and give an appearance of thyroidization. Blood vessels are thickened. There is presence of scattered chronic inflammatory cell infiltrates.
- Parameters in chronic kidney disease are given in Table 22.35. Etiology of chronic kidney disease is given in Table 22.36. Schematic representation of clinical manifestations of chronic kidney disease are

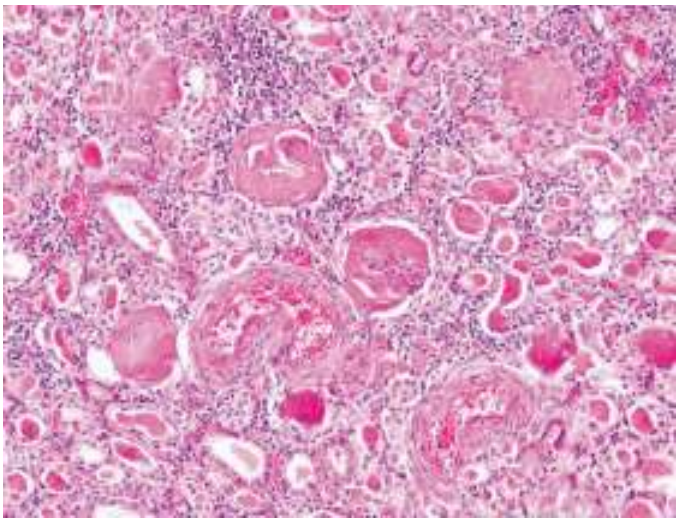

Fig. 22.64: Histology of chronic kidney disease. Hematoxylin and eosin-stained renal biopsy section shows glomerulosclerosis, tubular thyroidization (filled with colloid casts), tubular atrophy, hyalinization of blood vessels, intense diffuse lymphocytes and plasma cells in the interstitium and interstitial fibrosis (400X).

Table 22.35 Parameters in chronic kidney disease

Renal Reserve	Glomerular Filtration Rate (GFR)	Characteristics	
Diminished renal reserve	GFR (>50% of normal)	▪ Blood urea (normal range) ▪ Serum creatinine (normal range)	▪ Susceptible to uremia
Renal insufficiency	GFR (20–50% of normal)	▪ ↑Blood urea ▪ ↑Serum creatinine	▪ Sudden susceptible to uremia associated with hypertension, decreased concentrating ability of kidneys
Chronic renal failure	GFR (<20% of normal)	▪ ↑Blood urea ▪ ↑Serum creatinine	▪ Overt uremic manifestations (kidneys fail to regulate volume, solute composition and needing hemodialysis)
End stage renal disease	GFR (<5% of normal)	▪ ↑Blood urea ▪ ↑Serum creatinine	▪ Overt uremic manifestations with end stage kidney disease (kidneys fail to regulate volume, solute composition and needing hemodialysis)

Azotemia refers to accumulation of waste products in the body. Uremia refers to accumulation of waste products in the body with clinical manifestations.

Table 22.36 Etiology of chronic kidney disease

Etiology	Disorders	
Primary glomerular diseases	▪ Acute glomerulonephritis ▪ Antiglomerular basement membrane disease ▪ Chronic glomerulonephritis	▪ Goodpasture's syndrome ▪ Intercapillary glomerulosclerosis ▪ Rapidly progressive glomerulonephritis
Primary tubular diseases	▪ Chronic hypercalcemia ▪ Chronic potassium depletion	▪ Fanconi's syndrome ▪ Heavy metal poisoning (lead, cadmium)
Vascular diseases	▪ Ischemic renal diseases ▪ Long-standing nephrosclerosis	▪ Bilateral renal artery stenosis (congenital or acquired)
Infections	▪ Chronic pyelonephritis	▪ Tuberculosis
Obstructive disease	▪ Upper obstruction (calculi, neoplasms and retroperitoneal fibrosis)	▪ Lower obstruction (congenital anomalies of bladder or urethra, prostatic enlargement, urethral stricture)
Collagen diseases	▪ Diffuse systemic sclerosis (scleroderma) ▪ Systemic lupus erythematosus	▪ Polyarteritis nodosa
Metabolic diseases involving kidney	▪ Amyloidosis ▪ Chronic phenacetin over dosage ▪ Gout and hyperuricemic nephropathy	▪ Primary hyperparathyroidism ▪ Milk-alkali syndromes ▪ Sarcoidosis
Congenital anomalies	▪ Hypoplastic kidney ▪ Polycystic kidney disease	▪ Medullary cystic disease

shown in Fig. 22.65. Clinical manifestations in chronic kidney disease are given in Table 22.37.

Water and Electrolytes Imbalance

Electrolyte abnormalities in chronic kidney disease include either sodium loss (early) or sodium retention (late), hyperkalemia producing cardiac arrhythmias (potassium cannot be excreted, transcellular shift related to pH), and increased anion gap metabolic acidosis (retention of organic acids). Due to the diminished concentrating ability of kidney, patient develops polyuria leading to dehydration.

Acid–Base Equilibrium Imbalance

Under physiologic state, deamination of amino acids occurs in distal convoluted tubule (DCT) cells to form ammonia, which enters filtrate. Potassium and hydrogen ions also enter filtrate in exchange of sodium ions. Ammonia combines with hydrogen ions. In chronic glomerulonephritis, decreased formation of ammonia in the DCT cells, and decreased serum bicarbonate levels lead to decreased buffering action of hydrogen ions resulting in metabolic acidosis. Patient develops 'Kussmaul respiration' (sighing respiration).

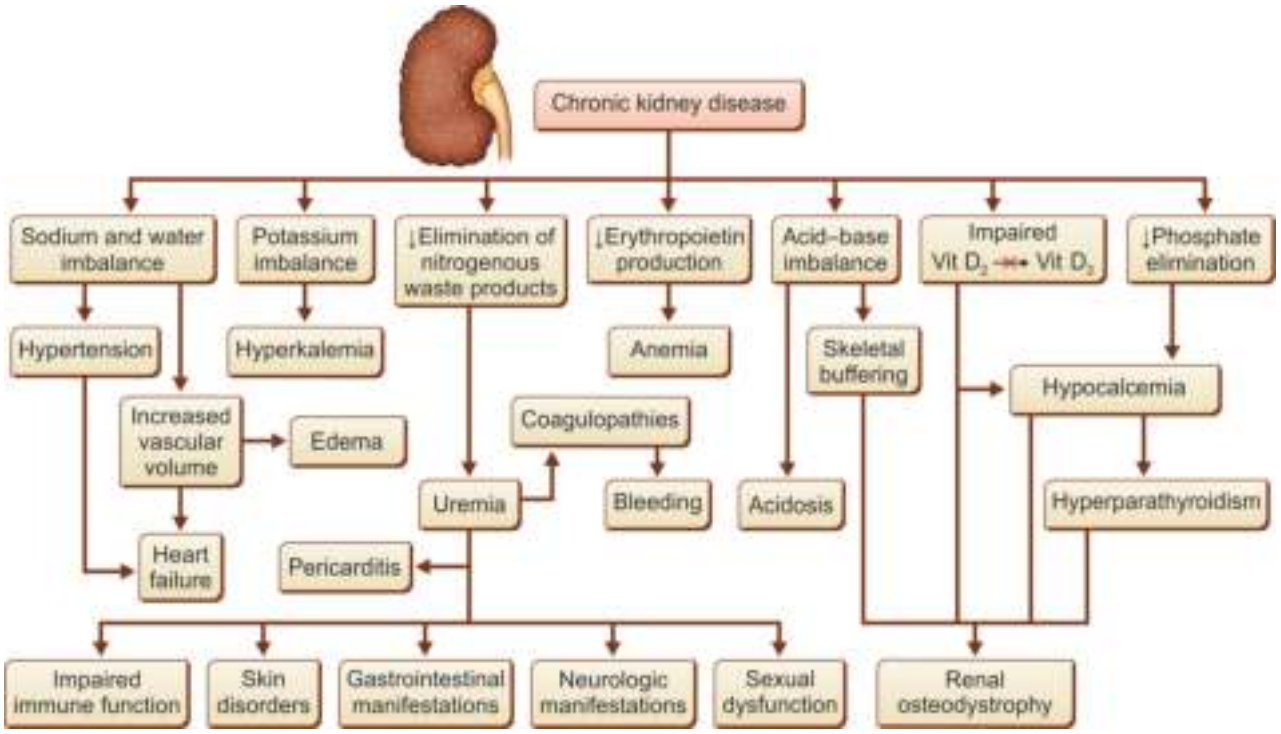

Fig. 22.65: Schematic representation of clinical manifestations of chronic kidney disease.

Table 22.37 Clinical manifestations in chronic kidney disease

System	Clinical Manifestations	
Cardiovascular system	▪ Hypertension present	▪ Serofibrinous pericarditis (occasional)
Respiratory system	▪ Hilar pneumonitis, X-ray shows 'batwing' opacity (uremic lung)	▪ Deep sighing respiration (Kussmaul respiration) ▪ Breath urine smell
Gastrointestinal tract	▪ Tongue is coated with ammoniacal or unpleasant taste, hiccup, anorexia, nausea, vomiting	▪ Diffuse or patchy ulcerations from mouth to anus results in gastrointestinal bleeding
Nervous system	▪ Headache, lassitude ▪ Drowsiness ▪ Weakness	▪ Muscle wasting ▪ Convulsions or coma
Ocular changes	▪ Eyelid swelling	▪ Arteriosclerotic retinopathy or hypertensive retinopathy
Dermal changes	▪ Skin grayish yellow due to urochrome deposit	▪ Pallor face
Hematological findings	▪ Normocytic normochromic picture with polychromasia	▪ Burr cells may appear
Biochemical abnormalities	▪ ↓ Glomerular filtration rate ▪ ↓ Creatinine clearance ▪ ↑ Blood urea ▪ ↑ Serum creatinine	▪ Urine concentrating ability decreased ▪ Disturbance of sodium, potassium, calcium, phosphate, and glucose metabolism ▪ Acidosis present
Urinary system	▪ Specific gravity fixed ▪ Urine analysis (proteinuria)	▪ Light microscopy reveals pyuria, hematuria, broadcasts

Cardiopulmonary Manifestations

In chronic kidney disease, patient develops hypertension, congestive heart failure and uremic pericarditis. Cardiopulmonary manifestations consist of accelerated atherosclerosis (increased VLDL from decreased catabolism), congestive heart failure with pulmonary edema (fine crepitations and dyspnea), hypertension (salt retention, volume overload, renin-angiotensin-aldosterone system), and uremic pericarditis (fibrinous pericarditis, often with hemorrhage), and uremic pneumonitis. Friction rub is heard on auscultation, which disappears, if the patient undergoes hemodialysis.

Gastrointestinal Tract Manifestations

Patients with chronic kidney disease develop gastrointestinal tract manifestations such as chronic esophagitis, hemorrhagic gastritis, peptic ulcer disease, enteritis, and intractable hiccups. Due to diffuse/patchy ulcerations in gastrointestinal tract, i.e. mouth to anus, patient presents with bleeding from gastrointestinal tract, nausea and vomiting. There is an increased susceptibility to infection (HBV, HCV, CMV, and HIV) owing to functional leukocyte abnormalities and the hazards of hemodialysis.

Hematologic Abnormalities

Normocytic anemias in chronic kidney disease most frequently occurs due to decreased synthesis of erythropoietin. Bleeding time is prolonged, because toxic metabolites cause functional defects of platelets, i.e. platelets aggregation and decreased platelet factor release. Patient has gastrointestinal tract bleeding.

Calcium and Phosphate Disturbances

Normally, vitamin D_2 to D_3 conversion takes place in kidney. Active metabolite D_3 maintains normal serum calcium level by enhancing calcium absorption at gastrointestinal tract level.

- In chronic kidney disease, vitamin D_3 active metabolite is not formed, hence leads to decreased absorption of calcium at gastrointestinal tract level. Hence, serum calcium is low.
- Hypocalcemia occurs owing to hypovitaminosis D due to loss of the 1α-hydroxylating enzyme and hyperphosphatemia as a result of decreased excretion, which drives calcium into tissue. Increased phosphate levels in blood reduce blood ionized calcium level, which stimulates parathyroid glands to produce parathormone. Hemodialysis fluid rich in aluminum inhibits calcium deposition in bones resulting in osteomalacia, osteoporosis and osteitis fibrosa cystica.

Pathology Pearls: Renal Osteodystrophy (Bone Changes in Chronic Renal Failure)

Renal osteodystrophy (skeletal abnormalities) occurs due to deranged calcium and phosphates metabolism. Bone alterations include osteomalacia (decreased bone mineralization), osteoporosis (decreased bone matrix; due to buffering action of metabolic acidosis), and osteitis fibrosa cystica from secondary hyperparathyroidism.

Osteomalacia

Osteomalacia refers to decreased mineralization of the organic bone matrix (osteoid). Hypovitaminosis D causes hypocalcemia leading to decreased bone mineralization. It produces fractures and bone pain.

Osteoporosis

Osteoporosis refers to decreased bone matrix due to metabolic acidosis. Loss of organic bone matrix and minerals causes an overall reduction in bone mass. It produces fractures and bone pain.

Osteitis Fibrosa Cystica

Hypovitaminosis D causes hypocalcemia, which stimulates production of parathormone resulting in secondary hyperparathyroidism, that increases bone resorption and causes cystic lesion in bone (jaw). Hemorrhage into the cystic lesions in jaw causes a brown discoloration. Histology of osteitis fibrosa cystica is shown in Fig. 22.66.

Dermatological Changes

Patient with chronic renal disease develops an array of cutaneous manifestations such as xerosis, pruritus, cutaneous pigmentation, sallow discoloration of skin due to accumulation of urochrome pigment in skin, skin infections, uremic frost and nail changes (e.g. half nails, koilonychia, splinter hemorrhages, onychomycosis, subungual hyperkeratosis, Mees lines, and Muehrcke's lines).

Neuromuscular Disturbances

Patient with chronic renal disease is most often afflicted with neurological complications, which can adversely affect the central and peripheral nerves. Common neurological complications in the patient include skeletal muscle weakness, functional peripheral nerve disease, encephalopathy, seizures, cerebral stroke and coma. Dietary potassium restriction may be useful to prevent peripheral neuropathy.

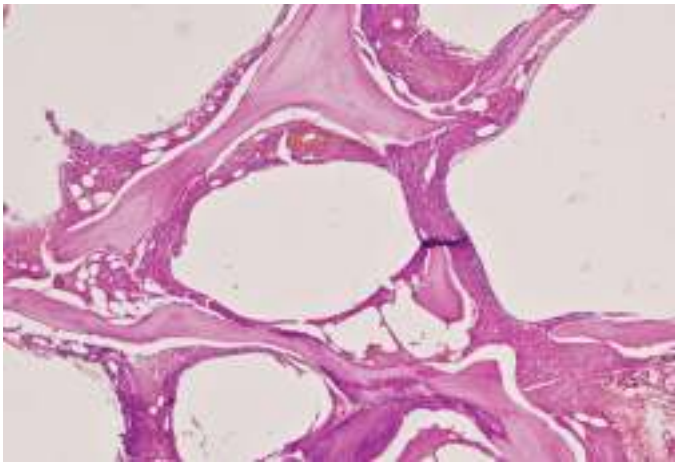

Fig. 22.66: Histology of osteitis fibrosa cystica. Renal osteodystrophy is the term used to describe different patterns of skeletal abnormalities that occur in patients with chronic renal disease and hyperparathyroidism. Osteitis fibrosa cystica is a manifestation of the effects of high levels of parathormone (PTH) on bone and is associated with a high bone turnover. Parathormone induces osteoclast activity which results in a bone breaks down. Hematoxylin and eosin-stained skeletal tissue section shows osteoclastic and osteoblastic activity with hemosiderin laden macrophages and cysts formation (400X).

CHRONIC KIDNEY DISEASE: MEDICAL/SURGICAL MANAGEMENT

Supportive care and treatment to manage symptoms of chronic kidney disease without performing dialysis or having a renal transplant, is called medical management.

Dialysis

Dialysis is the process of removing excess of waste metabolic waste products and toxins through selectively permeable membrane from the blood in patients whose kidneys no longer perform physiologic functions. Dialysis is performed by hemodialysis or peritoneal dialysis.

- In hemodialysis, the patient blood flows through a dialysis machine.
- In peritoneal dialysis, the dialysate is introduced into the peritoneal cavity; the peritoneum acts as the dialysis membrane.
- Dialysis machine itself can be thought of as an artificial kidney. Dialysate is the fluid that helps in removal of unwanted waste metabolic products from blood. In peritoneal dialysis, dialysate is introduced into the peritoneal cavity, in which peritoneum acts as the dialysis machine.

Renal Transplantation

Renal transplantation is the only surgical procedure of fully correcting the impaired renal functions for patient with end stage renal disease.

- **Indications:** All patients with chronic kidney disease stage 4 (GFR 15–29 ml/min) or end stage renal failure (GFR <15 ml/min) with progressive renal disease should be assessed for renal transplantation. It has been increasingly successful with renal graft survival in 80% of cases due to better ABO and HLA matching of the donor and improved post-transplant immunosuppression.
- **Contraindications:** Contraindications of renal transplantation include untreated malignancy, active infection, untreated HIV infection/AIDS, HBV or HCV infection and uncontrolled diabetes mellitus.
- **Complications:** Several complications can occur postoperatively, including delayed graft function, vascular and urethral complications. Patient with delayed renal graft function need dialysis in the first week after renal transplantation.
  - Early vascular complications includes renal artery and renal vein thrombosis, which can be recognized using a Doppler ultrasound. Aspirin and/or heparin should be administered postoperatively to reduce risk for renal vessels thrombosis.
  - Late vascular complications include renal artery stenosis several months after renal transplantation with uncontrolled hypertension. Renal angiography confirms the diagnosis and patients are treated by angioplasty.

RENAL BIOPSY EVALUATION AND INTERPRETATION

Evaluation of renal biopsy has a diagnostic role in renal disorders. Successful renal biopsy is a traumatic procedure; hence the patient's urine consists of RBCs after successful renal biopsy. Renal biopsy must consist of at least five glomeruli for diagnosing renal lesions. Kidney is composed of glomeruli, tubules, blood vessels and interstitial tissue. A renal biopsy specimen section is stained with H&E and examined by light microscopy, immunofluorescence microscopy, and electron microscopy (EM).

LIGHT MICROSCOPY

Routine and specialized stains help classify the glomerular disease as diffuse, focal, membranous, proliferative glomerulonephritis. In H&E stained tissue section, we should evaluate, overall cellularity, the symmetry and the thickness of the glomeruli.

- **Glomeruli:** With normal glomerular cellularity, cell nuclei are not clustered or overlapping. Clusters of cells in glomeruli, especially away from the hilum, indicate abnormal hypercellularity.
  - Glomerular cellularity is increased due to proliferation of glomerular cells (endothelial cells and mesangial cells), infiltration of leukocytes in glomeruli, and proliferation of extracapillary parietal cells of Bowman's capsule forming crescents.
  - Extracellular material is deposited in glomeruli such as amyloid deposit, fibrinoid necrosis in malignant hypertension, insudation of plasma proteins in benign hypertension (hyalinosis), and collagen matrix in glomerulosclerosis.
- **Tubules:** Normally tubules are arranged back-to-back. Inflammatory process of kidney widens intertubular space.
- **Blood vessels:** Blood vessels show nephrosclerotic changes in hypertension. There is increased extracellular material in glomeruli due to (a) immune complex deposits, (b) thickening or replication of glomerular basement membrane (GBM), (c) increase in collagen matrix (sclerosis), (d) insudation of plasma proteins (hyalinosis), (e) fibrinoid necrosis, and (f) amyloid deposit.
- **Interstitial tissue:** The renal interstitium is defined as the intertubular, extraglomerular, extravascular space of the kidney. It is bounded on all sides by tubular and vascular basement membranes, and diseased kidney.

Schematic representation of glomerular hypercellularity in various types of glomerulonephritis is shown in Fig. 22.67. Patterns of glomerular injury observed under light microscopy and some but not all diseases that cause patterns of glomerular injury are given in Table 22.38. Major glomerular patterns and differential diagnosis on light microscopy are given in Table 22.39. Histochemical stains used to evaluate renal biopsy are given in Table 22.40. Staining characteristics of normal and abnormal renal structures by selected histochemical stains are given in Table 22.41.

Pathology Pearls: Jones Methenamine Silver Stain used in Evaluation of Renal Biopsy

- Jones methenamine silver (JMS) stain is a histochemical stain, which highlights carbohydrates that can be oxidized to aldehydes. Aldehydes formed by oxidation of carbohydrates reduce silver solution, causing the silver ions to bind to the carbohydrate and can be visualized under light microscope.
- JMS stain highlights details of basement membrane of glomeruli, tubules, Bowman's capsule, elastic lamina of blood vessels and sclerotic segments of glomeruli (glomerulosclerosis).
- JMS stain delineates glomeruli within crescents and hence highlights the presence of extracapillary proliferation, also delineates mesangial regions of glomeruli, which are argyrophilic.

IMMUNOFLUORESCENCE MICROSCOPY

Immunofluorescence (IF) microscopy is a powerful technique that utilizes fluorescent labeled antibodies to detect specific target antigens. Fluorescein dye emits greenish fluorescence under UV light, which can be tagged to immunoglobulin molecules. Immunofluorescence microscopy identifies immune complex deposits, patterns of deposition of IgG, IgA, IgM, complement (C1q, C3), fibrin, light chains, and albumin.

Location of Immune Complex Deposits

Highly anionic macromolecules are excluded by glomerular basement membrane, which get trapped in subendothelial region of glomeruli. Cationic molecules bind to anionic sites, DNA nucleosome and other nuclear proteins. Highly cationic immunogens tend to cross subepithelial region of glomeruli. Neutral charged molecules are trapped in mesangial region of glomeruli.

- **Subendothelial immune complex deposits:** Immune complexes are deposited in subendothelial region in patient with systemic lupus erythematosus.
- **Subepithelial immune complex deposits:** Lumpy-bumpy (large size) immune complex deposits are demonstrated in poststreptococcal glomerulonephritis and membranous glomerulonephritis.

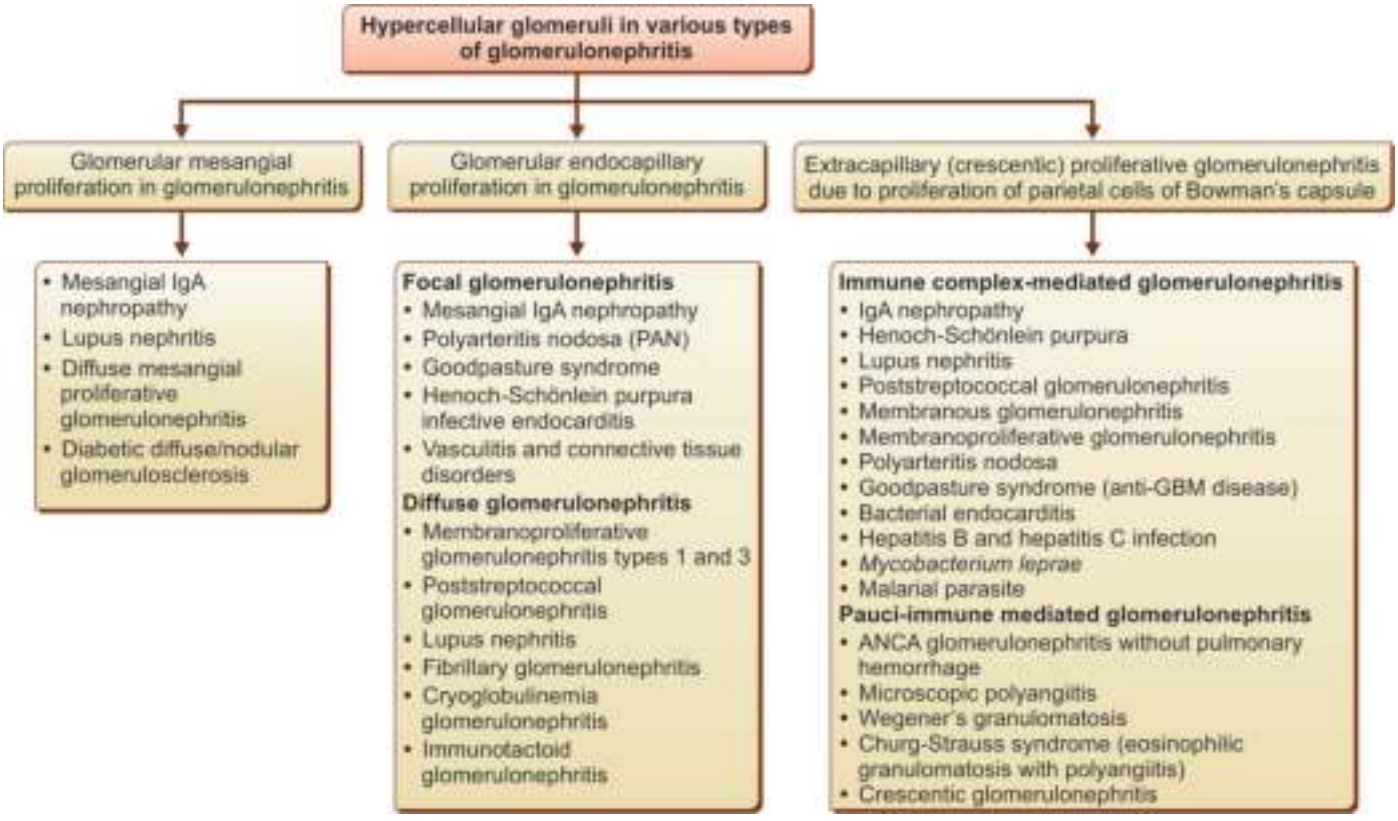

Fig. 22.67: Schematic representation of glomerular hypercellularity in various types of glomerulonephritis. It shows etiology of proliferation of mesangial cells, endocapillary and exocapillary hypercellularity.

Table 22.38 Patterns of glomerular injury observed under light microscopy and some but not all diseases that cause patterns of glomerular injury

No Glomerular Abnormality by Light Microscopy

- No glomerular disease
- Glomerular disease without light microscopic changes
  - Minimal change disease of glomeruli
  - Thin membrane disease of glomeruli
- Mild or early glomerular disease
  - Class 1 lupus nephritis
  - IgA nephropathy
  - C1q nephropathy
  - Membranous glomerulonephritis
  - Renal amyloidosis
  - Alport syndrome

Glomeruli with Thick Walls and Mesangial Expansion but Little or without Hypercellularity

- Diabetic glomerulosclerosis with diffuse glomerulosclerosis rather than nodular mesangial glomerulosclerosis (Kimmelstiel-Wilson disease)
- Secondary membranous glomerulopathy with mesangial immune deposits
- Dense deposit disease (type 2 membranoproliferative glomerulonephritis)
- Renal amyloidosis
- Monoclonal immunoglobulin deposition disease
- Fibrillary glomerulonephritis

Focal Segmental Glomerulosclerosis without Glomerular Hypercellularity

- Focal segmental glomerulosclerosis (primary or secondary)
- Chronic sclerotic phase of focal glomerulonephritis
- Alport syndrome (hereditary nephritis)

Mesangial or Endocapillary Glomerular Hypercellularity

- Focal or diffuse mesangioproliferative glomerulonephritis
- Acute (exudative) diffuse proliferative postinfectious glomerulonephritis
- Focal or diffuse endocapillary proliferative glomerulonephritis
- Membranoproliferative glomerulonephritis (type 1, type 2/dense deposit disease or type 3)

Extracapillary Glomerular Hypercellularity

- Antiglomerular basement membrane (anti-GBM) glomerulonephritis (granular immunoglobulin pattern by immunofluorescence microscopy)
- Immune complex crescentic glomerulonephritis (granular immunoglobulin deposit by immunofluorescence microscopy)
- ANCA crescentic glomerulonephritis (paucity of immunoglobulin deposit by immunofluorescence microscopy)
- Collapsing variant of focal segment glomerulosclerosis (including HIV nephropathy)

Membranoproliferative, Glomerular Lobular and Nodular Pattern

- Diabetic glomerulosclerosis with nodular mesangial glomerulosclerosis (Kimmelstiel-Wilson disease)
- Membranoproliferative glomerulonephritis (type 1, type 2/dense deposit disease or type 3B/3S)
- Monoclonal immunoglobulin deposition disease with nodular glomerulosclerosis
- Idiopathic (tobacco smoking associated) nodular glomerulosclerosis
- Thrombotic microangiopathy
- Fibrillary glomerulonephritis
- Fibrillary glomerulonephritis
- Immunotactoid glomerulopathy

Advanced Diffuse Global Glomerulosclerosis

- End stage glomerular disease
- End stage vascular disease
- End stage tubulointerstitial disease

Table 22.39 Major glomerular patterns and differential diagnosis on light microscopy

Parameters on Light Microscopy	Examples	
Minimal glomerular changes	▪ Minimal change disease (MCD) ▪ Thin glomerular membrane disease ▪ Early lupus nephritis	▪ Early mild IgA nephropathy ▪ Early diabetic nephropathy
Proliferative glomerulonephritis	▪ Post-infectious glomerulonephritis ▪ Lupus nephritis	▪ Henoch-Schönlein purpura
Focal segmental glomerulosclerosis	▪ Primary glomerulonephritis, NOS	▪ Secondary glomerulonephritis, NOS
Mesangial cell proliferation (hypercellular mesangial region)	▪ IgA nephropathy	▪ Lupus nephritis
Thick capillary loops	▪ Membranous glomerulonephritis ▪ Diabetic nephropathy	▪ Alport's syndrome ▪ Amyloidosis nephropathy (early stage)

Contd...

Table 22.39 Major glomerular patterns and differential diagnosis on light microscopy (*Contd...*)

Parameters on Light Microscopy	Examples	
Tram-track appearance	▪ Membranoproliferative glomerulonephritis ▪ Henoch-Schönlein purpura	▪ Lupus nephritis type 4
Nodular pattern	▪ Diabetic nephropathy ▪ Amyloid nephropathy	▪ Monoclonal immunoglobulin deposition disease (MIDD)
Crescents formation	▪ Goodpasture's syndrome ▪ Acute diffuse proliferative glomerulonephritis (occasional) ▪ Diffuse mesangioproliferative glomerulonephritis	▪ Henoch-Schönlein purpura ▪ Microscopic polyarteritis ▪ Wegener's granulomatosis ▪ Acute scleroderma involving kidney ▪ Segmental lupus nephritis with tuft necrosis

Table 22.40 Histochemical stains used to evaluate renal biopsy

Stains	Used to Demonstrate	
Hematoxylin and eosin stain	▪ Glomerular cellularity, symmetry and thickness ▪ Tubules	▪ Blood vessels ▪ Interstitial tissue
Periodic acid–Schiff (PAS) stain	▪ Glomerular basement membrane ▪ Tubular basement membrane	▪ Mesangial matrix
Jones methenamine silver stain	▪ Glomerular basement membrane	▪ Tubular basement membrane
Congo red stain	Amyloid deposit in glomeruli and blood vessels	
Masson's trichrome stain	Collagen deposition (focal segmental glomerulosclerosis)	
Fat stains (Sudan III, IV, black B, oil red O)	Fat microemboli in glomeruli	

Table 22.41 Staining characteristics of normal and abnormal renal structures by selected histochemical stains

Renal Tissue Components	PAS Stain	Masson's Trichrome Stain	Jones Methenamine Silver Stain
Normal renal structures			
Glomerular basement membrane	Red staining	Deep blue staining	Black staining
Tubular basement membrane	Red staining	Deep blue staining	Black staining
Mesangial matrix	Red staining	Deep blue staining	Black staining
Interstitial collagen fibers	No stained	Pale blue staining	No stained
Cell cytoplasm	No stained	Rust/orange granular	No stained
Abnormal renal findings			
Immune complex	Negative/positive	Bright red-orange homogenous	No stained
Fibrin	Weakly positive	Bright red-orange fibrillar	No stained
Amyloid	–	Light blue-orange	No stained
Tubular casts (Tamm-Horsfall protein)	Red	Light blue	Gray black
Insudative lesions	Negative/positive	Bright red-orange homogenous	No stained

- **Intramembranous immune-complex deposits:** Immune complex deposits are seen within glomerular basement membrane in systemic lupus erythematosus and membranoproliferative glomerulonephritis.
- **Mesangial deposits:** Immune complex comprising of IgA1 and complement are deposited in mesangial region of glomeruli in patient with IgA nephropathy.

Patterns of Immune Complex Deposits

Immune complexes deposited in glomeruli may show diffuse linear staining or lumpy bumpy or irregular (fluffy) patterns. Immunofluorescence microscopy is shown in Fig. 22.68A and B. Patterns of immune complex deposits by immunofluorescence microscopy in glomerulopathy are given in Table 22.42. Immunofluorescence microscopy is used to demonstrate

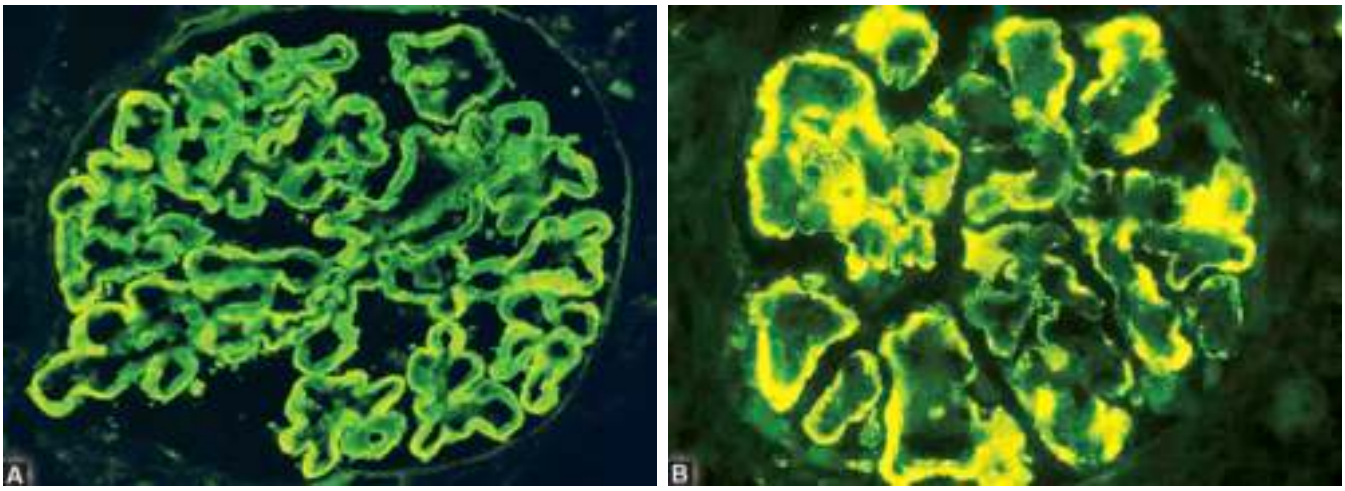

Fig. 22.68: Immunofluorescence microscopy in glomerulonephritis. Immunofluorescence and light microscopy is required for accurately diagnosing glomerulonephritis. (A) Linear deposition of endogenous immunoglobulin (Ig) along the glomerular basement membrane, (B) in contrast to a linear deposition of immunoglobulin, renal diseases associated with immune complex deposition has a granular 'lumpy-bumpy appearance.

Diffuse Linear Staining for IgG
Goodpasture's syndrome
Granular Lumpy-bumpy Immune Complex Deposits
▪ Poststreptococcal glomerulonephritis (subepithelial region) ▪ Membranous glomerulonephritis (intramembranous and subepithelial regions) ▪ IgA nephropathy (mesangial region) ▪ Lupus glomerulonephritis (subendothelial region)
Irregular (Fluffy) Immune Complex Deposits
Monoclonal light chains (AL amyloidosis), AA protein (AA amyloidosis)

immune deposits in glomerular diseases as given in Table 22.43.

- **Diffuse linear staining of GBM:** Diffuse linear staining for IgG is seen along the glomerular basement membrane in Goodpasture's syndrome.
- **Granular lumpy-bumpy immune complex deposits in glomeruli:** Granular lumpy-bumpy immune complex deposits are demonstrated in poststreptococcal glomerulonephritis (subepithelial region), membranous glomerulonephritis (intramembranous and subepithelial regions), IgA nephropathy (mesangial region) and lupus glomerulonephritis (subendothelial region). Their distribution is less uniform owing to differences in their charge, size, and solubility.
- **Irregular (fluffy) deposits in glomeruli:** Irregular (fluffy) staining is associated with monoclonal light chains (AL amyloidosis) and AA protein (AA amyloidosis).

Table 22.43 Immunofluorescence microscopy is used to demonstrate immune deposits in glomerular diseases

Subendothelial Immune Complex Deposits
Lupus nephritis (systemic lupus erythematosus)
Subepithelial Lumpy-bumpy Immune Complex Deposits
▪ Poststreptococcal glomerulonephritis ▪ Membranous glomerulonephritis
Intramembranous Immune Complex Deposits
▪ Membranoproliferative glomerulonephritis ▪ Lupus nephritis (systemic lupus erythematosus)
Mesangial Immune Complex Deposits
IgA nephropathy
Immune Complex Deposits along Glomerular Basement Membrane
Diffuse linear immunofluorescence for IgG and C3, fibrin in crescents is seen along the glomerular basement membrane in Goodpasture's syndrome.

ELECTRON MICROSCOPY

Electron microscopy (EM) is a useful diagnostic technique to supplement morphologic, immunohistochemical, cytogenetic and molecular analysis of tissues, although immunoperoxidase techniques have largely replaced EM for tumor diagnosis in surgical pathology.

- Electron microscopes are basically of two types: transmission electron microscopy (TEM) and scanning electron microscopy (SEM). Renal biopsy is fixed in 2% glutaraldehyde embedded in epoxy resin. Ultrathin sections are obtained with microtome. Sections are placed on a specimen grid end of electron microscope. Digital image is obtained and analyzed.

- Renal biopsy examined under electron microscopy reveals site of immune complex deposits, thickening and replication of glomerular basement membrane, collagen matrix and fibrillary deposits.
- Electron dense immune complex deposits are demonstrated by electron microscopic study in membranous glomerulonephritis (intramembranous and subepithelial region), IgA nephropathy (mesangial region) and lupus glomerulonephritis (subendothelial region). Electron microscopy identifies structural abnormalities in minimal change disease affecting children responsible for nephrotic syndrome (e.g. effacement of foot process).
- Electron microscopy in glomerulopathy and immunofluorescence are given in Table 22.44. Immune complex deposits demonstrated by various immunofluorescence, light and electron microscopy in renal biopsy are given in Table 22.45.

Table 22.44 Electron microscopy in glomerulopathy and immunofluorescence

Electron Dense Immune Complex in Glomeruli
▪ Membranous glomerulonephritis (intramembranous and subepithelial region) ▪ IgA nephropathy (mesangial region) ▪ Lupus glomerulonephritis (subendothelial region) ▪ Minimal change disease (effacement of podocytes) ▪ Poststreptococcal glomerulonephritis (subepithelial region)

Diffuse linear immune complex deposits	Not visible	Not visible
Granular immune complex deposits	Bright red (Masson's trichrome stain)	Electron dense immune complex

TUBULAR DISEASES OF KIDNEY

Each of the convoluted tubules is transmitting urine from the glomeruli to the renal pelvis in the kidney. Water and salts are reabsorbed into the blood along their length. Once the glomerular filtrate passes through the proximal tubule in renal cortex, descending and ascending limb of loop of Henle. It enters the distal convoluted tubule in renal cortex.

- Proximal tubule absorbs essential metabolites by active process such as Na^+, K^+, Cl^-, HCO_3^-, amino acids, glucose and phosphates and water (80%) by passive process.
- Descending limb of loop of Henle is only permeable to water, hence absorbs water (10%) by passive process. Ascending limb of loop of Henle is impermeable to water, but permeable to salts, hence absorbs Na^+, chloride, K^+, Ca^+, HCO_3^- and Mg^+ by active process.
- Distal tubules absorb essential metabolites such as Na^+, Cl^- (absorption of Na^+, Cl^-, by aldosterone), Ca^+ and Mg^+ by active process; and water (5%) by passive process.
- Collecting ducts absorb water (5%) by the action of antidiuretic hormone (ADH). Hydrogen ions and organic acids secreted by proximal tubules enter peritubular network of blood vessels. Hydrogen ions are also secreted by distal tubule.

ACUTE TUBULAR NECROSIS

Tubular epithelial cells are particularly sensitive to anoxia and toxins, which cause tubular epithelial cell necrosis. Acute tubular necrosis (ATN) is a clinicopathologic entity with pathologic changes in the tubules when ischemic or nephrotoxic injuries adversely affect the kidneys. Ischemia-induced ATN represents about 60% of cases.

- ATN is a severe clinicopathologic entity, but potentially reversible, impairment of tubular epithelial cell function resulting in acute renal failure within 24 hours. Kidneys are not able to excrete waste metabolic products (urea and creatinine) and maintain normal fluid and electrolyte homeostasis.
- Complications of ATN include water and salt overload and metabolic acidosis. Prognosis of AT depends on the clinical stage. Treatment is usually supportive. Recovery most often occurs during the first month after acute renal failure, but can be seen even after one year.

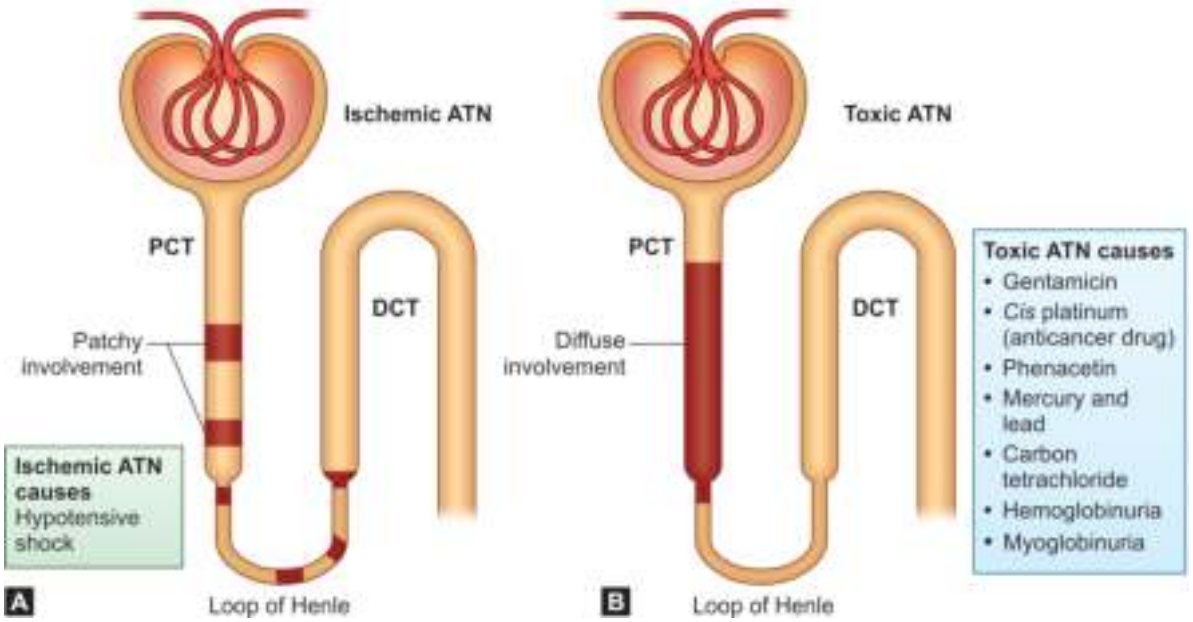

Fig. 22.69A and B: Schematic representation of acute tubular necrosis (ATN). ATN is classified as either ischemic or toxic types. Ischemic ATN occurs when the tubular epithelial cells do not receive enough oxygen that they are highly sensitive and susceptible to ischemia, due to their high metabolic activity. Toxic ATN occurs when the tubular cells are exposed to a nephrotoxic substance.

- Acute tubular necrosis is divided into ischemic and nephrotoxic. ATN is accompanied by oliguria (urine output <400 ml/24 hours) or anuria in most of cases. Some cases have polyuria (>800 ml/24 hours). Urine analysis shows hyaline granular or pigmented casts.
- Schematic representation of acute tubular necrosis (ATN) is shown in Fig. 22.69. Causes of acute tubular necrosis (ATN) are given in Table 22.46. Comparison between ischemic and nephrotoxic types of acute tubular necrosis (ATN) is given in Table 22.47.

ISCHEMIC ACUTE TUBULAR NECROSIS

Ischemic ATN results from reduced renal perfusion, usually associated with hypotension following massive hemorrhage, burns and septicemia including incompatible blood transfusion, acute pancreatitis and acute intestinal obstruction. Ischemia starts in outer cortex and extends inwards as blood pressure falls. Ischemic changes are marked in the cortical region (proximal tubule straight segment and thick ascending limb of loop of Henle), and medullary region (loop of Henle). Juxtamedullary nephrons usually escape ischemic injury, being closer to main renal arterial branches.

Pathogenesis

Tubular epithelial cells with their high rate of energy consuming metabolic activity and numerous organelles, are particularly sensitive to hypoxia and anoxia.

Table 22.46 Causes of acute tubular necrosis (ATN)

Ischemic Acute Tubular Necrosis
Major surgical procedures
Massive acute blood loss
Severe burns
Acute pancreatitis
Incompatible blood transfusion
Acute intestinal obstruction
Nephrotoxic Acute Tubular Necrosis
Endogenous products (e.g. hemoglobinuria, myoglobinuria)
Heavy metals (lead and mercury)
Antibiotics (e.g. gentamycin, penicillin, methicillin)
Anticancer drug (cisplatin)
Organic solvents (carbon tetrachloride, chloroform)
Nonsteroidal anti-inflammatory drugs (e.g. phenacetin)
Other toxic agents (ethylene, glycol, paraquat, poisonous fungi)
Radiographic contrast media

Acute tubular necrosis due to nephrotoxic agents is the most important cause of acute renal failure.

- Depletion of adenosine triphosphate (ATP) results in accumulation of intracellular calcium, which activates cellular hydrolytic enzymes.
- Phospholipase causes cell membrane injury. Protease causes rearrangement of cytoskeleton. Generation of reactive oxygen species amplify the tubular

Table 22.47 Comparison between ischemic and nephrotoxic types of acute tubular necrosis (ATN)

Ischemic Acute Tubular Necrosis (ATN)	Nephrotoxic Acute Tubular Necrosis (ATN)
Predisposing factors	
▪ Renal ischemia ▪ Major surgical procedures ▪ Massive acute blood loss ▪ Severe burns ▪ Acute pancreatitis ▪ Incompatible blood transfusion	▪ Hemoglobinuria ▪ Myoglobinuria ▪ Metals (lead, mercury) ▪ Drugs (gentamycin, penicillin, methicillin, phenacetin, cisplatin) ▪ Acute intestinal obstruction ▪ Chemical agents (carbon tetrachloride, chloroform, ethylene, glycol, paraquat poison) ▪ Poisonous fungi ▪ Radiographic contrast media
Proximal tubules and loop of Henle lesion patten	
Patchy lesions with detachment of tubular basement membrane	Diffuse lesions without detachment of tubular basement membrane
Regeneration of tubular epithelial cells	
Good regeneration on immediate restoration of blood supply	Poor regeneration
24 hours urinary output	
Oliguria (<400%)	Normal or increased urinary output

damage. Release of cytokines leads to recruitment of leukocytes. Influx of neutrophils leads to more tubular injury by liberating hydrolytic enzymes.

- Focal denudation of the tubular basement membrane occurs due to necrosis of individual tubular epithelial cells. Necrotic epithelial cells enter into some of tubular lumina. Ischemia causes patchy necrosis of proximal tubules and loop of Henle with intervening skip lesions.
- Tubular basement membranes are disrupted at ischemic sites, which prevent tubular cell regeneration. Ischemia and nephrotoxins cause necrosis of tubular cells as well as endothelial cells. Schematic representation of pathogenesis of acute tubular necrosis (ATN) is shown in Fig. 22.70.

Pathology Pearls: Pathogenesis of Acute Tubular Necrosis

- Necrosed tubular epithelial cells exfoliate and enter into distal tubular lumen, whih cells combine with Tamm-Horsfall proteins and form pigmented renal tubular cell casts in distal tubules. Tubular casts obstruct urinary outflow and increase intratubular pressure, which pushes fluid into the interstitium resulting in decreased glomerular filtration rate (oliguria).
- Vasoconstriction of renal afferent arterioles plays an important role in oliguria due to decreased glomerular filtration rate (GFR).
- GFR occurs as a result of decreased synthesis of vasodilators by injured endothelial cells such as nitric oxide and PGI_2; and increased synthesis of vasoconstrictor angiotensin II.
- Net result is decreased glomerular filtration rate. All these morphologic changes lead to reduced production of urine and cause oliguria. Initially, the changes induced by ischemia or toxins are reversible, but later become irreversible.

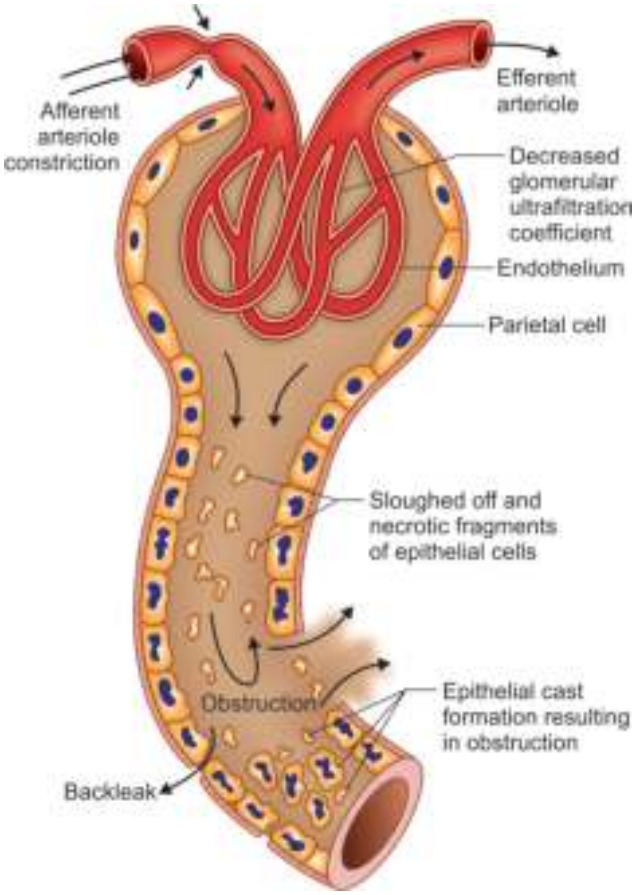

Fig. 22.70: Schematic representation of pathogenesis of acute tubular necrosis (ATN). Sloughing and necrosis of tubular epithelial cells lead to formation of casts in the tubules. Tubular casts cause obstruction and increase intraluminal pressure resulting in reduction of glomerular filtration rate. Tubular injury and increased intraluminal pressure are responsible for leakage of fluid from tubular lumen into the interstitium.

Clinical Features

Within 0–36 hours of ischemic tubular necrosis, patient presents oliguria (urinary output <400 ml/24 hours), salt and water overload, hyperkalemia, metabolic acidosis, uremia (elevated blood urea nitrogen and creatinine), BUN and creatinine ratio (<15) and urinary sediment showing tubular epithelial cells and granular casts. Patient needs dialysis to treat impaired renal functions. Mortality occurs in 5% of untreated cases if no damage to other organs occurs.

Pathology Pearls: Ischemic Acute Tubular Necrosis

Gross Morphology

The kidneys are usually enlarged. Cut surface reveals pale cortex and a congested medulla. No pathologic changes are seen in the glomeruli or blood vessels. The corticomedullary junction may be accentuated with deep red medullary regions.

Histologic and Ultrastructural Changes

There is a spectrum of morphologic changes in the renal tubules in acute tubular necrosis.

- **Early changes in tubules:** Initial ultrastructural changes in affected tubules vary from cell swelling, tubule dilated tubule, loss of periodic acid–Schiff (PAS) positive brush border of proximal tubules, blebbing of apical cell membrane, hyaline, granular and pigmented casts particularly in distal and collecting ducts, detachment of tubular epithelial cells forming eosinophilic tubular hyaline casts of Tamm-Horsfall protein (urinary glycoprotein normally secreted by these cells); white blood cells in dilated vasa recta, interstitial edema. Thinning of tubular epithelium occurs with enlargement of the lumen of the tubules. Changes in ischemic cases are usually milder and more focal than toxic ATN.
- **Late changes in tubules:** Early changes in tubules are followed by epithelial cell regeneration (flattened epithelium, dilated tubular lumina, large atypical nuclei with prominent nucleoli and mitotic figures and basophilic cytoplasm). If blood supply is not restored, irreversible changes in tubules occur such as detachment of tubular cell membrane. Nucleus undergoes changes such as pyknosis, karyorrhexis and karyolysis. Pigmented casts often represent hemoglobin or myoglobin in tubule lumen.

Electron Microscopy

Electron microscopic findings in acute tubular necrosis include simplification of tubular epithelium, cytoplasmic vacuolation, loss of brush borders, and small gaps in the lining of the tubular epithelium.

NEPHROTOXIC ACUTE TUBULAR NECROSIS

Nephrotoxic substances induced tubular epithelial injury is the most common cause of acute renal failure. Tubular epithelial cells being metabolically active absorb and concentrate these nephrotoxic agents. That is the reason that tubular cells are vulnerable to injury due to nephrotoxic substances.

- Nephrotoxic agents include antibiotics (penicillin, methicillin, cephalosporins, polymyxin), anticancer drugs (cisplatin), nonsteroidal anti-inflammatory drugs (NSAIDs, e.g. phenacetin), ethylene glycol, radiographic contrast media, heavy metals (mercury, lead) and organic solvents (carbon tetrachloride, chloroform). Prolonged intake of analgesic phenacetin causes renal papillary necrosis by inhibiting prostaglandin synthesis (vasodilator) resulting in ischemia of the renal medulla.
- Ethylene glycol also causes intratubular deposition of oxalate crystals visualized by polarized microscopy.
- Hemoglobinuria and myoglobinuria have nephrotoxic effect and cause acute tubular necrosis. Tubules show widespread necrosis of proximal tubular epithelial cells with sparing of distal and collecting tubules. Basement membrane of proximal tubules is intact and revealing vacuolation of cytoplasm. Nephrotoxic acute tubular necrosis is nonoliguric type of acute tubular necrosis.
- Patient has either normal urinary output or polyuria associated with more benign clinical course. Tubular findings in nephrotoxic acute tubular necrosis (ATN) are given in Table 22.48.

ACUTE KIDNEY DISEASE

Acute kidney disease (AKD), formerly known as acute renal failure is the sudden interruption of renal function as measured by glomerular filtration rate (GFR). AKD can lead to accumulation of water, sodium, and other metabolic products and cause electrolyte disturbances especially in hospitalized patients.

- According to KDIGO (kidney disease improving global outcomes), diagnostic criteria of acute kidney disease is the presence of any one of the parameters: (a) increase in serum creatinine by 0.3 mg/dl within 48 hours, (b) increase in serum creatinine 1.5 times of baseline within the prior seven days, and (c) urine output <0.5 ml/kg/hour for at least 6 hours. It is critical illness and treated promptly to restore renal functions.
- Acute kidney disease can also be caused by poor blood supply to kidney (prerenal etiology), or kidney disease (renal etiology) or obstruction to urine outflow (post-renal etiology). AKD is potentially reversible, however, if left untreated, permanent renal damage can lead to chronic renal failure.
- Hemolytic uremic syndrome (HUS) occurs due to ingestion of Shiga toxin-producing strains of *Escherichia coli* results in injury to glomerular

Table 22.48 Tubular findings in nephrotoxic acute tubular necrosis (ATN)

Nephrotoxic Agent	Extensive Necrosis of Tubular Cells along Proximal Tubule
Carbon tetrachloride	Neutral lipid accumulation/fatty change in injured cells, followed by tubular cell necrosis
Ethylene glycol	Ballooning and hydropic changes of proximal tubules, calcium oxalate crystals in tubular lumina
Hemoglobin/myoglobin	Numerous deeply pigmented, red-brown casts in distal and collecting ducts
Indinavir	Intraluminal clear crystals with mononuclear cell infiltration in tubules
Lead	Dark intranuclear inclusions and necrosis
Mercury	Large acidophilic inclusions
Tenofovir	Distinctive proximal tubular eosinophilic inclusions representing giant mitochondria
Vancomycin	Acute interstitial nephritis with lymphocytic and eosinophilic infiltrate and ATN

endothelial cells. It is not associated with angiopathy outside kidney. Patient presents with hemorrhagic diarrhea, microangiopathic hemolytic anemia and rapidly progressive renal failure.

ETIOPATHOGENESIS

Acute kidney disease (AKD) is defined as an abrupt impairment of renal function occurring over seven days or less. Chronic kidney disease refers to persistence of kidney disease for a period of >90 days. Untreated patients with AKD develop cardiovascular manifestations, end stage renal disease associated with diminished quality of life and mortality. Early identification of persistent acute kidney disease is important in order to initiate an extended evaluation and management protocol to prevent further kidney damage and associated mortality. Acute kidney disease occurs due to prerenal, renal and postrenal causes.

Prerenal Acute Kidney Disease

Prerenal acute kidney disease implies a reduction in the glomerular filtration rate (GFR) due to hypovolemia in the presence of normal renal function. This can be a part of systemic hypoperfusion resulting from hypovolemia or hypotension or selective hypoperfusion of kidney resulting from renal artery stenosis and aortic dissection.

- Hypovolemia may occur due to gastrointestinal fluid loss in settings of diarrhea, vomiting, massive hemorrhage and severe burns.
- Hypotension may result from deceased cardiac output in the settings of cardiogenic shock, massive pulmonary embolism, acute coronary syndrome, cardiac arrhythmias, cardiogenic shock, disseminated intravascular coagulation, arterial thrombi, eclampsia and malignant hypertension. Hypotension may result from systemic vasodilation in the settings of septic shock (gram-negative sepsis), anaphylaxis, anesthesia administration and hepatorenal syndrome.
- Renal blood flow may be decreased due to renal vasoconstriction caused by NSAIDs, radiographic iodinated contrast medium, amphotericin B and hepatorenal syndrome. If uncorrected, decreased renal blood flow most frequently progresses to ischemic acute tubular necrosis (ATN), which is the most common cause of acute kidney disease.

Intrarenal Acute Kidney Disease

Intrinsic renal diseases can target the glomeruli (e.g. acute glomerulonephritis, rapidly progressive crescentic glomerulonephritis), tubules (e.g. acute tubular necrosis due to ischemia, toxins), interstitial tissue (e.g. acute pyelonephritis and drug-induced acute interstitial nephritis), or blood vessels (e.g. malignant hypertension, polyarteritis nodosa), sickle cell disease, systemic lupus erythematosus, transfusion reaction, myeloma nephropathy, crush injuries and papillary necrosis. The tubular reabsorption of essential metabolites is greatly impaired leading to acute kidney disease.

Postrenal Acute Kidney Disease

Ureteral or urethral mechanical obstruction to urine outflow due to renal calculi, prostatic hyperplasia and invasive cervical carcinoma may result in acute renal failure. Renal causes of acute kidney disease other than acute tubular necrosis are given in Table 22.49.

CLINICAL FEATURES

Patient with acute kidney disease initially develops oliguria (urine output <400 ml/24 hours), azotemia (excess levels of urea in blood), and rarely, anuria (failure to secrete urine), which progresses to electrolyte imbalance, metabolic acidosis, uremic manifestations; renal dysfunction and disruption of systemic body systems. Patient develops headache, drowsiness, pulmonary edema. Kussmaul respiration, cardiac

Table 22.49 Renal causes of acute kidney disease other than acute tubular necrosis

Renal Disorder	Anatomical Renal Component Affected
Various glomerulopathies especially crescentic glomerulonephritis	Glomeruli
Crystal deposition (e.g. oxalates and sulphonamide)	Tubules lumen
Occlusion of renal artery, persistent vasoconstriction of intrarenal vessels, thrombotic thrombocytopenic purpura, malignant nephrosclerosis and bilateral cortical necrosis associated with separation of the placenta	Blood vessels
Acute interstitial nephritis of various types	Interstitial tissue of renal parenchyma

arrhythmias, heart failure, deranged blood pressure, systemic edema, dry mucous membrane and skin.

Urine analysis in acute kidney disease is given in Table 22.50. Laboratory diagnosis of acute kidney disease is given in Table 22.51.

- **Oliguric phase:** Patient with AKD develops oliguria (<400 ml/24 hours) due to poor renal perfusion (prerenal etiology). It results in impairment of kidney's ability to conserve sodium. There is increased blood urea nitrogen (BUN) and creatinine levels and decreased ratio of BUN to creatinine (from normal levels of 20:1 to abnormal decrease of 10:1).
- **Diuretic phase:** Patient with AKD develops slow rise in BUN and creatinine levels. Serum electrolytes (potassium, sodium) are decreased. Body water depletion occurs. Blood pressure falls. If untreated, patient has fatal outcome.
- **Recovery phase:** Well treated patient with AKD recovers with restoration of normal BUN and creatinine levels and urine output between 1 and 2 L/day.

Table 22.50 Urine analysis in acute kidney disease

Etiology of Acute Kidney Disease	Urinary Sediment Analysis
Acute tubular necrosis (ATN)	Dirty brown casts and exfoliated tubular epithelial cells
Acute tubulointerstitial nephritis	White blood cell casts and numerous pus cells
Acute poststreptococcal glomerulonephritis	Red blood cell casts, dysmorphic RBCs and proteinuria in nephritic range <2 g/24 hours

Table 22.51 Laboratory diagnosis of acute kidney disease

Laboratory Test	Prerenal Acute Kidney Disease	Intrinsic Acute Kidney Disease
FENa (fraction excretion of sodium; blood urea nitrogen and creatinine)	<1%	>1%
Blood urea nitrogen/ creatinine ratio	>20:1	<20:1
Urine sodium	<20 mEq/L	>20 mEq/L
Urine osmolality	>500 mOsm/kg	<500 mOsm/kg
Specific gravity of urine	>1.020	<1.010

TUBULOINTERSTITIAL DISEASES OF KIDNEY

Tubulointerstitial nephritis is inflammation of tubules and interstitial tissue, which occurs in the settings of infection, toxins, drugs, heavy metals (lead poisoning), irradiation, hypercalcemia, multiple myeloma and autoimmune disorders such as systemic lupus erythematosus, Sjögren's syndrome. Morphologic features of tubulointerstitial diseases are given in Table 22.52. Schematic representation of tubulointerstitial lesions in various renal disorders is shown in Fig. 22.71.

PYELONEPHRITIS

Pyelonephritis refers to bacterial infection of the renal parenchyma and/or renal pelvis. Depending on the course of disease, it is categorized: acute pyelonephritis or chronic pyelonephritis. Vesicoureteral reflux (VUR) with ascending bacterial urinary tract infections play an important role in the pathogenesis of pyelonephritis.

Table 22.52 Morphologic features of tubulointerstitial diseases

Nephrotoxic Agents
▪ Acute tubulointerstitial diseases ▪ Chronic tubulointerstitial diseases
Urate Nephropathy
Acute tubulointerstitial diseases in the setting of hyperuricemia
Hypercalcemia and Nephrocalcinosis
Deposition of calcium in renal parenchyma and tubular damage
Multiple Myeloma
Monoclonal light chains (Bence-Jones proteins) synthesized by plasma cells are directly toxic to the tubules resulting in formation of casts in tubules and thus obstruction to urine outflow and renal failure
Granulomatous Tubulointerstitial Diseases
▪ Tuberculous pyelonephritis ▪ Xanthogranulomatous pyelonephritis ▪ Wegener granulomatosis ▪ Sarcoidosis ▪ Fungal disease ▪ Malakoplakia

- **Acute pyelonephritis** produces severe symptoms as the kidneys are actively and aggressively attacked by bacteria. In some cases, bacteria may invade glomerular capillaries resulting in potentially life-threatening sepsis. Kidneys show radiating yellowish gray streaks in pyramids and abscess in cortex. There is moderate hydronephrosis and blunting of renal calyces.
- **Chronic pyelonephritis** results from incompletely treated acute pyelonephritis. The organisms continue to multiply and destroy the renal parenchyma. The process is slow and painless. The net result is permanent damage to kidneys with impaired renal function. Kidneys show wedge-shaped subcapsular scars, thinning of renal parenchyma, blunting of corticomedullary junctions and dilation and fibrosis of renal calyces in majority of cases.

ACUTE PYELONEPHRITIS

Acute pyelonephritis (APN) is inflammation of the renal parenchyma, calyces and pelvis, which often leads to scarring of the kidneys. Vesicoureteral reflux (VUR) with ascending infection is most common cause of acute pyelonephritis.

- Vesicoureteral reflux (VUR) carries infected urine up to the ureters into the renal pelvis and calyces resulting in entry of the bacteria through the papillae into the renal parenchyma. Bacteriuria is a typical finding in patients with acute pyelonephritis. Urinary tract infection is common due to shorter length of the female urethra especially during pregnancy.
- *Escherichia coli* from the feces causes distal colonization in the urethra especially in women due to short urethra.
- Ascending urinary tract infection by *Escherichia coli* is the most common cause of acute pyelonephritis in 85% of cases.

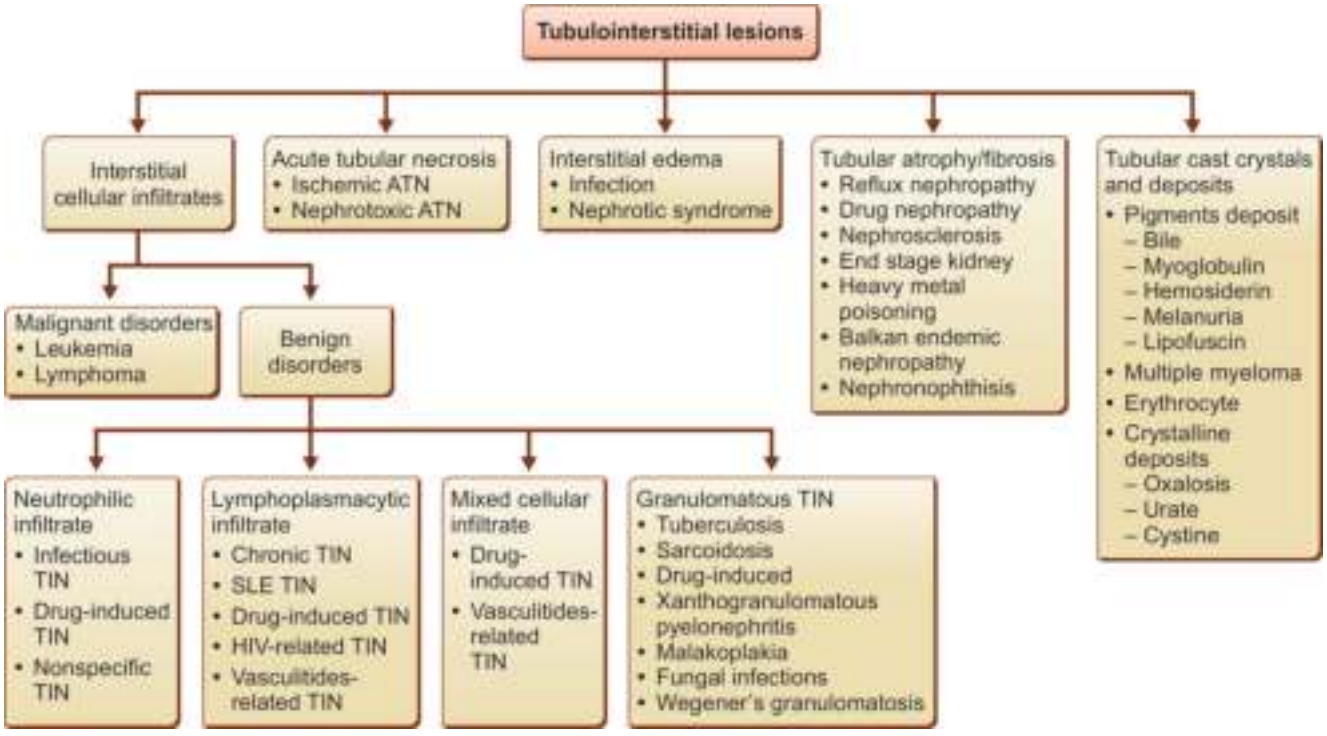

Fig. 22.71: Schematic representation of tubulointerstitial lesions in various renal disorders.

- Other gram-negative organisms include *Proteus vulgaris, Klebsiella pneumoniae*, enterococci, *Streptococcus faecalis*, Serratia, gram-positive pyogenic bacteria may cause acute pyelonephritis through hematogenous dissemination (uncommon cause) in the settings of repeated bacterial infections or hospital-acquired infection. Bacterial infection of the urinary bladder and urethra often precedes acute pyelonephritis.
- Acute pyelonephritis most often occurs in women than men, because women have short urethra injured during sexual intercourse resulting to urethritis and cystitis.

Predisposing Factors

Predisposing factors for acute pyelonephritis include urinary tract obstruction (e.g. calculi, prostatic hypertrophy), renal cystic diseases, diabetes mellitus, medullary sponge of kidney, vesicoureteral reflux (VUR), previous instrumentation of the urinary tract, pregnancy, sickle cell disease, immunosuppression, immunodeficiency, and neurogenic urinary bladder. Diabetic patients with glycosuria are at higher risk for developing acute pyelonephritis.

- **Vesicoureteral reflux (VUR):** Intravesical portion of the ureter is normally compressed during micturition, which prevents reflux of urine into the ureters. In vesicoureteral reflux, the intravesical portion of the ureter is not compressed during micturition, as a result urine refluxes into the ureters during micturition. If vesicoureteral reflux persists, infected urine ascends to the renal pelvis and renal parenchyma resulting in acute pyelonephritis and then progressing to chronic pyelonephritis.
- **Increased residual urine volume:** There is increased incidence of acute pyelonephritis in patients with atonic urinary bladder or flaccid urinary bladder caused by progesterone therapy; in which residual volume of urine is increased (normal residual volume 2–3 ml). Obstruction to urinary outflow due to nodular hyperplasia of prostate is also important cause of acute pyelonephritis.

Clinical Features

Patient with mild acute pyelonephritis may present with acute onset low-grade fever with or without flank pain in the lower back or costovertebral angle, frequent micturition, and voiding small quantity of urine at frequent intervals.

- In severe acute pyelonephritis, patient presents with sudden onset of spiking fever, flank pain, without gross hematuria, chills, nausea, vomiting, increased frequency of urination and painful urination (dysuria) if associated with lower urinary tract infection.
- Patient develops renal insufficiency in patients with bilateral and severe renal involvement with papillary necrosis.

Surgical Pathology: Acute Pyelonephritis

Gross Morphology

- Acute pyelonephritis is often a focal disease, and much of the kidney often appears normal. The kidneys develop grayish white areas of miliary pattern of small cortical microabscesses via hematogenous route in tubular lumens and interstitial tissue of cortex as well as medulla on the subcapsular surface.
- Accumulation of pus in the calyces and pelvis causes obstruction to urine outflow resulting in perinephric abscess in severe cases.
- Extension of suppuration through the renal capsule leads to formation of perinephric abscess.
- The urothelium of the renal pelvis and calyces may be hyperemic and covered by a purulent exudate. Gross morphology of acute pyelonephritis is shown in Fig. 22.72.

Light Microscopy

- Histologic examination shows an extensive neutrophil aggregate in the collecting tubules, collecting ducts lumina in the initial phase. Spillover of suppurative inflammation occurs into the interstitial tissue.
- Acute inflammation in calyceal and pelvic urothelium with occasional mucosal ulceration is present. Renal parenchymal destruction and abscess formation occur in severe cases. The glomeruli and blood vessels are spared initially. More severe inflammation occurs in renal papillae. Renal abscesses are more numerous in the cortex than medulla.
- Emphysematous pyelonephritis is characterized by empty spaces lacking epithelial cell lining distorting parenchyma, vascular thrombosis, ischemic necrosis, suppurative inflammation in adjacent parenchyma, widespread abscesses with papillary necrosis and cortical infarcts.
- Molding of neutrophils forms WBC casts in the tubules, which are passed in the urine along with free neutrophils and bacteria (pyuria). Histology of acute pyelonephritis is shown in Fig. 22.73.

Complications

Patients with acute pyelonephritis develop various complications, i.e. chronic pyelonephritis, pyonephrosis (due to obstruction to urine outflow), perinephric abscess, renal papillary necrosis and septicemia (endotoxic shock).

Laboratory Findings

Microscopic examination of urine reveals WBC casts, pus cells, hematuria and bacteriuria usually *E. coli*. Urine culture in suspected acute pyelonephritis cases is considered as significant, if excess of $(10)^5$ culture

forming units/milliliter is present, which excludes cases of extraneous bacterial contamination. Blood culture is positive in these cases.

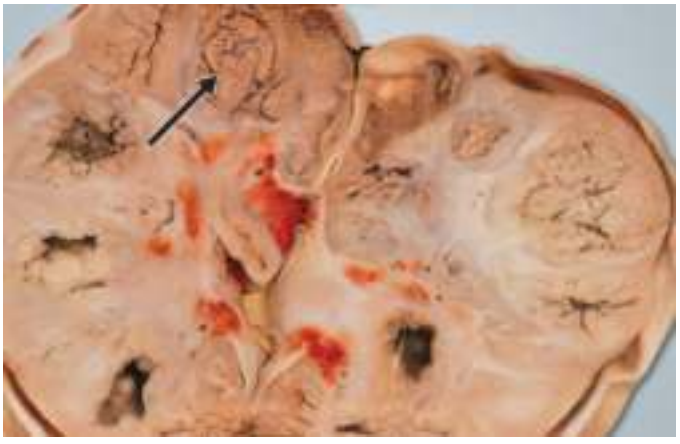

Fig. 22.72: Gross morphology of acute pyelonephritis. Acute pyelonephritis is a common bacterial pus forming infection of the collecting system and renal parenchyma most often occurs in young adult women, diabetics and immunocompromised individuals. *Escherichia coli* is the most common pathogen isolated from urine cultures or pus cultures in almost 70% of cases. Infection usually occurs via ascending route; however, it may also occur via hematogenous route. Signs and symptoms include sudden onset of pain in costovertebral angle, fever, pyuria or white blood cell casts in urine. Cut surface of kidney shows focal gray white, multiple abscesses or wedge-shaped areas of suppuration in the renal parenchyma (arrow). (*Courtesy:* Dr. Sujata Kanetkar, Senior Professor and Head of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

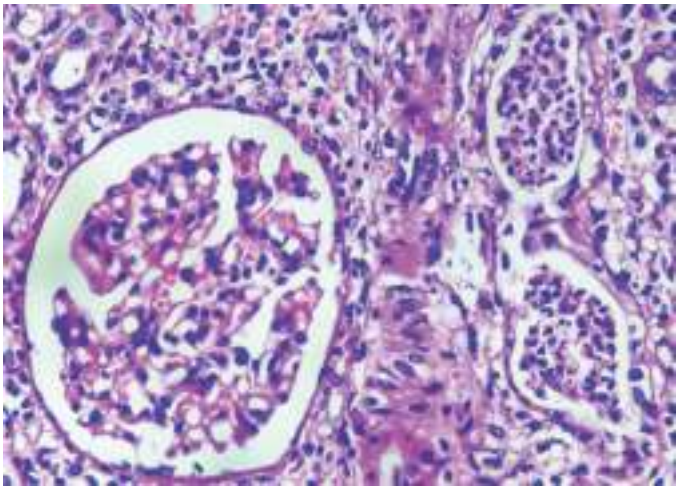

Fig. 22.73: Histology of acute pyelonephritis. Acute pyelonephritis is a common gram-negative bacterial infection of the renal pelvis and kidney in infants, children, women of childbearing age. Causative gram-negative organisms include *Escherichia coli*, Proteus, Klebsiella and Enterobacter from fecal flora. Patient presents with fever, chills, pain in groin region, nausea, vomiting, cloudy foul-smelling urine and frequent painful urination. Hematoxylin and eosin-stained renal tissue section shows patchy suppurative inflammation, primarily involving cortical region with edema, neutrophils in interstitium and tubular lumina, and also cortical abscess and necrosis (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

CHRONIC PYELONEPHRITIS

In chronic pyelonephritis, pathologic changes in the kidney occur as a result of recurrent and persistent ascending bacterial infection from urethritis or cystitis especially in young girls, secondary to vesicoureteral reflux (VUR), intrarenal reflux and urinary tract obstruction, which is termed reflux nephropathy. Inflammation usually affects one kidney causing small asymmetric contraction with scarred surface. The patient is usually asymptomatic.

Pathophysiology

Vesicoureteral reflux and urinary tract obstruction play key role in the pathogenesis of chronic pyelonephritis.

Vesicoureteral Reflux

Micturition is the process of emptying urine from urinary bladder. VUR is a condition in which urine flows backward from the urinary bladder to one or both ureters and sometimes to kidneys. Persons with VUR, the intravesical portion of the ureter is not compressed during micturition, as a result urine refluxes into the ureter, renal pelvis and renal parenchyma resulting in acute pyelonephritis and then progressing to chronic nonobstructive pyelonephritis. VUR targets children under 5 years of age due to an incompetent uretero-vesical junction.

Urinary Tract Obstruction

Obstruction may occur anywhere in the urinary system (e.g. renal tubules, renal pelvis, ureters, urethra, prostate, and bladder). Obstructive causes of obstructive uropathy in men are urinary bladder carcinoma, benign nodular hyperplasia of prostate, neurogenic bladder (e.g. spinal cord damage), and urethral stricture as a consequence of chronic urethritis. Pathologic changes in kidney occurs secondary to chronic obstruction to the urinary outflow leading to hydronephrosis.

- **Age group:** In children, the condition is most often congenital (e.g. posterior urethral valves and urethral strictures, ureteropelvic obstruction) and congenital ureteric abnormality (ureterocele). In adults, the condition is most often acquired as a result of urethral and ureteral strictures (instrumentation, radiation and inflammation), urinary tract tumors. In elderly persons, urinary tract obstruction occurs due to prostatic hyperplasia, prostatic cancer and nephrolithiasis.
- **Causes of obstruction:** Renal causes of obstructive uropathy include staghorn calculus, transitional cell carcinoma of renal pelvis and atrophic scarred cortex. Ureteric causes of obstructive uropathy include ureteral stone, transitional cell carcinoma, retroperitoneal fibrosis, surgical scars, and necrotic debris. Extrinsic obstructive causes of urinary tract

include pregnancy, endometriosis, and cervical carcinoma in women.

- **Pathologic renal changes:** Obstruction to urinary flow is associated with inflammation and dilatation of the ureter and renal pelvis, calyces especially polar compound papillae containing straight ducts with absence of valve-like action. Increased pressure in the urinary tract, reflux of urine with leakage into the interstitium, and ischemia of the inner medulla are key factors promoting renal atrophy, and diffuse U-shaped cortical fibrosis and scarring in renal polar areas.
- **Imaging technique:** Pathologic changes such as generalized atrophy of the kidney and dilatation of all portions of renal pelvis are visible with an intravenous pyelography (IVP) in chronic obstructive pyelonephritis. Treatment and prognosis depend on degree and chronicity of the obstruction.
- **Complications:** Complications of obstructive uropathy with urolithiasis are hydronephrosis, renal colic and superadded infection. Hydronephrosis leads to dilatation of the renal pelvis, collecting ducts, proximal and distal convoluted tubules. Calyces undergo atrophic changes and flattening with variable degrees of compression atrophy of the cortex and medulla. Loss of nephrons is accompanied by tubulointerstitial fibrosis.

Schematic representation of obstructive nephropathy is shown in Fig. 22.74. Causes of obstructive uropathy is given in Table 22.53. Schematic representation

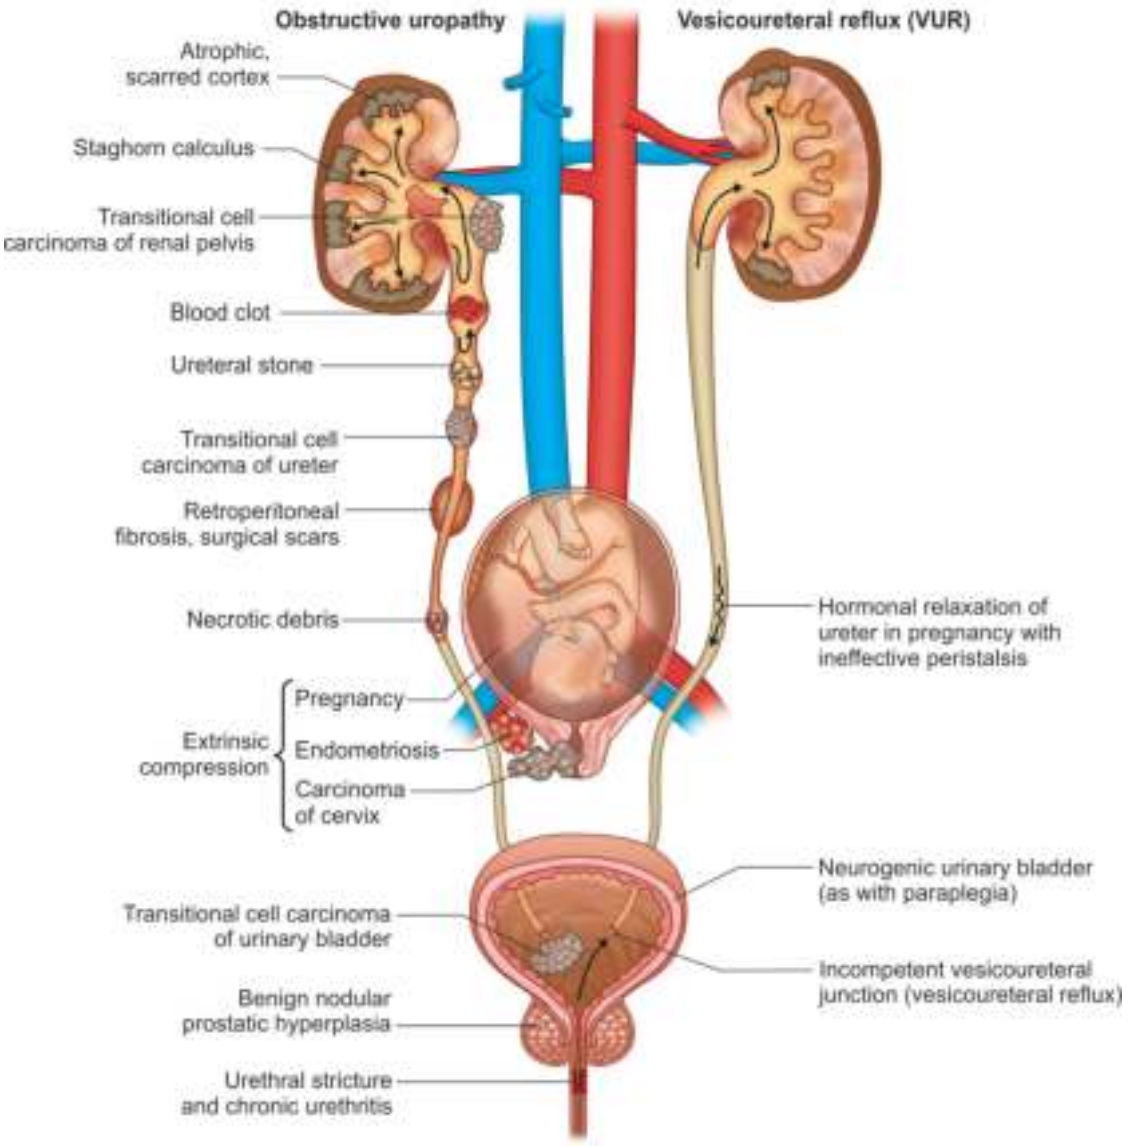

Fig. 22.74: Schematic representation of obstructive nephropathy. Obstructive uropathy is a disorder of the urinary tract that occurs due to obstruction in urinary flow and can be structural or functional. The back flow of urine into the unilateral or bilateral kidneys, depending on the location of the obstruction leads to hydronephrosis.

Table 22.53 Causes of obstructive uropathy

Renal Pelvis Obstruction
▪ Renal calculi
▪ Papillary necrosis
Ureter Obstruction
▪ Renal calculi
▪ Pregnancy
▪ Tumors that compress the ureter (ureteral stricture)
▪ Congenital disorders of the ureterovesical junction and ureteropelvic junction strictures
Urinary Bladder Obstruction
▪ Urinary bladder cancer
▪ Neurogenic urinary bladder
▪ Urinary bladder calculi
▪ Prostatic hyperplasia or prostate cancer
Urethra Obstruction
▪ Urethral strictures
▪ Congenital urethral defects

of chronic nonobstructive pyelonephritis is shown in Fig. 22.75. Schematic representation of vesicoureteral reflux (VUR) and role of chronic pyelonephritis is shown in Fig. 22.76. Comparison between chronic pyelonephritis and chronic glomerulonephritis is given in Table 22.54.

Clinical Features

Clinical presentation of chronic pyelonephritis is dependent on age and presence of prior diagnosis of urinary tract infections and vesicoureteral reflux.

- Patient presents with episodic manifestations of urinary tract infection or acute pyelonephritis, such as recurrent fever and flank pain.
- Bilateral involvement of kidneys leads to gradual loss of renal functions. Children with reflux nephropathy develop flank pain and other vague signs of inflammation, with or without hypertension and proteinuria resulting in chronic renal insufficiency.
- Radiologic findings show scars at the upper and lower poles of the kidney and dilatation of the renal pelvis. Prevention of recurrent urinary tract infections and surgical correction of severe vesicoureteral reflux in children can decrease the incidence of renal scarring.

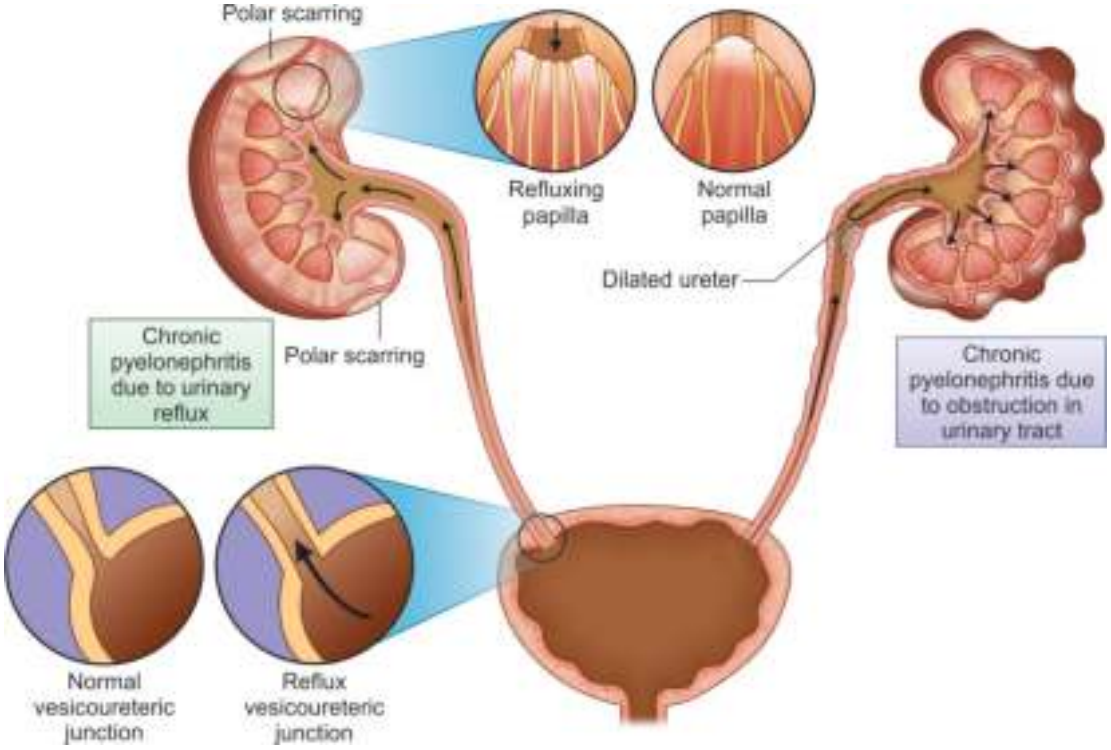

Fig. 22.75: Schematic representation of chronic nonobstructive pyelonephritis. Chronic pyelonephritis is characterized by renal inflammation and marked destruction of renal parenchyma due to recurrent or persistent infection of renal parenchyma, vesicoureteral reflux (VUR), anatomical anomalies or other causes of urinary tract obstruction such as strictures and calculi. Obstruction of the urinary tract leads to high pressure backflow of urine leading to destruction of all papillae in renal parenchyma. It leads to diffuse scarring at the poles of the kidney and thinning of overlying cortex.

Surgical Pathology: Chronic Pyelonephritis

Gross Morphology

- Renal parenchyma in chronic pyelonephritis is firm due to extensive fibrosis. External surface reveals broad asymmetric U-shaped scars involving cortex and medulla especially in upper pole well demarcated from the normal parenchyma.
- In chronic obstructive pyelonephritis, there is diffuse dilatation of the collecting system with occasional stones in the pelvis and calyces. Coarse scars are demonstrated on the cortical surface.
- Cut surface shows severe renal parenchymal thinning, deformity of the renal pelvis and calyces beneath the scars. Gross morphology of chronic obstructive pyelonephritis and hydronephrosis is shown in Fig. 22.77.

Light Microscopy

- Histologic examination of nephrectomy specimen shows scars consisting of a demarcated zone of diffuse atrophy of the renal parenchyma and loss of tubules, interstitial fibrosis, diffuse glomerulosclerosis, and interstitial inflammation as a result of lymphocytes and plasma cells infiltrate. Inflammation with lymphoid follicles beneath the urothelial lining of the renal pelvis suggests chronic inflammation. Scars are deep and involving renal medullary region in the upper and lower poles.
- Atrophic tubules contain eosinophilic proteinaceous casts, the resultant similarity in appearance to thyroid follicles is referred to as thyroidization. 'Thyroidization of the renal tubules' is characteristic finding but not pathognomonic.
- Thyroidization of tubules is less developed in chronic obstructive pyelonephritis. Inflammation with lymphoid follicles and neutrophils are present beneath the renal pelvis and urothelial lining in chronic obstructive pyelonephritis.
- Arteriosclerosis and hyaline arteriosclerosis are frequent when hypertension is present. Secondary focal segmental glomerulosclerosis and segmental renal dysplasia can be observed. Arteries can show endarteritis with narrowing of the lumen and fibrosis of media. Histology of chronic pyelonephritis is shown in Figs 22.78 to 22.80.

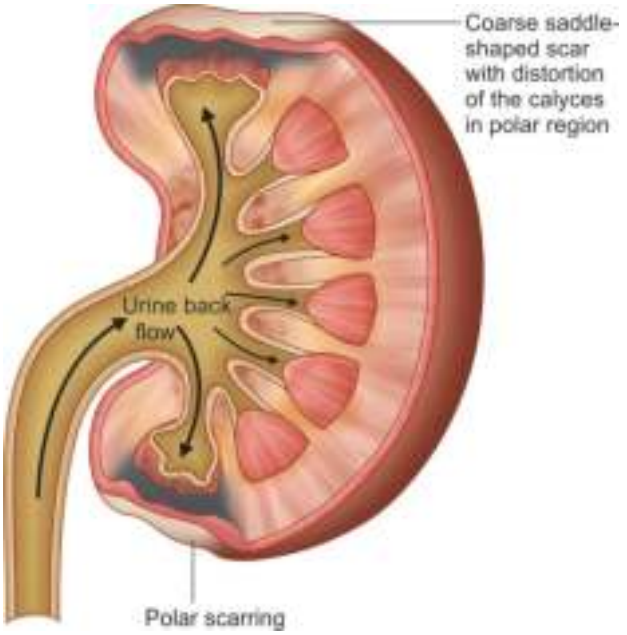

Fig. 22.76: Schematic representation of vesicoureteral reflux (VUR) and role of chronic pyelonephritis. Chronic pyelonephritis is characterized by renal inflammation with marked destruction of renal parenchyma and dilatation of the calyces resulting from previous infection induced by recurrent or persistent infection of renal parenchyma, vesicoureteral reflux, anatomical anomalies and urinary tract obstruction. VUR is a condition in which urine flows background from the urinary bladder to one or both ureters and sometimes to the kidneys leading to cause infection in the compound papillae located on the poles and then undergoing fibrosis. Note the relationship of the coarse saddle-shaped scars with distortion of the calyces.

Table 22.54 Comparison between chronic pyelonephritis and chronic glomerulonephritis

Parameters	Chronic Pyelonephritis	Chronic Glomerulonephritis
Gross morphologic features		
Kidney involvement	Unilateral involvement with coarse scars at poles	Bilateral involvement with diffuse granularity
Kidney contraction	Marked contraction	Moderate contraction
Histologic features		
Glomeruli involved	Patchy involvement	Diffuse involvement
Glomerular tuft proliferation	Absent	Present
Glomerular tuft thickening	Rare	Present
Changes in the Bowman's space	Relatively greater	Not usually present
Tubular loss relation to sclerosed glomeruli	Tubular loss not only confined to glomeruli	Tubular loss confined to glomeruli
Tubulointerstitial fibrosis	Coarse	Fine
Chronic inflammatory infiltrate	Marked	Less
Renal pelvis inflammation	Usually inflamed	Seldom inflamed
Vascular changes	Marked	Moderate
Necrotizing papillitis	Present	Absent

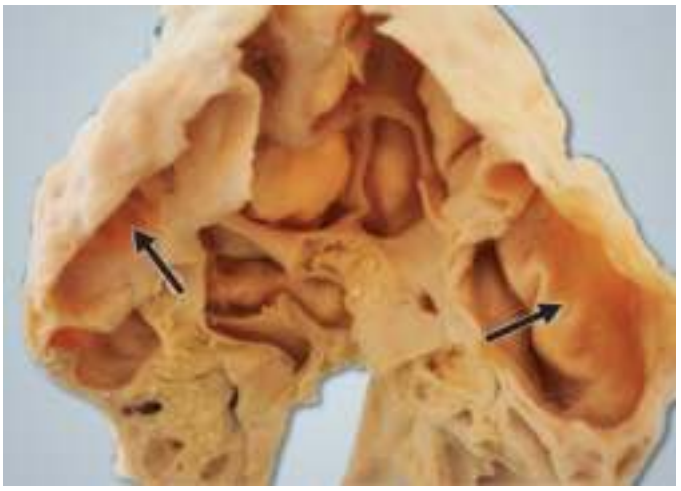

Fig. 22.77: Gross morphology of chronic obstructive pyelonephritis and hydronephrosis. Chronic pyelonephritis is defined as the marked reduction in kidney size, with marked destruction of renal parenchyma and dilatation of calyces forming cysts from previous persistent or recurrent infection. Cut surface shows marked dilatation of calyces caused by inflammatory destruction of papillae, with atrophy and scarring of the overlying cortex (arrows). (*Courtesy:* Dr. Sujata Kanetkar, Senior Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

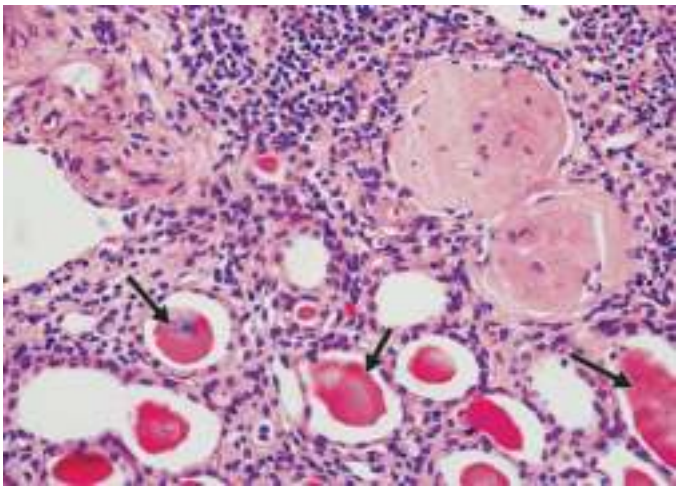

Fig. 22.78: Chronic pyelonephritis. Chronic pyelonephritis is characterized by tubulointerstitial nephritis, renal scarring with severe involvement of calyces and pelvis due to recurrent bouts of acute pyelonephritis. Hematoxylin and eosin-stained renal tissue section shows tubular thyroidization (filled with colloid casts), tubular atrophy, interstitial fibrosis and lymphocytes and plasma cells infiltrate in the interstitium, obliterative endarteritis of renal blood vessels and glomerulosclerosis (arrows) (400X).

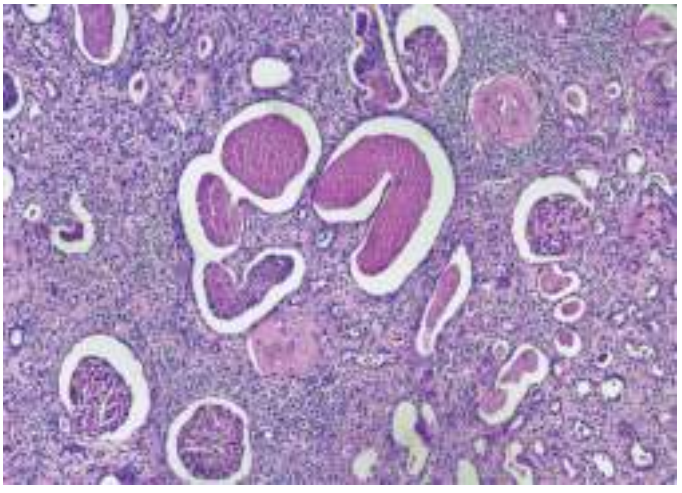

Fig. 22.79: Histology of chronic pyelonephritis. Chronic pyelonephritis is tubulointerstitial inflammation and renal scarring with severe involvement of calyces and pelvis. Patients may be asymptomatic, however can present with fever, malaise and flank pain. Diagnosis is with urine analysis, culture and imaging techniques. Hematoxylin and eosin-stained renal tissue section examination shows tubular thyroidization (filled with colloid casts), tubular atrophy, interstitial fibrosis and intense dense inflammation (numerous lymphocytes and plasma cells), obliterative endarteritis of blood vessels and interstitial Tamm-Horsfall protein. Normal glomeruli are observed in early disease course (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

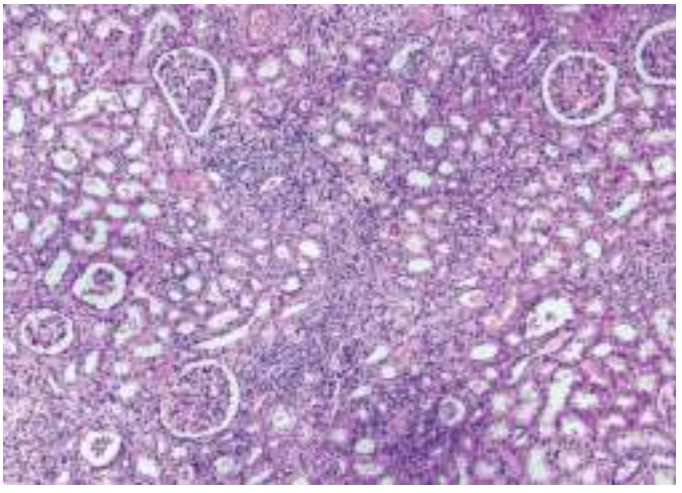

Fig. 22.80: Histology of chronic pyelonephritis. Chronic pyelonephritis is characterized by renal inflammation and scarring induced by recurrent or persistent renal infection in the settings of vesicoureteral reflux, urinary obstructions and major anatomic anomalies. It is more common in children than in adults. Hematoxylin and eosin-stained renal tissue section examination shows tubular thyroidization (filled with colloid casts), tubular atrophy, interstitial fibrosis and intense dense inflammation (numerous lymphocytes and plasma cells), obliterative endarteritis of blood vessels and interstitial Tamm-Horsfall protein. Normal glomeruli are observed in early disease course (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

XANTHOGRANULOMATOUS PYELONEPHRITIS

Xanthogranulomatous pyelonephritis is a destructive granulomatous inflammatory process of renal parenchyma resulting from long-standing urinary tract obstruction usually associated with staghorn calculus together with chronic infection with *Proteus mirabilis* and *Escherichia coli*.

- Sometimes long-standing infection may be localized by forming a destructive mass-like renal lesion. It

can be grossly and microscopically mistaken as clear cell variant of renal cell carcinoma.

- Xanthogranulomatous pyelonephritis usually affects 70% of middle-aged females. Urine cultures most frequently show *Escherichia coli* and *Proteus mirabilis*.
- Patient presents with pain and mass in the abdomen, lower urinary tract symptoms with gross hematuria and pyuria. Nephrectomy is curative for xanthogranulomatous pyelonephritis.

Surgical Pathology: Xanthogranulomatous Pyelonephritis

Gross Morphology

The kidney is enlarged with hydronephrosis. Renal pelvis contains calculi with characteristic 'staghorn' appearance, or some other evidence of obstruction. Cut surface reveals single or multiple yellow to orange nodules, which may mimic tumor nodules.

Light Microscopy

- In xanthogranulomatous pyelonephritis, the xanthogranulomatous inflammation is made up of mixed histiocytes with clear or foamy cytoplasm typically admixed with lymphocytes, plasma cells and multinucleated giant cells.
- Xanthogranulomatous nodules can have a zonal pattern with a central zone of neutrophils and necrosis rimmed by foamy histiocytes and fibroblastic response at the periphery. The pathologic changes include variable degree of renal tubular atrophy, tubular dilatation, squamous metaplasia of the urothelium, microabscesses and lymphoid follicle formation.
- The vascular stroma characteristic of clear cell variant of renal cell carcinoma is missing in xanthogranulomatous pyelonephritis.

Differential Diagnosis

- Xanthogranulomatous pyelonephritis should be differentiated from clear cell renal cell carcinoma for lipid-laden xanthomatous cells, sarcomatoid renal cell carcinoma and malakoplakia.
- Clear cell renal cell carcinoma has water clear cytoplasm, and is positive for cytokeratin and vimentin but negative for CD68.
- Sarcomatoid renal cell carcinoma is composed of prominent spindle cell proliferation or significant cytologic atypia in spindle cells. Epithelial component may be present.
- Malakoplakia is composed of eosinophilic histiocytes with Michaelis Guttmann bodies. Histology of xanthogranulomatous pyelonephritis is shown in Fig. 22.81.

TUBERCULAR PYELONEPHRITIS

Urogenital tuberculosis represent 25% extrapulmonary cases. Renal involvement in tuberculosis can be part of disseminated infection or localized genitourinary infection, which can evolve to pyonephrosis. Tubercular infection generally disseminates from the ureter to the urinary bladder causing granulomatous inflammation and fibrosis. Most patients have sterile pyuria which can be accompanied by microscopic hematuria. Urine analysis reveals acidic pH, proteinuria and pus cells.

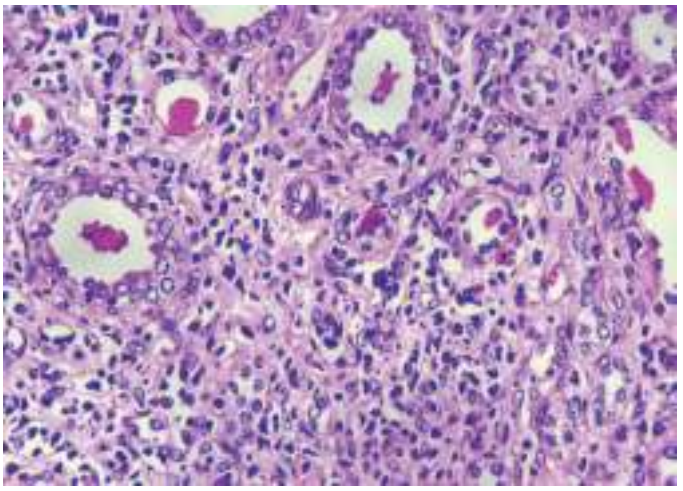

Fig. 22.81: Histology of xanthogranulomatous pyelonephritis. Xanthogranulomatous pyelonephritis is destructive inflammatory process that may complicate chronic pyelonephritis due to *Escherichia coli* and Proteus or nephrolithiasis, but resembling renal cell carcinoma. Xanthogranulomatous pyelonephritis is associated with pelvicalyceal obstruction and ulceration. Multiple yellow nodules are formed around calyces. Hematoxylin and eosin-stained renal tissue section shows replacement of renal parenchyma with CD68+ foamy histiocytes, occasional multinucleated giant cells and inflammatory cells (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Fig. 22.82: Gross morphology of tubercular pyelonephritis. Fibrous-walled abscess cavity filled with caseous material is shown on cut surface. This patient had a previous well-established history of pulmonary tuberculosis. Section from the patient's nephrectomy specimen shows a tuberculous granuloma, with central caseating necrosis and peripheral scarring (arrows). (*Courtesy:* Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

Surgical Pathology: Tubercular Pyelonephritis

Gross Morphology

Kidneys are enlarged. Cut surface reveals caseous material filling the renal pelvis. Gross morphology of tubercular pyelonephritis is shown in Fig. 22.82.

Light Microscopy

Tubercular pyelonephritis is characterized by a granulomatous reaction with epithelioid cell granulomas surrounding caseous necrosis material and Langhans' giant cells. Fibrosis and interstitial inflammation with lymphocytes and plasma cells are also observed around foci of caseous necrosis.

URATE NEPHROPATHY

Any condition associated with elevated levels of uric acid in the blood results in deposition of urate crystals in the tubules and interstitium, which is known as urate nephropathy.

- **Acute urate nephropathy:** Acute urate nephropathy occurs due to massive release of nucleic acid purines (uric acid) following aggressive treatment with allopurinol of disseminated hematolymphoid neoplasms (e.g. leukemia and lymphoma) resulting in increased serum uric acid level. Urate crystals are deposited in the renal tubules and interstitial tissue.
- **Chronic urate nephropathy:** Chronic urate nephropathy is characterized by deposition of crystalline monosodium urate in renal tubules and interstitial tissue in the medulla, forming pale yellowish '**tophi**' with surrounding foreign body inflammation, mononuclear cell infiltrates, and fibrosis. Patients with hyperuricemia may also develop nephrolithiasis with uric acid stones.

RENAL PAPILLARY NECROSIS

Renal papillary necrosis is characterized by coagulative necrosis involving papillae of renal medulla, classically associated with many underlying conditions, all of which predispose the patient to renal medullary ischemia.

- Majority of cases have one or more underlying predisposing factors such as chronic analgesic ingestion (acetaminophen, phenacetin, COX2 inhibitors), sickle cell anemia, diabetes mellitus, urinary tract obstruction/infection, vasculitis, tuberculosis, renal allograft and hepatocellular failure.
- Patient develops polyuria owing to an inability to concentrate urine, hematuria, renal colic resulting from renal papillae sloughing and urinary tract infection. Renal failure can rarely occur. Clinical course varies depending on underlying condition and number of renal papillae involvement.

Surgical Pathology: Renal Papillary Necrosis

Gross Morphology

Cut surface of kidney reveals necrotic medullary pyramids. Features of obstruction and fragments of sloughed papillae and calyces are possible present.

Light Microscopy

- Histologic examination in renal papillary necrosis reveals papillae showing geographic coagulative necrosis with ghosts of tubules visible. It shows overlying cortical atrophy, interstitial fibrosis and chronic inflammation. Distribution and duration of renal papillary necrosis vary due to underlying cause.
- In analgesic abuse induced renal papillary necrosis in various stages of progression, cut surface shows variable-sized foci of geographic necrosis, dystrophic calcification and sloughing of renal papillae.
- In diabetes mellitus induced renal papillary necrosis, all the renal papillae are at the same stage of acute coagulative necrosis, but dystrophic calcification is rare.
- In sickle cell disease or trait, only a few renal papillae may be focally affected, but dystrophic calcification is rare. In cases with urinary tract infection and obstruction, acute inflammation may indicate an underlying infection.

ACUTE INTERSTITIAL NEPHRITIS

Acute interstitial nephritis (AIN) is a clinicopathologic entity characterized by inflammation in the renal interstitium with various etiologies, often secondary to cell-mediated immune response to a drug acting as hapten. AIN is most common type of drug-induced kidney injury.

- AIN is characterized histologically by infiltrates of activated lymphocytes (T cells) and eosinophils in the renal interstitium, a pattern that indicates a type 4 cell-mediated immune reaction. Presence of eosinophilia and eosinophiluria indicates a type 1 hypersensitivity response. Urine analysis shows mild to moderate proteinuria, hematuria, and eosinophiluria (eosinophils in the urine). Withdrawal of the drug causes reversal of the disease.
- The most frequently implicated drugs in the pathogenesis of AIN include penicillin (particularly methicillin), rifampicin, sulfonamides, nonsteroid anti-inflammatory drugs (NSAIDs), allopurinol, and diuretics (thiazides, furosemide). AIN occurs two weeks after beginning a drug. Withdrawal of the drug usually results in reversal of the disease associated with excellent prognosis.
- Patient presents with classic triad: abrupt onset of fever, skin rash and eosinophilia with rapidly progressive acute renal failure, approximately 2 weeks following exposure to the drug administration. Eosinophilia and eosinophiluria are highly predictive. Renal functions are impaired with increased blood urea and serum creatinine. Hematuria, mild proteinuria and sterile leukocyturia are usually present.

Pathology Pearls: Analgesic Interstitial Nephritis

- Analgesic nephropathy is a common cause of chronic drug-induced interstitial nephritis. It is more common in women than men associated with chronic pain.
- The combination of acetaminophen (a metabolite of phenacetin) and aspirin in the setting of a patient (usually a woman) with chronic headache or pain is responsible for most cases.
- A cumulative analgesic ingestion of 3 kg or daily consumption of 1 g/day (>2 kg) over a span of 3 years is sufficient to produce analgesic interstitial nephritis.
- Complications of analgesic interstitial nephritis include renal papillary necrosis, hypertension, renal stones, hematuria, accelerated atherosclerosis, urothelial bladder transitional cell carcinomas (very high risk), tubulointerstitial fibrosis, and end stage renal disease are potential complications.

Pathogenesis

- Acetaminophen forms oxygen-derived free radicals, which bind with the renal tubular cells and cause oxidative cellular damage of renal tubules in the medulla.
- While aspirin inhibits prostaglandin synthesis, hence eliminating the vasodilator effects of prostaglandins.
- Vasoconstriction of renal vessels causes ischemic injury (coagulation necrosis) in the renal medullary papillae and tubulointerstitial fibrosis.
- Patient develops papillary necrosis of some or all papillae, which appears pale white infarcts. Sloughing of the necrosed renal papillae (renal papillary necrosis) is associated with gross hematuria, proteinuria, and colicky flank pain. An intravenous pyelogram reveals a ring defect where one or more renal papillae used to reside.
- Papillary necrosis may also occur in sickle cell anemia, diabetes mellitus, acute pyelonephritis, and obstructive uropathy.

Light Microscopy

Renal interstitial tissue is infiltrated by lymphocytes, plasma cells, macrophages, eosinophils and neutrophils. Eosinophils are frequently observed in drug-induced allergic acute interstitial nephritis, but represent a minor component of the inflammatory infiltrate. Tubulitis is common finding during active phase. Some degrees of tubular injury (tubular necrosis) can be found. Granulomatous inflammation is sometimes predominant.

LIGHT CHAIN CAST NEPHROPATHY IN MULTIPLE MYELOMA

Light chain cast nephropathy is the most common cause of death in multiple myeloma. Bence Jones proteins are the light chain of immunoglobulin filtered through the glomeruli, which are toxic to the tubules.

- At acidic pH of urine, the light chains of Bence Jones protein bind to Tamm-Horsfall glycoproteins synthesized by distal tubular epithelial cells and form casts in tubules. These casts in the tubules cause obstruction to urinary flow in the tubules. In some instances, the deposits of light chains do not become fibrillar and transform into AL amyloid.
- Nevertheless, these light chain deposits damage the glomerular basement membrane (GBM) and tubular basement membranes and cause renal failure. Hypercalcemia in multiple myeloma patient leads to nephrocalcinosis and urolithiasis.
- Light chain cast nephropathy may manifest either acute or chronic renal failure. Proteinuria is most often present in variable range (nephritic or nephrotic range).
- If patient presents with proteinuria in nephrotic range, AL amyloidosis or light chain deposition disease is more likely than light chain cast nephropathy.

Pathology Pearls: Light Chain Cast Nephropathy in Multiple Myeloma

Light Microscopy

- In light-chain cast nephropathy, tubular lesions show numerous dense hyaline casts in the distal tubules and collecting ducts in light chain cast nephropathy in multiple myeloma. These casts are brightly eosinophilic with angulated borders, which induce foreign body reaction, characterized by multinucleated giant cells and macrophages.
- Interstitial tissue is infiltrated by chronic inflammatory cells. More chronic lesions show tubular atrophy and interstitial fibrosis. Focal deposition of calcium is demonstrated in interstitial tissue.

Immunohistochemistry Technique

Immunohistochemical staining reveals that the casts containing light chains and Tamm-Horsfall glycoproteins.

RENAL TUBULAR FUNCTIONAL DISORDERS

FANCONI SYNDROME

Fanconi syndrome refers to generalized dysfunction of the proximal renal tubules, which may be hereditary or acquired. Patient has impaired absorption of glucose, amino acids, bicarbonate and phosphates. Patient presents with glycosuria, increased excretion of phosphates with decreased blood level of phosphates, amino acids and systemic acidosis.

CYSTINURIA

Cystinuria is an autosomal recessive disorder (few cases of autosomal dominant disorder) characterized by an inborn error of amino acid metabolism leading to excessive excretion of cystine due to defective reabsorption in renal proximal tubules.

- Cystinuria occurs due to mutations in the genes that encode the two subunits (neutral and basic amino

acid transport protein rBAT and b (0,+) amino acid transporter 1) of the amino acid transport system. Error in amino acid metabolism results in excess of cysteine in the urine associated with cysteine stones in urinary tract. The clinical symptoms of cystinuria are caused by the loss of poorly soluble cystine, which precipitates to form cystine stones in urinary tract. Most kidney stones are completely silent.

- Patient with large renal stones presents with an abrupt onset of severe, colicky pain in the flank radiating to the groin; and associated with either microscopic or macroscopic hematuria.

HARTNUP DISEASE

Hartnup disease is an autosomal disorder caused by the defective transport of neutral amino acids due to mutation in the neurotransmitter SLC6A19 in the small intestine and the renal proximal tubules. The abnormal urinary loss of tryptophan, a precursor of niacin leads to nicotinamide deficiency. Patient presents with pellagra-like skin eruptions, cerebellar ataxia, emotional instability and gross aminoaciduria.

NEPHROCALCINOSIS

Hypercalcemia may cause nephrocalcinosis or nephrolithiasis or urolithiasis. Nephrocalcinosis is a disorder in which there is too much calcium deposition in renal parenchyma and tubules with or without hypercalcemia. The disorders that can cause nephrocalcinosis include Alport syndrome, Bartter syndrome, medullary sponge renal disease, primary hyperoxaluria, renal tubular acidosis, renal transplant rejection and familial hypomagnesemia.

- Nephrocalcinosis is common in premature babies. In patients with nephrocalcinosis, extent of calcium deposition in renal parenchyma and tubules varies from microscopic to grossly visible demonstrated on abdominal radiographs.
- Majority of cases remain asymptomatic. Some cases have impaired concentrating ability of kidneys, however patients do not progress to end stage severe renal disease.
- In hypercalcemia, deposition of calcium in renal parenchyma is an example of metastatic calcification, in contrast to dystrophic calcification demonstrated at the site of renal parenchyma injury due to infarcts or cortical necrosis.
- Hypercalcemia due to primary hyperparathyroidism results in calcium deposition in renal parenchyma, which shows wedge-shaped scars interspersed with relatively normal renal tissue. These renal scars are composed of parenchymal atrophy and interstitial fibrosis. Etiology of hypercalcemia leading to nephrocalcinosis is given in Table 22.55.

Pathology Pearls: Nephrocalcinosis

Light Microscopy

- Basement membrane of renal tubules especially proximal tubules shows deposition of calcium. Calcium deposition also occurs in the cytoplasm of tubules and interstitial tissue.
- Tubular epithelial cells laden with calcium slough into the lumina in the form of aggregates as calcified casts. Scattered glomeruli show calcification in Bowman's capsule.
- Intrarenal arteries may also show calcification. Calcium deposits appear deeply basophilic in hematoxylin and eosin sections and black with von Kossa stain.

Electron Microscopy

Mitochondria of tubular epithelial cells contain abundant calcium deposits.

Table 22.55 Etiology of hypercalcemia leading to nephrocalcinosis

Increased Calcium Level due to Bone Resorption
▪ Primary hyperparathyroidism
▪ Renal osteodystrophy
▪ Neoplasms synthesizing parathormone or parathormone-like protein and metastases
Increased Intestinal Absorption of Calcium
▪ Milk-alkali syndrome
▪ Vitamin D excess
▪ Idiopathic hypercalcemia
▪ Sarcoidosis

UROLITHIASIS

Urolithiasis refers to the presence of stones in the kidneys, renal pelvis and calyces affecting both men and women. Ureterolithiasis refers to the presence of stones in the ureter. Urolithiasis refers to stones originating anywhere in the urinary system such as renal calyces, renal pelvis and urinary bladder in 80% of cases.

- Stone growth in urinary system starts with the formation of crystals of supersaturated urine which then adhere to the urothelium, thus creating the nidus

for subsequent stone growth in the setting of low urine volume and deficiency of urolithiasis inhibitors in urine such as pyrophosphate, diphosphonate, citrate, glycosaminoglycans and nephrocalcin, which prevent urolithiasis. Hypercalciuria promotes calcium oxalate/phosphate renal stones. Excessive intake of dairy products rich in oxalates and phosphates causes stone formation. Hydration prevents supersaturation of urinary solutes (e.g. calcium, oxalate, uric acid). Citrate chelates calcium constituent in urine, which binds calcium ions to form soluble complexes and thus decrease the free ion activity of unbound citrate and calcium.

- Recurrent urinary tract infection caused by urea splitting organisms such as *Proteus vulgaris*, *Klebsiella* species and Staphylococcus make the urine alkaline resulting in precipitation of ammonium magnesium phosphate stones known as staghorn stones filling entire renal pelvis and calyceal system.
- Renal stone requires a nidus to form, which comprises mucoprotein matrix (3–5%) and aggregated material derived from precipitation of urinary solutes, which constitutes 95–98% of the stone mass. Mucoprotein matrix of renal stones is composed of lipids, glycosaminoglycans (GAGs) and proteins (e.g. Tamm-Horsfall proteins, nephrocalcin, osteopontin, urinary prothrombin fragment 1, inter-alpha inhibitor, calgranulin, renal lithostathine, albumin, human urinary trefoil factor 1, hyaluronic acid, annexin II, CD44, matrix G1a protein, and monocyte chemoattractant protein 1).
- In most cases, the presence of a urinary stone is associated with an increased blood level and urinary excretion of its principal component. More than 90% of stones are radiodense on KUB radiographs.
- Complications of urolithiasis include acute kidney disease secondary to obstruction, anuria, urinary tract infection with renal obstruction and sepsis.
- Patient with renal stone presents with excruciating pain caused by acute distension of the ureter, usually by the transit of a small stone. Superadded infection is localized proximal to the site of obstruction, which may lead to infection of the renal parenchyma. Various cellular and extracellular molecular events during nephrolithiasis are given in Fig. 22.83.

Pathology Pearls: Risk Factors for Urolithiasis

- Anatomic anomalies of urinary tract (e.g. horseshoe kidney, ureteral structure)
- Family history of urinary tract stones
- Gout
- Hyperparathyroidism
- Relative dehydration, low urine volume, and deficiency of citrate in urine
- Metabolic disorders (e.g. hypercalciuria, hyperuricosuria, chronic metabolic acidosis)
- Cystinuria (an autosomal recessive inherited disorder)
- Drugs (e.g. diuretics and calcium/vitamin D supplements)
- Diet rich in oxalate (dairy products), urate, sodium and animal protein
- Obesity related nephrolithiasis

Pathology Pearls: Promoters and Inhibitors of Nephrolithiasis

Nephrolithiasis Promoters	Nephrolithiasis Inhibitors
▪ Calcium oxalate ▪ Calcium phosphate ▪ Sodium (promotes calcium absorption) ▪ Urate ▪ Low-urine volume ▪ Low-urine pH <5	▪ Citrate ▪ Magnesium ▪ Pyrophosphate ▪ Glycosaminoglycans ▪ Osteopontin ▪ Nephrocalcin ▪ High urine volume

Calcium phosphate and calcium oxalate aggregation are glycosaminoglycans, pyrophosphate and citrate.

MOLECULAR PATHOGENESIS OF UROLITHIASIS

Supersaturation of stone forming salts/solutes in urine is essential and excess of these salts by itself will not promote stone formation. The pathogenesis of calcium oxalate stone formation in the urinary tract is a multistep process and essentially includes nucleation, crystal growth, crystal aggregation and crystal retention.

- Promoters facilitate the stone formation while inhibitors prevent it. Besides low urine volume and low urine pH, high calcium oxalate, calcium phosphate, sodium, urate and cysteine also known to promote stone formation.
- High urine volume and many inorganic and organic substances such as citrate, magnesium pyrophosphate, diphosphonate, glycosaminoglycans, osteopontin, nephrocalcin are known to inhibit stone formation. Hydration prevents supersaturation of urinary solutes (e.g. calcium, oxalates, uric acid). Citrate chelates calcium constituent in urine. We shall discuss mechanism of stone formation and the role of promoters/inhibitors in crystallization.
- Upregulation of urolithiasis promoters and downregulation of urolithiasis inhibitors leads to stone formation within collecting system of kidney.
- Concentration of urinary urolithiasis promoters and inhibitors is influenced and regulated by both intestinal and renal transporters (gastrointestinal tract–renal axis). SLC26A1 gene encodes anion exchanger protein. SLC26A1 gene mutation causes

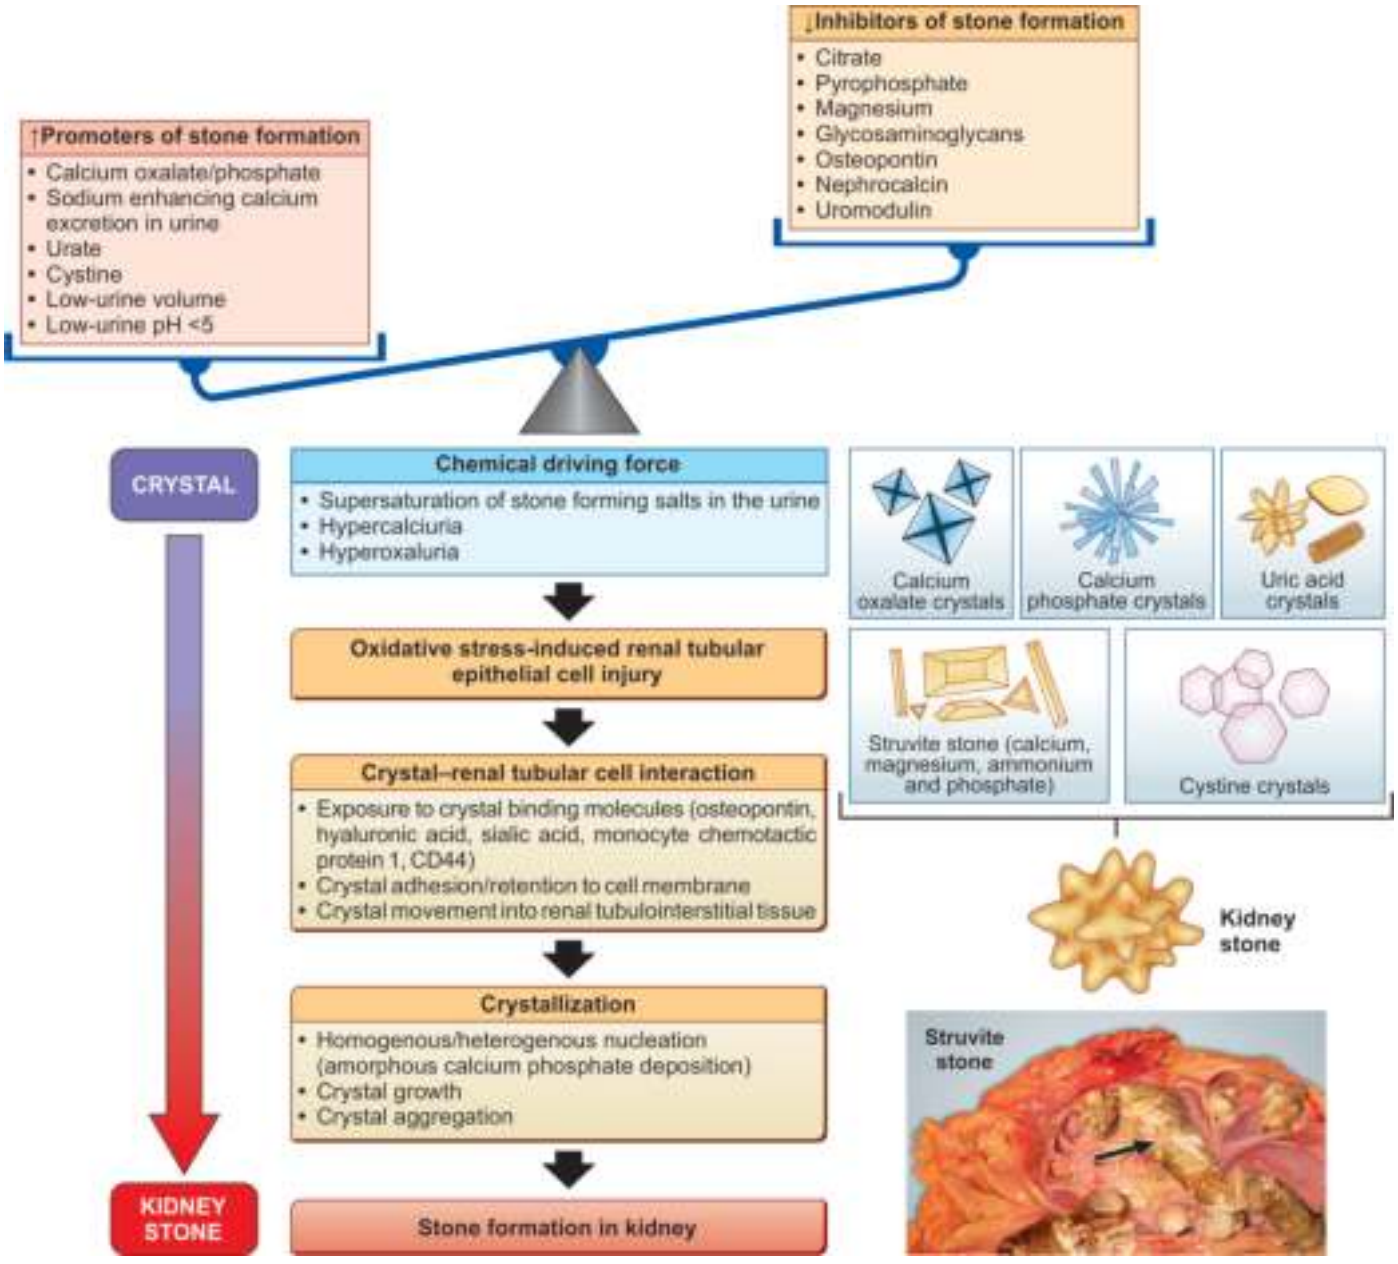

Fig. 22.83: Various cellular and extracellular molecular events during nephrolithiasis.

a recessive Mendelian form of nephrolithiasis. The transporters and ion exchangers are responsible for secretion and absorption of oxalates. Malabsorption of oxalates leads to urinary oxalate levels exceeding supersaturation and thereby promoting crystallization and consecutive stone formation.

- Depending on presence of salt constituents, urinary stones are of five types: (a) calcium oxalate/calcium phosphate (80–85%), (b) calcium, magnesium ammonium phosphate, also known as triple stones or struvite stones, forming staghorn calculus (5–10%), (c) uric acid/urate stones (5%), (d) xanthine stones, and (e) cystine stones (1–2%). With multifactor etiology and high recurrence rate, urinary tract stone disease provides a medical challenge. Composition, contributory factors and treatment of urinary stones are given in Table 22.56.

CALCIUM OXALATE AND PHOSPHATE STONES

Most renal stones contain calcium complexed with oxalate or phosphate, or a mixture of both anions. Calcium stones constitute 80–85% of urolithiasis, which are formed due to hypercalciuria (idiopathic 50%), increased absorption of calcium in the intestine and hypercalcemia.

- Hypercalcemia occurs in the settings of increased reabsorption of calcium by intestine, hyperparathyroidism (10% cases), ectopic production of

Table 22.56 Composition, contributory factors and treatment of urinary stones

Type of Stone	Frequency	Radiology	Conditions	Management
Calcium stones (calcium oxalate or calcium phosphate)	80–85%	Radiopaque	▪ Hypercalcemia and hypercalciuria ▪ Hyperparathyroidism ▪ Vitamin D intoxication ▪ Milk alkali syndrome ▪ Renal tubular acidosis ▪ Intestinal bypass surgery ▪ Hyperoxaluria	▪ Treatment underlying cause ▪ Increased fluid intake ▪ Diuretics ▪ Dietary restriction of food-rich in oxalates
Ammonium and magnesium phosphate or struvite stones (staghorn stones)	5–10%	Radiolucent	Infection (Proteus, *Klebsiella pneumoniae* and Pseudomonas) urine alkaline	▪ Increased fluid intake ▪ Treatment of UTI ▪ Acidification of urine
Uric acid stones (pH of approximately 5.5)	5–10%	Radiolucent	Hyperuricemia	▪ Increased fluid intake ▪ Uricosuric drug (allopurinol) ▪ Alkalization of urine
Cystine stones	1–2%	Radiolucent	Hereditary cystinuria	▪ Increased fluid intake ▪ Alkalization of urine

Calcium oxalate stones most often occur in adults and constitute 75–80% of cases.
Calcium phosphate stones are most common type of stones in children (10–20%).

parathormone in squamous cell lung carcinoma, osteolytic lesions, vitamin D intoxication, milk-alkali syndrome, sarcoidosis, and rarely primary hyperoxaluria. Excessive intake of dairy products rich in oxalates and phosphates causes stone formation.

- Increased serum calcium results in deposition of calcium in the basement membrane of renal tubules (nephrocalcinosis) and renal parenchyma. Calcium deposition is accompanied by and accumulation of macrophages and foreign body giant cells. Oxalate crystals are highlighted by polarized microscopy.
  - **Calcium oxalate stones:** Calcium oxalate stones most often occur in adults (75–80% of cases), which stones are radiopaque, which occur due to increased absorption of calcium oxalate from the bowel mucosa in Crohn's disease; and intake of certain foods (e.g. spinach, chocolate). The surface of calcium oxalate stone is rough, brown color probably due to old blood pigment.
  - **Calcium phosphate stones:** Calcium phosphate stones are most common type of stones in 10–20% of children. These stones are formed due to consumption of dairy products with recurrent urinary tract infections or distal renal tubular acidosis. Consistency of stones is hard/soft.

Pathogenesis of Calcium Oxalate or Phosphate Stones

Supersaturation of Urinary Salts

When the concentration of calcium oxalate or phosphate salt components increases beyond the saturation level, a state of supersaturation exists in the urine, which is thermodynamically unstable. Nephrolithiasis is a consequence of increased supersaturation of urinary salts in low urine volume and subsequent formation of crystalline particles. Renal stones are crystalline structures composed of calcium oxalate salts.

- The natural progression of the urine chemistry resulting in nephrolithiasis is urine saturation, urine supersaturation, crystal nucleation, crystal growth, crystal aggregation, crystal–cell interaction, endocytosis of calcium oxalate crystal by renal tubular epithelial cells, tubular cell injury, crystals retention by the urothelium and the continued growth of the renal stone on the retained crystals within kidneys.
- Nephrolithiasis occurs when concentration of ions such as calcium, oxalate, hydrogen, sodium and uric acid in the glomerular filtrate is higher than normal amounts. This condition is known as supersaturation and the supersaturated ions are more likely to come out of glomerular filtrate and crystalline. Risk factors for supersaturation of crystalline ions in glomerular filtrate include dehydration, high fat diet, animal protein, high salt intake and obesity.

Homogenous/Heterogenous Crystal Nucleation

The process of renal stone formation involves the formation of crystals that dissociate from the urine and accumulate on the lining surfaces of the urinary tract. Transformation from a liquid to a solid phase in a supersaturated solution is called crystal nucleation. Formation of renal stone occurs through homogenous or heterogenous nucleation.

- Homogenous nucleation occurs when calcium and oxalate ions complex to form small crystals that grow to larger pure calcium oxalate stones.

- Heterogenous nucleation occurs when calcium and phosphate ions complex to initially form small crystals of calcium phosphate. These small crystals of calcium phosphate form the substrate upon which calcium, oxalate subsequently deposits. This interaction results in a mixed calcium oxalate and calcium phosphate stone.
- Initially, homogenous crystal nucleation starts which progresses to heterogenous nucleation causing calcium oxalate crystal formation. Typically, the crystals form in the renal distal tubule, loop of Henle and/or collecting system. Most crystals are simply excreted unnoticed into the urine. However, sometimes, the crystals adhere to the epithelium of the tubules, particularly in the collecting system and form seed crystals that result in renal stone formation.

Crystal Growth

Crystal aggregation appears to be the major mechanisms for crystal growth. Crystal growth is one of the prerequisites for particle formation and thus stone formation. It has been postulated that after crystal nucleation within the renal tubule lumen, a nascent crystal either aggregates with other crystals to form a mass large enough to occlude the nephron or adheres to the urothelium.

Crystal Aggregation

Crystal aggregation has been recognized as an initial most crucial mechanism for renal stone pathogenesis. Microcrystals of calcium, oxalate and other salts can be found in concentrated normal urine or renal tubular fluid.

- Nevertheless, the individual urinary microcrystals are too small and are normally excreted by urinary or tubular fluid flow. In addition to crystal growth and adhesion of crystals to renal tubular epithelial cells, crystal aggregation causes the crystals to retain inside renal tubules by their rapidly enlarged size as a result of combination of several individual crystals into agglomerate.
- Many studies have revealed that deficiencies of urolithiasis inhibitors are associated with large aggregated crystals in the urine of renal stone cases. In addition, Tamm-Horsfall protein and various bacteria have been demonstrated to promote crystal aggregation.
- Quantitative analysis of crystal aggregation depends only on number of agglomerates and their size. Calcium oxalate crystal aggregate is analyzed by spectroscopy.

Crystal–Cell Interaction

Crystal–cell interactions are crucial in physiologic crystal retention and the early stage of calcium oxalate renal stone formation. Thus, crystals of calcium oxalate may be retained in the renal tubules to form stones by binding to the apical surface of tubular cells and subsequently undergoing endocytosis.

- Crystals of calcium oxalate are injurious to tubular epithelial cells due to oxidative stress and inflammatory response.
- The damaged tubular epithelial cells are released into the urine, which are capable of promoting crystal nucleation at much lower supersaturations of crystals.
- Damaged cell membrane tubules also provide sites for crystal attachment and eventual retention within the kidneys.
- Renal tubular epithelial damage cell may assist in movement of crystals from the intratubular lumen to the interstitial tissue leading to formation of apatitic Randall's plaques and ulceration to the renal papillary surface.

Endocytosis of Calcium Oxalate Crystals by Renal Tubular Epithelial Cells

Crystals are frequently precipitated in the renal tubular fluid of stone-forming as well as nonstone-forming persons. Following crystal precipitation in the nephron, these are rapidly excreted, which facilitates their excretion. This elimination process is thwarted, (prevented), when the crystals adhere to tubular epithelial lining.

- Many studies revealed endocytosis of calcium oxalate crystals occurs in renal tubular epithelial cells in a patient with primary hyperoxaluria, who received renal transplantation.
- Tamm-Horsfall proteins inhibit uptake of calcium oxalate crystals by renal tubular epithelial cells in distal tubular fluid.
- Nephrocalcin prevents attachment of calcium oxalate crystals to the plasma membrane and phagocytosis.

Relationship between Crystal–Cell Interaction and Renal Tubular Cell Injury

Both calcium oxalate crystals and oxalate ions induce an epithelial–mesenchymal transition (EMT) in the proximal tubular epithelial cells and contribute to renal tubular epithelial cell injury. TGF-β1 is the main cytokine synthesized by macrophages, which mediates of EMT.

- Macrophages exposed to calcium oxalate crystals stimulate TGF-β1 production and induce EMT in distal tubular epithelial cells. EMT plays a crucial role in both physiologic and pathologic states.
- The EMT is a process by which epithelial cells lose their polarity and cell-cell adhesion, and gain migratory and invasive properties to become mesenchymal stem cells.

- Hyperoxaluria induces crystalluria, tubular crystalline deposits of calcium oxalate, interstitial fibrosis, tubulointerstitial inflammation and progressive renal failure.

MAGNESIUM, AMMONIUM, CALCIUM PHOSPHATE STONES (STRUVITE STONES)

Magnesium, ammonium, calcium phosphate stones, or staghorn stones also known as struvite stones or triple phosphate stones are the second most common form of renal stones. These are formed in patients with recurrent urinary tract infections by urea-splitting bacteria such as *Proteus vulgaris*, *Klebsiella* species and Staphylococcus. These constitute 15% of renal stones.

- Urease produced by these organisms convert urea into NH_3, thus causes alkaline pH of urine, resulting in precipitation of magnesium ammonium phosphate (struvite) and calcium phosphate (apatite). Staghorn calculi fill the entire pelvis and calyces.
- The struvite stone has flaking surface and gray white color. Because of large size staghorn stone filling entire renal pelvis and calyceal system, surgical removal is done. Antibiotics are given to eliminate urease producing bacteria. Because of large size staghorn stone filling entire renal pelvis and calyceal system, surgical removal is done. Antibiotics are given to eliminate urease producing bacteria. Struvite stone or staghorn stone (triple phosphate stones, calcium, magnesium ammonium phosphate) in kidney is shown in Fig. 22.84.

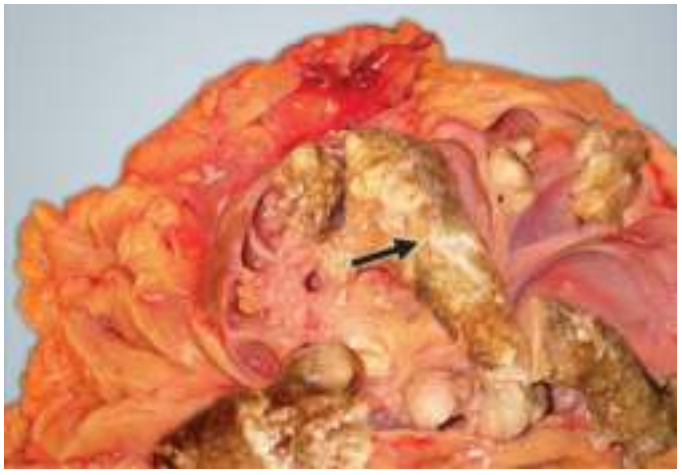

Fig. 22.84: Struvite stone or staghorn stone (triple phosphate stones, calcium, magnesium ammonium phosphate) in kidney. Staghorn stone, also sometimes called coral calculi that obtain its characteristic shape by forming a cast of the renal pelvis and calyces, thus resembling the horns of a stag. It can be complete or partial depending on the level of occupancy of the collecting system. It refers to struvite calculus involving the renal pelvis and extending into at least two calyces. Large staghorn stone is demonstrated (arrow).

URIC ACID STONES

Uric acid stones account for 6% of urolithiasis, which are formed due to increased serum uric acid in gout (hyperuricemia), chemotherapy for leukemia, uricosuric drugs or excess dietary proteins (meat).

- About 50% of patients lack elevated uric acid in blood or urine due to acidic pH. Long-standing diarrhea leads to small volume of very acidic urine responsible for uric acid stones formation.
- Uric acid stones are smooth light yellow-brown color, hard consistency and radiolucent. Initially uric acid stone is <2 cm in diameter, and may become staghorn calculi if located in renal pelvis.
- Uric acid crystals in collecting tubules are elongated and rectangular, or doubly refractile crystals in the interstitium with giant cell reaction. Allopurinol increases urinary pH and makes uric acid soluble in urine.

CYSTINE STONES

Cystine is a sulfur-containing amino acid obtained by the oxidation of two cystine molecules which are then linked via a disulphide bond. As the kidneys filter blood to create urine, cystine is normally reabsorbed back into the blood circulation. Persons with cystinuria cannot properly reabsorb cystine into their blood stream, so the amino acid cystine accumulated in their urine.

- As urine becomes more concentrated in the kidneys, excess cystine forms crystals. Aggregation of crystals become stones that may lodge in the urinary tract. Sometimes cystine crystals combine with calcium molecules in the kidneys to form large stones. These crystals and stones can block the urinary tract and reduce the ability of the kidney to eliminate waste metabolic products through urine. The cystine stones also provide sites for bacterial growth, where bacteria may cause urinary tract infections.
- Cystinuria is an autosomal recessive disorder due to mutations in the SLC3A1 (2p16.3) encoding heavy subunit (rBAT) or SLC7A9 (18Q13.1) genes that encode the two subunits leading to excess of cystine in the urine due to defective reabsorption in renal proximal tubules.
- Cystine stones are yellow-brown, round with smooth surface and radiopaque stones formed at low urinary pH. Cystine crystals are flat hexagons in urine. Most kidney stones are completely silent. Patient with large renal stones presents with an abrupt onset of severe, colicky pain in the flank radiating to the groin; and associated with either microscopic or macroscopic hematuria.

XANTHINE STONES

Xanthinuria is an autosomal recessive disorder, due to deficient xanthine oxidase, causing excessive xanthine levels and stones in one-third of patients. Xanthine stones are <2 cm, smooth, light yellow color, radiolucent; stones may or may not be visualized with plain radiograph.

STONE GRANULOMA

Endoscopic management of urolithiasis is one of the commonest urological procedures. A stone granuloma is a rare cause of ureteral obstruction following ureteroscopic stone fragmentation and removal. Stone granuloma can be caused secondary to recurrent ureteral obstruction and strictures. Delayed stone granuloma can also occur following pneumatic lithotripsy during ureteroscopy.

COMPLICATIONS OF UROLITHIASIS

Many complications may arise from urolithiasis especially if there is delay in diagnosis or inadequate treatment. The complications include acute or chronic kidney disease secondary to obstruction and uremia, anuria, urinary tract obstruction, chronic pyelonephritis, xanthogranulomatous pyelonephritis, pyonephrosis, renal calyceal rupture and urine extravasation, perinephric abscess and hypertension.

HYDRONEPHROSIS

Hydronephrosis describes urine-filled dilation of the renal pelvis and/or calyceal system as a result of obstruction. It is associated with progressive renal atrophy. The signs and symptoms of hydronephrosis depend upon whether the obstruction is acute (renal stone) or chronic, partial or complete, unilateral or bilateral. Renal stone produces acute hydronephrosis.

- Patient presents with sudden onset of intense pain in the flank region. Blood tests may demonstrate increased blood urea and serum creatinine or electrolyte imbalances. Urine analysis may indicate as elevated pH due to secondary obstruction of nephrons within the affected kidney. Clinical examination may detect a palpable abdominal or flank mass caused by the enlarged kidney due to hydronephrosis. Imaging studies, such as renal ultrasonography, intravenous pyelography, CT or MRI scan are important diagnostic tools in determining the presence and/or cause of hydronephrosis.
- Mild hydronephrosis appears to be relatively benign in nature, and in most cases, calyceal dilatation improves with time, and thus surgical intervention is not required. On the other hand, moderate or severe hydronephrosis often results in a significantly poor outcome and requires surgical intervention, and therefore, requires closer follow-up. Hydronephrosis due to nephrolithiasis is shown in Fig. 22.85.

Fig. 22.85: Nephrolithiasis inducing chronic pyelonephritis and hydronephrosis. Nephrolithiasis correlates with increased risk of chronic pyelonephritis with concurrent hydronephrosis. Cut surface of kidney shows a large calculus inducing hydronephrosis and chronic pyelonephritis (arrow). (*Courtesy:* Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

URINARY TRACT INFECTION

The most common complication of urolithiasis is the development of a urinary tract infection (UTI). When the urinary tract infection is associated with high fever, acute pyelonephritis is suspected. This is caused by bacteria spreading from urinary bladder to the kidney and invading the renal parenchyma. A urine culture is a test that can detect bacteria in urine. Urine analysis can find and identify the organisms that cause a urinary tract infection.

PYONEPHROSIS

Pyonephrosis is a disease causing suppurative destruction of the renal parenchyma. Hydronephrosis due to urolithiasis can be a cause of pyonephrosis, which is a urological emergency.

- Obstruction in the renal pelvis or upper part of ureter leads to superadded infection by *Escherichia coli*, Klebsiella, Proteus, enterococci, etc. and suppuration of the contents of the calyceal system known as pyonephrosis. The accumulation of purulent exudate in the hydronephrotic collecting system and abscess formation constitute the pathophysiology of pyonephrosis.

Fig. 22.86: Gross morphology of pyonephrosis. Pyonephrosis is characterized by accumulation of purulent debris and sediment in the renal pelvis and urinary collecting system resulting from urinary tract obstruction in the presence of pyelonephritis. The diagnosis of pyonephrosis is suspected when the clinical symptoms of fever and flank pain are combined with radiologic evidence of obstruction to the urinary tract (arrow). (*Courtesy:* Dr. Sujata Kanetkar, Senior Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

- The suppurative exudate fails to drain out due to obstruction. The surface of calyces becomes shaggy due to accumulation of pus. Extension of suppurative inflammation through the renal capsule leads to perinephric abscess. Gross morphology of pyonephrosis is shown in Fig. 22.86.

LABORATORY DIAGNOSIS OF UROLITHIASIS

Urine analysis is performed to demonstrate hematuria and crystals. It is also performed to study the composition of the stone (urine must be strained), since treatment is often tailored to the composition of the urinary stone.

- Approximately >50% of cases pass stones in urine within 48 hours. Recurrence of stone formation is seen in 50% of cases. X-rays kidney-ureter-bladder (KUB) may reveal radiopaque stones in >80% of patients.
- Enhanced spiral (helical) CT scan and ultrasonography are done to demonstrate urinary stones. Intravenous urography is helpful to locate urinary stone. Serum calcium and parathormone levels are increased in hyperparathyroidism.

MANAGEMENT OF UROLITHIASIS

Nephrolithotomy refers to removal of renal stones by making a small tract from the skin to the kidney. Extracorporeal shock wave lithotripsy (**ESWL**) is used to remove stones in the kidney or upper ureter. Shock waves are directed by a probe placed on the tummy or back. This shatters the stone into small fragments which then can be passed spontaneously. If ESWL does not work surgery can be used to remove staghorn stone. Urinary bladder stones are removed using a cystoscope, a special instrument which is passed through the urethra into the urinary bladder.

VASCULAR DISEASES OF KIDNEY

DIFFUSE RENAL CORTICAL NECROSIS SECONDARY TO SHOCK

Diffuse renal cortical necrosis refers to acute wide-spread ischemic necrosis limited to the large portions of the renal cortex of both kidneys; however the medulla is spared. Bilateral pale infarcts are seen in renal cortex. Massive tubular necrosis leads to fatal outcome. Renal cortical infarction may be patchy in some cases and compatible with survival. Vasa recta arising from juxtamedullary efferent arterioles supply arterial blood to the medulla. Thus, occlusion of the outer renal cortical vessels leads to cortical necrosis sparing medulla.

- Diffuse renal cortical necrosis occurs in the settings of hypovolemia and endotoxic shock. It most often occurs in pregnant women with pre-eclampsia, eclampsia, or abruptio placentae. Pregnant woman develops acute kidney disease. It is thought that the cause is a combination of end organ vasospasm and disseminated intravascular coagulation (DIC).
- Due to disseminated intravascular coagulation (DIC), necrosis is limited to renal cortex. Patient with severe renal cortical necrosis presents with acute renal failure. It is initially indistinguishable from that produced by acute tubular necrosis. Schematic representation of vascular lesions and histological patterns and their underlying causes is shown in Fig. 22.87.

Pathology Pearls: Diffuse Renal Cortical Necrosis

Gross Morphology

The extent of renal cortical necrosis varies from patchy to confluent. Complete occlusion of the arterial supply to renal cortex produces pale/while infarcts.

Light Microscopy

Kidneys show fibrin/platelets clots in arterioles and glomerular capillaries. Glomeruli, proximal and distal tubules are severely affected. Cellular outlines are maintained with loss of structural details. Dystrophic calcification occurs in areas of renal cortical necrosis.

RENAL INFARCTION

Renal infarction refers to ischemic necrosis due to obstruction of interlobar or larger branches of the renal artery. It most often occurs secondary to thromboembolic from the left heart (90%), in the settings of cardiac vegetations or complicated atherosclerotic plaque, nephrosclerosis (benign and malignant), vasculitis (e.g. polyarteritis nodosa), and sickle cell nephropathy. Gross morphology of renal infarct due to occlusion of arterial segment is given in Table 22.57.

SICKLE CELL NEPHROPATHY

Sickle cell nephropathy is the most common organ manifestation of sickle cell disease or sickle cell trait. Sickling of red blood cell may occur in peritubular capillaries in the medulla due to the low O_2 tension in the medulla.

- The rigidity of sickled erythrocytes results in obstruction of the microcirculation, with subsequent hypoxia and ischemic injury in many organs. The interstitial tissue in which the vasa recta course has a low oxygen tension. As a result, in patients with sickle cell disease, erythrocytes in the vasa recta tend to sickle and occlude the lumina. Infarcts in the medulla and papillae ensue, sometimes severe enough to cause renal papillary necrosis.
- The glomeruli are conspicuously congested with sickle cells. Patient develops renal papillary necrosis and pyelonephritis. Patient presents with asymptomatic hematuria (most common) due to infarction in the medulla. Kidneys lose concentrating ability of urine. Causes of renal papillary necrosis are given in Table 22.58.

NEPHROSCLEROSIS

Hypertension is defined as intermittent or sustained elevation of systolic blood pressure >139 mm Hg or diastolic blood pressure >89 mm Hg. Vascular changes in kidneys due to hypertension are known as benign or malignant nephrosclerosis. Features of benign and malignant nephrosclerosis in long-standing hypertension are given in Table 22.59.

- Approximately 15% of patients with mild to moderate hypertensive cause renal vascular changes known as benign nephrosclerosis. On gross morphologic examination, kidneys involvement shows fine granularity giving '**grain leather appearance**'.
- Renal vascular changes in severe hypertension are termed as malignant nephrosclerosis. Malignant

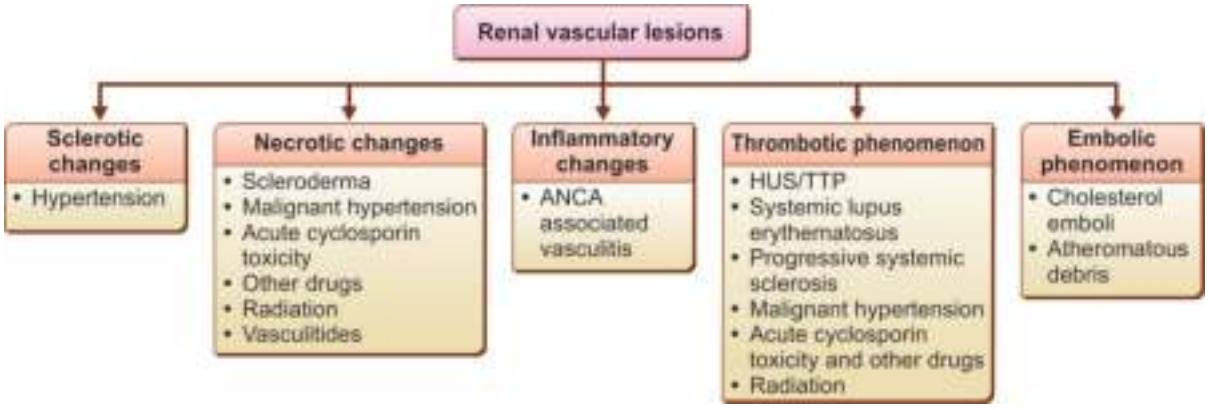

Fig. 22.87: Schematic representation of renal vascular lesions and histological patterns and their underlying causes.

Table 22.57 Gross morphology of renal infarct due to occlusion of arterial segment

Branch of Renal Artery	Size of Renal Infarct	Relationship to the Lobes
Segmental artery	4–5 cm	Entire lobe and portion of adjacent lobe
Interlobar artery	2–3 cm	Columns of Bertin and portion of adjacent lobe
Arcuate artery	0.5–1.0	One sixth to one eighth of a lobe extending to the middle of the lobe
Intralobular artery	0.1–0.2	Small portion of a lobe

Table 22.58 Causes of renal papillary necrosis

Disorder	Time Course of Papillary Necrosis	Number of Renal Papillae Affected	Infection	Calcification
Diabetic nephropathy with or without infection	10 years	Several renal papillae affected at same stage	80%	Rare calcification
Analgesic abuse most often associated with phenacetin	7 years	All renal papillae affected at different stages	25%	Frequent calcification
Sickle cell disease	Variable	Few renal papillae	–/+	Rare calcification
Lower urinary tract obstruction with or without infection	Variable	90% of renal papillae	90%	Frequent calcification

Table 22.59 Features of benign and malignant nephrosclerosis in long-standing hypertension

Parameters	Benign Nephrosclerosis	Malignant Nephrosclerosis
Incidence	Very common	Rarely occurs
Age group	Begins in <45 years of age and progresses	Young adults of 25–35 years
Sex distribution	Females > males	Males : females (1:1)
Etiology	Majority of cases suffer from primary/essential hypertension	Majority of cases develop malignant hypertension due to renal disease, however a few cases develop in long-standing primary/essential hypertension
Hypertension progression	Very slow progression over many years	Rapid progression within months to one or two years
Blood pressure range	Very slow rise of blood pressure with diastolic blood pressure ranging 90–120 mm Hg	Rapid rise of blood pressure with diastolic blood pressure ≥120 mm Hg
Injury to blood vessels	Mild to moderate injury to blood vessels	Severe injury to blood vessels
Large elastic and medium size arteries involvement	Potentiates slow formation of atheromatous plaque and accelerates arteriosclerosis	Potentiates formation of atheromatous plaque and accelerates arteriosclerosis
Arteriolar changes	Hyaline arteriolar thickening with narrowing of arteriolar lumen and reduplication of elastic lamina	Fibrinoid necrosis of vascular endothelium with occlusion of lumen by thrombus in vessels of kidney and other abdominal viscera
Pathogenesis of arteriolar changes	Benign hypertension increases endothelial permeability of arterioles resulting in deposition of plasma proteins beneath vascular intima and thus ischemia of tissue. These histologic changes are termed 'benign nephrosclerosis'.	Malignant hypertension causes severe damage to vascular endothelium of arterioles resulting in intravascular coagulation and fibrinoid necrosis with fixed vascular lumen. These histologic changes are termed 'malignant nephrosclerosis'.
Gross morphologic changes in kidneys	▪ Kidney size is decreased due to ischemia ▪ External surface shows grain leather appearance with thinned out cortex ▪ Tubular atrophy and increased interstitial fibrosis	▪ Small contracted kidneys due to marked diffuse glomerular sclerosis ▪ External surface shows flea-bitten kidney due to rupture of renal small vessels especially capillaries ▪ Tubular loss in relation to sclerosed glomeruli present
Clinical manifestations	Uremic manifestations are uncommon	Uremic manifestations are common due to chronic renal failure

hypertension causing necrosis of glomerular endothelial cells results in hemorrhage on the surface of kidney is known as 'flea-bitten kidney'. Other causes of flea-bitten kidneys are emboli from infective endocarditis, rapidly progressive glomerulonephritis, systemic lupus erythematosus, Goodpasture's syndrome and Henoch-Schönlein purpura. Causes of flea-bitten kidneys are given in Table 22.60.

Table 22.60 Causes of flea-bitten kidneys

Malignant hypertension
Emboli from infective endocarditis
Rapidly progressive glomerulonephritis
Systemic lupus erythematosus
Goodpasture's syndrome
Henoch-Schönlein purpura

BENIGN NEPHROSCLEROSIS LEADS TO OBLITERATION OF GLOMERULI

Benign nephrosclerosis refers to pathologic changes in the kidney secondary to chronic mild to moderate hypertension. Vascular disease of the kidneys can be both a cause and a consequence of hypertension.

- Renal involvement in hypertension is more common in Blacks than in Whites. Benign hypertension is most often asymptomatic until development of complications of the kidney and other organs.
- Vascular changes occur in interlobar, arcuate arteries and afferent arterioles located within the cortex of both kidneys in approximately 15% of patients with benign hypertension. End stage renal disease occurs in 25–30% of patients with long-standing benign hypertension. Maintaining normal blood pressure is the only way to slow the progression of benign nephrosclerosis.

Histologic Types of Vascular Changes

There are two types of vascular changes, i.e. hyaline arteriosclerosis and reduplication of elastic lamina. Similar changes are also seen in elderly persons (normal and hypertensive) and diabetes mellitus. Due to benign hypertension, persons develop increased permeability of vessels resulting in deposition of plasma proteins in subintimal regions of blood vessels. Lumina of the blood vessels is decreased leading to ischemic changes in organs.

Surgical Pathology: Benign Nephrosclerosis

Gross Morphology

- In benign hypertension, kidneys are symmetrically reduced in size and weight due to ischemia.
- Capsular surface of the kidneys is most often finely granular giving 'grain leather-like appearance', with V-shaped scars representing renal infarcts caused by the occlusion of medium-sized renal vessels.
- On cut section, cortex is thinned out. Simple cysts may also be present.

Light Microscopy

- Renal vascular changes in benign hypertension are known as benign nephrosclerosis. Focal global glomerulosclerosis, tubular atrophy and interstitial fibrosis are invariably seen with some degrees of chronic inflammation in the glomerulosclerotic regions.
- Renal artery branches such as afferent arterioles, interlobar and arcuate arteries exhibit intimal fibrosis, reduplication of the internal elastic lamina, and smooth muscle hyperplasia in concentric fashion and reduction of lumen size leading to hyaline arteriolosclerosis (thickening of the wall) and thus ischemia. It results in tubular loss or atrophy, increased interstitial fibrosis replacing nephrons, associated with infiltrates of lymphocytes without plasma cells. The eosinophilic deposits within arteriolar wall represent insudation of plasma proteins in small blood vessels.

Histochemical Stain

In benign nephrosclerosis, periodic acid–Schiff (PAS) stain shows arterial intimal thickening and atrophy of the media in the branch of renal artery.

Immunology

Immunoglobulin M (IgM) and C3 is most often present within hyaline layers of arterioles.

Electron Microscopy

Electron microscopy may reveal thickening and wrinkling of the glomerular capillary basement membrane.

MALIGNANT NEPHROSCLEROSIS LEADS TO FATAL RENAL DISEASE

Malignant nephrosclerosis is a form of thrombotic microangiopathy secondary to malignant hypertension (systolic blood pressure >220 mm Hg and/or diastolic blood pressure >130 mm Hg).

- Severely elevated blood pressure results in rapidly progressive vascular disease, which adversely affects the brain (cerebral stroke), heart (left ventricular hypertrophy and failure), kidney (renal failure), and retina (focal retinal hemorrhages and papilledema).
- Malignant nephrosclerosis can be a complication of either essential (primary) or secondary hypertension. Tobacco smokers, black young African-American persons and patients with underlying chronic renal disease are at higher risk of developing malignant nephrosclerosis.

Clinical Features

Patient presents with severe headache, blurred vision, neurologic symptoms, papilledema, congestive heart failure, acute renal failure. Microangiopathic hemolytic anemia and thrombocytopenia can be observed. Physical examination reveals very high blood pressure, pounding heart beat and bulging optic disc papilledema. The therapeutic goal is a gradual reduction of mean arterial pressure with intravenous vasodilators.

Surgical Pathology: Malignant Nephrosclerosis

Gross Morphology

Renal changes in severe hypertension are known as malignant nephrosclerosis. Renal arterioles and glomeruli rupture, resulting in 'flea-bitten kidney', multiple pinpoint petechial hemorrhages on the capsular surface of kidney.

Light Microscopy

Interlobular arteries show intimal edematous thickening with erythrocytes in the intima. Their lumen is greatly decreased and may be occluded by fibrin thrombi. Severe hypertension causes necrotizing arteriolitis and glomerulitis with intensely eosinophilic material giving fibrinoid necrosis and hyperplastic arteriolosclerosis (onion skin appearance). Renal tubules show atrophic changes. Tubules contain eosinophilic material known as thyroidization of tubules. There is tubular loss in relation to sclerosed glomeruli present. Patients develop chronic renal failure with manifestations of uremia.

- **Fibrinoid necrosis:** Severe hypertension injures glomerular capillary endothelial cells and causes increased vascular permeability, which leads to insudation of plasma proteins into the vessel wall. Severe endothelial injury causes intravascular coagulation and rupture of blood vessels. Lumen becomes narrow and fixed resulting in renal ischemia. This morphologic change in renal arterioles is known as fibrinoid necrosis. Focal acute tubular necrosis and small cortical infarcts may be present. Histologic features in fibrinoid necrosis in malignant hypertension is shown in Fig. 22.88.
- **Hyperplastic arteriolosclerosis:** Acute vascular injury is followed by smooth muscle proliferation with an increase in concentric layers of smooth muscle cells that yield the so-called 'onion skin appearance'. Smooth muscle hyperplasia occurs as a result of growth factors derived from platelets and inflammatory cells at the site of vascular injury. It is accompanied by the replication of elastic laminae, the growth of new cells beneath intima. Histologic features in hyperplastic arteriosclerosis in severe hypertension are shown in Fig. 22.89.

Immunopathology

Staining for fibrinogen and IgM may be observed in arterioles, small arteries and glomerular capillaries.

Electron Microscopy

Electron microscopy exhibits thickening and wrinkling of the glomerular capillary basement membranes. Glomerular capillary endothelial cells are swollen and the subendothelial space is widened by electron-lucent fluffy material. Platelet and fibrin thrombi may be present.

Consequences

Poor perfusion of the kidneys in malignant nephrosclerosis stimulates the release of renin, which serves to elevate systemic blood pressure even further by activation of renin-angiotensin-aldosterone system (renovascular hypertension).

THROMBOTIC MICROANGIOPATHY

Thrombotic microangiopathy refers to extensive endothelial damage due to multiple causes such as infections, drugs (cisplatin chemotherapy), autoimmune diseases, severe hypertension, and pregnancy.

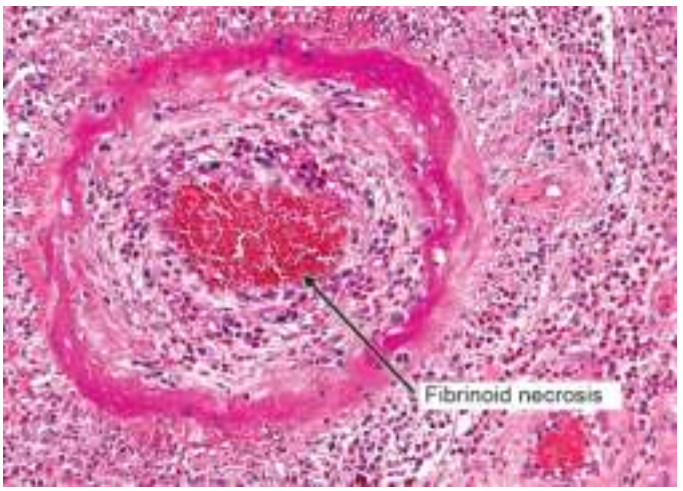

Fig. 22.88: Histologic features in fibrinoid necrosis in malignant hypertension. Malignant hypertension usually presents in 35–50 years of individuals and is characterized pathologically by fibrous endarteritis in the interlobular arteries and fibrinoid necrosis in the walls of a proportion of the efferent glomerular arterioles. The damage to the arteries leads to formation of pink fibrin, hence the term 'fibrinoid' (arrow) (400X).

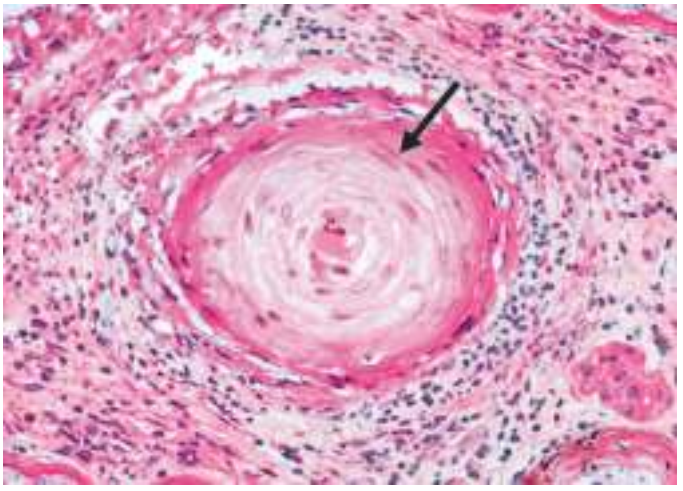

Fig. 22.89: Histologic features in hyperplastic arteriosclerosis in malignant hypertension. Pathologic changes in blood vessels observed in essential hypertension are similar to those seen in secondary hypertension due to renal disease or other diseases. Interlobular arteries exhibit intimal thickening and duplication of elastic lamina (elastosis) and there is hyaline change in the media of many arterioles (hyperplastic arteriosclerosis). Smooth muscle proliferation with an increase in concentric layers of smooth muscle cells that yield the so-called onion skin appearance (arrow) (400X).

- Alteration in blood flow leads to mechanical fragmentation of erythrocytes (schistocytes) and thrombocytopenia. This disorder is known as microangiopathic hemolytic anemia. Endothelial damage initiates a final common pathway of vascular changes such as thrombus formation resulting in focal ischemic necrosis. These vascular changes are to those seen in malignant nephrosclerosis.

- Histologic examination of affected kidneys exhibits arteriolar fibrinoid necrosis, arterial edematous intimal expansion, glomerular congestion, and vascular thrombosis.
- Patient presents with thrombocytopenia, hypertension, and renal failure. Causes of thrombotic microangiopathy are given in Table 22.61.

Table 22.61 Causes of thrombotic microangiopathy

Therapeutic Agents	
▪ Cisplatin	▪ Mitocin
▪ Cyclosporin	
Bacterial Infections	
▪ *Escherichia coli*	▪ Shigella
▪ Pseudomonas	
Autoimmune Disorders	
▪ Systemic lupus erythematosus	▪ Antiphospholipid antibody syndrome
▪ Scleroderma	
Other Disorders	
▪ Malignant hypertension	
▪ Pregnancy and postpartum period related factors	

TOXEMIA OF PREGNANCY INVOLVING KIDNEYS

Toxemia of pregnancy most often occurs during third trimester of first pregnancy. It most often affects kidneys, liver and brain (hemorrhages) in acute toxemia of pregnancy. Toxemia of pregnancy exists in two forms: pre-eclampsia and eclampsia.

- Pre-eclampsia refers to the triad of hypertension, proteinuria, and edema (fluid retention), during the third trimester of pregnancy. It usually begins insidiously after the 20th week of pregnancy.
- In eclampsia, pregnant women develop convulsion in addition to clinical manifestations observed in pre-eclampsia. Proteinuria is >3 g per day, and renal function declines. It is complicated by convulsions, and disseminated intravascular coagulation in eclampsia with fatal outcome.
  - Disseminated intravascular coagulation (DIC) is characterized by formation of fibrin thrombi in the liver, brain, and kidneys.

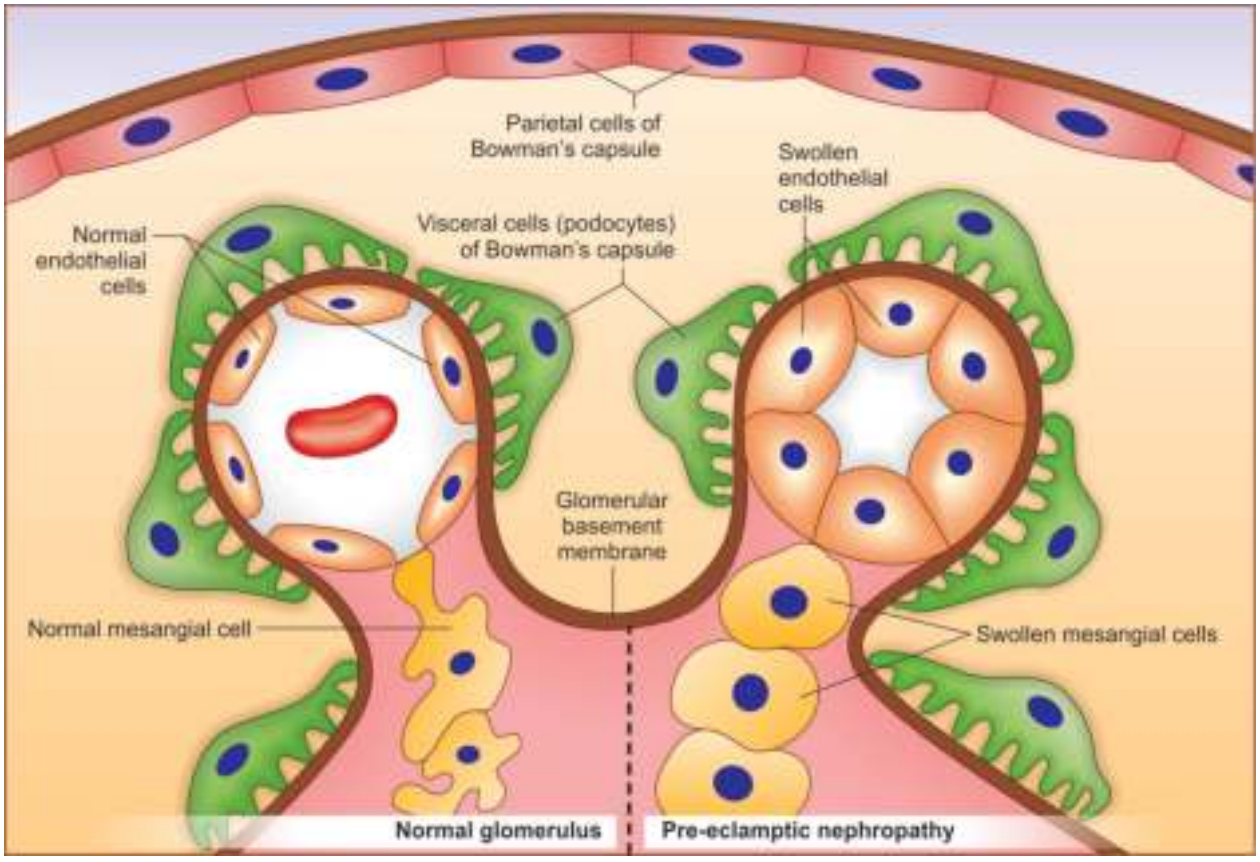

Fig. 22.90: Schematic representation of glomerulopathy in pre-eclampsia of pregnancy. Pre-eclampsia is a complication of pregnancy in the third trimester, usually primiparas, with maternal hypertension, proteinuria, periorbital edema, coagulation abnormalities, and disseminated intravascular coagulation in association with a characteristic glomerular lesion, endotheliosis. Glomerular endotheliosis represents a specific variant of thrombotic microangiopathy that is characterized by glomerular endothelial swelling with loss of endothelial fenestrae and occlusion of the capillary lumens.

- Patient develops puffiness on face, pitting edema and convulsions in true eclampsia. As the disease progresses the diastolic pressure persistently exceeds 110 mm Hg.

- Hematoxylin and eosin-stained section of kidney in pre-eclamptic nephropathy shows marked swelling of glomerular endothelial cells with marked narrowing of lumina. Mesangial cells and glomerular endothelial cells are enlarged and possess multiple vacuoles and vesicular structures. Schematic representation of glomerulopathy in pre-eclampsia of pregnancy is shown in Fig. 22.90.

VASCULITIS INVOLVING KIDNEYS

Renal vessels are involved in various types of vasculitis. Renal vasculitis (i.e. renal artery, interlobar arteries, arcuate arteries, efferent arterioles and glomeruli) may result in segmental/total infarction and renal parenchymal atrophy. Renal vasculitis tends to be severe and fulminant. Even with early diagnosis, about 33% of patients will progress to renal failure within five years. Vasculitis involving kidneys is given in Table 22.62.

Table 22.62 Vasculitis involving kidneys

Size of Vessel and Vascular Disorder	Renal Vessel Involved	Major Renal Manifestations
Small-sized vessel vasculitis		
▪ Immune complex-mediated vasculitis (Henoch-Schönlein purpura, cryoglobulinemia) ▪ Anti-GBM vasculitis (Goodpasture syndrome) ▪ ANCA vasculitis (Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome)	Glomeruli	Nephritis
Medium-sized vessel vasculitis		
▪ Polyarteritis nodosa ▪ Kawasaki disease	Interlobular arteries and arcuate arteries	Renal infarct and hemorrhage
Large-sized vessel vasculitis		
▪ Giant cell arteritis ▪ Takayasu's syndrome	▪ Main renal artery ▪ Main renal artery	▪ Renovascular hypertension ▪ Renovascular hypertension

CYSTIC DISEASES OF KIDNEY

The heterogenous group of renal cystic diseases comprises hereditary, developmental and acquired diseases. Each disease is distinguished by characteristic distribution of renal cysts. Accurate diagnosis of cystic renal diseases is important for two reasons: (a) appropriate management of delay onset of renal failure; and (b) appropriate genetic counseling in hereditary renal cystic diseases. Renal cystic diseases are given in Table 22.63.

ADULT POLYCYSTIC KIDNEY DISEASE

Adult polycystic kidney disease is autosomal dominant disorder. Though the genetic defect is present at birth, yet it most often manifests between 15 and 30 years of age. That is why this condition has also been called adult polycystic kidney disease. It is most often associated with berry aneurysm of the circle of Willis resulting in subarachnoid hemorrhage.

- Patient develops numerous bilateral cysts within the renal parenchyma that replace and ultimately destroy the renal parenchyma resulting in enlargement.
- The cysts originate from the tubules at any level, hence these cysts vary in size. Approximately 33% of patients develop hepatic cysts, whose lining resembles bile duct epithelium. PKD1, PKD2 and PKD3 gene mutations are associated with adult polycystic kidney disease. PKD1 gene encodes polycystin.
- Adult polycystic kidney disease manifests in the fourth decade or later life. Patient presents with sense of heaviness in the loins, bilateral flank and palpable large lobulated renal masses, hypertension, blood clots in the urine (hematuria), progression to end-stage renal disease after the age of 40 years. Secondary polycythemia may also occur. In women, adult polycystic kidney disease may be diagnosed at an earlier age during antenatal investigations, either as palpable masses or as impaired renal functions.

Table 22.63 Renal cystic diseases

Disorder	Inheritance	Pathology	Clinical Manifestations	Clinical Course
Adult polycystic kidney disease	Autosomal dominant	Kidneys and liver show large cysts. Berry aneurysm	Renal stones, hematuria, UTI and hypertension	Patient develops chronic renal failure at age of 40–60 years
Infantile polycystic kidney disease	Autosomal recessive	Patient presents with large cystic kidneys at birth	Liver fibrosis, splenomegaly, esophageal varices	Fatal during infancy and early childhood
Adult-onset medullary cystic disease	Autosomal dominant	Cysts at the junction of cortex and medulla	Salt wasting polyuria	Patient develops chronic renal failure at age of adulthood
Familial juvenile nephronophthisis	Autosomal recessive	Cysts at the junction of cortex and medulla	Anemia, growth retardation and salt losing polyuria	Patient develops chronic renal failure beginning at childhood
Medullary sponge kidney	None	Medullary cysts	Renal stones, hematuria and UTI	Patient has a benign course
Multicystic renal dysplasia	None	Kidneys are irregular with variable size cysts	It is associated with other renal anomalies	Surgery cures unilateral renal involvement. Patient with bilateral renal involvement develops chronic renal failure

- Diagnosis of adult polycystic kidney disease is established by ultrasonography, which demonstrates multiple bilateral renal cysts. Ultrasonography screening establishes diagnosis of adult polycystic kidney disease in 18 years of age in 95% of cases.
- Blood pressure control prevents development of chronic renal failure. Cardiac failure and urinary tract infection should be treated. Hemodialysis and renal transplantation are essential in management of these patients.

Surgical Pathology: Adult Polycystic Kidney Disease

Gross Morphology

Bilateral kidneys are enlarged up to 3 or 4 kg or more. The affected kidney contains large fluid-filled cysts up to 2 cm with areas of organized hemorrhage. Autosomal dominant adult polycystic kidney disease is shown in Fig. 22.91A and B.

Light Microscopy

- Adult polycystic kidney disease has saccular expansion of renal tubules and glomerular capsule that later dissociate and filled with fluid.
- Cysts are lined by cuboidal or flattened epithelium and possibly containing proteinaceous and serosanguineous fluid. Functional nephrons exist between the cysts with areas of global sclerosis, tubular atrophy, chronic inflammation and interstitial fibrosis.

INFANTILE POLYCYSTIC KIDNEY DISEASE

Infantile polycystic kidney disease is an autosomal recessive disorder. *In utero*, there is typically oligohydramnios because of poor renal functions and failure to form significant amounts of fetal urine. Cysts originate from the collecting ducts.

- Patient presents with multiple renal cysts evident at birth. The closed renal cysts are not in continuity with the collecting system. Infant suffering from polycystic kidney disease presents with bilateral flank masses, hypertension, oliguria and acute renal failure.
- Ultrasonography of kidneys shows cysts through cortex and medulla. Ultrasound of liver shows bile duct proliferation and hepatic fibrosis. Treatment is dialysis and renal transplantation.
- Ten-year survival rate is 80%. Death occurs shortly after birth in untreated cases. Infantile polycystic kidney disease is shown in Fig. 22.92.

Surgical Pathology: Infantile Polycystic Kidney Disease

Gross Morphology

- Both kidneys are markedly enlarged and tend to fill the retroperitoneum and displace abdominal contents.
- External surface of kidneys is smooth. The kidneys tend to be symmetrically enlarged. The cysts are quite small and uniform, perhaps 1–2 mm on average in cortex and medulla.

Light Microscopy

- The characteristic finding occurs in the later third trimester is renal cystic change with the cysts elongated and radially arranged. The cysts are lined by cuboidal epithelium.
- Cysts are smaller and present at right angles to the cortical surface.

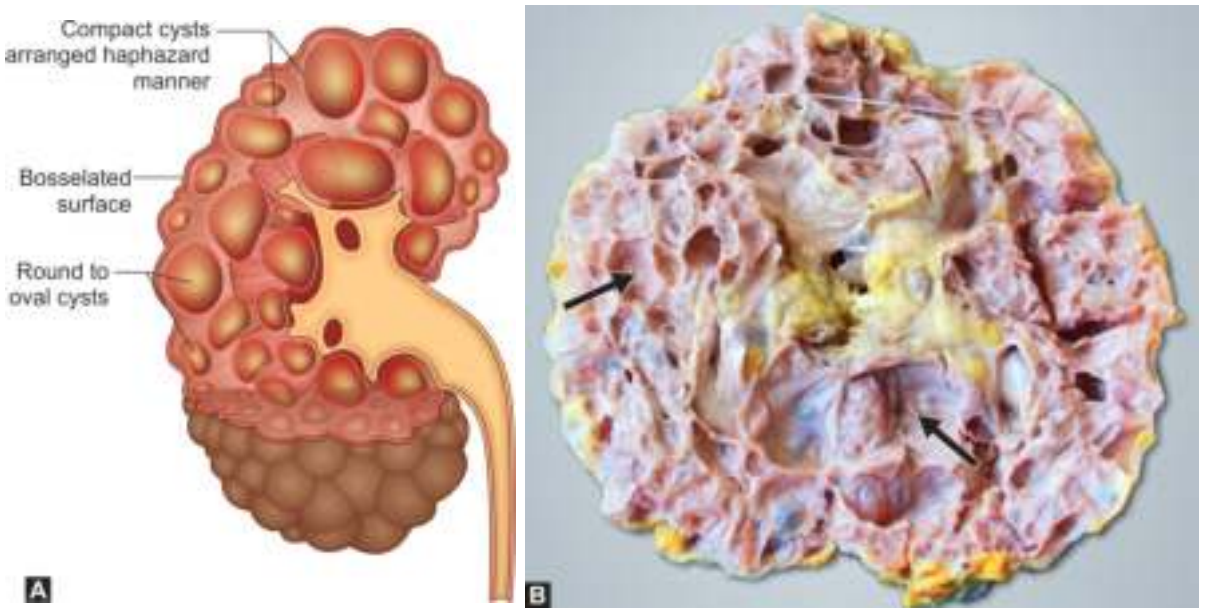

Fig. 22.91A and B: Autosomal dominant adult polycystic kidney disease. Autosomal dominant adult polycystic kidney disease occurs due to mutations in genes coding for polycystin 1 (PKD1 on chromosome 16p, most common) and polycystin 2 (PDK2, chromosome 4q). The renal parenchyma is almost completely replaced by cysts of varying size. The kidneys may be not much bigger than normal, but usually they are quite large (up to 8 kg). Cut surface shows subcapsular cysts up to 4 cm with very little normal renal tissue remaining. Cysts contain clear to brown fluid. Cut surface of kidney shows subcapsular multiple cysts (arrows).

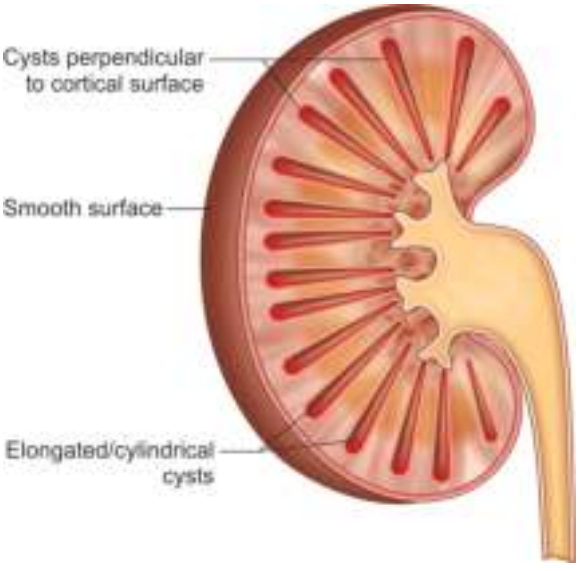

Fig. 22.92: Schematic representation of infantile polycystic kidney disease. Autosomal recessive polycystic kidney disease, also called infantile polycystic kidney disease usually presents with bilateral renal cystic disease at birth. Gross examination reveals large kidneys with smooth surface. Small cysts are present in the cortex and medulla. Dilated channels are perpendicular to cortical surface. Cysts are present in the medulla (collecting ducts). The disease has a poor prognosis.

SOLITARY RENAL CYST

Solitary renal cyst is comparatively rare. Renal cyst is solitary and well-defined and more common in women than men, which more often involves the lower pole of the kidney. Abdominal ultrasonography or computed tomography has led to the incidental detection of asymptomatic renal cyst. Complications of simple renal cyst include hemorrhage, infection, or rupture, which may result in development of complex cysts with calcification, and multiple lobules. Schematic representation of solitary renal cyst is shown in Fig. 22.93.

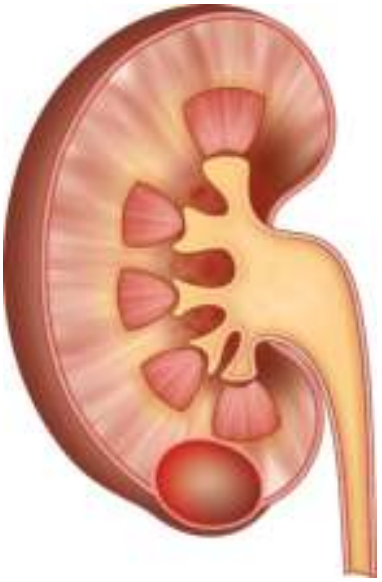

Fig. 22.93: Schematic representation of solitary renal cyst. Solitary renal cyst can occur in one or both kidneys. Simple cysts are usually round to oval in shape. These can range from the size of pea to the size of golf ball.

Surgical Pathology: Solitary Renal Cyst

Gross Morphology

- Solitary renal cyst is discrete lesion within kidney located in cortex. It extends outside the renal parenchyma and distorting the renal contour.
- Renal cyst is oval or circular in shape with well-defined outline. External surface is smooth, transparent, avascular, yellowish or bluish white in color. It is filled with homogenous clear or straw-colored fluid.

Light Microscopy

Light microscopy of solitary renal cyst is lined by a thin layer of fibrous tissue lined by a single layer of flattened or cuboidal epithelium.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney (also known as **Cacchi-Ricci disease**) is a congenital disorder of the kidneys and characterized by cystic dilatation of the collecting tubules in one or both fetus 'kidneys. In a normal fetus kidney, urine flows through collecting tubules, or tiny tubes as the kidney is being formed during a fetus' growth.

- Patient presents with renal colic (50–60%), urinary tract infection (20–35%), gross hematuria (10–20%) and hypercalcemia (30–50%). There is increased risk for development of kidney stones and urinary tract infection. Renal functions are impaired without development of renal failure.
- Radiologic findings are multiple small calculi within the renal papillae, dilated collecting ducts with the appearance of 'bristles on a brush'.
- Treatment focuses on complications (calculi and urinary tract infection) of medullary sponge kidney.

Surgical Pathology: Medullary Sponge Kidney

Gross Morphology

Kidney contains multiple small cysts (1–5 mm) involving the tip of renal papillae; one or multiple renal papillae possibly involved. Microcalculi are present in the dilated collecting ducts; possible lithiasis in the calyceal system. Medullary sponge kidney is shown in Fig. 22.94.

Light Microscopy

Dilated collecting ducts are lined by cuboidal or flattened epithelium, interstitium shows inflammation.

Fig. 22.94: Medullary sponge kidney. Medullary sponge disease, also known as Cacchi-Ricci disease, is a birth defect where changes occur in the tubules inside a fetus' kidneys. Patient presents with hematuria, calcium stone formation (nephrolithiasis) or signs of urinary tract infection such as polyuria and/or burning and pain during urination.

ACQUIRED RENAL CYSTIC DISEASE

Acquired renal cystic disease occurs in patients on long-term hemodialysis therapy in 10–20% of cases within the first three years of hemodialysis and 50% of cases within the first five years and 90% after ten years. Acquired cysts in kidney may form due to obstruction by oxalate crystals, hyperplasia or fibrosis. Multiple renal cysts, glomerular and tubular atrophy, and scarring are characteristic. The incidence of renal cell carcinoma is increased in 7% of patients. Atypical epithelial proliferations associated with gains of chromosome 7, 12, 17, 20 and Y, suggest these represent early neoplasms.

Surgical Pathology: Acquired Renal Cystic Disease

Gross Morphology

The kidneys are moderately enlarged weighing <800 g. Cut surface shows multiple cortical and medullary cysts containing clear fluid replacing >40% of renal parenchyma.

Light Microscopy

Renal cortical and medullary cysts are lined by flattened or cuboidal epithelium that may show focal pseudopapillae with nuclear enlargement and loss of polarity. These may contain oxalate crystals. Surrounding renal parenchyma shows global glomerulosclerosis, interstitial fibrosis and tubular atrophy.

CONGENITAL ANOMALIES OF KIDNEY

Congenital anomalies of kidney and urinary tract (CAKUT) can adversely affect functions of urinary tract, which occur from birth (congenital), although the abnormality may not become apparent until later in life.

RENAL AGENESIS

Renal agenesis is a condition in which a newborn is missing one or both kidneys. Unilateral renal agenesis (URA) is the absence of one kidney. Bilateral renal agenesis (BRA) is the absence of both kidneys, which is not compatible with life.

- Unilateral or bilateral renal agenesis is associated with other birth defects related to cardiovascular system, respiratory system, gastrointestinal system, skeletal muscles, bones, ears and eyes.
- Newborn babies with unilateral renal disease develop symptoms at birth or during childhood and not until later in life such as hypertension, proteinuria and swelling over face, hands and legs. Newborn babies with bilateral renal agenesis do not survive. Clinical examination reveals widely separated eyes with skin folds over eyes, low set eyes, flat broad nose, small chins, defects in arms and legs.
- Predisposing factors for renal agenesis and other defects include oligohydramnios, prepregnancy obesity, alcohol use and tobacco smoking. Potter syndrome in unborn infant is characterized by amniotic fluid, renal failure, duodenal atresia or with tracheoesophageal fistula.

MULTICYSTIC RENAL DYSPLASIA

Multicystic renal dysplasia results from the malformation of the kidney during fetal development. The kidney consists of irregular cysts of varying sizes leading to abdominal mass in infants. Multicystic renal dysplasia occurs in the setting of branchiootorenal (BOR) syndrome. BOR syndrome is characterized by malformations of the ears and kidneys. Mutations in three genes, EYA1 (located on 8q13, most common mutation in 40%), SIX1 and SIX5 have been observed in persons with BOR syndrome. Renal ultrasonography is the recommended initial imaging study.

Surgical Pathology: Multicystic Renal Dysplasia

Gross Morphology

Kidney is enlarged and distorted by variable-sized cysts involving one or both kidneys. Cut surface shows indistinct corticomedullary junction. Multicystic renal dysplasia is usually associated with ureteropelvic obstruction or ureteral atrophy/atresia.

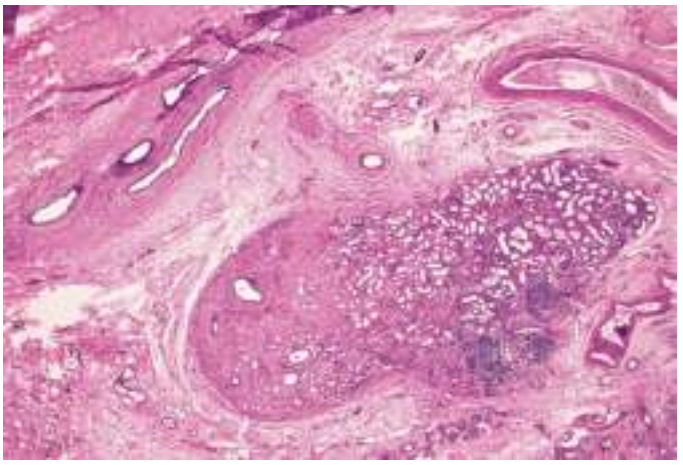

Fig. 22.95: Multicystic renal dysplasia. Multicystic renal dysplasia results from the malformation of the kidney during fetal development. The kidney consists of irregular cysts of variable sizes. Infants present with abdominal mass. Hematoxylin and eosin-stained renal tissue section shows disorganized renal parenchyma that is distorted by cysts of variable sizes, lined by flattened to cuboidal epithelium. It may contain nodular blastema (undifferentiated cells), islands of undifferentiated mesenchyme, cartilage (10–20%), immature collecting ducts and primitive glomerular structures (400X).

Light Microscopy

Multicystic renal dysplasia is composed of disorganized renal parenchyma due to multiple variable-sized renal cysts, which are lined by flattened to cuboidal epithelium. It may contain blastema component (undifferentiated cells), islands of mesenchyme, immature collecting ducts and primitive glomeruli. Histology of multicystic renal dysplasia is shown in Fig. 22.95.

SEVERE CONGENITAL ANOMALIES OF KIDNEYS AND URINARY TRACT

Severe congenital anomalies of kidneys and urinary tract (CAKUT) can result in life-threatening kidney failure and end-stage renal disease. Many different developmental abnormalities of urinary tract are classified as underdevelopment or absence of a kidney such as renal hypoplasia or renal agenesis; fluid-filled renal cysts, hydronephrosis, extra kidney or extra ureter; obstruction of ureter at ureteropelvic junction and posterior urethral valve. Genetic syndromes associated with severe congenital anomalies of kidneys and urinary tract are given in Table 22.64.

- CAKUT occurs due to combination of genetic and environmental factors. Role of genetic factors in pathogenesis of CAKUT is unknown in majority of cases.
- Many syndromes such as branchiootorenal syndrome, renal cysts and diabetes (RCAD) syndrome, renal

Table 22.64 Genetic syndrome associated congenital anomalies of kidney and urinary tract

Genetic Syndrome	Characteristics
Renal coloboma syndrome (also known as papillorenal syndrome)	Genetic disorder affects kidney and eye development, the kidneys are small and underdeveloped (hypoplastic), which can lead to end-stage renal disease (ESRD)
17q12 deletion syndrome	Severe malformation of kidney and urinary system, development of maturity-onset diabetes mellitus of young (MODY), intelligence instability (autism spectrum disorder, schizophrenia, bipolar disorder)
Renal cysts and diabetes (RCAD) syndrome	Maturity-onset diabetes mellitus of young (MODY); characterized by heterogeneous cystic renal disease and early-onset familial non-autoimmune diabetes mellitus
Fraser syndrome	Fused eyelids (cryptophthalmos), fusion of the skin between the fingers and toes (syndactyly), and abnormalities of genitalia and urinary tract
Townes-Brocks syndrome	Imperforate anus, abnormally shaped ears, and hand malformations that most often affect the thumb, and developmental anomalies of urinary system
Branchiootorenal syndrome (also called Melnick-Fraser syndrome)	Autosomal dominant disorder involving the kidneys, ears, and neck

coloboma syndrome, Fraser syndrome, and 17q12 deletion syndrome can cause urinary tract abnormalities.

- PAX2 genes encode proteins, which play important role in the embryogenesis of urinary tract. The genes most commonly involved in the pathogenesis of isolated cases of CAKUT include PAX2 associated with renal coloboma syndrome, HNF1B associated with 17q12 deletion syndrome, RCAD syndrome. Mutations in other genes are involved in the pathogenesis of isolated CAKUT. About 10–20% of CAKUT occur in families.
- In addition, environmental factors may play important role in the pathogenesis of isolated CAKUT.
- Risk for CAKUT is increased in those babies, whose mothers are suffering from diabetes mellitus, taking anti-epileptic drugs and diet deficient in vitamins and minerals such as folate and iron during pregnancy.
- Inherited CAKUT most commonly follows autosomal dominant pattern, which means one copy of altered gene in each cell is sufficient to cause CAKUT.
- In autosomal recessive pattern of CAKUT, both copies of the gene are mutated in each cell. Inheritance pattern is unknown in many cases of CAKUT. Congenital anomalies and malformations of the kidneys and urinary tract are given in Table 22.65.

Table 22.65 Congenital anomalies and malformations of the kidneys and urinary tract

Renal agenesis unilateral or bilateral (Potter disease)
Renal dysplasia
Renal hypoplasia
Renal fusion, ectopia, and duplication
Ureteropelvic junction obstruction
Vesicoureteral junction obstruction and vesicoureteral reflux
Ureteral duplication and ectopia
Ureterocele
Urethral atresia and posterior urethral valves
Urinary bladder exstrophy, persistent cloaca and rectovesical fistula

ECTOPIC KIDNEY

An ectopic kidney is a birth defect in which kidney does not reach the lumbar region and remains located in an abnormal position in pelvis or presacral region one in every 1,000 births.

- During fetal development, the baby's kidneys first appear as buds near the urinary bladder in the pelvic region.
- The fetal kidneys gradually move upward during fetal development. The fetal kidneys initially located in the lower abdomen move upward toward their permanent normal position in lumbar region.
- Sometimes, one of the kidneys fails to climb upwards and remains located in the pelvis or presacral region. Rarely, both the kidneys may remain in the pelvic region.
- Sometimes, ectopic kidney is observed as an incidental finding. Some patients may present with urinary problems.
- Vesicoureteral reflux (VUR) may cause urinary tract infection, urolithiasis and renal failure. Ectopic kidney can be detected by ultrasonography, nuclear scan, CT scan and MRI scan.

HORSESHOE KIDNEY

Fusion of both kidneys at their lower poles results in so-called horseshoe kidney in 90% of cases. It may

cause urinary tract obstruction because of impingement on the ureters.

- Predisposing factors for horseshoe kidney include abnormal migration of nephrogenic cells across the primitive streak, alterations in the intrauterine environment caused by intake of teratogenic drugs such as thalidomide and alcohol consumption during pregnancy. Horseshoe kidneys are often asymptomatic, and so are often identified incidentally.
- The kidneys are normally located in the retroperitoneal region between the transverse processes of T12 and L3. The left kidney is slightly higher than right kidney. The upper poles of the kidneys are normally positioned slightly medially and posteriorly relative to the lower poles. Horseshoe kidneys are different in three main ways: location, orientation, and vasculature.
- The horseshoe kidneys are located at L3 vertebra in the abdomen and pelvis, and exhibit great variation in the origin and number of renal arteries and veins.
- Normally, the renal ascent is coupled with a 90° medial rotation during six to eight weeks of development.
- Due to the isthmus, horseshoe kidneys experience malrotation, and consequently, the ureters need to either pass over the isthmus or down the anterior surface of the kidneys resulting in urinary drainage problems and stasis. Horseshoe kidney is detected by ultrasonography, CT scan and MRI.

URETER ANOMALIES

Ureter anomalies include congenital diverticulum, double ureters, ectopic ureter, hydroureter, megaureter, ureteral agenesis and ureteropelvic junction obstruction. Congenital diverticulum (all layers of ureter wall) occurs due to aberrant development of ureteric bud; and lined by urothelium, sometimes squamous metaplasia or urethritis glandularis. Patient may develop recurrent urinary tract infections.

- Double ureters are relatively incidental findings associated with duplication of renal pelvis in 2–3% of all persons. Ectopic ureter is more common in women than men, that may terminate into structures such as proximal urethra, seminal vesicle/ejaculatory duct, vas deferens, fallopian tube, uterus or vagina. Hydroureter may have neurogenic cause. Megaureter is often divided into obstructive type with smooth muscle defect and refluxing type with defective interstitial cell of Cajal-like cells.
- Ureteral agenesis occurs due to failure to develop mesonephric diverticulum, and is associated with failure of ipsilateral kidney to develop. Ureteropelvic junction obstruction occurs due to abnormal organization of smooth muscle bundles, which is the most common cause of hydronephrosis in children. Ureteropelvic junction obstruction is more common in males and on left side and bilateral in 20% of cases, which may be associated with agenesis of contralateral kidney.

NEOPLASTIC DISORDERS OF KIDNEY

Renal neoplasms are classified into two categories: primary (benign or malignant) and secondary tumors. Revised 2024 WHO classification of kidney neoplasms is given in Table 22.66. Common malignant neoplasms of the urinary tract are shown in Fig. 22.96. Classification of renal cell carcinomas has become challenging. According to the 2024 WHO classification, nomenclature of renal cell carcinomas is based on cytoplasmic appearance, architecture, combination of morphologic features, anatomic location, underlying disease, familial syndromes and specific genetic alterations. Panel of immunohistochemical markers applied in the renal neoplasms is given in Table 22.67.

Pathology Pearls: Metastases (Secondary Tumors) Involving Kidneys

- Metastatic (secondary) tumors to kidney include breast carcinoma, bronchus carcinoma, malignant melanoma and lymphomas.
- Metastases to kidneys are multiple involving both kidneys.
- Metastases exhibit central indentations, or umbilications, from necrosis.
- Clinical features in a patient with renal angiomyolipoma (hamartoma) initially are similar to renal cell carcinoma.

NEPHROBLASTIC AND CYSTIC TUMORS

According to 2024 WHO classification of renal tumors, nephroblastic and cystic tumors include nephrogenic rests, nephroblastoma (Wilms' tumor), cystic partially nephroblastoma and pediatric cystic nephroma.

WILMS' TUMOR (NEPHROBLASTOMA)

Wilms' tumor (nephroblastoma) is the most common pediatric solid malignant renal tumor, which can present a single nodule, as multifocal unilateral tumor or bilateral tumors. The tumor is often huge resulting

Table 22.66 Revised 2024 WHO classification of renal neoplasms

Renal Cell Neoplasms

- Clear cell renal neoplasms
  - Renal cell carcinoma clear cell variant
  - Multilocular cystic renal neoplasm of low malignant potential
- Papillary renal neoplasms
  - Papillary adenoma
  - Renal cell carcinoma papillary variant
- Oncocytic and chromophobe renal neoplasms
  - Renal oncocytoma
  - Renal cell carcinoma chromophobe variant
  - Other oncocytic neoplasms of kidney
- Collecting duct neoplasms
  - Collecting duct carcinoma
- Other renal tumors
  - Renal cell carcinoma papillary clear cell variant
  - Mucinous tubular and spindle cell carcinoma
  - Tubulocystic renal cell carcinoma
  - Acquired cystic disease-associated renal cell carcinoma
  - Eosinophilic solid and cystic renal cell carcinoma
  - Renal cell carcinoma, NOS
- Molecularly defined renal carcinomas
  - TFE_3-rearranged renal cell carcinoma
  - TFEB-altered renal cell carcinoma
  - ELOC (formerly TCEB1)-mutated renal cell carcinoma
  - Fumarate hydratase-deficient renal cell carcinoma
  - Hereditary leiomyomatosis and renal cell carcinoma
  - Syndrome-associated renal cell carcinoma
  - Succinate dehydrogenase-deficient renal cell carcinoma
  - ALK-rearranged renal cell carcinoma
  - Renal medullary carcinoma, NOS
  - $SMARCB_1$-deficient medullary-like renal cell carcinoma
  - $SMARCB_1$-deficient undifferentiated renal cell carcinoma, NOS
  - $SMARCB_1$-deficient dedifferentiated renal cell carcinoma

Contd...

Metanephric Tumors

- Metanephric adenoma
- Metanephric adenofibroma
- Metanephric stromal tumor

Mixed Epithelial and Stromal Neoplasms

- Mixed epithelial and stromal tumor
- Adult cystic nephroma
- Pediatric cystic nephroma

Renal Mesenchymal Neoplasms

- Adult renal mesenchymal renal neoplasms
- Angiomyolipoma
- Oncocytic angiomyolipoma with epithelial cysts
- Angiomyolipoma, epithelioid
- Hemangioblastoma
- Juxtaglomerular neoplasm
- Functioning juxtaglomerular cell neoplasm
- Renal medullary interstitial cell neoplasm
- Pediatric renal mesenchymal renal neoplasms
- Ossifying renal tumor of infancy
- Mesoblastic nephroma
- Classic congenital mesoblastic nephroma
- Cellular congenital mesoblastic nephroma
- Mixed congenital mesoblastic nephroma
- Malignant rhabdoid neoplasm of the kidney
- Clear cell sarcoma of kidney

Embryonal Neophroblastic Neoplasms of the Kidney

- Nephrogenic rests
- Perilobar nephrogenic rests
- Nephroblastomatosis
- Cystic partially differentiated nephroblastoma
- Nephroblastoma

Miscellaneous Germ cell Neoplasms

- Peripubertal-type teratoma
- Teratoma with carcinoid (neuroblastoma neoplasm)
- Renal hematopoietic neoplasms
- Yolk sac tumor, NOS
- Mixed teratoma yolk sac tumor

in abdominal distension. Patient usually presents with abdominal mass without symptoms or with abdominal pain, hematuria.

- Wilms' tumor is derived from embryonal mesonephric mesoderm. The tumor is composed of elements that resemble normal fetal tissue: (a) metanephric blastema component (abortive glomeruli, tubules), (b) immature mesenchymal stroma, and (c) immature epithelial elements. It occurs between 1–5 years of age and before 9 years of age in 90% of cases and rarely occurs after age of 9 years.
- In most instances, Wilms' tumor is sporadic (90%) and unilateral. However, in 5% of cases, tumor arises in the setting of several congenital syndromes in 10% of cases. It is diagnosed prior to six years of age in 90% of cases. Males and females are equally affected.
- WT1 tumor suppressor gene mutation is implicated in the development of Wilms' tumor. Molecular genetic signatures of Wilms' tumor, such as TP53 gene mutation and MYCN gene dysregulation may provide future additional prognostic and therapeutic information.
- Approximately 90% of Wilms' tumors have favorable histology. About 3–7% of tumors have anaplastic histology. Tumor resembles the fetal nephrogenic zone and attempts to form primitive glomeruli and tubules.
- The classic histologic pattern of Wilms' tumor is triphasic and composed of epithelial, blastemal,

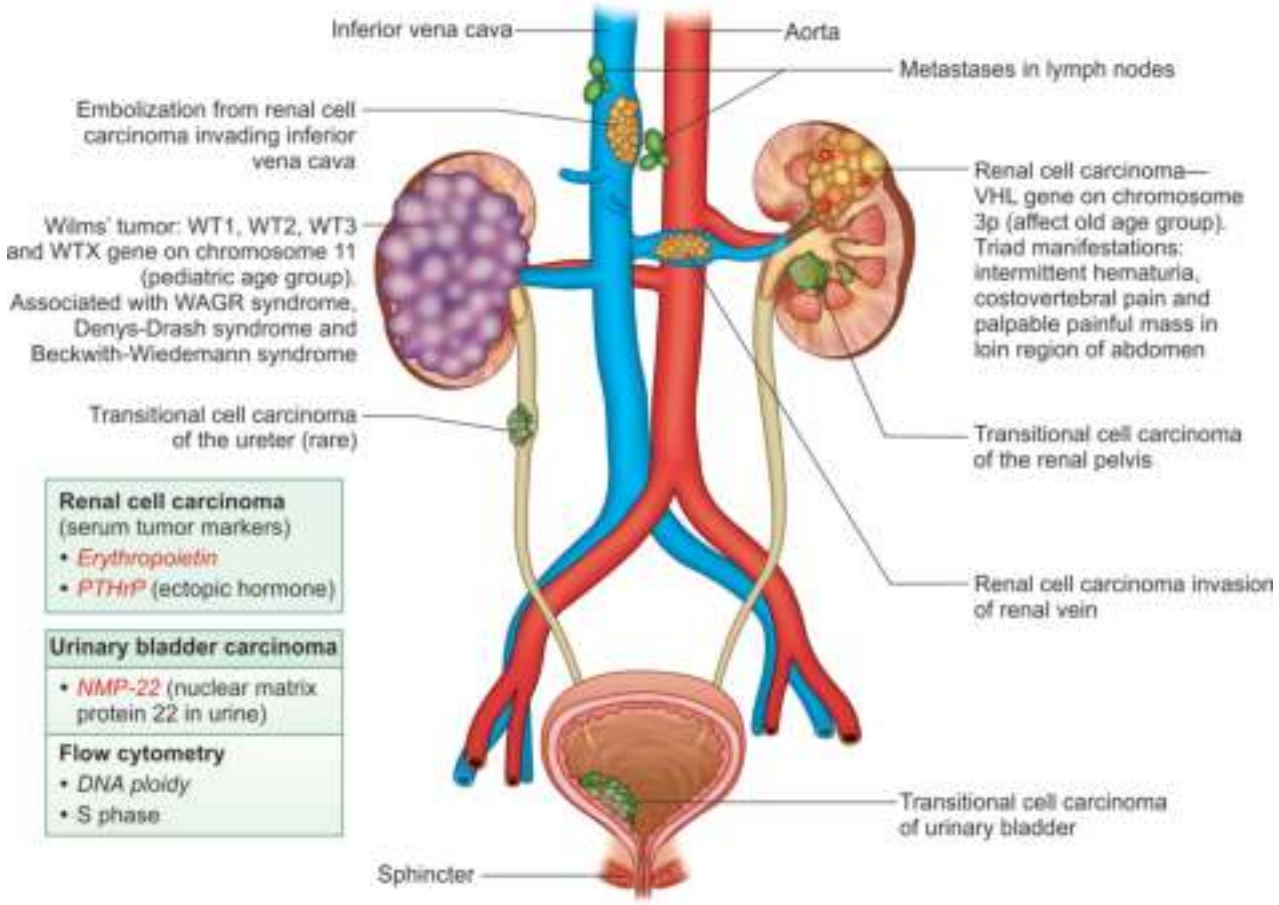

Fig. 22.96: Schematic representation of common malignant neoplasms of the upper and lower urinary tract.

Table 22.67 Panel of immunohistochemical markers applied in the renal neoplasms

Markers	Expression
Renal oncocytoma	
β-Defensin 1	Positive (100%)
Parvalbumin	Positive (100%)
Vimentin	Positive (100% to focal)
CD117 (proto-oncogene c-KIT is the gene encoding the receptor tyrosine-protein kinase, known as tyrosine-protein kinase, KIT, CD117)	Positive
CD7	Negative
GST-α	Negative
EpCAM	Negative
Clear cell renal cell carcinoma	
PAX2	Positive (best marker)
CAIX (carbonic anhydrase)	Positive (membranous diffuse staining), most sensitive and specific marker in inherited (100%) and sporadic cases (75%)
PAX8	Positive
RCC Ma	Positive
CD10	Positive
Vimentin	Positive
CK8	Positive
CK18	Positive
EMA	Positive
AE1/AE3	Positive
CAM5.2	Positive
α_1-Antitrypsin	Positive
S-100 protein	Positive
KS-cadherin	Negative/positive
CD117 (proto-oncogene c-KIT is the gene encoding the receptor tyrosine-protein kinase, KIT, CD117)	Negative/positive

Contd...

Table 22.67 Panel of immunohistochemical markers applied in the renal neoplasms (*Contd...*)

Markers	Expression
Papillary (chromophil) renal cell carcinoma	
CK7	Positive
Recemase	Positive
PAX8	Positive
PAX2	Positive
AMACR	Positive
AE1/AE3 (low molecular cytokeratin)	Positive
EMA	Positive
MUC1	Positive
RCC Ma	Positive
CD10	Positive
CD117 (proto-oncogene c-KIT is the gene encoding the receptor tyrosine-protein kinase, KIT, CD117)	Positive
Vimentin	Positive/negative (variable staining)
CAIX (carbonic anhydrase)	Negative (except in areas of necrosis)
Chromophobe renal cell carcinoma	
Hale's colloidal iron (HCI)	Positive (blue cytoplasmic staining)
EpCAM (epithelial cell adhesion molecule)	Positive (new marker)
CD117 (proto-oncogene c-KIT is the gene encoding the receptor tyrosine-protein kinase, KIT, CD117)	Positive
TFE-3	Positive
Cathepsin K	Positive
PAX8	Positive
EMA	Positive
CK8/CK18	Positive
E-cadherin	Positive
Claudin 7	Positive
Ki-67	Positive (low expression)
N-cadherin	Negative
Vimentin	Negative
Renal cell carcinoma with Xp11.2 translocation and TFE3 fusions	
TFE-3 transcription factor	Positive (nuclear staining)
TFE-B transcription factor	Positive (nuclear staining)
CD10	Positive
AMACR	Positive
Vimentin	Positive
E-cadherin	Positive (66%)
CK19	Positive (30–50%)
EMA	Positive (30%)
Cathepsin K	Positive
Collecting duct carcinoma of Bellini	
PAX8	Positive
PAX2	Positive
Ulex europaeus lectins (Ulex-1)	Positive
Peanut agglutinin (PNA)	Positive
Mucin	Positive
Vimentin	Positive
CK8/18	Positive
CK19	Positive
EMA	Positive
S-100A1	Positive
Urothelial carcinoma of renal pelvis	
CK7	Positive (93%)
p63	Positive (92%)
CK903	Positive (92%)
CK20	Positive (70%)
Renal clear cell sarcoma	
Vimentin	Positive (hallmark is absence of any differentiation)
Wilms' tumor (nephroblastoma)	
Blastema component	
▪ WT1 ▪ Desmin	▪ Positive ▪ Positive
Epithelial component	
▪ WT1 ▪ Cytokeratin ▪ EMA ▪ CD57	▪ Positive ▪ Positive ▪ Positive ▪ Positive
Stromal component	
▪ Myogenin ▪ S-100 protein	▪ Positive (rhabdomyoblastic component) ▪ Positive (neural component)
Renal angiomyolipoma	
HMB-45	Positive
Melan A	Positive
Actin	Positive
Vimentin	Positive
TFE3 (transcription factor E3)	Negative/positive
Cathepsin K	Negative/positive

Contd...

and stromal elements. The proportion and degree of maturation of these components in tumor are observed in varying proportion in hematoxylin and eosin-stained renal tissue section.

- Biphasic and monophasic Wilms tumors are not infrequent. Epithelial and stromal elements may demonstrate different lines and degrees of differentiation, i.e. from poor to well differentiated.

Sporadic Wilms' Tumor

WT1 gene mutation has been demonstrated in stromal component of Wilms' tumor in some sporadic cases. It suggests that the stromal component of Wilms' tumor is neoplastic, which raises the possibility that undifferentiated blastema cells are precursors of the stromal and heterologous elements. It has been suggested that in addition to WT1; WT2 gene mutation plays an important role in the genesis of sporadic cases of Wilms' tumors.

Wilms' Tumor in Familial Syndromes

WT1 tumor suppressor gene is located on short arm of chromosome 11 (11p13). Wilms' tumor is caused by deletion or inactivation of WT1 gene. WT1 gene mutation also affects contiguous genes and causes other lesions in 10% of familial cases. Patient with familial syndromes may develop Wilms' tumor.

- **WAGR syndrome:** WAGR syndrome is characterized by Wilms' tumor (WT1 gene mutation), aniridia (absence of the iris) due to mutation of contiguous aniridia gene (PAX6 gene located on chromosome 11), genitourinary malformations and mental retardation.
- **Denys-Drash syndrome:** Denys-Drash syndrome (DDS) is characterized by Wilms' tumor (WT1 gene mutation), genitourinary malformations, intersexual disorders, tumors of the gonads (ovaries or testes) and glomerulopathy (mesangial sclerosis) resulting in chronic renal failure.
- **Beckwith-Wiedemann syndrome:** Beckwith-Wiedemann syndrome (BWS) is characterized by Wilms' tumor, unusual 'hemihypertrophy' (ranging from gigantism to asymmetric growth), tumors of the liver and adrenal glands, hepatosplenomegaly, macroglossia, malformations around the ear; and abdominal wall defects near the navel (omphalocele). This is thought to be caused by an overactive copy of an IGF_2 oncogene on chromosome 11, if becomes overactive; then it results in uncontrolled cell growth.

Clinical Features

Patient presents with large abdominal unilateral nontender mass, hematuria, hypertension (due to increased renin secretion), and pain abdomen due to pressure exerted by tumor on surrounding structures. Constitutional symptoms are anorexia, loss of appetite, generalized weakness and weight loss. Patient may present with traumatic rupture or lung metastases.

Mode of Spread

Wilms' tumor spreads into the perirenal soft tissue. Tumor may metastasize to regional lymph nodes via lymphatic route. Wilms' tumor may invade renal vein and spreads via hematogenous route to various organs in decreasing frequency such as lung (most common), liver, brain and peritoneum.

- Tumor rarely metastasizes to bones in contrast to neuroblastoma, where bone is the principal site.
- Tumor may metastasize to opposite kidneys (5–10%), adrenal glands, bowel, vertebrae and paraspinal region.
- Histologic examination establishes the diagnosis of Wilms' tumor. Fine needle aspiration cytology and frozen sections are unreliable.
- About 80–90% of patients are cured. However, small percentage of children develop second neoplasms.

Surgical Pathology: Wilms' Tumor (Nephroblastoma)

Gross Morphology

- The kidney is extensively replaced by large well-circumscribed bulging fleshy, pale white tumor demarcated from renal parenchyma.
- Cut surface reveals gray-white or pink-gray, lobulated, homogenous soft tumor enclosed in a rim of renal cortex and capsule. Cysts and lobular pattern are common. In pretreated cases, hemorrhage and necrosis are quite extensive. It is important that gross sampling must include adequate tumor from main tumor mass, renal sinus and its blood vessels and ureter.
- About 10% of tumors are bilateral or multicentric. Adequate sampling of tumor is essential. It should include at least one block per centimeter of largest dimension.
- Sections are required from renal pelvis, renal sinus, tissues surrounding renal artery and vein and the junction between normal kidney and tumor, tumor capsule and uninvolved kidney. Tissue is taken for molecular studies, Gross morphology of nephroblastoma (Wilms' tumor) is shown in Fig. 22.97.

Light Microscopy

Wilms' tumor resembles the fetal nephrogenic zone and attempts to form primitive glomerular and tubular structures. Tumor is composed of triphasic components. Presence of anaplastic features is associated with poor prognosis. Histology of nephroblastoma (Wilms' tumor) is shown in Figs 22.98 and 22.99.

- **Metanephric blastema:** It is composed of poorly developed abortive glomeruli and tubules with elongated /ovoid nuclei having molded/wedged shapes. Undifferentiated blastema is composed of primitive small blue cells with scanty cytoplasm, overlapping nuclei with finely dispersed chromatin arranged in diffuse, nodular, cord-like or basaloid pattern.

- **Immature mesenchymal tissue:** It is composed of striated muscle together with myxoid tissue, cartilage, bone and fat and thus creating a rather bizarre mixture.
- **Immature epithelial tissue:** It consists of immature squamous or mucinous epithelial tissue.

Electron Microscopy

Wilms' tumor resembles developing metanephros with well-developed cell junctions, microvilli and layer of thick flocculent coating around cell surface.

Immunohistochemistry Technique

Panel of markers is applied to formalin-fixed paraffin-embedded sections to demonstrate various components of Wilms' tumor such as blastema (WT1, desmin), epithelial component (WT1, cytokeratin, EMA) and stromal component (myogenin for rhabdomyoblastic component; S-100 protein for neural tissue).

Markers	Expression
Blastema component	
▪ WT1 ▪ Desmin	▪ Positive ▪ Positive
Epithelial component	
▪ WT1 ▪ Cytokeratin ▪ EMA (epithelial membrane antigen) ▪ CD57	▪ Positive ▪ Positive ▪ Positive ▪ Positive
Stromal component	
▪ Myogenin ▪ S-100 protein	▪ Positive (rhabdomyoblast component) ▪ Positive (neural component)

Molecular/Genetic Alterations

WT1 tumor suppressor gene is located on short arm of chromosome 11 (11p13). Wilms' tumor is caused by deletion or inactivation of WT1 gene. WT1 gene mutation also affects contiguous genes and causes other lesions in familial cases. Molecular genetic alterations in Wilms' tumor are given in Table 22.68.

Staging of Wilms' Tumor

A staging system is a standard way for the cancer care team to sum up the extent of the tumor. Staging system is used most often to describe the extent of spread of Wilms' tumors. This system divides Wilms' tumors into five stages using Roman numerals I through V. Staging of Wilms' tumor is given in Table 22.69.

Poor Prognostic Factors

Large size Wilms' tumor in children over two years of age is associated with poor prognosis. Diffuse anaplasia in stage II, III or IV tumors is also associated with poor outcome. Even small foci of anaplasia in the Wilms' tumor are associated with poor prognosis due to chemotherapy resistance. Presence of predominant epithelial component is demonstrated in stage I. Most blastema predominant tumors are stage III/IV.

Sporadic and inherited Wilms' tumor

Sporadic cases • Wilms' tumor 1 (WT1) gene mutation (85%) • WT1 gene mutation on 11p13 (15%)	**WAGR syndrome** • Wilms' tumor 1 (WT1) gene mutation (33%) • Aniridia and genital anomalies (100%)
Denys-Drash syndrome • Wilms' tumor 1 (WT1) gene mutation • Congenital nephropathy • Inter-sex disorders	**Beckwith-Wiedemann syndrome** • Wilms' tumor 2 (WT2) gene mutation on 11p15.5 • Hemihypertrophy • Increased risk of other tumor

Fig. 22.97: Gross morphology of nephroblastoma (Wilms' tumor). Patient usually presents with abdominal mass without symptoms or with abdominal pain, hematuria, hypertension and anemia. The kidney is extensively replaced by large solitary, spherical, bulging, fleshy, and pale white tumor demarcated from renal parenchyma. Cut surface reveals gray-white or pink-gray, lobulated soft tumor enclosed in a rim of renal cortex and capsule. In pretreated cases, hemorrhage and necrosis are quite extensive. It is important that gross sampling must include adequate sample tumor from main tumor mass, renal sinus and its vessels and ureter. (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

Laboratory Diagnosis

Wilms' tumor is diagnosed by imaging techniques including abdominal ultrasonography, CT scan, and magnetic resonance imaging. Chest X-ray is done to rule out lung metastases. Kidney and liver function tests, FNAC and histologic examination are diagnostic tools.

RENAL ONCOCYTOMA

Renal oncocytoma is a benign epithelial tumor composed of uniform, round to polygonal cells with abundant, intensely mitochondria-rich eosinophilic

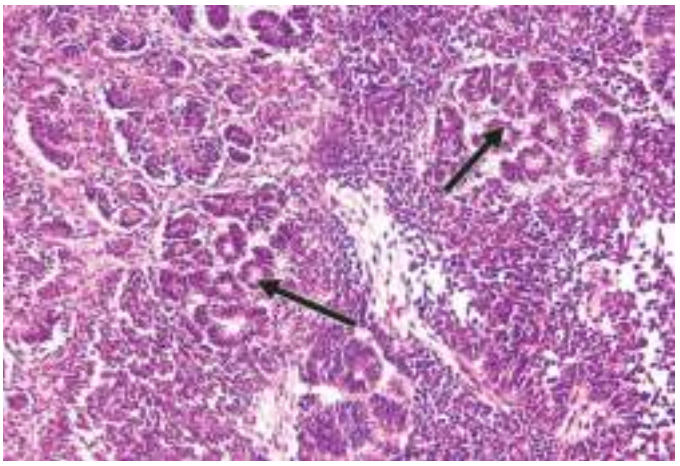

Fig. 22.98: Histology of nephroblastoma (Wilms' tumor). Nephroblastoma resembles the fetal nephrogenic zone and attempts to form primitive glomerular and tubular structures. Triphasic tumor consists of blastemal, epithelial and stromal components, which can be present in variable amount. Biphasic and monophasic tumors are not infrequent. Epithelial and stromal elements may demonstrate different lines and degrees of differentiation, i.e. from poor to well differentiated (arrows) (400X).

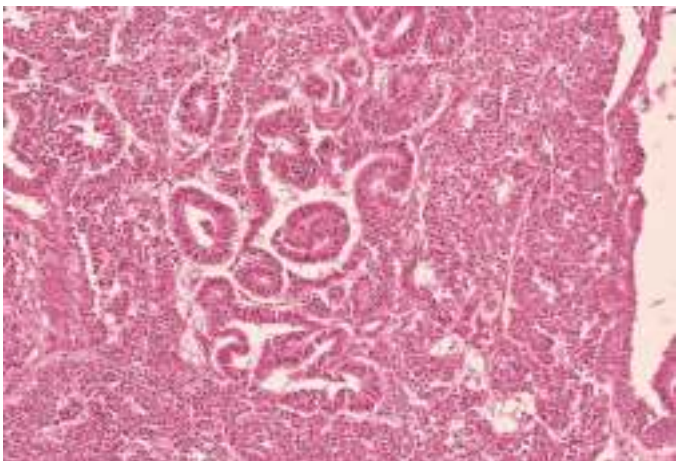

Fig. 22.99: Histology of nephroblastoma (Wilms' tumor). Wilms' tumor is most common pediatric renal tumor, which can present a single nodule, as multifocal unilateral lesions or a bilateral tumor. Approximately 90% of Wilms' tumors have favorable histology. About 3–7% of tumors have anaplastic histology. Molecular genetic signatures of Wilms' tumor, such as TP53 mutation and MYCN dysregulation may provide future additional prognostic and therapeutic information. The classic histologic pattern of Wilms' tumor is triphasic and composed of epithelial, blastemal, and stromal elements. The proportion and the degree of maturation of these components are present in varying proportion in hematoxylin and eosin-stained renal tissue section (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Table 22.68 Molecular genetic alterations in Wilms' tumor

Cytogenetics of Wilms' tumor are deletion or mutations involving WT1 (11p13), WT2 (11p15), or WTX (Xp11.1)
Implicated genes are tumor suppressor genes such as WT1, WT2, WT3, WTX
Normal WT1, WT2, WT3, WTX encode zinc-finger transcription factor (DNA-binding tumor suppressor protein) expressed early in urogenital system development
Related assay(s) include IPOX for WT1
p53 abnormalities are demonstrated in anaplastic foci of Wilms' tumor
FWT1 (17q12–121) and FWT2 (19q13) mutations have been demonstrated in familial Wilms' tumor
Absence of t(12;15) of cellular mesoblastic nephroma
Absence of t(11;22) of Ewing's/PNET
Absence of 22q11.2 abnormalities of rhabdoid tumor
Absence of N-Myc of neuroblastoma

Table 22.69 Staging of Wilms' tumor

Stage	Wilms's Tumor involving Structures
Stage I	Tumor limited to the kidney with intact capsule and completely resected. There is no rupture of blood vessels
Stage II	Tumor has invaded renal capsule involving surrounding structures
Stage III	Tumor has spread beyond the kidney area involving abdominal or pelvic lymph nodes. Resection of tumor is not possible
Stage IV	The tumor has spread to distant structures such as the lungs, liver or brain. Metastases of lymph nodes outside abdomen and pelvis
Stage V	Bilateral renal involvement at diagnosis

and granular cytoplasm with uniform small, round and central nuclei with evenly dispersed chromatin. It is thought to arise from intercalated cells of collecting duct in the kidney. It accounts for 4–7% of adult renal epithelial tumors. It has wide range of age distribution in adult men above 50 years of age with a peak incidence in the seventh decade of life.

- About 66% of cases are detected as incidental finding on imaging techniques. It may coexist with renal cell carcinoma. Rarely, it is associated with chronic renal failure due to multiple tumors or large bilateral tumor. Patient may have renal oncocytoma as a component of Birt-Hogg-Dubé syndrome. Patient with this syndrome is at higher risk for renal cell carcinoma, lung cysts and spontaneous pneumothorax.
- Most patients are asymptomatic, however, some patients present with classic triad of hematuria, flank pain and flank mass as observed in cases of renal cell carcinoma. Imaging studies demonstrate solid homogenous mass in renal parenchyma and a central irregular scar, although not specific and not always present. Renal oncocytoma is treated by radical nephrectomy and associated with excellent prognosis. Comparison of gross and histologic features of some benign renal tumors is given in Table 22.70.

Table 22.70 Comparison of gross and histologic features of some benign renal tumors

Renal Papillary Cortical Adenoma	Renal Oncocytoma	Metanephric Adenoma
Gross morphology		
▪ Size <2 cm in subcapsular region ▪ Cut surface is pale yellow to gray	Well-circumscribed tumor arising from proximal and distal tubules in poles. Cut surface has a uniform mahogany, brown color due to mitochondrial lipochrome pigments	Small solid lesion in the renal cortex
Light microscopy		
Tumor is composed of small uniform cells with clear to eosinophilic cytoplasm forming branching papillary fronds	Tumor is composed of large epithelial cells called oncocytes, which have abundant eosinophilic homogeneous or granular cytoplasm (mitochondria) and uniform small nuclei	Tumor is composed of small round cells with bland nuclei and scanty cytoplasm. These are arranged in tubules and papillae with scant stroma. Areas of calcification may be seen

Pathology Pearls: Renal Oncocytoma

- Renal oncocytoma is a benign neoplasm. It is believed to arise from renal duct intercalated cells and are packed with defective mitochondria under electron microscopy.
- Tumor is well circumscribed mass renal cortex replacing renal parenchyma. Cut surface is mahogany brown to tan or yellow.
- Hemorrhage may be present but lacking necrosis. Large tumor can extend into and expand the perinephric fat, renal sinus even renal vein.
- Tumor is composed of large round eosinophilic cells (oncocyte) with dense granular cytoplasm with round irregular nuclei containing even chromatin and conspicuous nuclei arranged in small solid sheets in a loose connective tissue. Mitotic figures are rare or absent.
- Other architectures in renal oncocytoma include tubular, microcystic and macrocytic, packed nests projecting a solid appearance.

Surgical Pathology: Renal Oncocytoma

Gross Morphology

- Renal oncocytoma is well-circumscribed and unencapsulated in renal cortex measuring 3–6 cm. Central satellite scar in large tumor may be present in 30% of cases.
- Cut surface is solid, homogenous and mahogany or dark brownish yellow. Hemorrhage may be present in 20% of renal oncocytoma, but necrosis is rarely demonstrated.
- Bilateral and multiple renal oncocytomas in the kidney can be demonstrated invading renal capsule and renal vein in 5% of cases. Gross morphology of renal oncocytoma is shown in Fig. 22.100.

Light Microscopy

- Renal oncocytoma is composed of uniform round-to-polygonal cells with abundant, intensely eosinophilic owing to cytoplasmic mitochondria and granular cytoplasm, with small uniform, round and central nuclei with evenly dispersed chromatin and smooth contour of nuclear membrane.
- Tumor cells are arranged in nests, alveolar or tubular patterns. Stroma is myxoid or hyalinized in the central scar.
- Renal oncocytoma frequently demonstrate oncoblasts, and small tumor cells with minimal cytoplasm dense hyperchromatic nuclei. Tumor may show extensive papillary structure in occasional case. Tumor extension to perinephric fat without stromal response can occur in 20% of cases.
- Occasional renal oncocytoma tumor may demonstrate psammoma bodies, cystic change, invasion of capsule, perinephric fat and renal vein in 5% of cases. Renal cell carcinoma should always be ruled out first. Oncocytosis refers to numerous oncocytic lesions involving the kidney. Histology of renal oncocytoma is shown in Fig. 22.101.

Histochemistry

Hale's colloidal iron is showing luminal staining.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections of renal oncocytoma shows positivity for β-defensin 1, parvalbumin, CD117, vimentin.

Markers	Expression
▪ β-Defensin 1	▪ Positive (100%)
▪ Parvalbumin	▪ Positive (100%)
▪ CD117 (c-KIT)	▪ Positive
▪ Vimentin	▪ Negative (majority)/focal positivity in tumor cells within septa
▪ CK7	▪ Negative
▪ GST-α	▪ Negative
▪ EpCAM	▪ Negative

RENAL CELL CARCINOMA

Renal cell carcinoma (RCC) is most common cancer in men and women with male to female ratio 1:2 above 50 years of age.

- Risk factors for renal cell carcinoma include obesity, tobacco smoking, hypertension, acquired cystic kidney disease due to end stage renal disease, occupational exposure to trichloroethylene, and treated cases of neuroblastoma.
- Genetic susceptibilities estimated to account for 2–4%. Renal cell carcinoma may be sporadic or familial.

Fig. 22.100: Gross morphology of renal oncocytoma. Renal oncocytoma is a benign neoplasm. It is believed to arise from renal intercalated cells and are packed with defective mitochondria under electron microscopy. Tumor is well circumscribed mass in renal cortex replacing renal parenchyma. Cut surface is mahogany brown to tan or yellow. Areas of hemorrhage may be present but lacking necrosis. Large tumor can extend into and expand the perinephric fat, renal sinus even renal vein. (*Courtesy:* Dr. Neha Kumari.)

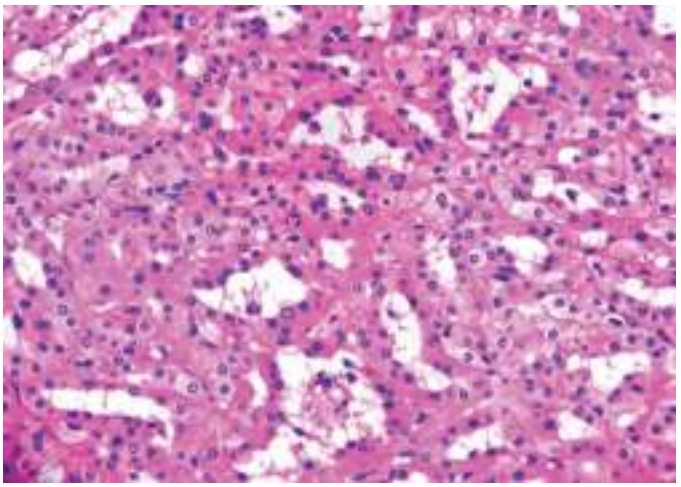

Fig. 22.101: Histology of renal oncocytoma. Renal oncocytoma is a benign neoplasm. It is believed to arise from renal intercalated cells and are packed with defective mitochondria under electron microscopy. Tumor is well circumscribed mass renal cortex replacing renal parenchyma. In hematoxylin and eosin-stained renal tumor tissue section, tumor is composed of large round eosinophilic cells (oncocyte) with dense granular cytoplasm with round irregular nuclei containing even chromatin and conspicuous nuclei arranged in small solid sheets in a loose connective tissue. Mitotic figures are rare or absent. Other architectures include tubular, microcystic and macrocytic, packed nests projecting a solid appearance (400X). (*Courtesy:* Dr. Neha Kumari.)

Pathology Pearls: Genetic Disorders Associated with Renal Cell Carcinoma

von Hippel-Lindau Disease

- von Hippel-Lindau (vHL) disease is an autosomal dominant disorder due to germline mutation of vHL gene mapped on 3p25. vHL is characterized by renal cysts and clear cell renal cell carcinoma. vHL is associated with bilateral and multifocal clear cell renal cell carcinomas.
- Other tumors in vHL disease include hemangioblastomas of cerebellum and retina, cysts of pancreas, liver, kidney, clear cell tumors at other sites, papillary cystadenoma of epididymis and pheochromocytoma.

Birt-Hogg-Dubé Syndrome

- Birt-Hogg-Dubé (BHD) syndrome is an autosomal dominant with incomplete penetration due to germline mutations in BHD gene mapped on chromosome 17p11.2, which codes for folliculin protein. This syndrome is characterized by renal oncocytoma, clear cell renal cell carcinoma and hybrid renal oncocytic/chromophobe renal cell carcinoma with areas of clear cells.
- Other lesions include lung cysts, spontaneous pneumothorax and skin lesions such as fibrofolliculomas, trichodiscomas, acrochordons.
- Renal tumors are detected mostly by imaging studies; and occasionally, patients present with flank pain, hematuria and palpable mass. It is essential for close follow-up of the renal tumors and minimal surgery with local resection of tumors to conserve renal function.
- Multiple tumor resections may be necessary in these patients. Hybrid renal oncocytoma tumor cells are positive for CD117 (c-KIT) and CK7 (patchy staining).

Hereditary Leiomyomatosis and Renal Cell Carcinoma (HLRCC) Syndrome

- Hereditary leiomyomatosis and renal cell carcinoma syndrome is an autosomal dominant disorder due to germline mutations of fumarate hydratase tumor suppressor gene mapped on 1q42.3–43 and contains 10 exons that encode fumarate hydratase protein, which is involved in tricarboxylic acid cycle. The fumarate hydratase gene biallelic inactivation is present in nearly all uterine leiomyomas and papillary (chromophil) renal cell carcinoma.
- Patient develops cutaneous or uterine leiomyomas and papillary (chromophil) renal cell carcinoma with characteristic large nucleus with a very prominent inclusion-like eosinophilic nucleolus.
- Cutaneous leiomyoma rarely progresses to leiomyosarcoma. Papillary (chromophil) renal cell carcinoma is aggressive neoplasm that grows quickly and metastasize early and the distant metastasis is most often detected at diagnosis.
- Majority of renal tumors are type 2 papillary (chromophil) renal cell carcinomas. Tumor is composed of large cells with abundant eosinophilic cytoplasm and large nucleus with prominent eosinophilic nucleoli with perinuclear halos.

Renal Tumors in Tuberous Sclerosis

Tuberous sclerosis (TSC) is the common genetic neurocutaneous disease due to mutations in TSC1 and TSC2 genes not involving vHL gene mutations and characterized by bilateral multifocal renal angiomyolipomas, clear cell renal cell carcinoma, renal oncocytoma, facial angiofibroma, periungual

fibroma, hypopigmented macules, giant astrocytoma, subependymal nodule, retinal hamartomas, cardiac rhabdomyomas, pulmonary lymphangioleiomyomatosis.

Constitutional Chromosome 3 Translocation Associated Renal Cell Carcinoma

Constitutional chromosome 3 balanced translocation has been linked to development of clear cell renal cell carcinoma, which is indistinguishable from that of sporadic clear cell renal cell carcinoma.

Pathology Pearls: Renal Cell Carcinoma—Histologic Variants

Histologic variants of renal cell carcinoma include clear cell variant, chromophil (papillary) variant, chromophobe variant, collecting duct carcinoma of Bellini in the medulla and Xp11 translocation pediatric renal cell carcinoma.

Clear Cell Renal Cell Carcinoma

- Clear cell renal cell carcinoma is most common variant and constituting 70–80% of cases, which arises from proximal tubular cells in cortex. von Hippel-Lindau (vHL) gene mutation on chromosome 3p has been demonstrated in sporadic and familial cases.
- Tumor is bright golden yellow tumor located in pole of kidney. On histologic examination, tumor is composed of round/polygonal cells with centrally placed round nuclei and abundant clear cytoplasm containing abundant glycogen and lipids; and arranged in solid cords, papillae, tubules or nests or alveolar pattern. Tumor cells express both cytokeratin and vimentin.

Papillary (Chromophil) Renal Cell Carcinoma

- Papillary (chromophil) renal cell carcinoma accounts for 10–15% of cases. It arises from distal tubular cells in cortex. It is never associated with vHL gene mutation located on chromosome 3.
- Trisomy or tetrasomy 7, 16 and 17 are common due to chromosomal gains. Loss of Y chromosome is seen in familial cases.
- PRCC gene on chromosome 1 fuses with TFE 3 gene on chromosome X. Fusion protein dysregulates mitotic checkpoints allowing abnormal segregation of chromosomes. It has worst prognosis. Tumor is composed of fibrovascular core lined by tumor cells arranged in papillary pattern. Psammoma bodies are observed in fibrovascular core.

Chromophobe Renal Cell Carcinoma

- Chromophobe renal cell carcinoma accounts for 5% of cases, which originates from intercalated cells of collecting ducts in cortex.
- Multiple chromosomal losses/hypoploidy occur in this variant. Tumor is composed of polyhedral cells with eosinophilic granular cells with prominent cell borders, eccentric nuclei, perinuclear halo and prominent cell borders resembling vegetable cells.
- Electron microscopy study reveals microvesicles 150–300 nm diameter. Hale's colloidal iron reacts with a substance present in the microvesicles. It has best prognosis.

Collecting Duct Carcinoma of Bellini

Collecting duct carcinoma of Bellini accounts for 2% of cases and arising from collecting ducts in medullary region. Tumor is circumscribed with central areas of necrosis. Reports on losses of chromosomes 1, 6, 14, 15, and 22 have been reported.

Pediatric Renal Cell Carcinoma with Xp11.2 Translocation and TFE3 Fusions

Pediatric renal cell carcinoma with TFE3 fusions occurs in children. Gene fusions are involving the TFE3 transcription factor. Gene is demonstrated on molecular and genetic analysis.

CLEAR CELL RENAL CELL CARCINOMA

Clear cell renal cell carcinoma is the most common histologic subtype of renal cell carcinoma. Essential features are neoplastic cells with clear or eosinophilic cytoplasm, characteristic delicate network of small blood vessels 'chicken wire vasculature', common molecular signature of vHL gene inactivation mapped on chromosome 3p12–3p26 (sporadic and familial cases) and upregulation of hypoxia-inducible factor (HIF).

- Clear cell renal cell carcinoma originates from proximal convoluted tubules in the renal cortex. Tumor accounts for 65–70% of adult renal carcinomas. It most often occurs in men than women, in the age group of 50–70 years.
- Tumor is bright golden yellow tumor located in upper (most common) or lower pole of kidney.
- Histologic examination reveals tumor cells with clear cytoplasm containing abundant glycogen and lipids. Tumor expresses both cytokeratin and vimentin on immunohistochemistry.
- Chromosome 3p alteration is present in almost all the cases. vHL gene alterations (loss of sequences or promoter hypermethylation) are present in 50–70% of sporadic clear cell renal cell carcinoma.

Pathology Pearls: von Hippel-Lindau Disease Associated Clear Cell Renal Cell Carcinoma

von Hippel-Lindau disease is an autosomal dominant disorder due to germline mutation of one allele of tumor suppressor in the von-Hippel-Lindau gene and characterized by a constellation of neoplasms, i.e. retinal hemangioma and cerebellar hemangioblastoma including renal cysts and clear cell renal cell carcinoma. Renal cysts are lined by clear cells. Renal tumors are bilateral and multifocal. Most renal tumors are asymptomatic and are detected in screening imaging studies.

- von Hippel-Lindau is a tumor suppressor gene located on 3p12 to 3p26. The vHL protein regulates hypoxia-inducible factor and hypoxia-induced genes. Loss of one allele of vHL

gene on 3p25–26 by loss of sequences or promoter hypermethylation has been demonstrated in sporadic (98%) and familial (2%) clear cell renal cell carcinomas.

- vHL gene mutation occurs by two mechanisms: (a) loss of sequences occurs on chromosome 3p either by deletion (3p12 to 3p26) or imbalanced translocation, i.e. (3;6, 3;8, 3;11), and (b) hypermethylation of vHL gene leads to inactivation of vHL gene in about 80% cases. When vHL gene is inactivated, the vHL protein complex cannot degrade HIF-1α, a transcription factor, that drives transcription of hypoxia associated genes including VEGF, PDGF and GLUT1.
- von Hippel-Lindau syndrome is an autosomal dominant disorder due to mutation of one allele of vHL tumor suppressor gene associated with tumors arising in multiple organs. Approximately 40% of all patients with vHL disease develop retinal hemangiomas, cerebellar hemangioblastomas and unilateral clear cell renal cell carcinoma.
- Metastatic renal cell carcinoma is the leading cause of mortality in patients with vHL disease. Early detection with nephron-sparing surgery is the basic aim for treatment of clear cell renal cell carcinoma. Patients with renal involvement in vHL disease have a better prognosis than do their sporadic counterparts.

Table 22.71 Risk factors for clear cell renal cell carcinoma

Sporadic Clear Cell Renal Cell Carcinoma
Prolonged tobacco smoking is major risk factor for sporadic clear cell renal cell carcinoma in 33% of cases
Obesity women are risk factor for sporadic clear cell renal cell carcinoma in obese women
Hemodialysis in chronic renal disease over five years induces acquired cystic disease of kidney leading to sporadic clear cell renal cell carcinoma
Loss of one allele from the short arm of chromosome 3 occurs in 90% of sporadic clear cell renal cell carcinoma and not inherited renal cell carcinoma
Inherited Clear Cell Renal Cell Carcinoma
Translocation t(3;8) or t(3;11) with breakpoint at the proximal end of 3p increases risk for inherited clear cell renal cell carcinoma occurs at 60 years in 85% of cases
vHL disease occurs due to mutation in vHL tumor suppressor gene close to oncogene raf-1 (chromosome 3p25). It is associated with inherited clear cell renal cell carcinoma in 28% of cases

Predisposing Factors

Tobacco smoking is most important risk factor for development of renal cell carcinoma in sporadic cases. Other risk factors are adult polycystic disease, patients on dialysis, obesity in women, hypertension, analgesic abuse, von Hippel-Lindau disease, tuberous sclerosis (but not via vHL mutations), occupation exposure to polycyclic hydrocarbons, lead and asbestos. Risk factors for clear cell renal cell carcinoma are given in Table 22.71.

Clinical Features

Clear cell renal cell carcinoma (CCRCC) is detected as incidental finding on imaging in 60–80% of cases. Hematuria is the single most common presenting sign. The tumor most often invades renal veins and can extend up the vena cava reaching right side of heart with early dissemination.

- Metastases via hematogenous route reach to lung, liver, bone, soft tissue, and adrenal glands. Hematuria is the most frequent presentation. Large tumor is palpable on clinical examination. Malignant cells are rarely detected in the urine in renal cell carcinoma.
- Renal oncocytoma and renal angiomyolipoma are often difficult to differentiate from renal cell carcinoma by imaging techniques.
- Patient with 10 cm size tumor presents with clinical triad: (a) grossly visible intermittent hematuria (50–60%), (b) costovertebral pain (45%) and (c) palpable mass with pain in loin region of abdomen (30%).
- Grossly visible painless hematuria should be considered a sign of urinary tract carcinoma until proven otherwise. Constitutional symptoms include fever, malaise, weakness, and weight loss.

Physical Examination

In clear cell renal cell carcinoma, edema in lower legs occurs due to extension of tumor in the inferior vena cava. Sudden onset of left-sided varicocele occurs in old persons due to obstruction of left testicular vein draining directly into left renal vein by the tumor. Metastases of clear cell renal cell carcinoma to pelvis bone and femur result to pathologic fracture. About 5% of patients develop manifestation related to metastases in lung, opposite kidney, adrenal gland, gingival, central nervous system, larynx, bronchi, nasal cavity, thyroid gland, skin and soft tissue.

Paraneoplastic Syndrome

In clear cell renal cell carcinoma tumor synthesizes ectopic hormones in 5% of cases resulting in clinical manifestations: hypertension (renin synthesis), polycythemia (erythropoietin synthesis), hypercalcemia (parathormone-like peptide synthesis) and feminization or masculinization (gonadotropins synthesis), Cushing's syndrome (ACTH synthesis). Patient may also develop hepatic dysfunction, acquired dysfibrinogenemia, and amyloidosis. Peripheral blood smear examination may reveal eosinophilia and leukemoid reactions in 5% of cases. Systemic manifestations of renal cell carcinoma are given in Table 22.72.

Table 22.72 Systemic manifestations of renal cell carcinoma

Substances Synthesis by Renal Cell Carcinoma	Systemic Manifestations
Prostaglandins synthesis	Fever
Parathyroid hormone-related peptide	Hypercalcemia
Erythropoietin synthesis	Increased RBCs count in 4% of cases
Prolactin	Galactorrhea
Renin synthesis	Hypertension
Exact mechanism unknown	Gynecomastia

Amyloidosis occurs in 3% of cases of renal cell carcinoma due to stimulation of serum amyloid (SAA) synthesis by liver.

Surgical Pathology: Clear Cell Renal Cell Carcinoma

Gross Morphology

- Clear cell renal cell carcinoma is unilateral solitary tumor in 90% of cases, bilateral involvement in 1% (usually with von Hippel-Lindau or tuberous sclerosis).
- Tumor can be unifocal (90%) or multifocal (10%). Tumor is well-circumscribed, partially encapsulated spherical renal cortical mass.
- Cut surface of tumor shows variegated appearance (solid and cystic areas), orange/golden yellow mass due to presence of lipids in tumor cells. Hemorrhage, necrosis and fibrosis are present. Soft fleshy areas may herald sarcomatous component.
- Frequent involvement of renal vein and renal sinus is present. Tumor may invade the perinephric fat, renal sinus (cavity within the kidney occupied by renal pelvis, renal calyces, blood vessels, nerves), adrenal gland, surrounding tissues and renal vein. Invasion of renal vein is a common mode of spread.
- During processing of the nephrectomy specimen, examination of renal vein determines metastatic potential of tumor.
- At least three blocks of tumor in renal sinus interface should be submitted. Uninvolved renal parenchyma should be sampled distant from tumor.
- Lymph nodes should be isolated in radical nephrectomy specimens performed in <10% of cases. Gross morphology of clear cell renal cell carcinoma is shown in Figs 22.102 and 22.103.

Light Microscopy

- Clear cell renal cell carcinoma is composed of large round/polygonal cells with distinct membrane, centrally placed round nuclei and abundant clear cytoplasm-rich in glycogen and fat washed during processing of tumor. In some cases, cytoplasm may be granular. Tumor cells form compact solid cords, papillae, tubules or nests or alveolar, microcystic (containing extravasated red blood cells or eosinophils) and occasional macrocytic architectural patterns.
- Tumor cells are arranged in nests and sheets and separated by a network of arborizing small, delicate, thin-walled blood vessels with dilated sinusoidal vascular spaces giving **'chicken wire' appearance**. Other minor patterns of arrangement of tumor cells include trabeculae, papillary, tubular and microcystic.
- The stroma may be reduced, but well vascularized. Some tumors may have pseudopapillary architecture due to high-grade changes and loss of cell cohesion. Cystic changes with serosanguineous fluid or blood are most often present.
- Renal vein margin is positive only when adherent tumor is visible microscopically at the actual margin.
- High-grade clear cell renal cell carcinoma shows rhabdoid or sarcoid differentiation with high-grade spindle cells containing homogenous eosinophilic cytoplasm and eccentric nucleus and globular eosinophilic inclusions. Heterologous elements may be present.
- Clear cell renal cell carcinoma, should be differentiated from chromophil (papillary) renal cell carcinoma, chromophobe renal cell carcinoma, renal oncocytomas, clear cell papillary (chromophil) renal cell carcinoma, and epithelioid angiomyolipoma. Histology of clear cell renal cell carcinoma is shown in Figs 22.104 and 22.105.

Histochemistry

- In clear cell renal cell carcinoma, tumor cells are rich in glycogen (PAS positive) and fat.
- Lipids are dissolved during processing of tissue in paraffin-embedded specimens. Fat can be demonstrated by frozen section technique by applying fat stains (Sudan III, Sudan IV, Sudan black or oil red O). There is absence of mucus in tumor cells.

Electron Microscopy

In clear cell renal cell carcinoma, tumor cells contain abundant glycogen, well defined long microvilli similar to brush border of normal proximal tubules, numerous cell junctions. These also demonstrate variable fat, scant organelles with scant microvesicles.

Immunohistochemistry Technique

- Clear cell renal cell carcinoma expresses both cytokeratins (8, 18) and vimentin. While other types express keratins 7 and 19.
- Other markers used include epithelial membrane antigen (EMA), α_1-antitrypsin, S-100 and angiotensinogen converting enzyme (ACE). Using immunostains potentially supporting primary or metastatic clear cell renal cell carcinoma include PAX2 or PAX8. PAX2 is the best marker with 50–80% sensitivity.

Markers	Expression
▪ PAX2	▪ Positive (best marker)
▪ CAIX (carbonic anhydrase)	▪ Positive (membranous diffuse staining), most sensitive and specific marker in inherited (100%) and sporadic cases (75%)
▪ PAX8	▪ Positive
▪ RCC-Ma	▪ Positive

▪ RCC-Ag	▪ Positive
▪ CD10	▪ Positive
▪ Vimentin	▪ Positive
▪ CK8	▪ Positive
▪ CK18	▪ Positive
▪ EMA	▪ Positive
▪ AE1/AE3	▪ Positive
▪ CAM5.2	▪ Positive
▪ α_1-Antitrypsin	▪ Positive
▪ S-100 protein	▪ Positive (rare case)
▪ CEA	▪ Positive (rare case)
▪ K903	▪ Negative
▪ KS-cadherin	▪ Negative/positive
▪ CD117 (proto-oncogene c-KIT gene encoding the receptor tyrosine-protein kinase, KIT, CD117)	▪ Negative/positive

Prognostic Factors

Prognostic factors for clear cell renal cell carcinoma are Fuhrman's nuclear grading and International Society of Urological Pathology (ISUP) nucleolar grading in clear cell renal cell carcinoma, histologic features and necrosis of tumor. Fuhrman's nuclear grading and ISUP nucleolar grading in clear cell renal cell carcinoma is given in Table 22.73.

Fuhrman Nuclear Grading System

Fuhrman classification of renal cell carcinoma is a 3-tiered system in which nuclear size, shape and nucleolar prominence are assessed simultaneously to assign a grade. An International Society of Urological Pathology (ISUP)/WHO Grading System based on nucleolar prominence appears to be a more powerful prognostic discriminator and has been recommended as a substitute.

- Grade 1: Nucleoli are inconspicuous or absent at objective magnification 400X

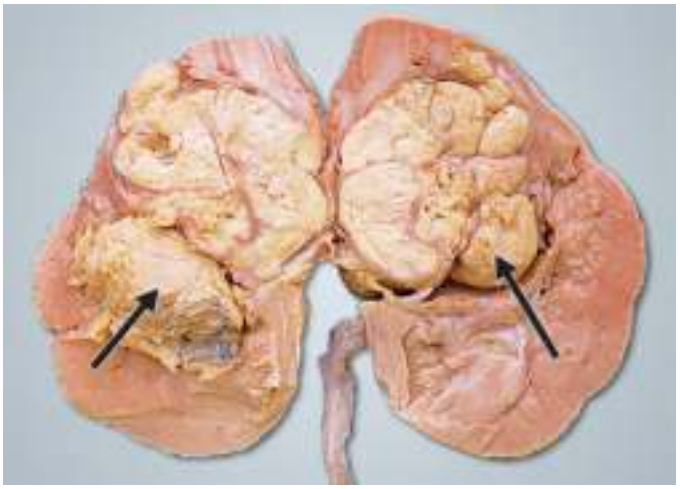

Fig. 22.102: Clear cell renal cell carcinoma. Tumor is well circumscribed, partially encapsulated spherical mass. Cut surface shows variegated appearance (solid and cystic areas). On cut surface, tumor is golden yellow mass due to presence of lipids in tumor cells. Areas of hemorrhage and necrosis are present (arrows) (400X). (*Courtesy:* Dr. Sujata Kanetkar, Senior Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

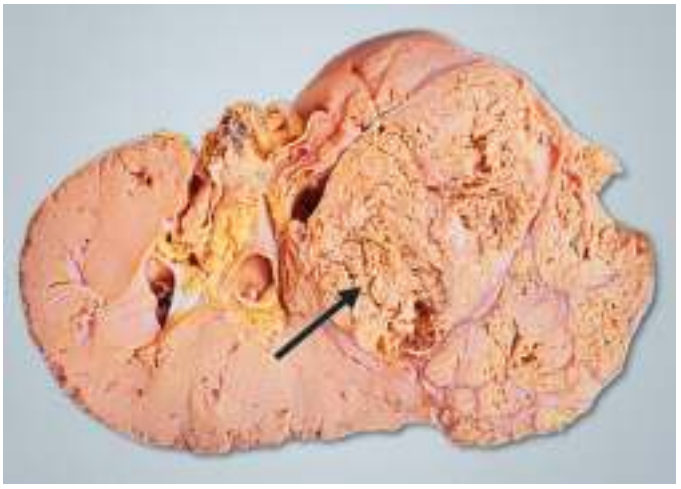

Fig. 22.103: Clear cell renal cell carcinoma. Tumor is well circumscribed, partially encapsulated spherical mass. Cut surface shows variegated appearance (solid and cystic areas). On cut surface, tumor is golden yellow mass due to presence of lipids in tumor cells. Areas of hemorrhage and necrosis are present (arrow). (*Courtesy:* Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

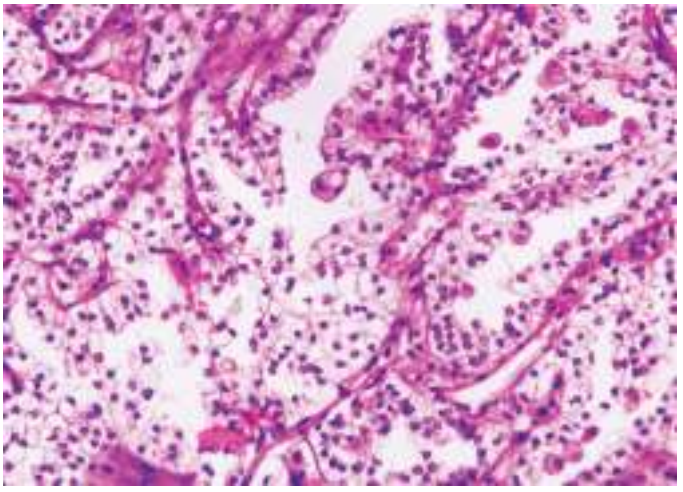

Fig. 22.104: Clear cell renal cell carcinoma. In hematoxylin and eosin-stained tumor section, tumor is composed of large round/polygonal cells with centrally placed round nuclei and abundant clear cytoplasm. The cytoplasm of tumor cells appears clear because it is rich in glycogen and fat, which are washed out during histologic processing of the tissue. Tumor cells are forming solid cords, papillae, tubules or nests or alveolar pattern. These cells are demarcated by a network of thin-walled blood vessels in the delicate supporting stroma. The stroma may be reduced, but well vascularized (400X).

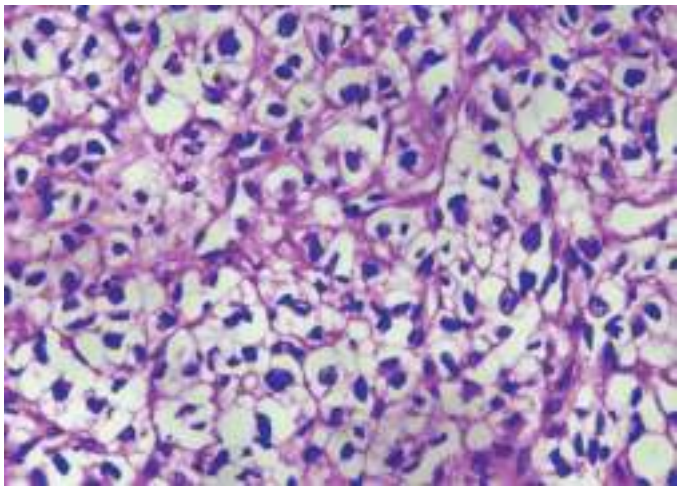

Fig. 22.105: Clear cell renal cell carcinoma, In hematoxylin and eosin-stained renal tumor tissue section examination, tumor is composed of tumor cells with clear cytoplasm and distinct membrane with clear to granular eosinophilic cytoplasm. Presence of network of arborizing small thin-walled blood vessels is important diagnostic feature for cases with granular eosinophilic cytoplasm. Tumor cells are arranged in solid nests and sheets, alveolar, microcystic (containing extravasated red blood cells or eosinophilic) and occasional macrocytic architectural patterns. High-grade clear cell renal cell carcinoma shows rhabdoid differentiation with high-grade tumor cells containing homogenous eosinophilic cytoplasm and eccentric nucleus and globular eosinophilic inclusions (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Table 22.73 Fuhrman's nuclear grading and ISUP/WHO nucleolar grading in clear cell renal cell carcinoma

Grade	Nuclear Features
Grade 1	▪ Nuclei small round and uniform (10 μm) ▪ Nucleoli inconspicuous or absent at objective magnification 400X
Grade 2	▪ Nuclear outline irregular (15 μm) ▪ Nucleoli prominent at objective magnification 400X
Grade 3	▪ Nuclei irregular (20 μm) ▪ Nucleoli prominent at objective magnification 100X
Grade 4	▪ Nuclei (20 μm size, extreme pleomorphism, hyperchromatic, multinucleated giant cells, sarcomatoid and/or rhabdoid change) ▪ Nucleoli (single or multiple) at objective magnification 400X

- Grade 2: Nucleoli are prominent at objective magnification 400X
- Grade 3: Nucleoli are prominent at objective magnification 100X
- Grade 4: Presence of extreme nuclear pleomorphism, multinucleated giant cells, sarcomatoid and/or rhabdoid change at objective magnification 400X.

Histology of Tumor

Clear cell renal cell carcinoma with sarcomatoid and rhabdoid differentiation have higher rates of tumor recurrence and metastasis. Presence of sarcomatoid and rhabdoid differentiation should be mentioned in the report.

Necrosis in the Tumor

Coagulative tumor necrosis has an independent prognostic significance. It is essential to report the amount and percentage of necrosis present in the tumor.

Mode of Spread

Clear cell renal cell carcinoma metastasizes in 30% of cases. Tumor invades renal capsule and perinephric fat. Tumor metastasizes to para-aortic and other lymph nodes via lymphatic route. Tumor has tendency to invade through renal vein into inferior vena cava (IVC) and then extends intraluminally, with thrombus formation in 5–50% of cases. Tumor may extend up to right chambers of heart in 1% of cases. Tumor can disseminate via hematogenous route to lungs (50–70%), bones (33%), liver (18%), skin (8%) and brain (8%).

Staging System

Staging system is a way of describing the size of tumor and whether it has spread into nearby lymph nodes or other parts of the body via hematogenous route. The stage is one of the most important factors in deciding how to treat the cancer and determining how successful treatment might be. Anatomic staging of clear cell renal cell carcinoma is given in Table 22.74.

Laboratory Investigations

Complete work up of clear cell renal cell carcinoma includes hemogram, urine examination for malignant cells, blood biochemical tests (serum calcium, liver and renal functions) and imaging techniques. Ultrasound of the abdomen especially kidneys, intravenous

Table 22.74 Anatomic staging of clear cell renal cell carcinoma

Stage	Extent of Spread of Tumor
Stage I	Tumor confined within capsule of kidney (prognosis 10 years survival in 70% of cases)
Stage II	Tumor invading perinephric fat
Stage III	Tumor invading the renal vein or inferior vena cava (A), or regional lymph node involvement (B), or both (C)
Stage IV	Tumor invading adjacent viscera (excluding ipsilateral adrenal) or distant metastases

pyelography, renal arteriography, bone scan may show involvement of the bones due to metastases. Diagnosis of clear cell renal cell carcinoma is confirmed on histologic examination.

Treatment and Prognosis

Stage 1 of clear cell renal carcinoma is treated by radical/nephrectomy, radiotherapy and arterial embolization. Systemic chemotherapy is not effective against advanced disease. About 15–20% of patients with advanced disease responds to immunotherapy. Receptor tyrosine kinase inhibitors are administered in advanced stage disease. About 30% of patients with clinically localized disease develop local and distant recurrence after surgery. Approximately 50% of patients have fatal outcome.

MULTILOCULAR CYSTIC RENAL CELL CARCINOMA

Multilocular cystic renal cell carcinoma is a variant of clear cell renal cell carcinoma. Tumor is composed of multiple cysts lined with low-grade clear cells, and without solid or expansile nodules. Tumor accounts for 5% of all clear cell renal cell carcinomas and has lower stage than other renal cell carcinomas. Patients are treated by partial or radical nephrectomy, who have excellent prognosis without recurrence or metastasis reported after surgical excision. Multilocular cystic renal cell carcinoma demonstrates chromosome 3p deletion and vHL gene mutations.

Surgical Pathology: Multilocular Cystic Renal Cell Carcinoma

Gross Morphology

Multilocular cystic renal cell carcinoma is a solitary well circumscribed and entirely cystic mass without solid tumor mass and necrosis.

Light Microscopy

In multilocular cystic renal cell carcinoma, cysts are lined by a single layer or focally stratified clear cells. The clear cells contain small uniform and round or oval without prominent nucleoli. Small nests of clear cells are present in the fibrous septa. There is no solid or expansile clear cell nodules.

Immunohistochemistry Technique

Markers	Expression
▪ EMA	▪ Positive
▪ CD10e	▪ Positive
▪ AE1/AE3	▪ Positive

PAPILLARY (CHROMOPHIL) RENAL CELL CARCINOMA

Papillary (chromophil) renal cell carcinoma is a histologic subtype of renal cell carcinoma (RCC) with predominant tubulopapillary architecture and characteristic genetic alterations.

- Tumor may be sporadic or familial and never associated with vHL gene mutation. Rarely, tumor is a part of hereditary papillary renal cell carcinoma syndrome or hereditary leiomyomatosis and renal cell carcinoma syndrome.
- Tumor, is derived from distal tubular epithelium of cortex with predominantly papillary or tubulopapillary architecture, often well-circumscribed and encapsulated features.
- Papillary (chromophil) renal cell carcinoma is second most common encountered renal cell carcinoma accounting for 10–15% of cases. It most often occurs in elderly males and females. Tumor has two morphologic subtypes with distinct molecular pathways and clinical behavior.

Clinical Features

Patient presents similarly to other subtypes of renal cell carcinoma; typical triad of palpable mass, flank pain and hematuria (uncommon seen in 5–10% of cases). Tumor has tendency to present at an early stage.

- Tumor is detected as incidental finding on imaging in more than 15% of cases. In majority of patients, tumor is unilateral.
- However, patients may have bilateral and multifocal tumors compared to other subtypes of renal cell carcinomas.
- Tumor fungates into calyces, involves renal pelvis, and extends into ureter. It may also invade the renal vein, inferior vena cava and right atrium.

Radiologic Findings

Papillary (chromophil) renal cell carcinoma may appear hypovascular due to spontaneous tumor necrosis. Foci of calcification are demonstrated in 30% of cases. Radiology techniques may detect differences between clear cell renal cell carcinoma, and papillary (chromophil) renal cell carcinoma.

Surgical Pathology: Papillary (Chromophil) Renal Cell Carcinoma

Gross Morphology

- Papillary (chromophil) renal cell carcinoma, is most often well-circumscribed with prominent pseudocapsule and friable located in renal cortex pouring out of kidney. Tumor may be solitary or multifocal.
- Cut surface is tan-yellow to red-brown with granular papillary architecture. Large tumor may show cystic degeneration, fibrosis, hemorrhage and extensive necrosis. Majority of papillary (chromophil) renal cell carcinoma has familial predisposition.

- Tumor looks necrotic on gross examination than microscopically less necrotic than expected. Gross morphology of papillary (chromophil) renal cell carcinoma is shown in Fig. 22.106.

Light Microscopy

- Papillary (chromophil) renal cell carcinoma is most often well-circumscribed with prominent pseudocapsule.
- Tumor is composed of papillary fronds or tubulopapillary architectures varying proportions with central fibrovascular cores lined by a single layer of tumor cells with round uniform nuclei without nucleoli; which may contain foamy macrophages, psammoma bodies and hemosiderin.
- The stroma is usually scanty but highly vascularized. Papillae can coalescence to impart a solid growth pattern with glomeruloid structures. About 5% of tumors demonstrate sarcomatoid change.
- It is essential to assess nucleolar prominence under high power field with greatest nuclear pleomorphism. Grading is done according to International Society of Urological Pathology (ISUP) nucleolar grade.
- Papillary (chromophil) renal cell carcinoma is further classified into type 1 and type 2 based on following morphology. Type 1 papillary (chromophil) renal cell carcinoma prognosis is better than type 2 subtype.
  - **Type 1 papillary (chromophil) renal cell carcinoma:** Tumor is composed of papillae lined by a single layer of cells with scanty basophilic cytoplasm and low nuclear grade associated with better prognosis; with molecular/cytogenetic alterations (+7, +17 and other trisomies, MET mutations).
  - **Type 2 papillary (chromophil) renal cell carcinoma:** Tumor is composed of papillae lined by pseudostratified layers of cells with more abundant eosinophilic cytoplasm and higher nucleolar grade associated with worse prognosis; with multiple molecular/cytogenetic alterations. Tumors may be multifocal involving both kidneys.
- Histology of papillary (chromophil) renal cell carcinoma is shown in Figs 22.107 and 22.108.

Electron Microscopy

Papillary (chromophil) renal cell carcinoma shows variably sized microvilli, small amounts of cytoplasmic lipid, but no glycogen.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections from papillary (chromophil) renal cell carcinoma expresses positivity for CK7, AMACR, AE1/AE3, EMA, MUC1, RCC-Ma, CD10, PAX2, PAX8 and vimentin. Tumor cells are positive for CK7 in type 1 (80%) and type 2 (20%).

Markers	Expression
CK7	Positive
Recemase	Positive
PAX8	Positive
PAX2	Positive
AMACR	Positive
AE1/AE3 (low molecular cytokeratin)	Positive
EMA	Positive
MUC1	Positive
RCC-Ma	Positive
CD10	Positive
CD117 (proto-oncogene c-KIT is the gene encoding the receptor tyrosine-protein kinase, KIT, CD117)	Positive
Vimentin	Positive/negative (variable staining)
CAIX (carbonic anhydrase)	Negative except in areas of necrosis

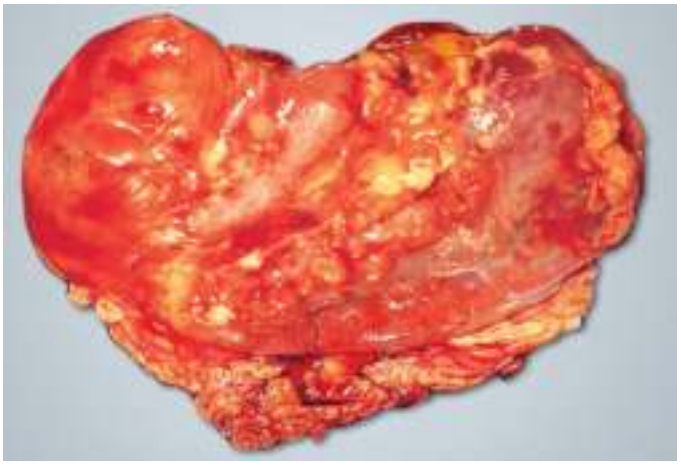

Fig. 22.106: Papillary (chromophil) renal cell carcinoma. Tumor is most often circumscribed with prominent pseudocapsule and friable located in renal cortex. Tumor may be multifocal. Cut surface shows tumor with papillary protrusions. Large tumor may contain cystic degeneration, fibrosis, hemorrhage and necrosis. The great majority of renal cell carcinoma, chromophil/papillary has familial predisposition.

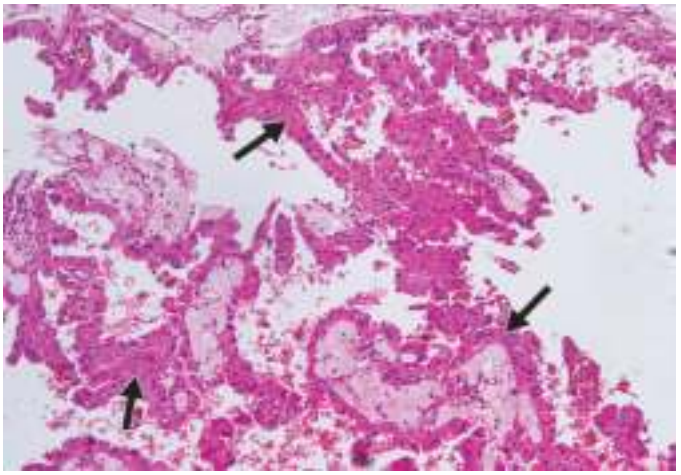

Fig. 22.107: Histology of papillary (chromophil) renal cell carcinoma. In hematoxylin and eosin-stained renal tumor section, tumor is composed of papillae or tubulopapillary architecture with fibrovascular cores covered by cuboidal or low-columnar cells with round, uniform nuclei without nucleoli. Fibrovascular cores may contain foamy macrophages, psammoma bodies and hemosiderin. The stroma is usually scanty but highly vascularized (arrows) (400X).

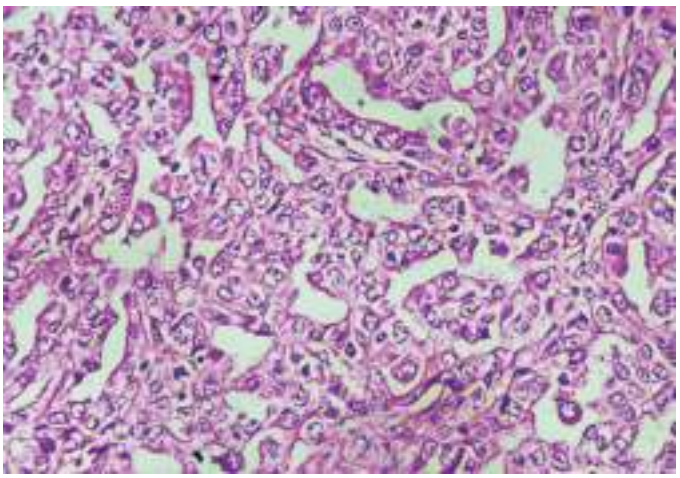

Fig. 22.108: Histology of papillary (chromophil) renal cell carcinoma (PRCC). Tumor has two histologic variants: type 1 and type 2 PRCC. Type 1 PRCC is composed or papillae lined by a single layer of tumor cells with scant basophilic cytoplasm and low-grade nuclear grade. Tumor has +7, 17+ and other trisomies, MET gene mutations and associated with better prognosis. Type 2 PRCC is composed of papillae lined by pseudostratified layer of tumor cells with more abundant eosinophilic cytoplasm and higher nuclear grade. Multiple genetic changes are present and associated with worse prognosis. Hematoxylin and eosin-stained renal tumor tissue section examination shows well circumscribed tumor with prominent pseudocapsule composed of papillae or tubulopapillary architecture with fibrovascular cores which may contain foamy macrophages, psammoma bodies and hemosiderin pigment (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Molecular Genetic Alterations

Papillary (chromophil) renal cell carcinoma is never associated with vHL gene mutation located on chromosome 3. There is typical gain of chromosomes 7 and 17 (trisomy) in sporadic cases.

- Type 1, papillary (chromophil) renal cell carcinoma demonstrates +7 (75%), +17 (80%), +12, +16, +20, +3q, –Y, –X (p or q for all chromosomes).
- Type 2 papillary (chromophil) renal cell carcinoma, demonstrates heterogenous cytogenetic alterations such as CpG island methylation or loss of CDKN2A tumor suppressor gene and associated with poor prognosis.
- Familial papillary (chromophil) renal cell carcinoma may be seen in familial papillary renal cell carcinoma syndrome (type 1 PRCC) and in Hogg-Dubé syndrome. Loss of Y chromosome is seen in familial cases in men. PRCC gene on chromosome 1 fuses with TFE 3 gene on chromosome X. Fusion protein dysregulates mitotic checkpoints allowing abnormal segregation of chromosomes.
- Patient develops bilateral hereditary papillary renal cell carcinoma due to **germline mutation MET proto-oncogene** mapped on chromosome 7q31 in hereditary papillary renal cell carcinoma syndrome or fumarate hydratase gene mapped on chromosome 1q42, 3–43 in hereditary leiomyomatosis and renal cell carcinoma syndrome.

Treatment

Patient with papillary (chromophil) renal cell carcinoma is treated by resection and tyrosine kinase inhibitor therapy. About 80% of type tumors have an alteration in MET gene sequence or copy number and may be susceptible to inhibitors of MET pathway.

CHROMOPHOBE RENAL CELL CARCINOMA

Chromophobe renal cell carcinoma is a subtype of renal cell carcinoma comprising large pale and/or pleomorphic eosinophilic cells with prominent cell borders, finely reticular pale cytoplasm, perinuclear halos and wrinkled, angulated (raisinoid) nuclei. Tumor arises from distal convoluted tubules and cortical intercalated cells collecting ducts.

- Out of three histologic variants of renal cell carcinoma, prognosis of chromophobe renal cell carcinoma is excellent. Men and women are equally affected. Majority are sporadic and incidental without gender preference with mean age 55 years.
- Birt-Hogg-Dubé syndrome is an autosomal dominant disorder characterized by multiple tumors (bilateral chromophobe renal cell carcinomas, renal oncocytomas or hybrid oncocytic/chromophobe tumor), small dome-shaped popular fibrofolliculomas over face, neck, and upper trunk, lung cysts and spontaneous pneumothorax. Mutations in the folliculin gene (FLCN) at 17p11.2 leads to premature truncation and loss of function of the folliculin protein.

Clinical Features

Chromophobe renal cell carcinoma confined within renal capsule is associated with good prognosis. Patient presents with hematuria, flank mass and pain. Prognosis of chromophobe renal cell carcinoma is much better than clear cell renal cell carcinoma with morality less than 10% and five-year survival in more than 90% of cases. Sarcomatoid morphological features in chromophobe renal cell carcinoma and invasion in perinephric fat are associated with worse prognosis. Patients are usually treated by partial nephrectomy.

Molecular Genetic Alterations

Multiple chromosomal losses or extreme hypoploidy is seen on cytogenetic study in chromophobe renal cell carcinoma.

Poor Prognostic Factors

Chromophobe renal cell carcinoma showing sarcomatoid change, microscopic necrosis, small vessel invasion and distant metastasis is associated with poor prognosis.

Surgical Pathology: Chromophobe Renal Cell Carcinoma

Gross Morphology

- Chromophobe renal cell carcinoma is well-circumscribed but not encapsulated with tan to light brown. Size of the tumor ranges 2–22 cm (mean 8 cm). Tumor is solid and well-circumscribed but not encapsulated.
- Cut surface is homogenous, light brown to tan. Areas of hemorrhage and small cysts are demonstrated in 25–30% of cases. Tumor can be solitary (85%) and may be multifocal (≤15%). Calcification is observed in 48% of tumors.
- Central scarring is demonstrated in ≤15%. It is difficult to differentiate chromophobe cell carcinoma from renal oncocytoma. Hemorrhage and necrosis are rare.

Light Microscopy

Classic variant of chromophobe renal cell carcinoma

- Classic variant of chromophobe renal cell carcinoma is composed of large pleomorphic cells with pale and highly reticulated cytoplasm, and distinct cell borders eccentrically placed angulated (raisinoid) nuclei with a perinuclear halo.
- Tumor cells are arranged in solid growth, nests or broad alveoli/trabeculae. These cells are commonly mixed with smaller cells with granular cytoplasm.
- Tumor cells appear as 'vegetative cells' due to retraction of cytoplasm giving cobblestone appearance.
- Tumor is composed of three types of cells: (a) small cells with solid slightly granular eosinophilic cytoplasm, (b) cells have perinuclear halo or translucent zone in a background of pale, flocculent but not clear cytoplasm; and (c) large, polygonal cells with hard cell border, abundant cytoplasm with reticular pattern. Tumor cells are arranged in solid sheets with a concentration of the largest cells around blood vessels. Histology of chromophobe renal cell carcinoma is shown in Fig. 22.109.

Eosinophilic variant of chromophobe renal cell carcinoma

- Eosinophilic variant of chromophobe renal cell carcinoma is composed entirely of intensely eosinophilic cells.
- Tumor cells appear as 'vegetative cells' due to retraction of cytoplasm imparting a '**cobble stone appearance**'. Tumor cells have varying degrees of eosinophilic cytoplasm and granularity in the periphery adjacent to the cytoplasmic membrane, and irregular, wrinkled, and angulated nuclei (raisinoid) with perinuclear clearing (halos).
- Medium-sized blood vessels with eccentrically hyalinized walls are observed. It is worth mentioning that formalin fixation may obscure cytoplasmic features.

Histochemistry

Hale's colloidal iron stain reveals strong blue cytoplasmic staining in chromophobe variant of renal cell carcinoma. This staining pattern is absent in clear cell variant and chromophil variant of renal cell carcinoma.

Electron Microscopy

- Electron microscopy of chromophobe renal cell carcinoma reveals numerous oval cytoplasmic microvesicles (possibly from mitochondrial outpouchings) measuring from 150 to 300 nm in diameter.
- These oval cytoplasmic microvesicles are not found in any other renal tumor and that are considered diagnostic.
- It is quite likely that Hale's colloidal iron reacts with a substance present in the microvesicles. Eosinophilic variant is similar but with more mitochondria.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections of chromophobe renal cell carcinoma expresses positivity for EMA, CK7, E-cadherin, claudin 7, EpCAM and CD117.

Markers	Expression
EpCAM (epithelial cell adhesive molecule)	Positive (new marker)
CD117 (c-KIT)	Positive
CK7	Positive
TFE3	Positive
Cathepsin K	Positive
PAX8	Positive
EMA	Positive
CK8/CK18	Positive
E-cadherin	Positive
Claudin 7	Positive
Ki-67	Positive (low expression)
N-cadherin	Negative
Vimentin	Negative

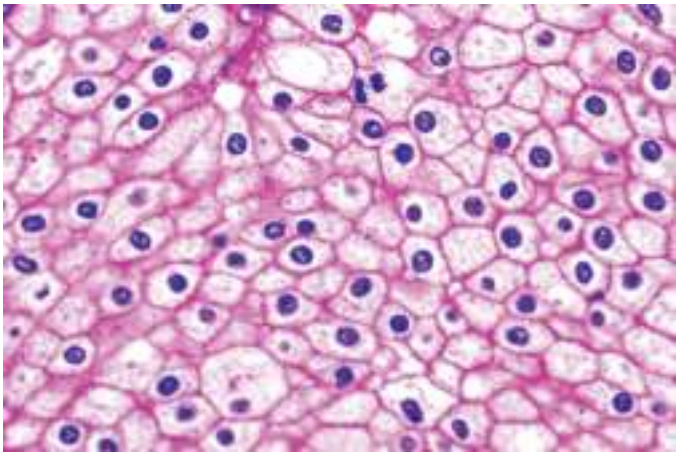

Fig. 22.109: Histology of chromophobe renal cell carcinoma. Hematoxylin and eosin-stained renal tumor tissue section examination shows confluent solid growth with nests, sheets or alveoli/trabeculae composed of two types of cells: (a) type 1 cells are pale polygonal cells with sharply defined plant-like cell borders (vegetative cells); abundant cytoplasm with eccentrically placed irregular, wrinkled and angulated nuclei with coarse chromatin and a perinuclear halo, and (b) type 2 cells are smaller cells with finely granular eosinophilic cytoplasm in predominant eosinophilic variant. Stroma is minimal and composed incomplete fibrovascular septae around solid sheets (400X).

Table 22.75 Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 fusions

Xp11 Chromosomal Translocation	Gene Fusion
t(X;17) (p11.2; q25)	ASPL-TFE3
t(X;1) (p11.2q21)	PRCC-TFE4
t(X;1) (p11.2q34)	PSF-TFE3
t(X;1) (p11.2q23)	CLTC-TFE3
inv(X) (p11.2; q23)	NONO-TFE3

Karyotyping Xp11 chromosomal translocation renal cell carcinoma is IPOX for TFE and cathepsin K. Alveolar soft part sarcoma shows der(17) t(X;17) (p11.2;q25) and gene fusion ASPL-TFE3.

PEDIATRIC RENAL CELL CARCINOMA WITH Xp11.2 TRANSLOCATION AND TFE3 GENE FUSION

Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 gene fusion is distinctive type of renal cell carcinoma characterized by chromosomal translocation involving TFE3 gene on chromosome Xp11.2 or TFEB gene on chromosome 11q12. It is also called MiT translocation subgroup renal cell carcinoma, which most often affects young patients. It represents 30–70% of pediatric renal cell carcinoma. Presence of dense calcifications in tumor resemble nephrolithiasis, and obstruction of the renal pelvis promotes extensive obscuring xanthogranulomatous pyelonephritis. Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 fusions is given in Table 22.75.

Clinical Features

Pediatric renal cell carcinoma with Xp translocation is associated with prior chemotherapy for other malignancies. Patient presents with high stage disease associated with poor prognosis. Majority of cases are reported in children and young adults. Clinical presentation is similar to renal cell carcinoma in adults. Patients are treated by nephrectomy. Patient has indolent clinical behavior in lymph node positive and metastasis negative. Clinical course is aggressive in metastasis positive children and adults.

Surgical Pathology: Pediatric Renal Cell Carcinoma with Xp11.2 Translocation and TFE3 Gene Fusion

Gross Morphology

- Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 gene fusion has a fibrous pseudocapsule ranging in size from 3 to 14 cm in diameter.
- Cut surface of tumor is yellow or gray white to tan yellow with frequent hemorrhage, necrosis and calcification. Sometimes, tumor imparts egg-shell consistency. Gross morphology of pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 fusion is shown in Fig. 22.110.

Light Microscopy

Pediatric renal cell carcinoma with different chromosomal translocations exhibits somewhat different morphological features.

- **ASPL-TFE3 gene fusion pediatric renal cell carcinoma:** Tumor is composed of cells with abundant partly clear or granular, eosinophilic cytoplasm with sharp, discrete borders and vesicular nuclei and prominent nucleoli. Tumor cells are arranged in nests and papillae or pseudopapillae surrounded by thin-walled capillary vessels. '**Psammomatous calcification**' and '**hyaline nodules**' are frequent. Sometimes central cells in nests are discohesive imparting an alveolar or bloody garland appearance. Mitoses are rare/absent. Stromal macrophages and psammoma bodies, if present are limited in number. Histology of pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 fusion is shown in Fig. 22.111.
- **PRCA-TFE3 gene fusion pediatric renal cell carcinoma:** Tumor is composed of cells arranged in more compact nested and less papillary pattern. Tumor cells have a less abundant cytoplasm, fewer psammomatous calcification and hyalinized fibrovascular cores.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections from tumor expresses positivity for TFE 3, TFEB, CD10, AMACR, vimentin, E-cadherin, CK19, EMA and cathepsin K.

Markers	Expression
TFE3 transcription factor	Positive (nuclear staining)
CD10	Positive
AMACR	Positive
Vimentin	Positive
E-cadherin	Positive (66%)
CK19	Positive (30–50%)
EMA	Positive (30%)
Cathepsin K	Positive

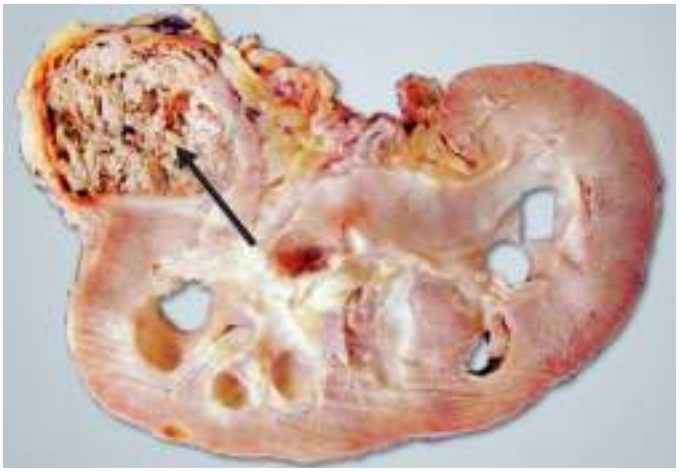

Fig. 22.110: Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 gene fusion. Tumor has a fibrous pseudocapsule. It is located at lower pole. Cut surface is tan yellow or gray white with varying degrees of hemorrhage, necrosis and calcification not distinct from other variants of renal cell carcinoma. It may sometimes, impart egg-shell consistency (arrow).

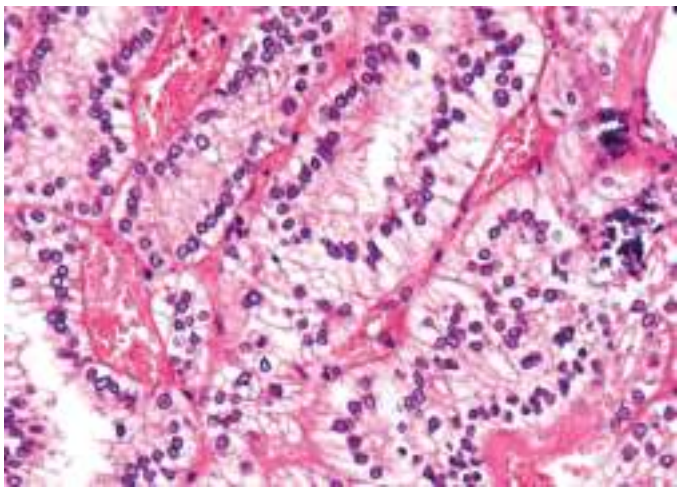

Fig. 22.111: Pediatric renal cell carcinoma with Xp11.2 translocation and TFE3 gene fusion. Tumor harbors gene fusions involving members of the MiT family of transcription factors including TFE3 and TFEB. MiT refers to microphthalmic associated transcription factors. In hematoxylin and eosin-stained renal tissue sections, tumors are histologically diverse, often has papillary, alveolar and nested growth pattern with clear eosinophilic cells, high-grade nuclei and psammoma bodies. Tumor cells are surrounded by thin-walled vessels. Tumor is more common in children and young adults (400X).

COLLECTING DUCT CARCINOMA OF BELLINI

Collecting duct carcinoma of Bellini is a rare highly aggressive renal cell carcinoma of renal medulla in adults accounting for 2% of cases, which arises from principal cells of distal collecting ducts of Bellini in the medulla and involving both medulla and cortex because of large size tumor. It affects elderly persons with mean age of 55 years and male predominance.

- Essential major diagnostic criteria of tumor are involvement of renal medulla, high-grade cuboidal cells or hobnail cells, predominant tubular architecture, infiltrative growth pattern, marked stromal desmoplasia.
- Minor diagnostic features of tumor are central location of tumor, tubulopapillary architecture, tumor cells with mucin, inflammatory polymorphonuclear cells in the stroma and extensive infiltration of tumor cells in the renal parenchyma, extrarenal tissue and blood vessels. Essential diagnostic features of collecting duct carcinoma of Bellini are shown in Table 22.76.

Clinical Features

Patients present with pain, gross hematuria, weight loss, flank mass and distant metastases in 66% of cases. Sometimes, tumor is detected incidentally on radiologic study.

- On CT scans, normal outer contours are usually maintained in affected kidneys; and the tumor mass involves medulla and protrudes into the renal sinuses. Cytology of urinary sediment shows malignant cells.
- Tumor usually invades surrounding tissue and metastasizes to regional lymph nodes via lymphatic route and liver, lungs, bones or contralateral kidney via hematogenous route. Majority of patients develop lymph node and widespread metastasis in liver, lungs, bone and adrenal glands at presentation.
- The tumor is highly aggressive associated with worst prognosis with fatal outcome within the first 2 years.
- Patients are treated by nephrectomy with adjuvant and immunotherapy.

Table 22.76 Essential diagnostic features of collecting duct carcinoma of Bellini

Major Diagnostic Criteria
Medullary involvement
Tubular architecture
Growth pattern infiltrative
Marked desmoplasia of stroma
Cytologically high-grade cuboidal or hobnail cells
No other renal cell or urothelial carcinoma
Minor Diagnostic Criteria
Centrally located large tumor
Tubulopapillary architecture
Inflammatory polymorphonuclear cells in the stroma
Extensive renal, extrarenal and vascular infiltration
Cytologically tumor cells with mucin positivity

Molecular Genetic Alterations

Molecular genetic information in collecting duct carcinoma of Bellini is still very limited in these tumors, but losses of chromosomes 1q32.1–32. 2, 6q, 8p, 14, 15, 21q; and 22 have been reported. It is not associated with loss of 3p, and trisomies 7 and 17. HER2/neu amplification has been demonstrated in 45% of cases. Other genomic alterations include NF2 (30%), SETD2 (25%), SMARCB1 (18%) and CDKN2A (12%). Loss of chromosome 3p is rare in these cases.

Radiologic Findings

CT imaging demonstrates good correlation with histologic findings, which shows solid mass with cystic component with infiltrative/expansile/exophytic growth in the renal medulla involving renal sinus, perinephric tissue, regional lymph nodes and distant metastases to liver, lungs, bones or contralateral kidney.

Surgical Pathology: Collecting Duct Carcinoma of Bellini

Gross Morphology

Collecting duct carcinoma of Bellini is predominantly located in the medulla and involving cortex. Tumor has irregular extensively infiltrating margins and infiltrative into renal sinus fat and perinephric tissue and renal vein. Cut surface of tumor is firm gray mass measuring 2.5–12 cm (mean 5 cm). Areas of cystic, hemorrhage and necrosis are common. Tumor may demonstrate satellite nodules and renal vein invasion.

Light Microscopy

- Collecting duct carcinoma of Bellini is complex, infiltrative and poorly circumscribed tumor. Tumor is composed of high-grade cuboidal cells or hobnail cells with large pleomorphic nuclei with prominent nucleoli and coarse chromatin arranged in cords, tubules, tubulopapillary or tubulocystic structures embedded into inflamed desmoplastic stroma. Intracytoplasmic and intraluminal mucin may be present. Numerous mitotic figures are present.
- Tumor may demonstrate microcystic change due to dilation of tubular structure. Marked stromal desmoplasia and inflammatory polymorphonuclear cells in the stroma are present.
- Tumor may exhibit sarcomatoid dedifferentiation. Adjacent to the tumor, tubular epithelium lining collecting ducts may appear dysplastic.

Electron Microscopy

- Collecting duct carcinoma of Bellini shows features of adenocarcinoma, including intracellular and extracellular lumina.
- Well-formed cell junctions, prominent basal lamina and short apical microvilli are demonstrated.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections from tumor expresses positivity for PAX8, PAX2, Ulex europaeus lectin 1 (Ulex-1), peanut lectin agglutinin (PNA), mucin, vimentin, CK8/18, CK19, EMA and S-100A1.

Markers	Expression
PAX8	Positive
PAX2	Positive
Ulex europaeus lectin 1 (Ulex-1)	Positive
Peanut lectin agglutinin (PNA)	Positive
Mucin	Positive
Vimentin	Positive
CK8/18	Positive
CK19	Positive
EMA	Positive
S-100A1	Positive
p63	Negative
Uroplakin II	Negative
CD10	Negative
AMACR	Negative
E-cadherin	Negative
CAIX	Negative
OCT3/4	Negative
CD117	Negative

UROTHELIAL CARCINOMA OF RENAL PELVIS

Renal pelvis, ureters and urinary bladder are lined by transitional epithelium. Urothelial carcinoma of renal pelvis is a morphologic variant of high-grade tumor similar to urothelial carcinoma of urinary bladder affecting adults. Tumor is composed of bland nested pattern, that could be difficult to differentiate from florid von Brunn's nests; but more irregular and most often invasive. It accounts for 5–10% of primary renal tumors. Clinical outcomes are similar to invasive high-grade urothelial carcinoma associated with poor prognosis.

Predisposing Factors

Cigarette smoking is the most common cause of renal pelvis carcinoma. There is increased risk of renal pelvis carcinoma in patients with intake of analgesic drugs (phenacetin), cyclophosphamide drug for longer period, and prolonged exposure of occupational workers in aniline dye and rubber industries.

- Patient presents with hematuria and flank pain. Risk factors of tumors of renal pelvis are similar to bladder cancer, suggesting a '**field effect**'.
- In aniline and rubber industries, prolonged exposure to β-naphthylamine absorbed by gastrointestinal tract reaches liver. In the liver, hydroxylation of β-naphthylamine forms 1-hydroxy-2-naphthylamine (active carcinogenic metabolite), that combines with glucuronic acid and excreted in the urinary tract.
- This molecule is deconjugated by urinary bladder mucosal enzyme glucuronidase, thus exposing the urothelium to the active carcinogen resulting in urothelial carcinoma of renal pelvis.

Clinical Features

Patient most frequently presents with hematuria and flank pain. Transitional epithelial cells lining papillae may detach and may be found in urine, important for diagnosis. Tumor fragmentation may block urinary outflow and cause flank pain and hydronephrotic changes. Even a small tumor may cause hematuria, renal colic, or urinary obstruction and can be diagnosed in early stages of development. Excision of the entire ureter is necessary because of the high frequency of concurrent and subsequent urothelial carcinoma of ureter.

Surgical Pathology: Urothelial Carcinoma of Renal Pelvis

Gross Morphology

Tumor is thickened, irregular with or without papillary component invading wall of renal pelvis. Tumor may invade renal vein and metastasize to various organs. It may result in fragments breaking off from the tips of fronds; and the tumor cells are detected in urine on cytologic examination.

Light Microscopy

- Urothelial carcinoma of renal pelvis is composed of anastomosing irregular-sized nests lacking cytoarchitectural orientation to overlying urothelium with more irregular projections into the stroma especially in the deep aspect. The overlying urothelium is most often unremarkable.
- Cytologically, tumor cells are bland with focal atypia. Central lumens of the nests contain necrotic cellular debris. Stroma of the tumor may be normal or desmoplastic.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections from tumor expresses positivity for CK7, p63, CK903, CK20, and p53.

Markers	Expression
CK7	Positive (93%)
p63	Positive (92%)
CK903	Positive (92%)
CK20	Positive (70%)
p53	Positive
BCL-2	Negative
p27	Negative

MESENCHYMAL TUMORS OCCURRING MAINLY IN CHILDREN

Mesenchymal tumors of kidney occurring in children include clear cell sarcoma, rhabdoid tumor, congenital mesoblastic nephroma and ossifying renal tumor of infancy.

CLEAR CELL SARCOMA OF KIDNEY

Clear cell sarcoma is a childhood kidney tumor most often diagnosed at 2–3 years of age. Tumor arises from renal medulla.

- There are many histologic variants of clear cell sarcoma: classic, myxoid, sclerosing, cellular, epithelioid (acinar or trabecular), palisading Verocay body, spindle cell, storiform and anaplastic.
- Classic clear cell sarcoma is composed of small plump tumor cells arranged in nests and cords and separated by networks of delicate fibrovascular stromal septa in only 20% of cases.
- BCOR gene mutation is implicated in the pathogenesis of clear cell sarcoma of kidney. Patients are treated by doxorubicin (adriamycin).

Clinical Features

Child presents with large well-circumscribed unilateral abdominal mass with mean size 11.5 cm. Bone metastases occur in 20–40% of patients more frequent than Wilms' tumor. About 5% of patients have metastatic disease at clinical presentation involving bone, lung, brain and liver.

Surgical Pathology: Clear Cell Sarcoma of Kidney

Gross Morphology

- Clear cell sarcoma of kidney is unilateral and unicentric renal mass with irregular but sharp margin in central region or medulla.
- Cut surface of tumor is homogenous tan/gray or gelatinous and firm with occasional cystic area.

Light Microscopy

- Classic pattern of clear cell sarcoma of kidney is composed of small and plump tumor cells arranged in nests and cords and separated by network of delicate fibrovascular septa (also called chicken wire appearance).
- Spindle shape cells are present near the vascular spaces, hence called septal cells, which contain smooth chromatin without prominent nucleolus, and chromatic appear washed out, similar to papillary carcinoma of thyroid gland.
- Clear cell sarcoma of kidney contains 20% clear cells as a result of intracytoplasmic vacuoles or an extracellular mucopolysaccharide matrix. Vascular invasion by tumor cells is common. Histology of clear cell sarcoma of the kidney (CCSK) is shown in Fig. 22.112.

Immunohistochemistry Technique

Markers	Expression
Vimentin	Positive
Cyclin D1	Positive
CD34 (highlights septal capillaries)	Positive
MIB1 (Ki-67)	Positive

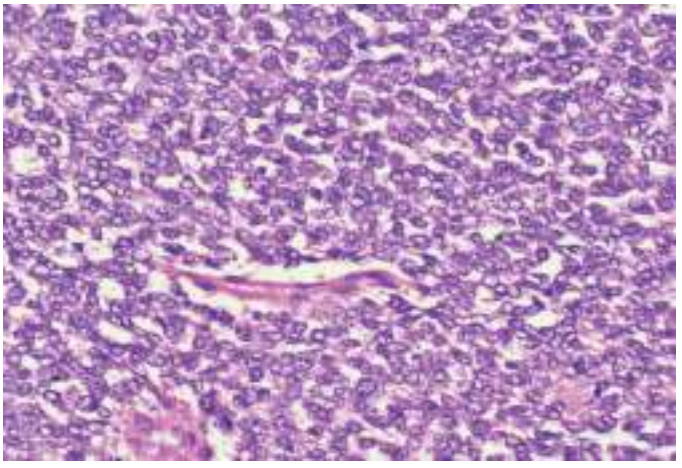

Fig. 22.112: Histology of clear cell sarcoma of the kidney (CCSK). CCSK is highly malignant neoplasm occurring in the same age group as Wilms' tumor. Originally, it was called bone metastasizing renal tumor of childhood. However, CCSK is resistant to conventional therapy, but often responsive to doxorubicin containing regimens, In H&E stained renal tissue section, tumor is highly cellular consisting of proliferating monotonous undifferentiated malignant cells of small to medium size with clear or faintly eosinophilic cytoplasm containing pleomorphic round to oval nuclei with inconspicuous nucleoli, 1–5 mitoses/high power field. Tumor shows delicate vascular stroma and extensive areas of necrosis. Tumor infiltration occurs beyond renal capsule with vascular embolization (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

TUMOR-LIKE LESIONS OF KIDNEY

RENAL ANGIOMYOLIPOMA (HAMARTOMA)

Renal angiomyolipoma is a hamartoma comprised of fat, smooth muscle and thick-walled blood vessels in varying proportion and haphazardly arranged, which may occur as sporadic or in association of tuberous sclerosis. It is often associated with tuberous sclerosis syndrome. It most often occurs in adults of 50 years of age. It rarely occurs in pediatric age group.

- **Sporadic renal angiomyolipoma:** Patient develops multifocal, small and bilateral renal asymptomatic or symptomatic (hematuria) lesions. Occasionally, lymph node involvement occurs but without fatal outcome.
- **Tuberous sclerosis associated renal angiomyolipoma:** It is caused by mutations in the TSC1 or TSC genes which encode the hamartin and tuberin proteins, respectively. Tuberous sclerosis is associated with multiple hamartomas within brain (as cortical tubers subependymal hamartomas), face, and kidneys (renal angiomyolipoma in 80% of cases).

Molecular Genetic Alterations

Renal angiomyolipoma in children exhibits molecular derangements such as 9q34, 16p13.3, 5q, TSC1, TSC2 and tumor suppressor genes.

Clinical Features

Patient may present with flank pain/loin mass and hematuria. Clinical picture mimics like renal cell carcinoma. Histopathologic examination confirms the diagnosis.

Surgical Pathology: Renal Angiomyolipoma

Gross Morphology

Renal angiomyolipoma reveals well circumscribed mass having variegated appearances replaces the upper pole of this kidney. In 25% of cases, the angiomyolipoma may be confused with malignancy because of extension outside the renal capsule. Gross morphology of renal angiomyolipoma is shown in Fig. 22.113.

Light Microscopy

Renal angiomyolipoma comprises mature adipose tissue, smooth muscle and thick-walled blood vessels in varying proportion and haphazardly arranged. Histology of renal angiomyolipoma is shown in Fig. 22.114.

Immunohistochemistry Technique

Panel of markers applied on formalin-fixed paraffin-embedded sections of renal angiomyolipoma expresses HMB-45, melan A, actin and vimentin.

Markers	Expression
▪ HMB-45	▪ Positive
▪ Melan A	▪ Positive
▪ Actin	▪ Positive
▪ Vimentin	▪ Positive
▪ TFE3 (transcription factor E3)	▪ Negative/positive
▪ Cathepsin K	▪ Negative/positive

Fig. 22.113: Gross morphology of renal angiomyolipoma. Tumor is usually unilateral and unifocal. Tumor ranges from 0.5 to 25 cm with a mean of 6 cm. Tumor is circumscribed, not capsulated with pushing border. Cut surface shows gray white (smooth muscle component) and yellow tissue (adipose tissue component) appearance. Tumor may involve the intrarenal venous system, renal vein or vena cava despite benign nature. Multiple or bilateral tumors suggest underlying tuberous sclerosis. Imaging often is sufficient to render the diagnosis. Radiologic findings depend on the amount of adipose tissue within the tumor. Definitive diagnosis of renal angiomyolipoma is done by histopathologic examination of tissue.

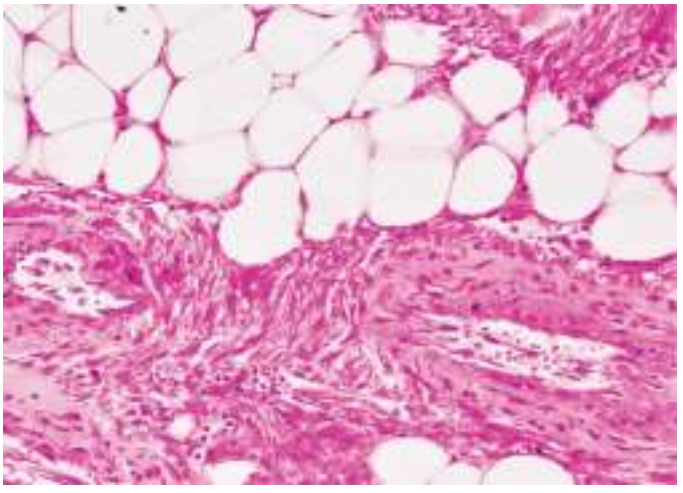

Fig. 22.114: Renal angiomyolipoma. Renal angiomyolipoma can occur sporadically or in younger patients with tuberous sclerosis. Sporadic angiomyolipoma cases are usually diagnosed in middle age adults. Renal angiomyolipoma, classic variant is a benign neoplasm composed of admixture of thick dysmorphic blood vessels, smooth muscle and adipose tissue in variable proportions and haphazardly arranged observed in hematoxylin and eosin-stained renal tissue sections (400X).

RENAL FUNCTION TESTS

The kidneys play a vital role in excretion of waste products (urea, creatinine, uric acid), reabsorption of essential metabolites, maintenance of acid–base equilibrium and calcium homeostasis, regulation of water and electrolytes; and synthesis of erythropoietin, renin and 1, 25-dihydroxyvitamin D.

- The functional unit of the kidney is the nephron which consists of the glomerulus, proximal and distal tubules, and collecting duct.
- Assessment of renal function is important in the management of patients with kidney diseases affecting various components of the kidneys.
- Generally, blood urea and serum creatinine are analyzed by taking random samples to assess renal functions. Other biochemical tests are performed such as blood sugar, serum proteins (total and albumin and globulin ratio), lipid profile and serum calcium.
- Clinically, the most practical tests to assess renal function is to get an estimate of the glomerular filtration rate (GFR) and to check for proteinuria (albuminuria).
- Azotemia refers to accumulation of nitrogenous products in the body. Uremia refers to clinical manifestations due to accumulation of nitrogenous metabolic products.
- Prerenal azotemia is caused by a decrease in cardiac output due to blood loss and congestive failure. Renal azotemia is caused by parenchymal damage to kidneys. Postrenal azotemia is caused by obstruction to urinary outflow below kidneys in the settings of prostatic hyperplasia, prostatic carcinoma and stones in ureters.
- Normal blood chemical values are given in Table 22.77. Laboratory investigations used in renal disease are given in Table 22.78.

Table 22.77 Normal blood chemical values

Substance	Normal Values
pH of blood	7.35–7.45
Blood urea nitrogen	8.0–20.0 mg/dl (2.9–7.1 mmol/L)
Creatinine	0.6–1.2 mg/dl (50–100 mmol/L)
Sodium	135–145 mEq/L
Potassium	3.5–5 mEq/L
Chloride	98–106 mEq/L
Carbon dioxide (CO_2 content)	24–29 mEq/L
Calcium	8.5–10.5 mg/dl (2.1–2.6 mmol/L)
Uric acid	▪ Male: 2.4–7.4 mg/dl (14–440 μmol/L) ▪ Female: 1.4–5.8 mg/dl (80–350 μmol/L)

Table 22.78 Laboratory investigations used in renal disease

Investigation	Reason to Evaluate	Comments
Serum potassium	▪ The kidneys are the main route of excretion of potassium ▪ Hyperkalemia occurs in acute renal failure. Levels may reach life-threatening state	Frequent monitoring of serum potassium levels, is therefore, essential
Serum sodium	Most renal diseases have a little impact on serum sodium levels. Serum sodium levels are vital in diabetes insipidus and syndrome of inappropriate ADH secretion (SIADH)	Close monitoring is vital if large volume of fluids are administered in acute renal failure and patient on hemodialysis
Blood urea	Urea is a nitrogenous waste product of proteins synthesized by the liver and excreted by kidneys	Its estimation provides a measure of the severity of the renal insufficiency in acute and chronic kidney disease
Serum creatinine	Creatinine is derived from muscle and normal levels exhibit muscle mass and racial variability	Serum creatinine levels are increased in acute and chronic kidney disease
Serum proteins	Serum proteins are decreased in nephrotic and nephritic syndrome	Proteins are lost in urine in variable proportion depending on severity of glomerular injury
Serum lipids	Serum lipids are increased in nephrotic syndrome	Liver compensates protein loss by synthesizing lipoproteins leading to increased serum lipid levels
Blood sugar	Blood sugar levels increased cause diabetic nephropathy	Blood sugar monitoring is essential in diabetes mellitus

Contd...

Table 22.78 Laboratory investigations used in renal disease (*Contd...*)

Investigation	Reason to Evaluate	Comments
Serum calcium and phosphate	Kidneys activate vitamin D_2 to D_3. This activation is impaired in chronic kidney disease	Hypocalcemia is accompanied by increased parathormone level as a consequence phosphate level are raised. Magnesium levels should be monitored
Serum complement concentration	Serum complement may be altered in systemic lupus erythematosus	Serum complement level is decreased in poststreptococcal glomerulonephritis
Arterial blood gases	Kidneys participate in maintaining acid–base equilibrium	Patient with acute renal failure develops metabolic acidosis
Serum autoantibodies	▪ Most relevance to nephrology is antineutrophilic cytoplasmic antibody (ANCA) in vasculitis ▪ Serum antinuclear antibodies (ANA) to double-stranded DNA for systemic lupus erythematosus	▪ Serum antineutrophilic cytoplasmic antibody (ANCA) is analyzed in renal vasculitis ▪ Serum antinuclear antibodies (ANA) to double-stranded DNA are analyzed in lupus nephritis
Serum immunoglobulins and electrophoresis	Serum immunoglobulins and electrophoresis are analyzed in suspected cases of myeloma causing renal impairment	Light chains form casts in tubules leading to renal impairment
Imaging techniques	▪ Plain abdominal radiograph is helpful to demonstrate calculi in urinary tract ▪ Ultrasonography evaluates obstruction, hydronephrosis and neoplasms	Nuclear medicine scans provide data of the overall excretory function of kidneys
Hemogram	Erythropoietin level is decreased in chronic renal failure. Patient develops anemia	Transferrin bound iron loss occurs in nephrotic syndrome resulting in iron deficiency anemia
Bleeding and coagulation studies	These studies are essential prior to renal biopsy	Kidney biopsy is contraindicated in bleeding and coagulation disorders. Hypercoagulable state may occur in nephrotic syndrome
Cystatin C (recent biomarker)	Cystatin C is encoded by CST3 gene. It belongs to type 2 cystine gene family. It is found in all tissues. It is excreted in urine	Increased cystatin C concentration in blood indicates impaired glomerular filtrate and renal functions

GLOMERULAR FILTRATION RATE ASSESSMENT

Glomerular filtration rate (**GFR**) represents the flow of plasma from the glomerulus into Bowman's space over a specified period and is the chief measure of kidney function. The normal GFR for an adult is 90–120 ml per minute.

- Glomerular filtrate should be freely filtered at the glomerulus. Glomerular filtrate rate depends upon: (a) renal blood flow, (b) hydrostatic pressure glomeruli (normal 60 mm Hg due to smaller lumen of efferent arterioles), (c) number of functional glomeruli, (d) blood colloidal pressure (normal 25 mm Hg), and (e) back pressure in tubules (normal 15 mm Hg).
- Filtration pressure is necessary to drive fluid across the glomerular basement membrane. It is equal to the difference between the blood pressure in the glomeruli (60 mm Hg) and sum of osmotic pressure exerted by plasma proteins (27 mm Hg) and intratubular pressure (15 mm Hg).
- Filtration pressure = Blood pressure in the glomeruli – (osmotic pressure 27 mm Hg in glomeruli + intratubular pressure 15 mm Hg).

EXOGENOUS MARKER OF GLOMERULAR FILTRATION RATE ASSESSMENT

Exogenous marker of glomerular filtration rate assessment includes infusion of inulin and then measurement of blood levels after a specified period to determine the rate of clearance of inulin. Its use is limited because purified inulin is expensive, difficulty in measuring glomerular filtration rate and time consuming for both patients and clinicians. Normal inulin clearance is 100–150 ml/minute.

- Other markers used for assessment of glomerular filtration rate are radioisotopes such as chromium-51 ethylenediaminetetra-acetic acid (**51 Cr-EDTA**), and technetium-99-labeled diethylenetriamine-pentaacetate (**^{99}Tc-DTPA**).

- The most promising exogenous marker used is the nonradioactive contrast agent such as **iohexol**, especially in children.

CREATININE CLEARANCE

Creatinine clearance is the most commonly used endogenous marker for assessment of glomerular function. Renal clearance of a substance is the amount of blood or plasma completely cleared off in a given time. The calculated clearance of creatinine is used to provide an indicator of glomerular filtrate rate. It involves the collection of urine specimen over a period of 24-hour preferably over an accurately timed period of 5–8 hours since 24-hour collected urine samples are notoriously unreliable. Creatinine clearance is then calculated using the equation: C = (U × V)/PC = clearance, U = urinary concentration, V = urinary flow rate (volume/time, i.e. ml/min), and P = plasma concentration.

- Normal creatinine clearance is 90–120 ml/minute. Creatinine is the by-product of creatine phosphate in skeletal muscle, and it is produced at a constant rate by the body. Creatinine clearance should be corrected for body surface area.
- Due to tubular secretion, creatinine overestimates glomerular filtration rate by around 10–20%. Creatinine clearance is decreased in elderly persons, acute and chronic kidney disease. Creatinine clearance is increased in normal pregnancy.
- The amount of creatinine produced per day depends on skeletal muscle bulk, and thus, there is a difference in creatinine ranges between males and females with lower creatinine values in children and those with decreased skeletal muscle bulk. Diet also influences creatinine clearance values.

TUBULAR REABSORPTION TESTS

The renal tubules play an important role in reabsorption of electrolytes, water, and maintaining acid–base balance. Electrolytes such as sodium, potassium, chloride, magnesium, phosphate can be analyzed in the urine as well as glucose. Urinary osmolality is analyzed to assess concentrating ability of urine tubules. A urinary osmolality greater than 750 mOsmol/kg H_2O indicates a normal concentrating ability of tubules.

- A water deprivation test can be performed to exclude nephrogenic diabetes insipidus as opposed to excessive intake of water. Nephrogenic diabetes insipidus (NDI) is an inability to concentrate urine due to impaired renal tubule response to vasopressin (ADH), which results in excretion of large amount of dilute urine. It can be inherited or occur secondary to conditions that impair renal concentrating ability.
- **Ammonium chloride test** can be performed to confirm diagnosis of distal renal tubular acidosis with failure to acidify the urine to a pH <5.3.
- Renal tubular acidosis is characterized by an hyperchloremic acidosis with a normal anion gap. Diagnosis is confirmed by alkaline urine pH >5 despite a metabolic acidosis (plasma bicarbonate <17.5 mmol/L) in the presence of a normal glomerular filtration rate.
- In ammonium chloride test, the ammonium chloride is converted to urea in the liver with the consumption of bicarbonate. The bicarbonate is replaced by renal synthesis with excretion of hydrogen ions. Ammonium chloride test stresses the ability of the kidneys to excrete acid and any failure to excrete acid will result in metabolic acidosis. Proximal renal tubular acidosis in Fanconi syndrome is characterized by aminoaciduria, glycosuria, and phosphaturia and bicarbonate wasting.

BLOOD BIOCHEMISTRY

BLOOD UREA NITROGEN

Urea or blood urea nitrogen (BUN) is a nitrogen-containing compound formed in the liver as the end product of protein metabolism (amino acid and pyrimidine) and urea cycle. About 85% of urea is eliminated via kidneys and rest is excreted via gastrointestinal tract. Urea is partially reabsorbed in the proximal tubules.

- Blood urea nitrogen levels depend on: (a) glomerular filtration rate, (b) protein content in diet, (c) proximal tubule reabsorption, and (d) functional status of the urea cycle. Normal serum blood urea nitrogen (BUN) is 7–18 mg/dl.
- Blood urea nitrogen is increased in prerenal diseases (gastrointestinal bleeding, dehydration, catabolic states, high protein diet, congestive heart failure), renal diseases (acute renal failure, chronic renal failure) and postrenal obstructive disorders (prostatic nodular hyperplasia, prostatic carcinoma, urolithiasis). Causes of increased blood urea nitrogen concentration are shown in Table 22.79.
- Blood urea concentration is decreased during pregnancy due to expansion of plasma volume. Blood urea concentration is also decreased in the settings of decreased synthesis of urea in cases of cirrhosis, fulminant hepatocellular failure; and dysfunctional urea cycle. Decreased amino acid degradation in the settings of kwashiorkor and starvation also results in decreased blood urea concentration.

Table 22.79 Causes of increased blood urea nitrogen concentration

Causes	Comments
Prerenal causes	▪ High protein diet, gastrointestinal hemorrhage ▪ Increased protein catabolism such as surgery, trauma, extreme starvation ▪ Impaired renal perfusion due to extracellular fluid loss, cardiac failure, hypoproteinemia
Renal causes	Reduced glomerular filtrate due to acute or chronic renal diseases
Postrenal causes	Obstruction to urine outflow due to benign prostatic hypertrophy, prostatic carcinoma, urethral stricture, obstruction and stone

SERUM CREATININE

Normal serum creatinine level is 0.6–1.2 mg/dl. Creatinine is metabolic end product of creatine in skeletal muscle. Creatine binds phosphate in skeletal muscle for ATP synthesis. Creatinine is filtered in the kidneys and not reabsorbed or secreted. It is excellent metabolic product for renal clearance testing. Serum creatinine concentration varies with age and skeletal muscle mass, i.e. increased with age and decreased in skeletal muscle wasting. Causes of increased and decreased serum creatinine are similar to those for serum blood urea nitrogen (BUN).

RATIO OF BLOOD UREA NITROGEN TO SERUM CREATININE

Ratio of blood urea nitrogen to serum creatinine is ≤15. Creatinine is filtered and is neither reabsorbed nor secreted in kidneys. Urea is filtered and partly reabsorbed in the proximal tubule. Ratio of blood urea nitrogen to serum creatinine depends etiology at the level of prerenal, renal and postrenal level. In prerenal disease the ratio is close to 20:1, while in intrinsic renal disease it is closer to 10:1.

SERUM CYSTATIN C

Cystatin C is an endogenous glomerular filtration rate marker encoded by CST3 gene. It is synthesized by all nucleated cells of body. It functions as protease inhibitor. Cystatin C is freely filtered at the glomerulus.

- Serum level of cystatin C is inversely correlated with the glomerular filtration rate (GFR). Increased serum cystatin C concentration indicates impaired glomerular filtration rate and renal functions. The renal handling of cystatin C differs from creatinine.
- While both cystatin C and creatinine are freely filtered by glomeruli, once cystatin C is filtered, it is reabsorbed and metabolized by proximal tubules, unlike creatinine.
- Unlike creatinine, cystatin C is not affected by age, skeletal muscle bulk, or diet. Hence, cystatin C is a more reliable marker of glomerular filtration rate than creatinine particularly in early stage of renal impairment. It is worth mentioning that cystatin C concentration may be affected due to malignant, thyroid disease, and tobacco smoking.

NOVEL SERUM, URINE AND TISSUE BIOMARKERS

Several novel serum, urine and tissue biomarkers have been reported to be useful to assess renal injury, which include serum biomarkers, urine biomarkers and tissue biopsy.

- Low-molecular proteins such as cystatin C, β_2-microglobulin, and retinol-binding protein present in the systemic circulation are filtered by glomeruli.
- Glomerulopathy leads to elevated concentration in the blood. Some proteins synthesized in response to cellular/tissue injury neutrophil gelatinase-associated lipocalin (NGAL).
- Novel biomarkers include kidney injury molecule 1 (KIM-1), L-type fatty acid-binding protein (L-FABP), and fibroblast growth factor 23 (FGF23). Their optimum clinical utility will be realized with ongoing studies.
- Serum neutrophil gelatinase-associated lipocalin (NGAL) is a novel biomarker for acute renal injury in critically ill children with septic shock. Kidney injury molecule (KIM-1), a transmembrane protein is a novel biomarker for human renal proximal tubular injury.
- L-type fatty acid-binding protein (L-FABP) is present in the cytoplasm of human renal proximal tubules. It is upregulated in renal proximal tubular injury.
- Fibroblast growth factor 23 (FGF23) is synthesized by bone, which acts on kidney indicating that FGF23 is systemic novel biomarker.
- Anti-phospholipase A2 receptor (PLA2R) antibodies are highly specific for the diagnosis of primary membranous glomerulopathy. Novel biomarkers for renal injury are given in Table 22.80.

URINE ANALYSIS

The best specimen for urine analysis is a freshly voided midstream urine. Midstream urine is utilized as it is less likely to be contaminated by commensal between bacteria and epithelial cells. Urine analysis involves 24 hours urine output, physical observation

Table 22.80 Novel biomarkers for renal injury

Markers	Role in Clinical Practice
Serum biomarkers	
Serum creatinine	Glomerular filtrate rate assessment
Serum cystatin C	Glomerular filtrate rate assessment (specific and accurate)
Serum neutrophil gelatinase-associated lipocalin (NGAL)	Marker of glomerular injury in children with septic shock (elevated serum NGAL in acute and chronic renal injury)
Serum kidney injury molecule 1 (KIM-1)	Unregulated in human renal proximal tubular injury
Serum L-type fatty acid-binding protein (L-FABP)	Upregulated in human renal proximal tubular injury
Serum asymmetric dimethylarginine (ADMA)	Analysis of endothelial function (inhibits nitric oxide synthase), elevated in disease progression and death
Serum PLA2R antibody	Specific marker for primary membranous glomerulonephritis
Urine biomarkers	
Urine creatinine	Analysis of renal clearance
Urine protein/albumin	Nonspecific marker of renal injury, degree of proteinuria correlates with progression of disease
Urine L-FABP	Correlates with proteinuria and predicts disease progression
Urine NGAL	Marker for tubular epithelial cell injury in acute and chronic renal disease
Urine IGFBP7 and TIMP-2	Marker of acute renal injury and cell cycle arrest
Urine uromodulin	Decreased excretion in diabetic nephropathy
Urine collage fragments	Decreased excretion in chronic renal disease
Urine MMP-7	Marker of Wnt/β-catenin signal pathway
Urine α_1-antitrypsin	Marker of glomerulopathy with nephrotic syndrome
Urine retinol binding protein (RBP)	Marker correlated with renal function
Urine β-trace protein	Marker correlated with renal function
Urine β_2-microglobulin	Marker correlated with renal function
Urine inulin	Exogenously administered marker to assess glomerular filtration rate (inulin better marker than creatinine)
Urine iothalamate	Exogenously administered marker to assess glomerular filtration rate
Urine iohexol	Exogenously administered marker to assess glomerular filtration rate
Renal DTPA scan	Exogenously administered marker to assess glomerular filtration rate by renal DTPA scan
Urine EDTA	Exogenously administered marker to assess glomerular filtration rate
Tissue biopsy	
α-SMA	Predicts renal disease progression marker for myofibroblasts
Tissue transglutamase	Positive immunohistochemical staining correlated with worsened fibrosis
MMP-1, MMP-9, IL-8, β_4-integrin, urokinase receptor	Gene subset that predicts disease progression from renal biopsy samples
PLA2R	Anti-PLA2R: a serological marker for primary membranous nephropathy

DTPA: Diethylenetriaminepentaacetic acid; EDTA: Ethylenediaminetetra-acetic acid; GFR: Glomerular filtration rate; L-FABP: Liver-type fatty acid-binding protein; MMP: Matrix metalloproteinase; NGAL: Neutrophil gelatinase-associated lipocalin; PLA2R: Phospholipase A2 receptor; RBP: Retinol-binding protein; SMA: Smooth muscle actin.

(color), pH, specific gravity, chemical and microscopic analysis by dipstick. Normal values for routine urinalysis are given in Table 22.81. Correlations of urine analysis and renal diseases are given in Table 22.82.

24 HOURS URINE OUTPUT

The normal range for 24-hour urine volume in adults is 800–2,000 ml/24 hours; with two liters fluid intake per day. Normal value ranges may vary slightly among different laboratories.

Table 22.81 Normal values for routine urinalysis

Parameters	Urinary Finding
General characteristics and measurements	
Total 24 hours urinary output	600–2500 ml (average 1200 ml)
Color	Yellow
pH	4.5–8.0 (average 5 or 6)
Specific gravity	1.005–1.025 with normal fluid intake
Chemical determinants	
Proteins	Nil
Sugar	Nil
Ketone bodies	Nil
Blood	Nil
Bilirubin	Nil
Leukocyte esterase	Nil
Nitrate for bacteria	Nil
Urobilinogen	0.5–4.0 mg/dl
Urinary sediment analysis	
Hyaline casts	Nil/occasional
Red blood cells	Nil
White blood cells	Nil
Epithelial cells	Present
Calcium oxalate crystals	Present

Contd...

Table 22.82 Correlations of urine analysis and renal diseases

Disorder	Urine Analysis	Comments
Glomerular disorders		
Acute glomerulonephritis	▪ Macroscopic hematuria (smoky colored urine) ▪ Proteinuria in nephritic range ▪ Red blood cell casts	▪ Poststreptococcal glomerulonephritis • Periorbital edema • Hypertension • Serum proteins and complement decreased • Blood urea, serum creatinine increased
Goodpasture syndrome	▪ Macroscopic hematuria ▪ Proteinuria ▪ Red blood cell casts	Antibodies directed against glomerular basement membrane
Wegener's granulomatosis	▪ Macroscopic hematuria ▪ Proteinuria ▪ Red blood cell casts	Antineutrophilic antibody
Henoch-Schönlein purpura	▪ Macroscopic hematuria ▪ Proteinuria ▪ Red blood cell casts	Following respiratory infections in children
Membranous glomerulonephritis	▪ Microscopic hematuria ▪ Proteinuria	▪ Autoimmune disorder of adults ▪ Generalized edema ▪ Serum proteins decreased ▪ Hypercholesterolemia
IgA nephropathy	▪ Hematuria ▪ Proteinuria	IgA immune complexes in mesangial region
Nephrotic syndrome	▪ Proteinuria in nephrotic range ▪ Renal tubular epithelial cells ▪ Oval fat bodies ▪ Fatty and waxy casts	Caused by many glomerulopathies (e.g. minimal change disease, membranous GN, membrano-proliferate GN, diabetic nephropathy, amyloid nephropathy)
Minimal change disease	▪ Proteinuria in nephrotic range ▪ Fat droplet	▪ Following allergic reactions in children ▪ Generalized edema ▪ Serum proteins decreased ▪ Hypercholesterolemia ▪ Prognosis excellent after steroid therapy

Contd...

Table 22.82 Correlations of urine analysis and renal diseases (*Contd...*)

Disorder	Urine Analysis	Comments
Focal segmental glomerulosclerosis	▪ Proteinuria ▪ Hematuria	▪ Drugs abuse ▪ HIV infection
Tubular disorders		
Acute tubular necrosis	▪ Renal tubular epithelial cells and casts ▪ Positive blood reagent strip	Induced by ischemia, hemoglobinuria, myoglobinuria and antibiotics
Fanconi's syndrome	▪ Proteinuria ▪ Glycosuria	General failure of tubular reabsorption
Renal glycosuria	Glycosuria	Failure of active transport of only glucose
Tubulointerstitial disorders		
Cystitis	▪ High pH ▪ Leukocyte esterase positive ▪ Nitrite positive ▪ WBCs ▪ Bacteria	Urinary bladder infection
Acute pyelonephritis	▪ Leukocyte esterase positive ▪ Nitrite positive ▪ WBC casts	Tubular infection indicated by presence of WBC casts
Chronic pyelonephritis	▪ High pH ▪ Leukocyte esterase positive ▪ Nitrite positive ▪ WBCs granular, waxy and broadcasts	Pyogenic infection due to major anatomic abnormalities may presents with fever, malaise and flank pain
Acute interstitial nephritis	▪ Hematuria ▪ Proteinuria ▪ WBC casts	▪ Induced by medications ▪ Eosinophils in urine ▪ Bacteria absent
Renal lithiasis (calculi)	Microscopic hematuria	Patient presents with severe renal colic

- Oliguria is defined as urine output <400 ml/24 hours. Urine output is decreased in dehydration, hypovolemic shock, acute and chronic kidney disease, multiple organ failure and urinary dysfunction retention.
- Polyuria is excessive or an abnormally large production or passage of urine (>2.5–3.0. L/24 hours in adults). Polyuria occurs in the settings of diuretics use, uncontrolled diabetes mellitus, central diabetes insipidus and nephrogenic diabetes insipidus.

PHYSICAL EXAMINATION

The normal color of urine is straw colored in the presence of dehydration urine is a darker color.

- Cloudy or milky urine usually accompanied by bad smell possibly indicates urinary tract infection.
- Red urine may indicate hematuria or porphyria or represent the dietary intake of food like beets.
- Pink, red or light brown urine is caused by hemolytic anemia, neoplasms located in kidney or urinary bladder and porphyria.
- Dark yellow or orange urine, indicates recent intake of vitamin B containing nutrient supplement, carotene, phenazopyridine, rifampicin, warfarin and laxative. Urine color in various conditions is given in Table 22.83.

pH AND SPECIFIC GRAVITY

Normal urine pH is 4.5–8.0 (average 5 or 6) and specific gravity as 1.005–1.025 with normal fluid intake. Urine specific gravity is a measure of the ratio of the density of urine to the density of water. Specific gravity is estimated by Vogal's urinometer.

- Increased urine specific gravity means increased concentration of solutes in the urine in the settings of dehydration, diarrhea, excessive sweating, glucosuria, renal artery stenosis decreased renal blood flow and hepatorenal syndrome.
- Specific gravity is decreased in the settings of renal failure, pyelonephritis, diabetes mellitus, acute tubular necrosis, interstitial nephritis and excessive intake of fluids.

Table 22.83 Urine color in various conditions

Color	Conditions
Normal urine color	Yellow amber colored
Dark yellow or orange color	▪ Concentrated urine ▪ Diet-rich in carotene and vitamin B complex ▪ Durgs—rifampicin, warfarin, laxative and phenazopyrine
Red color	▪ Hematuria ▪ Myoglobinuria ▪ Hemoglobinuria ▪ HbO_2
Cloudy or milky color	Leukocytes in urinary tract infection
Orange	Urates
Brown	Bilirubin
Brown black color	▪ Melanin ▪ Methemalbuminemia
Blue/green color	▪ Sorbitol therapy ▪ M-Dopa therapy
Yellow color	▪ Pus cells ▪ Tetracycline therapy

CHEMICAL EXAMINATION

Urine dipstick provides qualitative analysis of different analytes in urine using chemical analysis. Dipstick uses dry chemical methods to detect for the presence of protein, glucose, blood, ketones, bilirubin, urobilinogen, nitrite, and leukocyte esterase. The color changes following interaction of the urine with the chemical reagents impregnated on the paper of the dipstick are compared to the color chart guide to interpret the results. Analytes tested on urine dipstick-protein should not be detectable in normal urine specimens. Schematic representation of dipstick is shown in Fig. 22.115.

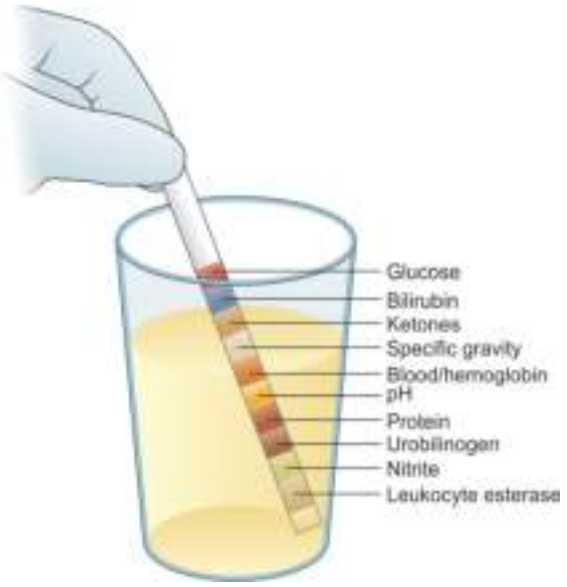

Fig. 22.115: Schematic representation of dipstick. Dipstick is a bedside qualitative estimation of specific gravity, leukocyte esterase and pH, urinary chemical constituents such as, protein, glucose, ketone bodies, bilirubin, urobilinogen, hemoglobin.

Albuminuria/Proteinuria

Normal persons excrete proteins 150 mg/24 hours in urine (30% albumin; 30% globulins; 40% Tamm-Horsfall protein).

- Microalbuminuria refers to the presence of albumin 30–300 mg per day, which is a marker of glomerular endothelial dysfunction and cardiovascular disease.
- Urine albumin may be analyzed in 24-hour urine sample in early morning/random specimens as an albumin/creatinine ratio. Presence of albuminuria on two occasions with the exclusion of a urinary infection indicates glomerular dysfunction.
- Functional proteinuria is observed in fever, congestive heart failure and orthostatic position.
- Frank proteinuria is defined >300 mg/24 hours. Selective proteinuria refers to presence of albumin in urine. Nonselective proteinuria refers to presence of both albumin and globulin in the urine.
- Increased amount of protein in urine may be due to injury to glomeruli (glomerulonephritis), incomplete tubular reabsorption of proteins (interstitial nephritis, Fanconi syndrome due to inability to absorb glucose, amino acids, phosphate, bicarbonate and uric acid; and Hartnup's syndrome due to defect in reabsorption of neutral amino acids (tryptophan) in the gastrointestinal tract and kidneys), overflow proteinuria (multiple myeloma—Bence Jones proteins, myoglobinuria) and urinary tract infection and tumors.
- Nephritic syndrome is characterized by proteinuria (<2 g/24 hours), oliguria (<400 ml/24 hours), passage of smoky colored urine, periorbital edema and hypertension.
- Nephrotic syndrome is characterized by massive proteinuria (≥3.5 g/24 hours), hypoproteinemia, hypercholesterolemia and generalized edema.

Glucosuria

Glucose is the main type of sugar in the bloodstream, which is the major source of energy for body's cells. Glucose is derived from foods and other substances. Several hormones including insulin and glucagon regulate glucose levels in the blood. Glucose is not detectable in urine samples of normal persons. Glucosuria may be present in diabetes mellitus and pregnancy. Renal glycosuria occurs when the renal threshold is decreased.

Ketone Bodies

Ketone bodies are produced by the liver and used as an energy source when glucose is not readily available. Acetoacetate and 3β-hydroxybutyrate exist in

abundance. While acetone is least abundant. Ketone bodies are normally present in the blood. Blood ketone bodies level is increased in the settings of fasting, vomiting, prolonged exercise and diabetic ketoacidosis. Therefore, these persons excrete abundant ketone bodies in the urine.

Bile Salts

Bile salts are composed of the four different types of free **bile acids** such as cholic acid, deoxycholic acid, chenodeoxycholic acid and lithocholic acid. Each of these bile acids may turn combine with glycine or taurine to form more complex acids and salts. Normal urine does not contain bile salts. Bile salts are detected in the urine in obstructive jaundice.

Bile Pigments

Bile pigment is the product of hemoglobin breakdown excreted in bile. There are two types of bile pigments: (a) bilirubin (yellow in color) and (b) biliverdin (green in color). Biliverdin is the oxidized form of bilirubin in the bile pigment excreted through urine. Normal urine does not contain bilirubin. The presence of bile pigments is an indication of liver dysfunction. Jaundice occurs due to liver dysfunction, which results in the detection of abnormally high levels of bilirubin in the bloodstream and urine, as the liver is unable to filter out excess bilirubin.

Urobilinogen

Urobilinogen is a by-product of bilirubin that is eventually eliminated through urine and stool. A urobilinogen in urine analysis measures the quantity of urobilinogen in a urine sample ranging from 0.1 to 1.8 mg/dl. Urobilinogen is formed from reduction of bilirubin. Bilirubin is a yellow-colored pigment produced by breakdown of red blood cells. Normal urine contains some quantity of urobilinogen. Urobilinogen is absent in urine in conjugated hyperbilirubinemia and increased in the settings of liver diseases such as hepatitis and cirrhosis.

MICROSCOPIC EXAMINATION

The microscopic urine analysis involves wet-preparation analysis of urine to assess in the presence of red blood cells, white blood cells, hyaline casts, and crystals as well as microorganisms. In normal urine red blood cells per high-power field is between 0 and 3 and white blood cells (WBCs) per high-power field is between 0 and 5.

Hematuria

Presence of red blood cells indicates renal injury. Causes of hematuria are glomerulonephritis, interstitial renal disease, renal papillary necrosis, renal cell carcinoma, transitional cell carcinoma of urothelium, urinary tract infection, urolithiasis, renal tuberculosis and exacerbation by anticoagulants. Causes of hematuria are given in Table 22.84.

Table 22.84 Causes of hematuria

Glomerulonephritis
Interstitial renal disease
Renal papillary necrosis
Renal cell carcinoma
Transitional cell carcinoma of urothelium
Urinary tract infection
Urolithiasis
Renal tuberculosis
Exacerbation by anticoagulants

Pus Cells in Urine

Pus cells are demonstrated in urinary tract infection. Presence of nitrites and leucocyte esterase in urine are indicators of urinary tract infection. Some bacteria, for example, Enterobacteriaceae, convert nitrates to nitrites.

Casts in Urine

Hyaline casts consist of proteins and occur in glomerular disease. Red blood cell casts usually denote glomerulonephritis. White blood cell casts are demonstrated in patients of pyelonephritis.

Crystals in Urine

Crystals may also be detected in urine. The type of crystals formed depends on urine pH. Calcium oxalate, uric acid, amorphous urate, leucine, tyrosine and cysteine crystals are present in acidic pH urine. Amorphous phosphate, triple phosphate, calcium carbonate and ammonium biurate crystals are present in alkaline pH urine.

- Calcium oxalate crystals are envelope-shaped and are present in ethylene glycol poisoning or primary and secondary hyperoxaluria.
- Uric acid crystals are needle-shaped and are associated with gout.
- Triple phosphate crystals are rectangular are demonstrated in pseudogout.
- Cysteine crystals are hexagonal and seen in cystinuria. Schematic representation of urinary sediment analysis is shown in Figs 22.116 and 22.117.

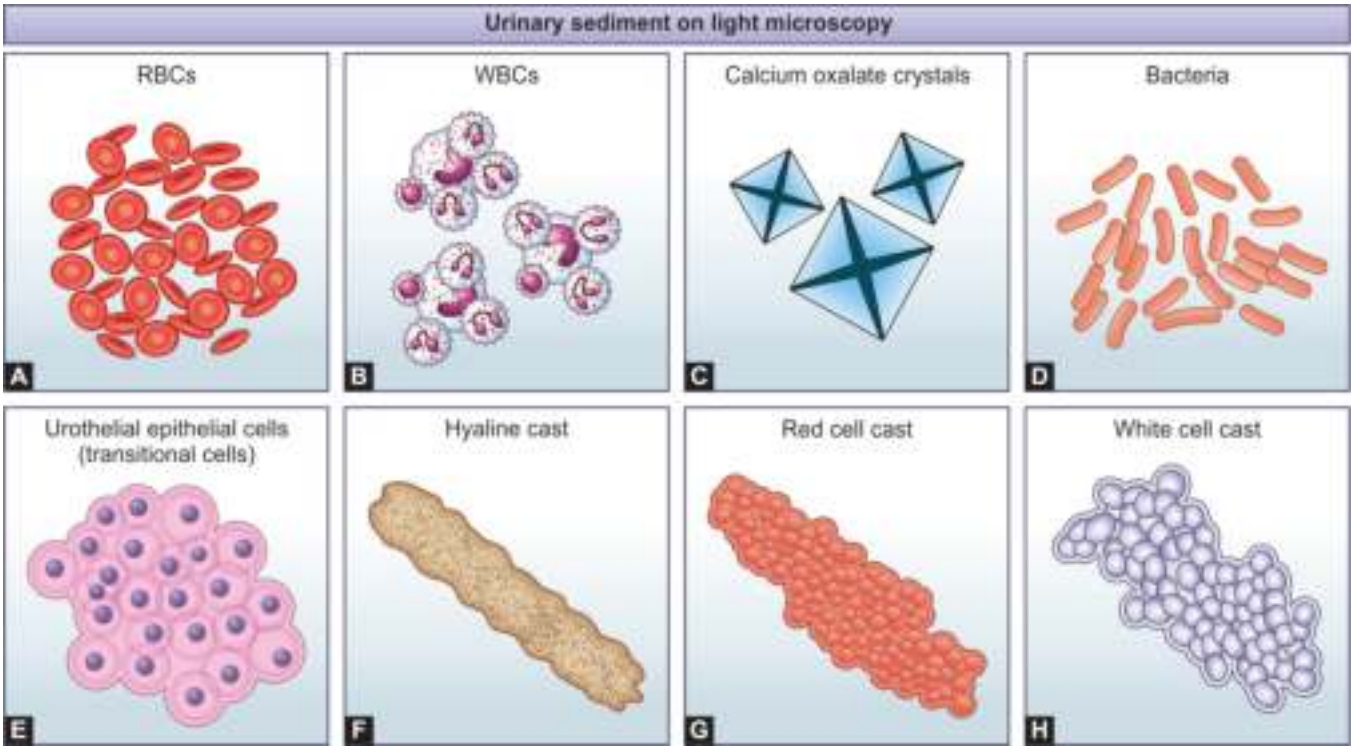

Fig. 22.116A to H: Schematic diagram of urinary sediment. Urinary sediment is examined under light microscopy to demonstrate RBCs, pus cells, crystals, bacteria, epithelial cast, hyaline cast and white cell cast in various urinary tract disorders.

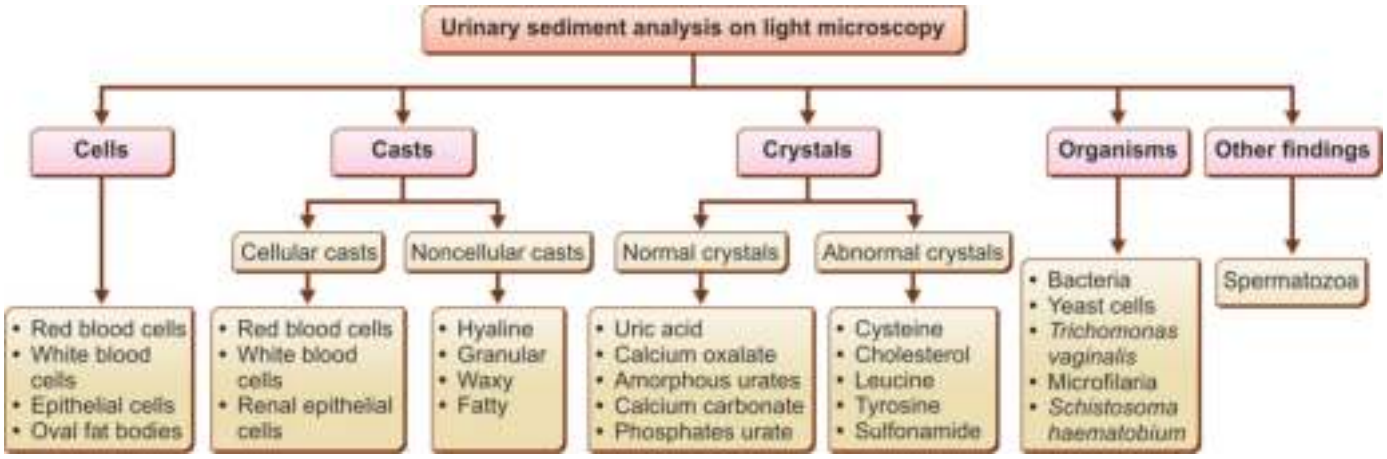

Fig. 22.117: Urinary sediment analysis by light microscopy.

URINE CULTURE AND SENSITIVITY TEST

Urine contains a low-level of bacterial community, known as a microbiota in healthy adults, who are free from a urinary tract infection (UTI). The female and male urinary tracts are relatively same except for the length of urethra. Female urethra is short, hence prone to urinary tract infection.

- Certain conditions can also increase the risk for urinary tract infection, including diabetes mellitus, nephrolithiasis, an enlarged prostate in men, pregnancy, as well as urinary tract surgery. However, in the process of urine specimen collection, some contamination occurs from skin microbiota.
- Patients with urinary tract infection present with pain or burning during urination. Urine may look cloudy or bloody, and it might give off a bad smell. UTI is diagnosed by taking a urine sample and checking for bacteria.
- Urine culture and sensitivity is used to diagnose UTI and to identify the bacteria or yeast causing urinary tract infection. If bacteria multiply, an antibiotic sensitivity or susceptibility test can identify the antibiotic most likely to eradicate those bacteria.

Urinary Bladder and Male Reproductive System

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

DISORDERS OF URINARY BLADDER

- Anatomy and histology
- Benign non-neoplastic disorders
  - Acute cystitis
  - Chronic cystitis
  - Granulomatous cystitis
  - Interstitial cystitis
  - Hemorrhagic cystitis
  - Papillary and polypoidal (bullous) cystitis
  - Eosinophilic cystitis
  - Cystitis glandularis and/or cystitis cystica
  - Malakoplakia of urinary bladder
  - Exstrophy of urinary bladder
  - Urachal sinus
  - Urachal diverticulum
  - Urinary bladder diverticula
- Primary urothelial neoplasms
  - Urothelial carcinoma
    - Noninvasive papillary urothelial neoplasia
    - Endophytic/inverted urothelial neoplasia
    - Flat urothelial lesions with atypia
    - Invasive urothelial carcinoma
  - Primary squamous cell carcinoma
  - Primary adenocarcinoma
  - Botryoid rhabdomyosarcoma

DISORDERS OF TESTES

- Testes: overview
  - Anatomy
  - Histology
  - Spermatogenesis
  - Semen (seminal fluid)
    - Semen analysis
    - Cryopreservation of spermatozoa
- Inflammatory disorders of testis
  - Bacterial orchitis
  - Mumps orchitis
  - Tuberculous epididymo-orchitis
  - Granulomatous orchitis
  - Syphilitic orchitis
- Neoplastic disorders of testis
  - Germ cell tumors of testis
    - Seminoma of testis
    - Spermatocytic seminoma of testis
    - Embryonal carcinoma of testis
    - Yolk sac tumor
    - Teratoma of testis
    - Choriocarcinoma of testis
    - Mixed germ cell tumors of testis
    - Burnt-out germ cell tumors of testis
  - Sex cord/stromal tumors of testis
    - Sertoli cell tumor (androblastoma) of testis
    - Leydig cell tumor of testis
  - Other malignant tumors of testis
    - Testicular lymphoma
    - Testicular plasmacytoma
    - Leukemic infiltration and myeloid sarcoma of testis
    - Metastases in testis
- Neoplastic disorders of mesothelium
  - Adenomatoid tumor
- Non-neoplastic disorders of mesothelium
  - Testicular torsion
  - Hydrocele
  - Hematocele
  - Spermatocele
  - Varicocele
  - Male hypogonadism
  - Male impotence
  - Cryptorchidism
  - Testicular atrophy
  - Male pseudohermaphroditism

DISORDERS OF PROSTATE GLAND

- Anatomy and histology—prostate
- Inflammatory disorders—prostate
  - Acute bacterial prostatitis
  - Asymptomatic inflammatory prostatitis
  - Chronic prostatitis
  - Nonspecific granulomatous prostatitis
- Benign nodular hyperplasia of prostate gland
- Neoplastic disorders of prostate
  - Prostatic intraepithelial neoplasia
    - Genetic alterations and immunohisto-chemical markers
  - Intraductal and invasive prostatic adenocarcinoma
    - Molecular genetic alterations
    - Clinical features
    - Diagnostic modalities
    - Serum tumor markers in prostatic adenocarcinoma
    - Gleason grading system
    - Gleason staging system
    - Prognostic factors
    - Therapeutic correlation

DISORDERS OF PENIS

- Anatomy of penis
- Congenital anomalies of penis and miscellaneous disorders
- Inflammatory disorders of penis
- Neoplastic disorders of penis

DISORDERS OF URINARY BLADDER

ANATOMY AND HISTOLOGY

Urinary bladder is a hollow musculomembranous sac, which acts as a reservoir for the urine. It is the most anterior organ of the pelvic viscera. It has superior, right inferolateral, left inferolateral and posterior surfaces. It is subperitoneal organ and has parietal peritoneum only on its superior surface. Urine enters the urinary bladder via ureters and exits via the urethra.

- Body of the urinary bladder is lined by transitional epithelium, which can hold 400–1000 ml of urine.
- Trigone urinary bladder has the shape of inverted triangle found on the fundus formed by right and left ureteral orifices. Once the trigone is stretched to a certain degree, signal is transmitted to the brain that urinary bladder needs to be emptied.
- Ureteral orifices are slit-like openings through which ureters enter the urinary bladder on the posterolateral angles of the trigone of the urinary bladder.
- Neck is the lowest portion of urinary bladder through which the urethra arises. Internal urethral sphincter is composed of smooth muscle located at the junction of urethra and the urinary bladder innervated by S2–S4 nerves of the pelvic plexus, which prevents the retrograde ejaculation of semen into the urinary bladder.
- Detrusor muscle is composed of inner and outer longitudinal, and middle circular layer.
- Urinary bladder is supplied by parasympathetic pelvic nerve, pudendal somatic nerve and sympathetic hypogastric nerve.
- Urinary bladder is supplied by internal iliac arteries. Superior vesical arteries supply anterosuperior surface of the urinary bladder. In males, inferior vesical arteries supply fundus and neck of the urinary bladder. In females, vaginal arteries, obturator and inferior gluteal arteries supply the posteroinferior surface of the urinary bladder. The veins draining from the urinary bladder correspond to the arteries. Veins from the vesical venous plexus drain into internal iliac veins.
- Lymphatic vessels in both sexes leave the superior surface of the urinary bladder and drain into external iliac lymph nodes. Lymphatic vessels from the fundus drain into the internal iliac lymph nodes. Lymphatic vessels from the neck of the urinary bladder drain into the sacral and common iliac lymph nodes.
- Urinary bladder is lined by specialized stratified epithelium, the urothelium termed 'transitional epithelium'. Urothelium is present in ureter, urinary bladder and proximal urethra. Apical layer of urothelium is umbrella-shaped, intermediate layer consists of two to three layers of polygonal cells; and basal layer is composed of two to three layers of small cuboidal cells. Lamina propria is the suburothelial layer separating the urothelium by a basement membrane and underlying muscularis mucosa. Muscularis propria is composed of smooth muscle coat with the underlying tissue. Serosa is connective tissue covered with the mesothelial lining partially on the surfaces of the urinary bladder, that has a peritoneal covering, which also contains blood vessels of various sizes.

BENIGN NON-NEOPLASTIC DISORDERS

Benign non-neoplastic disorders of urinary bladder include cystitis (acute, chronic, granulomatous, interstitial, hemorrhagic, papillary polypoid, eosinophilic), cystitis glandularis, malakoplakia, exstrophy, persistence of the urachal sinus, vesicoumbilical fistula or urachal diverticulum and urinary bladder diverticulum. Benign non-neoplastic disorders of urinary bladder are given in Table 23.1.

Table 23.1 Benign non-neoplastic disorders of urinary bladder

Benign Non-neoplastic Disorders	Etiology
Acute infectious cystitis. Intermittent urinary obstruction in females	▪ *Escherichia coli* (85%) ▪ *Klebsiella pneumoniae* ▪ *Proteus vulgaris* ▪ Enterococci
Chronic infectious cystitis	Cystoscopy or indwelling catheters for prolonged periods and intermittent urinary obstruction
Granulomatous cystitis	Bacteria, fungi, parasites and intravesical immunotherapy
Chronic interstitial cystitis	Middle-aged and elderly women
Hemorrhagic cystitis	▪ Cyclophosphamide therapy ▪ Adenovirus infection in immunocompromised persons
Papillary and polypoid (bullous) cystitis	Prolonged indwelling catheter

Contd...

Table 23.1 Benign non-neoplastic disorders of urinary bladder (*Contd...*)

Benign Non-neoplastic Disorders	Etiology
Eosinophilic cystitis	▪ Lamina propria of urinary bladder is infiltrated by eosinophils due to allergic and parasitic disorders ▪ Eosinophils may be present in the adjoining areas of urothelial carcinomas
Cystitis glandularis	▪ Chronic bladder inflammation ▪ Urinary bladder exstrophy ▪ Chronically infected neurogenic bladder ▪ Urinary bladder stones ▪ Urinary bladder with indwelling catheter
Malakoplakia	Soft yellow mucosal plaque shows abundant epithelioid histiocytes (known as Hansemann histiocytes) containing basophilic intracytoplasmic granules known as Michaelis-Gutmann bodies containing iron (Perls' stain) and calcium (von Kossa)
Exstrophy of urinary bladder	Absence of the anterior part of the urinary bladder and abdominal wall
Persistence of the urachal sinus	Persistence of the urachal sinus results in drainage of urine from the umbilicus of a newborn
Vesicoumbilical fistula or urachal diverticulum	Occur due to failure of the urachus to involute
Urinary bladder diverticulum	Benign nodular hyperplasia prostate resulting in obstruction and recurrent infections

ACUTE CYSTITIS

Ascending infection from the urethra is the most common route of infection causing cystitis. It most often occurs in women because of short urethra, especially during pregnancy. In acute cystitis, urinary bladder stroma is edematous and hemorrhagic; infiltrated by neutrophils of variable intensity. Patient presents with dysuria, increased frequency of urination, a sense of urgency, and discomfort over the urinary bladder (Fig. 23.1).

Pathogenesis

Escherichia coli is the most common cause of acute cystitis in 85% of cases. *Proteus vulgaris*, *Klebsiella pneumoniae*, and Enterococci are also responsible for acute cystitis in some cases. *Staphylococcus saprophyticus*, a coagulase negative bacterium, is associated acute cystitis in 10–20% of young sexually active females.

- Predisposing factors for acute cystitis prior instrumentation or catheterization, radiation therapy and chemotherapy. Urine examination reveals inflammatory cells.
- Causative agent can be identified by urine culture. Most cases of acute cystitis respond well to treatment with antimicrobial agents.

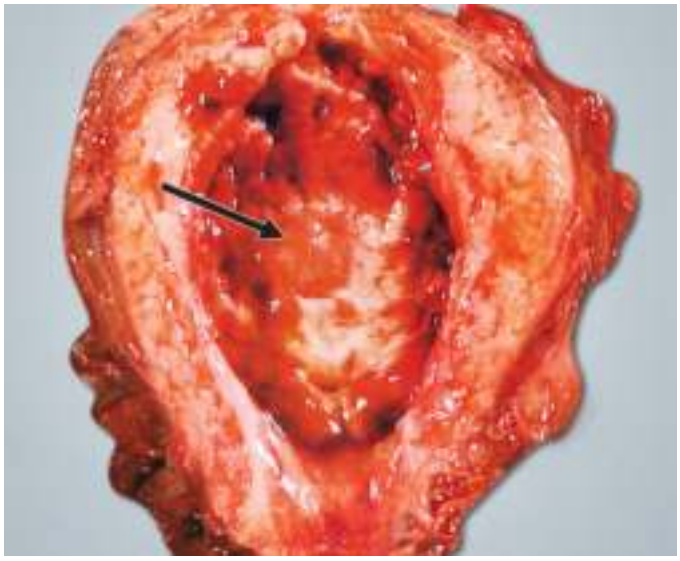

Fig. 23.1: Acute cystitis. The mucosal surface of urinary bladder is red and inflamed. The patient had an indwelling catheter for many weeks before death from other pathology (arrow) 400X.

CHRONIC CYSTITIS

Chronic cystitis is associated with lack of resolution of the inflammatory reaction in patients with acute cystitis. It occurs due to introduction of pathogens into the urinary bladder during cystoscopy or indwelling catheter remaining for prolonged periods. Urinary bladder stroma shows predominance of lymphocytes and fibrosis of the lamina propria.

GRANULOMATOUS CYSTITIS

Granulomatous cystitis is caused by bacteria, fungi, parasites and intravesical immunotherapy. Histologic features of urinary bladder biopsy specimen show granulomas and chronic inflammatory cells.

INTERSTITIAL CYSTITIS

Interstitial cystitis, also referred as Hunner's ulcer, which may be of autoimmune nature. The disorder is most commonly seen in middle-aged women with systemic lupus erythematosus or other autoimmune disorders. Mucosa and submucosa of urinary bladder show infiltration by chronic inflammatory cells with numerous mast cells. Patient presents with

suprapubic pain, frequency and urgency with or without hematuria.

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis is caused by cyclophosphamide therapy and adenovirus infection in immunocompromised persons.

PAPILLARY AND POLYPOID (BULLOUS) CYSTITIS

Papillary polypoid (bullous) cystitis occurs due to prolonged indwelling catheter. Lesion is difficult to differentiate from low-grade urothelial neoplasm.

EOSINOPHILIC CYSTITIS

Eosinophilic cystitis is characterized by presence of eosinophils in lamina propria of urinary bladder due to allergic conditions and parasitic infestations. Eosinophils may be present in the adjoining areas of urothelial carcinomas.

CYSTITIS GLANDULARIS AND/OR CYSTITIS CYSTICA

Cystitis glandularis occurs due to number of chronic stimuli such as recurrent cystitis, neurogenic urinary bladder, exstrophy of urinary bladder and urinary bladder chronically irritated by stones or an indwelling catheter. Nests of urothelium (Brunn nests) grow inward and undergo metaplastic changes (cystitis glandularis) and/or cystic dilatation (cystitis cystica). There is no evidence that cystitis glandularis/cystitis cystica predisposes to urinary bladder carcinoma.

Surgical Pathology: Cystitis Glandularis
Gross Morphology
Cystitis glandularis takes the form of focally or diffusely inflamed edematous or polypoid bladder mucosa.
Light Microscopy
Histologic examination of biopsy specimen reveals glandular structures and cystic spaces within the urinary bladder wall infiltration by chronic inflammatory cells and intestinal metaplasia (Fig. 23.2).

MALAKOPLAKIA OF URINARY BLADDER

Malakoplakia is granulomatous disorder of urinary bladder of unknown etiology, which involves skin and other organs such as kidneys, colon, lung and prostate gland. Predisposing factors for malakoplakia of urinary bladder are chronic infections, immunosuppressive state and cancers. Malakoplakia is characterized by formation of soft yellow-brown plaques on the mucosal surface of the urinary bladder.

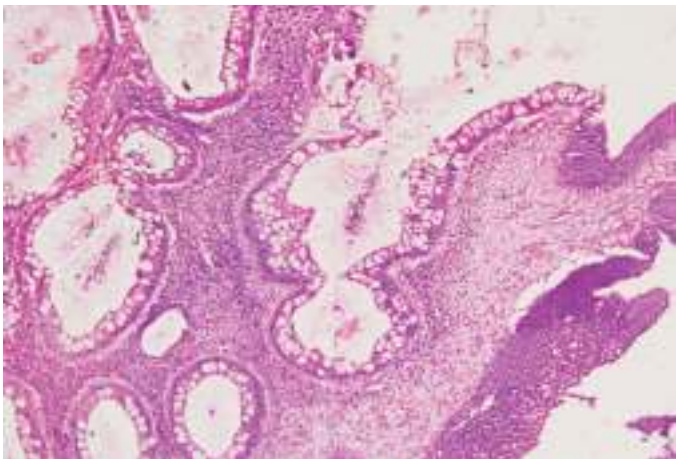

Fig. 23.2: Cystitis glandularis. Histologic examination of urinary bladder specimen reveals glandular structures and cystic spaces within the urinary bladder wall infiltration by chronic inflammatory cells and intestinal metaplasia (400X).

- Malakoplakia of urinary bladder probably occurs due to deficient phagocytic function of macrophages and recurrent infections by *Escherichia coli* and *Proteus vulgaris*.
- On cystoscopy, malakoplakia mimics neoplasia in patient with a long history of recurrent urinary infection, and recent hematuria.
- Soft yellow-brown plaques on the mucosal surface of urinary bladder represent expansion of mucosa by the presence of numerous histiocytes with lysosomal dysfunction, abundant eosinophilic cytoplasm containing PAS positive granules.
- Some of the macrophages show laminated, basophilic deposits of calcium termed **Michaelis-Gutmann bodies**. Histologic features of malakoplakia of urinary bladder are shown in Fig. 23.3.

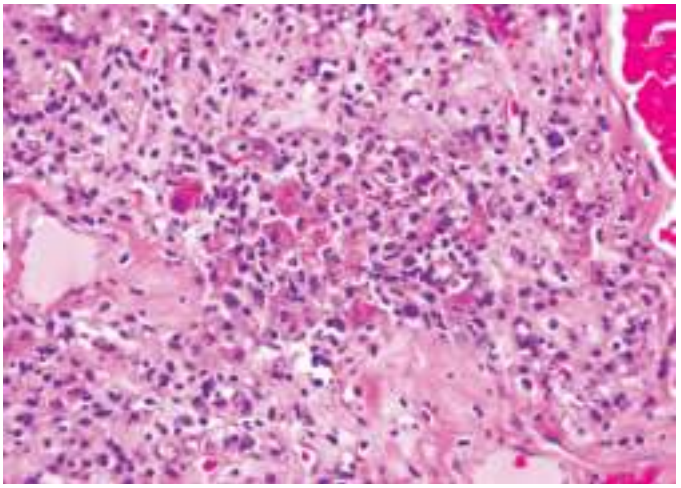

Fig. 23.3: Malakoplakia of urinary bladder. It shows intracellular and extracellular target-like structures termed Michaelis-Gutmann bodies formed due to deposition of calcium (400X).

EXSTROPHY OF URINARY BLADDER

Exstrophy of urinary bladder refers absence of the anterior surface of the urinary bladder and abdominal wall; that can be recognized at the time of birth. In some male infants, exstrophy of urinary bladder is associated with epispadias (incomplete formation of the penile urethra).

- In patients with exstrophy of urinary bladder, posterior wall of urinary bladder undergoes mechanical trauma and undergoes squamous or glandular metaplasia and recurrent infections.
- Despite surgical repair, there is an increased risk for squamous cell carcinoma or adenocarcinoma of urinary bladder in the age group of 50–60 years.

URACHAL SINUS

Urachal sinus is a rare type of vitellointestinal duct anomaly. Vitellointestinal duct or omphalomesenteric duct (OMD) is an embryonic structure, which connects the yolk sac to the midgut and failure of its involution results in various anomalies including Meckel's diverticulum, patent vitellointestinal duct, sinus tract, sinus cyst and umbilical polyp.

- Clinical presentation is persistent umbilical discharge such as urine and fecal matter in pediatric age group. Moreover, urachal sinus has different clinical course in adults than pediatric age group in which it undergoes involution and has a benign clinical course.
- The remnants of urachal sinus are prone to recurrent infection and development of malignancy.
- A proper diagnostic workup by clinical examination and imaging tool is required.
- Early excision of the urachal sinus at initial diagnosis is key for preventing further morbidities.

URACHAL DIVERTICULUM

Urachal diverticulum is the rarest type of congenital urachal anomaly, which occurs due to failure of the distal urachus to close its point of connectivity to the urinary bladder. The disorder is usually asymptomatic but can be associated with recurrent urinary tract infections and other complications such as vesicoumbilical fistula.

URINARY BLADDER DIVERTICULA

Urinary bladder diverticula secondary to benign nodular hyperplasia of prostate is a complication that can lead to obstruction to urinary flow, stone formation in urinary bladder, urinary tract infection (UTI) and development of tumors in the urinary bladder.

Cystoscopy can demonstrate solitary or multiple sac-like outpouchings in the urinary bladder wall.

PRIMARY UROTHELIAL NEOPLASMS

UROTHELIAL CARCINOMA

Urothelial carcinoma (historically known as transitional cell carcinoma) accounts for 90% of all primary tumors of the urinary bladder. Most cases of urothelial carcinoma *in situ* progress subsequently to invasive urothelial carcinoma by invading the lamina propria.

- Development of urothelial carcinoma seems to be dependent on a combination of genetic and environmental factors (tobacco smoking, industrial petrochemical exposure, aniline dyes particularly benzidine and β-naphthylamine).
- *Schistosoma haematobium* is pathogenetically related to both urothelial carcinoma and squamous cell carcinoma but not adenocarcinoma of urinary bladder.

Table 23.2 Features of urothelial lesions with atypia, noninvasive papillary urothelial neoplasms and invasive urothelial neoplasms

Urothelial Lesion	Morphological Features on Cystoscopy	Histologic Features	Malignant Potential and Recurrence after Surgery
Flat urothelial lesions with atypia			
Urothelial dysplasia	Flat lesion	▪ Dysplastic urothelial cells with loss of polarity ▪ Nuclei enlarged with coarse chromatin	▪ Malignant potential (15%) ▪ No recurrence after surgery
Urothelial carcinoma *in situ* (CIS)	Flat lesion	Dysplastic cells of entire urothelium from basal layer to surface	▪ Malignant tumor ▪ No recurrence after surgery
Papillary urothelial neoplasms			
Urothelial papilloma	Single papillary frond associated with painless hematuria	▪ Tumor cells with delicate papillary frond ▪ Minimal branching or fusion	▪ Malignant potential (2%) ▪ Recurrence after surgery (<80%)
Inverted papilloma	Sessile or polypoidal growth	▪ Tumor cells are forming anastomosing cords growing towards lamina propria ▪ Urothelial cells bland	▪ No malignant potential ▪ Rare recurrence after surgery

Contd...

Table 23.2 Features of urothelial lesions with atypia, noninvasive papillary urothelial neoplasms and invasive urothelial neoplasms (*Contd...*)

Urothelial Lesion	Morphological Features on Cystoscopy	Histologic Features	Malignant Potential and Recurrence after Surgery
Noninvasive papillary urothelial neoplasm of low malignant potential (PUNLMP)	Single papillary frond of 2–5 cm size	▪ Tumor cells are with large nuclei forming fused papillae ▪ Mitotic figures rare in basal cells	▪ Malignant potential tumor (4%) ▪ Recurrence after surgery (25–30%)
Noninvasive papillary urothelial carcinoma (low-grade)	Single or multiple tumors	▪ Tumor cells are pleomorphic forming frequent branching and fusion of papillae ▪ Mitoses occasional at any level	▪ Malignant potential tumor (2–20%) ▪ Recurrence after surgery (64–70%)
Noninvasive papillary urothelial carcinoma (high-grade)	Tumor invading urinary bladder wall	▪ Tumor cells are pleomorphic forming frequent branching and fusion of papillae ▪ Mitoses frequent	▪ Malignant potential high-grade tumor (18%) ▪ Recurrence after surgery (56–68%)
Invasive urothelial neoplasms			
Urothelial carcinoma with squamous differentiation or glandular differentiation and trophoblastic differentiation	Exophytic cauliflower-like or ulcerated growth	▪ Tumor cells contain hyperchromatic nuclei (well differentiated to poorly differentiated showing squamous, glandular or trophoblastic differentiation) ▪ Mitoses numerus	▪ Malignant potential high-grade tumor ▪ Recurrence after surgery (100%)
Squamous cell carcinoma	Large fungating solitary tumor with necrosis	Well-differentiated squamous cell carcinoma	▪ Malignant potential high-grade tumor ▪ Recurrence after surgery (100%)
Adenocarcinoma	Growth invading smooth muscle	Well-differentiated adenocarcinoma	▪ Malignant potential high-grade tumor ▪ Recurrence after surgery (100%)

- Most cases of urothelial carcinoma of urinary bladder affect persons over the age of 50 years. However, it may rarely affect young adults and children. Men are more affected than women. Features of urothelial lesions with atypia, noninvasive papillary urothelial neoplasms and invasive urothelial neoplasms are given in Table 23.2.

Noninvasive Papillary Urothelial Neoplasia

Recent 2016 WHO and the International Society of Urological Pathology (ISUP) classified noninvasive papillary neoplasms into flat lesions and papillary neoplasms: urothelial papilloma, papillary urothelial neoplasm of low-malignant potential (PUNLMP), low-grade papillary urothelial carcinoma; and high-grade papillary urothelial carcinoma. Histologic features used to classify urothelial papillary lesions according to recent 2016 WHO and International Society of Urological Pathology (ISUP) are given in Table 23.3.

- Noninvasive urothelial papilloma of exophytic type is composed of relatively simple branching papillary excrescences, histologically normal lining epithelium with orientation of the neoplastic cells, perpendicular to the basement membrane.
- Noninvasive urothelial neoplasm of low-malignant potential (PUNLMP) is similar, but epithelial lining appears hyperplastic compared with normal epithelium.
- Noninvasive low-grade papillary carcinoma has a more disorganized urothelium that loses polarity with mild atypia. The papillae may be more complex and confluent compared to PUNLMP.
- Noninvasive high-grade papillary urothelial carcinoma is composed of neoplastic cells of variable size and shape with hyperchromatic nuclei.

Endophytic/Inverted Urothelial Neoplasia

Endophytic/inverted urothelial neoplasia is a benign epithelial tumor, which usually affects adults and elderly males. It is usually a solitary tumor located in the trigone or neck regions of urinary bladder or prostatic urethra.

- Patient presents with hematuria and/or urinary obstruction.

Table 23.3 Histologic features used to classify urothelial papillary lesions according to recent 2016 WHO and International Society of Urological Pathology (ISUP)

Parameters	Noninvasive Papilloma	Noninvasive Papillary Neoplasms of Low Malignant Potential	Noninvasive Low-grade Papillary Carcinoma	Noninvasive High-grade Papillary Carcinoma
Neoplasm architecture				
Papillae	Delicate papillae	Delicate papillae, occasionally fused	Papillae delicate, fused, branching	Papillae delicate, fused, branching
Organization of cells	Organization of cells identical to normal	Polarity of cells identical to normal; any thickness; cohesive	▪ Predominantly ordered organization of cells ▪ Minimal cells crowding and loss of polarity ▪ Variable thickness ▪ Cells cohesive	▪ Predominantly disordered organization of cells ▪ Loss of polarity frequent ▪ Variable thickness ▪ Cells discohesive
Cytomorphological features				
Nuclear size	Identical to normal cells	Nuclear size may be uniformly enlarged	Nuclear size may be uniformly enlarged	Nuclear size enlarged with variation in size
Nuclear shape	Identical to normal cells	Cells elongated, round-oval with uniform size	Cells round-oval; slight variation in size and shape and contour	Moderate or marked pleomorphism
Nuclear chromatin	Fine chromatin	Fine chromatin	Mild variation of chromatin within cells and between cells	Moderate-to-marked variation both within and between cells with hyperchromasia
Nucleoli	Nucleoli absent	Nucleoli absent or inconspicuous	Nucleoli inconspicuous	Nucleoli multiple and prominent may be present
Mitotic figures	Mitoses absent	Mitotic figures rare, basal	Mitotic figures occasional, at any level	Mitotic figures usually frequent, at any level
Umbrella cells	Uniformly present	Present	Usually present	May be absent

- Cystoscopy reveals a polypoid and pedunculated lesion with smooth contour. Histologic examination of tumor specimen shows invagination of the urothelial epithelium, which usually lacks atypical features. Papillae are absent, or focally present.

Flat Urothelial Lesions with Atypia

Diagnostic categories of flat urothelial lesions with atypia include reactive urothelial atypia, urothelial atypia of unknown significance, urothelial dysplasia and urothelial carcinoma *in situ*. Urothelial cells show nuclear enlargement, chromatin clumping and loss of polarity (Fig. 23.4).

- Urothelial carcinoma *in situ* refers to areas of urinary bladder mucosa, where normal urothelium has been replaced by neoplastic epithelium that does not invade through the basement membrane. Compared with normal urothelium, nuclei are more often rounded and enlarged with coarse chromatin and thick nuclear membrane and presence of atypical mitotic figures in carcinoma *in situ*.
- Carcinoma *in situ* is a recognized precancerous lesion, but usually remains asymptomatic. It is detected as a flat lesion in 90% of cases in association with other urothelial neoplasms. Most cases of urothelial carcinoma *in situ* progress to invasive urothelial carcinoma.

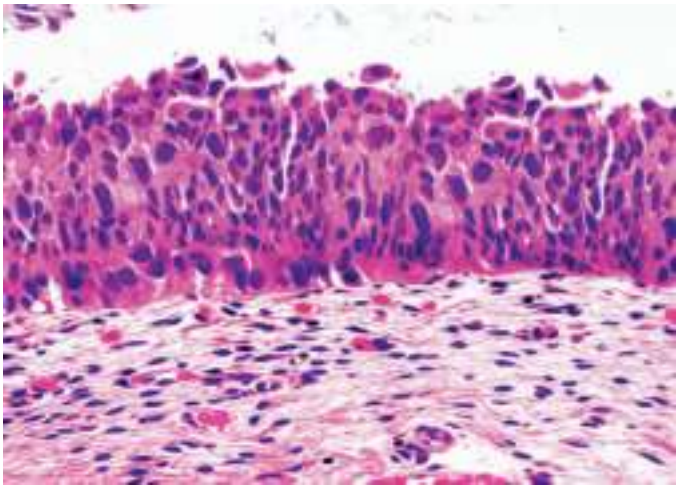

Fig. 23.4: Urothelial dysplasia shows good preservation of cellular polarity with uniform nuclear size and shape. There is presence of mitotic figures in the urothelium (400X).

Surgical Pathology: Flat Urothelial Lesions with Atypia	
Light Microscopy	
Histologic examination of biopsy specimen shows cellular atypia of the entire mucosa, from the basal layer to the surface (Fig. 23.5).	
Immunohistochemistry Technique	
Immunohistochemistry study shows positivity for CK20, CD44, p53, Ki-67, CK5/CK6 and SAT B2.	
Markers	**Expression**
▪ CK20	▪ Positive
▪ CD44	▪ Positive
▪ p53	▪ Positive (89%)
▪ Ki-67	▪ Positive
▪ CK5/CK6	▪ Positive
▪ SAT B2	▪ Positive

Invasive Urothelial Carcinoma

Invasive urothelial carcinoma is a high-grade tumor, which may have papillary, polypoid, nodular or ulcerative configurations. Cystoscopy may reveal multiple, red, velvety, flat patches. Pathologic stage depends on anatomic depth of invasion in the urinary bladder wall by tumor. There are several different histologic patterns: urothelial carcinoma, squamous cell carcinoma, adenocarcinoma, small cell carcinoma; and urothelial carcinoma with squamous differentiation (20%) or glandular differentiation (6%) and trophoblastic differentiation (hCG positivity and elevated serum hCG).

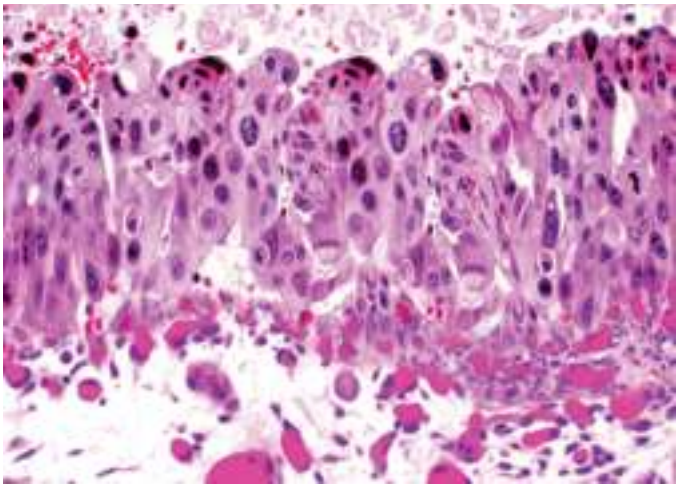

Fig. 23.5: Carcinoma *in situ*. Urothelial cells are pleomorphic with high nucleocytoplasmic ratio, irregular nuclear contours, hyperchromatic nuclei and prominent nucleoli. Cellular polarity is lost. Mitotic figures are atypical. Diagnosis of urothelial carcinoma *in situ* does not require full-thickness involvement. The superficial umbrella cell layer may be intact (400X).

Risk Factors

Pathogenesis of urothelial carcinoma and serum and urine markers is shown in Fig. 23.6. Indirect acting chemical carcinogens linked to urothelial carcinoma and other tumors are given in Table 23.4. Types of metaplasia in urothelium of urinary bladder and their clinical significance are given in Table 23.5.

- Tobacco smoking is the most important risk factor for urothelial carcinoma. Tobacco smoke

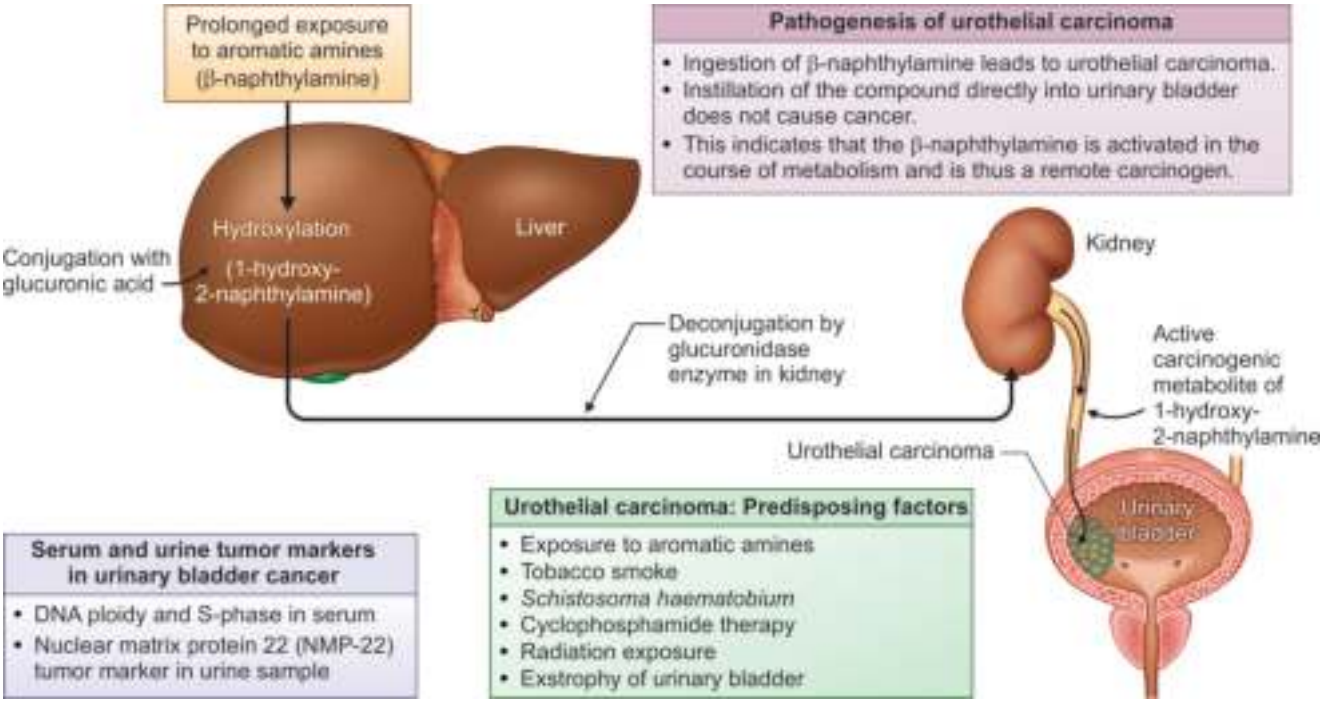

Fig. 23.6: Urothelial carcinoma: Pathogenesis of urothelial carcinoma and serum and urine markers.

Table 23.4 Indirect acting chemical carcinogens linked to urothelial carcinoma and other tumors

Chemical Carcinogen	Exposure to Carcinogens	Associated Cancers
Polycyclic hydrocarbons	▪ Tobacco smoke ▪ Consumption of smoked meat and fish	▪ Urothelial carcinoma ▪ Oral carcinoma ▪ Esophagus carcinoma (middle and distal) ▪ Pancreas carcinoma (lung carcinoma) ▪ Renal pelvis transitional cell carcinoma
Aromatic amines	▪ Aniline dye and rubber industries, benzidine-O, anisidine-O and toluidine ▪ Unlike polycyclic hydrocarbons, aromatic amines produce no local carcinogenic effect	▪ Urothelial carcinoma ▪ Mechanism: Mucosal glucuronidase in the urinary bladder converts β-naphthylamine glucuronide (aromatic amine) to the carcinogenic molecule β-naphthylamine results in urinary bladder cancer
Aromatic hydrocarbons	Benzene presents in crude oil (petrochemical), benz(a) anthracene and benz(a) pyrene	▪ Urothelial carcinoma ▪ Acute leukemia ▪ Hodgkin's disease

Table 23.5 Types of metaplasia in urothelium of urinary bladder and their clinical significance

Type of Metaplasia	Comments on Metaplasia	Clinical Significance
Intestinal metaplasia in cystitis glandularis/cystitis cystica	Intestinal metaplasia without dysplasia	▪ No risk for urothelial carcinoma ▪ Increased risk for urothelial carcinoma
Squamous metaplasia	▪ Nonkeratinizing metaplasia in trigone region of urinary bladder ▪ Keratinizing metaplasia in trigone region of urinary bladder	▪ No risk for squamous cell carcinoma of urinary bladder ▪ Increased risk for squamous cell carcinoma of urinary bladder
Nephrogenic metaplasia/ adenoma	Nephrogenic metaplasia/adenoma	▪ Benign lesion in urinary bladder ▪ Tubular component of nephrogenic metaplasia/adenoma involves the superficial muscularis mucosa mimicking malignant lesion ▪ Immunohistochemical markers positive P504S, CK7 and PAX2

containing polycyclic hydrocarbons are converted to ultimate carcinogen (benzo(a)pyrene), which may produce lung carcinoma at local site and urothelial carcinoma and renal cell carcinoma at distant sites.

- Persons working in aniline dye and rubber industries are heavily exposed to β-naphthylamine, which is absorbed by gastrointestinal tract resulting in urothelial carcinoma. In the liver, hydroxylation of β-naphthylamine forms 1-hydroxy-2-naphthylamine (water-soluble active carcinogenic metabolite), that combines with glucuronic acid and excreted in the urinary tract. Molecule is deconjugated by urinary bladder mucosal enzyme glucuronidase, thus exposing the urothelium to the active carcinogenic metabolite resulting in urothelial carcinoma.
- ***Schistosoma haematobium*** infection (in Egypt, Middle East and parts of Africa) is linked to urothelial carcinoma and squamous cell carcinoma of urinary bladder. Parasite causes foci of squamous metaplasia of urinary bladder epithelium resulting in squamous cell carcinoma of the bladder.
- Administration of cyclophosphamide and analgesics increase risk of urothelial carcinoma. Radiation therapy for cervical, prostate, or rectal cancer may increase the risk of urinary bladder carcinoma.
- Exstrophy of urinary bladder is absence of the anterior surface of the urinary bladder and abdominal wall, that can be recognized at the time of birth. In patients with exstrophy of urinary bladder, posterior wall of urinary bladder undergoes mechanical trauma resulting in squamous or glandular metaplasia and recurrent infections. Despite surgical repair, there is an increased risk for squamous cell carcinoma or adenocarcinoma of urinary bladder in 50–60 years of age group.

Molecular Genetic Alterations: Urothelial Carcinoma

Genetic profile of urothelial carcinoma is complex. There are two independent pathways of urothelial carcinoma development. However, occasional overlaps between these two pathways can occur.

RAS-MAPK Signaling Pathway

- RAS-MAPK signaling pathway is represented by low-grade papillary urothelial neoplasm including urothelial neoplasm of low malignant potential (PUNLMP) and low-grade papillary urothelial carcinoma. It is characterized by frequent local recurrence but no metastatic potential.
- PUNLMP and low-grade papillary urothelial carcinoma occasionally progress to high-grade papillary urothelial carcinoma or muscle-invasive urothelial carcinoma. Low-grade papillary urothelial carcinomas show activation of RAS-MAPK pathway, due to amplification of fibroblast growth factor receptor 1 (FGFR1) gene (60–80%) or H-RAS gene (15–30%).
- H-RAS is a signal-transducing protein, that participates in intracellular guanosine triphosphate signaling.
- Chromosome 9q deletion is common with several candidate genes have been implicated, including TSC1 (tuberous sclerosis complex 1), PTCH (patched homolog) and DBC1 (deleted in bladder cancer 1). PI13KCA gene mutation is demonstrated in 10–27% of cases.

Second Molecular Signaling Pathway

- Second molecular signaling pathway is less common pathway and represented by urothelial carcinoma *in situ* (CIS) and ≥pT2 urothelial carcinoma.
- Urothelial carcinoma *in situ* has tendency to progress into ≥pT2 in 60–80% of cases within five years. Urothelial carcinoma *in situ* most often demonstrates mutations in the tumor suppressor genes such as TP53 (70%), RB gene on locus 13p14 (37%) and PTEN (35%), frequently accompanied by deletion of chromosome 9.
- Similar changes are demonstrated in smooth muscle invasive urothelial carcinomas (pT12–pT4).
- But there are additional cytogenetic alterations such as deletions of chromosomes 3p, 5q, 6q, 10q, 11p and 18q.

Third Molecular Signaling Pathway

- Third molecular signaling pathway may be involved in high-grade papillary urothelial carcinoma and pT1 urothelial carcinoma. It may evolve from flat dysplasia or low-grade papillary urothelial carcinoma.
- High-grade papillary urothelial carcinoma and pT1 urothelial carcinoma demonstrate deletion of chromosome 9, with homologous deletion of CDKN2A (INK4A) gene, which encodes p16. FGFR3 and TP53 mutations may be present.
- Other commonly reported genetic abnormalities involve TERT and NOTCH.
- Oncogenes and tumor suppressor genes associated with urothelial carcinoma and other cancers are given in Table 23.6. Chromosomal abnormalities in urothelial carcinoma are given in Table 23.7.

Clinical Features

The earliest sign of invasive urothelial carcinoma is sudden painless hematuria in urine, which may be red- or rust-colored. In the later stages, the urinary bladder may become irritable with painful urination.

Table 23.6 Oncogenes and tumor suppressor genes associated with urothelial carcinoma and other cancers

Category	Proto-oncogene	Mechanism	Associated Malignancies
Growth factors			
Fibroblast growth factors (FGF)	▪ HST1 ▪ FGF3	▪ Overexpression ▪ Amplification	▪ Urothelial carcinoma ▪ Osteosarcoma ▪ Gastric carcinoma ▪ Breast carcinoma ▪ Melanoma
Signal-transduction proteins			
GTP-binding (G) proteins	H-RAS	Point mutation	▪ Urothelial carcinoma ▪ Renal cell carcinoma
Mitogenic signaling pathway inhibitor			
RB tumor suppressor gene	Retinoblastoma gene (locus 13q)	Deletion and nonsense mutation	▪ Urothelial carcinoma ▪ Retinoblastoma (familial or sporadic) ▪ Osteosarcoma (familial or sporadic) ▪ Breast carcinoma ▪ Colon carcinoma ▪ Prostatic carcinoma ▪ Lung carcinoma

Table 23.7 Chromosomal abnormalities in urothelial carcinoma

Chromosome Number	Comments
Chromosome 1 aberration	Represents secondary change in urothelial carcinoma
5p isochromosome	▪ Urothelial carcinoma (40% cases) ▪ Isochromosome arises from transverse division of the centromere during meiosis instead of the normal longitudinal division
Chromosome 9q deletion or monosomy	▪ Monosomy of chromosome 9 in superficial papillary tumors (50%) ▪ 9q deletion in advanced bladder cancer 67% of cases
Chromosome 11p deletion	▪ Urothelial carcinoma (40% cases) ▪ Represents secondary change related to invasiveness of urothelial carcinoma
Chromosome 17p deletion	▪ Chromosome 17p deletion results in p53 tumor suppressor gene mutation ▪ 17p deletion demonstrated in invasive urothelial carcinoma (63%)
Chromosome 7 trisomy	▪ Trisomy of chromosome 7 demonstrated in few cases of urothelial carcinoma ▪ Amplification of epidermal growth factor (EGF) located on chromosome 7 is demonstrated in invasive urothelial carcinoma (80%) and superficial urothelial lesions (27%)

Surgical Pathology: Invasive Urothelial Carcinoma

Gross Morphology

The lesions in urinary bladder may show various morphologic patterns: flat (carcinoma *in situ*), papillary (small lesion), exophytic (cauliflower-like) or ulcerated lesions. Invasive urothelial carcinoma often presents as ulcerated growth with indurated margins, that usually invades into the deeper layers of the urinary bladder and extends into the surrounding structures and pelvic organs (Fig. 23.7A and B).

Light Microscopy

Histologic examination of invasive urothelial carcinoma reveals cellular atypia of the entire mucosa, from the basal layer to the surface invading the lamina propria. The prognosis of urothelial carcinoma depends on the grade and stage of the tumor.

- Well-differentiated invasive urothelial carcinoma is grade 1 tumor associated with good prognosis (Fig. 23.8A and B).
- Papillary invasive urothelial carcinoma is grade 2 neoplasm and composed of broad papillae and solid areas associated with intermediate prognosis. Solid anaplastic invasive urothelial carcinoma is classified as grade 3 tumor associated with poor prognosis (Fig. 23.9A to D).

Histologic Variants: Invasive Urothelial Carcinoma

- **Micropapillary invasive urothelial carcinoma:** Micropapillary invasive urothelial carcinoma histologically mimics ovarian serous carcinoma. Tumor is composed of neoplastic cells arranged in nests with back to back pattern. Micropapillary carcinoma invades muscularis propria at diagnosis and metastases to regional lymph nodes and distant organs in majority of cases.
- **Plasmacytoid invasive urothelial carcinoma:** Tumor is morphologically similar to lobular carcinoma of breast and diffuse-type gastric carcinoma (linitis plastica).
  - Tumor is composed of monomorphic round discohesive neoplastic cells with homogenous eosinophilic cytoplasm and eccentrically placed nucleus arranged either scattered or in clusters. Intracytoplasmic vacuoles are also common in scarred neoplastic cells.
  - Plasmacytoid invasive urothelial carcinoma has a pattern of spread distinct from typical urothelial carcinoma.
  - Tumor involves serosal surfaces, ovary and causes recurrent malignant effusions. A recent study has demonstrated frequent somatic CDH-1 loss of function mutations in plasmacytoid carcinoma.
  - Immunohistochemical analysis of plasmacytoid invasive urothelial carcinoma demonstrates positivity for CD138, CK20 and GATA3. But p63 is less sensitive marker.
- **Nested invasive urothelial carcinoma:** Tumor is composed of rounded aggregates of cytologically bland urothelium invading in subepithelial tissue. Some tumors demonstrate central cystic change (microcystic variant) mimicking cystitis glandularis or cystitis cystica, but former invades subepithelial tissue.
- **Lymphoepithelioma-like invasive urothelial carcinoma:** Tumor is a nonkeratinizing carcinoma associated with heavy inflammatory infiltrate. Some tumors are pure masked by heavy inflammatory infiltrate.
- **Sarcomatoid (spindle cell, metaplastic) invasive urothelial carcinoma:** Tumor is a high-grade neoplasm of urinary bladder, in which malignant epithelial component with exhibiting urothelial, glandular, squamous differentiation or undifferentiation or spindled sarcoma-like appearance (such as osteosarcoma, chondrosarcoma, liposarcoma, pleomorphic rhabdomyosarcoma, or pleomorphic undifferentiated sarcoma) is present in the neoplasm.
  - The tumor is most often large and polypoid lesion, which usually affects elderly males, which involves ureter and renal pelvis and usually metastasizes to regional lymph nodes and distant organs.
  - Tumor at metastatic site is composed of epithelial component or the sarcoma-like component.

Immunohistochemistry Technique

Invasive urothelial carcinoma shows positivity for p63, thrombomodulin, uroplakin III, GATA, CK7 and CK20.

Markers	Expression
▪ p63	▪ Positive (81–96%) (more specific but less sensitive)
▪ Thrombomodulin	▪ Positive (69–91%)
▪ Uroplakin III	▪ Positive (57%)

▪ GATA (most sensitive marker)	▪ Positive
▪ CK7	▪ Positive (65–100%)
▪ CK20	▪ Positive (65–100%)
▪ Prostate-specific antigen (PSA)	▪ Negative
▪ Prostate-specific acid phosphatase	▪ Negative
▪ Prostein (P501S)	▪ Negative
▪ Prostate-specific membrane antigen	▪ Negative

Treatment and Prognosis

Treatment strategy for invasive urothelial carcinoma depends on age of the patient, surgical risk, the extent of stage and histologic grade of tumor, the presence of urothelial carcinoma *in situ* elsewhere in the urinary bladder. Recommended treatment for extensive urothelial carcinoma *in situ* is total cystectomy. Small and apparently localized urothelial lesions are treated

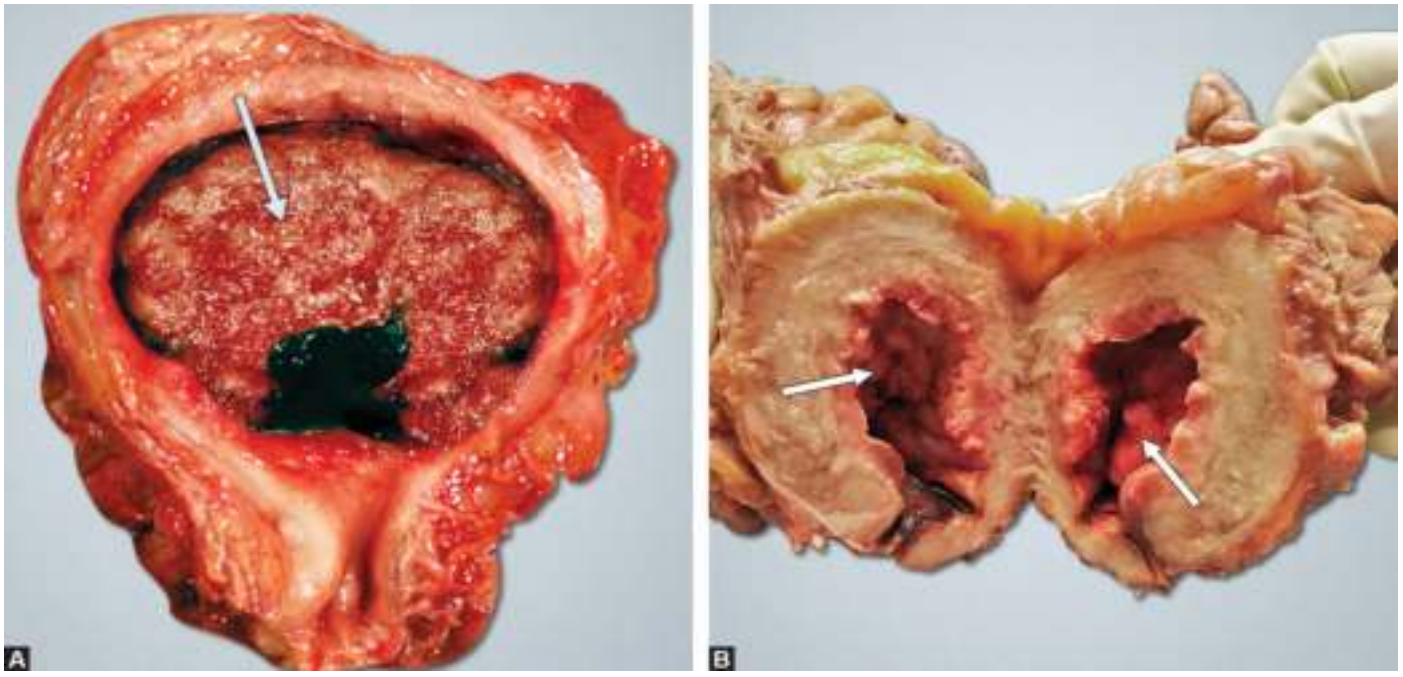

Fig. 23.7: Urothelial carcinoma. (A) Cut opened urinary bladder specimen shows exophytic (cauliflower-like) growth filling cavity with areas of hemorrhage (arrow). Macroscopic findings range from subtle urinary bladder wall thickening to obvious exophytic mass. (B) Cut opened cystectomy specimen shows a tumor arising from the lining epithelium forms thickening of the wall of urinary bladder, and at places forming fungating tumor mass (arrows). (*Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

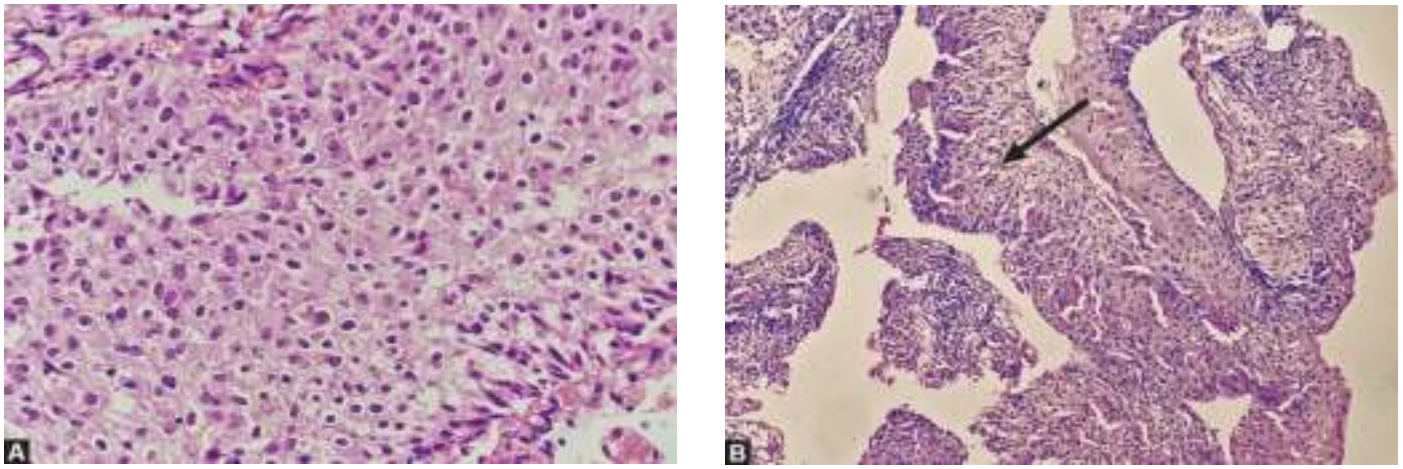

Fig. 23.8: (A) Low-grade urothelial carcinoma. Neoplastic proliferation of the urothelium shows papillary configuration without invasion through the basement membrane. Neoplasm demonstrates low-grade architectural and cytologic features such as slight variation in cells and few mitotic figures, without high-grade features such as irregular pleomorphic nuclei, with frequent, prominent nucleoli and mitoses (400X), (B) low-grade urothelial carcinoma with squamous differentiation. Tumor is composed of neoplastic cells forming papillary configuration without invasion through the basement membrane. Tumor is composed of neoplastic cells, which demonstrate slight variation in cells, few mitotic figures, and squamous metaplasia (arrow) (400X). (*Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

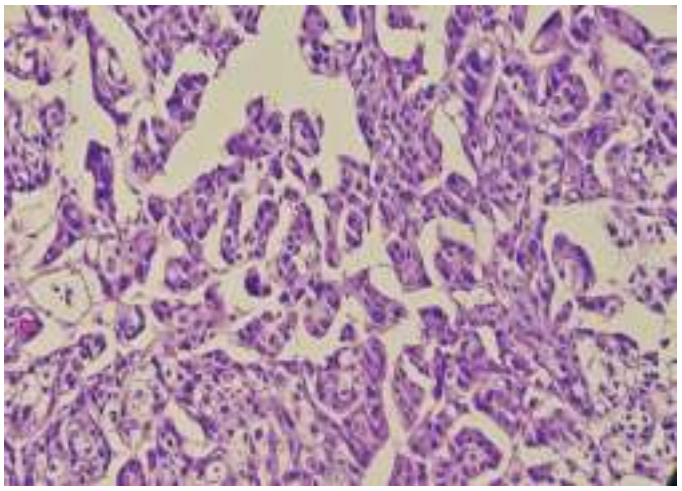

Fig. 23.9A: Micropapillary urothelial carcinoma. On histologic examination, tumor mimics ovarian serous carcinoma. It is composed of neoplastic cells arranged in nests with back-to-back pattern. Most micropapillary carcinoma invades muscularis propria at diagnosis and metastases to regional lymph nodes and distant organs (400X). (*Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

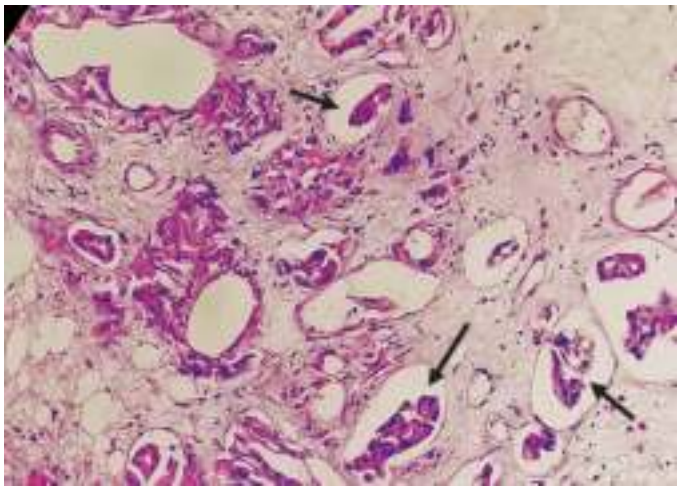

Fig. 23.9B: Vascular invasion by micropapillary urothelial carcinoma. On histologic examination, tumor mimics ovarian serous carcinoma. Tumor is composed of neoplastic cells arranged in nests with back-to-back pattern invading blood vessels. Most micropapillary carcinoma invades muscularis propria at diagnosis and metastases to regional lymph nodes and distant organs (400X). (*Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

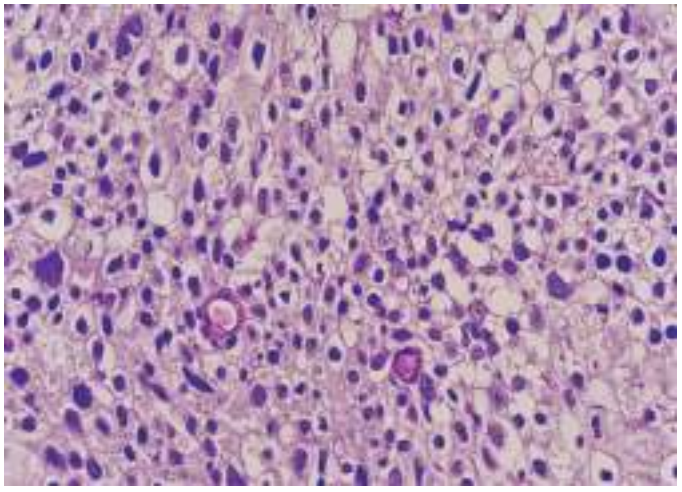

Fig. 23.9C: High-grade urothelial carcinoma. Neoplastic cells are arranged in irregular nests or single cells invading lamina propria and muscularis propria. Tumor is composed of pleomorphic cells with high-grade nuclear features such as hyperchromasia, high nucleocytoplasmic ratio with frequent mitotic figures. It is worth mentioning that nested urothelial carcinoma demonstrates bland low-grade cytological features (400X). (*Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

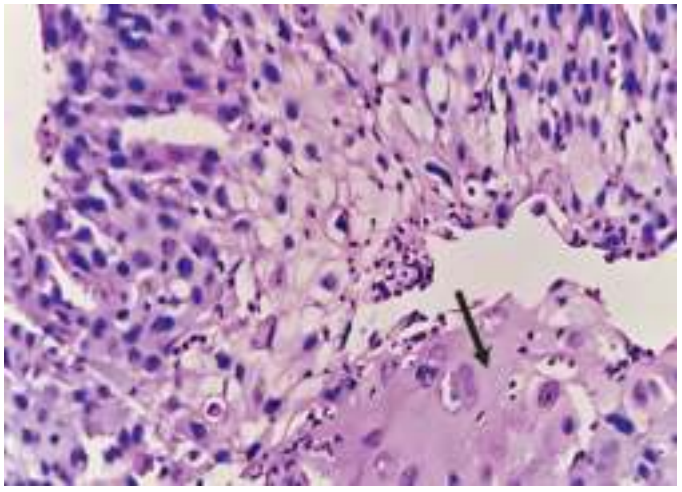

Fig. 23.9D: High-grade urothelial carcinoma with squamous differentiation. Neoplastic cells are arranged in irregular nests or single cells invading lamina propria and muscularis propria. Tumor shows high-grade nuclear features such as nuclear pleomorphism, hyperchromasia, high nucleocytoplasmic ratio with frequent mitotic figures and squamous differentiation (400X). (*Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

by intravesical chemotherapy. Urothelial carcinoma without invasion of muscularis propria is usually treated initially by transurethral resection.

High-grade invasive urothelial carcinoma is treated by intravesical administration of chemotherapy. Radical cystectomy in the males with invasive urothelial carcinoma includes the urinary bladder, prostate, seminal vesicles and the adjacent perivesical tissue. Radical cystectomy in the females with invasive urothelial carcinoma includes urinary bladder, uterus, fallopian tubes, ovaries, anterior vagina, and urethra. The addition of neoadjuvant chemotherapy to the radical cystectomy has improved survival of patients with advanced invasive urothelial carcinoma.

Urothelial Neoplasms Reporting Protocol: Transurethral Resection and Cystectomy Specimens

- Urothelial neoplasms should be sampled with a cold biopsy instrument. Ideally, the biopsy should include tumor and a portion of the underlying muscle tissue and normal adjacent mucosa from three other sites (one lateral to each ureteral orifice and one from the upper posterior wall).
- These biopsies should be submitted separately in different containers and processed.
- Pathologist must report whether the tumor is invasive (depth of invasion of muscularis propria or muscle) or noninvasive, histologic grade, lymphovascular invasion and foci of urothelial carcinoma *in situ*.
- Detection of residual tumor cells in the biopsy specimens from patients having had a prior biopsy or transurethral resection can be challenging.
- Immunohistochemical stains for cytokeratins should be performed only with great care since reactive myofibroblasts are usually positive as well. Panel of immunohistochemical markers in the urinary bladder tumors is given in Table 23.8.

PRIMARY SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is the most common tumor in urinary bladder, across world, where *Schistosoma haematobium* is endemic (e.g. Egypt linking Middle East and North East of Africa). It represents only 5% of urinary bladder tumors in the Western countries.

- Predisposing factors for SCC of urinary bladder include chronic cystitis, long-term indwelling catheters, tobacco smoking, diverticula, nonfunctioning and exstrophy of urinary bladder, and renal transplant cases. Exstrophy of the urinary bladder may predispose to SCC or adenocarcinoma.
- Squamous cell carcinoma of urinary bladder presents as invasive carcinoma and has a worse prognosis than invasive urothelial carcinoma.
- Squamous metaplasia and urothelial carcinoma *in situ* are commonly demonstrated in areas adjacent to invasive SCC, supporting the notion that SCC in the urinary bladder arises through usual metaplasia–dysplasia sequence.

Surgical Pathology: Squamous Cell Carcinoma of Urinary Bladder

Gross Morphology

Cystectomy specimen reveals large fungating solid necrotic tumor that can fill the entire bladder. Verrucous squamous cell carcinoma (exophytic growth) is exclusively associated with *Schistosoma haematobium*.

Light Microscopy

Invasive squamous cell carcinoma of urinary bladder is well-differentiated tumor. It shows well-defined islands of squamous cells with keratinization, keratin pearls, prominent intercellular bridges, and minimal nuclear pleomorphism (Fig. 23.10A).

Table 23.8 Panel of immunohistochemical markers in the urinary bladder tumors

Immunohistochemical Markers	Expression
Normal urothelium or reactive urothelial atypia	
p53	Negative
CK20	Positive (umbrella cells only)
E-cadherin	Positive (all layers)
CD44	Positive (basal layers)
Urothelial carcinoma *in situ*	
p53	Positive (89%)
CK20	Positive (all layers)
E-cadherin	Negative or low expression
CD44	Negative or low expression
Ki-67	Positive
Invasive urothelial carcinoma	
CK903 (HMWCK)	Positive
p63	Positive (more specific but less sensitive)
Thrombomodulin	Positive
Uroplakin III	Positive
GATA3	Positive
CK7	Positive (strongly positivity suggests urothelial carcinoma)
CK20	Positive (strongly positivity suggests urothelial carcinoma)
Prostate-specific antigen (PSA)	Negative
Prostatic-specific acid phosphatase	Negative
Prostein (P501S)	Negative
Prostate-specific membrane antigen (PSMA)	Negative
Primary adenocarcinoma of urinary bladder	
SATB2	Positive (50%)
CDX2	Positive/negative
CK20	Positive/negative
CK7	Positive/negative
Thrombomodulin	Positive/negative
Racemase	Negative
Prostate-specific antigen	Negative
Prostate-specific acid phosphatase	Negative
Prostein	Negative
Prostate-specific membrane antigen	Negative
β-Catenin (nuclear)	Negative

Contd...

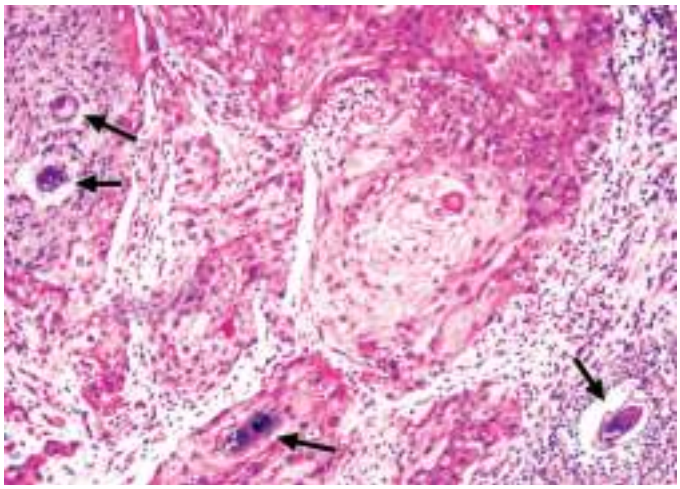

Fig. 23.10A: Invasive well differentiated squamous cell carcinoma of urinary bladder. It shows well-defined islands of squamous cells with keratinization, keratin pearls, prominent intercellular bridges, and minimal nuclear pleomorphism. It demonstrates *Schistosoma haematobium* (arrows) (400X).

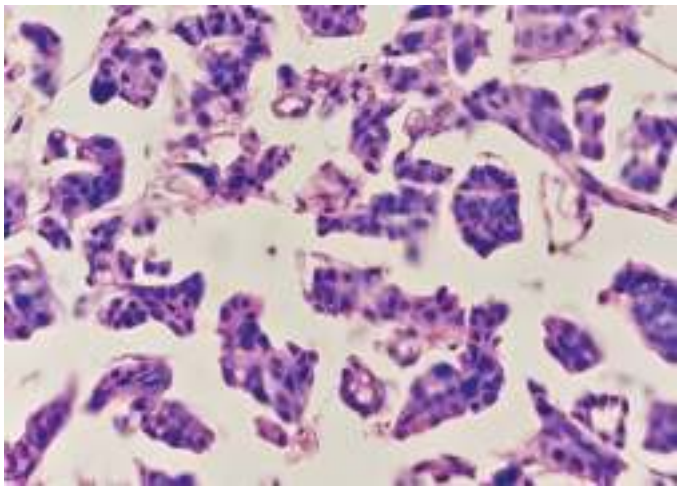

Fig. 23.10B: Adenocarcinoma of urinary bladder. Histologic variants of urothelial adenocarcinoma include intestinal type, mucinous type, signet ring cell type and associated with *in situ* component. On histologic examination, the tumor resembles colonic adenocarcinoma. Neoplastic glands are lined by pleomorphic mucin producing pseudostratified columnar epithelium. Central necrosis is commonly demonstrated (400X). *Courtesy*: Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

PRIMARY ADENOCARCINOMA

In situ adenocarcinoma is extremely rare form of intraepithelial carcinoma, which is associated with an increased risk for development of high-grade urothelial carcinoma, small cell carcinoma or micropapillary carcinoma.

Adenocarcinoma accounts for 2% of all malignant tumors of the urinary bladder. Most important risk factor is exstrophy of urinary bladder. Tumor arises from foci of cystitis glandularis or intestinal metaplasia, remnants of urachal epithelium in urinary bladder dome and urinary bladder diverticula. Tobacco smoking is associated with urothelial carcinoma and squamous cell carcinoma but not adenocarcinoma.

Surgical Pathology: Primary Adenocarcinoma of Urinary Bladder

Gross Morphology

Advanced adenocarcinoma of the urinary bladder usually grows as a polypoidal mass in the trigone region, that may undergo ulceration of mucosa and invasion of the urinary bladder wall. The mucosal surface of the mucin-secreting tumor is covered by gelatinous material.

Light Microscopy

Tumor exhibits wide range of glandular differentiation with intestinal metaplasia. Tumor may be superficial or deep invading the muscle. Sometimes, tumor behaves like a signet ring carcinoma, with diffuse infiltration of urinary bladder wall and associated with fatal outcome. Histology of adenocarcinoma of urinary bladder is shown in Fig. 23.10B.

Immunohistochemistry Technique

A recent study documented SATB2 nuclear expression in 50% of cases.

Markers	Expression
▪ SATB2	▪ Positive (50%)
▪ CDX2	▪ Positive/negative
▪ CK20	▪ Positive/negative
▪ CK7	▪ Positive/negative
▪ Thrombomodulin	▪ Positive/negative
▪ β-Catenin (nuclear)	▪ Negative
▪ Racemase	▪ Negative
▪ Prostate-specific antigen	▪ Negative
▪ Prostate-specific acid phosphatase	▪ Negative
▪ Prostein	▪ Negative
▪ Prostate-specific membrane antigen	▪ Negative

Prognosis

Overall prognosis of adenocarcinoma of urinary bladder is poor with five-year survival in 18% of cases. Stage of tumor is the most important prognostic factor.

BOTRYOID RHABDOMYOSARCOMA

Botryoid rhabdomyosarcoma of urinary bladder most often affects in children. Cystoscopy reveals grape-like polypoidal lesions on mucosal surface of urinary bladder trigone. Almost all cases in genitourinary tract show embryonal rhabdomyosarcoma variant.

Surgical Pathology: Botryoid Rhabdomyosarcoma of Urinary Bladder

Gross Morphology

Most embryonal rhabdomyosarcomas of the urinary bladder present as polypoidal intraluminal masses resembling cluster of grapes hence named botryoid type.

Light Microscopy

Botryoid rhabdomyosarcoma tumor of urinary bladder is composed round to oval cells admixed with spindle cells in loose myxoid stroma. A cambium layer of tightly packed undifferentiated neoplastic cells is demonstrated beneath mucosal lining of urinary bladder (Fig. 23.11A and B).

Immunohistochemistry Technique

Tumor cells show positivity for desmin, myogenin, myoglobin and MyoD1.

Markers	Expression
▪ Desmin	▪ Positive
▪ Myogenin	▪ Positive
▪ Myoglobin	▪ Positive
▪ MyoD1	▪ Positive

Treatment

Combined radiation therapy and chemotherapy increase survival rates in these children with botryoid rhabdomyosarcoma.

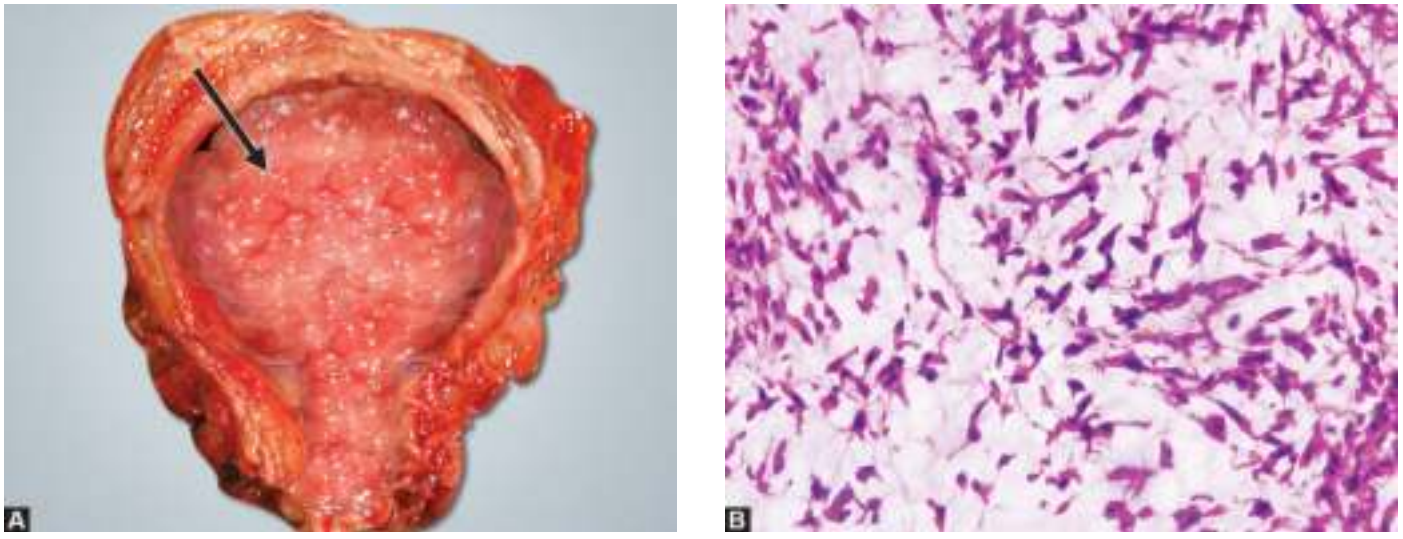

Fig. 23.11: Botryoides rhabdomyosarcoma of urinary bladder. (A) Embryonal rhabdomyosarcoma in the cut opened urinary bladder demonstrates polypoidal intraluminal masses resembling cluster of grapes hence named botryoid type (arrow), (B) tumor is composed of round to oval cells admixed with spindle cells in loose myxoid stroma (400X).

DISORDERS OF TESTES

TESTES: OVERVIEW

Scrotum is a pouch containing extra-abdominal testis, which helps in maintaining the low temperature of testes 2–2.5°C less than the body temperature, necessary for spermatogenesis. Each testis is connected with abdomen or pelvic cavity by the inguinal canal. Testes descend from abdominal cavity through inguinal canal and pulls blood vessels, nerves, ductus deferens and cremasteric muscle and connective tissue forming spermatic cord.

ANATOMY

Testes are covered by tunica vaginalis and enclosed in scrotum-site of production of spermatozoa. Excretory genital tract comprises ductus epididymis, ductus deferens or vas deferens, urethra (prostatic part, membranous part and penile part), which opens into penile meatus.

- Accessory glands comprise seminal vesicles, prostate gland and bulbourethral glands. Their secretion is rich in fructose, calcium and enzymes.
- Secondary sexual organs in males include seminal vesicles, prostate gland and bulbourethral glands and penis. External genitalia (penis) is erectile copulatory organ, which consists of three columns of erectile tissue (two cylinders of corpus cavernosa dorsally and one cylinder of urethral corpus spongiosum ventrally) covered by tunica albuginea. Glans penis is the extended tip part of penis.

- Each testis measures approximately 4.5×2.5×3 cm and weighs 20 g. Testicular size is measured by commercially available plastic testes models orchidometer.
- Each testis is surrounded by a small extension of peritoneal cavity, the tunica vaginalis, with visceral layer of peritoneal sac lying on the tough fibrous capsule of the testis known as tunica albuginea. A small amount of fluid is present between parietal and visceral layers lined by mesothelium.

HISTOLOGY

Testis is composed of compound tubular glands enclosed in scrotum and covered by tunica vaginalis and enclosed in tough tunica albuginea. Testis consists of 250 testicular lobules.

- Each testicular lobule contains 1–3 highly coiled seminiferous tubules lined by 4–8 layers of spermatogenic cells and surrounded by a basement membrane (tunica propria) and supported by a delicate fibrovascular stroma, in which Leydig cells are present.
- Sertoli cells are elongated and pyramidal cells; apical end extends into the lumen of the seminiferous tubules, which support spermatogenic cells and provide nutrition to the spermatozoa act as barrier to infectious agents. Sertoli cells synthesize estrogens, some androgens and androgen-binding proteins (ABP), which bind testosterone and keep its concentration high in the seminiferous tubules. Sertoli cells also secrete inhibin, which inhibits FSH, so help in the rate of spermatogenesis. Normal germ cell to Sertoli cell ratio is 13:1 in seminiferous tubules.
- Leydig cells (interstitial cells) discovered by Franz von Leydig are present between seminiferous tubules, which synthesize testosterone and other androgenic hormones involved in growth and development; protein anabolism, spermatozoa maturation and development of secondary sex characters.
- The seminiferous tubules converge to empty into rete testis at the testicular hilum, and these in turn anastomose with the efferent ductules, external to the testis, coil to form head of epididymis. At the hilum, the rete seminiferous tubules are supported by a fibrous tissue stroma and together comprise the testicular mediastinum.
- The epididymis is present on the posterior surface of testis, and it gives rise to the ductus (vas) deferens, which empties into the seminal vesicle.
- Male genital system produces spermatozoa and transfers of spermatozoa to female reproductive system.

SPERMATOGENESIS

Germinal elements account for over 75% of testicular mass. Under physiologic state, various hormones, i.e. growth hormone, testosterone synthesized by Leydig cells play an important role in spermatogenesis. Sertoli cells convert some portion of testosterone into estrogens.

- Estrogens play vital role in spermiogenesis by maturation of spermatids into spermatozoa. During spermatogenesis, spermatogonium (stem cells) (2n) form primary spermatocytes (2n), secondary spermatocytes (n), maturation of spermatids (n) into spermatozoa (n). Sertoli cells synthesize androgen binding protein, which binds and transports both testosterone and estrogens into seminiferous tubules, which promote maturation of spermatozoa.
- Pathway of semen from seminiferous tubules in testis to penile meatus is: tubuli recti (short segments of straight tubules), rete testis (highly anastomosing labyrinth of cuboidal epithelium lined channels), ductus efferent (10–20 fine tubules, intragenital duct system), epididymis (tail, body and head), vas ductus (vas deferens 6 meters long), enclosed in spermatic cord along with blood vessels, nerves, cremasteric muscles pass through inguinal canal and joins ejaculatory ducts and opens into urethra passing through prostate gland.
- Urethra consists of prostatic part, membranous part, and penile part, that opens into penile meatus. Tearing of inguinal canal results in the bulging of a loop of intestine into scrotum is called inguinal hernia.
- Spermatozoa consist of head, neck, midpiece and tail. Head region of spermatozoa contains nucleus with haploid number of chromosomes. Neck portion consists of proximal and distal centrioles. Midpiece consists of mitochondria/ tail (axoneme) consists of microtubule. Various enzymes are produced by acrosome of spermatozoa. Hyaluronidase acts on ground substance of follicular cells. Corona penetrating enzyme dissolves corona radiata. Zona lysine and acrosin digest zona pellucida. These enzymes are collectively called 'sperm lysins'.
- Human male ejaculates 3–4 ml of semen and 200–300 million spermatozoa during coitus. Semen is composed of seminal plasma and sperms. About 60% of spermatozoa have normal shape and at least 40% of them must show vigorous motility. Secretions of epididymis, vas deferens, seminal vesicle and prostate are essential for the maturation and motility of spermatozoa. Capacitation refers to activation of spermatozoa, that takes 5–6 hours.

- Storage of semen at –196°C preserves spermatozoa for many years. Spermatozoa are stored mainly in alkaline medium. In temperate regions, spermatozoa motility is increased but lifespan decreased. Life span in female genital system is 1–2 days. The various stages of development of spermatozoa (Fig. 23.12A and B).

Johnsen Score System for Quantifying Spermatogenesis

Johnsen defined 10-point scoring system for quantifying spermatogenesis according to the profile of the cells encountered along seminiferous tubules. Johnsen score of 10 indicates maximum spermatogenesis activity, i.e. formation of mature spermatozoa, whereas score of 1 indicates complete absence of germ cells in seminiferous tubules.

SEMEN (SEMINAL FLUID)

Semen is the male reproductive fluid containing spermatozoa in suspension. Volume of the ejaculate is contributed mainly by seminal vesicle (60%), prostate gland (30%), small amount from the bulbourethral glands and epididymis.

- Precise analysis of volume is essential in any evaluation of semen analysis, because it allows the total number of spermatozoa and non-sperm cells in the ejaculate to be calculated.
- Prostatic fluid is milky white with alkaline pH, containing citrate ion, calcium, acid phosphatase and profibrinolysin. Alkaline pH neutralizes acidic pH of vas deferens and vaginal acidic pH (3.5–4).
- Seminal vesicle synthesizes fructose, prostaglandins and fibrinogen. Fructose provides nutrition to sperms.
- Prostaglandins play an important role in fertilization of spermatozoa with ovum by reacting with cervical mucus to make susceptible to sperms and possibly cause reverse peristaltic contraction in the uterus and fallopian tube to move spermatozoa upwards towards ovaries.

Semen Analysis

Normal sperm count is 60–120 million per ml. In case of infertility, two or more specimens are necessary with two days abstinence.

- Freshly ejaculated specimen is a coagulum. Prostatic lysozyme and α-amylase liquefy the semen within 30 minutes.
- Coagulum is not formed in patients with underdeveloped seminal vesicle or lacking vas deferens.
- Fructose levels are below normal in these patients. Normal semen values as suggested by WHO are given in Table 23.9. Causes of male infertility are given in Table 23.10.

Cryopreservation of Spermatozoa

Semen from healthy fertile donors may be stored at –196°C for future use. These donors should be ejaculated, scrutinize by 'sperm bank' and their spermatozoa used anonymously. Alternatively, the recipients may know the donors. The donors' spermatozoa can be used for IVF (*in vitro* fertilization). IVF is one of the more widely known types of assisted reproductive technology, which works by using a combination of medicines and surgical procedures and can help the fertilized egg implant in uterus.

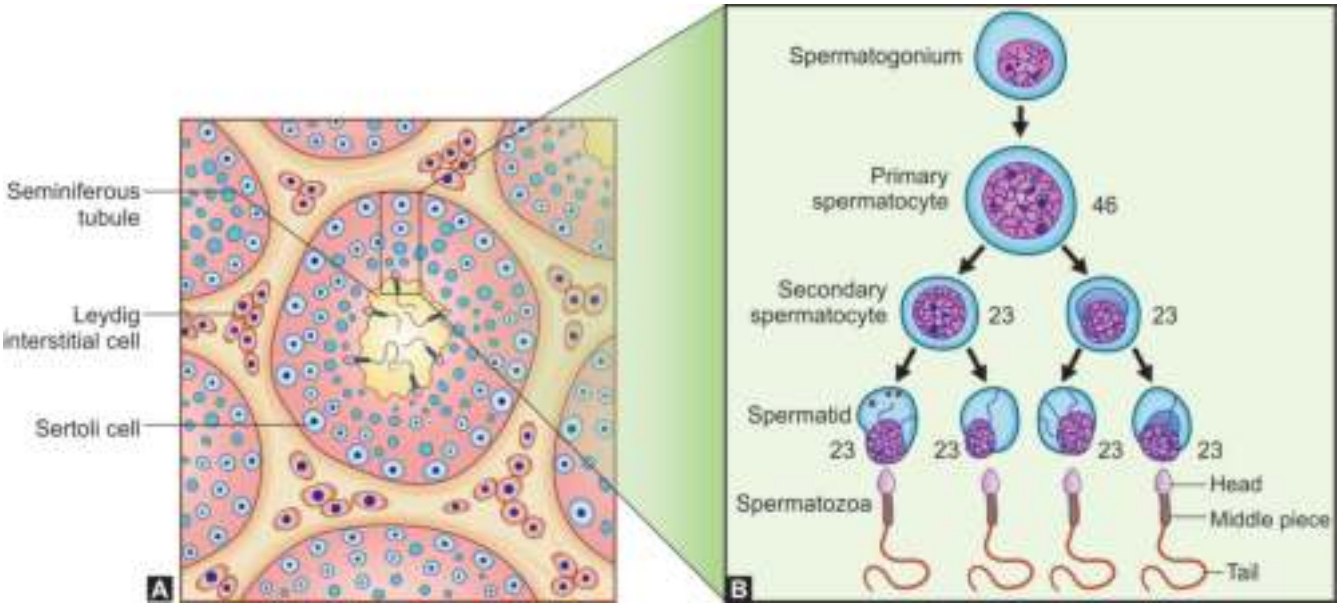

Fig. 23.12: The various stages of spermatogenesis. (A) Cross-section of seminiferous tubule, (B) stages of development of spermatozoa.

Table 23.9 Normal semen values as suggested by WHO

Parameters	Normal Spermiogram	Comments
Volume	≥2–6 ml	≥2.0 ml
Color and odor	Milky-cloudy, chestnut blossom aroma	Homogenous, grey-opalescent (less opaque due to low spermatozoa)
pH (measured after 30 minutes)	7.2–7.8	▪ ≥8 (acute prostatitis, acute vesiculitis and bilateral acute epididymitis) ▪ 6.6–7 (chronic prostatitis, chronic vesiculitis, bilateral chronic epididymitis, occlusion of ejaculatory duct)
Unprepared spermiogram		
Motility of spermatozoa	≥50% overall motility, at least 30% progressive motility	Actively motile, moderately motile and immotile spermatozoa must be analyzed
Counting chamber used analyze number and density of spermatozoa		
Number of spermatozoa per ejaculate	40–800 × 10^6 spermatozoa	Must be assessed after liquefaction of semen after 30 minutes
Spermatozoal density	20–250 × 10^6 spermatozoa	▪ Oligospermia (<20 million/ml) ▪ Polyspermia (>250 million/ml) ▪ Cryospermia (spermatozoa not discovered until after sedimentation) ▪ Azoospermia (no spermatozoa)
Stained smear to analyze morphology of spermatozoa		
Morphology of spermatozoa	50% normal morphology of spermatozoa	% of abnormal morphology with malformation of head, midpiece and tail must be analyzed
Vitality of spermatozoa by eosin technique		
Vitality of spermatozoa using eosin-nigrosin technique	80% live spermatozoa	Test increases the contrast between the background and spermatozoa heads
Fructose level	>1200 μg/ml or 1.2 g/liter	Low fructose value indicative of an obstruction of the seminal vesicle
Leukocytes, lymphocytes	<500,000/ml	Pyospermia (leukocytospermia) weakens genetic material of spermatozoa

Table 23.10 Causes of male infertility

Causes	Comments
Chronic alcoholism	Decreased gonadotropin and testosterone levels
Drugs	Heroin and methadone adversely affect hypothalamic-hypophyseal axis, ejaculation volume and spermatogenesis
Exposure to diethylstilbestrol *in utero*	Epididymal cysts and obstructive changes
Exposure to DDT (dichlorodiphenyltrichloroethane) and chlordecone	Decreased spermatogenesis
Colchicine, alkylating agents and nitrofurantoin	Spermatozoa structure and motility abnormality
Diabetes mellitus	Partial or complete retrograde ejaculation or impotence
Varicocele	Poor quality and retrograde ejaculation (spermatozoa in urine)
Vasectomy and hernia repair and decreased blood supply	Sterility in men
Tuberculous epididymo-orchitis	Cause epididymis obstruction
Mumps orchitis	Testicular atrophy
Renal diseases	Oligospermia
Fertilization of ovum with sperm from undescended testes	Spontaneous abortion

INFLAMMATORY DISORDERS OF TESTIS

BACTERIAL ORCHITIS

Bacterial epididymitis is more common than orchitis, which is often associated with epididymitis. It is sexually acquired infection due to *Neisseria gonorrhoeae* (gonorrhea) or *Chlamydia trachomatis*. *Escherichia coli* associated urinary tract infection.

- Patient presents with intrascrotal pain and tenderness, with or without associated fever. Bilateral, orchitis may result in sterility due to atrophy of the seminiferous tubules.
- Serum testosterone is decreased, whereas pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are increased.

MUMPS ORCHITIS

Mumps orchitis begins 4–8 days after swelling of the parotid gland, and is caused by the mumps virus transmitted via the respiratory route by inhalation or oral contact with infected respiratory droplets or secretions. Patient presents with painful parotitis and orchitis after puberty. The virus is highly neurotropic, with laboratory evidence of central nervous system (CNS) infection in approximately half of cases (Fig. 23.13).

TUBERCULOUS EPIDIDYMO-ORCHITIS

Tuberculous epididymo-orchitis is usually a complication of pulmonary and renal tuberculosis (Fig. 23.14). The epididymis is enlarged and indurated and usually associated with testicular involvement by tuberculosis. Isolated tuberculous epididymo-orchitis may closely mimic testicular tumor particularly in patients with no history of systemic tuberculosis thereby posing a diagnostic and treatment challenges. Adequate evaluation of patients with testicular mass by means of abdominal and scrotal ultrasound coupled with fine needle aspiration cytology is critical in diagnostic accuracy, optimal treatment and possibility of avoiding surgery in those patients with testicular tuberculosis. Histologic examination reveals caseous necrosis, epithelioid cell granulomas and occasional Langhans' giant cells.

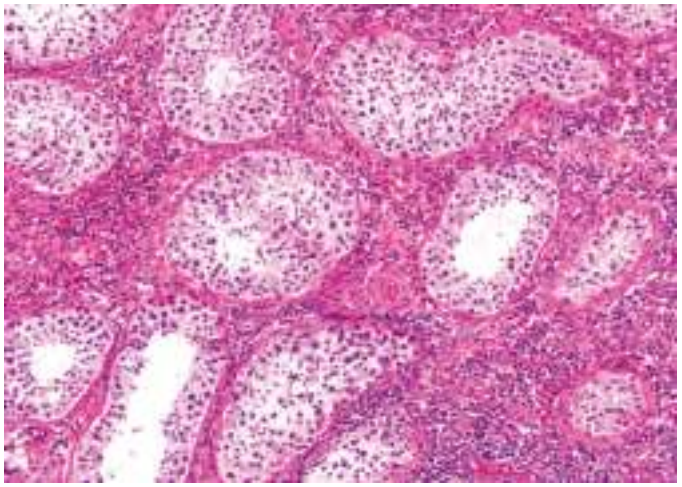

Fig. 23.13: Mumps orchitis. Testes become painful and swollen 4–6 days after parotitis. Testes show widespread foci of acute and chronic inflammatory cells destroying seminiferous tubules. Bilateral testes involvement may result in infertility (100X).

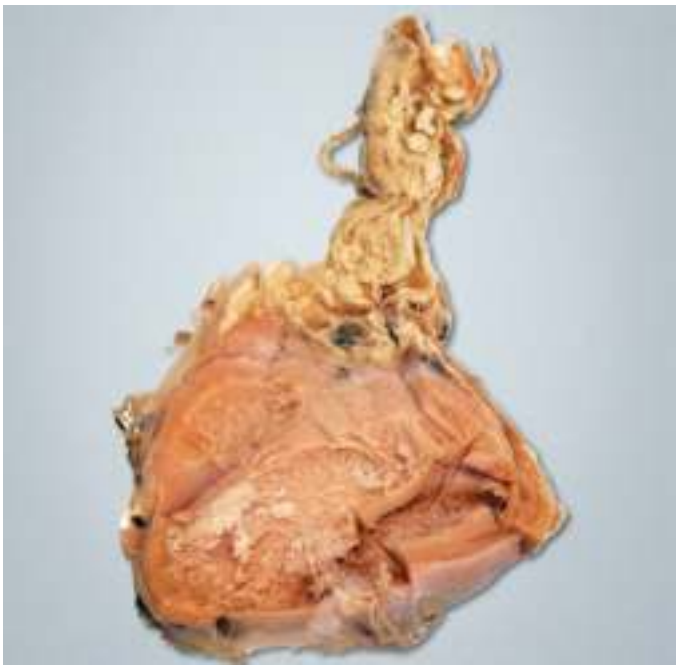

Fig. 23.14: Tuberculous epididymo-orchitis. The testis contains multiple rounded granulomatous lesions. The epididymis is almost completely replaced by similar tissue. The patient had disseminated tuberculosis.

GRANULOMATOUS ORCHITIS

Granulomatous orchitis is usually associated with trauma to testis. Some consider it as an autoimmune disorder, which affects middle-aged males.

- Some cases are associated with urinary tract infections, history of prostatectomy, inguinal hernia repair and trauma.
- Testicular involvement may be total or partial resulting in vaguely nodular, firm painful testicular enlargement associated with fever.
- Granulomatous orchitis is usually accompanied by sudden onset of painful testicular enlargement, tenderness in scrotal region and fever.
- Histologic examination reveals lymphocytes, plasma cells, macrophages, fibroblasts and scattered multinucleated giant cells.

SYPHILITIC ORCHITIS

Syphilitic orchitis is a rare manifestation of gumma in tertiary syphilis. Histologic examination of syphilitic

orchitis reveals multiple discrete epithelioid cell granulomas with central necrosis and peripheral fibrosis.

- Initially, there is edema of the tunica albuginea and interstitium, lymphocytic infiltration in interstitium, congestion and hemorrhage progressing to necrosis of the seminiferous tubules sparing Sertoli cells.
- The seminiferous tubules are infiltrated by lymphocytes, plasma cells and histiocytes.
- Clinically, syphilitic orchitis can resemble a neoplasm, which is confirmed by immunohistochemistry and PCR testing for *Treponema pallidum* DNA polymerase 1 gene using paraffin-embedded tissue sections.

NEOPLASTIC DISORDERS OF TESTIS

Testicular tumors are one of the most common neoplasms that occurs in males, which include germ cell tumors, sex cord-gonadal stromal tumors and secondary testicular tumors. About 95% of testicular tumors are germ cell tumors derived from primordial germ cells, which arise in midline locations such as gonads, retroperitoneum, mediastinum, and central nervous system (called germinoma). Spermatocytic seminoma arises from primary spermatocytes.

- Germ cell tumors are classified as seminomatous and nonseminomatous tumors. Seminoma is an example of seminomatous germ cell tumor. Nonseminomatous germ cell tumors include embryonal carcinoma, yolk sac tumor, choriocarcinoma, teratoma. Germ cell tumors exist in pure form in 40% and mixed form in 60% of cases. Seminoma is most radiosensitive germ cell tumor.
- Testicular germ cell may present as a painless scrotal mass as an incidental radiologic finding, post-traumatic symptom, scrotal pain. Diagnosis of testicular germ cell tumors involves the evaluation of serum tumor markers α-fetoprotein, human chorionic gonadotropin and lactate dehydrogenase, but clinically several types of immunohistochemical markers are more useful and more sensitive in germ cell tumors but not in teratoma.
- These new biomarkers are genes expressed in primordial germ cells/gonocytes and embryonic pluripotency related cells but not in normal adult germ cells , which include PLAP, OCT3/4 (POU5F1), NANOG, SOX2, REX1, AP-2γ (TFAP2C) and LIN28. Revised 2024 WHO classification of tumors of the testes is given in Table 23.11. Cystic lesions in testes during childhood are given in Table 23.12. Classification of testicular tumors is shown in Fig. 23.15.

Table 23.11 Revised 2024 WHO classification of tumors of the testes

Germ Cell Tumors derived from Germ Neoplasia *in situ*

- **Non-invasive germ cell neoplasia**
  - Germ cell neoplasia *in situ*
  - Specific forms of intratubular germ cell neoplasia
  - Intratubular seminoma
  - Intratubular embryonal carcinoma
  - Intratubular trophoblastic tumor
  - Intratubular yolk sac tumor
  - Intratubular teratoma
  - Gonadoblastoma
- **Germinoma family of tumors**
  - Seminoma
  - Seminoma with syncytiotrophoblastic element
- **Nonseminomatous tumors**
  - Embryonal carcinoma
  - Yolk sac tumor, post-pubertal type
  - Choriocarcinoma
  - Placental site trophoblastic tumor of the testis
  - Epithelioid trophoblastic tumor
  - Cystic trophoblastic tumor
  - Teratoma postpubertal type
  - Teratoma somatic type malignancy
- **Mixed germ cell tumors of the testis**
  - Mixed germ cell tumors
  - Polyembryoma
  - Diffuse embryoma
- **Germ cell tumors of unknown type**
  - Regressed germ cell tumors

Germ Cell Tumors Unrelated to Germ Cell Neoplasia *in situ*

- Spermatocytic seminoma
- Spermatocytic seminoma with sarcomatous differentiation
- Teratoma prepubertal-type
- Dermoid cyst
- Epidermoid cyst
- Yolk sac tumor, prepubertal type
- Well-differentiated neuroendocrine tumor (monodermal teratoma)
- Mixed teratoma and yolk sac tumor prepubertal-type

Sex Cord-Stromal Tumors

- **Leydig cell tumors**
  - Leydig cell tumor
  - Malignant Leydig cell tumor
- **Sertoli cell tumors**
  - Sertoli cell tumor
  - Malignant Sertoli cell tumor
  - Large cell calcifying Sertoli cell tumor
- **Granulosa cell tumors**
  - Adult granulosa cell tumor
  - Juvenile germ cell tumor
- **Fibroma thecoma family of tumors**
  - Thecoma
  - Fibroma

Contd...

Table 23.11 Revised 2024 WHO classification of tumors of the testes (*Contd...*)

- **Mixed and other sex cord-stromal tumors**
  - Mixed sex cord-stromal tumor
  - Signet ring stromal tumor
  - Mixed gonadal stromal tumor
  - Sex cord stromal tumor, NOS

Tumors of the Testicular Adnexa

- **Ovarian-type tumors of the collecting ducts and rete testis**
  - Serous cystadenoma, NOS
  - Serous borderline tumor, NOS
  - Serous cystadenocarcinoma
  - Mucinous cystadenoma
  - Mucinous borderline tumor
  - Mucinous cystadenocarcinoma
  - Endometrioid borderline tumor
  - Endometrioid adenocarcinoma
  - Clear cell adenocarcinoma
  - Brenner tumor
- **Tumors of the colleting ducts and rete testis**
  - Adenoma
  - Adenocarcinoma
- **Paratesticular mesothelial tumors**
  - Adenomatoid tumor
  - Well differentiated papillary mesothelial tumor
  - Mesothelioma
  - Epithelioid mesothelioma
  - Sarcomatoid mesothelioma
  - Biphasic mesothelioma
- **Tumors of the epididymis**
  - Cystadenoma of the epididymis
  - Papillary cystadenoma
  - Adenocarcinoma of the epididymis
  - Squamous cell carcinoma
  - Melanotic neuroectodermal tumor

Hematolymphoid Tumors

- Diffuse large B cell lymphoma
- Follicular lymphoma, NOS
- Extranodal NK/T cell lymphoma, nasal type
- Plasmacytoma
- Myeloid sarcoma
- Rosai-Dorfman disease

GERM CELL TUMORS OF TESTIS

Tumor confined to seminiferous tubule is known as intratubular neoplasia. Seminoma directly originates from primordial germ cell. Seminoma is not end stage neoplasm, but may also act as precursor of other germ cell tumors such as embryonal carcinoma. Germ cell differentiates into totipotent stem cells. Tumors arising from totipotent stem cells may show embryonic differentiation (e.g. embryonal carcinoma and teratoma), and extra-embryonic differentiation (e.g. yolk sac tumor and choriocarcinoma). Occurrence of germ cell tumors of testes in various age groups is given in Table 23.13.

Table 23.12 Cystic lesions in testes during childhood

Yolk sac tumor
Teratoma
Dermoid cyst
Epidermoid cyst
Granulosa cell tumor (juvenile type)
Cystic lymphangioma
Cystic dysplasia of rete ridges
Simple cyst

- **Etiopathogenesis:** Although the cause of testicular germ cell tumors is unknown, there is a possible genetic link and geographic risk for acquiring these tumors. Approximately 95% of testicular germ cell tumors arising in the testis are germ cell tumors. Risk factors for testicular germ cell tumors are given in Table 23.14.
- **Molecular genetic alterations:** Molecular genetic alterations in germ cell tumors include isochromosome 12, random gain of chromosomes, novel gene, DAD-R gene, aneuploid DNA content and increased telomerase activity (Table 23.15).
- **Clinical features:** Often the first sign of testicular germ cell tumor is a slight enlargement of the testicle that may be accompanied by some degree of discomfort. There may be an ache in the abdomen or groin or a sensation of dragging or heaviness in the scrotum. Pain may be experienced in the later stage as germ cell tumor grows rapidly.
- **Mode of spread:** Testicular germ cell tumors spread by lymphatic and hematogenous routes (Table 23.16), which can spread when the tumor may be barely palpable. Signs of metastatic spread include swelling of the lower extremities, back pain, neck mass, cough, hemoptysis, and/or dizziness.
- **Diagnostic approach:** Thorough urologic clinical history and physical examination are essential for diagnosis of a painless testicular mass. Conditions that produce an intra-scrotal mass similar to testicular germ cell tumor include epididymitis, orchitis, hydrocele, or hematocele.
  - Clinical examination for testicular lumps should include palpation of the testes and surrounding structures, transillumination of the scrotum, and abdominal palpation.
  - Testicular ultrasonography can be used to differentiate testicular masses. CT scan and MRI are used in assessing metastatic spread. Serum tumor markers are used to evaluate testicular mass for diagnosis,

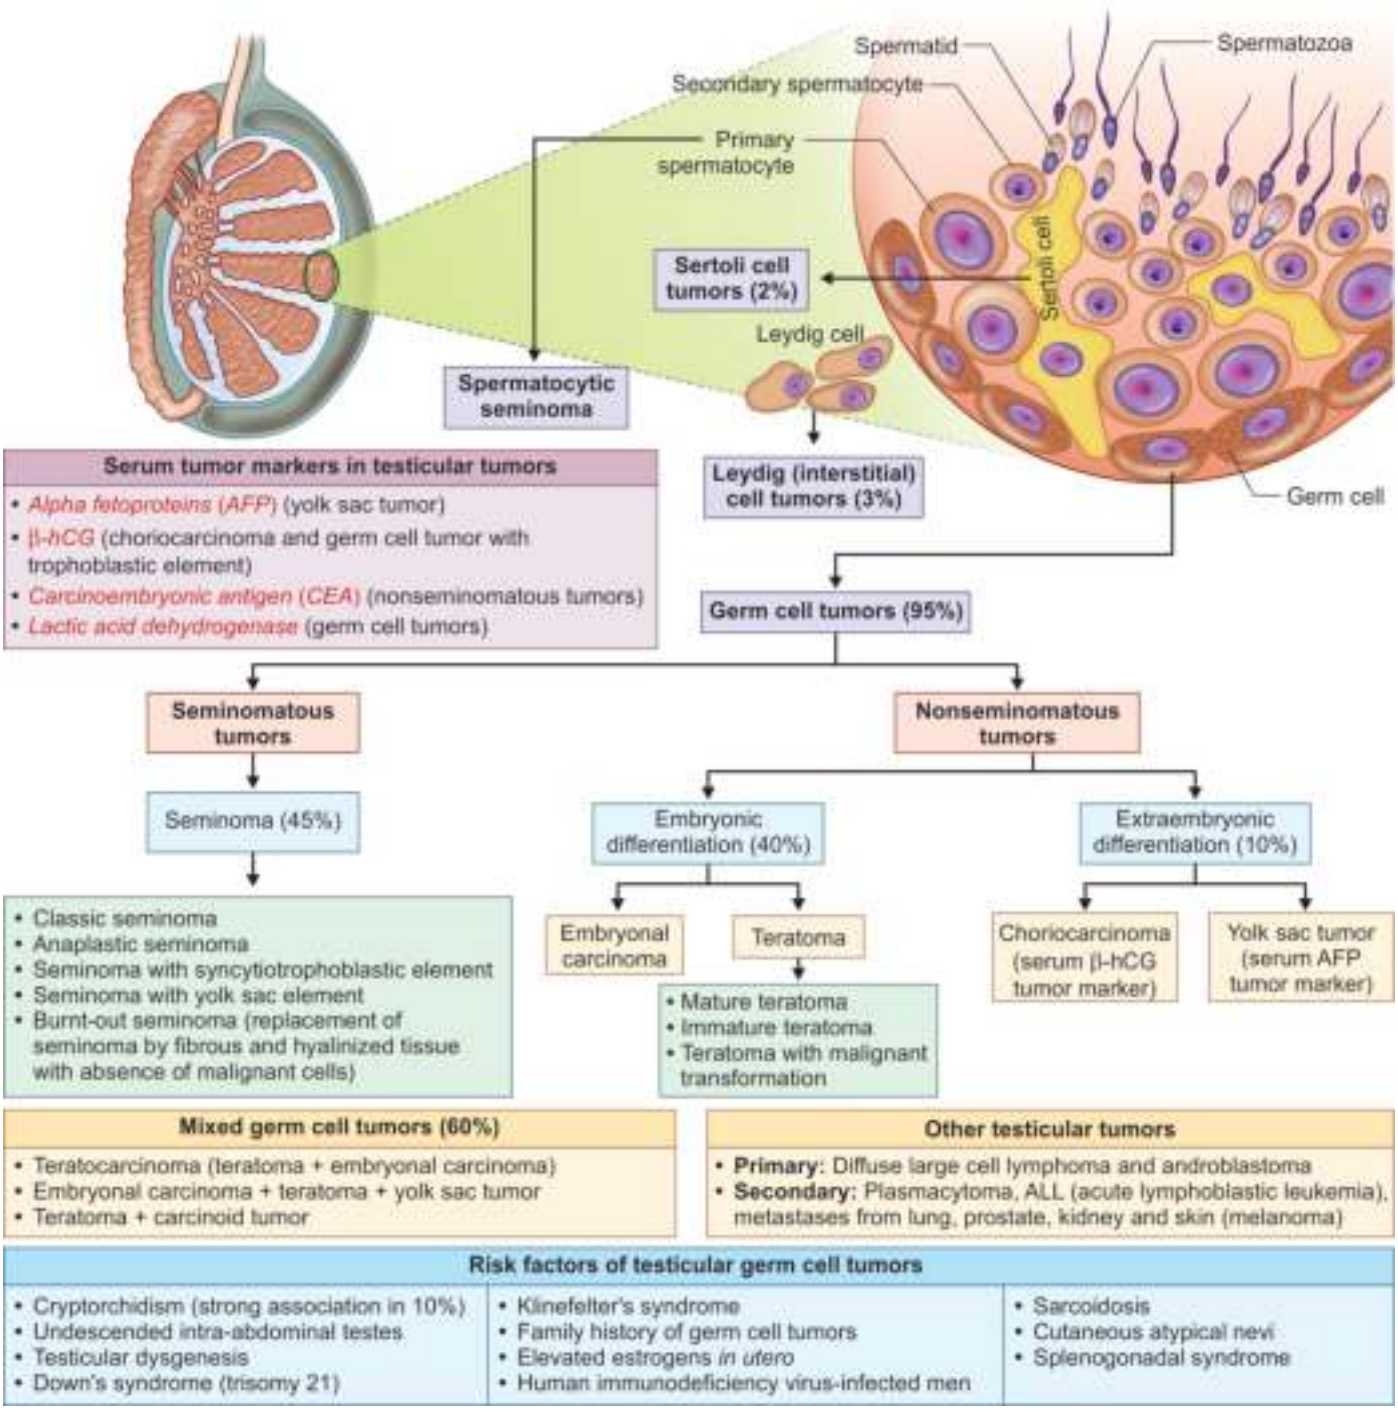

Fig. 23.15: Classification of testicular tumors.

staging, monitor response to therapy, detect relapse and assess tumor burden.

- A potential diagnostic pitfall of new biomarkers is their expression in fetal germ cells. Tumor markers that measure protein antigens produced by malignant cells provide information about the existence of a testicular germ cell tumor and the type of tumor present. These biomarkers may detect tumors that are too small to be found on physical examination or radiographs (Table 23.17).
- **Molecular diagnostics:** Transcription factor encoded by OCT 3/4 gene is expressed in primordial germ cells as well as in seminoma and embryonal carcinoma analyzed by immunoperoxidase technique. Testicular germ cell tumors show inactivation of X chromosome detected by polymerase chain reaction (PCR) technique.

Table 23.13 Occurrence of germ cell tumors of testes in various age groups

Germ Cell Tumors	Age Group	Protein Synthesized by Germ Cell Tumor	Effect of Radiation Therapy
Seminoma	▪ 30–40 years (most common) ▪ Prepuberty and >70 years (rare)	hCG (15% of cases)	Radiosensitive
Spermatocytic seminoma	>40 years of age	None	Unknown
Embryonal carcinoma	▪ 20–30 years (mean 30 years) ▪ Prepuberty and >50 years (rare)	AFP (in mixed tumor)	Radioresistant
Yolk sac tumor	▪ Prepubertal yolk sac tumor (3 to 39 months) ▪ Postpubertal yolk sac tumor (25 to 30 years)	AFP	Radioresistant
Choriocarcinoma	20–30 years	hCG	Radioresistant
Teratoma	▪ Prepubertal teratoma (20 months) ▪ Postpubertal teratoma (20–30 years and mean age 18 years)	None	Radioresistant
Mixed germ cell tumors	▪ 28 years (if NSGCT component present) ▪ 33 years (if seminomatous component present)	Variable	Radioresistant

AFP (α-fetoprotein), hCG (human chorionic gonadotropin)

Table 23.14 Risk factors for testicular germ cell tumors

Cryptorchidism (strong association in 10%)
Undescended intra-abdominal testes
Testicular dysgenesis
Down's syndrome (trisomy 21)
Klinefelter's syndrome
Family history of germ cell tumors
Elevated estrogens *in utero*
Human immunodeficiency virus-infected men
Sarcoidosis
Cutaneous atypical nevi
Splenogonadal syndrome

- **Clinical staging:** The clinical staging (TNM classification) for testicular germ cell tumor is as follows: stage I, tumor is confined to testes, epididymis, or spermatic cord; stage II, tumor spreads to retroperitoneal lymph nodes below the diaphragm; and in stage III, metastases occur outside the retroperitoneal nodes or above the diaphragm. In stage IV, germ cell tumor has spread beyond the abdomen to other parts of the body. Staging procedures include CT scans of the chest, abdomen, and pelvis; ultrasonography for detection of bulky inferior nodal metastases; and occasionally lymphangiography.
- **Treatment:** The basic treatment of all testicular germ cell tumors includes orchiectomy, which is done at the time of diagnostic exploration. Surgical excision is advantageous, because it enables precise diagnosis of the disease.

Table 23.15 Molecular genetic alterations in germ cell tumors of testes

Features	Comments
Isochromosome 12p	Germ cell tumors (90%)
Random gain of chromosomes 1, 7, 9, 12, 17, 21, 22, X	Germ cell tumors (70%)
Novel DAD-R gene amplification	Germ cell tumors (majority cases)
DNA ploidy (abnormal number of chromosomes analyzed by flow cytometry)	▪ Germ cell tumors (majority cases) ▪ Hyperdiploid (triploid or tetraploid) ▪ Mean DNA indices higher in seminoma than NSGCT ▪ Spermatocytic seminoma is diploid and or near hyperdiploid
Telomerase activity	▪ Increased in all germ cell tumors except teratoma ▪ Inverse relationship between telomerase activity and differentiation stage of germ cell tumors

Table 23.16 Mode of spread of testicular germ cell tumors

Mode of Spread	Sites of Metastases of Germ Cell Tumors
Lymphatic route	▪ Para-aortic, iliac lymph nodes and later to mediastinal and left supraclavicular lymph nodes ▪ Para-aortic lymph nodes involved in embryonal carcinoma (adults) and yolk sac tumor (children) ▪ Retroperitoneal lymph nodes below renal vessels involved on same side (80–85%) and both sides (13–20%) ▪ Inguinal lymph nodes involved even without invasion of skin or scrotum by germ cell tumor ▪ Inguinal lymph nodes can also be involved in recurrence of germ cell tumor in a cutaneous scar, or a history of previous operation in the area
Hematogenous route	▪ Seminoma metastasizes to lungs, liver, brain, and bone ▪ Embryonal carcinoma metastasizes early to distant organs ▪ Choriocarcinoma metastasizes to lungs, liver, brain, and bones

Mature teratoma in the postpubertal testis is accompanied by metastases. Conversely, mature teratoma of the prepubertal testis has never been shown to metastasize.

Table 23.17 Immunohistochemical markers of germ cell tumors of testes

Immunohistochemical Markers	Seminoma	Embryonal Carcinoma	Yolk Sac Tumor	Spermatocytic Seminoma
LIN28 (RNA binding protein)	Positive (>80%)	Positive (>80%)	Positive (>80 %)	Positive (<20%)
SALL4 (nuclear staining)	Positive (>80%)	Positive (>80%)	Positive (>80 %)	Positive (variable)
PLAP (placental alkaline phosphatase)	Positive (>80%)	Positive (>80%)	Positive (>80 %)	Positive (<20%)
c-KIT (CD117)	Positive (>80%)	Positive (<20%)	Positive (<20%)	Positive (variable)
OCT4	Positive (>80%)	Positive (>80%)	Positive (<20%)	Positive (<20%)
CD30	Positive (<20%)	Positive (>80%)	Positive (variable)	Positive (<20%)
Vimentin	Positive (strong staining)	Positive	Positive	Positive
LDH (lactic dehydrogenase)	Positive (strong staining)	Negative	Negative	Negative
Podoplanin	Positive (strong staining)	Negative	Negative	Negative
α_1-Antitrypsin	Negative	Negative	Positive (strong staining)	Negative
α-Fetoprotein (AFP)	Negative (positive in seminoma with yolk sac tumor element)	Negative	Positive (strong staining)	Negative
hCG	Negative (positive in seminoma with syncytiotrophoblastic element)	Negative	Negative	Negative
Cytokeratin (in choriocarcinoma +)	Negative	Positive	Positive (strong staining)	Negative

α-Fetoprotein (AFP) is synthesized by fetal gut, liver and yolk sac. One year after birth, it is less than 16 ng/ml in serum and undetectable except by most sensitive methods. It is increased in cases of yolk sac tumor.

β-hCG is increased in choriocarcinoma and seminoma with syncytiotrophoblastic cells.

Testicular germ cell tumors show inactivation of X chromosome detected by polymerase chain reaction (PCR).

- Recommendations for further therapy of testicular germ cell tumors (e.g. retroperitoneal lymph node dissection, chemotherapy, radiation therapy) are based on the pathologic findings from the surgical procedure.
- Treatment of germ cell tumor of testes after orchiectomy depends on the histologic characteristics of the tumor and the clinical stage of the disease. With appropriate treatment, the prognosis for men with testicular germ cell tumor is excellent. Comparison of seminomatous and nonseminomatous germ cell tumors is given in Table 23.18.

▪ **Prognosis:** Men with stage I and stage II disease do very well. Men, who have retroperitoneal lymph node dissection may experience retrograde ejaculation or failure to ejaculate because of severing of the sympathetic plexus. Infertility may result from retrograde ejaculation or the toxic effects of

Table 23.18 Comparison of seminomatous and nonseminomatous germ cell tumors

Characteristics	Seminomatous Tumors	Nonseminomatous Tumors (NSGCTs)
Germ cell tumors	Seminoma	▪ NSGCTs with embryonic differentiation (embryonal carcinoma and teratoma) ▪ NSGCTs with extraembryonic differentiation (yolk sac tumor and choriocarcinoma)
Diagnosed in stage	70% of patients are diagnosed in stage I	Majority of patients are diagnosed in stage II/III
Mode of spread	Lymphatic spread (retroperitoneal/para-aortic, mediastinal, and supraclavicular lymph nodes) followed by hematogenous route (in lungs, liver, brain and bone)	Lymphatic, hematogenous route (lungs, liver, bones and brain)
Metastasis	Late metastases	Early metastases
Management	Seminoma is radiosensitive tumor. Stage I and II seminomas are treated by irradiation of retroperitoneum up to diaphragm. Bulky retroperitoneal or distant metastases of seminoma are treated by chemotherapy	Nonseminomatous germ cell tumors are radioresistant tumors and treated by chemotherapy, or retroperitoneal lymph node dissection
Prognosis	▪ Good prognosis ▪ Poor prognosis (tumor >4 cm and rete ridges invasion)	▪ Good prognosis (teratoma) ▪ Poor prognosis (vascular invasion, S phase fraction >29%)

chemotherapy or radiation therapy. Sperm banking should be considered for men undergoing treatment of testicular germ cell tumors.

Seminoma of Testis

Seminoma is most common malignant testicular germ cell tumor, which is analogous to dysgerminoma, a germ cell ovarian tumor. It accounts for 50% of all testicular germ cell tumors. The tumor replaces the whole testis and rarely involves tunica vaginalis. Seminoma occurs commonly between the ages of 25–50 years with peak incidence at mid-30s age group. Seminoma is virtually nonexistent before puberty and rare in adolescence. Undescended (cryptorchid) testis is major predisposing factor for seminoma. Burnt out seminoma refers to replacement of seminoma by fibrous and hyalinized tissue (sometimes calcification in scar) and absence of malignant cells.

Clinical Features

Patient presents with painless unilateral testicular swelling; and about 10% of patients experience local discomfort and pain. Clinical manifestations occur due to metastases of seminoma include supraclavicular and retroperitoneal lymphadenopathy.

- Seminoma with syncytiotrophoblastic element is associated with gynecomastia due to increased serum human chorionic gonadotropin (hCG). The serum human chorionic gonadotropin level can also be elevated in choriocarcinoma and combined germ cell tumors.
- Prognosis is poor in patient with seminoma >4 cm and infiltration of tumor cells in the epithelium of rete testis. The risk of tumor relapse after orchidectomy is directly proportional to the tumor diameter.
- Patient treated with chemotherapy often experience late complications such as metabolic syndrome, secondary neoplasms and myocardial infarction.

Surgical Pathology: Seminoma of Testis

Gross Morphology

- Small seminoma is well-circumscribed and homogenous. Large seminoma replaces entire testis in 50% of cases.
- The tumor is well circumscribed, solid, rubbery-firm, bulky mass, sometimes attains 10 times the size of normal testis.
- Tunica albuginea is mostly intact without penetration by the tumor.
- Epididymis is usually uninvolved. Occasionally extension of tumor involves epididymis, spermatic cord or scrotal sac.
- On cut section, tumor bulges above the testicular parenchyma and appears lobulated, well circumscribed but without a capsule, gray-white to pinkish, homogenous, and inconspicuous necrosis and hemorrhages.
- Presence of extensive areas of hemorrhage, firm or cystic areas are strongly suggestive of an NSGCT component. Extensive sampling is required if >4 cm size tumor shows these morphologic features. Gross morphology of seminoma is shown in Fig. 23.16.

Light Microscopy

Histologic variants of seminoma are classic seminoma (85–90%), anaplastic seminoma, seminoma with syncytiotrophoblastic element and seminoma with yolk sac tumor element (Table 23.19).

Classic Seminoma

- Classic seminoma shows lobules composed of a few dozen to 100 uniform, round tumor cells separated by thin fibrous

septa and arranged in sheets. The monomorphic cells resemble immature spermatogonia. The cytoplasm is rich in glycogen and lipids and therefore appears water clear in formalin-fixed specimen. The tumor cells contain centrally located nuclei and prominent nucleoli with distinct cell borders. The nucleolus has characteristics amphophilic staining pattern, apparent multiplicity, elongated shape, and irregular contours. The number of mitoses is highly variable.

- Fine to thick fibrous septa separate lobules of tumor cells. These fibrous septa are infiltrated by numerous lymphocytes (CD8+ cytotoxic T cells and CD4+ helper T cells and some NK cells and B cells), plasma cells, macrophages and eosinophils. Noncaseating granulomatous reaction containing Langhans' type multinucleated giant cells and epithelioid cell granulomas may also be present in 25% of cases. The noncaseating granulomatous reaction is patchy but immunologic response can obscure the morphology of neoplastic cells. It is therefore crucial to examine closely any testis with an extensive noncaseating granulomatous reaction for a residual seminoma tumor cells or intratubular germ cell neoplasia before accepting such as granulomatous orchitis (Fig. 23.17).
- Intratubular germ cell neoplasia is a precursor lesion known as intratubular germ cell neoplasia (ITGCN) often identified in the background seminiferous tubules (Fig. 23.18A).

Anaplastic Seminoma

Anaplastic seminoma is a histologic subtype of seminoma with marked cellular pleomorphism with 6 or more atypical mitotic figures per high power field. Prognosis of anaplastic seminoma is worse than classic seminoma (Fig. 23.18B).

Seminoma with Syncytiotrophoblastic Component

- Presence of multinucleated giant cells of syncytiotrophoblastic element around blood vessels reveals foci of hemorrhages around them within 7% of seminomatous tumors. Prognosis of this variant is relatively poor (Fig. 23.19).
- Serum hCG levels, elaborated by syncytiotrophoblastic element present in seminoma, are elevated in about 15% of cases, but these elevations are not as high as those seen in choriocarcinoma.

Seminoma with Yolk Sac Component

- Seminoma exhibits foci consistent with yolk sac differentiation, by virtue of the architectural arrangement, hyaline globules, and immunoreactivity for **α-fetoprotein** (AFP).
- Sometimes yolk sac element is missed during reporting. Seminoma associated with yolk sac component is usually associated with increased serum AFP.

Histochemistry

The tumor cells in seminoma are rich in glycogen. It can be demonstrated by periodic staining (PAS) with diastase pretreatment.

Immunohistochemistry Technique

- Panel of markers is used in surgical specimens of seminoma is mentioned as follows:

Markers	Expression
▪ LIN28 (RNA binding protein)	▪ Positive (>80%)
▪ SALL4 (nuclear staining)	▪ Positive (>80%)
▪ PLAP (placental alkaline phosphatase)	▪ Positive (>80%)
▪ c-KIT (CD117)	▪ Positive (>80%)
▪ OCT4	▪ Positive (>80%)
▪ CD30	▪ Positive (<20%)
▪ Vimentin	▪ Positive (strong staining)
▪ LDH (lactic dehydrogenase)	▪ Positive (strong staining)
▪ Podoplanin	▪ Positive (strong staining)
▪ α-Fetoprotein (AFP)	▪ Positive (seminoma with yolk sac tumor element)
▪ hCG	▪ Positive (seminoma with syncytiotrophoblastic element)
▪ α_1-Antitrypsin	▪ Negative
▪ Cytokeratin (in choriocarcinoma +)	▪ Negative

Seminoma with syncytiotrophoblastic element shows positivity for human hCG. The prognosis of this variant is relatively more aggressive.

DNA Ploidy and Cytogenetics in Seminomas

All seminomas are aneuploid, mostly with hypertetraploid stem cells. Like all germ cell tumors, seminomas demonstrate consistent gain of isochromosome p12; the number of copies is however lower than in nonseminomatous germ cell tumors (NSGCTs). Seminomatous and nonseminomatous germ cell tumors (NSGCTs) also show gain of chromosomes 1,

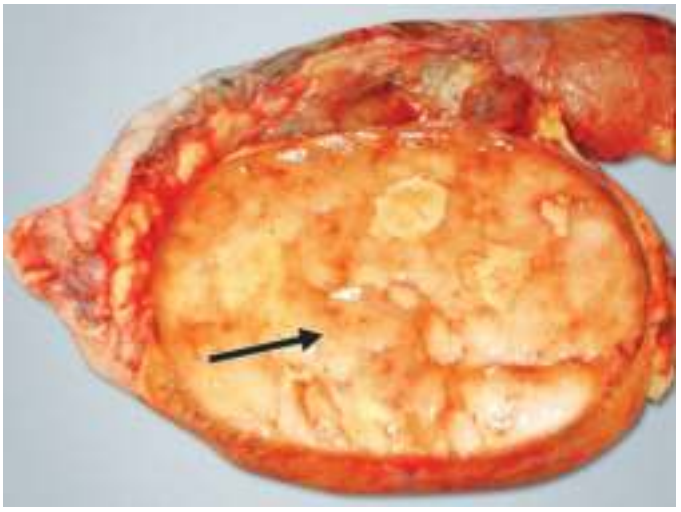

Fig. 23.16: Seminoma of the testis. Large seminoma replaces entire testis in 50% of cases. The tumor is well circumscribed, solid, rubbery-firm, bulky mass, sometimes attains 10 times the size of normal testis. Tunica albuginea is mostly intact without penetration by the tumor. On cut section, tumor bulges above the testicular parenchyma and appears lobulated, well circumscribed but without a capsule, gray-white to pinkish, homogenous, and inconspicuous necrosis and hemorrhages (arrow).

Table 23.19 Features of histologic variants of seminoma

Histologic Variants of Seminoma	Characteristics
Classic seminoma	▪ Monomorphic tumor cells are arranged in sheets divided by fibrous septa. Fibrous septa are infiltrated by chronic inflammatory cells ▪ A granulomatous reaction containing Langhans' type multinucleated giant cells and epithelioid cells may also be present in 25%
Anaplastic seminoma	▪ Marked cellular pleomorphism with 6 or more mitotic figures per high power field ▪ Prognosis of this variant is worse than classic seminoma
Seminoma with syncytiotrophoblastic element	Syncytiotrophoblastic element synthesizes hCG leading to increased serum levels
Seminoma with yolk sac element	Tumor cells show immunoreactivity for α-fetoprotein (AFP)

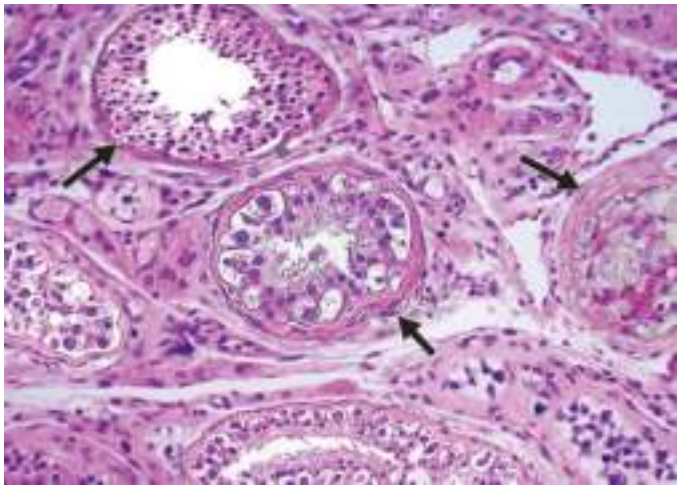

Fig. 23.17: Intratubular seminoma with syncytiotrophoblastic cells. The seminiferous tubules are entirely filled with seminoma cells. In most instances, invasive foci are observed in the specimen (arrows) (400X).

2, 7, 8, 20, and X; and loss of chromosomes 4, 5, 9, 11q, 13 and 18. Additionally, seminomas can demonstrate gain of chromosomes 3p, 6p, 10, and 22; and loss of chromosomes 1q, 9p, 11p, 16p, and 17p.

Management

Seminomas are exclusively sensitive to radiation and chemotherapy (carboplatin) even when the metastases are present in the abdominal para-aortic and paracaval lymph nodes. These modalities usually represent the primary forms of treatment following orchidectomy. Cure rates exceeding >95% can be expected in these cases.

- The most important prognostic factor of seminoma is tumor stage, which includes tumor bulk. Seminoma with syncytiotrophoblastic component and high hCG may have poor prognosis and survival.
- Presence of a lymphoid infiltrate and prominent noncaseating granulomatous reaction in seminoma

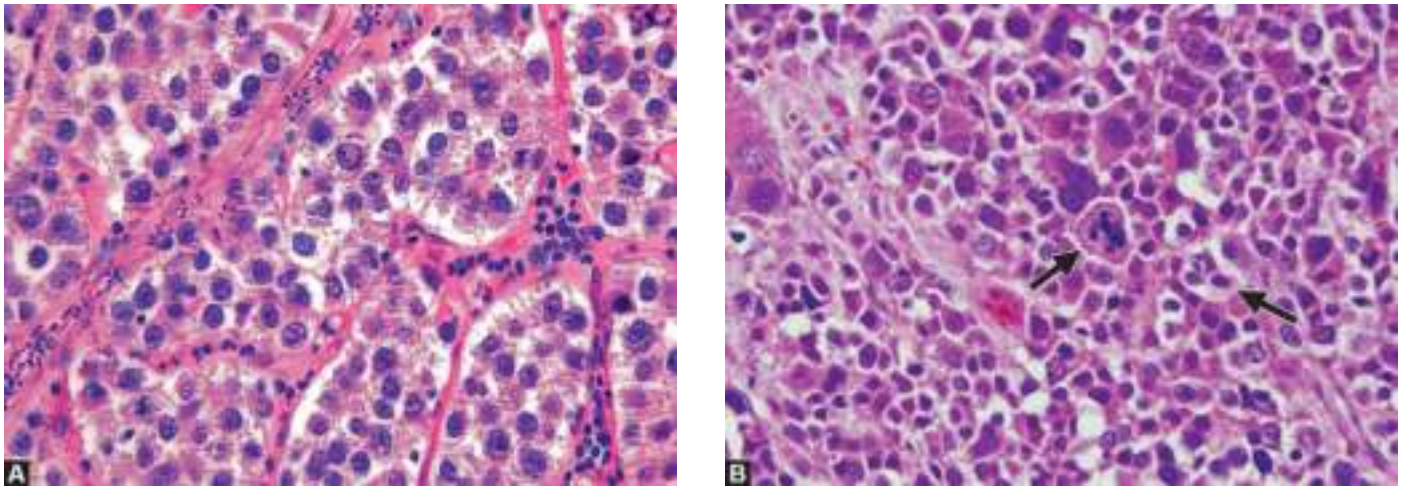

Fig. 23.18: Classic seminoma. (A) Seminoma shows lobules composed of a few dozen to 100 uniform, round neoplastic cells with clear cytoplasm, contain centrally located nuclei and prominent nucleoli with distinct cell borders separated by thin fibrous septa and arranged in sheets. Fibrous septa are infiltrated by numerous lymphocytes, plasma cells, macrophages and eosinophils. Noncaseating granulomatous reaction containing Langhans' type multinucleated giant cells and epithelioid cells may also be present in 25% of cases. (B) Anaplastic seminoma shows marked cellular pleomorphism with 6 or more mitotic figures per high power field. Prognosis of this variant is worse than classic seminoma (arrows) (400X).

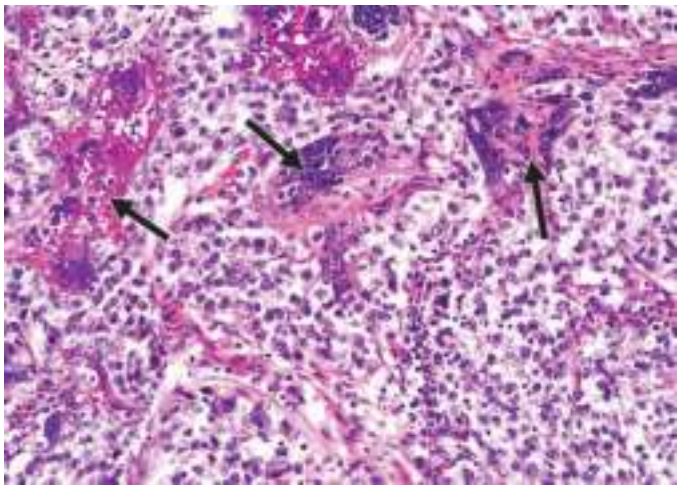

Fig. 23.19: Seminoma with syncytiotrophoblastic element. Presence of multinucleated giant cells of syncytiotrophoblastic element around blood vessels reveals foci of hemorrhages around them within 7% of tumors (arrows) (100X).

may be associated with borderline favorable prognosis. Anaplastic seminoma is associated with poor prognosis.

Spermatocytic Seminoma of Testis

Spermatocytic seminoma is a rare slow-growing tumor seen in older men (average age >65 years), which constitutes <1% of all germ cell tumors. However, it can affect younger patients between 30 and 40 years of age. Spermatocytic seminoma originates from primary spermatocyte and not primordial germ cells.

- There is no predisposing factor such as cryptorchidism for spermatocytic seminoma.
- In contrast to classic seminoma, spermatocytic seminoma is never seen in combination with non-seminomatous germ cell tumor (NSGCT). Metastases of spermatocytic seminoma are rare; hence prognosis is excellent following simple orchidectomy.

Clinical Features

Patient presents with painless swelling in the scrotal region. Metastases are practically non-existing. Sometimes, spermatocytic seminoma exhibits highly malignant component of sarcomatous element of skeletal muscle differentiation resulting in widespread metastases with associated fatal outcome.

Surgical Pathology: Spermatocytic Seminoma of Testis

Gross Morphology

The tumor measures 3–4 cm in size but sizes up to 15 cm. The outline of the tumor well is wall-circumscribed, soft and grayish white in color. Tumor bulges out on cut surface. Cut surface is soft, friable, edematous and gelatinous/mucinous appearance. Hemorrhage and necrosis are limited (Fig. 23.20).

Light Microscopy

- The tumor cells resemble primary spermatocytes showing marked degree of pleomorphism. Tumor is composed of three distinct cell types: small cells (6–8 micron), medium cells (15–20 micron) and scattered single mononucleated or multinucleated giant cells (50–150 micron).
- Tumor is composed of tumor cells with filamentous nuclear chromatin resembling spermatocytes. The cytoplasm is devoid of glycogen. Main part of the tumor shows an expansile growth pattern, surrounding seminiferous tubules are greatly extended and filled with neoplastic cells. Tubular rupture in more than one area explains the occurrence of multiple distinct nodules in one testis.
- In contrast to other germ cell tumors (GCTs); carcinoma *in situ* (CIS) cannot be demonstrated in the adjoining seminiferous tubules in spermatocytic seminoma. These seminiferous tubules may show normal spermatogenesis. The stroma is conspicuous and lacking lymphocytic infiltration.
- Tumor demonstrates large edematous areas similar to those of microcystic seminomas.
- Tumor may demonstrate skeletal muscle differentiation (rhabdomyosarcomatous component) associated with poor prognosis (Fig. 23.21). Differences between classic seminoma and spermatocytic seminoma are given in Table 23.20.

Immunohistochemistry Technique

Panel of markers is used for work up of spermatocytic seminoma.

Markers	Expression
LIN28 (RNA binding protein)	Positive (<20%)
SALL4 (nuclear staining)	Positive (variable)
PLAP (placental alkaline phosphatase)	Positive (<20%)
c-KIT (CD117)	Positive (variable)
OCT4	Positive (<20%)
CD30	Positive (<20%)
Vimentin	Positive
NUT (recent marker)	Positive (variable)
GAGE7 (recent marker)	Positive (variable)
NY-ESO-1 (recent marker)	Positive (variable)
LDH (lactic dehydrogenase)	Negative
Podoplanin	Negative
α_1-Antitrypsin	Negative
α-Fetoprotein (AFP)	Negative
hCG	Negative
Cytokeratin	Negative

DNA Ploidy and Cytogenetics in Spermatocytic Seminoma

Numerical chromosomal aberrations are common. Gain of chromosome 9 and loss of isochromosome 12p are characteristics in spermatocytic seminoma. Tumor expresses NY-ESO-1 (the product of a cancer testis gene), like normal spermatogonia, primary spermatocytes, and

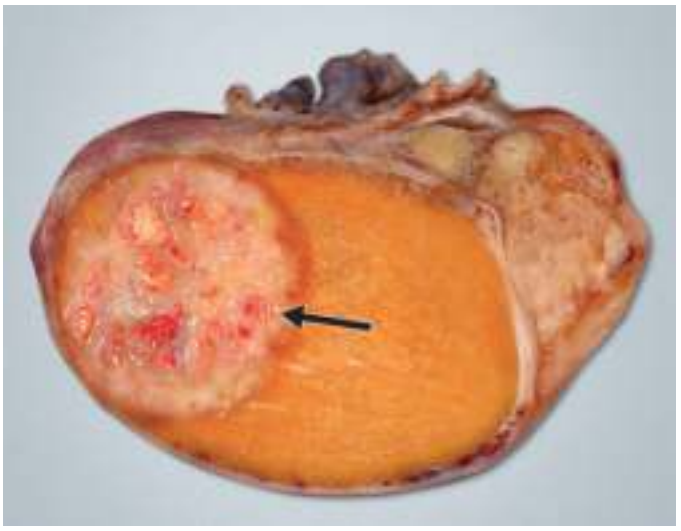

Fig. 23.20: Spermatocytic seminoma. The tumor measures 3–4 cm in size but sizes up to 15 cm. The outline of the tumor well is well-circumscribed, soft and grayish white in color. Tumor bulges out on cut surface. Cut surface is soft, friable, edematous and gelatinous/mucinous appearance. Hemorrhage and necrosis are limited in extent (arrow).

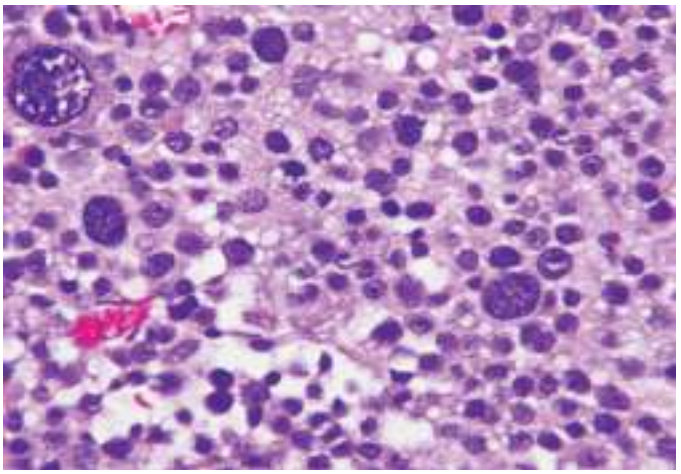

Fig. 23.21: Spermatocytic seminoma. The tumor cells are of three types. Small (6–8 mm), medium (15–20 mm) and large cells (50–100 mm) exhibit a filamentous or "spireme" chromatin distribution (400X).

the cells of intratubular germ cell neoplasia (IGCN), in contrast to classic seminoma and nonseminomatous germ cell tumors.

Table 23.20 Differences between classic seminoma and spermatocytic seminoma

Parameters	Classic Seminoma	Spermatocytic Seminoma
Origin	Primordial germ cell	Primary spermatocyte
Peak age	4th decade	>65 years of age
Frequency	Most common (40–50%)	Uncommon (1–2%)
Sites	Testes, mediastinum, retroperitoneum (seminoma testes counterpart of dysgerminoma ovary)	Testes only
Bilateral involvement	Bilateral testes (2%)	Bilateral testes (9%)
Association with cryptorchidism	Yes	No
Combined with other germ cell tumors	Yes (≤15%)	Never
Combined with germ cell neoplasia *in situ* (GCNIS)	Yes (>90%)	Never
Intercellular edema	Uncommon	Common
Molecular genetic alterations	Gain of isochromosome p12, 1, 2, 7, 8, 20 and X, 3p, 6p	NY-ESO-1 (the product of a cancer-testis gene)
Growth	Rapid growth	Slow growth
Gross morphology		
Replacement of testis	Complete replacement of testes in 50% of cases	Partial replacement of testis
Tumor size	Well circumscribed, solid, rubbery-firm, bulky mass, sometimes attains 10 times the size of normal testis	The tumor measures 3–15 cm
Cut surface of tumor	Cut surface appears lobulated gray-white homogenous	Tumor bulges on the cut surface and soft, friable, edematous and gelatinous/mucinous appearance
Histologic features		
Histologic variants	Classic seminoma, anaplastic seminoma, seminoma with syncytiotrophoblastic element and seminoma with yolk sac component	Spermatocytic seminoma

Contd..

Table 23.20 Differences between classic seminoma and spermatocytic seminoma (*Contd...*)

Parameters	Classic Seminoma	Spermatocytic Seminoma
Cell morphology	Monomorphic tumor cells are divided by fibrous septa	Tumor consists of polymorphous triphasic cells with eosinophilic cytoplasm and round dark nuclei, and lacks fibrous septa
Stroma	Scanty prominent	Stroma scanty
Lymphoid reaction	Lymphoid reaction prominent	Lymphoid reaction scanty
Granulomas	Often present	Extremely rare
Sarcomatous transformation	Absent	Occasional
Histochemistry		
Glycogen in tumor cells	Abundant (PAS positive)	Absent to scanty (PAS negative)
Immunohistochemistry Technique		
LIN28 (RNA binding protein)	Positive (>80%)	Positive (<20%)
SALL4 (nuclear staining)	Positive (>80%)	Positive (variable)
PLAP (placental alkaline phosphatase)	Positive (>80%)	Positive (<20%)
c-KIT (CD117)	Positive (>80%)	Positive (variable)
OCT4	Positive (>80%) diffuse staining	Positive (<20%)
CD30	Positive (<20%)	Positive (<20%)
Vimentin	Positive (strong staining)	Positive
NUT (recent marker)	Negative	Positive (variable)
GAGE7 (recent marker)	Negative	Positive (variable)
NY-ESO-1 (recent marker)	Negative	Positive (variable)
LDH (lactic dehydrogenase)	Positive (strong staining)	Negative
Podoplanin	Positive (strong staining)	Negative
α_1-Antitrypsin	Negative	Negative
α-Fetoprotein (AFP)	Negative (positive in seminoma with yolk sac tumor element)	Negative
hCG (human chorionic gonadotropin)	Negative (positive in seminoma with syncytiotrophoblastic element in 10%)	Negative
Cytokeratin	Negative	Negative
Chromosomal abnormality		
Chromosome	Inversion p12	Gain of chromosome 9
Prognosis		
Metastasis	Frequent	Extremely rare

Young age does not exclude the diagnosis of spermatocytic seminoma.

Prognosis

Spermatocytic seminoma may involve bilateral testes. Metastases are practically nonexistent associated with excellent prognosis and, therefore, simple orchiectomy may be sufficient therapy.

Embryonal Carcinoma of Testis

Embryonal carcinoma is a highly malignant nonseminomatous germ cell tumor (NSGCT), which is analogous to a similar tumor occurring in the ovary. Tumor is composed of primitive cells that retain the ability to differentiate toward somatic or extraembryonic structures. It most often occurs in younger age group between 25 and 35 years of age. This tumor is rare in children and persons over 50 years of age. Pure embryonal carcinoma accounts for 2–10% of all germ cell tumors. But embryonal carcinoma is very frequent (80%) in mixed germ cell tumors with more than one germ cell tumor component. It most often occurs mixed with teratoma in 40% of cases and known as teratocarcinoma, that shows an increase in both carcinoembryonic antigen (CEA) and α-fetoprotein (AFP) in 90% of cases.

Clinical Features

Patient presents with painless unilateral testicular swelling. Tumor invades the testis, epididymis, blood vessels and metastasizes to retroperitoneal para-aortic lymph nodes (40%), supradiaphragmatic lymph nodes (20%), lungs, liver, brain and other organs. Teratocarcinoma often metastasizes as embryonal carcinoma, and the reverse also occurs. About 10% of patients suffer from systemic manifestations such as fever, weight loss, night sweats, headache.

Surgical Pathology: Embryonal Carcinoma of Testis

Gross Morphology

- Embryonal carcinoma is the smallest pure form of germ cell tumor measuring 2.5 cm and not replacing entire testis.
- Cut surface of tumor reveals variegated, soft, gray-white, granular or smooth, bulging surface with areas of hemorrhage and necrosis.
- Approximately, 20% of embryonal carcinomas have invaded the adjacent epididymis or tunica albuginea at the time of excision (Fig. 23.22).

Light Microscopy

- Pure embryonal carcinoma is composed of highly pleomorphic polygonal, cuboid or columnar epithelial cells with hyperchromatic nuclei, prominent large single or multiple nucleoli and indistinct cell borders that are similar to cells from early embryos. The color of the cytoplasm changes from clear to eosinophilic, or basophilic.
- Tumor cells are arranged in glandular, papillary structures or solid pattern; and variable areas of undifferentiated sheets of tumor cells exhibiting syncytial growth surrounded by dilated vascular channels filled with red blood cells.
- Tumor shows high mitotic activity, tumor giant cells and areas of hemorrhage.
- Syncytiotrophoblastic component may be present all over the tumor.
- Peritumoral invasion of blood vessels and lymphatics is important feature to document (Fig. 23.23).

Immunohistochemistry Technique

Panel of markers is used on surgical specimens of embryonal carcinoma.

Markers	Expression
LIN28 (RNA binding protein)	Positive (>80%)
SALL4 (nuclear staining)	Positive (>80%)
PLAP (placental alkaline phosphatase)	Positive (>80%)
c-KIT (CD117)	Positive (<20%)
OCT4	Positive (>80%)
CD30	Positive (>80%)
Vimentin	Positive
LDH (lactic dehydrogenase)	Negative
Podoplanin	Negative
α_1-Antitrypsin	Negative
α-Fetoprotein (AFP)	Negative
hCG	Negative
Cytokeratin	Positive

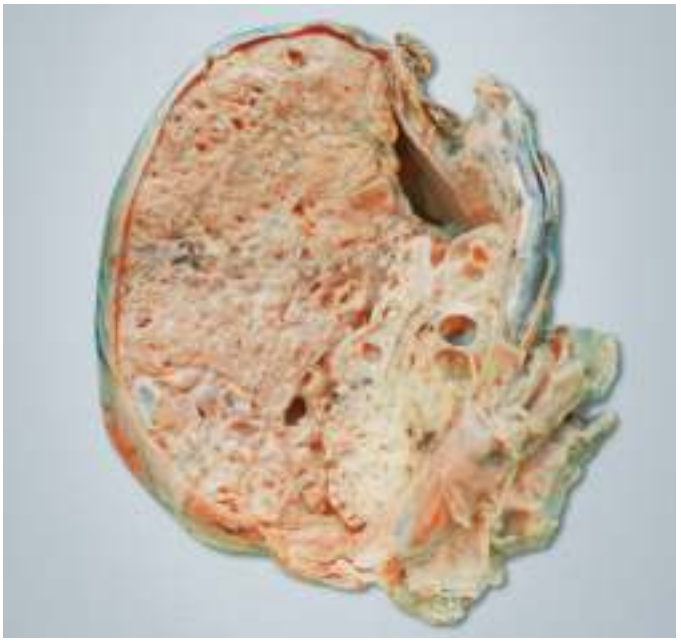

Fig. 23.22: Embryonal carcinoma. In adults, embryonal carcinoma is almost invariably a component of a mixed germ cell tumor. Cut surface reveals variegated, gray-white, granular or smooth, bulging surface with areas of hemorrhage and necrosis.

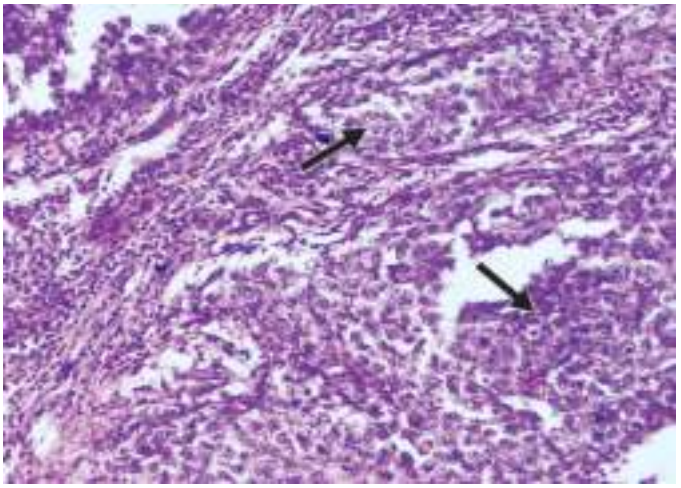

Fig. 23.23: Embryonal carcinoma. Tumor architecture is variable. Tumor cells often grow in diffuse sheets and may be arranged to resemble poorly formed glands. Tumor cells are large and tend to overlap one another, and cell membranes are difficult to discern, exhibiting a syncytial appearance to the tumor. Tumor cell nuclei are vesicular with irregular outlines, coarse chromatin, and prominent nucleoli. Atypical mitotic figures and apoptotic cells are abundant (arrows) (400X).

DNA Ploidy and Cytogenetics in Embryonal Carcinoma

Embryonal carcinomas are triploid or hypoploid neoplasms. Cytogenetic analysis has confirmed the presence of isochromosome 12p in many cases. There is a correlation between the aggressiveness of the tumor and the number of isochromosome copies.

Prognosis

Embryonal carcinoma is less sensitive to radiation than seminoma and hence more aggressive and lethal. The prognosis is much worse than for seminoma. Embryonal carcinoma is highly sensitive to chemotherapy, and the cure rates are now over 90%.

Yolk Sac Tumor

Yolk sac tumor is the most common malignant nonseminomatous germ cell tumor in infants and children under 34 years of age, but rare in adults. Telium first described this entity and named 'endodermal sinus tumor'. Yolk sac tumor arises from primordial germ cell showing differentiation towards yolk sac and allantoic membrane. It is analogous to endodermal sinus tumor of the ovary.

- Serum α-fetoprotein (AFP) can be identified in the cytoplasm of most yolk sac tumors with the frequency from 55 to 100%. Levels of AFP are elevated in most preoperative cases of yolk sac tumor. AFP is oncofetal glycoprotein synthesized during intrauterine fetus by liver and the visceral endoderm of the yolk sac.
- Hypermethylation of the RUNX3 gene promoter is thought to play a pathogenetic role in yolk sac tumor. Yolk sac tumor may be a component of mixed germ cell tumor.

Clinical Features

A painless testicular tumor and elevated serum α-fetoprotein (AFP) are the features of pure yolk sac tumor in infants and children under the age of 3 years. About 80% of prepubertal patients present with stage I disease of yolk sac tumor. Disorders associated with elevated serum α-fetoprotein (AFP) are given in Table 23.21.

Table 23.21 Disorders associated with elevated serum α-fetoprotein (AFP)

Yolk sac tumor of gonads
Conventional hepatocellular carcinoma
Hepatoblastoma
Cirrhosis
Massive hepatocellular necrosis with regeneration
Chronic hepatitis
Pregnancy

Surgical Pathology: Yolk Sac Tumor of Testis

Gross Morphology

Yolk sac tumor measures 2–6 cm in size. Tumor is lobulated and demarcated from surrounding tissues. Cut surface reveals grayish white to yellow solid tumor with mucinous texture and cystic areas. Hemorrhage and necrosis may be seen (Fig. 23.24).

Light Microscopy

- Yolk sac tumor is composed of interlacing strands of cuboidal to columnar epithelial cells surrounded by loose myxoid connective stroma. About 80% of tumors are composed of microcystic (reticular) and solid patterns. Solid pattern has intracellular hyaline globules known as basement deposits.
- The classic finding is the 'Schiller-Duval bodies' attempting to form the yolk sac. The lobular arrangement of cells, surrounded by empty spaces, results in the formation of glomeruloid structures containing a central fibrovascular core referred to as Schiller-Duval bodies.
- The presence of α-fetoprotein (AFP) in the tumor cells is highly characteristic of differentiation of tumor into yolk sac cells (Fig. 23.25A and B).

Histologic Patterns

Yolk sac tumor has various histologic patterns: endodermal sinus, endometrioid, glandular-alveolar, hepatoid, macrocystic, microcystic/reticular, myxomatous, papillary, parietal, sarcomatoid/spindle cell, solid pattern and vitelline.

Immunohistochemistry Technique

Tumor cells contain hyaline globules, which stain with diastase-resistant PAS. Panel of markers is used in surgical specimen of yolk sac tumor.

Markers	Expression
LIN28 (RNA binding protein)	Positive (>80%)
SALL4 (nuclear staining)	Positive (>80%)
PLAP (placental alkaline phosphatase)	Positive (>80%)
c-KIT (CD117)	Positive (<20%)
OCT4	Positive (<20%)
CD30	Positive (variable)
α_1-Antitrypsin	Positive (strong staining)
α-Fetoprotein (AFP)	Positive (strong staining)
Cytokeratin	Positive (strong staining)
Vimentin	Positive
LDH (lactic dehydrogenase)	Negative
Podoplanin	Negative
hCG	Negative

Fig. 23.24: Yolk sac tumor. This is the commonest testicular tumor in children, the majority of whom are <2 years old. In children, yolk sac tumor is typically pure in its makeup. It has completely replaced the normal testicular tissue. It tends to be bulging, shiny, or mucoid (creamy), and may show areas of cystic degeneration. The cut surface of embryonal carcinoma is often somewhat granular in consistency; necrosis and hemorrhage are common and may be extensive. It is typically smaller than seminoma and its interface with adjacent normal parenchyma may be somewhat indistinct (arrow).

DNA Ploidy and Cytogenetics in Yolk Sac Tumors

The DNA stem line of yolk sac tumor is peritetraploid and occasionally even diploid. Anomalies of 1p, 6q and 13q are present in pediatric yolk sac tumors, whereas isochromosome 12p is missing.

Treatment

The treatment of adult patients with yolk sac tumor is similar to that of other nonseminomatous germ cell tumors.

- Prognosis is excellent in children under 3 years of age following timely orchidectomy in a 95% of cases. Retroperitoneal lymph node dissection is no longer performed in children.
- Serum AFP analysis can be used to monitor the recurrence of disease following surgery, which is one of the major oncofetal antigens. Many children with yolk sac tumors are managed by close follow-up after orchidectomy.

Teratoma of Testis

Teratoma is composed of mature or immature (fetal/embryonal) tissue components derived from all three embryonic germinal layers: ectoderm, endoderm and mesoderm.

- Multiple tissues can be present in the tumor: neural tissue, cartilage islands, ciliated epithelium of bronchi, thyroid tissue, liver cells, embryonic gut, or striated muscle embedded in fibrous or myxoid stroma. Because of the different histogenesis and prognosis, the new WHO classification distinguishes a prepubertal and a postpubertal teratoma.
- Prognosis is good prepubertal teratomas in infants and children (4–12 years). But in postpubertal period, all teratomas are regarded as malignant and capable of metastatic behavior regardless of elements are mature or immature.
- A few teratomas may contain carcinoid tumor component (argyrophil and secretory granules containing neuron-specific enolase (NSE), chromogranin, synaptophysin, but not associated with the carcinoid syndrome).

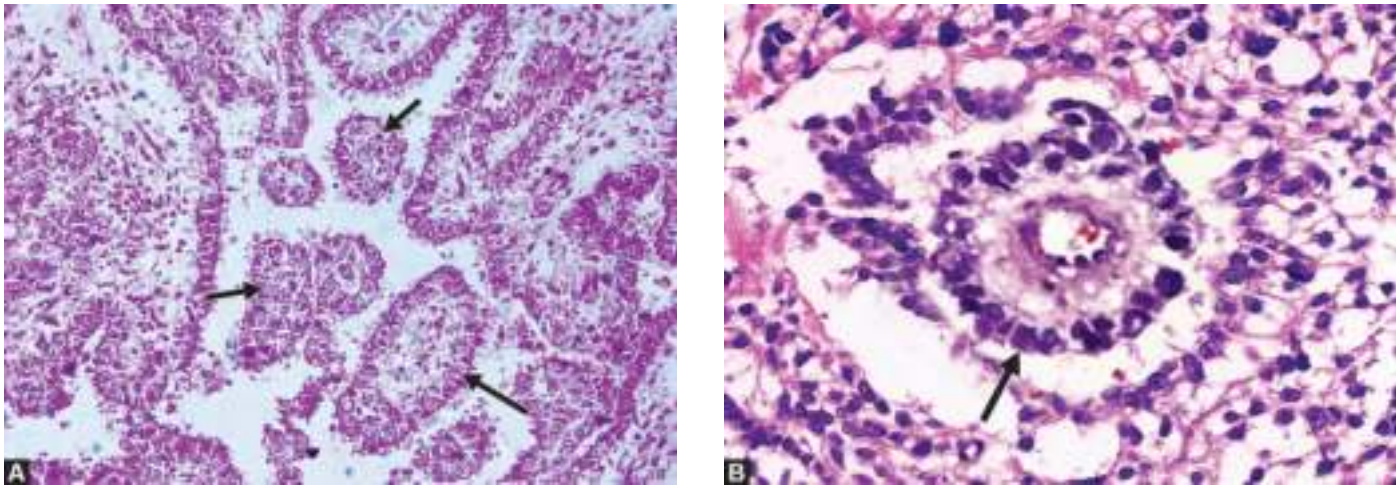

Fig. 23.25: Yolk sac tumor. (A) The endodermal sinus pattern of yolk sac tumor is characterized by the presence of irregular interconnecting labyrinthine-like spaces and Schiller-Duval bodies, several of which are nicely illustrated (arrows), (B) tumor is showing Schiller-Duval bodies (arrow) (400X).

Epidemiology

After yolk sac tumors, teratomas are the second most frequent nonseminomatous germ cell tumors accounting for 14–20% during childhood and 66% before the age of two years. Pure teratomas account for 3–7% of germ cell tumors during 20–30 years of age group. Teratoma can be present as a tumor component in 50% of all mixed germ cell tumors. Mixed teratomas consist of two components in 45% of cases: teratoma and embryonal carcinoma.

Clinical Features

Patient presents with painless testicular swelling. Since prepubertal teratomas do not metastasize, hence parenchyma sparing surgery is performed for small teratoma. Postpubertal teratomas metastasize first to the retroperitoneal lymph nodes and then to distant organs (lung, liver, brain, bones). These patients are resistant to chemotherapy and radiotherapy. Surgical excision of the lymph nodes and organ metastases. Prognosis is better in stage I and poor in stage III.

Surgical Pathology: Teratoma of Testis

Gross Morphology

On macroscopic examination, teratoma measures 5–10 cm in diameter. Cut surface has a variegated appearance with cystic and solid areas. The cysts are filled with hair mucus, or sebaceous material. Cartilage takes the shape of a glassy nodule. Presence of pigmented areas simulates retina. Presence of hemorrhage necrosis indicates admixture of teratoma with embryonal carcinoma or choriocarcinoma or both. Mature teratoma is shown in Fig. 23.26.

Light Microscopy

Teratomas are classified according to the degree and type of differentiation seen.

- **Mature teratoma:** Mature teratoma is well differentiated tumor composed of tissue components derived from ectoderm, mesoderm, and endoderm.
  - Tumor contains cysts lined with squamous or glandular epithelium of the ciliated-type respiratory or enteric-type epithelium. The cysts can be filled with ferritin or mucus.
  - Organized structures simulating bronchus or gut are composed of the corresponding epithelium encircled by smooth muscle.
  - Organized structures may contain scattered neuroendocrine cells producing gastrin, somatostatin and bombesin.
  - Mesodermal tissue derived components such as smooth muscle, cartilage and bone with or without hematopoietic bone marrow embedded in fibrous or myxoid stroma are present.
  - Neuroglia with ependymal differentiation is most often present.
  - Pigmented retinal epithelium may be seen in occasional tumor.
  - Differentiated liver, prostate, thyroid and pancreas are rarely present.
  - Mature teratoma is almost always malignant with metastatic potential, whereas the analogous ovarian tumor is almost always benign (Fig. 23.27).
- **Immature teratoma:** Immature teratoma is less differentiated tumor composed of primitive elements such as undifferentiated spindle cells and small immature glandular structures.
  - Squamous epithelium is arranged in solid nests without keratinization.
  - Other components of immature teratoma are primitive neuroepithelium, rhabdomyoblasts, renal blastema, and fetal adipose tissue with lipoblasts. Immature tissue is more often encountered in adult patients than in children. Gross morphology and light microscopy of immature teratoma are shown in Figs 23.28 and 23.29.
- **Teratoma with somatic malignant transformation:** Teratoma may contain malignant tissue such as squamous cell carcinoma, mucin secreting adenocarcinoma and sarcoma.

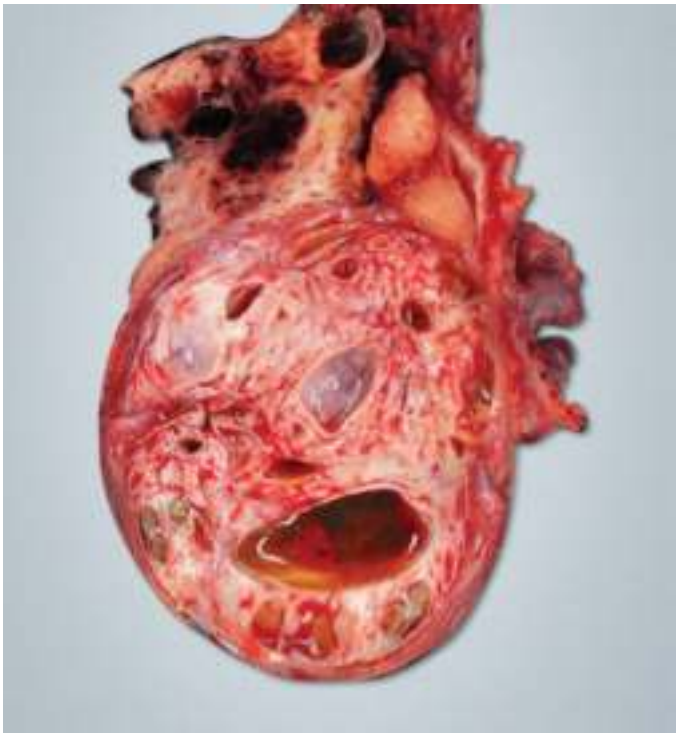

Fig. 23.26: Mature teratoma—teratomas typically have both solid and cystic components. The solid component is sometimes recognizable as cartilage. The material within the cysts may be serous, mucoid, or keratinous. This tumor arose in the testis of a 2-year-old boy, and as such was considered benign. However, teratomas in 20–30 years of malignant behavior.

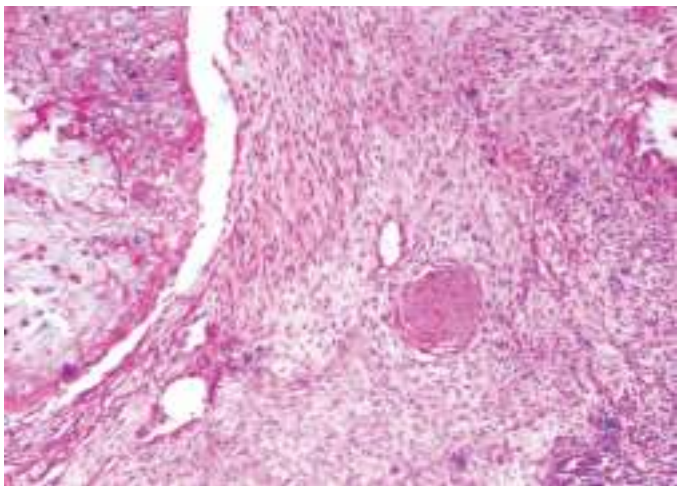

Fig. 23.27: Mature teratoma. Mature teratoma is well differentiated tumor composed of components derived from ectoderm, mesoderm and endoderm. It shows cartilage and an island of squamous epithelium set in a fibrous stroma (400X).

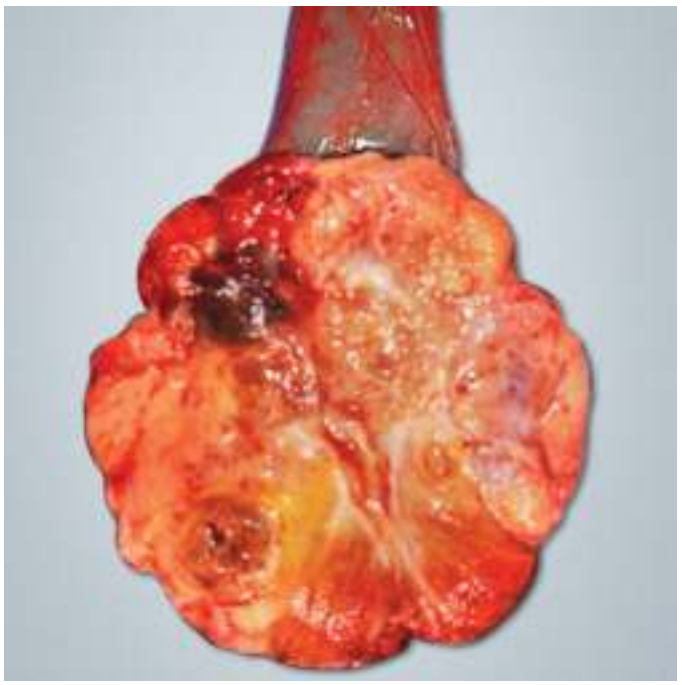

Fig. 23.28: Teratoma with immature elements. This teratoma has a very extensive component of immature elements in the form of primitive neuroectodermal tumor, perhaps accounting for its fleshy bulging encephaloid appearance and the areas of hemorrhage.

DNA Ploidy and Cytogenetics in Teratomas

Prepubertal teratomas are diploid and postpubertal teratoma as hypotriploid. Postpubertal teratoma demonstrates isochromosome 12p. Teratomas with somatic malignant transformation can demonstrate chromosomal aberrations (translocation) typical of the respective somatic tumor as well as isochromosome 12p that is specific for germ cell tumors.

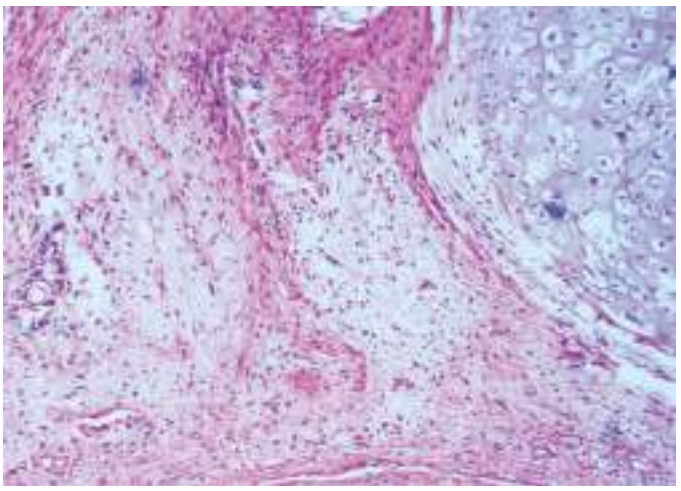

Fig. 23.29: Teratoma with immature elements. This teratoma with mature adipose, cartilage and squamous elements has an area of immature tissue at upper right. Immature elements, if limited, appear to have no influence on prognosis (100X).

Mode of Spread

The majority of nonseminomatous germ cell tumors (e.g. teratoma) spread via lymphatic route to retroperitoneal, para-aortic, mediastinal and supraclavicular lymph nodes, and via hematogenous routes to lungs, liver, brain, bones and are not radiosensitive, hence their natural history is markedly different from that of seminomas. Teratocarcinoma often metastasizes as embryonal carcinoma, and the reverse also occurs.

Choriocarcinoma of Testis

Choriocarcinoma is highly malignant rapidly growing nonseminomatous germ cell tumor. This tumor is analogous to choriocarcinoma of the ovary. Identical choriocarcinomas are also seen in placenta, ovary, sequestrated nests of totipotent cells in mediastinum and abdomen. Tumor synthesizes β-hCG representing germ cell differentiation to an extraembryonic structure, namely the placenta. Choriocarcinoma is highly chemosensitive tumor. It most often occurs in the second to third decades.

Clinical Features

Patient presents with widespread metastases via hematogenous routes to lungs (100%), liver (86%), brain (56%), gastrointestinal tract (70%) and bones with fatal outcome. Tumor is detected as a small palpable nodule without testicular enlargement. The high serum hCG levels >100,000 IU/L cause gynecomastia. Choriocarcinoma is a very aggressive tumor treated by chemotherapy. Profuse intracranial, pulmonary and gastrointestinal bleeding with substantially increased serum β-hCG (>50,000 IU/L) is referred to as 'choriocarcinoma syndrome'.

Surgical Pathology: Choriocarcinoma of Testis

Gross Morphology

- Choriocarcinoma is usually small size tumor surrounded by extensive areas of hemorrhage and necrosis.
- Sometimes, primary tumor is replaced by fibrous scar but widespread metastases occur.
- The invasive growth of trophoblastic cells in the tumor is associated with hemorrhage (Fig. 23.30).

Light Microscopy

- Choriocarcinoma is composed of syncytiotrophoblastic cells, which cap a cluster of cytotrophoblastic cells giving the impression of a placental villus.
- Cytotrophoblastic element cells are more regular polygonal cells with distinct cell membrane, abundant vacuolated cytoplasm and a vesicular nucleus arranged in cords and masses.
- Syncytiotrophoblastic element cells are large multinucleated with many irregular, hyperchromatic vesicular nuclei with abundant eosinophilic vacuolated cytoplasm.
- Since the tumor does not have its own stroma, the syncytiotrophoblastic giant cells directly invade the local blood vessels (Fig. 23.31).

Immunohistochemistry Technique

Mononuclear cytotrophoblastic cells of choriocarcinoma of tests are variable positive for SALL-4 staining.

Markers	Expression
All three layers: syncytiotrophoblastic, cytotrophoblastic and intermediate trophoblastic cells show positivity.	
CK7	Positive
CK8	Positive
CK19	Positive
CAM 5.2	Positive
AE1/AE3	Positive
α-Inhibin	Positive
Cytotrophoblastic cells show positivity	
hCG	Positive
EMA (epithelial membrane antigen)	Positive
Syncytiotrophoblastic cells and intermediate trophoblasts show positivity	
Human placental lactogen	Positive
Pregnancy-specific β_1-glycoprotein	Positive
Proliferative marker	
MIB-1	Positive

SALL-4 reacts with mononuclear tumor cells, but not for syncytiotrophoblastic and cytotrophoblastic cells.

Ploidy and Cytogenetics in Choriocarcinoma

Choriocarcinoma demonstrates isochromosome 12p.

Fig. 23.30: Choriocarcinoma—the testis is replaced by a bloody bulging mass. More typically, choriocarcinoma tends to be somewhat smaller, and may not significantly distort the testis (arrows).

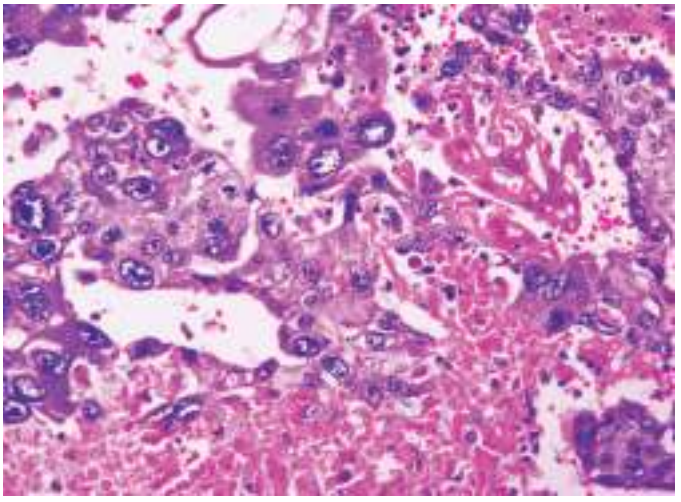

Fig. 23.31: Choriocarcinoma—the tumor is composed of multinucleated syncytiotrophoblastic and cytotrophoblastic cells. The multinucleated syncytiotrophoblasts have voluminous eosinophilic cytoplasm and large darkly staining irregular nuclei with prominent nucleoli. The smaller mononuclear cytotrophoblasts are fairly uniform in size with amphophilic cytoplasm and distinct cellular outlines resembling to the tumor cells of solid yolk sac tumor (400X).

Treatment

Choriocarcinoma is treated similarly to other nonseminomatous tumors. Orchidectomy is primary treatment for nonmetastatic choriocarcinoma. Retroperitoneal lymph node dissection or chemotherapy for pT_2 or higher. A choriocarcinoma syndrome with hemorrhagic visceral metastases is associated with poor prognosis.

Mixed Germ Cell Tumors of Testis

Mixed germ cell tumors most often occur in adults (20–30 years), which account for 30–55% of all germ cell tumors. Mixed germ cell tumors are as frequent as seminomas.

- The gross morphology and histologic features of mixed germ cell tumors are dependent on the number of different components. Some preferred combinations of mixed germ cell tumors occur.
- Embryonal carcinoma is most frequent tumor with other germ cell tumor in 80% of cases. Teratocarcinoma is composed of teratoma and embryonal carcinoma in 45% of cases.
- Seminoma can be present with teratoma, embryonal carcinoma, yolk sac tumor or choriocarcinoma in 15% of cases. For the purpose of treatment, it is important that seminomas are extensively sampled to rule out nonseminomatous component.
- High serum α-fetoprotein (AFP) in seminoma indicates that a nonseminomatous component has been overlooked.
- The invasion of the lymph nodes and blood vessels is the powerful predictor of metastases or relapse. A large embryonal carcinoma component also negatively influences the prognosis. Presence of teratoma is marker of favorable prognosis. Teratoma elements may be mature or immature (fetal/embryonal).
- The combination of percentage embryonal carcinoma and vascular invasion permits correct prediction for the final pathologic stage in 90% of patients.
- A few teratomas may contain carcinoid tumor component (argyrophil and secretory granules containing neuron-specific enolase, chromogranin, synaptophysin, but not associated with the carcinoid syndrome).
- Mixed germ cell tumor may be composed of teratoma, embryonal carcinoma and yolk sac tumor. In combined tumor (seminoma + NSGCT), the latter component is the one most likely to metastasize. Gross morphology and light microscopy of mixed germ cell tumor are shown in Figs 23.32 and 23.33.

Burnt-out Germ Cell Tumors of Testis

Burnt-out germ cell tumors refer to a germ cell tumor in extragonadal tissues with spontaneous regression of an intragonadal tumor.

- Extragonadal germ cell tumors are usually found in the retroperitoneal region.
- Many studies suggested that germ cell tumors could regress spontaneously.
- Conclusive evidence for spontaneous regression was established by Azzopardi and his associates, who conducted autopsy on patients, who died of metastatic germ cell tumor but lacked primary testicular germ cell tumor. Out of germ cell tumors of testes, seminoma regresses spontaneously.

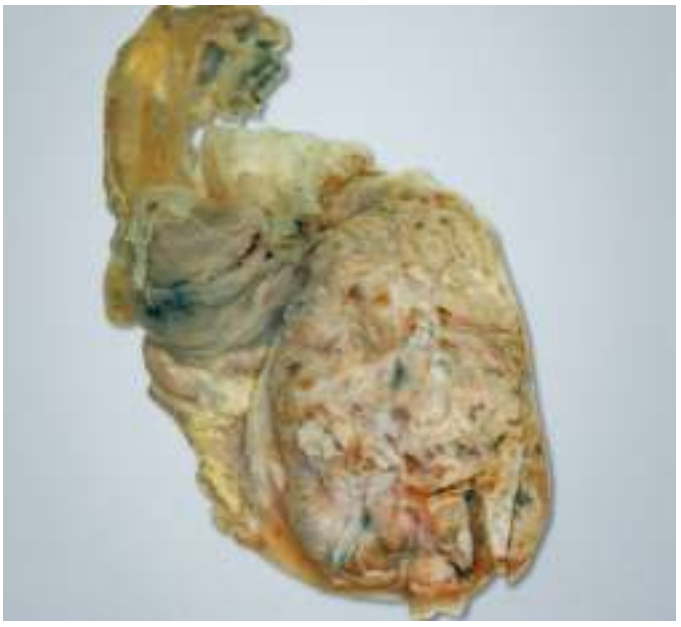

Fig. 23.32: Mixed germ cell tumor of testis. Tumor consists of teratoma, yolk sac and embryonal carcinoma.

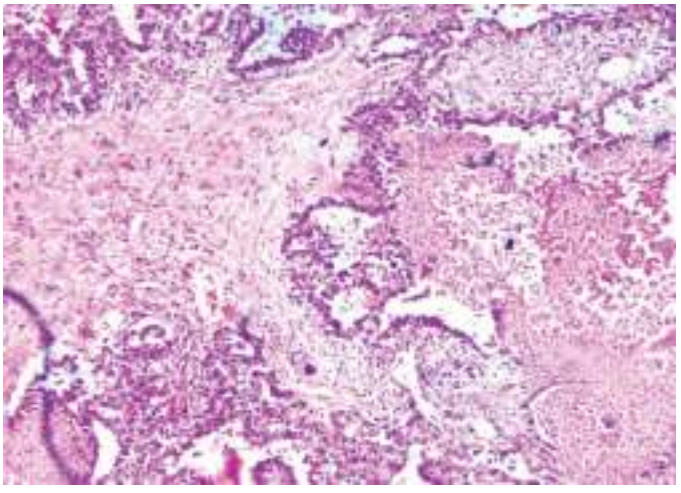

Fig. 23.33: Teratocarcinoma. Tumor is composed of components of teratoma and embryonal carcinoma (100X).

Surgical Pathology: Burnt-out Germ Cell Tumors of Testis
Gross Morphology
The burnt-out germ cell tumor consists of single or multiple well demarcated nodular scars and sometimes cystic or cartilaginous areas.
Light Microscopy
▪ Aggregates of proliferated Leydig cells in the surrounding atrophic testis are demonstrated. ▪ The seminiferous tubules of the surrounding parenchyma are atrophic and hyalinized with microliths. Foci of carcinoma *in situ* (CIS) may be identified.

Clinical Features

The prognosis and management of regressed germ cell tumor depend on the morphologic features of the primary tumor. Retroperitoneal metastases in young males are always suspicious for a primary germ cell tumor in the testis. Histologic examination of biopsy or surgical exploration with intraoperative frozen section is essential to establish diagnosis.

SEX CORD-STROMAL TUMORS OF TESTIS

Normally, Sertoli cells support primordial germ cells and form basement membrane of seminiferous tubules, which synthesize estrogens and up to some extent androgens. Leydig cells produce testosterone and other androgens. Sex cord/gonadal stromal tumors arise in the gonads of both genders, which account for 3–5% of testicular tumors. Over 30% of infants and children are affected by sex cord/gonadal stromal tumors.

Sertoli Cell Tumor (Androblastoma) of Testis

Sertoli cell tumor is a non-germ cell tumor derived from the sex cord stroma of testis. It is characterized by a paucity of endocrine manifestations. Sertoli cell tumors are most often benign, but malignant in 10% of cases metastasizing to iliac and para-aortic lymph nodes.

Clinical Features

Patient presents with testicular swelling. If Sertoli cell tumor synthesizes estrogen, clinical manifestations are loss of libido and impotence. Gynecomastia occurs more frequent in malignant Sertoli cell tumor. Malignant Sertoli cell tumors have also been reported in children. Orchidectomy is the only therapeutic option.

Surgical Pathology: Sertoli Cell Tumor of Testis

Gross Morphology

Tumor is small size (average size 3.5 cm), firm, encapsulated and well circumscribed nodule. Cut surface is gray white to yellow, homogenous cut surface with focal cystic areas.

Light Microscopy

- Well differentiated Sertoli cell tumors are lined by Sertoli cells having clearly visible basement membrane, oval vesicular nuclei and prominent reddish nucleoli and eosinophilic cytoplasm sometimes large amount of lipids.
- Tumor cells are arranged in distinctive trabeculae with tendency to form tubular structures resembling well-formed or poorly formed tubules lined by elongated cells having the appearance of Sertoli cells (Fig. 23.34).
- Less differentiated Sertoli cell tumor is composed of spindle-shaped cells growing in solid sheets.

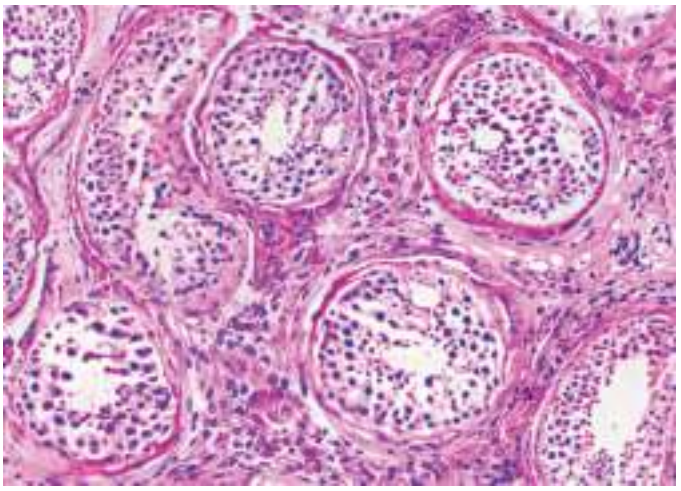

Fig. 23.34: Sertoli cell tumor. Tumor is composed of Sertoli cells or may have a component of granulosa cells. Tumor cells contain vesicular nuclei, prominent reddish nucleoli and eosinophilic cytoplasm sometimes large amount of lipids. These are arranged in distinctive trabeculae with tendency to form tubular structures resembling well-formed or poorly formed tubules lined by elongated cells having the appearance of Sertoli cells (400X).

- Tumor also consists of bands of fibrous tissue in variable proportion.
- Malignant Sertoli cell tumor is quite large measuring 7–15 cm, which shows nuclear pleomorphism and occasionally invasion of the lymphatic channels.

Immunohistochemistry Technique

Panel of markers is performed on paraffin-embedded sections from Sertoli cell tumor. FOXL2, β-catenin and WT1 are best markers. In many cases, immunohistochemistry technique is not very helpful in establishing correct diagnosis.

Markers	Expression
FOXL2	Positive (83%)
β-Catenin	Positive (83%)
WT1	Positive (82%)
Cytokeratin	Positive (78%)
SF1	Positive (75%)
Inhibin	Positive (67%)
Melan A	Positive (67%)
Calretinin	Positive (56%)
CD99	Positive (56%)
Synaptophysin	Positive (24%)
S-100	Positive (28%)

DNA Ploidy and Cytogenetics in Sertoli Cell Tumors

In various studies, Sertoli cell tumors demonstrate gain of X chromosome and loss of chromosome 2. Mutation of CTNNB1 (cadherin-associated protein β1) gene is likely to be involved in the pathogenesis of Sertoli cell tumor resulting in nuclear accumulation of β-catenin and expression of cyclin D1.

Leydig Cell Tumor of Testis

Leydig cell tumor (LCT) arises from Leydig cells, which accounts for 3% of testicular tumors. Leydig cell tumor is composed of more or less well-differentiated Leydig cells. The average age of LCT diagnosis is between 30 and 50 years in 20% of cases. However, LCT may occur in children under 10 years and adults. Tumor most often involves unilateral testis in 97% and bilateral testis in 3% of cases. Cryptorchidism and Klinefelter syndrome are considered predisposing factors. Approximately 25% of all LCTs show evidence of malignant behavior in the form of metastatic disease, particularly to lymph nodes, lung and liver.

Clinical Features

About 50% of patients present with unilateral testicular swelling and gynecomastia. Leydig cell tumors can synthesize androgens, estrogens and sometimes corticosteroids. Approximately 25% of adult patients suffer from loss of libido and impotence due to synthesis of estrogens by LCT.

- Prepubertal Leydig cell tumor synthesizes testosterone, in which penile growth, pubic hair and precocious puberty are the most common presenting symptoms, followed by deep voice and facial acne.
- About 20% of patients with malignant LCTs have already metastasizing to retroperitoneal lymph nodes and via hematogenous route to lungs (43%), liver (38%) and bones (28%) at the time of diagnosis.
- Malignant LCT is resistant to chemotherapy. Hence, the patient is treated by orchidectomy with retroperitoneal lymph nodes dissection (RPLND) and chemotherapy. Patient has fatal outcome within six months.

Surgical Pathology: Leydig Cell Tumor of Testis

Gross Morphology

- On gross examination, Leydig cell tumors are on average 2–3 cm (range: 0.5–10 cm).
- Tumor is well circumscribed nodule due to presence of fine thin fibrous capsule. It forms a golden-brown nodule within the body of the testis and homogenous on cut surface; and also, at metastatic sites.
- Tumor with a diameter of ≥5 cm is almost without exception malignant.

Light Microscopy

Benign Leydig Cell Tumor

- Benign Leydig cell tumor is composed of large round or polygonal cells arranged in sheets or tubules or trabecular pattern.
- Tumor cells have distinct borders, abundant granular deeply eosinophilic cytoplasm and round to oval nuclei with prominent nucleoli. Multiple nuclei may be present in few tumor cells.
- Tumor cells contain intracytoplasmic rod-shaped Reinke crystals demonstrated with Masson trichrome stain.
- The stroma is scant with a network of capillaries typical of endocrine tumors. Some tumors are composed of spindle cells with abundant intracytoplasmic lipids.
- Psammoma bodies and calcifications can be demonstrated in these tumors (Fig. 23.35).

Malignant Leydig Cell Tumor

- Malignant Leydig cell tumor measures about 7 cm in size. Tumor is composed of polymorphic spindled cell shape tumor cells with nuclear atypia and frequent mitoses, areas of necrosis, vascular invasion and invasion of surrounding tissues.
- The number of proliferating tumor cells is also more in malignant Leydig cell tumor demonstrated by proliferative Ki-67/MIB-1 marker.
- Diagnostic criteria for malignancy in Leydig cell tumor and Sertoli cell tumor are given in Table 23.22.

Immunohistochemistry Technique

Panel of markers is performed on paraffin-embedded sections from Leydig cell tumor.

Markers	Expression
Inhibin and calretinin	Positive (97%)
Melan A	Positive (94%)
SF1	Positive (92%)
CD99	Positive (74%)
Synaptophysin	Positive (65%)
β-Catenin	Positive (50%)
S-100	Positive (28%)
Cytokeratin	Positive (22%)
FOXL2	Positive (21%)

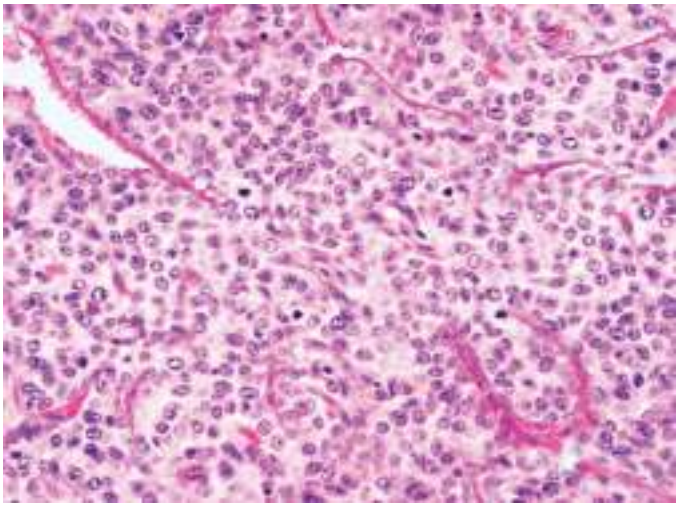

Fig. 23.35: Leydig cell tumor. Leydig cell tumor is composed of large round or polygonal cells arranged in sheets or tubules or trabecular pattern. The tumor cells have distinct borders, abundant granular deeply eosinophilic cytoplasm and round to oval nuclei with prominent nucleoli. Multiple nuclei may be present in few tumor cells. These cells contain intracytoplasmic rod-shaped Reinke crystals demonstrated with Masson trichrome stain. The stroma is scant with as network of capillaries typical of endocrine tumors. Some tumors are composed of spindle cells with abundant intracytoplasmic lipids (400X).

Table 23.22 Diagnostic criteria for malignancy in Leydig cell tumor and Sertoli cell tumor

Features	Leydig Cell Tumor	Sertoli Cell Tumor
Gross morphology		
Tumor size >5 cm	Present	Present
Histologic features		
High mitotic count numerous (normal average 1.9/HPF)	Present	Present
Spindled shape pleomorphic malignant cells	Present	Present
Nuclear atypia	Present	Present
Areas of necrosis	Present	Present
Vascular invasion by tumor cells	Present	Present
Invasion of surrounding tissues by tumor cells	Present	Present

DNA Ploidy and Cytogenetics in Leydig Cell Tumor

Leydig cell tumors can demonstrate gain of chromosome X, or 19p, and loss of chromosomes 8 and 16. LH-receptor gene mutations may be detected.

Clinical Behavior

About 90% of Leydig cell tumors are benign in adults, while 10% have a potential for invasion and metastases. Only the diameter of tumor is a reliable prognostic factor in adults and not in infants. Poor prognostic factors are tumor size >5 cm, high mitotic count (normal 1.9/HPF), spindled cell shape, nuclear atypia and polymorphism, necrosis, vascular invasion and invasion of surrounding tissue.

OTHER MALIGNANT TUMORS OF TESTIS

Testicular Lymphoma

Primary testicular lymphomas constitute 5% of testicular neoplasms. Primary testicular lymphoma most commonly represents dissemination from extratesticular sites, although is occasionally in primary testicular neoplasm.

- Testicular lymphoma is a disease of elderly persons with mean age of 60–70 years. Patient presents with testicular swelling, fever and weight loss. Children are more to develop follicular lymphoma than adults.
- Bilateral testicular involvement in a patient over 60 years should suggest systemic non-Hodgkin's lymphoma rather than primary germ cell tumors.
- Treatment involves multimodality approach involving surgery, chemotherapy and radiotherapy. Outcome remains poor in spite of aggressive therapy.
- Diffuse large B cell lymphoma (DLBCL) is relatively common and represents 30–58% of non-Hodgkin's lymphomas. Most DLBCLs originate in lymph nodes, but 40% initially present in extranodal sites such as testes and central nervous system. DLBCL is diagnosed by clinical history, physical examination, molecular analysis, and immunophenotyping.

Surgical Pathology: Testicular Diffuse Large B Cell Lymphoma

Gross Morphology

On gross examination, the diffuse large B cell lymphoma tumor replaces testicular parenchyma as fleshy gray to tan pink neoplasm that resembles seminoma.

Light Microscopy

- The most important clue to the diagnosis occurs at scanning magnification where an interstitial pattern, with relative tubular preservation is identified.
- The tumor cells of DLBCL are large 45 times diameter of small lymphocytes with round to oval nucleus, with either 2–3 nucleoli located adjacent to the nuclear membrane or a single nucleolus centrally placed and moderate pale or basophilic cytoplasm.
- Mitoses are frequent. Tumor cells are arranged in diffuse pattern. More anaplastic tumors may contain multinucleated Reed-Sternberg-like cells with large, inclusion-like nucleoli, and these may be termed immunoblastic lymphoma (Fig. 23.36A).

Immunophenotyping

The tumor cells often mark with CD19, CD20, CD22, CD45 and CD79a. Most express surface immunoglobulin (Fig. 23.36B).

Markers	Expression
CD19	Positive
CD20	Positive
CD22	Positive
CD45	Positive
CD79a	Positive

Treatment

Diffuse large B cell lymphoma of the testis is treated with orchiectomy and chemotherapy, sometimes combined with radiation therapy.

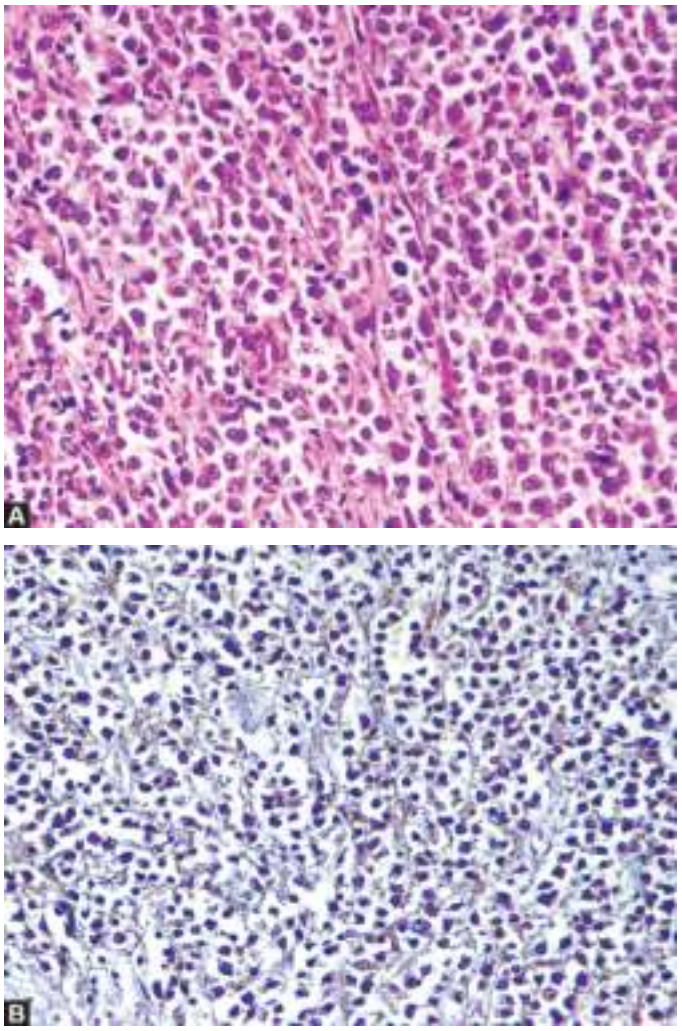

Fig. 23.36: (A) Diffuse large lymphoma of testis (H&E staining 400X), (B) neoplastic cells show CD45+ staining (immunohistochemistry).

Testicular Plasmacytoma

Testicular plasmacytoma is rare neoplasm. It is most commonly a manifestation of diagnosed case of multiple myeloma in 2% of cases.

- Testicular plasmacytoma is occult and apparently an isolated finding on autopsy. Mean age is approximately 55 years.
- Diagnosis of multiple myeloma is based on the combination of clinical, morphologic, radiological and immunological findings.
- On gross examination, testicular plasmacytoma is usually soft and fleshy, tan to gray white and often with foci of hemorrhage.
- Histologic features of testicular plasmacytoma are similar to those of plasmacytomas at other sites. Mature clonal plasma cells measure 20–30 μm in diameter with abundant cytoplasm and eccentrically placed nuclei with dense clumped chromatin giving cartwheel appearance. The seminiferous tubules are effaced centrally but preserved at the periphery of the tumor.
- Some seminomas may have a plasmacytoid morphology and also show intratubular growth, potentially mimicking plasmacytoma.
- The presence of germ cell *in situ* neoplasia indicates seminoma over plasmacytoma.
- The presence of OCT3/4 indicates seminoma over plasmacytoma.

Leukemic Infiltration and Myeloid Sarcoma of Testis

Leukemic infiltration in the testes most often occurs in the course of acute myelogenous/lymphoblastic leukemias (40–65%) of patients and chronic lymphocytic leukemia (20–35%).

- Testicular involvement is generally occult. It is clinically evident in 5% of cases. Testicular involvement at clinical presentation is seen in 2% of cases.
- Boys with acute lymphoblastic leukemia are more prone to develop bilateral testicular involvement with a positive biopsy even in otherwise complete clinical and bone marrow remission in 5% of cases.
- The major differential diagnosis includes orchitis, plasmacytoma, lymphoma and seminoma.
- On gross examination of testes in acute lymphoblastic leukemia resembles lymphoma (Fig. 23.37).
- On histologic examination, myeloid sarcoma may be mistaken for lymphoma and plasmacytoma.
- Radiotherapy is most effective in controlling the testicular involvement, but bone marrow relapse will develop in most cases.
- Myeloid sarcoma is tumorous myelogenous leukemia infiltrates in testes and other tissues outside bone marrow.

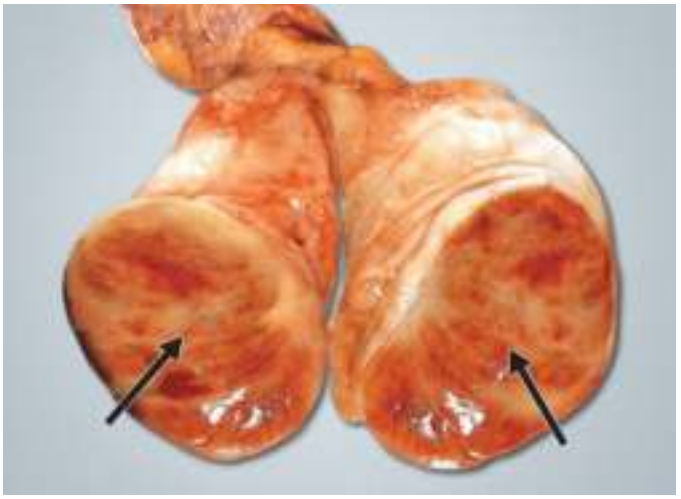

Fig. 23.37: Acute lymphoblastic leukemia infiltrating both testes. The normal testicular tissue has been completely replaced by creamy, slightly hemorrhagic tumor tissue. When patients have responded to chemotherapeutic treatment of acute lymphoblastic leukemia, the first manifestation of recurrence is frequently in the testes (arrows).

Metastases in Testis

Metastases of the testis frequently occur in patients with a known malignancy in prostate, lung, stomach, colon, kidney, urinary bladder, pancreas and others including melanoma.

- Neuroblastoma, rhabdomyosarcoma and Wilms' tumor in children may also metastasize to testes. In some instances, testicular mass may be presenting feature of an occult neoplasm.
- Prostatic adenocarcinoma may extensively involve the rete testis. Prostatic adenocarcinoma metastasizing to testes has better prognosis than involving penis. Some high-grade prostatic carcinomas may prominently grow within the seminiferous tubules as well as the interstitium and resemble seminoma. Intratubular growth of urothelial carcinoma may mimic intralobular embryonal carcinoma.
- Metastatic renal cell carcinoma of clear cell can be misinterpreted as Sertoli cell tumor. Melanoma may have foamy cytoplasm that resembles that of Leydig cell tumor. Melanoma with discohesive cells between tubules may simulate lymphoma. Most frequent sites of primary tumors metastasizing to the testes are given in Table 23.23.

NEOPLASTIC DISORDERS OF MESOTHELIUM

ADENOMATOID TUMOR

Adenomatoid tumor is the most common benign tumor of testicular adnexa, which represents almost 60% of cases. Tumor is of mesothelial origin. Adenomatoid tumor arises in upper or lower pole of the epididymis.

Table 23.23 Most frequent sites of primary tumors metastasizing to the testes

Primary Tumors	Frequency
Malignancy in adults	
Prostatic adenocarcinoma	35–60%
Lung carcinoma	5–15%
Melanoma	9–15%
Colon carcinoma	5–9%
Renal cell carcinoma	5–9%
Gastric carcinoma	4%
Miscellaneous tumors	1–10%
Malignancy in children	
Neuroblastoma	Some patients
Rhabdomyosarcoma	Some patients
Wilms' tumor	Some patients

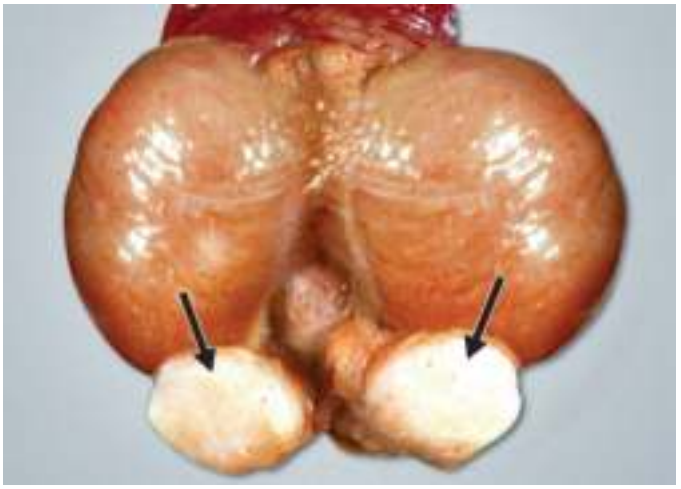

Fig. 23.38: Adenomatoid tumor of the epididymis. There is a creamy, well circumscribed tumor in the epididymis (arrows).

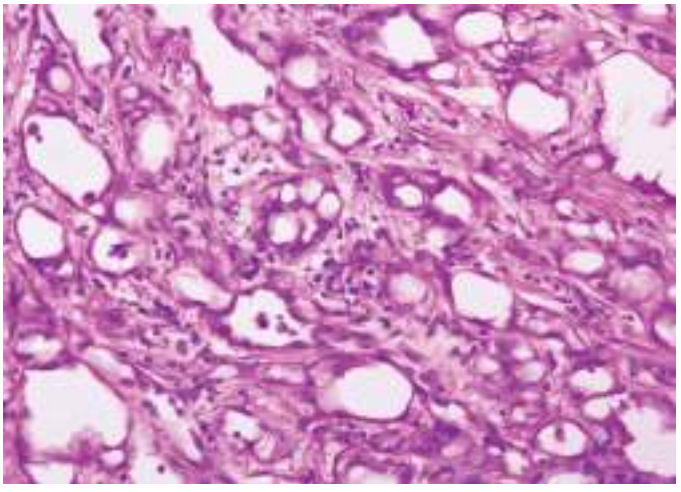

Fig. 23.39: Adenomatoid tumor of the epididymis. Tumor is composed of round to oval or slit-like tubules in fibrous, hyalinized, and/or muscular stroma. The lining cells are columnar or flat having vacuolated cytoplasm (400X).

Surgical Pathology: Adenomatoid Tumor
Gross Morphology
Tumor is solitary, round to oval in shape measuring 5 cm in diameter (Fig. 23.38).
Light Microscopy
Tumor is composed of round to oval or slit-like tubules in fibrous, hyalinized, and/or muscular stroma. The lining cells are columnar or flat having vacuolated cytoplasm (Fig. 23.39).
Immunohistochemistry Technique
Tumor cells are immunoreactive for expression of cytokeratin, calretinin, EMA and WT1. Tumor cells are negative for factor VIII-related antigen and CD31, a profile indicating mesothelial origin rather from vascular endothelium.

Markers	Expression
▪ Cytokeratin	▪ Positive
▪ Calretinin	▪ Positive
▪ Epithelial membrane antigen (EMA)	▪ Positive
▪ WT1	▪ Positive
▪ Factor VIII-related antigen	▪ Negative
▪ CD51	▪ Negative

NON-NEOPLASTIC DISORDERS OF MESOTHELIUM

TESTICULAR TORSION

Testicular torsion is a true surgical emergency with a peak presentation in adolescence between 12 and 16 years of age.

- Faulty anchoring of testis on wall of the scrotum allows testis to rotate. As the testicle twists around the spermatic cord, venous blood flow is cut off, resulting in venous congestion, hemorrhage and ischemic necrosis of the testicle. The testicle will become tender, swollen.
- Ultrasonography is the primary diagnostic modality beyond physical examination of testicular torsion. It is approximately 93% sensitive and 100% specific. Doppler can be employed to evaluate for both venous and arterial flow.
- Patient presents with excruciating sudden pain in the testis, swelling scrotal region, nausea and vomiting.
- On physical examination, scrotal swelling and diffuse testicular tenderness is universal. Cremasteric reflex is absent on affected side.
- On gross examination, torsion testis becomes enlarged, necrotic and hemorrhagic (Fig. 23.40).
- Histologic examination reveals hemorrhage and necrosis of seminiferous tubules and interstitial tissue.

Fig. 23.40: Testicular torsion. On gross examination, torsion testis becomes enlarged, necrotic, hemorrhagic with blackish discoloration.

HYDROCELE

Hydrocele is an abnormal collection of serous fluid between the visceral and parietal layers of the tunica vaginalis covering the testes in the scrotum and/or along the spermatic cord.

- In the normal scrotum 1–2 ml of serous fluid may be observed in the potential tunica vaginalis cavity and should not be mistaken for hydrocele. In most cases, underlying cause of hydrocele is idiopathic.
- Congenital hydrocele occurs due to persistence of continuity of the tunica vaginalis with the peritoneal cavity. It is the most common cause of scrotal swelling in infants often associated with inguinal hernia.
- Acquired hydrocele occurs in adults secondary to infection, lymphatic obstruction by tumor or trauma affecting scrotum.
- Positive transillumination test differentiates hydrocele from testicular tumors. Preoperative ultrasound is widely used to diagnose hydrocele in adults.

HEMATOCELE

Hematocele is accumulation of blood between the visceral and parietal layers of the tunica vaginalis covering the testes in the scrotum and/or along the spermatic cord. Hydrocele is commonly associated with a history of scrotal trauma, usually characterized by scrotal pain and acute onset. It may be caused in the setting of testicular tumors and infections. Rarely, hematocele can be idiopathic with a mild onset, following spontaneous bleeding.

SPERMATOCELE

Spermatocele is a spermatozoa-containing cyst formed from the protrusions of widened efferent ducts of the rete testis or epididymis. The exact cause of spermatoceles is not clear, but they might be due to a blockage in one of the tubes that transport spermatozoa. Spermatocele is located above and posterior to the testis and attached to the epididymis, but separate from the testes. Most spermatoceles are small. A spermatocele causes no symptoms and might remain stable in size. Large size spermatocele may cause pain or discomfort in the affected testis. Spermatocele is unlikely to cause complications. Large size spermatocele is treated by surgery.

VARICOCELE

Varicocele results from dilation of the multiple veins of the spermatic cord. Patient presents with nodularity on the lateral side of the scrotum. Most patients are asymptomatic and discovered during routine physical examination.

- Varicocele is palpated as a bag of worms. It is considered a common cause of male infertility and oligospermia due to unknown reason.
- Surgical resection of varicocele by ligation of the internal spermatic vein often improves reproductive function.

MALE HYPOGONADISM

Male hypogonadism refers to failure of the Leydig cells to produce testosterone, failure of seminiferous cells to generate spermatozoa, or an abnormality in androgen receptors.

- Approximately 90% of male infertility is due to hypogonadism resulting in impaired spermatogenesis in the presence of normal production of testosterone (seminiferous tubule dysfunction).
- Primary hypogonadism involves testicular problems in synthesizing testosterone in the Leydig cells (increased LH levels, decreased spermatozoa count, normal FSH) or generating spermatozoa in the seminiferous tubules [increased FSH (decreased inhibin), low sperm count, normal LH and testosterone].
- Secondary hypogonadism refers to disorders in the pituitary hypothalamic axis or to receptor deficiencies.

MALE IMPOTENCE

Male impotence is defined as persistent inability to obtain an erection during attempted sexual intercourse, which occurs in 10–35% of adult men. Testosterone deficiency accounts for 15–20% of cases. Other causes of male impotence include psychological problems, autonomic neuropathy, endocrine disease (hypothyroidism, hypopituitarism) or drugs.

- The most useful finding that excludes an organic cause of male impotence is the presence of nocturnal penile tumescence (erections that normally occur during sleep).
- Drugs associated with male impotence include tranquillizers (phenothiazines), lithium, sedatives (barbiturates or benzodiazepines), antihypertensive drugs (methyl dopa or debrisoquine or clonidine), alcohol, estrogens and drug abuse (heroin or methadone).

CRYPTORCHIDISM

In majority of these infants, the testis will descend into the scrotum during the first year of life. Cryptorchidism is developmental failure of a testis to descend into the scrotum especially in premature newborns. According to their location, the cryptorchid testes can be classified as abdominal, inguinal, or upper scrotal. Anorchia refers to congenital absence of testes. Cryptorchidism is associated with testicular atrophy and sterility. There is increased incidence of germ cell tumors such as seminoma and embryonal carcinoma, even if the testis is surgically moved from its ectopic location back to the scrotum. It is the most common urologic disorder requiring surgical treatment in infants.

TESTICULAR ATROPHY

Testicular atrophy occurs due to mumps orchitis, trauma, Klinefelter's syndrome (47,XXY) as a result of meiotic nondisjunction during oogenesis, chronic debilitating disease, cryptorchidism, old age and hormonal imbalance. Hormonal excess or deficiency occurs due to disorders of hypothalamus or pituitary, cirrhosis of liver and estrogen therapy. Klinefelter's syndrome is characterized by infertility, and the testicular atrophy and loss of meiotic and postmeiotic germ cells.

On gross examination, testes are small and brown in adults. On histologic examination, the testicular seminiferous tubules are atrophic, and their basement membrane is greatly thickened and hyalinized. Scattered patent seminiferous tubules with markedly thickened walls are present, but may contain only Sertoli cells and absence of germ cell elements. The Leydig cells are prominent; some of them may be present inside the tubules.

MALE PSEUDOHERMAPHRODITISM

Male pseudohermaphroditism is congenital disorder also known as testicular feminization syndrome, which occurs due to a congenital deficiency of the androgen receptor. Males have a normal 46XY karyotype. Patient presents with cryptorchid testes, but the external genital organs appear feminine or ambiguously female, with signs of virilization. Patients with congenital adrenal hyperplasia have a normal 46XX karyotype.

DISORDERS OF PROSTATE GLAND

ANATOMY AND HISTOLOGY—PROSTATE

Prostate gland is located at the base of urinary bladder. The seminal vesicles are located posterior to the prostate. The urethra exits from the urinary bladder and traverses the prostate gland before exiting to the penile urethra. A thin layer of connective tissue surrounding prostate merges with surrounding soft tissues, including nerves. There is no distinct capsule. Normal weight of prostate gland is 20 g for 20–50 years and 30 g for 60–80 years.

- Prostate gland comprises glandular and nonglandular components. Based on presence of group of glands, the prostate gland is subdivided into three main glandular zones: (a) peripheral zone, (b) the central zone, and (c) the transition zone, and in addition a smaller periurethral gland region.
  - The peripheral zone constitutes 70% of the prostate gland. The ducts protrude from the lateral side and posteriorly from the urethral wall. Most prostatic carcinomas arise in the peripheral region.
  - The central zone forms about 25% of the prostate gland and the ducts surround the ejaculatory ducts which lie in the distal urethra. Prostatic carcinoma rarely arises in the central zone. The transition zone constitutes 5% of the prostate.
- Benign nodular hyperplasia (BPH) occurs in the transition zone which lies in the angular region of the urethra between the verumontanum and the urinary bladder neck. The periurethral gland region consists of small ducts and acini, which stain for prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP). The nonglandular component of prostate gland is composed of periprostatic sphincter, striated sphincter, anterior fibromuscular stroma and prostatic gland capsule (Fig. 23.41).
- The basic function of the prostate gland is to synthesize proteins into the seminal vesicle fluid.
- The prostate gland develops from the urogenital sinus during embryogenesis, and differentiation process requires the interaction of epithelial cells with the mesenchyme.
- Dihydrotestosterone (**DHT**) is the primary androgen responsible for stimulation of glands and stroma in the prostate via androgen signaling pathway.
- Prostate gland is composed of tubuloalveolar glands and supporting fibromuscular stroma in equal proportions. The glands are radiating from the urethra. The luminal glands are lined by two cell layers, i.e. outer cuboidal cells and inner tall columnar mucin-secreting epithelium, forming inward papillary projections. The glandular component synthesizes laminated concretions of prostatic gland secretions known as corpora amylacea within the glandular lumina. The prostate epithelium consists of three types of cells: luminal, basal and neuroendocrine glands.
  - The luminal cells are secretory cells, which synthesize seminal vesicle fluid. Luminal cells also demonstrate androgen receptor, cell surface markers such as CD57 and PSA.
  - The basal cells do not possess secretory function. Basal cells express antiapoptotic genes such as BCL-2 and DNA damage protecting genes such as p53 related protein, c-Met, and prostatic stem cell antigen (PSCA).
  - Neuroendocrine cells are also present in small proportion in all prostatic gland zones.
- Most common prostatic gland sampling is done by needle biopsy, transurethral resection of prostate

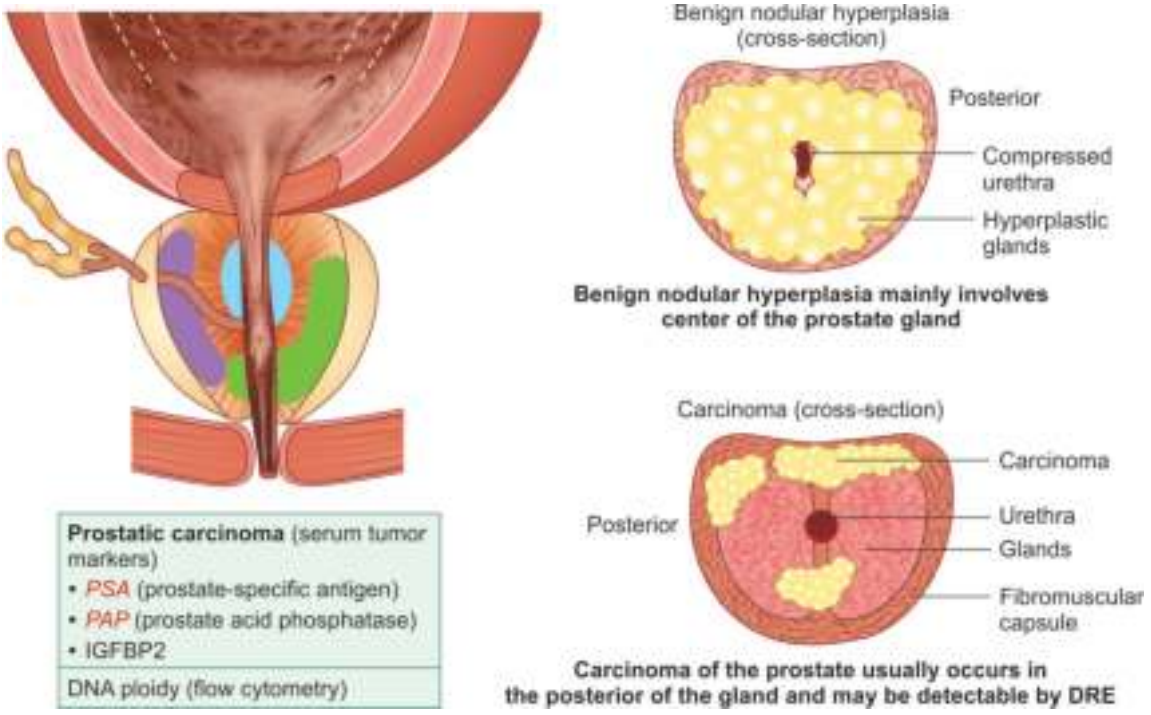

Fig. 23.41: Prostate gland shows site of benign nodular hyperplasia and prostatic adenocarcinoma with serum tumor markers (prostate-specific antigen, prostate acid phosphatase, IGFBP2) and flow cytometry DNA ploidy.

(TURP), fine needle aspiration cytology, open simple and radical prostatectomy. Needle biopsy and prostate chips are fixed in 10% neutral buffered formalin.

INFLAMMATORY DISORDERS—PROSTATE

Inflammatory disorders of prostate gland include acute bacterial prostatitis, asymptomatic inflammatory prostatitis, chronic prostatitis and nonspecific granulomatous prostatitis. Clinical manifestations and elevated serum PSA may mimic prostatic carcinoma. Physician must perform digital rectal examination. Urine examination should be performed to rule out urinary tract infection.

ACUTE BACTERIAL PROSTATITIS

Acute bacterial prostatitis is the most common urologic disease in males younger than 50 years usually associated with urinary bladder outlet obstruction secondary to benign nodular hyperplasia or an immunocompromised person. Urinary tract infection by coliform organisms as well as *Neisseria gonorrhoeae* results into acute prostatitis and may be associated with some dysuria. On histologic examination, the prostatic glands are filled with neutrophils, and the intervening prostatic stroma may also contain a few neutrophils (Fig. 23.42).

ASYMPTOMATIC INFLAMMATORY PROSTATITIS

Asymptomatic inflammatory prostatitis is characterized by the incidental finding of prostatic inflammation without genitourinary complaints. The disorder is diagnosed during a workup for infertility and elevated serum PSA level. The disorder can produce elevated white blood cells in the ejaculate (leukocytospermia) and can cause male infertility, if left untreated.

CHRONIC PROSTATITIS

Chronic prostatitis affects men under the age of 50 years with or without clinical symptoms, which has negative impact on quality of life, as it difficult to treat owing to its wide symptomatology. It may follow acute bacterial prostatitis. *Chlamydia trachomatis* bacteria may also cause chronic prostatitis. Patient presents with dysuria along with low-grade pelvic pain or low back pain. Prostatic stroma is infiltrated by lymphocytes, plasma cells, and macrophages (Fig. 23.43).

NONSPECIFIC GRANULOMATOUS PROSTATITIS

Nonspecific granulomatous prostatitis probably occurs in response to prostatic gland secretions released into the prostatic stroma due to rupture of the ducts and acini. It consists of a lobular inflammatory infiltrate composed of lymphocytes, plasma cells, foamy histiocytes, and small number of neutrophils. In the early stages, a dilated prostatic duct is evident.

- The disorder causes symptoms of obstruction and infection of the urinary tract.
- In nonspecific granulomatous prostatitis, prostatic nodularity on palpation is accompanied by elevated PSA clinically mimic prostatic carcinoma.
- It is worth mentioning that nonspecific granulomatous prostatitis must be differentiated from other specific cause of prostatitis. Mycobacterial prostatitis produces caseating granuloma. Allergic prostatitis is associated with allergic disorders such as bronchial asthma. Post-biopsy granulomas consist of a central region of fibrinoid necrosis surrounded by palisaded histiocytes in prostate gland. Nonspecific granulomatous prostatitis is shown in Fig. 23.44.

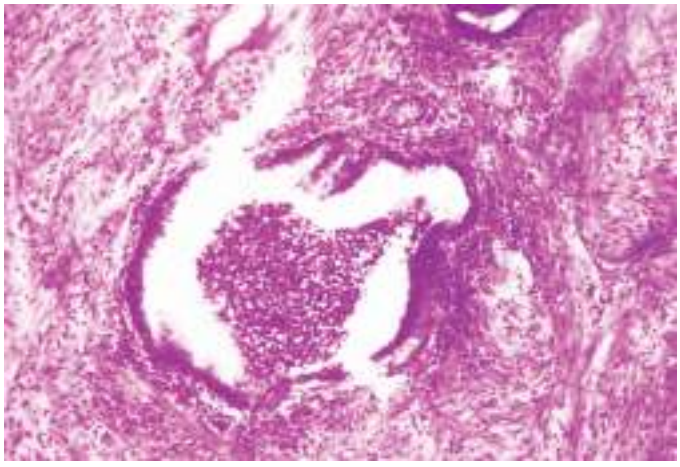

Fig. 23.42: Acute prostatitis. Prostatic glandular luminal space is filled with neutrophils. Neutrophilic infiltrate is also seen in the prostatic stroma (400X).

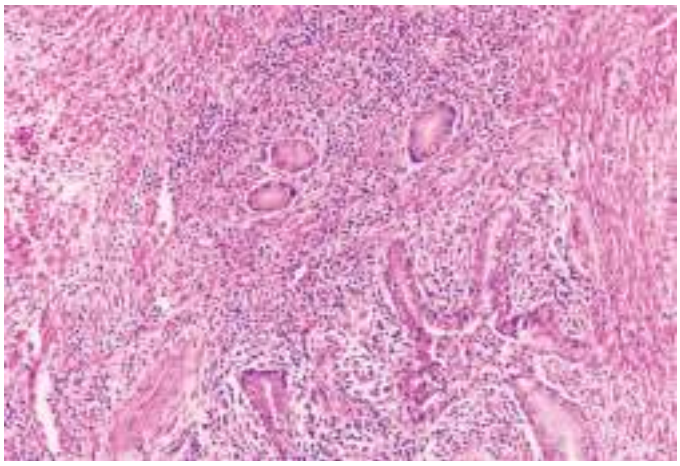

Fig. 23.43: Chronic prostatitis, no specific. There is prominent periductal inflammation. The inflammatory infiltrate is composed of lymphocytes and histiocytes (400X).

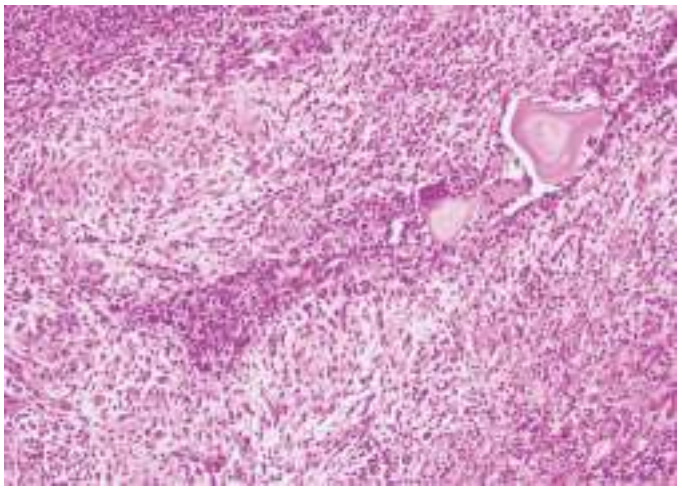

Fig. 23.44: Nonspecific granulomatous prostatitis. There is polymorphous infiltrate of lymphocytes, macrophages, plasma cells, neutrophils, multinucleated giant cells and occasional eosinophils (400X).

XANTHOGRANULOMATOUS PROSTATITIS

Xanthogranulomatous prostatitis is benign inflammatory rare disorder of prostate gland that can clinically and even biochemically with elevated PSA mimic prostatic carcinoma.

- A high degree of suspicion and close co-operation with histopathologist is necessary for the diagnosis of xanthogranulomatous prostatitis.
- Generally, xanthogranulomatous inflammatory prostatitis is observed in kidney and gallbladder and very rarely in the prostate gland. In xanthogranulomatous prostatitis, histiocytes are observed in large amounts of inflammatory infiltrate, that is accompanied by numerous lymphocytes and plasma cells.
- Presence of numerous histiocytes in the prostatic biopsy may be misdiagnosed as prostatic adenocarcinoma with hypernephroid pattern (Gleason 4B).

BENIGN NODULAR HYPERPLASIA OF PROSTATE GLAND

Benign nodular hyperplasia of prostate gland is also known as benign prostatic hypertrophy (BPH). It is detected in 20% at age 40 years, 50% at age 50 years and 70% at age 60 years. It primarily affects periurethral and transitional zones. Involvement of periurethral portion of the prostate gland compresses urethra side to side resulting in a vertical slit.

It is the most common cause of urinary tract obstruction. Digital rectal examination reveals a firm, enlarged, and nodular prostate gland.

PATHOGENESIS

It has been established that benign nodular hyperplasia of prostate gland occurs in persons with intact testes and it is considered as an androgen-dependent disorder. It has been suggested that benign nodular hyperplasia of prostate gland may result from an initial activation of mesenchymal clones and embryonal functions that stimulate its development of the glandular component. In turn, it may result from dihydrotestosterone (DHT) within the prostate gland due to decreased catabolism of DHT molecule and enhanced intracellular binding to nuclear for DHT receptors and triggering prostatic hyperplasia of both glandular and fibromuscular stromal elements.

- Dihydrotestosterone is a major growth factor for prostate gland. DHT is derived from testosterone by the action of 5α-reductase enzyme.
- Therapeutic administration of drug inhibiting 5α-reductase enzyme is useful in the medical management of nodular hyperplasia of prostate gland.
- Age-related increase in estrogens level also plays an indirect role by stimulating the production of DHT receptors. The estrogens promote expression of nuclear receptors for DHT in prostate gland.
- The α-adrenergic blockers cause relaxation of smooth muscle in prostate and help in relieving obstruction.

CLINICAL FEATURES

Patient's symptoms are related to urethral obstruction of urine outflow. Patient presents with frequency of micturition, difficulty in urination, nocturia, dribbling, incomplete emptying of urinary bladder and dysuria.

- Persistent urethral obstruction to urine outflow may result in urinary bladder distension, muscular hypertrophy, and formation of diverticulum and trabeculae.
- Urine retained inside a diverticulum of urinary bladder is often infected, a complication that may lead to the formation of urinary bladder stones. There is risk for urinary tract infection, hydroureter, hydronephrosis and renal failure (Fig. 23.45).

Surgical Pathology: Benign Nodular Hyperplasia of Prostate Gland

Gross Morphology

- Benign nodular hyperplasia of prostate gland occurs in periurethral and transitional zones, that compresses urethra side to side resulting in a vertical slit space. The nodular lesion can be large, discrete in periurethral region, weighing 50–100 g (normal 20–30 g).
- Cut surface of benign nodular hyperplasia of prostate gland shows solid and cystic areas, yellow-pink and soft in consistency with oozing of prostatic fluid.
- Prostatic stromal hyperplasia is gray-white nodules of variable sizes with rubbery consistency (Fig. 23.46).

Light Microscopy

Histologically, benign nodular hyperplasia of prostate gland is diagnosed on samples like transurethral resection of prostate (TURP) chips, simple or radical prostatic specimens. It should not be diagnosed in needle biopsy samples.

- The earliest change in benign nodular hyperplasia of prostate gland is a stromal proliferation about small sinusoidal spaces in the periurethral regions and to a lesser degree, in the periductal and intralobular areas. The lesion begins around urethra where ejaculatory ducts enter the prostatic transitional or periurethral zone. Stromal changes include increase in smooth muscle and reduced elastic tissue.
- Benign nodular hyperplasia of prostate gland is composed of hyperplasia of glands and stroma in variable proportions forming papillary buds, infoldings and cysts.
  - The lining epithelium ranges from flat to columnar, sometimes facing each other in the same gland.
  - Basal layer is demonstrated immediately above a sell-developed epithelium. It is associated with squamous metaplasia and infarction.
  - The glands are dilated or even cystic and containing an inspissated secretion of glycoprotein nature (corpora amylacea), which is sometimes calcified.
  - Small clusters of lymphocytes are demonstrated in the interstitial tissue and around the ducts.
  - Many morphologic variants occur due to proliferation of one component over the other component (Fig. 23.47A and B).
- Mixed epithelial (glandular) and stromal hyperplasia in various proportions are present. The glands show irregular sized glandular spaces lined by epithelium, i.e. inner columnar layer and outer flattened myoepithelial cell layer.
- Pure stromal nodules are uncommon and composed of hyalinized leiomyomatous nodules with spindled or myxoid (stellate cells).

TREATMENT

The treatment of benign nodular hyperplasia of the prostate gland includes medical or surgical treatment. Medical treatment includes administration of medicines aimed at blocking the actions of androgens such as dihydrotestosterone (DHT) by preventing their secretion or their conversion to active form in tissue, or at relaxing stromal muscle cells. The nodular region of prostate is excised by various techniques such as transurethral resection of prostate (TURP), suprapubic prostatectomy and laser enucleation. It is worth mentioning that these procedures remove only the newly formed nodules.

NEOPLASTIC DISORDERS OF PROSTATE

The prostate gland is the most common site of neoplastic disorders in men. Prostatic intraepithelial neoplasia lesion is regarded as a precursor lesion, which undergoes neoplastic transformation of prostatic epithelium. Intraductal prostatic carcinoma can undergo invasive and metastatic prostatic carcinoma, which is characterized by unpredictable biologic behavior, and a long latency before diagnosis.

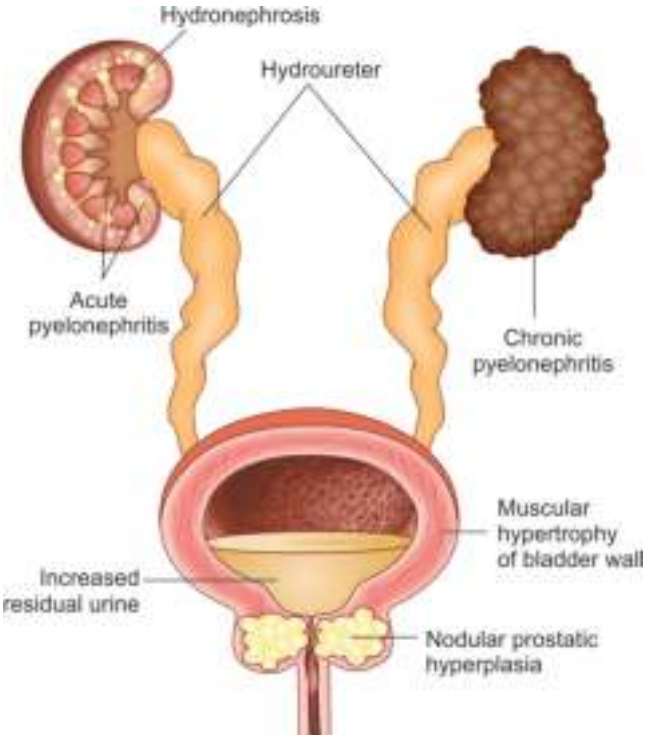

Fig. 23.45: Benign nodular hyperplasia of prostate. Persistent obstruction to urine outflow has produced hydroureter, hydronephrosis and acute pyelonephritis.

Fig. 23.46: Nodular hyperplasia of prostate. The prostate is considerably enlarged. Its cut surface shows a creamy, lobulated solid and cystic areas appearance.

PROSTATIC INTRAEPITHELIAL NEOPLASIA

Proliferation of luminal cells of the ducts with dysplasia results in prostatic intraepithelial neoplasia (PIN). PIN

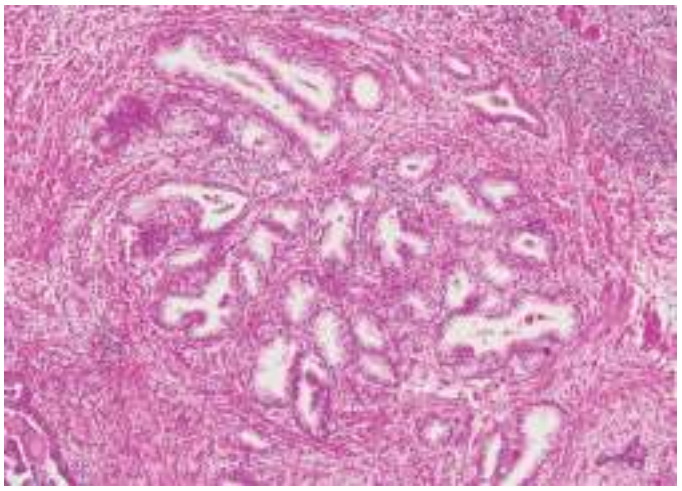

Fig. 23.47A: Benign nodular hyperplasia prostate. The acini are relatively uniform and evenly spaced. The acini are lined by columnar secretory cells. The basal cell layers may be inconspicuous, but may be highlighted by high molecular weight cytokeratin immunohistochemical stain (400X).

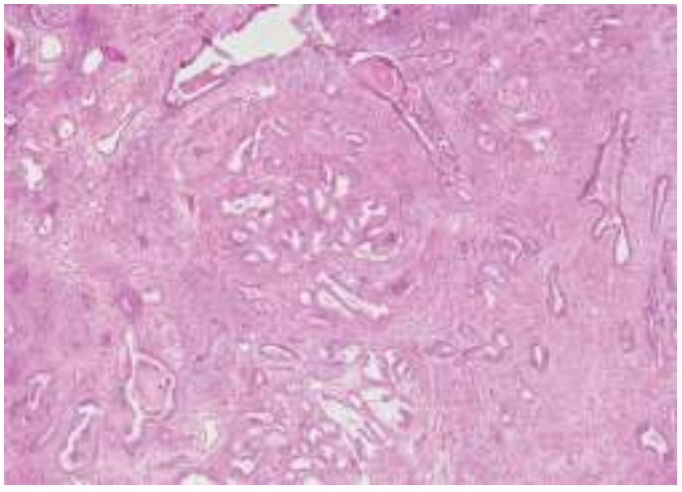

Fig. 23.47B: Benign nodular glandular hyperplasia of prostate gland. The lesion is composed of variably sized glandular structures lined by basal and secretory cells. Glands demonstrate dilatation with papillary infoldings and cysts, often containing corpora amylacea and sometimes calcification. Epithelial lining ranges from flat to columnar, with pink pale cytoplasm, regular, centrally located nuclei and inconspicuous nucleoli (400X).

occurs in two forms: low-grade PIN (**LGPIN**), or high-grade PIN (**HGPIN**). The basal layer is intact in LGPIN but absent in HGPIN. A key immunohistochemical marker protein to indicate the presence or absence of the basal cell layer is the antikeratin stain 34bE12.

- In general, HGPIN is considered to be a precursor of invasive prostatic adenocarcinoma. Changes accumulating in LGPIN and HGPIN evolve in intraductal and invasive prostatic adenocarcinoma.
- Digital rectal examination, transrectal ultrasound scan (TRUS), transurethral resection of prostate (TURP), and PSA analysis may be used to detect PIN.

Genetic Alterations and Immunohistochemical Markers: Transition of HGPIN to Prostatic Adenocarcinoma

- Some of the immunohistochemical marker, oncoproteins are amplified and involved in the transition of HGPIN to prostatic adenocarcinoma, which include BCL-2, C-erb B2, C-erb B3, c-Met, racemase, telomerase, AMACR and PSCA.
- Secretory immunohistochemical marker proteins such as prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP) are downregulated in advanced PIN and invasive prostatic adenocarcinoma.
- Common allelic loss in chromosomal loci of 8p, 10q, and 16q are demonstrated in prostatic intraepithelial neoplasia (PIN) and invasive prostatic adenocarcinoma. Epigenetic regulation of GSTP1 where promoter is hypermethylated observed in both PIN and invasive prostatic adenocarcinoma.

INTRADUCTAL AND INVASIVE PROSTATIC ADENOCARCINOMA

It is generally accepted that dysplastic precursor lesion, i.e. HGPIN in prostatic ducts progresses to intraductal and invasive prostatic adenocarcinoma.

- In intraductal prostatic adenocarcinoma, the lumen of ducts and acini are filled with malignant cells with preservation of basal cells with solid or dense cribriform pattern or loose cribriform or micropapillary pattern with either marked nuclear atypia and comedonecrosis. In invasive prostatic adenocarcinoma, neoplastic cells invade basal cell layer as compared to HGPIN and intraductal prostatic adenocarcinoma. Invasive prostatic adenocarcinoma most often arises from the peripheral group of glands (ducts and acini) of prostate gland in elderly persons of >50 years of age. There is no evidence that prostatic adenocarcinoma originates from nodular hyperplasia prostate.
- The primary known major risk factors for prostatic adenocarcinoma are older age, strong family history, obesity, dietary factors (excessive consumption of saturated fat, milk products, calcium), obesity, hypertension, lack of exercise, persistently elevated testosterone levels, exposure to 'agent orange' (rainbow herbicide chemical used in warfare by US army), occupational exposure to cadmium (used in batteries and metal paintings), ethnicity and gene mutations. Dietary consumption of vitamin D, selenium, soya products and tomatoes product containing lycopene prevent prostatic adenocarcinoma. Hereditary and familial genetic factors are linked to prostatic adenocarcinoma.
- Hormones are integral part of the prostate, which regulate its growth, differentiation and maintenance. Androgenic hormones such as dihydrotestosterone (DHT) are demonstrated in the prostate gland.

- Testosterone diffuses into the prostate gland and gets converted to dihydrotestosterone (DHT) in the prostate gland.
- Androgen ablation therapy is commonly used to counter the growth prostatic adenocarinoma which results in the blockage of the androgen supply. However, it has not been established that androgenic hormones are the cause of prostatic adenocarcinoma.

Molecular Genetic Alterations

Many molecular genetic alterations have been described in prostatic adenocarcinoma. Allelic loss in chromosomes 8p, 10q, 13q, 16p, and 17p, which are the sites of tumor suppressor genes have been demonstrated in 50% of cases.

- Approximately 50% of prostatic adenocarcinomas demonstrate fusion of the androgen-responsive serine protease gene TMPRSS2 (21q22.2) with one of the ETS transcription factor gene family members such as ERG (21q22.2), ETV1 (7p21.2), ETV4 (17q21) and ETV (3p27), with ERG accounting for >90% of cases. TMPRSS2-ERG fusion gene most often results from an insertional deletion of 21q22.2-22.3 which causes juxtaposition of the two genes.
- Point mutation in SPOP is demonstrated in 10% of prostatic adenocarcinomas. Loss of PTEN tumor suppressor gene (10q23) is demonstrated by FISH in 10–70% of cases. TP53 tumor suppressor gene mutation is associated with aggressive behavior of prostatic adenocarcinoma. RB gene mutation is seen in significant number of cases. BRCA2 gene mutation has been linked to prostatic adenocarcinoma.
- BRCA2 gene (13q) mutation has been associated with prostate adenocarcinoma. BRCA2 regulates DNA repair by binding to RAD51, a molecule that mediates DNA double-strand repair breaks. BRCA2 encodes protein involved in checkpoint functions related to progression of the cell cycle into S phase.
- HER2/neu gene amplification is demonstrated in 33% of prostatic adenocarcinoma. HOXB13 gene mutation also predisposes to prostatic adenocarcinoma. Patients with mutation of mismatch repair genes in HNPCC (Lynch syndrome) have increased risk for prostatic adenocarcinoma. Molecular genetic alterations associated with increased risk for prostatic adenocarcinoma are given in Table 23.24.
- Hereditary and familial genetic factors account for 10% of prostatic adenocarcinoma. Risk of prostatic adenocarcinoma increases with first degree relative with prostate adenocarcinoma especially at an early age.
- Besides genetic mutations, many epigenetic alterations occur in prostatic adenocarcinoma. The term epigenetics refers to the external modification of DNA bases which are inherited but do not cause a change in the DNA sequence.
- Epigenetic modifications vary from methylation of DNA to acetylation, phosphorylation and methylation of histones, which have been linked to aberrant activity of the enzymes and reader proteins involved in these epigenetic processes, leading to the search for dedicated inhibitory compounds.
- Genes implicated in hereditary prostatic adenocarcinoma differ from those affecting sporadic prostatic adenocarcinoma.
- In hereditary prostatic adenocarcinoma, some of the genes implicated in hereditary prostatic

Table 23.24 Molecular genetic alterations associated with increased risk of prostatic adenocarcinoma

Cytogenetic and Molecular Genetic Alterations	Comments	Frequency
Chromosomal allelic losses	Chromosomes 8p, 10q, 13q, 16p, and 17p, which are the sites of tumor suppressor genes	50% cases
TMPRSS2-ERG fusion	Fusion of the androgen-responsive serine protease gene TMPRSS2 (21q22.2) with one of the ETS transcription factor gene family members	>90% cases
SPOP gene	Point mutation	10% cases
PTEN tumor suppressor gene (10q23)	Loss of PTEN	10–70% cases
RB gene mutation	Gene mutation	Significant cases
BRCA2 gene	Gene mutation	Significant cases
HER2/neu gene	Gene mutation	33%
TP53 tumor suppressor gene	Gene mutation	Significant cases associated with aggressive behavior
HOXB13 gene	Gene mutation	Significant cases
Mismatch repair genes	Gene mutations in HNPCC (Lynch syndrome)	Significant cases

Table 23.25 Genes implicated in hereditary and familial prostatic adenocarcinoma

Genes	Locus on Linkage Analysis	Comments
HPC1 (hereditary prostate cancer gene 1)	1q24-25	RNASEL gene with normal apoptotic function mapped to the HPC2 locus, is mutated in hereditary prostatic adenocarcinoma
HPCX	Xq27-28	Hereditary prostatic adenocarcinoma (some cases)
PCAP	1q42-43	Hereditary prostatic adenocarcinoma with early onset disease in families
HPC2/ELAC	17p11	HPC2 encodes a hydroxylase which acts like DNA repair. Mutation responsible for high risk prostatic adenocarcinomas in families
NKX3.1	8q21	Tumor suppressor gene mutation associated with hereditary prostatic adenocarcinoma

adenocarcinoma are HPC1, HPCX, PCAP, HPC2/ELAC and NKX3.1.

- Signaling pathways are activated in the process of development of prostatic adenocarcinoma.
- The signaling pathways are interconnected and ligands affect more than the immediate downstream target in their respective signaling pathways. Genes implicated in hereditary and familial prostatic adenocarcinoma are given in Table 23.25.

Clinical Features

Patient is asymptomatic in the initial phase and becomes symptomatic, when prostatic adenocarcinoma spreads beyond the prostate gland invading surrounding structures, i.e. ejaculatory ducts in the space between the seminal vesicles or perivesicular fascia, urinary bladder and rectum. Local invasion of tumor into the urethra and urinary bladder neck may cause frequency of micturition and difficulty in passage of urine. This is followed by involvement of draining lymph nodes and metastases to bones. When disseminated, the prostatic adenocarcinoma may respond to endocrine therapy because tumor growth is partially related to the activity of androgens.

Diagnostic Modalities

Prostatic adenocarcinoma is most often diagnosed by rectal examination, ultrasound-guided (TRUS) prostatic tissue biopsies and serum PSA.

- Serum prostate-specific antigen is widely used for early detection of prostate adenocarcinoma. Newer diagnostic modalities include total and free PSA levels, PCA3 urine testing, prostate health index (PHI) scoring, the "4K" test, genomic analysis, MRI imaging, PIRADS scoring, and MRI-TRUS fusion-guided biopsies. When prostatic adenocarcinoma is limited to the prostate gland, it is considered localized and potentially curable.
- Outcomes depend on age, associated health problems, tumor histology and the extent of prostatic adenocarcinoma.

Serum Tumor Markers in Prostatic Adenocarcinoma

Both prostate-specific antigen (PSA) and serum prostate-specific acid phosphatase are increased in prostatic adenocarcinoma. Concentration of prostate-specific antigen values in different age groups is given in Table 23.26. Percentage of total PSA levels and free PSA in serum is given in Table 23.27.

- **Prostate-specific antigen:** PSA is a product of prostatic epithelium normally synthesized in the semen. It is serine protease, whose function is to cleave and liquefy the seminal vesicle coagulum formed after ejaculation. In most laboratories, normal cut off point of serum level of prostate-specific antigen is 4 ng/ml. Serum PSA levels may be increased in prostatic adenocarcinoma, nodular hyperplasia of prostate, prostatitis, and prostate infarct. Prostatic adenocarcinoma is associated with increased total PSA levels in serum and decreased free form. On the other hand, increased total PSA levels in serum with

Table 23.26 Prostate-specific antigen (PSA) values in different age groups

Age Group (Years)	Serum Prostate-specific Antigen (ng/ml)
40–49	2.5 ng/ml
50–69	3 ng/ml
70–79	6.5 ng/ml

Older men have higher serum PSA level than younger one.

Table 23.27 Percentage of total prostate-specific antigen (PSA) levels and free PSA in serum

Prostate Disorders	Total Serum PSA Levels	Serum-free Levels
Prostate carcinoma	High	<10%
Benign nodular hyperplasia	High	>25%

Percentage of free PSA/total PSA levels in serum is lower in men with prostate carcinoma than with benign nodular hyperplasia.

a proportionate increase in the fraction of free PSA suggests nodular hyperplasia of prostate.

- **Serum prostate-specific acid phosphatase:** Its level increases when prostatic adenocarcinoma invades capsule and surrounding tissues, but it lacks sensitivity in early disease. Therefore, estimation of serum prostate-specific acid phosphatase along with PSA is useful in the follow-up cases of widespread metastases.
- **Serum alkaline phosphatase:** Serum alkaline phosphatase is an indicator of bone osteoblastic metastases in advanced disease.

Surgical Pathology: Prostatic Adenocarcinoma

Gross Morphology

Tumor shows gray-white to yellowish poorly delineated and firm areas when compared to the native parenchyma (Fig. 23.48).

Light Microscopy

Prostatic carcinomas can be divided into two major histologic categories: acinar and ductal patterns, which may coexist in the same prostatic carcinoma. The large majority of prostatic carcinomas demonstrate acinar histologic type. The diagnosis of prostatic adenocarcinoma is based on the careful analysis of hematoxylin and eosin stained slides using a systemic approach. Histologic types of prostatic adenocarcinoma is given in Table 23.28.

- **Prostatic adenocarcinoma with acinar pattern:** This variant exhibits a wide spectrum of histologic appearances, ranging from highly differentiated neoplasms to rare anaplastic prostatic carcinoma. Four major cytoarchitectural patterns are: medium-sized glands, small-sized glands, diffuse individual cell infiltration and cribriform. Presence of prostatic glands within perineural spaces is common in these tumors. This finding is strong indicator of malignancy. An additional glomeruloid pattern of growth has recently been described, which is characterized by the presence of intraluminal ball-like clusters of tumor cells.
  - Prostatic adenocarcinoma is composed of medium-sized glands are detected on low power examination by virtue of the closely spaced back-to-back arrangement of glands, the prominent luminal cytoplasm with orientation of normochromatic nuclei against the basement membrane, smooth luminal surface and the scanty intervening stroma. Atypical mitoses are rare in well-differentiated neoplasm composed of medium-sized glands (Fig. 23.49A and B).
  - Prostatic adenocarcinoma is composed of small glands exhibits individual glands with round configuration containing hyperchromatic nuclei and prominent nucleoli. Atypical mitoses are also of significance, but these are rarely present in well-differentiated neoplasm composed of small glands.
  - Prostatic adenocarcinoma composed of diffuse cell infiltration resembles somewhat that of invasive lobular carcinoma of the breast.
  - Prostatic adenocarcinoma composed of cribriform pattern varies in the dimension of the epithelial aggregates ranging from anastomosing epithelium to small- or medium-sized glands with complex intraluminal proliferations.
- **Prostatic adenocarcinoma with ductal pattern:** It is usually seen in a periurethral location. Cystoscopy reveals polypoid villous or infiltrative urethral component. Tumor is composed of papillary and cribriform architecture lined by columnar pseudostratified malignant epithelium. Many prostatic carcinomas present as cystadenocarcinomas.
- **Prostatic carcinoma of other histologic types:** These are prostatic adenocarcinoma with neuroendocrine differentiation, small cell prostatic carcinoma, mucinous prostatic adenocarcinoma, signet ring prostatic carcinoma, adenosquamous prostatic carcinoma, squamous cell carcinoma, adenoid basal carcinoma, basal cell carcinoma with adenoid cystic carcinoma, lymphoepithelioma-like carcinoma and sarcomatoid carcinoma.

Immunohistochemistry Technique

- Panel of immunohistochemical markers in the assessment of benign/noninvasive lesions and invasive prostatic adenocarcinoma is shown in Table 23.29 and Fig. 23.50.
- Prostate-specific antigen (PSA) and prostate-specific acid phosphatase (PSAP) immunohistochemical markers are used to demonstrate prostatic epithelium in benign and malignant process. But these are of great use in identifying the prostatic origin of metastatic tumors. NXK3.1 is a recently described nuclear marker for prostatic adenocarcinoma that has improved sensitivity and specificity over PSA and PSAP.
- Alpha-methylacyl-CoA racemase (AMACR) is a new immunohistochemical marker for prostatic adenocarcinoma that can be very helpful in difficult cases when limited amount of tumor is present in biopsies.
- The distinction between poorly differentiated prostatic carcinoma and urothelial carcinoma is challenging. GATA3 is the most specific sensitive immunohistochemical marker for urothelial carcinoma.
- Other markers for urothelial carcinomas are p53, thrombomodulin, uroplakin III and cytokeratins. Immunohistochemical markers of prostatic adenocarcinoma and urothelial carcinoma are given in Table 23.30.

Markers	Expression
PSA (prostate-specific antigen)	Positive (94–100%)
PSAP (prostate-specific acid phosphatase)	Positive (89–100%)
Prostate-specific membrane antigen (PSMA)	Positive (92%)
NXK3.1	Positive (95%)
AMACR	Positive (new marker)
P504S	Positive (new marker)
Prostein (P501S)	Positive (100%)
p63 (basal cell marker)	Positive (0–3%
Cytokeratins (high molecular weight) detected by antibody 34bE12	Positive (0–10%)

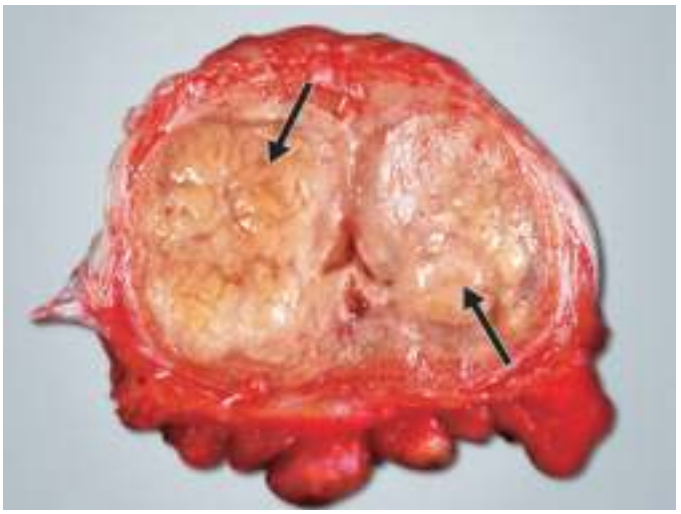

Fig. 23.48: Prostatic adenocarcinoma. It shows a large yellow tumor presents in the posterolateral aspect of the prostate gland (arrows).

Gleason Grading System

Gleason system of grading of prostatic adenocarcinoma is done based on histologic architecture of tumor rather than nuclear atypia.

- Most pathologists grade prostatic adenocarcinoma according to the Gleason score, which assigns a grade (1–5) based on how the malignant cells look compared with normal prostatic cells.
- Gleason system of grading based on differentiation of prostatic adenocarcinoma helps in prediction of course. The higher the Gleason score, the more likely that prostatic adenocarcinoma will grow and metastasize rapidly.
- Most prostatic adenocarcinomas detected by needle biopsies are given Gleason score of 6 or 7. Prostatic adenocarcinoma with Gleason score 7 or higher needs treatment.
- Prostatic adenocarcinoma with a high Gleason score is more aggressive and associated with poor prognosis. Gleason system of grading of prostatic adenocarcinoma is given in Table 23.31.

Gleason Staging System

After the diagnosis of prostatic adenocarcinoma, it is important to know its spread to the draining lymph nodes and distant organs. This process is called staging, which helps in determining the seriousness of prostatic adenocarcinoma. Staging of prostatic adenocarcinoma is based on diagnostic tests such as PSA and histologic examination of the biopsy. American Joint Committee on Cancer (AJCC) TNM staging system, which was most recently updated in 2018.

- The TNM system for prostatic adenocarcinoma is based on five pieces of information: (i) the extent of the primary tumor (T category), (ii) whether the

Table 23.28 Histologic types of prostatic adenocarcinoma

Histologic Type	Comments
Prostatic adenocarcinoma of acinar type (most common)	Four major cytoarchitectural patterns are: Medium-sized glands, small glands, diffuse individual cell infiltration and cribriform ranging from well-differentiated to anaplastic prostatic carcinoma
Prostatic adenocarcinoma of ductal type	Located as polypoid villous or infiltrative in periurethral location detected on cystoscopy. Tumor is composed of papillary and cribriform architecture lined by columnar pseudostratified malignant epithelium or as cystadenocarcinomas
Prostatic adenocarcinoma with neuroendocrine differentiation	This variant expresses neuroendocrine markers by histochemistry and is associated with good prognosis
Mucinous prostatic adenocarcinoma	This variant is accompanied by the formation of large amount of intracellular and extracellular mucin comprising 25% or more of the tumor. Tumor expresses PSAP and PSA. It is associated with poor prognosis
Signet ring prostatic adenocarcinoma	This variant is highly malignant and composed of neoplastic cells laden with mucin arranged in a solid, acinar, or single file pattern
Adenosquamous prostatic carcinoma	This variant may arise in *de novo* or after radiation or hormonal therapies in prostatic carcinomas
Squamous cell carcinoma	This variant may arise in *de novo* or after radiation or hormonal therapies in prostatic carcinomas and present as a well-circumscribed nodule in the prostatic transition zone
Adenoid basal carcinoma	This variant resembles adenoid cystic or basal cell carcinoma of salivary gland and presents as expansile pattern of growth. PSA and PSAP staining is negative or focally positive
Basal cell carcinoma with adenoid cystic carcinoma	This variant is rare and highly aggressive neoplasm, in which MYB rearrangement may be demonstrated
Lymphoepithelioma-like carcinoma	This variant is analogous to nasopharyngeal lymphoepithelioma
Sarcomatoid carcinoma	This variant combines histologic features of recognizable prostatic carcinoma with sarcomatoid elements

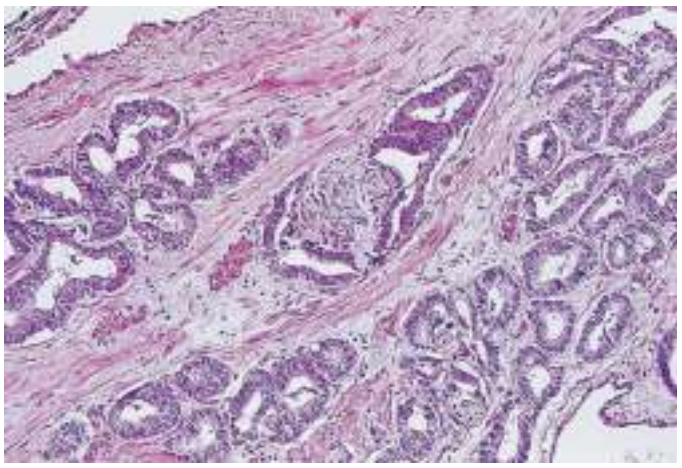

Fig. 23.49A: Prostatic adenocarcinoma with perineural invasion. Perineural invasion finding is strong indicator of malignancy. Acid sulfated and nonsulfated mucins are often present in malignant acini, appearing as amorphous or delicate thread-like faintly basophilic intraluminal secretions. Tumor is composed of medium sized glands with back-to-back arrangement of glands containing normochromatin nuclear against basement membrane (400X).

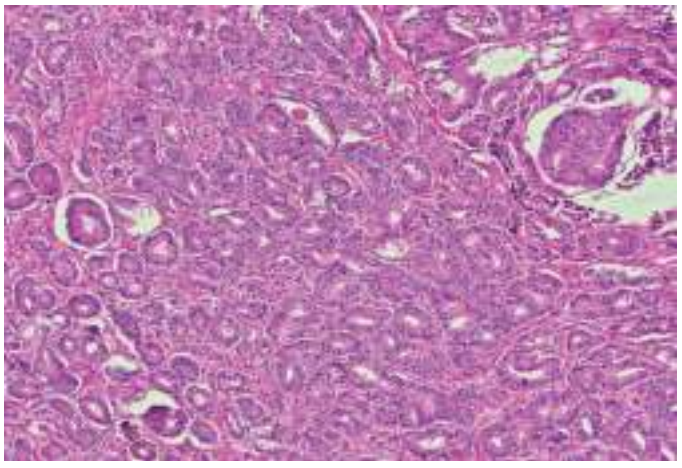

Fig. 23.49B: Prostatic adenocarcinoma. Histologic patterns depend on Gleason grading. Invasive prostatic adenocarcinoma is composed of closely packed small- to medium-sized glands (Gleason grade 3) irregular outline, smooth luminal surface, splitting stromal fibers. Neoplastic cells contain nuclear enlargement, hyperchromasia and prominent nucleoli. Neoplastic cells are arranged in papillary or cribriform glands or solid growth or single cells (400X).

Table 23.29 Panel of immunohistochemical markers in the assessment of benign/noninvasive lesions and invasive prostatic adenocarcinoma

Prostatic Cells	Immunohistochemistry (Benign/Noninvasive Lesion)	Immunohistochemistry (Invasive Neoplasm)
Prostatic basal cells	▪ Prostatic basal cell present ▪ CK903+ (cytoplasm) ▪ p63 negative	▪ Prostatic basal cell absent ▪ CK903 negative ▪ p63 negative
Prostatic acinar cells	▪ Prostatic acinar cell present ▪ AMACR negative	▪ Prostatic acinar cell present ▪ AMACR positive (cytoplasmic staining)

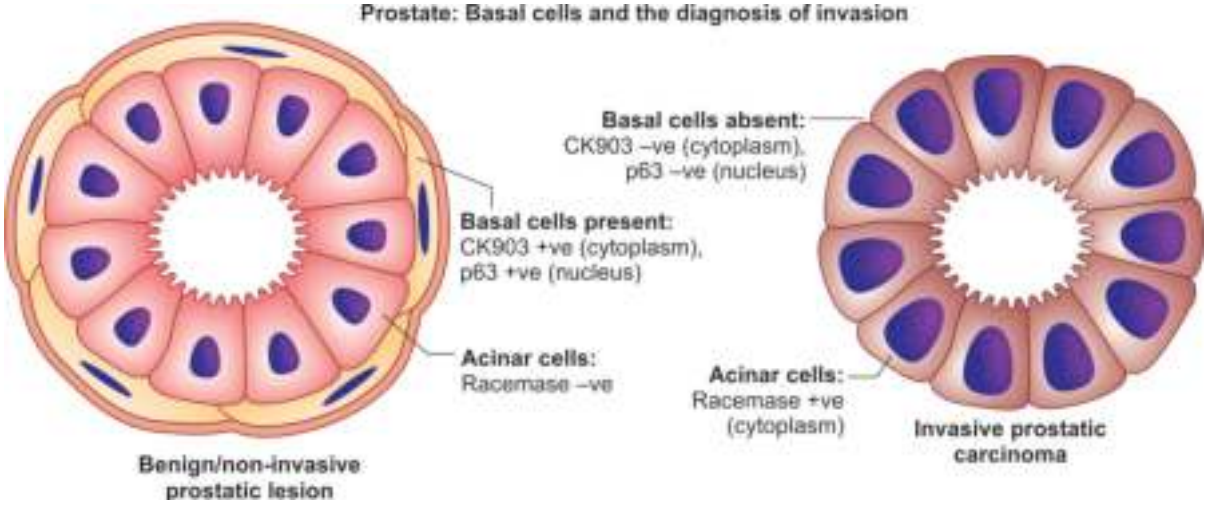

Fig. 23.50: Panel of immunohistochemical markers in the assessment of benign/noninvasive lesions and invasive prostatic adenocarcinoma.

prostatic adenocarcinoma has spread to nearby draining lymph nodes (N category), (iii) whether the prostatic adenocarcinoma has metastasized to distant organs (M category), and (iv) the prostate-specific acid phosphatase high level in prostatic adenocarcinoma at the time of diagnosis.

- The grade group based on the Gleason score, which indicates rapid growth and metastasis of prostatic carcinoma. There are two types of T categories for prostatic carcinoma: (i) the clinical T category is based on the extent of disease on clinical examination including digital rectal examination and

Table 23.30 Immunohistochemical marker of prostatic adenocarcinoma and urothelial carcinoma

Markers	Prostatic Carcinoma (% of Cases Expression)	Urothelial Carcinoma (% of Cases Expression)
PSA (prostate-specific antigen)	Positive (94–100%)	Negative
PSAP (prostate-specific acid phosphatase)	Positive (89–100%)	Negative
PSMA (prostate-specific membrane antigen)	Positive (92%)	Negative
NXK3.1	Positive (95%)	Negative
Prostein	Positive (100%)	Positive (6%)
GATA	Negative	Positive (most specific marker)
p63	Positive (0–3%)	Positive (81–96%)
Thrombomodulin	Negative	Positive (69–91%)
Uroplakin III	Negative	Positive (57%)
Cytokeratins (high molecular weight) detected by antibody 34bE12	Negative/positive (0–10%)	Positive (65–100%)

Mean of 3% prostatic carcinoma cases are positive. Up to 20% of cases of metastatic prostatic carcinoma can be positive.

Table 23.31 Gleason grading of prostatic adenocarcinoma

Parameters	Pathologic Features
Histologic patterns of prostatic carcinoma	
Gleason pattern 1 (rarely demonstrated)	▪ Prostatic adenocarcinoma closely resembles normal prostate tissue. It is composed of closely packed small, well-formed uniform, round to oval medium-sized acini. The glandular acini are larger than pattern 3 ▪ Pattern 1 closely resembles well differentiated prostatic adenocarcinoma
Gleason pattern 2 (rarely demonstrated)	▪ Prostatic adenocarcinoma is fairly circumscribed prostatic nodule with periphery showing minimal infiltration ▪ Prostatic carcinoma has well-formed, loose, and uniform glands with increased stroma between the glands; but not as uniform demonstrated in Gleason pattern 1
Gleason pattern 3 (well differentiated tumor most common)	▪ Prostatic adenocarcinoma is composed of small glands with darker cells than demonstrated in Gleason pattern 1 and Gleason pattern 2 ▪ At higher magnification, some of these cells have left the prostatic glands and are beginning to invade the surrounding tissue or having an infiltrative pattern. This corresponds to a moderately differentiated prostatic adenocarcinoma
Gleason pattern 4 (moderately differentiated tumor)	▪ Prostatic tissue has few recognizable microacinar glands of ill-defined glands with poorly formed glandular lumina. Many neoplastic cells invading the surrounding tissue are arranged in clusters ▪ This histologic appearance corresponds to a poorly differentiated prostatic carcinoma
Gleason pattern 5 (poorly differentiated tumor)	▪ Prostatic tissue lacks glandular differentiation with central necrosis, however may demonstrate a few recognizable glands. It demonstrates neoplastic cells arranged in papillary or cribriform or solid sheets throughout the surrounding tissue ▪ This histologic appearance corresponds to an anaplastic prostatic carcinoma
Primary, secondary and tertiary grades	
Primary grade	Primary grade is assigned to the dominant pattern of prostatic carcinoma. Dominant pattern of the tumor must to be >50% of the total pattern.
Secondary grade	Secondary grade is assigned to the next—most frequent pattern of prostatic carcinoma. Dominant pattern of the tumor must be <50%, but at least 5% of the total prostatic carcinoma
Tertiary grade	Tertiary grade is assigned to the increasingly pattern of prostatic carcinoma, where there is small component of a third generally more aggressive pattern

Final score is the combination of the predominant and minor architectural patterns (e.g. Gleason grade 3 plus minor component of grade 4 = 3 + 4)

prostatic biopsy and any imaging tests, and (ii) the pathology T category (written as pT) is more accurate than clinical T category and based on histologic examination of the prostate. Staging of prostatic adenocarcinoma is given in Table 23.32.

Prognostic Factors

Patient with well differentiated prostatic adenocarcinoma with free resected margins, lack of invasion of nerves, blood vessels and Gleason's capsule has good prognosis.

Therapeutic Correlation

Tumor cells of prostatic adenocarcinoma exhibit androgen-dependent growth. Chemical castration by the administration of androgenic antagonists (e.g. leuprolide) is used in the treatment of prostate adenocarcinoma.

Table 23.32 Staging of prostatic adenocarcinoma

Stage	Comments
Stage I	▪ Stage T1a and T1b are clinically unsuspected tumors found in transurethral resection of prostate (TURP) or enucleation post-mastectomy specimens removed for benign prostatic hyperplasia. There is absence of metastasis in lymph node or distant organs ▪ Stage T1c is a nonpalpable prostatic carcinoma diagnosed on needle biopsy
Stage II	Prostatic adenocarcinoma is confined to the prostate
Stage III	Prostatic adenocarcinoma is extending out of the prostate gland: Stage T3a without involvement of seminal vesicle and stage T3b with involvement of seminal vesicle

DISORDERS OF PENIS

ANATOMY OF PENIS

The penis, an external organ of male genital system consists of shaft and glans is used for sexual activity and urination.

- Glans (i.e. head or tip) is the most sensitive part of the penis.
- Penile shaft contains three columns of erectile tissue, i.e. two columns of spongy corpus cavernosa dorsally, and one column of corpus spongiosum ventrally, containing urethra wrapped in dartos fascia that also wraps foreskin, and scrotum.
- Male urethra is a tube inside the penis that runs from the urinary bladder to the glans penis.
- Meatus is the opening at the tip of the glans penis through which urine or semen exits the body.
- Prepuce is a loose fold that covers the glans penis. Surgical removal of the prepuce is referred to as circumcision.
- Deep structures of the penis are supplied by internal pudendal artery, a branch of the internal iliac artery. Venous drainage of the penis happens via one of the three systems: superficial, intermediate, and deep venous system.
- The penis is innervated by terminal branch of pudendal nerve, dorsal nerve, and branch of the ilioinguinal nerve. The sympathetic and parasympathetic afferent fibers of penis run together with the pudendal nerves arise in S2–S4 or T12–L1.
- When there is an increased flow of blood into the erectile tissues of corpus cavernosa and corpus spongiosum stiffen, causing an erection of penis. The corpus spongiosum prevents the urethra from closing during an erection.
- Ejaculation is the discharge of semen from the penis that involves a series of simultaneous involuntary muscle contractions.

CONGENITAL ANOMALIES OF PENIS AND MISCELLANEOUS DISORDERS

Congenital anomalies of the penis may range from the absolute lack of penis to segmentary anomalies. Hypoplasia and hyperplasia of the penis are usually associated with endocrine abnormalities.

- Epispadias occurs when the location of urethral meatus opens on the dorsal surface of the penis, which is less common than hypospadias.
- Glandular epispadias occurs when the opening of the urethra opens in the dorsal aspect of the glans.
- Hypospadias refers to location of urethral meatus opens on the ventral surface of the penis anywhere from the glans to the perineum, which results from incomplete closure of the urethral folds of the urogenital sinus. The classification of hypospadias depends on the anatomic location of the defect. It can be glandular (most common), coronal, penile, penoscrotal or perineal. Hypospadias is repaired by surgical procedure.

- In phimosis, abnormal tight foreskin of penis leads to narrowing of the orifice of prepuce resulting in difficulty to retract over the glans penis. Phimosis may be congenital or result from inflammation or from trauma. In paraphimosis, forceful retraction of narrow prepuce may strangulate the glans and obstruct venous blood flow.
- Normally, bone is absent in penis. Presence of heterotopic bone in penis is usually demonstrated in the Peyronie disease, in which subcutaneous fibrosis occurs in the dorsum of the penis in the elderly persons.
- Priapism is an intractable, often painful erection of penis due to venous thrombosis of the corpora cavernosa, sickle cell anemia, hypercoagulable states, spinal injuries, chronic myelogenous leukemia and some drugs.

INFLAMMATORY DISORDERS OF PENIS

BACTERIAL INFECTIONS

Bacterial infections of the genitourinary tract occur in especially uncircumscribed (phimosis) males at any age.

- Pathogenic bacteria adhere and colonize the mucosal surface of the prepuce. Bacterial inflammation of the glans penis is known as balanitis. Extension of inflammation from glans to the foreskin is called balanoposthitis. Patient presents with mild burning, pruritus, itching, swelling, erythematous patches, and plaques or bullae involving the glans penis, satellite eroded pustules and moist curd-like accumulations.
- Balanitis has worse clinical presentation in diabetic and immunocompromised patients, with fulminating edema or ulcers in severe cases.
  - Significant complications of balanitis are stricture of the meatus, phimosis, and paraphimosis. *Neisseria gonorrhoeae* infection is sexually transmitted.
  - Patient presents with urethral discharge, typically purulent and greenish yellow. Deep infections of the penis are rare caused by *Neisseria gonorrhoeae*. Tuberculosis of the penis can be involved by direct spread from nearby areas or via hematogenous route in generalized tuberculosis.
- Fournier gangrene, a necrotizing fasciitis of the genitalia, perianal and perianal region, is a life-threatening disorder. There is involvement of dartos and penile fascia. Thrombosis of the small blood vessels, known as '**obliterative endarteritis**' plays important role in the pathogenesis of Fournier gangrene, which is caused by polymicrobial infection especially in diabetes mellitus. Most important organisms are Streptococci, Staphylococcus, gram-negative bacteria and anaerobic bacteria. The source of infection may be urologic, colorectal or cutaneous.
- Gangrenous balanitis is known as '**Corbus disease**', which is a rapidly progressing necrotizing inflammatory disorder caused by anaerobic bacteria especially in diabetes mellitus. Disorder is characterized by total necrosis of the glans penis.

FUNGAL INFECTIONS

Fungal infections of the penis are probably more common especially in immunocompromised persons and diabetes mellitus. Mycotic infections of penis can be superficial or deep. Superficial infections are caused by dermatophytes and *Candida albicans*.

- Dermatophytes usually infects the penis via local spread of infection in groin region.
- *Candida albicans* is sexually transmitted and involving penis. In superficial fungal infections, numerous neutrophils are present in the squamous epithelium and keratin layer.
- Deep mycotic infections of the penis may be caused by *Histoplasma capsulatum* and *Cryptococcus neoformans*, but these are rare.

SEXUALLY TRANSMITTED INFECTIONS

Penile Syphilis

Treponema pallidum causes penile syphilis by sexual transmission of the organism. Patient presents with an elevated, painless, superficially ulcerated, firm papule (chancre) on the glans penis or prepuce that ordinarily heals within 2–6 weeks. *Treponema pallidum* is demonstrated by dark field examination and polymerase chain reaction (PCR).

Granuloma Inguinale

Calymmatobacterium granulomatis is a gram-negative bacterium, that causes granuloma inguinale. Patient presents with small, relatively painless nodule on the prepuce, glans, penile shaft or scrotum, that later ulcerates resulting in exuberant granulation tissue and pseudoepitheliomatous hyperplasia. Granuloma inguinale spreads by peripheral extension and attains a large size. On histologic examination, numerous plasma cells, neutrophils and mononuclear cells with Donovan bodies are present in the granulation tissue. There is absence or paucity of lymphocytes.

Lymphogranuloma Venereum

Chlamydia trachomatis is sexually transmitted disease. Patient presents with infrequent primary penile lesion, secondary lymphadenitis with bubo formation leading to fibrosis, edema and fistula formation.

- Lymphadenopathy occurs within one to two weeks after the appearance of primary lesion.

- On histologic examination, primary penile lesion demonstrates nonspecific granulation tissue infiltrated by plasma cells and lymphocytes. There is presence of noncaseating epithelioid cell granulomas composed of epithelioid cells and a few giant cells surrounded by plasma cells. Lymph node shows focal accumulation of neutrophils in the necrotic foci in early stage. Later, lymphoid hyperplasia with massive plasma cell infiltration distorts the architecture of lymph node resulting in formation of sinus tracts.
- Diagnosis can be confirmed by culture of skin biopsy or lymph node and serology.

Genital Chancroid

Haemophilus ducreyi is a gram-negative organism causing chancroid, which requires special media, not easily available in most laboratories, to ensure its growth. Organism results in papule formation.

- Gene clusters have been observed in *Haemophilus ducreyi* which encode for a cytolethal distending toxin, that causes irreversible cell death of epithelial cells and may lead to the development of the skin breakdown and subsequent painful necrotizing genital ulcer development accompanied by inguinal lymphadenopathy and inguinal abscess.
- *Haemophilus ducreyi* can cause widespread necrosis and destruction of external genitalia and forming giant chancroid.
- On histologic examination, there is a zonation phenomenon at the base of the ulcer.
  - The uppermost layer shows necrosis, fibrin and numerous neutrophils.
  - Middle layer demonstrates abundant granulation tissue with prominent blood vessels, some of which have potential thrombosis.
  - The deepest layer shows an intense infiltration by plasma cells and lymphocytes. Fusobacterium organisms can cause phagedenic chancroid.

Anogenital Condyloma Acuminatum

Human papillomavirus (HPV) is associated with anogenital wart known as '**condyloma acuminatum**'. Low risk types of HPV 6 and 11 are associated with condyloma acuminatum'. High risk types of HPV 16, 18, 31, 33, 39, 45, 52, 58 and 59 have been linked to cervical, vulvar, penile and oropharyngeal carcinomas. HPV is a double-stranded DNA virus primarily spread through sexual contact. Condyloma acuminatum can occur on the glans, prepuce and shaft of penis, that may extend to the meatus.

- Patient presents with soft, fleshy plaques with cobblestone or filiform appearance.
- The lesions vary from small flat and patchy to large cauliflower-like growth, which may occur sporadically or in the setting of immunosuppression state. There is increased risk for penile condyloma acuminatum in men, whose life partners have cervical HPV infection.
- HPV can be analyzed by immunohistochemistry, polymerase chain reaction (PCR) and fluorescence *in situ* hybridization techniques. Penile condyloma acuminatum may attain >8 cm size.

Surgical Pathology: Condyloma Acuminatum

Light Microscopy

- On histologic examination, surface of the condyloma acuminatum shows exophytic lesion characterized by acanthosis, papillomatosis, and a sharp fairly regular bulbar base.
- The hallmark of condyloma acuminatum is the presence of cytopathic viral effect, namely koilocytosis. Cellular changes are more marked on upper levels of epithelium.
- Koilocytes contain enlarged wrinkled nuclei surrounded by a perinuclear halo. Binucleated and multinucleated forms and dyskeratotic cells may be present (Fig. 23.51).

Genital Ulcers

Herpes simplex virus 2 (HSV-2) is a DNA virus that is efficiently sexually transmitted through intimate genital tract contact and causes persistent infection that cannot be eliminated. HSV-2 may cause frequent symptomatic self-limited genital ulcers, but in most persons infection is subclinical. Patient presents with multiple millimeter sized vesicles that rupture and form genital painful ulcers. Patient can also develop fissures and ulcerations. On histologic examination, intraepithelial vesicles contain prominent rounded acantholytic keratinocytes, demonstrate cytopathic changes that consist of nuclear ground glass appearance and molding. There is also presence of multinucleated keratinocytes with classic nuclear changes. Well-defined acidophilic inclusions can be present.

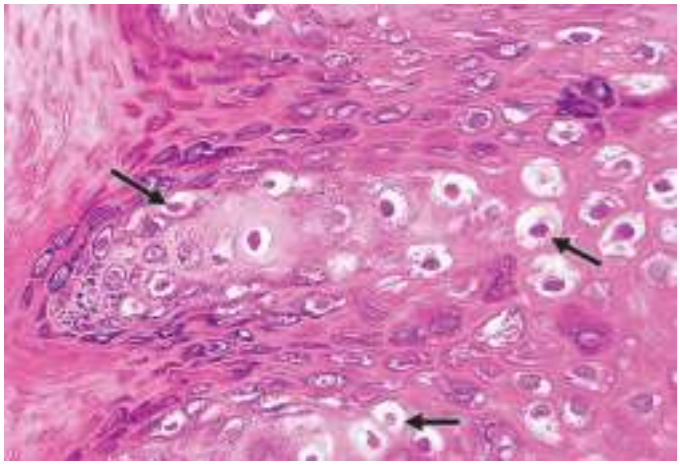

Fig. 23.51: Condyloma acuminatum. It shows vacuolization of epidermal cells (koilocytic change) in upper epithelium with wrinkled nuclei surrounded by clear halo (arrows) (400X).

Genital Molluscum Contagiosum

Genital molluscum contagiosum is a viral cutaneous infection in childhood that occurs worldwide and caused by a DNA poxvirus. Genital lesions are mainly transmitted by sexual contact.

- MCV-1 is transmitted by direct skin-skin contact or sharing infected clothes. MCV-2 is transmitted via sexual contact in adults. DNA poxvirus most often occurs in children and adolescents. Patient presents with umbilicated, dome-shaped papules over body, arms and legs.
- Average incubation period is 6 weeks. Umbilication of lesion occurs as a result of intracytoplasmic viral inclusions extruding infected cell on the surface with central pore.
- On histologic examination, epidermis grows deeper down into the dermis and form closely packed lobules. Epidermal cells contain large intracytoplasmic eosinophilic stained inclusion bodies known as molluscum bodies (**Henderson-Paterson bodies**), displace the nuclei at the periphery of epidermal cells (Fig. 23.52).
- In the center of the lesion, stratum corneum disintegrates and release the molluscum bodies together with keratinous debris resulting in formation of central crater.
- Dermis shows prominent acute and chronic inflammatory infiltrate and foreign body giant cells.

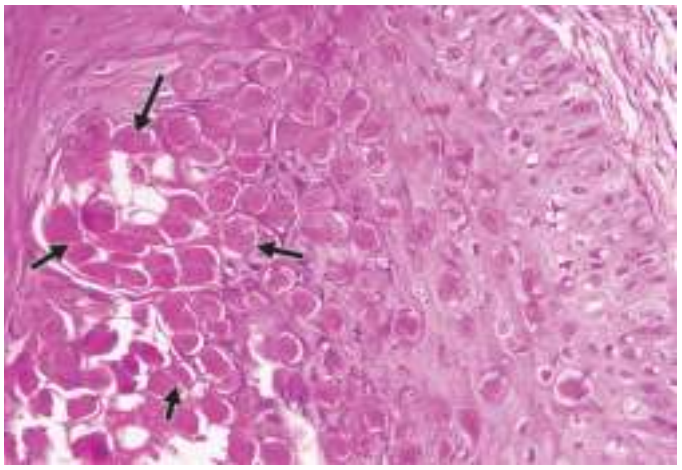

Fig. 23.52: Molluscum contagiosum. Epidermal cells contain large intracytoplasmic eosinophilic stained inclusion bodies known as molluscum bodies (arrows) (400X).

NEOPLASTIC DISORDERS OF PENIS

PENILE INTRAEPITHELIAL NEOPLASIA

Penile carcinomas occur in the form of carcinoma *in situ* or invasive squamous cell carcinoma, which mainly show a bimodal pathway of carcinogenesis: HPV related and HPV unrelated.

- Penile intraepithelial neoplasia refers to microscopically full-thickness atypia of the squamous epithelium. The term penile intraepithelial neoplasia (**PeIN**) is preferred over old term squamous intraepithelial lesion (SIL), erythroplasia of Queyrat, and Bowenoid disease.
- Both erythroplasia of Queyrat, and Bowenoid disease are synonymous with carcinoma *in situ*.
  - Erythroplasia of Queyrat is a disease of shaft to penis characterized by solitary or multiple, shiny, soft, erythematous plaques on the glans and foreskin.
  - Bowen disease is characterized by a sharply demarcated erythematous plaque or grayish plaque most often on the shaft of the penis or on the scrotum in younger persons, that may progress to invasive carcinoma. PeINs may be solitary or multiple.
- Gross appearance of penile intraepithelial neoplasia (PeIN) is heterogenous and does not allow one to distinguish between two types. Lesions vary from flat to slightly elevated, pearly white or moist erythematous, black to dark brown macules, papules, or plaques. The contours may be subtle or sharp and irregular.
- Histologic examination of PeIN shows thickened epithelium, usually associated with elongated and anastomosing rete ridges, subtle abnormal maturation (enlarged keratinocytes with abundant eosinophilic cytoplasm), whirling and keratin pearl formation usually in the deep rete ridges, prominent intercellular bridges and atypical basal cell with hyperchromatic nuclei. Parakeratosis is frequent finding.

PENILE INVASIVE SQUAMOUS CELL CARCINOMA

Penile invasive squamous cell carcinoma is an aggressive tumor of the skin of the glans or of the inner layer of the prepuce, which occurs in the sixth to seventh decades of life. It is characterized by invasive growth and early metastatic spread to lymph nodes. About 50% of tumors originate from nonkeratinized epithelium of the glans or inner foreskin of prepuce near coronal sulcus as a slow-growing, irregular mass. In high incidence areas, tumor can involve multiple anatomical compartments of penis in ≤50% of cases.

Predisposing Factors

Predisposing factors for penile squamous cell carcinoma include poor personal hygiene, phimosis, accumulation of smegma, chronic inflammation (balanoposthitis), lichen sclerosus, psoriasis treated with UVB radiation, penile rash >1 month, immunosuppression, radiation therapy, uncircumcised men, tobacco smoking, and

venereal disease. Disease is often associated with HPV infection serotypes 16, 18, 31, 33, 45, 56, and 65 in 66% of cases.

HPV Positive or Negative Penile Carcinoma

There are two different pathogenic pathways involved in the development of penile carcinomas. Approach to tumor classification of penile carcinoma is related to the presence or absence of human papillomavirus (HPV).

- Immunohistochemical detection of p16 is used as a surrogate parameter for HPV association. Most common serotypes are HPV 16, 18, 31, 33, 45, 56, and 65.
- Penile carcinomas related to presence of HPV infection include basaloid, warty and warty-basaloid carcinomas in 33% of cases.
- Penile carcinomas related to absence of HPV infection include verrucous, pseudohyperplastic and cuniculatum carcinomas. HPV is rarely present in papillary and sarcomatoid carcinomas. The second pathogenic pathway involved in the pathogenesis of penile carcinomas includes lichen sclerosis or chronic inflammation of the foreskin related to phimosis.
- Molecular techniques such as polymerase chain reaction (PCR) or immunohistochemistry are used to detect HPV.
- Because of these two different pathogenic pathways of penile carcinoma, the WHO classification distinguishes between HPV-associated and non-HPV-associated penile carcinomas in various histologic subtypes. Revised 2024 WHO classification of penile squamous cell carcinoma is given in Table 23.33.

Tumor Growth Patterns of Penile Carcinoma

Classification of penile squamous cell carcinoma according to growth pattern is related to prognosis.

Table 23.33 Revised 2024 WHO classification of tumors of the penis and scrotum

Benign and Precursor Squamous Lesions

- Condyloma accuminatum
- Squamous cell carcinoma precursors, HPV associated
- High-grade squamous intraepithelial lesion
- Squamous cell carcinoma precursors, HPV independent
- Differentiated penile intraepithelial neoplasia

Invasive Epithelial Tumors of the Penis and Scrotum

- **Invasive squamous epithelial tumors**
  - Squamous cell carcinoma, HPV associated
  - Squamous cell carcinoma, HPV independent
  - Squamous cell carcinoma, usual type
  - Squamous cell carcinoma, NOS
  - Basaloid squamous cell carcinoma
  - Warty basaloid carcinoma
  - Clear cell squamous cell carcinoma
  - Lymphoepithelial carcinoma
  - Verrucous carcinoma (including carcinoma cuniculatum)
  - Papillary squamous cell carcinoma
  - Sarcomatoid squamous cell carcinoma
- **Other epithelial tumors**
  - Adenosquamous carcinoma
  - Mucoepidermoid carcinoma
  - Paget disease, extramammary

Others

- Basal cell carcinoma
- Unclassified carcinoma

About 33% of penile carcinomas show mixed pattern of growth in clinically advanced stages. Various growth patterns of penile carcinoma include superficial spreading, vertical, verruciform, multicentric. Growth patterns of penile carcinoma are given in Table 23.34.

Table 23.34 Growth patterns of penile carcinoma

Pattern of Growth	Features
Superficial spreading growth pattern	▪ Minimally invasive tumor throughout epithelium involving foreskin ▪ Usual type SCC slow growing in superficial layers of the sulcus, and/or glans ▪ Prognosis better
Vertical growth pattern	▪ Deeply invasive carcinoma large fungating and/or ulcerative growth invading corpus spongiosum with frequent penetration of the tunica albuginea and corpora cavernosa ▪ Basaloid, sarcomatoid and high-grade usual squamous cell carcinoma ▪ Metastases in regional lymph nodes ▪ Poor prognosis
Verrucous growth pattern	▪ Histologic types: Verrucous, warty (condylomatous), papillary SCC ▪ Slow growing, large granular, exophytic growth on glans (most common site)
Multicentric growth pattern	▪ Presence of two or more independent foci of carcinoma separated by benign tissues ▪ Recurrence common unless all compartments are excised
Mixed and multicentric growth patterns	▪ Histologic types: Mixed hybrid/verrucous and common SCC ▪ Advanced stage penile carcinoma (30% cases)

Clinical Features

Penile squamous cell carcinoma with or without keratinization is the most common aggressive subtype tumor in 70–75% of cases by early metastatic potential. Other aggressive penile tumors include basaloid, sarcomatoid and warty subtypes in 10% of cases. In contrast, the verrucous and condylomatous subtypes only spread in exceptional cases and have a much better prognosis.

- Patient presents with fungating or ulcerative growth most often on the shaft of penis. Occasionally, patient presents with inguinal lymph node metastases with occult penile carcinoma due to severe phimosis or very small primary carcinoma. About 5% of patients have metastases at the time of diagnosis.
- Common sites of metastases are inguinal and pelvic lymph nodes, liver, lung, heart or bone. Local recurrence in one-third is due to insufficient surgery or positive margins, which also increases risk of regional inguinal and pelvic nodal metastases.
- Early suspicion of penile carcinoma, biopsy is necessary to prevent delays in treatment initiation.

Surgical Pathology: Penile Squamous Cell Carcinoma

Gross Morphology

Grossly examined growth patterns of penile carcinoma may have prognostic implications.

- **Superficial spreading penile carcinoma:** Tumor is limited to lamina propria or superficial corpus spongiosum and usually extend horizontally through multiple anatomical compartments.
- **Vertical growth penile carcinoma:** Tumor invades deep anatomical levels, surface is non-verruciform and frequently ulcerated.
- **Verruciform penile carcinoma:** Tumor is exophytic and papillomatous with a cauliflower-like aspect; and may be limited to surface (verrucous) or invade deep anatomical levels (cuniculatum). Invasive penile exophytic growth may involve glans and coronal sulcus completely obstructing urethra (Fig. 23.53).
- **Mixed patterns penile carcinoma:** Tumor is observed in 10–15% of all cases. In some cases, multicentric tumors (2 or more independent foci of carcinomas) are identified.

Light Microscopy

Usual penile squamous cell carcinoma is an infiltrative carcinoma that can be classified with three-grade system based on the level of keratinization, cellular pleomorphism and the presence of regular nests or sheets of tumor cells. Features to report include depth of invasion measured from deepest malignant cells to highest overlying dermal papilla; resection margin.

- **Well differentiated SCC (grade 1):** Tumor is composed of well differentiated squamous cells, almost undistinguishable from normal squamous cells except for the presence of minimal basal/parabasal cell atypia. Tumor cells are arranged in nests or sheets with central keratinization and keratin pearls. It is less common than grade 2 (Fig. 23.54).
- **Moderately differentiated SCC (grade 2):** All tumors are not fitting into criteria for grade 1 or 3. Tumor is composed of cells with high nuclear to cytoplasmic ratio, abundant cytoplasm and monomorphic nuclei and irregular outlines arranged in small nests with scant keratinization. This grade is more common along with transition to grade 3.
- **Poorly differentiated SCC (grade 3):** Tumor is composed of anaplastic cells arranged in nests, cords and solid sheets with focal areas containing spindle, trabecular and clear cells.

Fig. 23.53: Invasive penile carcinoma. There is exophytic growth involving glans and coronal sulcus completely obstructing urethra (arrow).

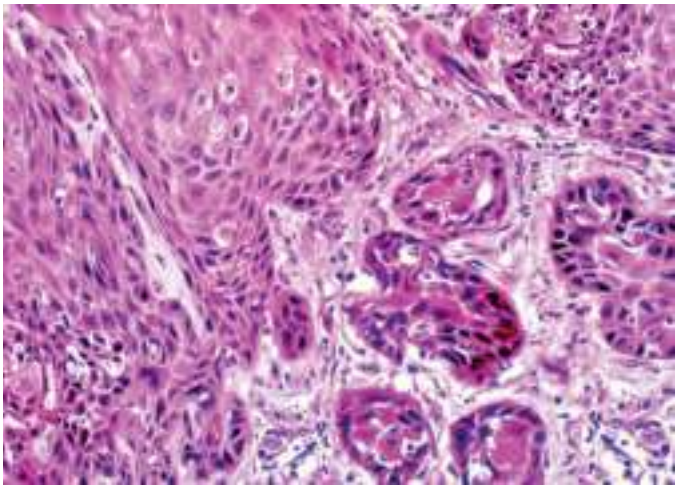

Fig. 23.54: Penile well differentiated squamous cell carcinoma. Tumor is composed of well differentiated squamous cells, almost undistinguishable from normal squamous cells except for the presence of minimal basal/parabasal cell atypia. Tumor cells are arranged in nests or sheets with central keratinization and keratin pearls (400X).

Molecular Genetic Alterations

HPV-DNA has been demonstrated in 40–45% of penile carcinomas. High risk HPV-16 is most frequent type associated with penile carcinoma, followed by HPV-18. Two viral oncoproteins, E6 and E7, appear crucial in the process of carcinogenesis.

- Oncoprotein E6 interferes with the p53 pathway leading to suppression of p53 normal inhibitory function of cell cycle. Oncoprotein E7 interferes with $p16^{INK4a}$/cyclin D/retinoblastoma pathway. Oncoproteins E6 and E7 work independently and together to cause enhanced immortalization of human cells.
- Particularly common genetic alterations are losses of alleles in the regions 9p21 and 17p, coding the tumor suppressor genes p16 and p53, respectively. Inactivation of p16 and p53 is also affected by the HPV oncogenes E6 and E7. P16 promoter hypermethylation and LOH as well as other changes of other tumor suppressor genes (KAI1, nm23H1) are associated with metastatic spread of penile carcinoma.

Clinical Course

Low-grade penile carcinoma with ≤6 mm superficial invasion has no regional lymph node metastases. Intermediate grade of penile carcinoma with 5–10 mm invasion has 15% risk of metastases. High-grade penile carcinoma with 8–10 mm deep invasion into corpus spongiosum, dartos or corpora cavernosa is associated with 80% rate of metastases.

Prognostic Factors of Penile Carcinoma

Poor prognostic factors of penile squamous cell carcinoma are based on depth of tumor invasion (anatomic levels—epithelium, lamina propria, corpus spongiosum, corpus cavernosum and glans penis), high-grade tumor, advanced stage of tumor, lymphovascular invasion, perineural invasion, histologic subtypes of tumor such as anaplastic, basaloid, pseudoglandular, sarcomatoid or solid; and lymph node density. Prognostic factors for squamous cell carcinoma of the penis are given in Table 23.35.

Table 23.35 Prognostic factors for squamous cell carcinoma of the penis

Prognostic Factors	Comments
Histologic subtypes	▪ Broad correlation with histologic subtypes and rates of regional or systemic dissemination ▪ Low risk: Verrucous, papillary, warty (condylomatous), pseudohyperplastic and cuniculatum carcinomas ▪ High-grade: Basaloid, sarcomatoid, adenosquamous, and solid poorly differentiated carcinomas associated with high-grade histology, deep invasion of corpora cavernosa, and frequent lymph node metastases
Lymph node status	▪ Positive lymph node in pelvis and mediastinum: Poor prognosis ▪ Negative lymph node: Better prognosis
Histologic grade	▪ Grade 1 well differentiated SCC: good prognosis ▪ Grade 2 moderately differentiated SCC: intermediate prognosis ▪ Grade 3 poorly differentiated SCC: poor prognosis
Depth of invasion and anatomical levels of invasion	Prognosis depends on depth of tumor and anatomical level of invasion in penis
Urethral invasion	Adverse prognostic factor
Perineural invasion	Independent prognostic factor associated with 5–10 mm depth of invasion
Lymphovascular invasion	Lymphovascular embolization associated with poor prognosis
Modality of tumor growth, front pattern of invasion	▪ High mortality associated with vertical growth pattern ▪ Verrucous tumors belong to low-risk group ▪ Usual SCC and pleomorphic variant belong to intermediate risk group ▪ High-grade, deeply invasive tumors such as basaloid, sarcomatoid and adenosquamous carcinomas and poorly differentiated carcinoma belong to high-risk group
Proliferative index	Ki-67 positive tumor cells in tumor and nodal metastases

Contd...

Table 23.35 Prognostic factors for squamous cell carcinoma of the penis (*Contd...*)

Prognostic Factors	Comments
Molecular factors	Accumulation of p53 protein independent predictive factor associated with poor outcome
Positive resection margins of tumor	Positive resection margins of tumor associated with poor prognosis
Staging status	▪ Risk of metastases to lymph nodes and distant organs increases in tumors infiltrating >5 mm in the glans, dermis in the skin ▪ Stage 1 is superficially invasive (better prognosis) ▪ Stage 2 invades the corpus spongiosum or cavernosum ▪ Stage 3 invades urethra or multiple positive lymph nodes (poor prognosis) ▪ Stage 4 invades pelvis or distant metastases (worst prognosis)

Mode of Spread

Penile squamous cell carcinoma can spread by local invasion, lymphatic route and hematogenous route.

- Superficial spreading tumors may spread from one mucosal compartment to the other; whereas arising from foreskin may spread to the skin of shaft, coronal sulcus, or glans; or tumor originating from glans may spread to the coronal sulcus and foreskin.
- Vertical spreading tumor involves from surface to deep regions in glans involving lamina propria, corpus spongiosum, albuginea and corpus cavernosum; the foreskin involving lamina propria, dartos and outer skin; and the sulcus involving lamina propria and fascia.
- Lymphatic or perineural invasion may be demonstrated at the margins.
- Penile squamous cell carcinoma may spread to the bilateral inguinal lymph nodes. The first site of metastases is in the '**sentinel lymph node**' demonstrated by preoperative lymphoscintigraphy. Systemic dissemination of penile squamous cell carcinoma may involve retroperitoneal lymph nodes, lungs, liver and bones via hemato genous route.

Management

Penile squamous cell carcinoma is treated by local resection or partial/total penectomy. Local excision and partial penectomy are inadequate for sarcomatoid and basaloid carcinomas (outcomes with metastatic disease).

There is higher risk for recurrence if node positive or partial penectomy. Tumor confined to glans may be treated by brachytherapy, that involves placing radioactive material inside body. Patients with prognostic index scores of 5–7 may benefit from prophylactic groin dissection.

CHAPTER

24

Female Reproductive System

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

- Female genital system: overview
  - Embryology of female genital system
  - Anatomy of female genital system
  - Fertilization and development of embryo
  - Pathologic disorders

DISORDERS OF VULVA

- Inflammatory disorders of vulva
  - Human papillomavirus (HPV) infection
  - Lymphogranuloma venereum
  - Granuloma inguinale
  - Genital herpes simplex virus 2 (HSV-2) infection
- Non-neoplastic disorders of vulva
  - Vulvar cysts
  - Bartholin cyst
  - Carbuncle
  - Toxic shock syndrome
  - Lichen sclerosus
- Neoplastic disorders of vulva
  - Papillary hidradenoma of vulva
  - Angiomyofibroblastoma of vulva
  - Leukoplakia of vulva
  - Bowen's disease of vulva
  - Squamous cell carcinoma of vulva
  - Paget's disease of vulva
  - Melanoma of vulva

DISORDERS OF VAGINA

- Inflammatory disorders of vagina
  - Bacterial vaginosis
  - *Candida albicans* infection
  - *Trichomonas vaginalis* infection
  - *Gardenerella vaginalis* infection
  - *Chlamydia trachomatis* infection
  - *Treponema pallidum* infection (syphilis)
  - *Haemophilus ducreyi* infection (chancroid)
  - Pelvic inflammatory disease (PID)
- Neoplastic disorders of vagina
  - Vaginal intraepithelial neoplasia
  - Squamous cell carcinoma of vagina
  - Verrucous carcinoma of vagina
  - Clear cell adenocarcinoma of vagina
  - Botryoid rhabdomyosarcoma of vagina
  - Leiomyosarcoma of vagina
  - Melanoma of vagina

DISORDERS OF UTERINE CERVIX

- Uterine cervix: overview
- Inflammatory disorders of uterine cervix
  - Acute cervicitis
  - Chronic cervicitis
  - Viral cervicitis
- Neoplastic disorders of uterine cervix
  - Endocervical polyp
  - Cervical intraepithelial neoplasia
  - Cervical carcinoma
  - Neuroendocrine tumors of cervix

DISORDERS OF UTERINE ENDOMETRIUM

- Menstrual cycle
- Menstrual cycle disorders
  - Amenorrhea
  - Dysmenorrhea
  - Dysfunctional uterine bleeding
- Inflammatory disorders of uterine endometrium
  - Acute endometritis
  - Chronic endometritis and infertility
- Non-neoplastic disorders of uterine endometrium
  - Endometrial hyperplasia
  - Arias-Stella reaction
  - Adenomyosis uteri
  - Endometriosis
- Neoplastic disorders of uterine endometrium
  - Endometrial polyp
  - Endometrial carcinoma
  - Endometrial stromal tumors
  - Mixed Müllerian tumor

DISORDERS OF UTERINE MYOMETRIUM

- Neoplastic disorders of uterine myometrium
  - Leiomyoma (fibroid/fibromyoma/myoma)
  - Smooth muscle tumor of uncertain malignant potential (STUMP)
  - Leiomyosarcoma

DISORDERS OF FALLOPIAN TUBES

- Fallopian tubes: anatomy
- Inflammatory disorders of fallopian tubes

  - Chronic salpingitis
  - Salpingitis isthmica nodosa
- Non-neoplastic disorders of fallopian tubes
  - Tubal endometriosis
  - Tubal ectopic pregnancy
- Neoplastic disorders of fallopian tubes
  - Adenomatoid tumor of fallopian tubes
  - Adenocarcinoma of fallopian tubes

DISORDERS OF OVARIES

- Inflammatory disorders of ovaries
  - Acute oophoritis
  - Autoimmune oophoritis
  - Noninfectious granulomatous oophoritis
- Ovarian cysts
  - Follicular cyst
  - Corpus luteal cyst
  - Polycystic ovary syndrome (Stein-Leventhal syndrome)
  - Surface epithelial inclusion cysts
  - Paraovarian or paratubal cysts
  - Endometriosis (chocolate cysts)
  - Theca luteal cysts

NEOPLASTIC DISORDERS OF OVARY

- Krukenberg's tumor (metastatic tumor)
- Surface epithelial tumors of ovary
- Germ cell tumors of ovary
- Sex cord-stromal tumors of ovary
- Sertoli-Leydig cell tumors of ovary
- Laboratory diagnosis of ovarian tumors

GESTATIONAL TROPHOBLASTIC NEOPLASTIC DISORDERS AND RELATED TUMOR-LIKE LESIONS

- Gestational trophoblastic disease
- Hydatidiform mole
  - Complete hydatidiform mole
  - Partial hydatidiform mole
  - Invasive hydatidiform mole
- Gestational trophoblastic neoplastic disorders
  - Gestational choriocarcinoma
  - Placental site trophoblastic tumor
  - Epithelioid trophoblastic tumor

PREGNANCY ASSOCIATED NON-NEOPLASTIC DISORDERS

- Toxemia of pregnancy
- Ectopic pregnancy
- Thromboembolism
- Amniotic fluid embolism
- Gestational diabetes mellitus
- Sheehan's syndrome

FEMALE GENITAL SYSTEM: OVERVIEW

EMBRYOLOGY OF FEMALE GENITAL SYSTEM

A central principle of genital tract development in both sexes holds that the Müllerian tubes develop along female lines unless specifically impeded by embryonic testicular factors. In males, Sertoli cells in the developing testis produce Müllerian-inhibiting substance, a protein that causes the Müllerian ducts to regress. Müllerian ducts are the precursors of the fallopian ducts, uterus, and upper-third of the vagina. Formation of the ovary and vulva is not affected by Müllerian inhibitory protein.

ANATOMY OF FEMALE GENITAL SYSTEM

Organs of female genital system include ovaries, fallopian tubes, uterus (corpus cervix), vagina and external genitalia (labia majora, labia minora and clitoris).

- Functions of female genital system are conception, delivery of the baby, synthesis of estrogen and progesterone. Ovaries participate in ovulation.
- Fertilization takes place in fallopian tubes. Fertilized ovum is transported from fallopian tubes to uterine cavity. Implantation of fertilized ovum and placenta formation occurs within uterine cavity.
- Ovaries and placenta function as hormones producing organs to maintain the pregnancy.
- Mammary glands are integrated structurally and functionally to support the process of ovulation, fertilization, pregnancy, baby birth and childcare.
- Induction of labor and delivery of baby occur through vagina. Organs of female genital system are shown in Fig. 24.1.

Ovaries

Ovaries are located in pelvic cavity and attached to pelvic wall and uterus by ligaments. Each ovary measures 3 × 1.5 × 1.0 cm. Outer surface is lined by epithelium and covered by mesovarium, a layer of peritoneum.

- Cut section of ovary has cortex and medulla. Cortex contains large number of graafian follicles. A large number of primary graafian follicles degenerate from birth to puberty. Only 60,000–80,000 primary graafian follicles are left in each ovary. Tunica albuginea consists of dense connective tissue.
- Oogenesis occurs under the influence of endocrine hormones during embryonic development to form oocytes by mitosis, when the female fetus is 25 weeks old. Each ovary consists of two lacs graafian follicles. Total number of ova produced during reproductive period is 450. In each menstrual cycle, one ovum is released. Ovulation occurs between 14th day to 21st day of menstrual cycle. In an oocyte, equatorial division is completed only if fertilization occurs.

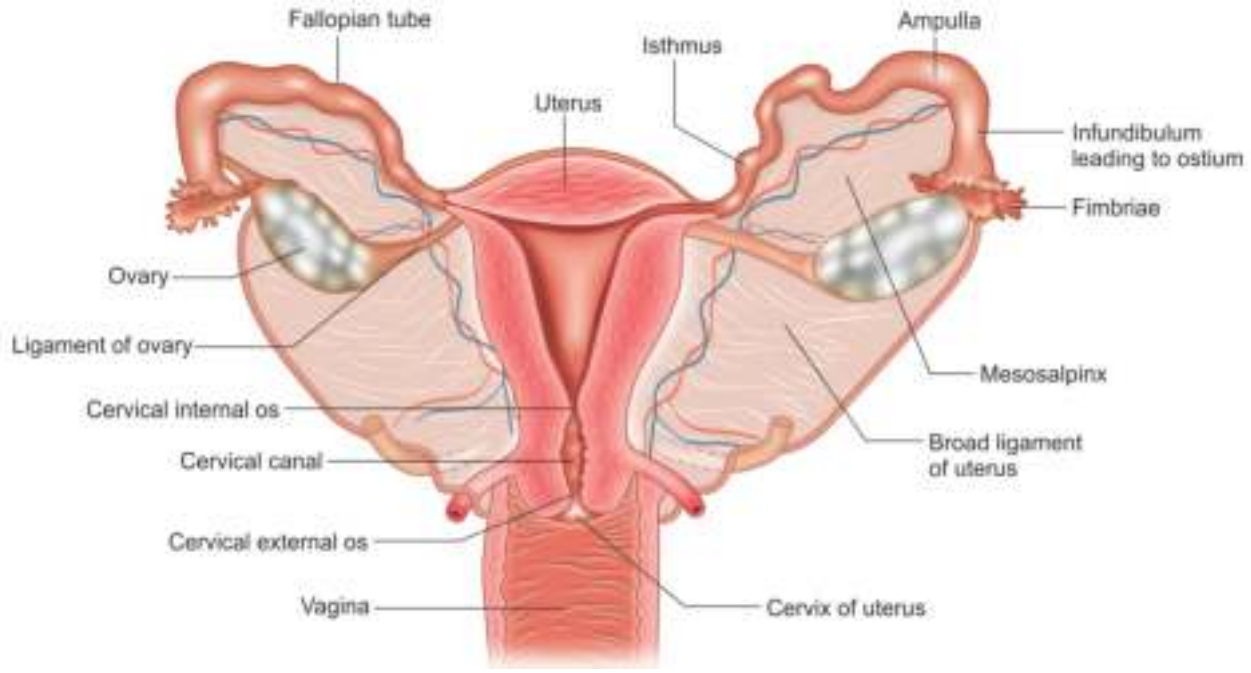

Fig. 24.1: Organs of female genital system. These include ovaries, fallopian tubes, uterus (corpus cervix), vagina and external genitalia (labia majora, labia minora and clitoris).

- After ovulation, corpus luteum secretes progesterone; which prepares the endometrium for receiving blastocyst. Corpus luteum inhibits the contraction of uterus and development of new graafian follicle. If fertilization does not take place, then rising level of progesterone inhibits the release of GnRH, which in turn inhibits production of FSH, LH and progesterone. As the progesterone level drops, the corpus luteum degenerates to become corpus albicans.
- Zona pellucida layer (glycoprotein in nature) secreted by follicular cells or granulosa cells surrounds ovum or oocyte.
- Corona radiata is formed by elongation of granulosa cells in the vicinity of the ovum and zona pellucida. Fluid accumulates in graafian follicle forming liquor follicle.
- Ovum or oocyte is attached with a pedicle called cumulus oophorus formed by granulosa cells. After liberation of the ovum from the graafian follicle, the remaining structure is called corpus luteum.
- Corpus luteum is a mass of granulosa cells and interstitial cells of ovary after ovulation, which is a temporary endocrine gland; which synthesizes progesterone in large quantity and oestrogens.
- Progesterone is essential for maintenance of endometrium. Such an endometrium is necessary for implantation of fertilized ovum and other events of pregnancy. In the absence of fertilization, the corpus luteum degenerates, which causes disintegration of endometrium leading to menstruation, marking a new menstrual cycle.
- Follicular atresia is regression and disappearance of graafian follicles due to phagocytosis, which occurs if ovum does not get fertilized. After follicular atresia, some thecal cells are formed from the stroma and located around the graafian follicle; these are called interstitial cells. The interstitial cells secrete small amount of estrogens.

Fallopian Tubes

Fallopian tubes are also called uterine tubes or oviducts. Each fallopian tube is 10–12 cm in length. Its wall is composed of mucosa, muscular layer and serous layer. Region of fallopian tube close to ovary is called infundibulum, which possesses finger-like projections called fimbriae, which collects ovum from the ovary after ovulation. Region of fallopian tube close to uterus is called isthmus. Wider region of fallopian tube is called ampulla lying between isthmus and infundibulum. Fallopian tube is lined by ciliated columnar epithelium as well as secretory cells. Secretory cells produce viscous liquid medium, which provides nutrition and protection to the ovum.

Uterus

Normal uterus is a pear-shaped hollow organ, which weighs 40–80 g in adult women. Uterus is divided into upper corpus and lower cervical segments. The uterine cavity is triangular measuring 6 cm in length. Uterus is composed of inner endometrial lining consisting of endometrial glands, middle muscular wall and outer serous coat. Serous coat extends to the peritoneal reflection. The peritoneal reflection is short in anterior region than in posterior region. Therefore, it may be used for orienting hysterectomy specimens.

- Uterine cervix has internal os and external os, that projects slightly into an elastic muscular tube, the vagina, which is a checkpoint of vaginal bacterial flora, which secretes mucin to control bacterial growth in vagina. Cervix prevents preterm labor by acting as stopper for conceptus before term.
- Tissue sampling of uterus includes endometrial biopsy and curettage specimens, products of conception, and hysterectomy specimens. The samples are processed and examined by light microscopy to establish diagnosis.
- Menstrual cycle has three phases: menstrual phase, proliferative phase and secretory phase.
  - Menstrual phase occurs for 3–4 days due to disintegration of uterine mucosa, which is sloughed off and discharged from uterus as menstrual bleeding.
  - Proliferative phase occurs from 5th day to 13th day of menstrual cycle. Estrogen levels are high in this period.
  - Secretory phase starts at 14th day and continues till 28th day of menstrual cycle. Progesterone levels are high.

Vagina

Vagina consists of mucosa, muscular layer and serous layer without glands, which is covered by hymen, a thin ring of tissue. Vagina is composed of labia majora, labia minora and accessory genital glands.

External Genital Organs

External genital organs include mons pubis and clitoris. Mons pubis is fatty tissue covered by skin and pubic hair. Clitoris is tiny finger-like structure lined by stratified squamous epithelium, which is analogous to the male's glans penis.

FERTILIZATION AND DEVELOPMENT OF EMBRYO

Fertilization can occur only if the ovum and spermatozoa are transported simultaneously to the ampullary-isthmic junction. The process of fusion of ovum and sperm is called fertilization.

- Ejaculation of semen in the vagina triggers an increase in motility by muscular contraction of uterus and

oviducts, and secondly by secretions liberated by secretory cells of epithelial lining of oviduct mucosa. This phenomenon is called 'capacitation'.

- Spermatozoa comes in contact with zona pellucida layer of ovum and induces changes in its membrane that blocks the entry of additional spermatozoa.
- Activated spermatozoa undergo acrosomal reaction and release various chemicals like substances synthesized by acrosome of spermatozoa such as hyaluronidase, corona penetrating enzyme and zona lysin or acrosin: (a) hyaluronidase that acts on the ground substances of follicle cells, (b) corona penetrating enzyme dissolves corona radiata, and (c) zona lysin or acrosin helps to digest the zona pellucida.
- Secretion of the acrosome helps spermatozoa entry into the cytoplasm of the ovum through zona pellucida and plasma membrane. This induces the completion of meiotic division of the secondary oocyte. About 3–4 ml of semen contains 80–100 million spermatozoa, out of which only one will succeed in entering ovum. Ovum becomes activated and then undergoes depolarization of its membrane.
- During fertilization, genetic material from a spermatozoa cell merges with that of an oocyte to form a single nucleus. Fertilization takes place in ampullary portion of fallopian tube. Spermatozoa pronucleus and ovum pronucleus fusion takes place to form zygote.
- Progesterone is a pregnancy hormone required continuously during entire period of pregnancy or gestation. Other hormones synthesized by placenta during pregnancy are human choriogonadotropin hormone, human placental hormone, estrogens, progesterone, cortisol, prolactin and thyroxine.
- During embryonic stage, holoblastic cleavage is a process in which zygote divides by mitotic division and the subsequent formation of daughter cells (blastomeres). Such cleavage is called 'holoblastic cleavage'.
  - Formation of blastomeres occurs by formation of 2 daughter cells → 4 daughter cells → 8 daughter cells → 16 daughter cells in morula stage. Morula stage is 16 celled stage of embryo. The embryo at the 16 celled stage is called the morula and named from mulberry fruit. Morula continues to divide and transforms into blastocyst.
  - Blastomeres in blastocyst are arranged into outer trophoblast (trophoectoderm cells) and inner cell mass.
  - Trophoblast layer gets attached to the endometrium; while inner cell mass develops into embryo. Peripheral cells become trophoblast or trophoectoderm cells.
- Trophoblast forms four extraembryonic membranes and part in formation of the placenta. Trophoblastic cells secrete fluid into the morula to form blastocoel and resulting in blastocyst, and inner cell mass developing into embryo proper.
- Umbilical cord connects fetus to the placenta, which consists of two umbilical arteries and one umbilical vein. Placenta consists of two parts: (a) chorion or fetal part invades uterine mucosa with chorionic villi bathed in blood, and (b) maternal part or decidua basalis.
- Placenta plays an important role in supporting gestation, which acts as a barrier of maternal immune response and fetus. Cell surface major histocompatibility complex (MHC) class II protein of placenta is involved in immune response. It is maternal–fetal interface for molecular exchanges such as gases, inorganic and organic substances, nutrients, hormones and antibodies. Placenta is physical protector of fetus. It participates in elimination of nitrogenous waste products. Placenta acts as endocrine gland by secreting human chorionic gonadotropin (hCG) hormone, estrogens, progesterone, and chorionic corticotropin. The hCG stimulates corpus luteum of pregnancy that continues to secrete progesterone until the end of the pregnancy.
- In the later phase of pregnancy, relaxin synthesized by placenta and ovary facilitates parturition by softening the connective tissue of pubic symphysis.
- Average gestation period in human is nine months. Parturition (labor) is induced by signals from 'fetal ejection reflex'. Powerful contraction of uterus occurs due to the action of oxytocin secreted by posterior pituitary gland. Opening of cervix results in rupture of amniotic fluid-watery fluid. After delivery, umbilical cord of the newborn baby is cut and tied to cease the blood. Infant breathes and lung expands.
- Ductus arteriosus (communication between arch of aorta and pulmonary artery) closes and becomes ligamentum arteriosum. Foramen ovale (communication between left and right atria) closes and becomes fossa ovalis. Normal blood circulation is established in newborn baby. Placenta is expelled after parturition.

PATHOLOGIC DISORDERS

Common reproductive health concerns for women are endometriosis, uterine leiomyomas, gynecologic cancers, HIV/AIDS, interstitial; cystitis, polycystic ovarian syndrome, sexually transmitted diseases (STDs), tubal pregnancy and molar pregnancy. Pathologic disorders of female genital tract are shown in Fig. 24.2.

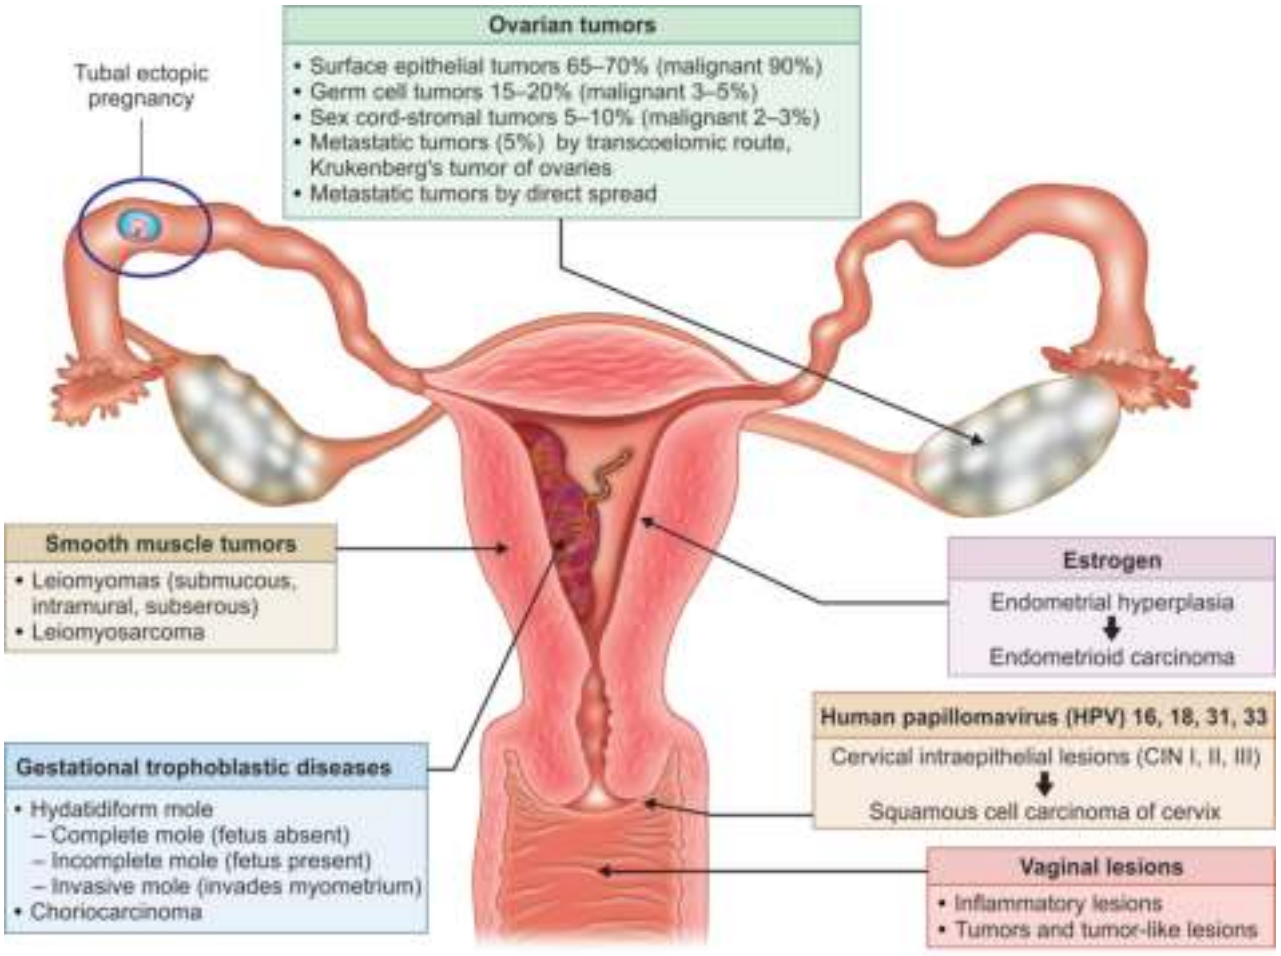

Fig. 24.2: Pathologic disorders of female genital system.

DISORDERS OF VULVA

INFLAMMATORY DISORDERS OF VULVA

Inflammation of vulva most often occurs in post-menopausal women, which is related to thin atrophy of the skin, which has very thin epithelial covering at this phase of life and is easily abraded. Inflammation during reproductive period of life frequently involves Bartholin's gland. The duct of Bartholin's glands may become blocked to form cyst, which may become infected to form Bartholin's abscess. The vulva is most often involved by infections, especially those that flourish in moist areas (e.g. *Candida albicans*), or involve hair follicles to form boils by Staphylococcus. Skin of the vulva may be involved with any other skin disease such as psoriasis or eczema.

HUMAN PAPILLOMAVIRUS (HPV) INFECTION

More than 95% of cervical carcinoma is due to the high-risk human papillomavirus (HPV) strains 16, 18, 31, 33, 45, 52 and 58. Low risk HPV strains (6 and 11) cause about 90% of genital warts on vagina and cervix, which rarely develop into cancers.

- Genital wart, also known as condyloma acuminatum, is a tumor-like exophytic, papillomatous lesion on the skin or mucous membranes of the lower female genital tract (perineum, vulva and vagina). The median incubation period from infection to first detection of HPV is 3 months. HPV types 6 and 11 are detected in over 80% of macroscopically visible condylomata.
- Transmission of low-risk HPV 6 and 11 occurs direct contact between individuals, or autoinoculation.
- Some risk factors such as young age, early age (≤15 years) at first sexual intercourse, sexual promiscuity and immunosuppression have been consistently associated with HPV infection in women. The risk of HPV (16, 18) infection increases with increasing number of recent and lifetime sexual partners, which

may contribute to the pathogenesis of squamous cell carcinoma of vulva and vagina.
- Generally, genital warts are self-limited lesions, often undergo regression spontaneously within six months to two years or even more. Untreated cases due to HPV (16, 18) infections develop cervical carcinoma in a span of 10–30 years.

Clinical Features

Most precursor and premalignant HPV infections are asymptomatic. Infections with low-risk HPV may cause condylomas and genital warts commonly seen as multiple (or single) white, flat or pedunculated, keratotic lesions that may cause pruritus or pain.

Surgical Pathology: HPV-related Epithelial Changes in Vulva

Light Microscopy

- Histologically, the changes involve only the lower 1/3rd of the epithelium due to HPV infection. Koilocytes (intracytoplasmic vacuolation caused by HPV 6 and 11 infection) are superficial or intermediate squamous cells with large and irregular, well-defined perinuclear halos with a cookie cutter border and cytoplasmic thickening. Nuclei of epithelial cells are enlarged (2–3 times of normal).
- Infected cells may demonstrate two or multiple nuclei, which are also apparent in cytopathological Papanicolaou smear. The virus particles can be demonstrated in nucleus by electron microscopy and immunohistochemistry (Fig. 24.3).

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is an ulcerative disease of the genital region due to infection by gram-negative *Chlamydia trachomatis* (L1, L2, or L3 serotypes) transmitted by sexual contact, which primarily affects the lymphatic system. Binding of *Chlamydia trachomatis* occurs via heparin sulfate receptors.

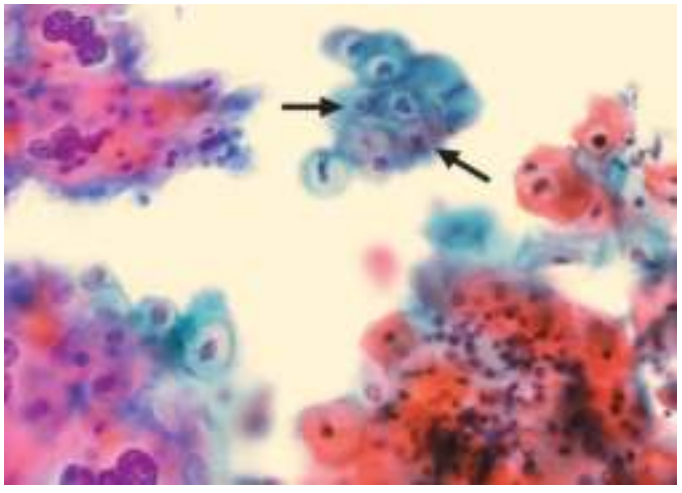

Fig. 24.3: Human papillomavirus (HPV) infection. Pap smear shows koilocytosis, the typical appearance of cervical squamous cell infected by HPV. There is a halo of cleared cytoplasm surrounding an enlarged nucleus (arrows) (400X).

Clinical Features

During clinical course, lymphogranuloma venereum disease has three stages after a month of infection: (a) primary stage is characterized by development of painless genital ulcer or papule at the site of inoculation, (b) secondary stage is characterized by unilateral or bilateral tender inguinal and/or femoral and pelvic lymphadenopathy, also called bubos resulting in chronic suppurative fistulas in the pelvic viscera, and (c) late stage is characterized by formation of rectal strictures, fibrosis due to lymphatic obstruction and fistulae in the anogenital region.

Late sequelae usually occur in untreated cases, which include necrosis and rupture of lymph nodes, fibrosis and stricture in the anogenital; and elephantiasis of the genital organs. The recommended treatment regimen is doxycycline 100 mg orally twice a day given for three weeks.

GRANULOMA INGUINALE

Granuloma inguinale is a bacterial disease caused by *Klebsiella granulomatis*. It was formerly known as *Calymmatobacterium granulomatis*. Disease begins as a papule after about 40 days of infection on the vagina, perineum or vagina, which can spread widely, resulting in extensive ulceration and destruction of tissue. It is endemic in many less-developed regions. The diagnosis of granuloma inguinale is based on the patient's sexual history and clinical examination revealing a painless, 'beefy-red ulcer' with rolled edge of granulation tissue.

Surgical Pathology: Granuloma Inguinale

Light Microscopy

- Histologic examination reveals granulomatous lesion.
- Donovan bodies represent macrophages stuffed with numerous *Klebsiella granulomatis*.

GENITAL HERPES SIMPLEX VIRUS 2 (HSV-2) INFECTION

Herpes simplex virus 2 (HSV-2) is a DNA virus, which is transmitted through intimate genital tract contact. Persistent HSV-2 infection may cause frequent, symptomatic self-limited small vesicles and shallow genital ulcers, that can involve the cervix, vagina, clitoris, vulva, urethra, and perianal skin. In most cases, HSV-2 infection is subclinical. Recent studies have demonstrated that HSV-2 is frequently shed from genital surfaces even in the absence of signs or symptoms of

clinical disease and that the HSV-2 can be transmitted during these periods of shedding, which contributes to increased risk for HIV acquisition.

Clinical Features

Patient presents with vesicles on vulva 3–7 days after sexual intercourse in 30% of women. Genital ulcers may persist for 1–3 weeks but heal spontaneously without scarring. HSV-2 migrates along the nerves to the lumbar ganglia, and remains dormant. HSV-2 can be activated, that may descend to the vulva to produce recurrent vesicles.

Surgical Pathology: Genital Herpes Simplex Virus 2 Infection
Light Microscopy
Multinucleated giant cells with viral inclusions, nuclear molding, and margination of the chromatin are demonstrated in cytological smears from lesions.

NON-NEOPLASTIC DISORDERS OF VULVA

VULVAR CYSTS

Epidermoid cysts are the most common vulvar cysts, which usually develop as a result of invagination of superficial squamous epithelium within epidermis. Vulvar cysts are usually located in the anterior half of the labia majora. Hymenal cysts are common in the newborns. Type of vulvar cysts is given in Table 24.1.

BARTHOLIN CYST

The Bartholin glands are located in the lower right and left portions at the 4 o'clock and 8 o'clock positions of the vaginal introitus, which produce a clear mucoid secretion that continuously lubricates the vestibular surface.

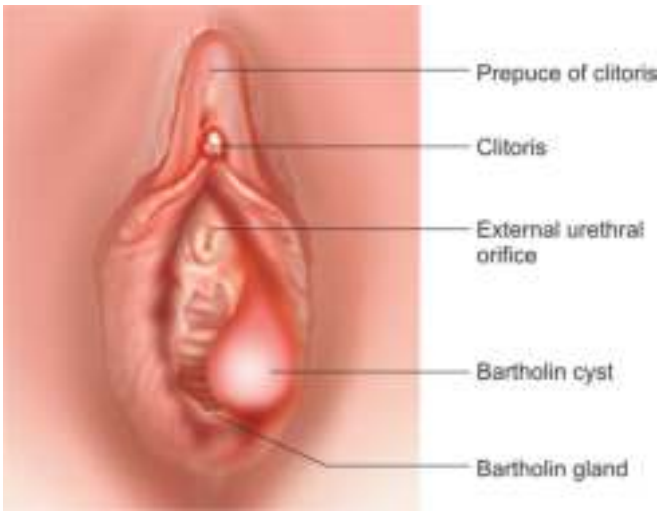

Fig. 24.4: Bartholin cyst. Obstruction of Bartholin ducts results in Bartholin cyst. The cyst usually measures 2–4 cm in diameter, that may cause dyspareunia, urinary irritation, and vague pelvic pain.

- Obstruction of Bartholin ducts results in Bartholin cyst. It may be secondarily infected by *Neisseria gonorrhoeae* or Staphylococci, or *Chlamydia trachomatis* resulting in Bartholin gland abscess. It is treated with incision and drainage.
- Bartholin cyst and abscess are often found after the onset of puberty and a decrease in incidence after menopause. The Bartholin cyst usually measures 2–4 cm in diameter, that may cause dyspareunia, urinary irritation, and vague pelvic pain.
- Bartholin cyst is usually filled with nonpurulent fluid that contains Staphylococcus, Streptococcus, and *Escherichia coli*. Asymptomatic Bartholin cyst does not require further treatment.
- Bartholin cyst or abscess is managed conservatively with sitz bath and analgesics. Bartholin cyst is shown in Fig. 24.4.

Table 24.1 Type of vulvar cysts

Type	Origin	Lining Epithelium
Epidermoid cyst	Invagination of superficial squamous epithelium within epidermis	Squamous epithelium
Bartholin duct cyst	Bartholin duct	Transitional epithelium
Pilonidal cyst	Hair follicle	Squamous epithelium
Hymenal cyst	Hymen	Squamous epithelium
Skene duct cyst	Skene duct	Transitional epithelium
Cyst of canal of Nuck	Processus vaginalis	Mesothelium
Mucinous duct cyst	Minor vestibular glands	Mucus secreting epithelium
Gartner duct cyst	Mesonephric/wolffian	Non-mucus secreting epithelium
Fox-Fordyce disease	Apocrine gland	Hair follicle wall
Endometriotic cyst	Endometriotic foci	Endometrium

CARBUNCLE

Carbuncle is an exophytic or often ulcerated, polypoid mass of 1–2 cm in diameter present near the female urethral meatus resulting in pain and bleeding. Carbuncle most often affects perimenopausal women. Histologic examination of carbuncle reveals acute and chronic inflammatory granulation tissue and hyperplasia of lining epithelium.

TOXIC SHOCK SYNDROME

Toxic shock syndrome occurs due to production of superantigens by certain strains of invasive *Staphylococcus aureus* and Streptococci infection. Patient presents with fever, shock, desquamative erythematous rash, vomiting, diarrhea, myalgias, neurologic signs and decreased platelets count. Patient may develop disseminated intravascular coagulation (DIC).

LICHEN SCLEROSUS

Lichen sclerosus is an inflammatory disease of the vulva most often associated with autoimmune disorders such as vitiligo, pernicious anemia, and Hashimoto's thyroiditis. Patient presents with dry, scaly, itchy (pruritus) white plaques and atrophic skin with a parchment paper-like or wrinkled appearance resulting in marked contracture of the vulvar tissues (dyspareunia). TP53 gene mutation has been demonstrated in some cases of Lichen sclerosus.

Surgical Pathology: Lichen Sclerosus

Light Microscopy

- Skin lesion from lichen sclerosus shows hyperkeratosis, epithelial thinning with flattening of the rete pegs and homogeneous, a cellular zone in the upper dermis.
- A band of chronic inflammatory cells typically lies beneath this layer.
- Minority of patients may develop squamous cell carcinoma in 15% of cases.

NEOPLASTIC DISORDERS OF VULVA

PAPILLARY HIDRADENOMA OF VULVA

Papillary hidradenoma is the most common well circumscribed benign tumor of the vulva, which is sometimes clinically mistaken for a malignant tumor because of its tendency to undergo ulceration. Tumor occurs in labia majora and labia minora, which arises from anogenital ectopic breast tissue or apocrine sweat glands. Patient presents with labial nodule that may ulcerate and bleed.

Surgical Pathology: Papillary Hidradenoma of Vulva

Light Microscopy

- Papillary hidradenoma tumor is composed of cells arranged in complex glandular and papillary pattern with scant stroma.
- Luminal layer is lined by cuboidal epithelium with apocrine differentiation, and basal layer of myoepithelial cells.
- Surgical excision cures the patient.

ANGIOMYOFIBROBLASTOMA OF VULVA

Angiomyofibroblastoma is a well circumscribed mesenchymal tumor derived from subepithelial myxoid stromal zone of vulva, vagina or perineal in middle-aged women.

Surgical Pathology: Angiomyofibroblastoma of Vulva

Gross Morphology

- Angiomyofibroblastoma is well circumscribed mass measuring 1–15 cm.
- Cut surface is homogeneous, pink, gray without hemorrhage or necrosis.

Light Microscopy

- Angiomyofibroblastoma is composed of spindle cells or oval cells with minimal myxoid stroma.
- The tumor cells are arranged in whirling pattern around blood vessels.

Immunohistochemistry Technique

Immunohistochemistry of tumor cells of angiomyofibroblastoma shows positivity with desmin and hormone receptors (ER/PR), CD34 expression is demonstrated in 50% of cases.

Markers	Expression
Desmin	Positive
Hormone receptors (ER/PR)	Positive
CD34	Positive (50%)

LEUKOPLAKIA OF VULVA

Leukoplakia is a firmly attached white plaque-like thickening on a mucous membrane of vulva noticed on naked eye examination. The edges of the lesion undergoes abrupt changes with time. Histologic examination shows increased keratin build up with or without abnormal cells, but is not diagnostic. Leukoplakia is associated with an increased risk for carcinoma.

BOWEN'S DISEASE OF VULVA

Bowen's disease is a multicentric lesion in vulva and also known as vulvar carcinoma *in situ*, which has the potential of progression to invasive carcinoma. Bowen's disease appears as a slow-growing flat or slightly raised,

persistent reddish-brown dry scaly patch or plaque on vulva. The vulvar lesions are normally not associated with any symptoms, but occasionally can itch, ooze pus, bleed or become crusted and/or tender.

SQUAMOUS CELL CARCINOMA OF VULVA

Squamous cell carcinoma of vulva is the most common malignant tumor of the vulva. Cytokeratins are expressed in neoplastic cells. It constitutes 85% cancers of vulva. It is the end result of a multistep process that has its origin as vulvar intraepithelial neoplasia.

- Human papillomavirus (HPV) 16, 18, 31, or 33 (HPV 16 most common) commonly infects vulva in 85% of elderly women.
- Patient develops HPV-induced premalignant vaginal intraepithelial neoplasia (grades 1, 2 and 3 lesions) resulting in vaginal invasive squamous cell carcinoma, which may also develop in association with dysplastic precursor known as 'lichen sclerosus'. Clinical photograph of squamous cell carcinoma of vulva is shown in Fig. 24.5.

Mode of Spread

Squamous cell carcinoma of vulva spreads slowly and invades contiguous skin, vagina, and rectum. Tumor metastasizes by lymphatic route to the superficial inguinal lymph nodes and then involving the deep inguinal, femoral, and pelvic lymph nodes. Tumor metastasizes to lung, and liver via hematogenous route. The frequency of metastases is related to the size and local extension of tumor.

Fig. 24.5: Clinical photograph of squamous cell carcinoma of vulva. Fungating growth with ulceration is visible.

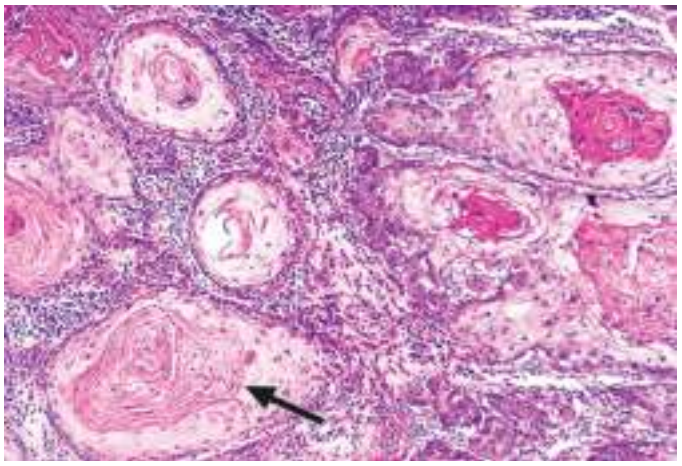

Fig. 24.6: Squamous cell carcinoma of vulva. At high magnification, nests of neoplastic squamous cells are invaded through a chronically inflamed stroma. This cancer is well-differentiated, as evidenced by keratin pearls (400X).

Surgical Pathology: Squamous Cell Carcinoma of Vulva
Gross Morphology
Growth is most often exophytic (66%) and may be ulcerative and endophytic.
Light Microscopy
▪ Tumor shows well-differentiated squamous cell carcinoma with keratin pearls in majority of cases. ▪ Some may be poorly differentiated (basaloid) carcinoma (Fig. 24.6).

PAGET'S DISEASE OF VULVA

Paget's disease of vulva is similar to Paget's disease of the breast. It is primarily an intradermal adenocarcinoma of vulva derived from multipotent cells in the epidermis, adnexa or anogenital glands, which usually occurs on the labia majora in elderly women. Diagnosis of Paget's disease of vulva must be confirmed on histologic examination. Underlying adenocarcinoma should be ruled out by complete pelvic examination, colposcopy and radiologic examination. Clinical photograph of Paget's disease of vulva is shown in Fig. 24.7.

Clinical Features

Patient presents with pruritic, eczematous raised rash in the vulvar perianal, or perineal areas, which may persist for decades and often recurs following surgical excision.

Surgical Pathology: Paget's Disease of Vulva
Gross Morphology
Paget's disease of vulva has sharply demarcated plaque.

Light Microscopy

- Intraepidermal single or clusters of large tumor cells characterized by abundant eosinophilic, clear or amphophilic cytoplasm containing glycosaminoglycans (mucin) surrounded by a clear, halo-like area of vacuolation, round/ovoid vesicular nuclei, open chromatin and small nucleoli.
- The intraepithelial cells are known as Paget's cells are arranged in nests at the epidermal–dermal interface and within the epidermis (pagetoid spread).
- Basal layer is preserved but may be attenuated. Clefting between tumor cells and the surrounding epidermis may be present, due to absence of desmosomes (Fig. 24.8).

Histochemistry

Mucopolysaccharides present in the tumor cells are stained with PAS, mucicarmine and Alcian blue.

Immunohistochemistry Technique

The tumor expresses carcinoembryonic antigen (CEA), epithelial membrane antigen and CK7. But CK20 is negative in tumor cells.

Markers	Expression
CEA	Positive
EMA	Positive
CK7	Positive
CK20	Negative

Prognostic Factors

Most important prognostic indicators of Paget's disease of vulva include clinical detection of a nodule within the primary lesion, Paget's disease of vulva, palpable lymphadenopathy, the level of tumor invasion and lymph node metastases. Histologic features of Paget's disease of vulva are associated with tumor progression and invasion include increased expression of p53, cyclin D1 and Ki-67; and decreased expression of E-cadherin. Patient with clitoris involvement may need more aggressive treatment.

Fig. 24.7: Paget's disease of vulva. Eczematous raised rash is seen in the vulvar region.

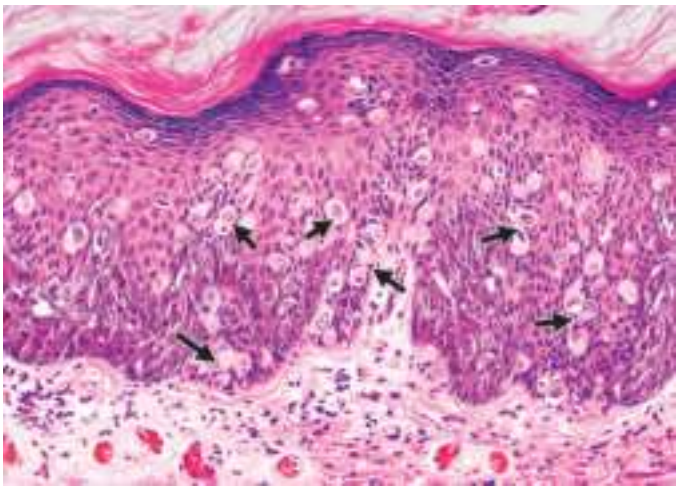

Fig. 24.8: Paget's disease of vulva. The tumor cells in the overlying epidermis are called Paget's cells. These are large cells with abundant clear cytoplasm and large nuclei with prominent nucleoli, arranged singly or in clusters; represent intraepithelial extension of an underlying carcinoma *in situ* or invasive ductal carcinoma (arrows) (400X).

Treatment

Paget's disease of vulva is treated by Mohs' micrographic surgery or wide local excision, topical imiquimod, radiotherapy, photodynamic therapy or CO_2 laser ablation.

MELANOMA OF VULVA

Melanoma of vulva is a rare lesion affecting elderly women (60–70 years), which accounts for approximately 10% of malignant tumors of the vulva. Labia (minora and majora) are the most commonly affected sites, followed by clitoris in some studies. Melanoma of vulva may be discovered during routine gynecologic examinations. Patient usually presents with spreading pigmented patch or multiple lesions (satellitosis) or sometimes nonpigmented lesions (macules, patches, nodules). Spreading pigmented patch resembles extramammary Paget's disease of vulva.

Imaging Techniques

Computed tomography (CT) and magnetic resonance imaging (MRI) and scans are done for staging of disease. Lymphoscintigraphy is performed for identification of sentinel nodes.

Surgical Pathology: Melanoma of Vulva

Gross Morphology

Preservation of specimen orientation is critical for thorough evaluation of peripheral and deep tissue margins. Lesion can be pigmented patch or multiple lesions (satellitosis).

Light Microscopy

- Melanoma of vulva is evaluated and staged similar to cutaneous melanoma involving the cutaneous surface (superficial spreading being the most common type at this site). Melanoma involving mucosal surface is classified as lentiginous type.
- Tumor is composed of melanoma cells larger than nevus cells. These cells contain large nuclei with irregular contours with eosinophilic nuclei. Chromatin is clumped at the periphery of the nuclear membrane (Fig. 24.9).

Immunohistochemistry Technique

Tumor shows positivity for S-100 protein, MART-1 (melan-A), Ki-67, CAM 5.2 and HMB-45.

Markers	Expression
Melanin antigen recognized by T cells (MART1) (melan-A)	Positive
HMB-45 (human melanoma black 45)	Positive (epithelioid melanoma)
S-100 protein (calcium binding protein)	Positive (cytoplasmic or nuclear)
Ki-67	Positive
CAM 5.2	Positive
Tyrosinase	Positive
SOX-10	Positive
MITF (microphthalmia-associated transcription factor)	Positive
SOX-100	Positive
PNL2	Positive
MUM1	Positive

Molecular Genetic Alterations

KIT mutations and amplifications appear to be more commonly demonstrated in vulvar melanomas. N-RAS mutation is also present. BRAF V600E mutations are rarely present. Vulvar melanoma may have copy number alterations in 1q and 6p.

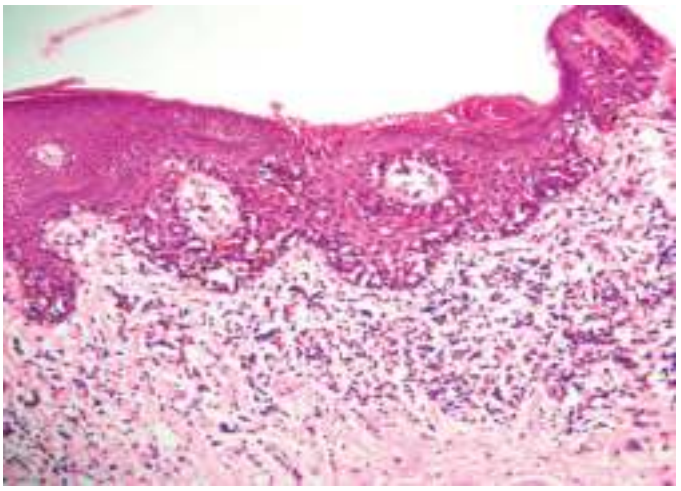

Fig. 24.9: Malignant melanoma. Tumor is composed of melanoma cells (400X).

Prognostic Factors

Histologic parameters of melanoma of vulva include Breslow depth (tumor thickness) and feasibility of complete resection with appropriate margins, mitotic rate, ulceration and margin status and stage. Free margin of ≥1.0 mm is associated with better prognosis. Patient with localized disease (stages 0, I, II) is associated with better prognosis. Presence of higher number of positive lymph nodes is associated with worse prognosis. Serum lactate dehydrogenase levels >200–225 U/L are associated with poor survival.

Treatment

Melanoma of vulva is surgical resection with adequate margins is the principal management, radiation, chemotherapy and topical imiquimod therapy.

DISORDERS OF VAGINA

INFLAMMATORY DISORDERS OF VAGINA

Vaginal discharge is a common complaint in multiparous women. Physiologic vaginal discharge is scanty, mucoid and colorless. Pathologic vaginal discharge occurs due to *Trichomonas vaginalis* or *Candida albicans* or bacterial vaginosis. Primary mode of transmission of sexually transmitted infections is through vaginal or anal sexual contact or vertical transmission from mother to fetus. There are however a number of inflammatory conditions which arise primarily in vagina.

BACTERIAL VAGINOSIS

Bacterial vaginosis is a common vaginal infection caused by an overgrowth of bacteria, which involves an imbalance in the hormonal and bacterial flora of the vagina. The *Lactobacillus* species dominates normal vaginal microbiota. Bacterial vaginosis is associated with a decline in the overall number of Lactobacillus, resulting in vaginal discharge, irritation and increased risk of transmission of sexually transmitted diseases and pelvic inflammatory diseases and complicated

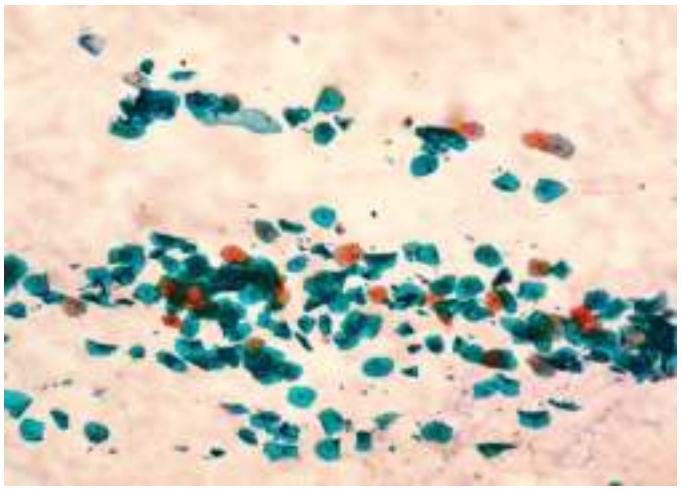

Fig. 24.10: Pap smear from normal women. Normal Pap smear shows superficial and intermediate squamous epithelial cells (400X).

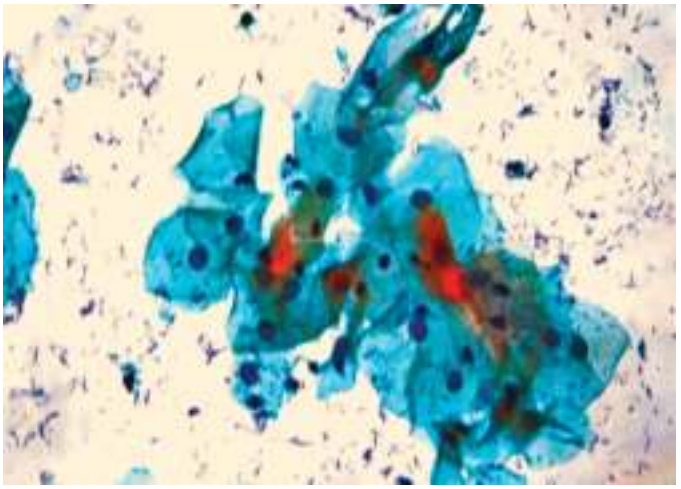

Fig. 24.11: Pap smear in bacterial vaginosis. Pap smear demonstrates clue cells (400X).

pregnancy. The hallmark of diagnosis of bacterial vaginosis relies on examination of vaginal fluid on a wet mount under light microscope. Bacterial vaginosis is characterized by the presence of clue cells, which are epithelial cells of the cervix that are embedded with rod-shaped bacteria (Figs 24.10 and 24.11).

CANDIDA ALBICANS INFECTION

Candida albicans causes vulvovaginitis affecting 10% of women. *Candida albicans* is a normal vaginal flora. Infection is commonly associated with pregnancy, diabetes mellitus, broad-spectrum antibiotic therapy, oral contraceptive use, and immunosuppression resulting in fungal growth. Patient presents with white curd-like vaginal discharge that may cause intense itching. Per vaginal examination shows white patches on the mucosal surface of vagina covered with vaginal discharge. Diagnosis is best made microscopically on wet mounts or Papanicolaou smear showing fungal pseudohyphae (Fig. 24.12).

TRICHOMONAS VAGINALIS INFECTION

Trichomonas vaginalis is the second most common cause of vaginitis. It is commonly transmitted by sexual contact. Patient presents with a profuse opaque or creamy colored frothy discharge with fishy smell. Vaginal discharge may cause vulvar irritation and burning micturition due to urethral inflammation. *Trichomonas vaginalis* is best demonstrated in freshly prepared unfixed wet smears from vaginal discharge, in which the flagellate protozoa keep moving (Fig. 24.13).

GARDNERELLA VAGINALIS INFECTION

Gardnerella vaginalis is a common cause of vaginal discharge, which grows on vagina due to loss of the normal vaginal lactobacilli. Patient presents with thin

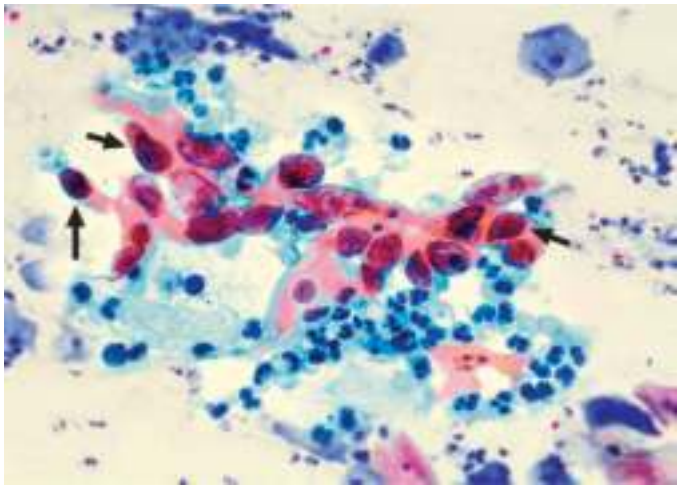

Fig. 24.12: *Candida albicans*. Pap smear demonstrates *Candida albicans* (arrows) (400X).

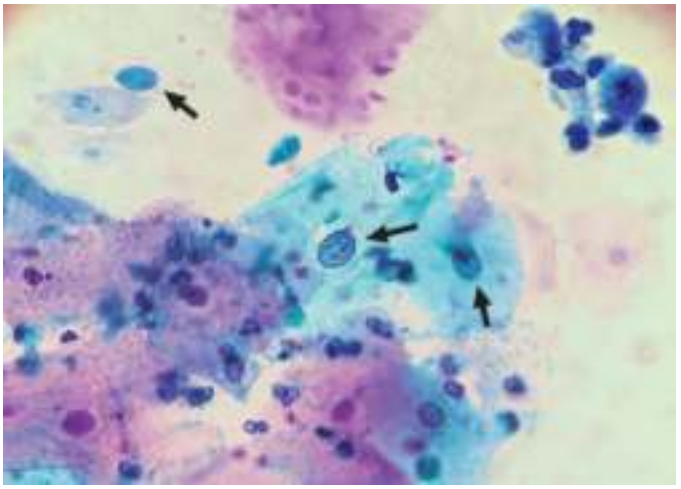

Fig. 24.13: *Trichomonas vaginalis*. Pap smear demonstrates *Trichomonas vaginalis* (arrows) (400X).

homogeneous vaginal discharge with a malodorous, fishy amine odor, especially on addition of 10% potassium hydroxide. *Gardnerella vaginalis* is best recognized on Papanicolau smear due to presence of clue cells (i.e. squamous cells covered with clumped nuclei, folded cytoplasm, and numerous bacteria attached to their surface).

CHLAMYDIA TRACHOMATIS INFECTION

Chlamydia trachomatis (serotypes D–K) is transmitted by sexual contact, which infects squamocolumnar or transitional epithelial cells leading to cervicitis and pelvic inflammatory disease (PID) in women and urethritis in men. *Chlamydia trachomatis* manipulates an array of host processes to support their obligate intracellular developmental cycle, which leads to activation of signaling pathways resulting in disproportionate influx of innate immune cells and the release of tissue damaging proteins and proinflammatory cytokines.

- *Chlamydia trachomatis*-induced pelvic inflammatory disease results in reproductive sequelae such as ectopic pregnancy, infertility and chronic pelvic pain. The disease is most often asymptomatic.
- Patient may present with vaginal discharge, vesicles and ulcers on vulva, pelvic pain or pelvic mass, and discomfort during intercourse.
- Patient is treated with azithromycin (1 g, single dose) or doxycycline (100 mg twice daily × 7 days).

TREPONEMA PALLIDUM INFECTION (SYPHILIS)

Treponema pallidum is a spirochete and the etiologic agent of syphilis. It is transmitted by sexual contact. Patient presents with firm, painless ulcer known as a chancre, which is usually not apparent clinically. During secondary syphilis, patient sometimes develops gray, flattened, wart-like lesions known as **condylomata lata**. Syphilis is hazardous during pregnancy because spirochetes can cross the placenta and resulting in fetal malformation.

HAEMOPHILUS DUCREYI INFECTION (CHANCROID)

Chancroid is an exceedingly rare sexually transmitted infection, soft and painful ulcerated lesion known as chancroid on the cervix, vagina, vulva, or perianal region after 3–5 days of sexual contact with infected partner by *Haemophilus ducreyi*. It is a small gram-negative rod which requires special media, not easily available in most laboratories, to ensure its growth.

- Chancroid is a similar lesion to the primary lesion in syphilis, but instead chancroid is painful. Chancroid is most common in tropical areas, but rare in the United States, which may be associated inguinal lymphadenopathy, fever, chills, and malaise. It sometimes causes urethral stenosis.
- Histologic examination of the chancroid lesion shows a granulomatous inflammatory reaction. Gene clusters have been observed in *Haemophilus ducreyi* which encode for a cytolethal distending toxin similar to those found in invasive enteric bacteria such as Campylobacter, Shigella, and *Escherichia coli*. This toxin causes irreversible cell death of epithelial cells and may result in development of the skin breakdown and subsequent ulcer development.

PELVIC INFLAMMATORY DISEASE (PID)

Extension of infection from vagina, fallopian tubes or ovaries into pelvis is known as pelvic inflammatory disease. It most often affects women in reproductive age group between 20 and 40 years. Pelvic inflammatory disease is most often a complication of sexually transmitted infections (40–45%) caused by *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.

- Polymicrobial infections (Staphylococci, Streptococci, or enteric bacteria) during delivery or abortion are responsible for pelvic inflammatory disease in 45–50% of cases. Other causes of PID include tuberculosis (5%), vaginal amoebiasis, and *Actinomyces israelii* in women with intrauterine contraceptive device.
- Tuberculosis and *Chlamydia trachomatis* spread via intraluminal route hence cause infertility. Patient develops acute or chronic pelvic inflammatory disease depending on the causative organisms. Papanicolau smear shows cotton ball-like pseudofilamentous appearance. *Actinomyces israelii* in woman with intrauterine contraceptive device (Fig. 24.14).

Clinical Features

Patient presents with abdominal tenderness (direct/rebound), tenderness on movement of cervix and uterus, adnexal tenderness, positive endocervical smear for

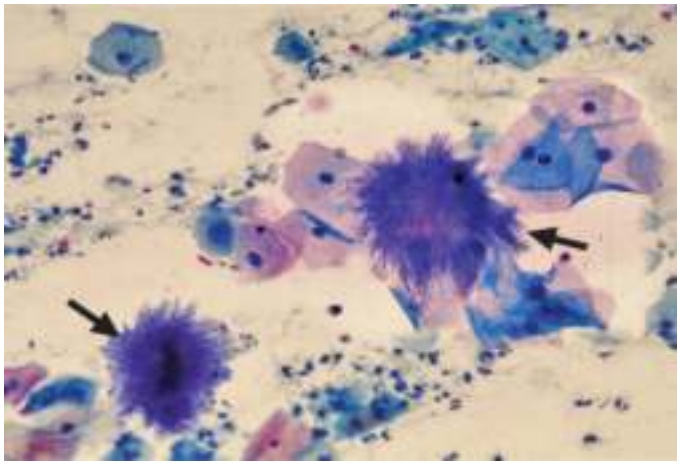

Fig. 24.14: *Actinomyces israelii.* Papanicolau smear shows cotton ball-like pseudofilamentous appearance in woman with intrauterine contraceptive device (arrows) (400X).

gonococcal infection, fever, leukocytosis, and purulent material on laparoscopy or culdocentesis. Infection spreads via periluminal route, hence chances of fertility are bright.

Complications

Infertility occurs due to occlusion of fallopian tubes. Patient with chronic nonspecific infection presents with fever, malaise, and fatigue. Pelvic mass, which is tender and often associated with pain during urinary bladder distension or defecation or sexual intercourse (dyspareunia). Patient develops peritoneal adhesions or generalized bacteremia.

Differential Diagnosis

Pelvic pain may occur due to disorders of uterus, ovaries, pelvic adhesions and endometriosis. Pelvic inflammatory disease is characterized by generalized lower abdominal shooting gripping pain more on one side. Endometriosis presents with shooting cramping pain, that builds up during menstrual period. Uterine pathology is characterized by bleeding per vagina, cramping pain in mid abdominal region before or during menstrual cycle. Ovarian cyst presents with sudden intermittent pain in iliac fossa of affected side.

NEOPLASTIC DISORDERS OF VAGINA

Tumors of vagina include vaginal intraepithelial neoplasia, squamous cell carcinoma, verrucous carcinoma, botryoides, rhabdomyosarcoma, leiomyomas and malignant melanoma.

VAGINAL INTRAEPITHELIAL NEOPLASIA

Vaginal intraepithelial neoplasia (VIN) is defined as presence of squamous cell dysplasia without invasion in upper third of the vagina, which affects women 20–80 years of age. HPV has been implicated in pathogenesis of vaginal intraepithelial neoplasia and associated with multifocal and lesions.

- Risk factors for VIN include early age at first intercourse especially with multiple sexual partners.
- Low-grade vaginal intraepithelial neoplasia is caused by low-oncogenic risk HPV 6, 11, that may undergo malignant transformation in 5% of cases. On contrary, high-grade vaginal intraepithelial neoplasia occurs due to high-oncogenic risk HPV 16, 31, 33, 35, and 39. Comparison of vaginal intraepithelial neoplasia (VIN) types is given in Table 24.2.

Clinical Features

Patient is usually asymptomatic but may present with vaginal discharge or postcoital spotting. Most common presentation of vaginal intraepithelial neoplasia is abnormal cytology. Vaginal intraepithelial neoplasia is a histologic diagnosis typical based on colposcopy assessment and biopsy of the vaginal intraepithelial neoplasia (VIN). Lugol iodine solution can be used to detect VIN and confirm boundaries prior to excision. On application of 3–5% acetic acid in the vagina, VIN appears as raised or flat white, granular epithelium with sharply demarcated borders with punctation and mosaic pattern more prevalent in vaginal intraepithelial 2 and 3. High-grade vaginal intraepithelial hyperplasia is a precursor of invasive squamous cell carcinoma of the vagina.

Surgical Pathology: Vaginal Intraepithelial Neoplasia

Gross Morphology

Vaginal intraepithelial neoplasia appears as an exophytic growth to verrucopapillary lesion.

Light Microscopy

- Squamous epithelium of vaginal intraepithelial neoplasia shows hyperchromatic nuclei and irregular nuclear membrane.
- Grading is based on the extent of thickness of squamous epithelium (VIN-1, VIN-2 and VIN-3) sharing dysplastic changes.

Table 24.2 Comparison of vaginal intraepithelial neoplasia (VIN) types

Parameters	Vaginal Intraepithelial Neoplasia Usual Type	Differentiated Vaginal Intraepithelial Neoplasia Type
Age group	Younger women	Postmenopausal women
Etiology	HPV related cytopathic effect	Not related to HPV without cytopathic effect, but associated with lichen sclerosus
Histologic features	Cells with hyperchromatic nuclei, prominent nuclear membrane and mitoses, lesion may be warty, basaloid or mixed subtypes	Cells with hyperchromatic nuclei, prominent nuclear membrane, mitoses and eosinophilic cytoplasm
Grading	VIN-1, VIN-2 and VIN-3	VIN-3
Progression to squamous cell carcinoma	Low progression to squamous cell carcinoma (SCC)	High progression to keratinized squamous cell carcinoma (SCC)

Treatment

Clinical management of VIN-1 is simple follow-up of the patient. VIN-2 and VIN-3 are treated by simple excision or laser ablation.

SQUAMOUS CELL CARCINOMA OF VAGINA

Squamous cell carcinoma originates in vagina without involvement of surrounding structures, such as cervix or vulva, which accounts for 1–3% of gynecologic cancers. About 80–90% of primary vaginal cancers are squamous cell carcinomas, which usually occur in the 6th decade of life (median age 58–68) but can also be seen in younger women associated with HPV infection.

- Most common site of squamous cell carcinoma is in the upper half of vagina. Small tumor may be missed on initial examination and involves lower two-thirds of vagina. In some cases, vaginal intraepithelial neoplasia (VIN) can be present prior to development of invasive squamous cell carcinoma.
- History of prior hysterectomy is present in 50% of cases. Vaginal squamous cell carcinoma is also associated with vaginal or uterovaginal prolapse. Squamous cell carcinoma of vagina can spread to regional lymph nodes, lungs, liver, brain and bones.

Etiopathogenesis

There is strong relationship of vaginal squamous cell carcinoma with high risk human papillomavirus, especially HPV 16 (80%), HPV 18 and HPV 31. It is more common in tobacco smokers, because tobacco smoking increases the risk for high-grade VIN in women with oncogenic HPV.

Clinical Features

Patient presents with vaginal bleeding or discharge (most common), urinary symptoms and lower abdominal pain. Small tumor is asymptomatic.

Laboratory Diagnosis

Patient is diagnosed by clinical history along with histologic examination of biopsy/resection specimen. Tumor involving both vagina and cervix should be classified as a cervical carcinoma; similarly, a tumor involving both vagina and vulva should be considered a vulvar squamous cell carcinoma. Imaging is required to determine extent of disease and to look for distant metastasis to lymph nodes and via hematogenous route to lung, liver, brain and bones.

Surgical Pathology: Squamous Cell Carcinoma of Vagina

Gross Morphology

Squamous cell carcinoma of vagina can be exophytic or ulcerative with necrosis.

Light Microscopy

- Histologically tumor is graded as well differentiated, moderately differentiated, poorly differentiated or undifferentiated.
- Well differentiated squamous cell carcinomas has polygonal squamous cells with ample eosinophilic cytoplasm, abundant keratin pearls and intercellular bridges. Nuclear pleomorphism and mitotic activity increases from well to poorly differentiated.
- Poorly differentiated squamous cell carcinomas has small cells with scant cytoplasm and hyperchromatic nuclei.
- Moderately differentiated squamous cell carcinomas has histologic features intermediate between well and poorly differentiated.
- Human papillomavirus (HPV) positive tumors are more frequently of nonkeratinizing, basaloid or warty type squamous cell carcinoma than HPV negative tumors. Histology of well-differentiated squamous cell carcinoma is shown in Fig. 24.15.

Prognostic Factors

FIGO stage of squamous cell carcinoma of vagina is most important predictor of overall survival. Prognosis is poor in patient with tumor size >4 cm and decreased local control of the disease. Total radiation dose in excess of 70 Gy is associated with improved local control of disease is associated with relatively good prognosis. Vaginal squamous cell carcinoma can directly spread to vulva, cervix, urinary bladder, rectum and through lymphatics can metastasize to obturator, hypogastric, external iliac and groin lymph nodes. Rarely, tumor may metastasize to liver, lungs, bones and brain.

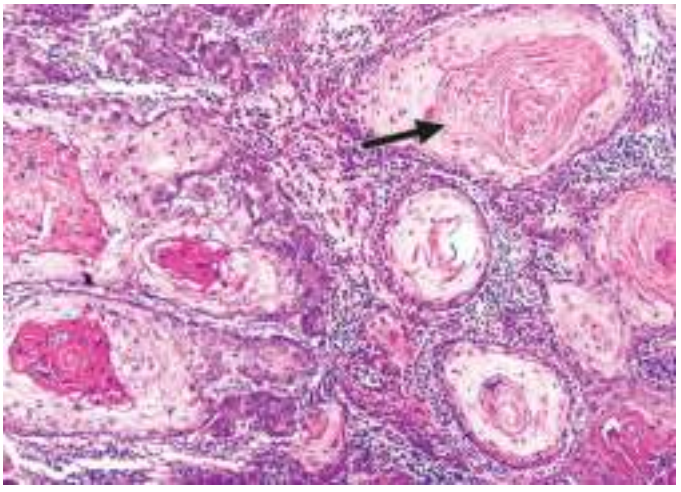

Fig. 24.15: Squamous cell carcinoma of vagina. At high magnification, nests of neoplastic squamous cells are invaded through a chronically inflamed stroma. This cancer is well-differentiated, as evidenced by keratin pearls. However, most cervical squamous carcinomas are nonkeratinizing (arrow) (400X).

Treatment

Vaginal squamous cell carcinoma can be treated with external beam radiation therapy/EBRT, interstitial brachytherapy, intracavitary brachytherapy, cisplatin based chemotherapy and surgical resection. Surgical resection is recommended for early stage of vaginal squamous cell carcinoma involving upper posterior vagina. For stage I disease, surgery consists of radical hysterectomy, upper vaginectomy and pelvic lymphadenectomy.

VERRUCOUS CARCINOMA OF VAGINA

Verrucous carcinoma of vagina is a distinct entity without HPV etiology. It is a slow-growing variant of squamous cell carcinoma, which most often occurs in the elderly postmenopausal women. Most common sites are labia majora > labia minora > posterior commissure. Local or distant metastases are very rare.

- Patient presents with slow growing firm mass, usually accompanied by pruritus and occasionally pain and vaginal discharge especially if large ulcerated or infected verrucous carcinoma.
- Histologic examination alone can be misleading due to superficial sampling of tissue or lack of obvious invasive component of the tumor. Therefore, clinical history indicating exophytic tumor in an elderly woman is often helpful. Imaging techniques may be useful to assess extent of tumor and exclude metastases of verrucous carcinoma.

Surgical Pathology: Verrucous Carcinoma of Vagina

Gross Morphology

Tumor is large, hyperkeratotic papillary or exophytic lesion, usually slow growing. Rarely multiple tumors are demonstrated in vagina.

Light Microscopy

- Exo-endophytic, well circumscribed tumor is composed of closely packed (arranged back to back), papillary structures lined by well differentiated stratified squamous epithelium, with minimal cellular atypia without invasion by single or cluster of cells. Epithelium demonstrates massive hyperkeratosis and parakeratosis, prominent acanthosis with (bulbous) expansion of rete ridges that push into the dermis/submucosa with rounded borders or a broad front.
- Tumor cells contain abundant pale, eosinophilic cytoplasm with low nuclear to cytoplasmic ratio, no/mild nuclear pleomorphism, basally located mitotic figures.
- Mild to moderate chronic inflammation in stroma is common. Lymphovascular invasion and perineural invasion are extremely rare.

Immunohistochemistry Technique

Ki-67 proliferation index is variably increased in 70–78% of cases. Ki-67 expression is localized to basal layer of squamous epithelium of verrucous carcinoma of vagina.

Prognostic Factors

Most important prognostic factors of verrucous carcinoma of vagina are depth of invasion and surgical margin status of verrucous carcinoma.Local recurrence is common (30–50%), especially after surgical resection with inadequate margins.

CLEAR CELL ADENOCARCINOMA OF VAGINA

Clear cell adenocarcinoma of vagina occurs in young daughters of below 20 years, whose mothers have taken diethylstilbestrol during pregnancy. It can also occur in postmenopausal women without exposure to DES. Most common site of tumor is anterior vaginal wall but can also occur in elsewhere in vagina. It accounts for 5–10% of primary vaginal malignancies.

Pathophysiology

Clear cell adenocarcinoma of vagina usually occurs in young women, who has been exposed *in utero* from maternal use of diethylstilbestrol (DES) used to prevent abortion during pregnancy.

- Diethylstilbestrol causes persistence of Müllerian epithelium while inducing contact between epithelium and the vaginal mesenchyme. Unopposed estrogen and obesity lead to increase in the peripheral conversion of steroid hormones to estrone by the enzyme aromatase resulting in hyperestrogenic environment.
- Endometriosis of vagina and perivaginal region may be a precursor lesion in non-DES exposed females. The frequency of vaginal clear cell adenocarcinomas arising in endometriosis ranges from 4 to 11%. Vaginal adenosis (especially tuboendometrial adenosis) is associated with clear cell adenocarcinoma in 90% of cases, suggesting adenosis is a precursor lesion.
- Vaginal adenosis is characterized by mucosal columnar epithelium lined crypts in areas normally lined by stratified squamous epithelium. Vaginal adenosis is thought to be a precursor of clear cell adenocarcinoma of vagina.

Clinical Features

Patient presents with abnormal vaginal bleeding or discharge in young daughters or postmenopausal bleeding.

- Lymphatic and vascular spread of tumor can occur and metastasize to regional lymph nodes, lungs, kidney, peritoneum, omentum, ovary, liver and brain.
- Patient can develop malignant pericardial effusion and cardiac tamponade. Tumor may recur in distant sites even in absence of pelvic disease. About 16–25% of patients remain asymptomatic.

- There is increased risk for development of malignant melanoma and other cancers in these patients. Metastases to distant organs are demonstrated by imaging techniques.

Surgical Pathology: Clear Cell Adenocarcinoma of Vagina
Gross Morphology
Superficially located polypoid, exophytic mass that typically originates from the anterior wall of the upper two-thirds of the vagina.
Light Microscopy
▪ Clear cell adenocarcinoma of vagina exhibits glandular/tubular, papillary, cystic and solid architectural patterns with focal necrosis. ▪ Tumor is composed of large cuboidal cells with distinct cell membranes, abundant clear cytoplasm, round to irregular hyperchromatic nuclei and conspicuous nucleoli. **Hobnailing** is a prominent feature with nuclei protruding into the lumen.
Electron Microscopy
▪ Clear cell carcinomas of vagina, cervix or endometrium have similar ultrastructural features. Glands have short, thick microvilli in the lumina. ▪ Glandular cells are attached by desmosomes and interdigitating cytoplasmic processes, which contain abundant glycogen granules, many uniform mitochondria and 'stacked' parallel rows of granular endoplasmic reticulum.
Immunohistochemistry Technique
Neoplastic cells of clear cell adenocarcinoma of vagina are immunoreactive to CK7, CAM 5.2, 34βE12, CEA, vimentin, BCL-2, p53 and CA125. These express variable positive staining with ER and HER2/neu. Neoplastic cells are negative for CK20 and PR.

Markers	Expression
▪ CK7	▪ Positive
▪ CAM 5.2	▪ Positive
▪ 34βE12	▪ Positive
▪ CEA	▪ Positive
▪ Vimentin	▪ Positive
▪ BCL-2	▪ Positive
▪ p53	▪ Positive
▪ CA125	▪ Positive
▪ ER	▪ Positive (variable)
▪ HER2/neu	▪ Positive (variable)
▪ CK20	▪ Negative
▪ PR	▪ Negative

Molecular Genetic Alterations

Neoplastic cells of clear cell adenocarcinoma of vagina show p53 nuclear staining of different intensity. TP53 gene mutation is not due to inactivation but rather due to persistent DNA damage or genetic instability. Persistence of wild type TP53 gene mutation in tumors may correlate with their favorable prognosis and sensitivity to radiation.

Fig. 24.16: Botryoid rhabdomyosarcoma of the vagina. Tumor resembles cluster of grapes projecting from vagina.

Treatment

Stage 1 or early stage clear cell adenocarcinoma of vagina is treated by radical hysterectomy with partial or complete vaginectomy, pelvic lymphadenectomy, vaginal reconstruction if needed.

- Small tumors are excised, evaluated for retroperitoneal lymph nodes followed by local radiation to the bed of the tumor.
- Large tumors are treated by neoadjuvant chemotherapy combined radiotherapy. Ovarian function is usually preserved in young women. Postmenopausal women should be followed up with cytologic Papanicolau smears and histologic examination of biopsy of cervix and vagina.

BOTRYOID RHABDOMYOSARCOMA OF VAGINA

Botryoid rhabdomyosarcoma is most common vaginal malignant tumor in children under 8 years of age. Most common sites of botryoid rhabdomyosarcoma are wall of hollow organs or beneath mucosal lining of urinary bladder, vagina, nasopharynx and middle ear. Clinical photograph of botryoid rhabdomyosarcoma is shown in Fig. 24.16.

Surgical Pathology: Botryoid Rhabdomyosarcoma of Vagina
Gross Morphology
Tumor resembles cluster of grapes hence named as botryoid rhabdomyosarcoma.
Light Microscopy
▪ Tumor is composed of round to oval cells with eosinophilic cytoplasm admixed with spindle cells in loose myxoid stroma. ▪ A cambium layer of tightly packed undifferentiated neoplastic cells is demonstrated beneath mucosal lining in at least one microscopic field (Fig. 24.17).

Immunohistochemistry Technique	
Tumor cells of botryoid rhabdomyosarcoma show positivity for muscle-specific actin (MSA), desmin, MyoD1, vimentin, myoglobin, and myogenin.	
Markers	**Expression**
▪ MSA ▪ Desmin ▪ MyoD1 ▪ Vimentin ▪ Myoglobin ▪ Myogenin	▪ Positive ▪ Positive (cytoplasmic staining) ▪ Positive (nuclear staining) ▪ Positive ▪ Positive ▪ Positive (nuclear staining)

Treatment and Prognosis

Botryoid rhabdomyosarcoma of vagina is fatal with 5-year survival rate in 10–35% of cases. Combined surgical excision, radiation therapy and chemotherapy increase survival rates in these children. Prognosis is most often excellent.

LEIOMYOSARCOMA OF VAGINA

Vaginal leiomyosarcoma is rare neoplasm in infants with an aggressive course, high recurrence, and undetermined ideal treatment regimen. Its diagnosis can be delayed due to its variable presentation.

Surgical Pathology: Leiomyosarcoma of Vagina	
Gross Morphology	
Tumor measures 3–5 cm in diameter. It is soft in consistency with irregular borders and areas of necrosis on gross examination or not bulging above the surface when cut.	
Light Microscopy	
▪ Tumor is composed of pleomorphic spindle-shaped cells with moderate to marked nuclear atypia and ≥5 mitoses per 10 high power fields and foci of necrosis with infiltrating margins. ▪ Single best criterion for predicting the behavior of smooth muscle tumors is mitotic activity (Fig. 24.18).	
Immunohistochemistry Technique	
Tumor cells show positivity for SMA and S-100 protein.	
Markers	**Expression**
▪ SMA ▪ S-100 protein	▪ Positive ▪ Positive

MELANOMA OF VAGINA

Primary melanoma of the vagina is a rare gynecological malignancy in postmenopausal women in the lower-third of the anterior vaginal wall. It accounts for 4–10% of all valvular malignancies. It is second most common malignant neoplasm after squamous cell carcinoma.

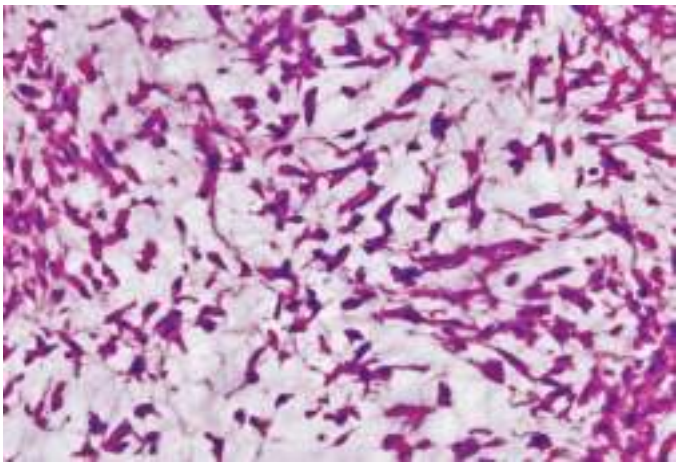

Fig. 24.17: Botryoid rhabdomyosarcoma of vagina. Tumor is composed of round to oval cells admixed with spindle cells in loose myxoid stroma (400X).

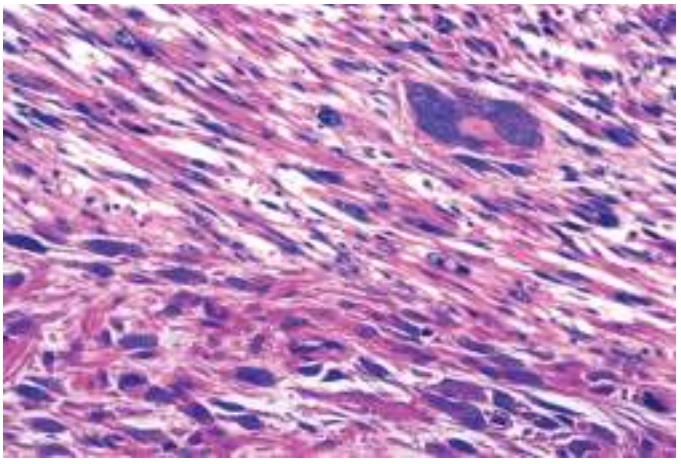

Fig. 24.18: Leiomyosarcoma. As with sarcomas in general, leiomyosarcomas have spindle cells. Several mitoses are seen here, just in this one high power field (400X).

Labia (minora and majora) are the most commonly affected sites, followed by clitoris in some studies. Tumor is associated with high risk of recurrence, distant metastases and a short survival time. Patient is treated by surgical excision, radiotherapy and chemotherapy.

Clinical Features

Primary malignant melanoma of the vagina may be discovered during routine gynecologic examinations. Patient presents with pigmented and sometimes nonpigmented lesions (macules, patches, nodules), that may be ulcerated. Patient may present with lesions (satellitosis).

Imaging Techniques

Lymphoscintigraphy for identification of sentinel nodes. CT and MRI scans are for staging the disease.

Surgical Pathology: Melanoma of Vagina

Gross Morphology

Tumor is bulky mass with or without pigmentation. Preservation of specimen orientation is critical for thorough evaluation of peripheral and deep tissue margins.

Light Microscopy

- Tumor is composed of melanoma cells larger than nevus cells. These cells contain large nuclei with irregular contours with prominent eosinophilic nucleoli (Fig. 24.19).
- Chromatin is clumped at the periphery of the nuclear membrane.

Immunohistochemistry Technique

Tumor cells show positivity for S-100 protein, MART-1 (melan-A), Ki-67, CAM 5.2, tyrosinase, SOX-10, MITF, SOX-100, PNL2, MUM1 and HMB-45. Extramammary Paget's disease shows positivity for mucin, but melanoma not.

Markers	Expression
S-100 protein (calcium binding protein)	Positive (cytoplasmic or nuclear)
Melanoma antigen recognized by T cells 1 (MART-1) (melan-A)	Positive
Ki-67	Positive
CAM 5.2	Positive
Tyrosinase	Positive
SOX-10	Positive
MITF (microphthalmia-associated transcription factor)	Positive
SOX-100	Positive
PNL2	Positive
MUM1	Positive
HMB-45 (human melanoma black 45)	Positive (epithelioid melanoma)

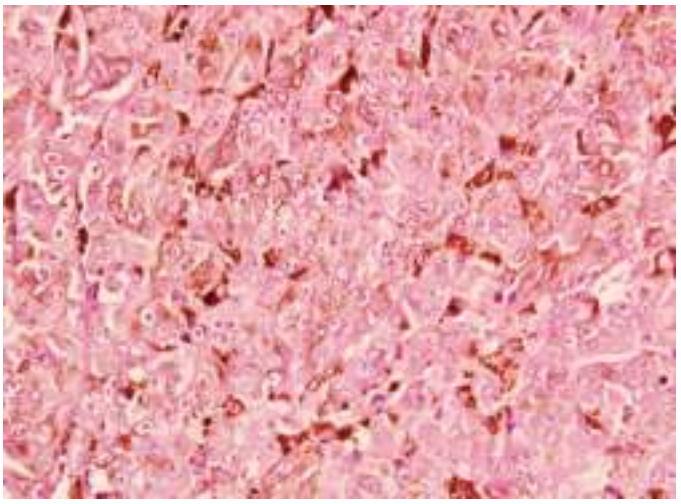

Fig. 24.19: Melanoma. Tumor is composed of melanoma cells with large nuclei with irregular contours and clumped cromatin (400X).

Prognosis

Patients of 68-year-old or younger women at diagnosis have a better prognosis. Prognosis depends on tumor thickness, feasibility of complete resection with appropriate margin status, mitotic rate and ulceration. Free surgical margin of ≥1.0 mm is associated with better prognosis. Patients with localized disease (stages 0, I, II) have a better prognosis. Higher number of positive lymph nodes is associated with worse prognosis. Strong and diffuse c-KIT expression may be associated with a worse prognosis.

Treatment

Primary vaginal melanoma is treated by surgical resection with adequate margins, radiotherapy, chemotherapy and topical imiquimod therapy.

DISORDERS OF UTERINE CERVIX

UTERINE CERVIX: OVERVIEW

The cervix is the lower portion of the uterus, that connects to the vagina through the endocervical canal. It is divided into two parts, portio vaginalis (part that protrudes into the vagina) and supravaginalis (part that lies above the vaginal vault). The outer surface of the portio vaginalis is known as the exocervix or ectocervix, and the portion related to the endocervical canal is known as endocervix.

- Ectocervix is the most readily visible portion of the cervix; endocervix is largely invisible and lies proximal to the external os. Endocervical canal is lined with glandular epithelium and the ectocervix is lined with nonkeratinizing squamous epithelium.
- The cervix has several different epithelial linings. Extocervix is lined by nonkeratinized squamous epithelium, and endocervix (endocervical canal) is lined by mucus secreting glandular epithelium. The squamous epithelium of ectocervix meets the glandular epithelium of endocervix at squamocolumnar junction (SCJ). The original squamocolumnar junction is dynamic and moves during early adolescence and during first pregnancy. The original squamocolumnar junction originates in the endocervical canal, but as the cervical remodeling process occurs during adolescence and first pregnancy, the squamocolumnar junction comes to lie on the ectocervix and becomes the new squamocolumnar junction.

- The subcolumnar reserve cells located at or near squamocolumnar junction are involved in the process of cervical intraepithelial neoplasia I, II, III (CIN I, II, III) and cervical carcinoma.
- The stroma of the cervix is composed of fibrous tissue admixed with elastic fibers and smooth muscle fibers.
- The cervix is both a sentinel for potentially serious upper genital tract infections and a target for viruses and other carcinogens, which may lead to invasive cervical carcinoma. Worldwide, cervical carcinoma is the second most common cancer in women, with an estimated 493,000 new cases each year, over 50% are fatal.
- Carcinoma of cervix arising from ectocervix is usually squamous cell carcinoma. Adenocarcinoma originates from endocervix. Cervical squamous cell carcinoma accounts for 80% and adenocarcinoma accounts for 50% in young women. Adenosquamous and small cell carcinoma of cervix are relatively rare. Primary sarcoma of the cervix has been occasionally described and malignant lymphoma of the cervix, both primary and secondary, has been reported.

INFLAMMATORY DISORDERS OF UTERINE CERVIX

Acute cervicitis is a pattern of inflammation caused by bacteria, viruses, fungi and protozoa and marked by neutrophilic infiltrate in stroma and epithelium, which shows edema and reactive epithelial atypia.

- Chronic cervicitis comprises lymphocytes and plasma cells infiltrate.
- Papillary endocervicitis refers to inflammation of endocervical mucosa forming papillary structures.
- Noninfectious cervicitis can occur due to chemical exposure, pessary, tampons and surgical trauma. Cervix may show infiltration by neutrophils or lymphocytes and plasma cells or granulomatous lesions.

ACUTE CERVICITIS

Acute cervicitis is caused by *Neisseria gonorrhoeae* (sexual transmission) and *Chlamydia trachomatis*. Patient presents with mucopurulent discharge. *Chlamydia trachomatis* may produce follicular cervicitis in chronic cases. *Actinomyces israelii* infection is associated with intrauterine device use and demonstrated in pseudofilamentous structures in Papanicolau smears. Ophthalmia neonatorum, a neonatal conjunctival infection is acquired at delivery caused by *Neisseria gonorrhoeae.*

CHRONIC CERVICITIS

Chronic cervicitis occurs due to *Candida albicans*, *Trichomonas vaginalis* and *Chlamydia trachomatis*. Chronic cervicitis caused by *Chlamydia trachomatis* is associated with reactive lymphoid follicles. Erosion of cervix is characterized by columnar epithelium replacing squamous epithelium, grossly resulting in an erythematous area. Sometimes it is a manifestation of acute cervicitis. The condition is most often asymptomatic. It may be manifested by cervical discharge. Granulomatous cervicitis is caused by *Mycobacterium tuberculosis* and *Treponema pallidum*. Clinical photograph of chronic cervicitis is shown in Fig. 24.20. Histology of chronic cervicitis is shown in Fig. 24.21.

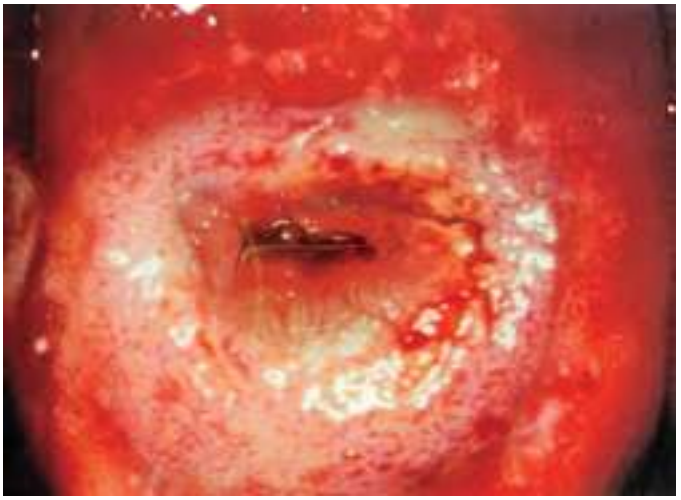

Fig. 24.20: Chronic cervicitis with ectropion of the cervix. Columnar epithelium has replaced squamous epithelium. Squamous epithelium is showing as an extensive reddened zone. The cervix is also scarred and deformed from previous deliveries.

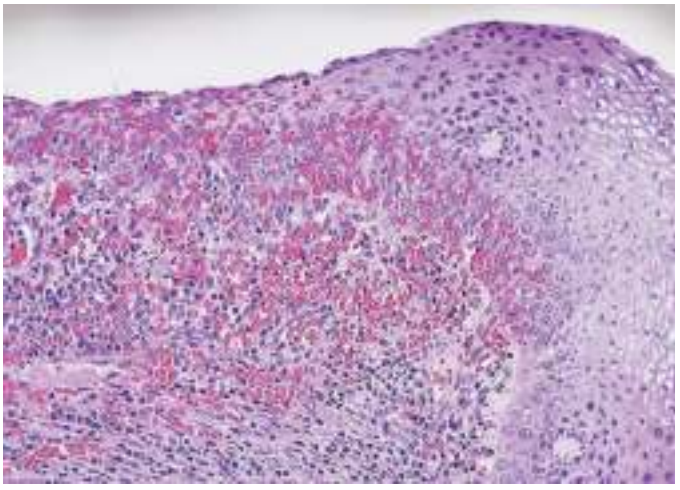

Fig. 24.21: Chronic cervicitis. It shows infiltration by numerous lymphocytes and hemorrhage (100X).

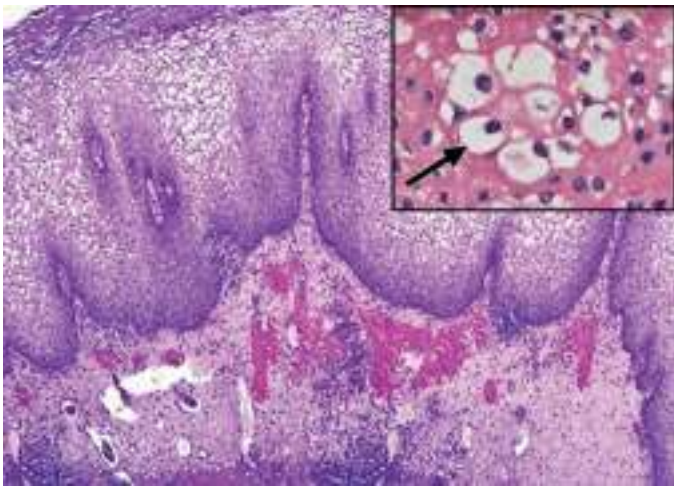

Fig. 24.22: Viral cervicitis. Cervical biopsy demonstrates a thickened squamous epithelium. Squamous cells (inset) have a vacuolated appearance showing koilocytotic change. A condyloma accuminatum would have a similar appearance (arrow) (100X).

Surgical Pathology: Chronic Cervicitis
Gross Morphology
Cervix shows extensive reddened areas.
Light Microscopy
▪ Chronic cervicitis occurs at the squamocolumnar junction of the cervix. ▪ Submucosa of cervix is infiltrated by chronic inflammatory cells.

VIRAL CERVICITIS

Herpes simplex virus type 2 causes ulceration of cervix resulting in cervicitis and characterized by enlarged epithelial nuclei, molding of nuclei, multinucleation, and margination of chromatin in virally infected at the edge of ulcer. Cytomegalovirus causes nuclear and cytoplasmic inclusions in infected cervix. Adenovirus causes smudged nuclear inclusions. Molluscum contagiosum caused by poxvirus generates large round eosinophilic inclusions in cytoplasm. Human papillomavirus (16, 18, 31, 33 or 45) infection is responsible for cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and cervical carcinoma (Fig. 24.22).

NEOPLASTIC DISORDERS OF UTERINE CERVIX

ENDOCERVICAL POLYP

Endocervical polyp is a benign exophytic proliferation composed of fibrovascular core and endocervical glandular or metaplastic squamous epithelium in variable proportion. It is common in patients over 40 years of age in cervix/endocervix. Chronic inflammation, surface erosion and reactive epithelial changes are common in endocervical polyp.

Clinical Features

Patient presents with abnormal vaginal bleeding (postcoital or contact) or discharge as a result of cervical erosions and granulation tissue. Per vaginal examination or colposcopy reveals single smooth or lobulated mass measuring <3 cm in greatest dimension protruding through the cervical os (Fig. 24.23A). Cervical Papanicolau smear may demonstrate atypical cells due to reactive changes in surface epithelial cells. Polypectomy is recommended for symptomatic and large (>3 cm) endocervical polyp.

Fig. 24.23A: Endocervical polyp. Per vaginal examination or colposcopy reveals single smooth or lobulated mass measuring <3 cm in greatest dimension protruding through the cervical os (arrow).

Fig. 24.23B: Endocervical polyp. It is usually solitary, smooth or lobulated mass measuring <3 cm in diameter protruding through the cervical os and can be detected during routine gynecologic examination or colposcopy (arrow). (*Courtesy*: Department of Pathology, Sher-E-Kashmir Institute of Medical Sciences, Srinagar, J&K.)

Surgical Pathology: Endocervical Polyp

Gross Morphology

Endocervical polyp is single smooth or lobulated mass measuring <3 cm in greatest dimension (Fig. 24.23B).

Light Microscopy

- Endocervical poly is composed of fibrovascular core containing variable sized blood vessels and chronic inflammatory cells.
- Fibrovascular core is lined endocervical by mucinous epithelium with varying degrees of squamous metaplasia, erosion and reactive changes. Mitotic activity may be demonstrated, especially in cases with marked inflammation or florid microglandular hyperplasia.
- Endocervical polyp may rarely harbor *in situ* or invasive squamous and glandular lesions (Fig. 24.24).

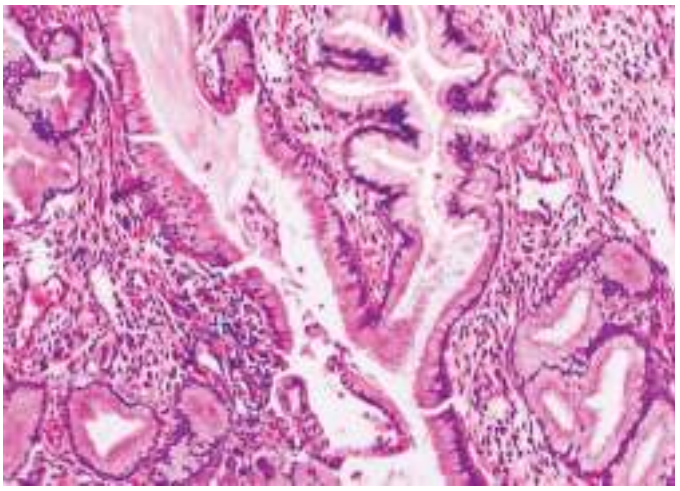

Fig. 24.24: Endocervical polyp. Endocervical poly is composed of fibrovascular core lined endocervical by mucinous epithelium with varying degrees of squamous metaplasia, erosion and reactive changes (400X).

CERVICAL INTRAEPITHELIAL NEOPLASIA

Cervical intraepithelial neoplasia (CIN) is disordered epithelial dysplastic precancerous lesion associated with both low and high risk HPV subtypes. The principal significance of CIN is its precursor role in the genesis of invasive cervical carcinoma.

- Cervical intraepithelial neoplasia is manifested by loss of polarity and nuclear hyperchromasia beginning at the basal layer and extending upwards.
- Based on the extent of involvement of cervical epithelium, cervical intraepithelial neoplasia lesions are subclassified into 3 types seen on histopathologic examination: CIN I, CIN II, and CIN III.
- Recently simplified classification has been proposed with CIN I renamed as low-grade squamous intraepithelial lesion (LSIL) and CIN II and CIN III combined into one category as high-grade squamous intraepithelial lesion (HSIL).
- The categories of cervical intraepithelial neoplasia include: (a) flat mature LSIL (flat condyloma or CIN I), (b) mature exophytic LSIL (exophytic condyloma, condyloma acuminatum), (c) extensive exophytic LSIL (giant condyloma), (d) immature exophytic LSIL (immature condyloma, squamous papilloma, papillary immature metaplasia), and (e) immature flat metaplastic LSIL.
- The recommended terminology for HPV-associated squamous lesions of the lower anogenital tract is LSIL and HSIL, which may be further classified by the applicable intraepithelial neoplasia subcategorization. Genomic integration of HPV DNA sequences, most often high risk types 16, 18, 31, 33 or 45 is associated with CIN, as well as with frank malignant change in cervix. Development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma is shown in Fig. 24.25. Histology of CIN I, CIN II and CIN III is shown in Figs 24.26 to 24.28. Procedure for Papanicolaou smear is shown in Fig. 24.29A and B.
- Oncogenic risk of anogenital human papillomavirus associated with histologic features is given in Table 24.3. Terminologies for cervical intraepithelial neoplasia for development of cervical carcinoma is given in Table 24.4. Criteria used to diagnose squamous epithelial cell abnormalities of cervix are given in Table 24.5. Criteria used to diagnose atypical squamous cells (ASCs) are given in Table 24.6.

Pathology Pearls: Cervical Intraepithelial Neoplasia (CIN)

- **CIN I (mild dysplasia):** CIN I is a low-grade lesion. It affects 20–30 years old women. It involves the innermost one-third of the cervical epithelium affecting 20–30 years old women. More than 85% of CIN I lesions regress spontaneously, 10% progress to CIN III, and 2–3% progress to invasive carcinoma.
- **CIN II (moderate dysplasia):** CIN II involves innermost two-thirds of thickness of epithelium affecting 30–40 years old women. It may progress to CIN III in many patients.
- **CIN III (severe dysplasia):** CIN III involves the full thickness of the cervical epithelium affecting 30–40 years old women, which does not invade the basement membrane. Approximately 25% of CIN III untreated cases may progress to invasive carcinoma within 10 years of diagnosis. Such involved cervix must be excised by conization (i.e. removal of the involved cone of tissue around the endocervical canal and the transformation zone by laser vaporization or cryosurgery). It is not possible to predict whether the lesion will progress to invasive carcinoma or regress. Therefore, all patients with CINs are treated as potential cervical carcinoma.

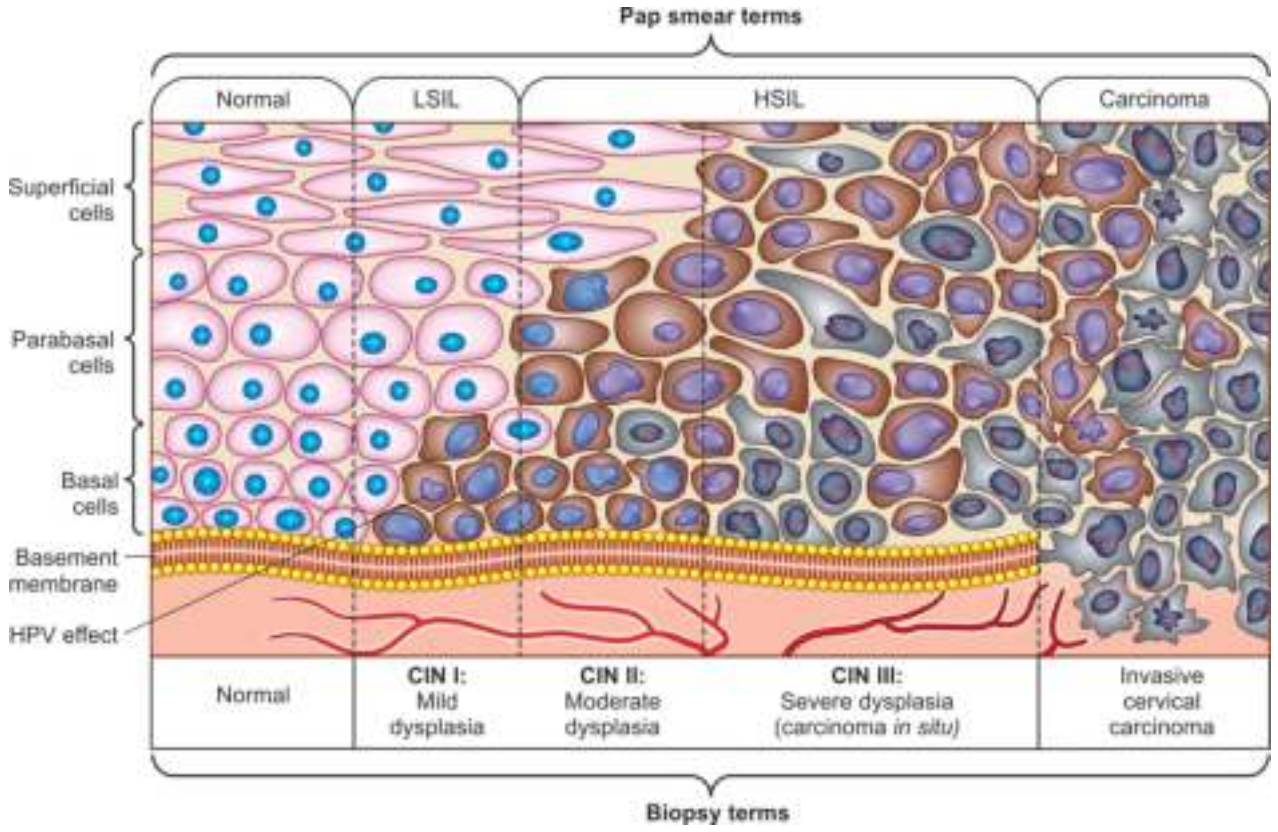

Fig. 24.25: Development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma.

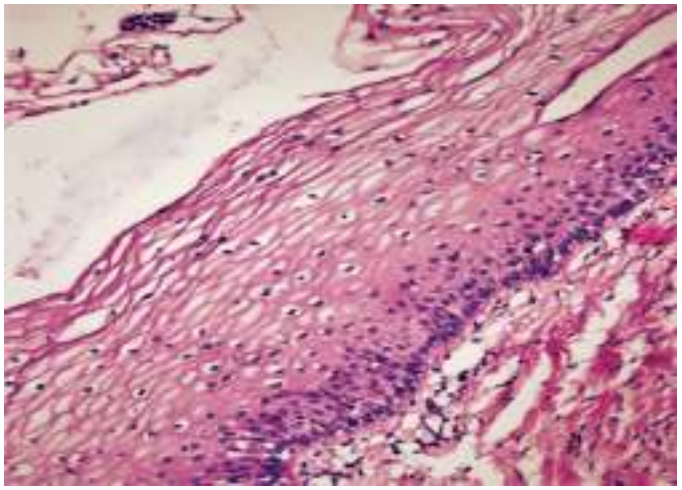

Fig. 24.26: Cervical intraepithelial neoplasia I (CIN I). Cervix shows moderate dysplastic epithelium in the lower one-third. The upper dermis is infiltrated by inflammatory cells (100X).

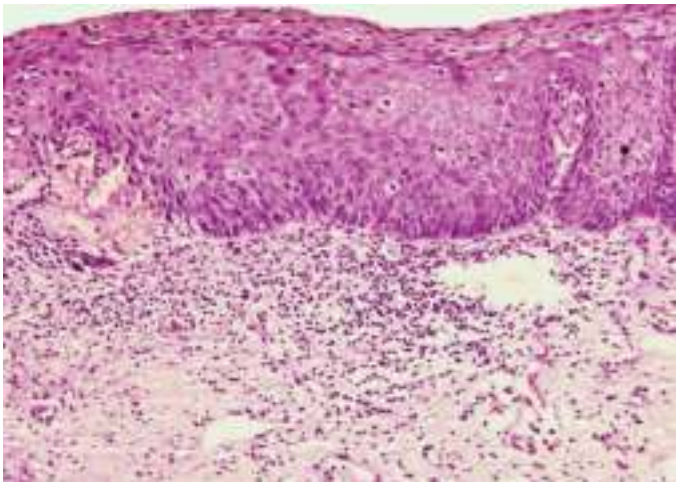

Fig. 24.27: Cervical intraepithelial neoplasia II (CIN II). Cervix shows moderate dysplastic epithelium in the lower two-thirds. The upper dermis is infiltrated by numerous inflammatory cells (100X).

CERVICAL CARCINOMA

Cervical carcinoma is most common malignant invasive tumor of the female genital tract. It has biphasic age incidence 20–39 years and >50 years and rarely occurs in younger than age 20 years. Clinical features depend on stage of the disease.

- Squamous cell carcinoma of cervix is invasive tumor, which shows squamous differentiation arising at the squamocolumnar junction of external 'os'. The squamocolumnar junction is defined as the junction between the squamous epithelium and the columnar epithelium. Its location on the cervix is variable during adolescence and first pregnancy.

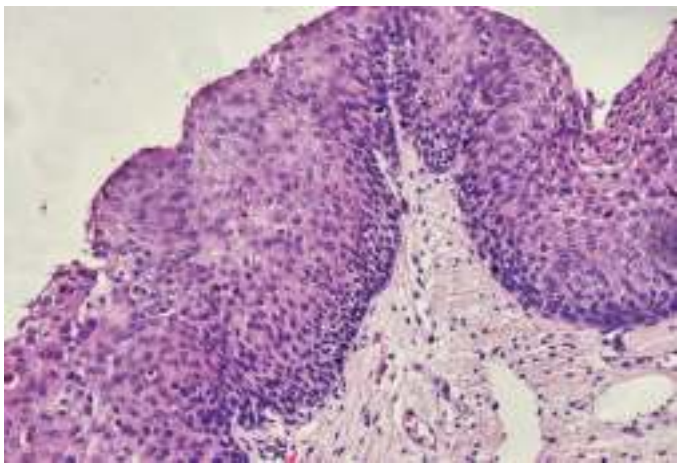

Fig. 24.28: Cervical intraepithelial neoplasia III (CIN III). This is cervical squamous dysplasia at high magnification extending from the center to the right. The epithelium is normal at the left. Note how the dysplastic cell nuclei are larger and darker, and the dysplastic cells have a disorderly arrangement (400X).

- The squamocolumnar junction is the result of a continuous remodeling process resulting from uterine growth, cervical enlargement and hormonal status.
- Risk factors for cervical carcinoma include early sexual activity and with multiple sexual partners, high risk human papillomavirus 16, 18, 31, 33, 45, human simplex virus 2, activation of RAS gene, mutation of TP53 gene, cigarette smoking and oral contraceptive use.
- Cervical carcinoma is detected clinically via white patches after application of acetic acid to cervix; cervix also has mosaic vascular patterns at colposcopy. Papanicolaou smear examination is performed to detect premalignant lesions. Recent 2020 WHO classification of tumors of the uterine cervix is given in Table 24.7.

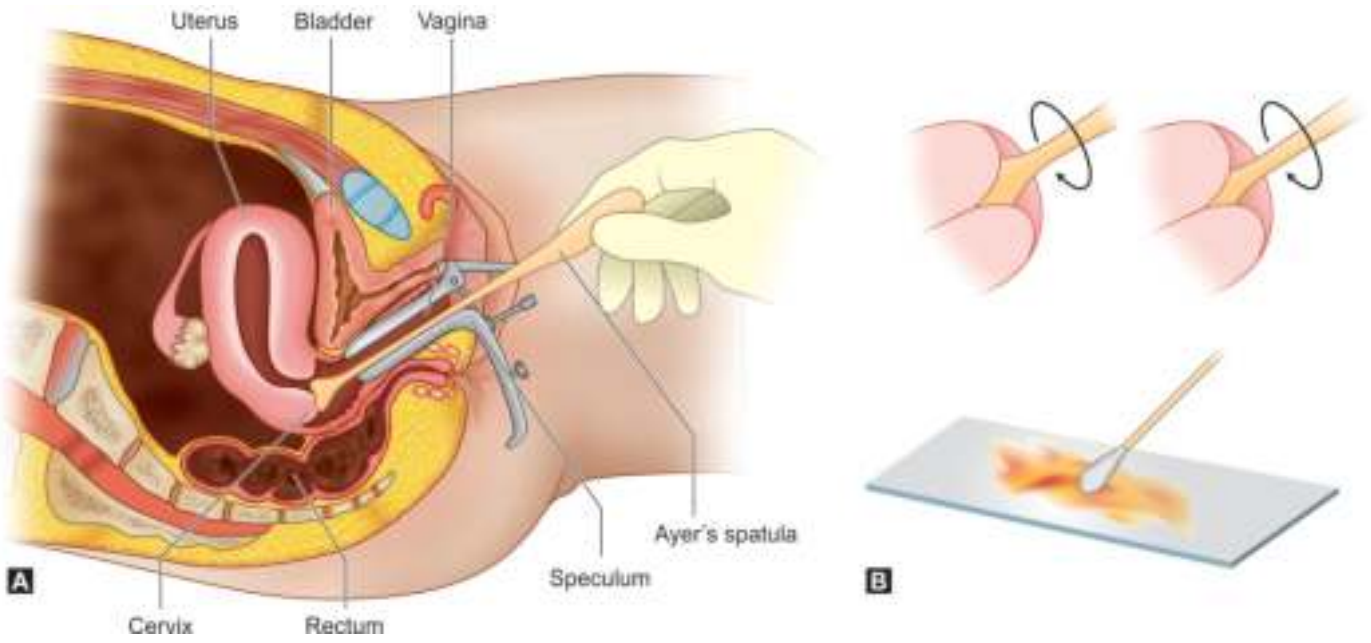

Fig. 24.29: Procedure for Papanicolaou smear. (A) Ayer's spatula is inserted per vagina for taking Pap smear, (B) preparation of Pap smear.

Table 24.3 Oncogenic risk of anogenital human papillomavirus associated with histologic features

Oncogenic Risk for Cervical Cancer	Human Papillomavirus	Histologic Features	
High oncogenic risk	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 68, 59, 66	▪ HSIL ▪ Koilocytosis occasional present ▪ Aneuploidy usually	▪ Abnormal mitoses frequent ▪ Undifferentiated cells and mitoses in upper two-thirds of cervical epithelium
Low oncogenic risk	6, 11, 42, 43, 44, 53	▪ LSIL ▪ Koilocytosis frequently present ▪ Diploid or polyploid most often	▪ Abnormal mitoses absent ▪ Undifferentiated cells and mitoses in lower third of cervical epithelium

Medium risk human papillomavirus includes 33, 35, 39, 51, 52, 56–59, 68; HSIL (high-grade squamous intraepithelial lesion); LSIL (low-grade squamous intraepithelial lesion).

Table 24.4 Terminologies for cervical intraepithelial neoplasia for development of cervical carcinoma

Old Classification Terminology	WHO Classification Terminology	Bethesda System Terminology
Mild dysplasia	CIN I	LSIL
Moderate dysplasia	CIN II	HSIL
Severe dysplasia/carcinoma *in situ*	CIN III	HSIL

CIN: Cervical intraepithelial neoplasia

Table 24.5 Criteria used to diagnose squamous epithelial cell abnormalities of cervix

Old Classification Terminology	Mild Dysplasia	Moderate Dysplasia	Severe Dysplasia/ Carcinoma *in situ*	Invasive Carcinoma
WHO classification terminology	CIN I	CIN II	CIN III	—
Bethesda system terminology	LSIL	HSIL	HSIL	—
Cell type and arrangement	Superficial or intermediate cells arranged in single or sheets	Parabasal cells arranged in single or sheets	Basal cells arranged in single or sheets	Basal, spindle, pleomorphic arranged in single or sheets or syncytium
Number of abnormal cells	+	++	+++	++++
Koilocytosis	+++	+	+/–	+/–
Nucleus size	+++	++	+	+
Hyperchromatic nucleus	+	++	+++	++++
Nuclear/cytoplasmic ratio	+	++	+++	++++

Table 24.6 Criteria used to diagnose atypical squamous cells (ASC)

Features	Atypical Squamous Cells of Undermined Significance (ASCUS)	Atypical Squamous Cells cannot Exclude HSIL (ASC-H)
Cells resemble	Superficial or intermediate squamous round to oval cells in size and configuration with nuclei 2–3 times the size of a normal intermediate cells	Parabasal or basal cells in size configuration
Nuclear features	▪ Nuclear contour minimally irregular ▪ Normochromatic to slight hyperchromatic nuclei	▪ Nuclear contour irregular ▪ Hyperchromatic nuclei with uneven chromatin

Clinical Pearls: Risk Factors for Cervical Carcinoma

- **Sexual activity:** The risk of both squamous cell carcinoma and adenocarcinoma of uterine cervix is strongly related to the lifetime number of sexual partners, and, independently, to age at first intercourse. Risk is increased for cervical carcinoma in women with early sexual activity below the age of 16 years; and who have sexual contact with high risk sexual partners, who had either former wife with cervical carcinoma or penile condylomas or not undergone penile circumcision.
- **Human papillomavirus:** Human papillomavirus plays an important role in the pathogenesis of cervical carcinoma. Genomic integration of HPV DNA sequences, most often types 16, 18, 31, 33 or 45 transmitted by sexual contact is associated with CIN, as well as with cervical carcinoma. Vaccines against some of human papillomavirus are available. HPV 16, 18 are associated with cervical carcinoma, HPV 16, 18 infect immature epithelial basal cells at the squamocolumnar junction. HPV (16, 18) infection produces koilocytic atypia, consisting of nuclear atypia and a cytoplasmic perinuclear halo. HPV cannot infect the mature superficial squamous cells that cover the ectocervix, vagina, or vulva.
- **Herpes simplex virus II:** Herpes simplex virus acts as a promoter. HPV viral proteins E6 and E7 bind and inactivate the gene products of p53 and Rb, respectively. HPV and herpes simplex may be synergetic.
- **Molecular genetic alterations:** Activation of the RAS oncogene and TP53 tumor suppressor gene mutation play an important role in cervical oncogenesis.
- **Cigarette smoking:** Tobacco smoking has an important co-carcinogenic role. Long duration of tobacco smoking (≥20 years) is associated with a two-fold increase in the risk of squamous cell carcinoma, but tobacco smoking is not associated with the risk of adenocarcinoma. Further studies are needed to confirm the suggestion from this and other studies of differences in risk related to smoking between squamous cell and adenocarcinomas of the cervix.

- **Oral contraceptive use:** The risk of squamous cell carcinoma and adenocarcinoma of uterine cervix is increased with increasing duration of use of oral contraceptives, and this effect is most marked in current and recent users of oral contraceptives.
- **Parity:** The risk of squamous cell carcinoma is associated with high parity and the risk of both squamous cell carcinoma and adenocarcinoma increased with early age at first birth.
- **Immunosuppression:** It increases risk of cervical carcinoma manifolds in immunosuppressive state.

Pathology Pearls: Human Papillomavirus (HPV) Oncoproteins Role in Cervical Carcinoma

- Principles of HPV E6 and E7 oncogene activity in cervical carcinoma is shown in Fig. 24.30. Human papillomavirus in cervix is shown in Fig. 24.31.
- Once, human papillomavirus enters host cervical epithelial cells, it synthesizes HPV oncoproteins E6 and E7. HPV oncoprotein E6 causes increase degradation of p53 tumor suppressor protein and HPV oncoprotein E7 leads to inactivation of regulatory retinoblastoma protein (pRb). Thus, allowing escape from p53 induced apoptosis and normal cell cycle control in G1.
  - **HPV E7 oncoprotein** increases activity of CDK4/cyclin D by inactivating CDK inhibitors (p21 and p27). It binds to the RB protein and displaces transcription factor E2F. Now E2F is free to bind to the promoters of genes (like c-Myc) that cause the cell to enter the cell cycle. Therefore, inhibition of p21 and RB-E2F causes increased activity of CDK4/cyclin D results in genome instability.
  - **HPV E6 oncoprotein** degrades p53 protein. It also stimulates the expression of TERT, the catalytic subunit of telomerase resulting in increased tyrosine kinase activity. These changes cause genome instability. The host cells enter the cell cycle resulting in increased proliferation.
- Laboratory methods to diagnose HPV infection include Papanicolau smear cytology or H&E morphology, fluorescence *in situ* hybridization (FISH), DNA HPV testing and immunohistochemistry p16 as a surrogate marker.

Pathology Pearls: Evolution of Cervical Carcinoma

Development of cervical intraepithelial neoplasia (CIN I, II, III) and invasive cervical carcinoma is shown in Fig. 24.32.

- **Cervical intraepithelial neoplasia:** Initially, patient developing cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) is usually asymptomatic.
- **Microinvasive cervical carcinoma:** It refers to stromal invasion <5 mm beneath the basement membrane without evidence of lymphatic or vascular involvement.
- **Early invasive carcinoma:** It refers to invasion of basement membrane and underlying stroma by cervical carcinoma. Per vagina examination reveals fungating, ulcerative or diffusely infiltrative cervical growth resulting in barrel-shaped cervix.
- **Advanced invasive carcinoma:** It can spread directly invades adjacent pelvic structures, via lymphatic route to lymph nodes (e.g. paracervical, obturator, external iliac, internal iliac, common iliac and aortic lymph nodes), and via hematogenous route to liver, lungs, bones or brain. Cervix becomes indurated with necrosis and ulceration, resulting in formation of large fungating mass.

Table 24.7 Recent 2020 WHO classification of tumors of the uterine cervix

Squamous Epithelial Tumors
- Squamous metaplasia
- Cervical atrophy
- Condylomata accuminatum
- Low-grade squamous intraepithelial lesion
  - Cervical intraepithelial neoplasia grade I
- High-grade squamous intraepithelial lesion
  - Cervical intraepithelial neoplasia grade II
  - Cervical intraepithelial neoplasia grade III
- Squamous cell carcinoma, HPV-associated
- Squamous cell carcinoma, HPV-independent
- Squamous cell carcinoma, NOS

Glandular Tumors and Precursors
- Endocervical polyp
- Müllerian papilloma
- Nabothian cyst
- Tunnel clusters
- Microglandular hyperplasia
- Lobular laminar endocervical hyperplasia
- Mesonephric remnants and hyperplasia
- Arias-Stella reaction
- Endocervicosis (pseudoneoplastic glandular lesions)
- Tuboendometrioid metaplasia
- Ectopic prostate tissue
- Adenocarcinoma *in situ*, NOS
- Adenocarcinoma *in situ*, HPV-associated
- Adenocarcinoma *in situ*, HPV-independent
- Adenocarcinoma, NOS
- Adenocarcinoma, HPV-associated
- Adenocarcinoma, HPV-independent gastric type
- Adenocarcinoma, HPV-independent clear cell type
- Adenocarcinoma, HPV-independent mesonephric type
- Adenocarcinoma, HPV-independent, NOS
- Endometrioid adenocarcinoma, NOS
- Carcinosarcoma, NOS
- Adenosquamous carcinoma
- Mucoepidermoid carcinoma
- Adenoid basal carcinoma
- Carcinoma, undifferentiated, NOS

Mixed Epithelial and Mesenchymal Tumors
- Adenomyoma, NOS
  - Mesonephric type adenomyoma
  - Endocervical type adenomyoma
- Adenosarcoma

Germ Cell Tumors
- Mature teratoma, NOS
- Dermoid cyst, NOS
- Endodermal sinus tumor
- Yolk sac tumor, NOS
- Choriocarcinoma, NOS

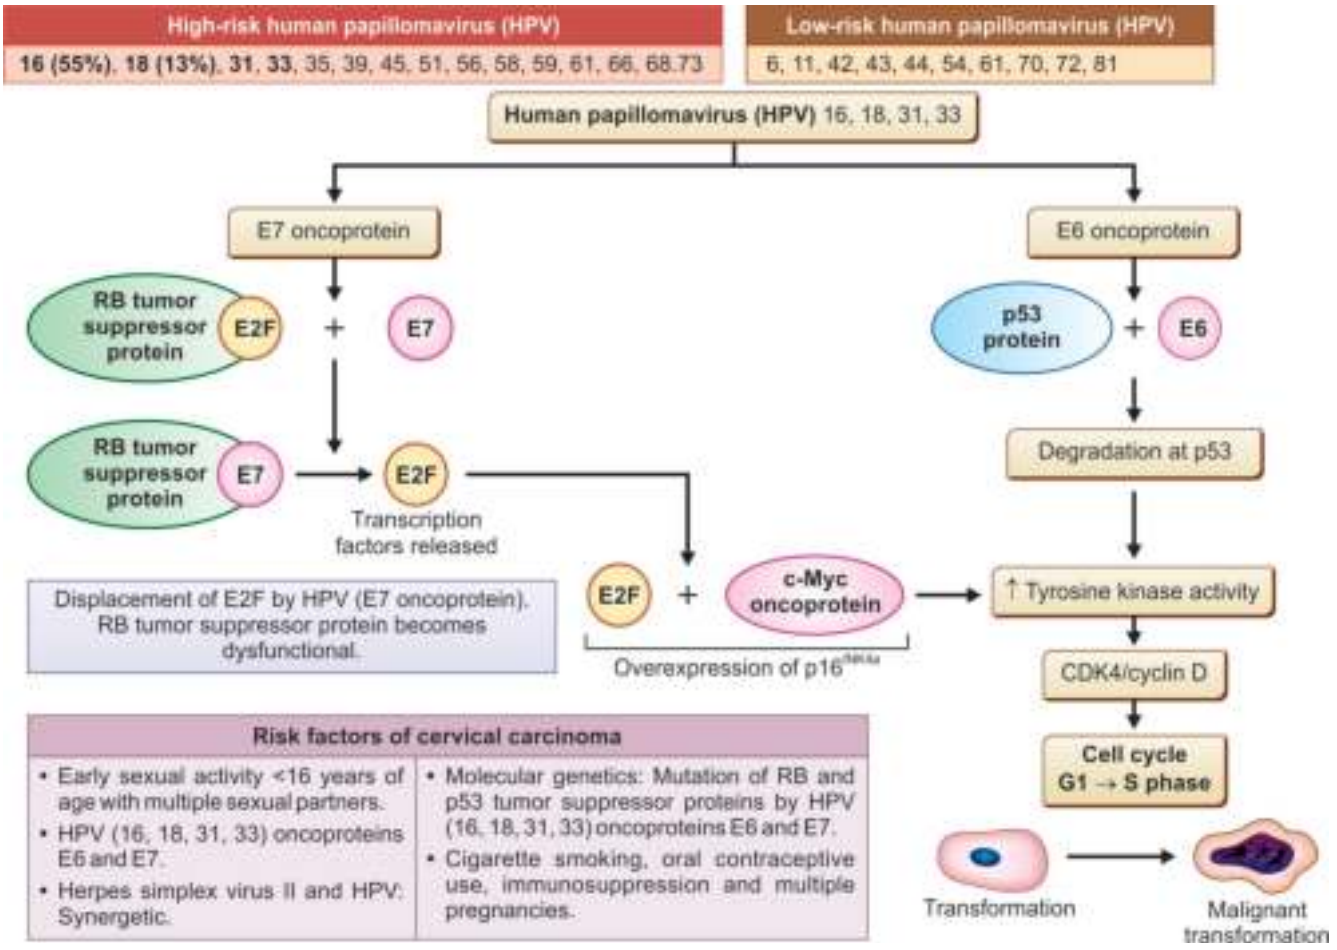

Fig. 24.30: Principles of HPV E6 and E7 oncogene activity in cervical carcinoma.

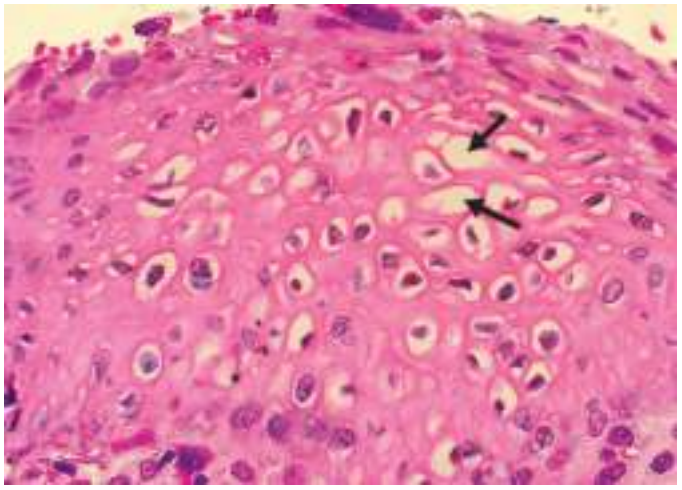

Fig. 24.31: Human papillomavirus in cervix. High power view of HPV infection characterized by cells with pyknotic, irregular nuclei and clear cytoplasm. Moderate squamous dysplasia is also present (arrows) (400X).

Clinical Features

Patient is asymptomatic in early stage of cervical carcinoma. Later, patient presents with abnormal persistent bleeding or spotting between menstrual periods or postcoital bleeding and pain. In advanced stage, patient presents with pelvic pain, foul smelling vaginal discharge (saprophytic infection), vaginal passage of stool or urine from a fistula, anorexia, cachexia, weight loss and anemia. Cytomorphologic features of cervical squamous cell carcinoma are shown in Papanicolaou stained smear (Fig. 24.33).

Surgical Pathology: Cervical Carcinoma

Gross Morphology

Early stage of cervical carcinoma often manifests as poorly defined, granular, eroded lesions or progressing to nodular and exophytic mass (Fig. 24.34).

Light Microscopy

Histologic variants of cervical carcinoma are given in Table 24.8. Invasive squamous cell carcinoma of cervix is microscopically divided into three major categories depending upon the presence or absence of keratinization and the tumor cell size: (a) large keratinizing squamous cell carcinoma (Fig. 24.35), (b) large cell nonkeratinizing squamous cell carcinoma (70%), (c) small cell nonkeratinizing squamous cell carcinoma (5%), and (d) other microscopic types of squamous

cell carcinoma such as verrucous carcinoma (well differentiated variant with a polypoid pattern of growth), spindle cell carcinoma (sarcomatoid carcinoma), basaloid carcinoma, lymphoepithelioma-like carcinoma and transitional carcinoma.

- **Squamous cell carcinoma of cervix:** It accounts for 80–90% of cases. It is further subclassified as large cell nonkeratinizing and large cell keratinizing carcinoma producing keratinizing pearls and prickle cells; and small cell variant of squamous cell carcinoma. In almost all cases, large cell keratinizing squamous cell carcinoma varies from well differentiated to moderately differentiated and highly anaplastic carcinoma.
  - **Well differentiated squamous cell carcinoma (grade 1):** Tumor is composed of mature squamous cells with abundant keratin pearls, occasional well-developed intercellular bridges, minimal pleomorphism, and minimal mitotic activity (Fig. 24.36).
  - **Moderately differentiated squamous cell carcinoma (grade 2):** Tumor is composed of cells with less distinct cell borders and less cytoplasm than well differentiated tumors; and also, more nuclear pleomorphism and more mitotic activity (Fig. 24.37).
  - **Poorly differentiated carcinoma (grade 3):** Tumor is composed of small primitive appearing cells with scant cytoplasm, hyperchromatic nuclei and marked mitotic activity; absent/rare keratinization; resembles HSIL (Fig. 24.38).
- **Adenocarcinoma of cervix:** It accounts for 10–20% of malignant cervical tumors, which arises from mucus producing endocervical glands. It affects elderly women (mean 55 years). It shares etiological factors of squamous cell carcinoma of the cervix and spreads similarly. Malignant cells are frequently infected with HPV types 16 and 18 (Figs 24.39 and 24.40).
- **Adenosquamous carcinoma of cervix:** It accounts for 4% of cervical malignant tumors. It arises from reserve cells in cervix with favorable prognosis (Fig. 24.41).
- **Small cell carcinoma of cervix:** It is rare tumor having more aggressive course than the conventional squamous cell carcinoma (Fig. 24.42).

Immunohistochemistry Technique

Neoplastic cells of squamous cell carcinoma of cervix are immunoreactive to p16, pan-keratin (CK5/CK6), AE1/AE3, CEA, p63, CD10, CD146, inhibin and β-hCG.

Markers	Expression
p16	Positive (100%)
Pan-keratin (CK5/CK6)	Positive (100%)
AE1/AE3	Positive (100%)
CEA	Positive (80%)
p63	Positive (80%)
CD10	Positive (20%)
CD146	Positive (20%)
Inhibin	Positive (20%)
β-hCG	Positive (10%)

Mode of Spread

Cervical carcinoma spreads via direct extension to vagina, uterus, parametrium, lower urinary tract, uterosacral ligaments; via lymphatic route to aortic and mediastinal lymph nodes, and via hematogenous route to lung, bones and ovary (1%). Mode of spread of cervical carcinoma is given in Table 24.9.

- **Direct invasion:** In early stage, local extension of cervical carcinoma into surrounding tissues (parametrium) leads to ureteral compression resulting in hydroureter, hydronephrosis and ultimately renal failure with fatal outcome in 50% of patients. In later stage, urinary bladder and rectal involvement by cervical carcinoma may lead to fistula formation. Spread of tumor along the uterosacral ligaments involves the sacral nerves, causing severe pain. In some cases, tumor growth encircles the 'external os', and obstructs the cervical canal leading to development of pyometra.
- **Lymphatic route:** Cervical carcinoma involves the chains of pelvic nodes (e.g. paracervical, obturator, external iliac, internal iliac, common iliac and aortic lymph nodes). The tumor most commonly extends into contiguous parametrial structures.
- **Hematogenous route:** In later stages of disease, distant metastases may occur in lungs, liver, bones or brain.

Staging and 5-Year Survival

The clinical stage of cervical carcinoma is the most important prognostic factor for survival. Staging of cervical carcinoma has been developed by FIGO as given in Table 24.10.

Prognostic Factors

Prognostic factors for cervical carcinoma include clinical stage, nodal status, size of largest lymph node and number of involved lymph nodes, tumor size, depth of invasion, endometrial extension, parametrial involvement, angiolymphatic invasion.

Laboratory Diagnosis

Various diagnostic methods adopted for cervical carcinoma include Papanicolaou smear, cervical biopsy, colposcopy, colpomicroscopy, colposcopy with directed biopsy, cone biopsy, punch biopsy and immunohistochemistry.

- **Exfoliative cytology:** Cervical carcinoma and its precursors (cervical intraepithelial neoplasia) can be detected by vaginal exfoliative cytology. Papanicolaou smears can be obtained directly or under colposcopic guidance. Positive exfoliative cytology findings need to be confirmed by biopsy. For occult lesions (contact bleeding and vaginal discharge), Papanicolaou smear, colposcopy examination and cervical biopsy are performed.

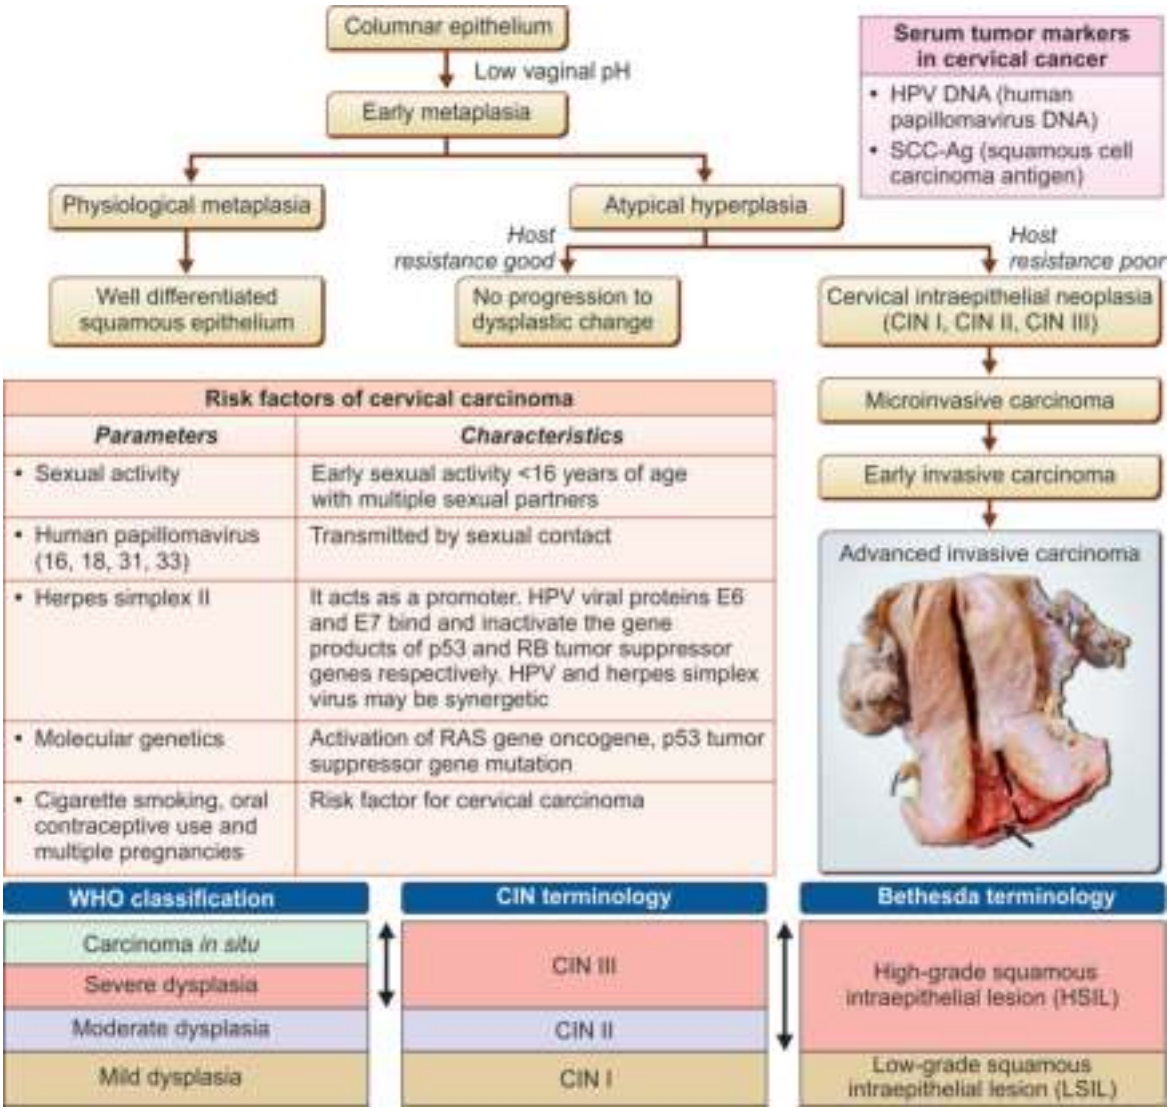

Fig. 24.32: Development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma (arrow).

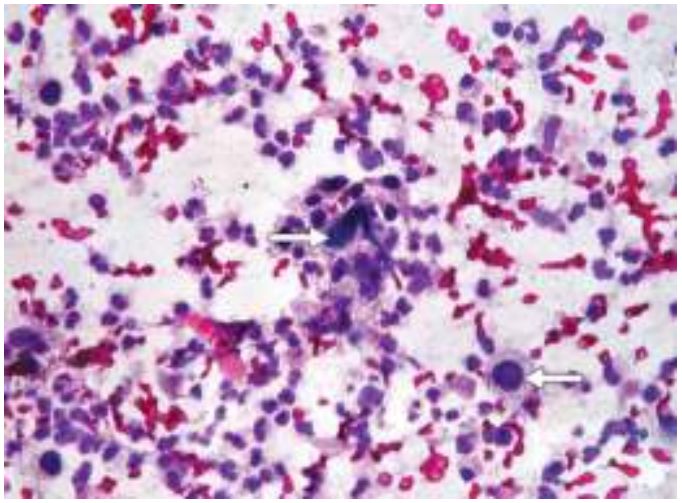

Fig. 24.33: Papanicolaou's stained smear in cervical carcinoma: It shows atypical tadpole cells with squamous differentiation in the background of inflammatory cells (arrows) (400X).

Fig. 24.34: Cervical carcinoma. Growth is seen in cervical region (arrow).

Table 24.8 Histologic variants of cervical carcinoma

Histological Variants	Frequency	Characteristics
Squamous cell carcinoma of cervix	80–90%	▪ Large cell nonkeratinizing squamous cell carcinoma (70%) ▪ Large cell keratinizing squamous cell carcinoma producing keratinizing pearls and prickle cells (25%) ▪ Small cell carcinoma nonkeratinizing carcinoma (5% associated with poor prognosis) ▪ Other microscopic types of squamous cell carcinoma such as verrucous carcinoma (well differentiated variant with a polypoid pattern of growth), spindle cell carcinoma (sarcomatoid carcinoma), basaloid carcinoma, lymphoepithelioma-like carcinoma and transitional carcinoma
Adenocarcinoma of cervix	10–20%	Adenocarcinoma arises from endocervical glands. Malignant cells are frequently infected with HPV 16 and 18
Adenosquamous carcinoma of cervix	4%	Adenosquamous carcinoma arises from reserve cells in cervix. It has favorable prognosis
Small cell carcinoma of cervix	Rare	More aggressive course than the conventional cervical squamous cell carcinoma

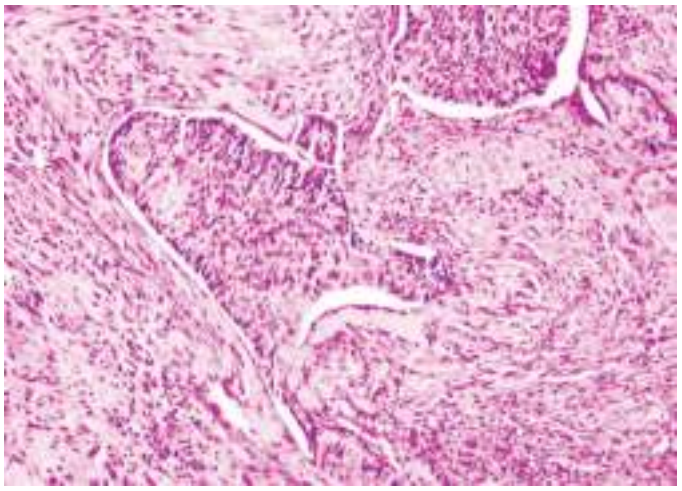

Fig. 24.35: Cervical large cell nonkeratinizing squamous cell carcinoma. Tumor is composed of cells with hyperchromatic nuclei. Cells are devoid of keratinization (400X).

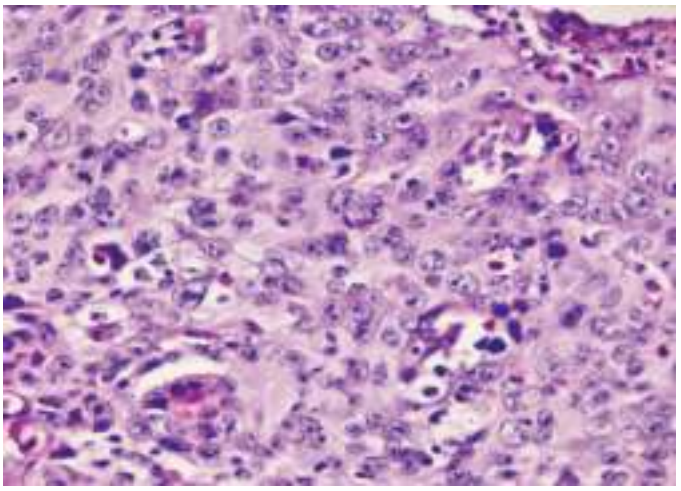

Fig. 24.37: Moderately differentiated squamous cell carcinoma (grade 2) of cervix. Tumor is composed of cells with less distinct cell borders and less cytoplasm than well differentiated tumors; and also, more nuclear pleomorphism and more mitotic activity (400X).

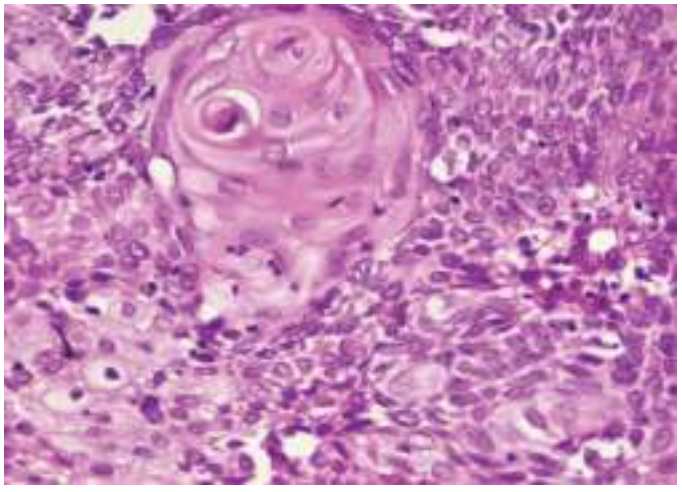

Fig. 24.36: Well differentiated squamous cell carcinoma (grade I) of cervix. Tumor is composed of mature squamous cells with abundant keratin pearls, occasional well-developed intercellular bridges, minimal pleomorphism, minimal mitotic activity (400X).

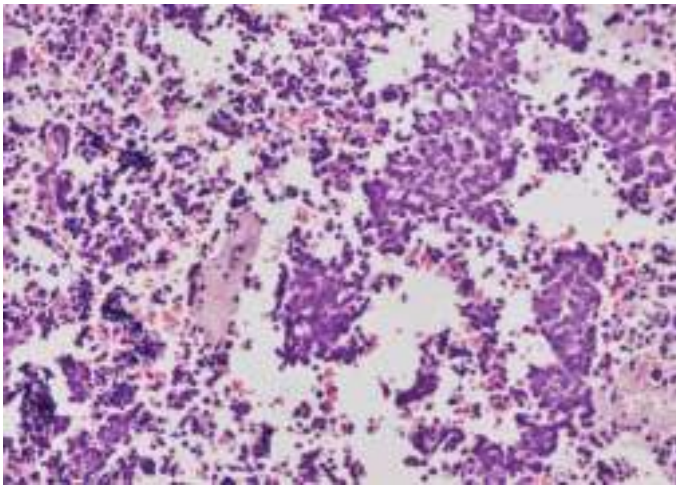

Fig. 24.38: Poorly differentiated carcinoma (grade 3) of cervix. Tumor is composed of small primitive appearing cells with scant cytoplasm, hyperchromatic nuclei and marked mitotic activity; absent/rare keratinization; resembles HSIL (400X).

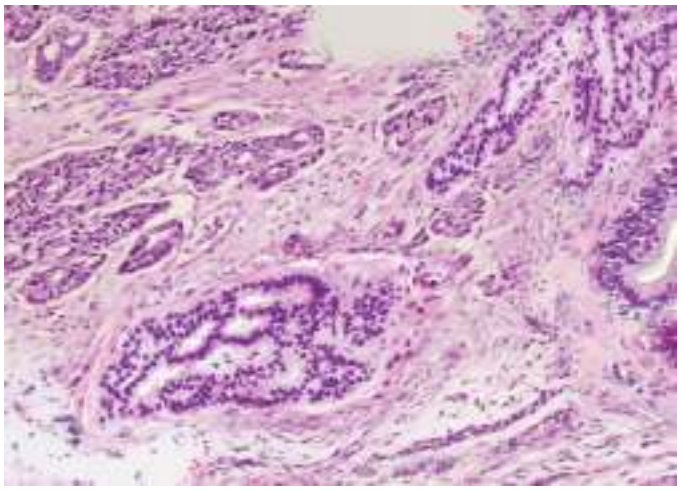

Fig. 24.39: Adenocarcinoma of cervix. Tumor arises from mucus producing endocervical glands is composed of malignant cells arranged in glandular pattern (200X).

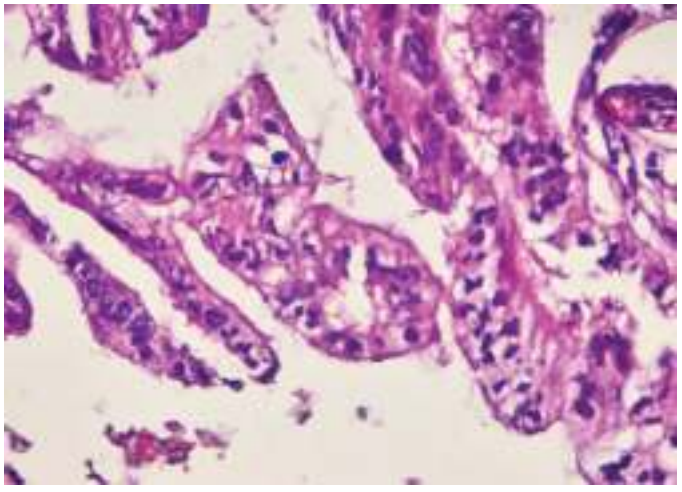

Fig. 24.40: Adenocarcinoma of cervix. Tumor arises from mucus producing endocervical glands is composed of malignant cells arranged in glandular pattern (400X).

Table 24.9 Mode of spread of cervical carcinoma

Mode of Spread	Characteristics
Direct invasion	Tumor invades parametrium and causes compression of ureter resulting in hydroureter, hydronephrosis and ultimately acute renal failure (50%)
Lymphatic route	Pelvic nodes (e.g. paracervical, obturator, external iliac, internal iliac, common iliac and aortic lymph nodes)
Hematogenous route	Distant metastases to lungs, liver, bones and brain

- **Colposcopy:** 3% Acetic acid is applied to cervical transformation zone for visualization of vascular alterations of cervical carcinoma growth.

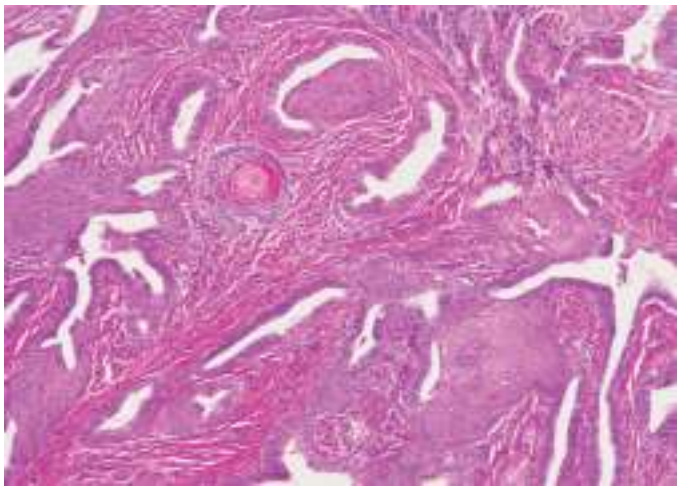

Fig. 24.41: Adenosquamous carcinoma of cervix. It arises from reserve cells in cervix with favorable prognosis. Tumor is composed of glandular and squamous components (400X).

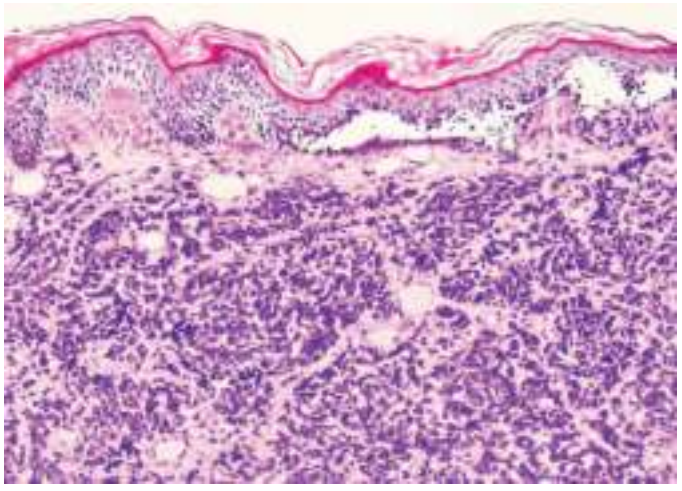

Fig. 24.42: Small cell carcinoma of cervix. Tumor is composed of small atypical cells. It has poor prognosis (400X).

- **Schiller's test:** Normal cervical epithelial cells are rich in glycogen, while absent in malignant cells. Schiller's test is performed by applying Lugol's iodine (a solution of iodine and potassium iodide). Normal cervical epithelial cells give mahogony brown discoloration; while cancerous cells of cervical carcinoma fail to take up the stain.
- **Cervical biopsy:** Punch or wedge biopsy of tumor is done at 12, 3, 6 and 9 o'clock position of cervix.
- **Endocervical curetting:** It is done with cold knife, which is useful in endocervical carcinoma when portio vaginalis appears healthy and cervix feels barrel-shaped.
- **Conization:** It is done with cold knife. It is indicated in following situations: (a) If no visible lesion is seen on colposcopy, (b) if cytologic follow-up is not possible, and (c) if there is discrepancy between vaginal cytology and directed biopsy.

Table 24.10 Staging of cervical carcinoma developed by FIGO

Stage	Cervical Carcinoma Involving Structures	5-Year Survival after Treatment
Stage 0	Cervical carcinoma involves superficial layers of the cervix	100%
Stage I	Cervical lesion (microscopic to 4 cm in diameter)	80–90%
Stage II	Extension from cervical carcinoma into the surrounding cervix area, vagina or tissues surrounding uterus	75%
Stage III	Cervical carcinoma involves lower vagina and/or the pelvic wall. Large growth blocking the outflow of urine through the urethra. Pelvic lymph nodes may be involved	36%
Stage IV	Cervical carcinoma involves urinary bladder, rectum or metastases via hematogenous route to distant organs such as liver, lungs and other organs	10%

- **Fractional curettage:** Fractional curettage also includes assessment of the endocervix, ectocervix, and squamocolumnar transformation zone. It helps to differentiate endocervical carcinoma from endometrial adenocarcinoma. Other indications of fractional curettage include abnormal uterine bleeding: irregular bleeding, menorrhagia, suspected malignant or premalignant condition.
- **Immunohistochemistry:** Immunohistochemical p16 and MIB-1 (Ki-67) markers in the differential diagnosis of squamous and glandular lesions of the uterine cervix is given in Table 24.11.

NEUROENDOCRINE TUMORS OF CERVIX

Neuroendocrine carcinoma of the cervix (NECC) is a rare variant of cervical cancer. It is associated with poor prognosis because there is no standardized therapy for this type of malignancy based on controlled trials. The most common primary treatment for neuroendocrine tumor of cervix is radical surgery combined with chemotherapy either as neoadjuvant or adjuvant chemotherapy and radiotherapy. Histologic and electron microscopic features for distinguishing neuroendocrine tumors of the uterine cervix are given in Table 24.12.

Table 24.11 Immunohistochemical p16 and MIB-1 (Ki-67) markers in the differential diagnosis of squamous and glandular lesions of the uterine cervix

Features	p16	MIB-1 (Ki-67)
LSIL (low-grade squamous intraepithelial lesion) (CIN I)	Positive/negative staining	Positive staining
HSIL (high-grade squamous intraepithelial lesion) (CIN II, III)	Positive staining	Positive staining (full thickness)
AIS (adenocarcinoma *in situ*)	Positive staining	Positive staining
AIM (atypical immature metaplasia)	Negative/positive staining	Negative/positive staining
Reactive squamous or glandular atypia	Negative/positive staining	Positive staining
Tubal metaplasia	Positive/negative staining	Negative staining

CIN: Cervical intraepithelial neoplasia

Table 24.12 Histologic and electron microscopic features for distinguishing neuroendocrine tumors of the uterine cervix

Features	Typical Carcinoid	Atypical Carcinoid Tumor	Small Cell Neuroendocrine Carcinoma	Large Cell Neuroendocrine Carcinoma
Histologic features				
Cellular patterns	Trabecular, insular, sheet-like patterns	Trabecular, insular, sheet-like patterns	Sheets, nests, trabecular and cord-like patterns	Sheets, trabecular, cord-like organ patterns
Mitotic figures	Rare	5–10/10 HPF	10/10 HPF	10/10 HPF
Nuclear atypia	Absent	Moderate atypia	Moderate atypia	Marked atypia
Necrosis	No necrosis	Focal necrosis	Extensive necrosis	Moderate necrosis
Electron microscopy				
Neurosecretory granules	Present	Present	Sometimes present	Present

Neuroendocrine markers are synaptophysin (SYN), chromogranin A (CHR), neuron-specific enolase (NSE) and CD56 (neuronal cell adhesion molecule).

DISORDERS OF UTERINE ENDOMETRIUM

MENSTRUAL CYCLE

The endometrium is the inner epithelial layer along with its mucous membrane of the uterus. It has a basal layer and a function layer. The basal layer contains stem cells which regenerate the functional layer. The functional layer thickens and then it is shed during menstruation in women during reproductive period.

- Endometrial thickness is ≤5 mm in the postmenopausal women with vaginal bleeding.
- A thin endometrium is associated with a lower implantation rate, but no absolute cut off for endometrial thickness exists.
- Normal menstrual cycle is divided into menstrual, proliferative and secretory phases.

MENSTRUAL PHASE

In an ideal 28-day menstrual cycle, menstrual phase lasts 3–4 days and is characterized by glandular and stromal shedding and inflammation. Endometrial thickness is 1–4 mm. Estrogen eventually declines, the corpus luteum involutes, and progesterone level drops, resulting in menstruation. Normal menstrual fluid is non-clotted due to the presence of **fibrinolysin**. A patient with passage of blood clots indicates uterine pathology.

PROLIFERATIVE PHASE

Proliferative phase begins on day 4 of menstrual cycle. Early proliferative phase (days 4–7) is characterized by progressive increase in the thickening of surface endometrium, mitotic activity of endometrial glands and stromal changes secondary to estrogen stimulation.

- In mid-proliferative phase (days 8–10), the surface epithelium becomes columnar, endometrial glands longer and curved, the stroma mildly edematous, and mitotic activity brisk.
- Late proliferative phase (days 11–14) is characterized by undulant surface epithelium, coiled endometrial glands with stratification, high mitotic activity, dense stroma, and appearance of subnuclear vacuoles in fewer than 50% of endometrial glands. Interval epithelium is defined as late proliferative with coiled endometrial glands and subnuclear vacuoles in fewer than 50% of glands.
- During proliferative phase, endometrium becomes **3–4 mm** in thickness. Estrogen is derived from aromatization of testosterone in the granulosa cells of ovaries. Testosterone and 17-ketosteroids (DHEA and androstenedione) are synthesized in the theca interna of ovary under influence of LH.
- Estrogen has a negative feedback on FSH, the later resulting in the LH surge at mid-cycle induction of ovulation. The epithelium is cuboidal, growing taller as ovulation is approached. The glands are simple. The stromal cells are narrow spindles to begin with, become plump.
- Glands especially those of cervical region secrete a thin mucus which helps in guiding spermatozoa towards uterus. Histology of normal proliferative endometrium is shown in Fig. 24.43.

SECRETORY PHASE

Secretory phase starts on the 14th day of menstrual cycle till 21st day under the influence of progesterone hormone. Luteinizing hormone (LH) stimulates ovarian theca interna cells resulting in progesterone synthesis. Progesterone increases the body temperature, which is useful in documenting ovulation. Progesterone also increases salt and water retention and inhibits LH. Endometrium becomes 5–6 mm in thickness.

- During secretory phase, fertilization occurs in the ampullary portion of the fallopian tube. It requires 3 days for the embryo to move through the tube and another 2–3 days to implant in the endometrium (day 21).
- Syncytiotrophoblastic tissue of the developing placenta synthesizes β-hCG and LH analogue. Placenta maintains the production of progesterone by the corpus luteum for 8–10 weeks, after which the placenta takes over hormone production. If fertilization does not take place, the endometrium coupled

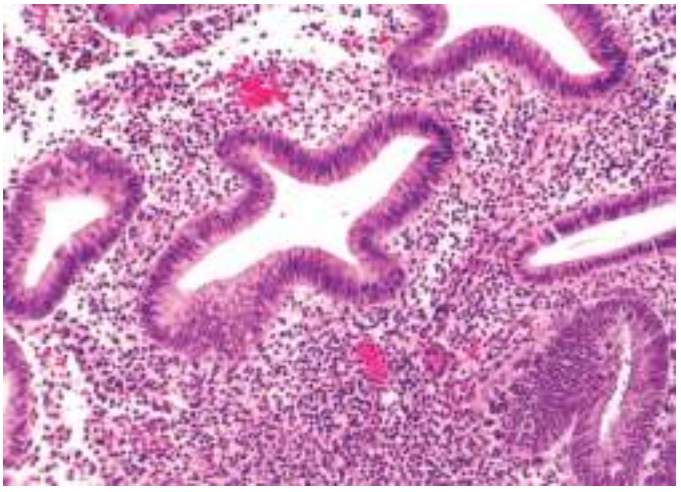

Fig. 24.43: Normal proliferative endometrium. This is the microscopic appearance of normal proliferative endometrium in the menstrual cycle. The proliferative phase is the variable part of the cycle. In this phase, tubular glands with columnar cells and surrounding dense stroma are proliferating to build up the endometrium following shedding with previous menstruation (400X).

with blood and mucus from the vagina and cervix make up the menstrual flow (menstruation) that leaves the body through vagina.

Surgical Pathology: Uterine Endometrium during Menstrual Cycle

Light Microscopy

Endometrial glands in secretory endometrium are dilated, tortuous, lined by tall epithelial cells associated with basal nuclei, clear cytoplasm and subnuclear vacuoles (Figs 24.44 and 24.45).

- **Early secretory endometrium (postovulatory days 2–5):** It occurs soon after ovulation. It is characterized by coiled endometrial glands in which >50% of glandular cells show cytoplasmic vacuoles, which constitute the marker of early secretory phase. The precise dating early secretory endometrium depends on location of cytoplasmic vacuoles (subnuclear or supranuclear) and the degree of mitotic activity.
- **Mid-secretory endometrium (postovulatory days 6–8):** It displays fully coiled endometrial glands lined by cells with round, vesicular nuclei and cytoplasm without vacuoles. Luminal secretion is present. The stroma does not demonstrate predeciduation. More precise dating mid-secretory endometrium depends on degree of stromal edema and extent of glandular luminal secretion.
- **Late secretory endometrium (postovulatory days 9–14):** It is characterized by prominent spiral arteries and appearance of predeciduation. The predeciduation is first observed around spiral arteries and later extends to the superficial stroma. At the ends of the secretory phase, decidual regions become confluent. Interstitial hemorrhage appears at the beginning of menstrual phase. Predeciduation is associated with increase in number of granulocytes in stroma.

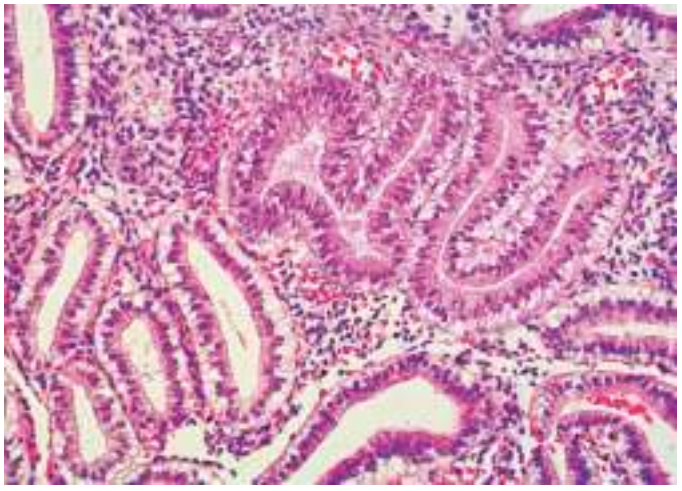

Fig. 24.44: Early secretory endometrium. The appearance with prominent subnuclear vacuoles in cells forming the glands is consistent with post-ovulatory day 2. The histologic changes following ovulation are quite constant over the 14 days to menstruation and can be utilized to date the endometrium (400X).

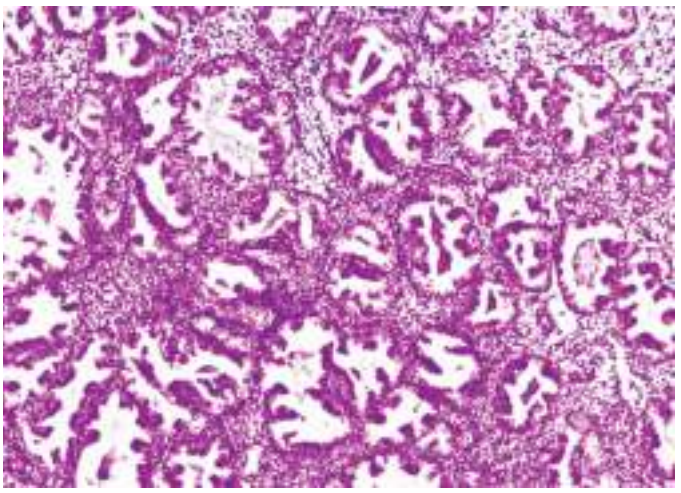

Fig. 24.45: Late secretory endometrium. This is normal secretory phase endometrium. Note the larger tortuous glands with secretions. The secretory phase starts at 14th day course leading to either implantation of a fertilized ovum or menstruation.

MENSTRUAL CYCLE DISORDERS

AMENORRHEA

Amenorrhea is the abnormal absence of menstruation. Amenorrhea occurs during normal pregnancy, lactation, before puberty and after menopause. Amenorrhea may be subdivided into primary or secondary. Primary amenorrhea is the absence of menarche in an adolescent girl after 16 years of age. Secondary amenorrhea is the absence of menstruation for at least 3 months after the normal onset of menarche.

- **Primary amenorrhea:** Imperforate hymen is the most important cause of primary amenorrhea. Dysfunctional hypothalamic-pituitary-ovarian axis causes primary amenorrhea. Turner's syndrome is the most common genetic cause of prepubertal ovarian failure. Anovulation occurs due to deficient synthesis of gonadotropins, estrogens, FSH and LH. Decreased estrogen levels may be secondary to a hypothalamic-pituitary disturbance (low FSH and LH). FSH and LH levels are increased in primary ovarian disorder.
- **Secondary amenorrhea:** Pregnancy and menopause are most common causes of secondary amenorrhea. Hypogonadotropic hypoestrogenic anovulation, endometrial adhesions (Asherman syndrome) and premature ovarian failure cause secondary amenorrhea. Patient presents with absence of menstruation, hirsutism, vasomotor flushes and vaginal atrophy. Acne is observed in secondary amenorrhea.

Laboratory Diagnosis

Radiograph establishes age of the patient. Blood pituitary gonadotropin level, thyroid profile, progesterone,

androgen and FSH levels are analyzed. Histologic examination of cervical mucus is performed to detect 'fern test' (estrogenic effect) to assess ovulation and to detect rupture of membranes. Vaginal secretions are inspected under a microscope for crystallization (ferning pattern), which occurs due to an increased concentration of protein and electrolytes within the fluid.

DYSMENORRHEA

Dysmenorrhea refers to the symptom of painful menstruation. It can be divided into two broad categories: (a) primary dysmenorrhea is defined as cramping pain in the lower abdomen occurring in the absence of inflammatory disease; and (b) secondary dysmenorrhea is resulting from identifiable organic disorders (e.g. endometriosis). Primary dysmenorrhea occurs just before or during menstruation in adolescence. Women with primary dysmenorrhea have increased production of prostaglandins resulting in increased uterine tone and stronger frequent uterine contraction. These cases with dysmenorrhea are treated by nonsteroidal anti-inflammatory drugs with the addition of oral contraceptive pills, when necessary.

DYSFUNCTIONAL UTERINE BLEEDING

Dysfunctional uterine bleeding (DUB) is defined as bleeding not associated with any structural abnormality in uterus and its appendages pelvis. The uterus and its appendages are structurally normal. DUB is presumably related to hormonal changes. The main causes of dysfunctional uterine bleeding include failure of ovulation (anovulatory cycle) and inadequate luteal phase. Causes of vaginal bleeding are given in Table 24.13.

- **Anovulatory cycle (failure of ovulation):** Dysfunctional uterine bleeding is presumably related to hormonal changes. Dysfunctional uterine bleeding may also be caused by neuroendocrine disturbances (e.g. anxiety and anorexia nervosa), severe malnutrition, and debilitating diseases.
- **Inadequate luteal phase:** If the corpus luteum does not secrete progesterone in adequate amounts, the level of progesterone may not be sufficient for full transition of proliferative endometrium to secretory endometrium. Such irregular maturation of the endometrium is usually associated with spotting, premature onset of menstrual bleeding or prolonged vaginal bleeding.

Table 24.13 Causes of vaginal bleeding

Age Group	Causes
Pre-puberty	Unexplained menstrual-like cyclic vaginal bleeding for many days without uterine and vaginal anomaly
Adolescence	Anovulatory cycles
Reproductive period	▪ Complication of pregnancy ▪ Organic lesion ▪ Anovulatory cycle ▪ Dysfunctional uterine bleeding
Perimenopausal women	Anovulatory cycle associated with irregular shedding
Postmenopausal women	▪ Atrophic endometrium ▪ Organic lesion

Pathology

If ovulation does not occur during secretory phase, the endometrium will continue to proliferate until it outgrows its own blood supply. At that point, the surface portion of the endometrium becomes ischemic and starts dying off. This leads to bleeding per vagina, which typically occurs 2 or 3 weeks after the date of the missed menstruation.

Clinical Features

Patient may present with menorrhagia (episodes of vaginal bleeding between menstrual cycles) or heavy or prolonged menstruation persisting for longer than 8 days, fatigue due to anemia and infertility as a result of anovulation.

Laboratory Diagnosis

Ovulatory body temperature monitoring, serum progesterone level and endometrial biopsy are performed in dysfunctional uterine bleeding cases. Patient should be investigated to rule out infections, polyps and cancers of the genital tract.

INFLAMMATORY DISORDERS OF UTERINE ENDOMETRIUM

ACUTE ENDOMETRITIS

Endometritis results from infection of the endometrium, which may be acute or chronic depending on underlying cause.

- Acute endometritis is common and symptomatic common often caused by *Staphylococcus aureus* or *Streptococcus* species, and sexually transmitted diseases (*Chlamydia trachomatis*, *Neisseria gonorrheae*). Acute endometritis is most often associated with intrauterine contraceptive devices, intrauterine trauma from instrumentation, and postpartum retention of placental fragments.
- Acute endometritis is characterized by microabscess formation and neutrophil invasion in the endometrial superficial epithelium, gland lumina, and uterine cavity. '**Cervical stenosis**' may also result in accumulation of pus in uterine cavity known as '**pyometra**'.

CHRONIC ENDOMETRITIS AND INFERTILITY

Chronic endometritis is rather silent without noticeable signs or mild symptoms involving the breakdown of the peaceful co-existence between microorganisms and the host immune system in the endometrium. It is diagnosed by endometrial biopsy.

- Chronic endometrial inflammation can alter endometrial cytokine production and damage endometrial function, resulting in the formation of abnormal patterns of lymphocyte subsets in the endometrium, and induction of altered secretion of paracrine factors, which ultimately may reduce the receptivity of embryos in the endometrium.
- Tuberculosis is most important cause of chronic endometritis in endemic regions. *Actinomyces israelii* infection is also responsible for chronic endometritis due to intrauterine contraceptive device.
- Patient presents with abnormal bleeding, pain, discharge, fever, and infertility.
- Fluid hysteroscopy is another powerful tool for diagnosing chronic endometritis, which demonstrates micropolyps, stromal edema, and focal or diffuse hyperemia.

Surgical Pathology: Chronic Endometritis

Light Microscopy

- Normal endometrium contains lymphocytes and lymphoid follicles but lack plasma cells.
- Presence of plasma cells in the endometrial stroma is diagnostic of chronic endometritis.
- Chronic endometritis is associated with infertility-related conditions such as repeated implantation failure and recurrent miscarriage. Histology of chronic endometritis is shown in Fig. 24.46.

Immunohistochemistry Technique

- Hematoxylin and eosin (H&E) staining in women with infertility and patients with a history of repeated spontaneous miscarriages had a low diagnostic rate.
- Recently, an immunohistochemical (IHC) stain capable of detecting CD38+ and CD138+ plasma cell specific surface antigens have been introduced for the confirmation of the presence of plasma cells inside the endometrium.
- Additional immunohistochemical staining for CD138 in H&E-stained tissue specimens have increased the diagnostic concordance between pathologists.

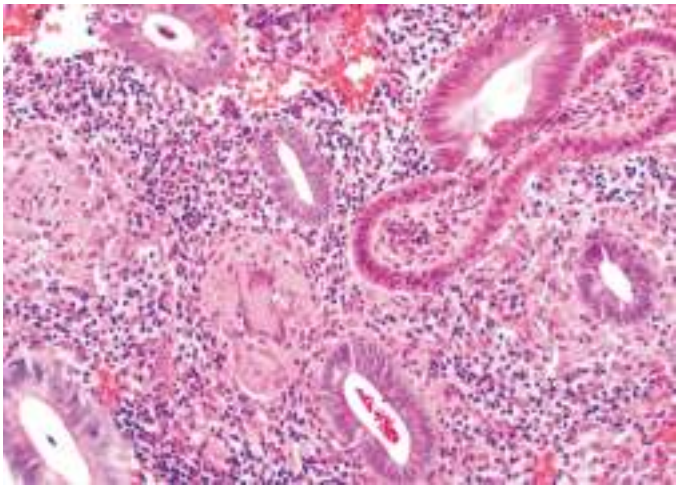

Fig. 24.46: Chronic endometritis. Chronic endometritis can occur in patients with chronic pelvic inflammatory disease, as a postpartum or post-abortion complication, in association with intrauterine devices (IUDs), or with tuberculosis. In a sixth of patients there is no definable cause for chronic endometritis (400X).

NON-NEOPLASTIC DISORDERS OF UTERINE ENDOMETRIUM

ENDOMETRIAL HYPERPLASIA

Endometrial hyperplasia refers to abnormal proliferation of endometrial glands. According to new 2014 WHO classification of endometrial hyperplasia, endometrial hyperplasia has been classified into two categories: (a) Nonatypical endometrial hyperplasia (benign hyperplasia) and (b) typical endometrial hyperplasia or endometrial intraepithelial neoplasia (EIN)/well differentiated carcinoma.

- The new scheme has improved the reproducibility and clearly distinguishes between clinicopathologic entities that are managed differently. Thereby, it should be considered for the diagnosis of endometrial biopsy/curettage specimens.
- Differential diagnosis between benign uterine lesions and atypical hyperplasia/EIN is based mainly on morphologic criteria but may be supported by additional immunohistochemical markers and molecular alterations in problematic cases.
- Endometrial hyperplasia is usually caused by estrogenic stimulation, which occurs in anovulatory menstrual cycles as a result of estrogenic effect not opposed by progesterone. Excess of estrogens also occurs in women with polycystic ovary disease, estrogen-secreting ovarian tumors, i.e. granulosa cell tumor, estrogen replacement therapy and ovarian cortical stromal hyperplasia.
- Endometrial hyperplasia may progress to atypical hyperplasia and ultimately endometrial carcinoma and manifest with postmenopausal bleeding. Young women manifest with menorrhagia and anovulation.

Surgical Pathology: Endometrial Hyperplasia

Gross Morphology

Uterine endometrium is diffusely thickened due to prolonged action of estrogens (Fig. 24.47).

Light Microscopy

Endometrial hyperplasia refers to a spectrum that ranges from simple glandular crowding to conspicuous proliferation of atypical glands, which is often difficult to distinguish from endometrial carcinoma. Estrogen exposure is thought to be a risk factor for both endometrial hyperplasia and endometrial carcinoma. Endometrial hyperplasia is of three types (e.g. simple, complex without atypia and complex with atypia) on histopathologic examination of endometrial biopsy described as under.

- **Simple (cystic) endometrial hyperplasia:** It demonstrates an increased number of dilated glands separated from each other by normal stroma giving '**Swiss cheese pattern**' (Fig. 24.48).
- **Complex (adenomatous) endometrial hyperplasia without atypia:** The irregularly shaped glands appear overcrowded and are surrounded by relatively scant stroma. The glandular epithelium is lined by uniform cells showing no atypia. Only 5% of patients with complex hyperplasia without atypia ultimately progress to endometrial carcinoma in a span of 10 years (Fig. 24.49).
- **Complex (adenomatous) endometrial hyperplasia with atypia:** It is characterized by cytologic atypia and marked glandular crowding with stratification of cells that often protrude into the lumen. Endometrial glands frequently show back-to-back arrangement. Most reliable diagnostic criteria are presence of round rather than oval cells with hyperchromatic nuclei, prominent nucleoli and high nuclear-to-cytoplasmic ratio. Approximately 25% of complex atypical endometrial hyperplasia may progress to endometrial carcinoma in a span of 4 years (Fig. 24.50).

ARIAS-STELLA REACTION

Arias-Stella reaction is an exaggerated hypersecretory response of the endometrium to hCG stimulation (endometrial hyperplasia), which may be observed in normal intrauterine pregnancy and ectopic pregnancy. It may provide initial information of ectopic pregnancy. Arias-Stella reaction can also be observed due to exogenous hormonal therapy, hydatidiform mole, choriocarcinoma and endometriosis.

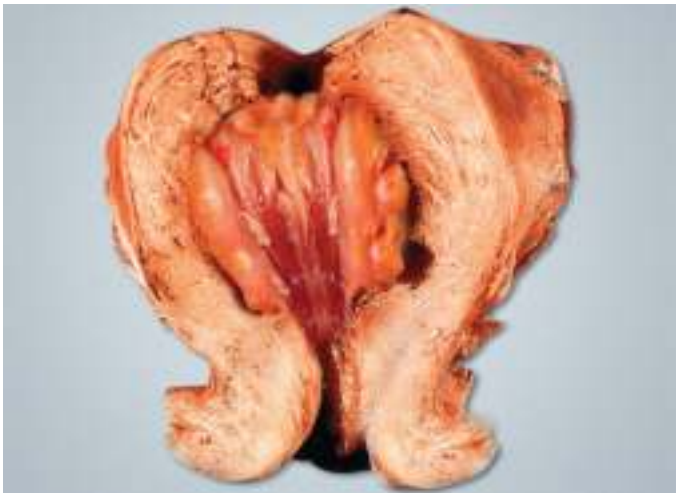

Fig. 24.47: Endometrial hyperplasia. The whole endometrium is involved, rather than there being a discrete polyp. It results with conditions of prolonged estrogen excess. The patient presented with metrorrhagia (uterine bleeding at irregular intervals), menorrhagia (excessive bleeding with menstrual periods), or menometrorrhagia.

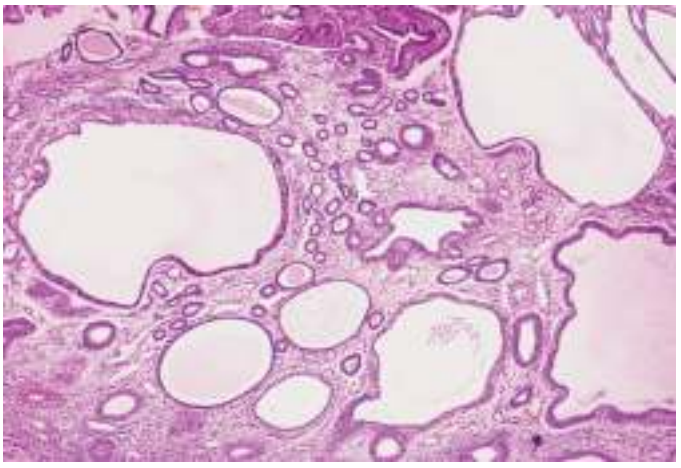

Fig. 24.48: Simple endometrial hyperplasia. This is endometrial cystic hyperplasia in which the amount of endometrium is abnormally increased and not cycling as it should. The glands are enlarged and irregular with columnar cells that lack atypia (100X).

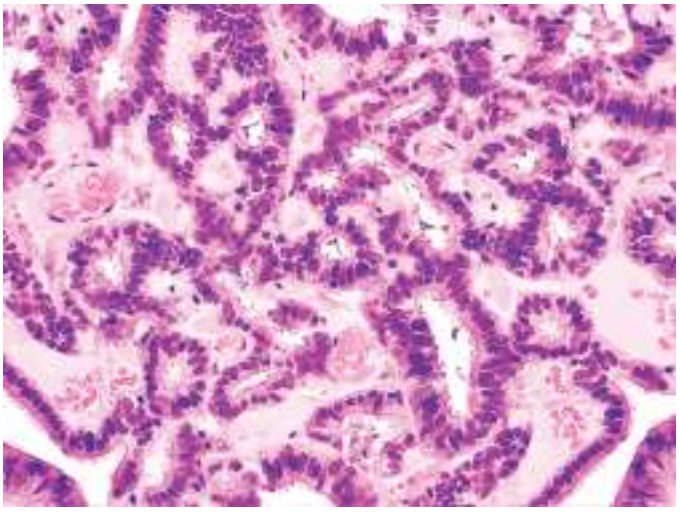

Fig. 24.49: Complex (adenomatous) hyperplasia without atypia. The irregularly shaped glands appear overcrowded and are surrounded by relatively scant stroma. The glandular epithelium is lined by uniform cells showing no atypia (400X).

Surgical Pathology: Arias-Stella Reaction

Light Microscopy

- Endometrial glands are hypersecretory with back-to-back arrangement. The cells of endometrial gland are large with abundant clear or eosinophilic cytoplasm, large hyperchromatic pleomorphic and smudged nuclei.
- There is presence of decidualized stroma. It may provide initial information of ectopic pregnancy (Fig. 24.51).

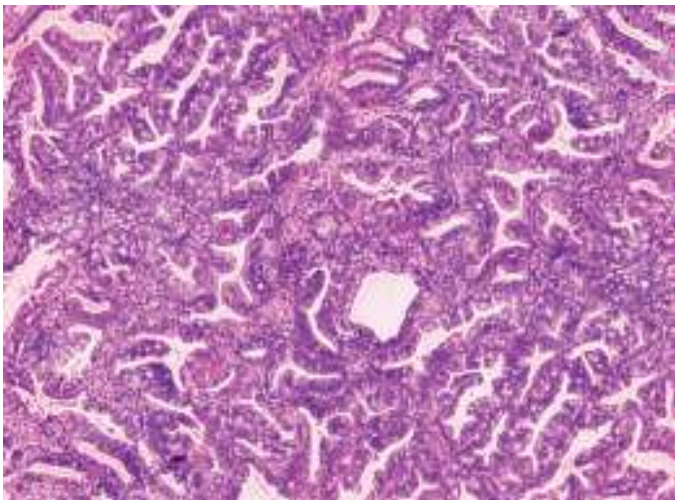

Fig. 24.50: Complex (adenomatous) endometrial hyperplasia with atypia. It shows marked glandular crowding with back-to-back arrangement and stratification of cells that often protrude into the lumen. Cells lining glands are round with hyperchromatic nuclei, prominent nucleoli and high nuclear-to-cytoplasmic ratio (400X).

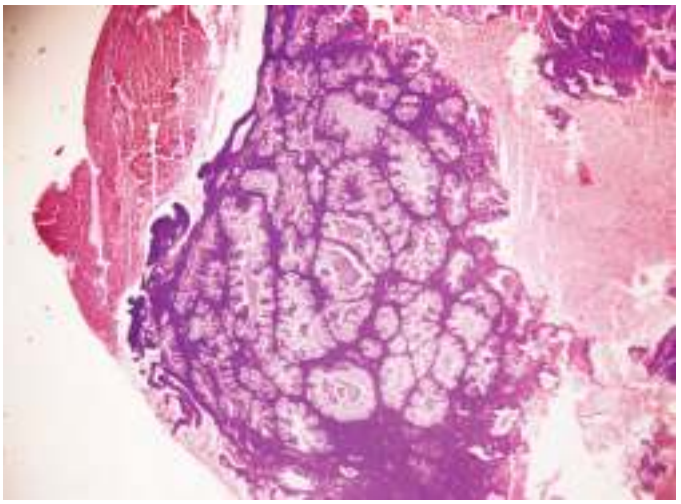

Fig. 24.51: Arias-Stella reaction. Endometrial glands are hypersecretory with back-to-back arrangement. The cells of endometrial gland are large with abundant clear or eosinophilic cytoplasm, large hyperchromatic pleomorphic and smudged nuclei. There is presence of decidualized stroma. It may provide initial information of ectopic pregnancy (400X).

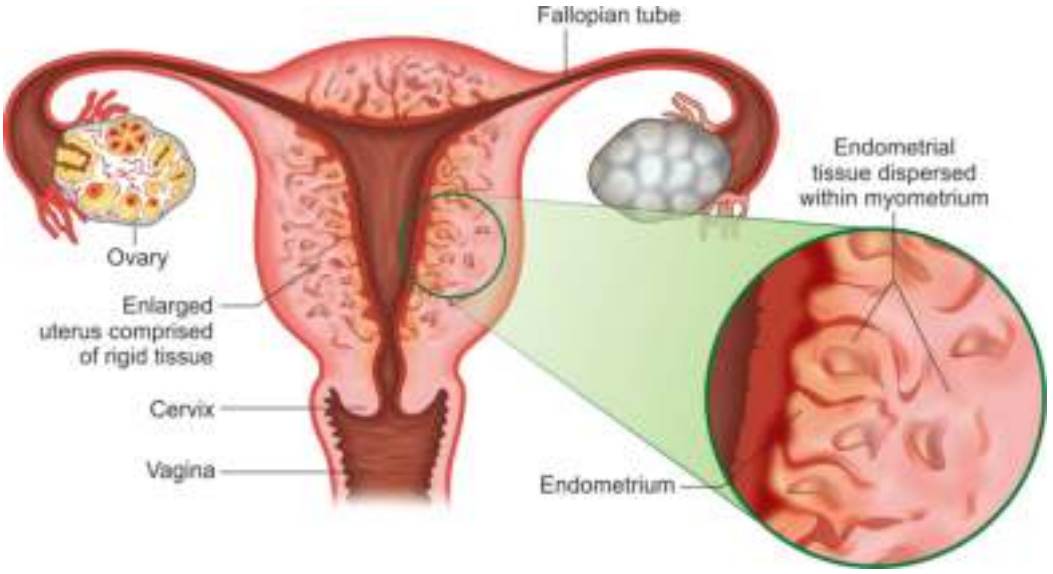

Fig. 24.52: Adenomyosis uterus. The thickened and spongy appearing myometrial wall of this sectioned uterus is typical of adenomyosis. This condition leads to uterine enlargement and irregular bleeding.

ADENOMYOSIS UTERI

Adenomyosis uteri occurs when the endometrial islands that normally lines the uterus grows into the muscular wall of the uterus. Approximately, 15–20% of all resected uteri show some evidence of adenomyosis. The endometrial islands continue to act normally by thickening, breaking down and painful prolonged bleeding during each menstrual cycle. Sometimes, patients remain asymptomatic. However, adenomyosis uteri can cause heavy painful menstrual bleeding during menstrual cycle, severe pelvic pain during menstrual cycle and painful intercourse (dyspareunia).

Surgical Pathology: Adenomyosis Uteri
Gross Morphology
Adenomyosis uteri reveals asymmetrical hyperplasia of uterus. Multiple small hemorrhagic cysts are seen in myometrium (Fig. 24.52).
Light Microscopy
Adenomyosis uteri shows presence of nests of endometrial glands lined by mild proliferative to inactive endometrium, surrounded by endometrial stroma with varying degrees of fibrosis in the myometrium (Fig. 24.53).

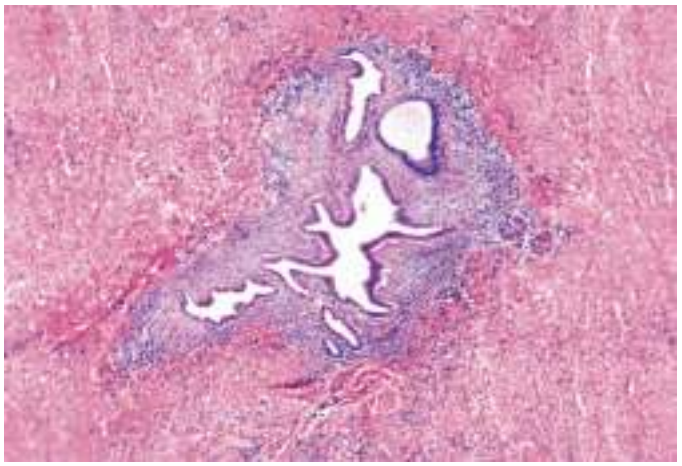

Fig. 24.53: Adenomyosis uterus. Adenomyosis occurs when endometrial glands and stroma are found in the myometrium, not just in the endometrium where they belong. This condition leads to uterine enlargement and irregular bleeding (100X).

ENDOMETRIOSIS

Endometriosis is presence of benign endometrial glands and stroma outside the uterus. It is an important cause of infertility. It affects 5–10% of women of reproductive age and regresses after menopause.

- Endometriosis occurs either by retrograde dissemination of endometrial fragments through fallopian tubes during menstruation, resulting in their implantation on the ovary, or lymphatic-hematogenous dissemination of endometrial fragments.
- Uterine as well as ectopic endometrial glands respond to estrogen and progesterone during each menstrual cycle resulting in sloughing and bleeding in ectopic endometrial glands forming large cysts. It leads to inflammation and fibrosis. Laparoscopy is the gold standard for screening, which shows red-blue to yellow-brown nodules measuring 1–5 mm. In occasional case, the ovarian chocolate cysts are formed measuring 20 cm in diameter.

Locations

The **ovaries** are the most common sites (80%), followed by the uterine ligaments, fallopian tubes, rectovaginal septum, rectosigmoid colon, and pelvic peritoneum (Table 24.14). Since the fimbriae openings of fallopian tubes are in the posterior area of pelvis, most ectopic endometrial glands are generally confined to the pelvic region. Other sites of endometriosis include urinary bladder, lung, pleura, kidneys, extremities and operated scars of abdomen (Fig. 24.54).

Clinical Features

Patient presents with severe menstrual-related pelvic pain due to inflammation and fibrosis in areas around ectopic endometrial glands.

Table 24.14 Locations of endometriosis

Ovaries (most common site in 80%)
Cul-de-sac (common site)
Broad ligament (common site)
Fallopian tubes (fimbriae openings)
Umbilical region
Urinary bladder
Ileum
Abdominal wall operated scar
Vulva
Perineum
Lymph nodes
Kidneys
Liver
Diaphragm

- Pain begins 5–7 days before onset of menstruation, peaks and lasts for 2–3 days. Patient may develop painful sexual intercourse. The inflammation causes fibrosis and adhesions often resulting in infertility.
- Endometriosis in the colon causes abdominal cramps, pelvic pain, painful defecation, constipation and bloody stools.
- Endometriosis in the urinary bladder causes suprapubic pain, dysuria and hematuria.

Surgical Pathology: Endometriosis

Gross Morphology

Menstrual-type bleeding occurs into the ectopic endometrial glands resulting in formation of blood-filled cysts up to 15 cm in diameter containing chocolate-colored material known as 'chocolate cysts' (Fig. 24.55).

Light Microscopy

The diagnosis of endometriosis is based on finding endometrial glands, stroma, and hemosiderin in the stroma on light microscopy of biopsy tissue. Foci of healed endometrium in the form of hemosiderin on the peritoneal surface are referred to as powder burns (Fig. 24.56).

NEOPLASTIC DISORDERS OF UTERINE ENDOMETRIUM

ENDOMETRIAL POLYP

Endometrial polyp most often occurs in the perimenopausal period. It is solitary finger-like benign lesion found in the uterine cavity. Most polyp is diagnosed

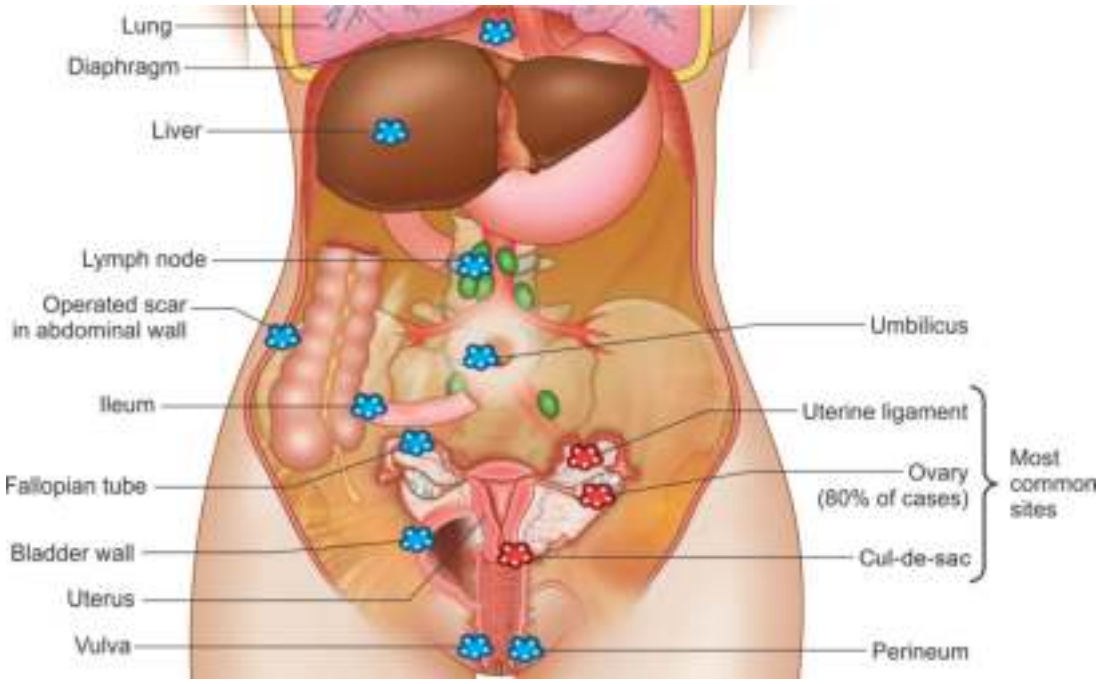

Fig. 24.54: Endometriosis shows some of the sites where endometrial deposits can occur. Red highlights the three most common sites; ovary, uterine ligaments and cul-de-sac.

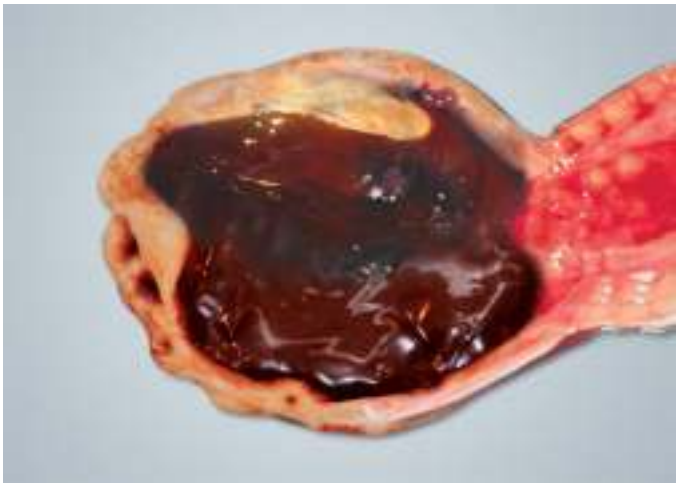

Fig. 24.55: Chocolate cyst in endometriosis. This is a section through an enlarged 12 cm ovary to demonstrate a cystic cavity filled with old blood typical for endometriosis with formation of an endometriotic, or chocolate cyst. The hemorrhage from endometriosis into the ovary may give rise to a large chocolate cyst so named because the old blood in the cystic space formed by the hemorrhage is broken down to produce much hemosiderin and a brown to black color.

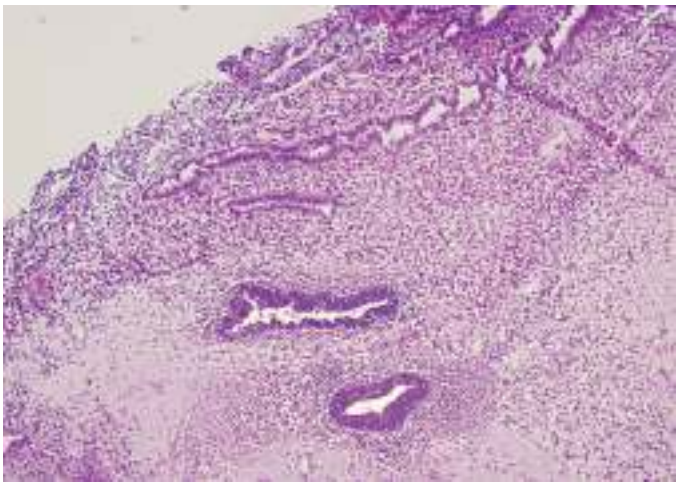

Fig. 24.56: Endometriosis. Endometriosis is derived from the word 'endometrium'. Endometrial glands and stroma that line the uterus grow outside the uterus and affects women during reproductive age. Women may present with infertility, difficulty to have pregnancy, excessive menstrual cramps, heavy menstrual flow, and pain during intercourse. Laparoscopy can be used to diagnose and treat endometriosis (100X).

in perimenopausal women complaining of spotting or irregular bleeding. Polyp is easily removed by curettage. Differential diagnoses of a polypoid lesion of the endometrial cavity include benign endometrial polyp, atypical polypoid adenomyoma, adenosarcoma, polyp with component of carcinoma and carcinosarcoma.

Pathogenesis

It is thought that endometrial foci are hypersensitive to estrogenic stimulation or unresponsive to progesterone. Hence, these endometrial foci do not slough during menstruation and continue to progress. Patient presents with spotting or irregular bleeding during menstrual cycel.

Surgical Pathology: Endometrial Polyp
Gross Morphology
Endometrial polyp protrudes into the uterine cavity. The lesion is believed to arise from endometrial foci that are hypersensitive to estrogen stimulation and that fails to slough with menstruation. Such benign polyp may cause uterine bleeding (Fig. 24.57).
Light Microscopy
Endometrial polyp consists of core covered by surface endometrium. Core of endometrial polyp comprises dilated and hyperplastic endometrial glands embedded in fibrous endometrial stroma containing thick-walled, coiled.

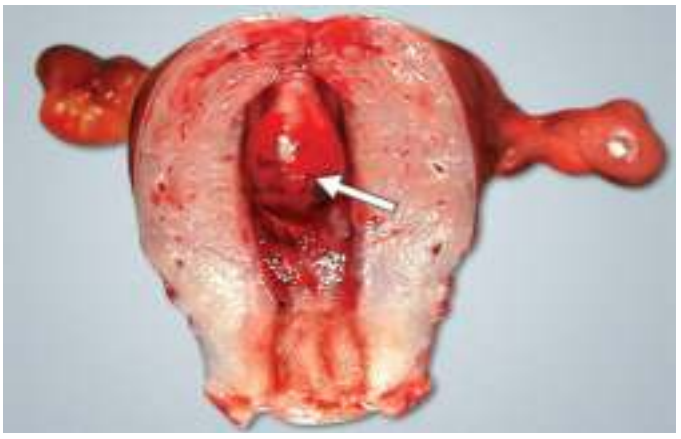

Fig. 24.57: Endometrial polyp protrudes into the uterine cavity. The lesions are believed to arise from endometrial foci that are hypersensitive to estrogen stimulation and that fail to slough with menstruation. Such benign polyps may cause uterine bleeding (arrow).

ENDOMETRIAL CARCINOMA

Endometrial carcinoma is most common gynecologic malignancy, which most frequently arises in the corpus uteri, and may also originate in the lower uterine segment. Well documented conditions known to be associated with an increased risk for endometrial carcinoma include obesity, nulliparity, early menarche, and late menopause. Obesity appears to be the greatest risk factor. Aromatization of androstenedione to estrone, which occurs in the peripheral adipose tissue, appears to be the source of the increased circulating levels of estrogen in obese patients. Diabetes mellitus, hypertension, family history and a high-fat diet and previous radiation have been implicated in the increased incidence of endometrial carcinoma. Tobacco smoking in conjunction with the use of exogenous estrogen significantly multiplies the risk for developing endometrial carcinoma, especially in thin women.

- In low volume disease, it is common to find no evidence of residual disease after diagnostic endometrial curettings. Localized disease (endometrial carcinoma) manifests as round, polypoid expansile masses that are friable and often hemorrhagic. Diffuse involvement of endometrium by endometrial carcinoma may show an indurated-appearing endometrial surface without a visible exophytic component. Foci of myometrial invasion by tumor usually appear grossly as well-demarcated gray-white areas that appears as lighter in color in the surrounding uninvolved myometrium.
- With the revised International Federation of Gynecologists and Obstetrics (FIGO) staging system, this important information may affect the remaining course of the surgical procedure. Intraoperative pathology consultation may be obtained to determine the depth of gross myometrial invasion by endometrial carcinoma or cervical extension. Ideally, the pathologist should measure both the width of the myometrium and depth of the tumor myometrial invasion.
- General principles in the macroscopic appearance, histologic classification, diagnosis and management of endometrial carcinoma are defined in the recent recommendations by the International Society of Gynecological Pathologists. Recent 2020 WHO classification of tumors of the uterine endometrium is given in Table 24.15.
- Incidence of endometrial carcinoma is higher in North America, whereas lower in developing countries and Japan. Incidence of endometrial carcinoma is twice high in white than black population.
- Based on clinicopathological features and molecular genetic features, endometrial carcinoma can be broadly classified into numerous histologic categories on the basis of clinicopathologic features, molecular features and immunohistochemistry: type 1 endometrioid carcinoma and type 2 nonendometrioid carcinoma.
  - **Type 1 endometrioid adenocarcinoma (85%):** It is the most common cell type also known as endometrial adenocarcinoma that occurs in the settings of endometrial hyperplasia, unopposed estrogen stimulation in obese women especially receiving exogenous estrogen in 85% of women. Many studies established that these patients have elevated serum estrogen level.
  - **Type 2 nonendometrioid carcinoma:** It originates in atrophic endometrium, and it is not related to hyperestrogenic state. Salient features of endometrial carcinoma are shown in Fig. 24.58. Comparison of type 1 endometrioid carcinoma and type 2 nonendometrioid carcinoma is given in Table 24.16.
- Histologic variants of type 1 endometrioid carcinoma include villonodular, secretory, ciliated cell, and adenocarcinoma with squamoid differentiation. Overall, the epidemiologic characteristics of the

Table 24.15 Recent 2020 WHO classification of tumors of the uterine endometrium

Endometrial Epithelial Tumors and Precursors
▪ Endometrial hyperplasia without atypia
▪ Atypical hyperplasia of the endometrium
▪ Endometrioid adenocarcinoma, NOS
• POLE-ultramutated endometrioid carcinoma
• Mismatch repair-deficient endometrioid carcinoma
• TP53-mutant endometrioid carcinoma
• No specific molecular profile (NSMP) endometrioid carcinoma
▪ Serous carcinoma (aggressive type)
▪ Clear cell adenocarcinoma, NOS (aggressive type)
▪ Carcinoma, undifferentiated, NOS
▪ Mixed cell adenocarcinoma
▪ Mesonephric adenocarcinoma
▪ Squamous cell carcinoma, NOS (aggressive type)
▪ Mucinous carcinoma, intestinal type (low-grade type)
▪ Mesonephric-like adenocarcinoma
▪ Carcinosarcoma, NOS
Tumor-like Lesions
▪ Endometrial polyp
▪ Endometrial metaplasia
▪ Arias-Stella reaction
Mixed Epithelial and Mesenchymal Tumors
▪ Adenomyoma, NOS
▪ Adenosarcoma
▪ Atypical polypoid adenomyoma
Miscellaneous Tumors
▪ Primitive neuroendocrine tumor, NOS
▪ Germ cell tumors, NOS
• Yolk sac tumor
• Mature teratoma, NOS
• Immature teratoma, NOS

1. Serous adenocarcinoma, mucinous adenocarcinoma, undifferentiated carcinoma and de-differentiated carcinoma are associated with poor prognosis.

2. Recent molecular genetic analysis supports that both components in these biphasic mixed type carcinomas are clonally derived from a transformed epithelial cell.

3. Clear cell adenocarcinomas share features with type 1 endometrioid carcinoma and serous endometrial carcinoma type 2.

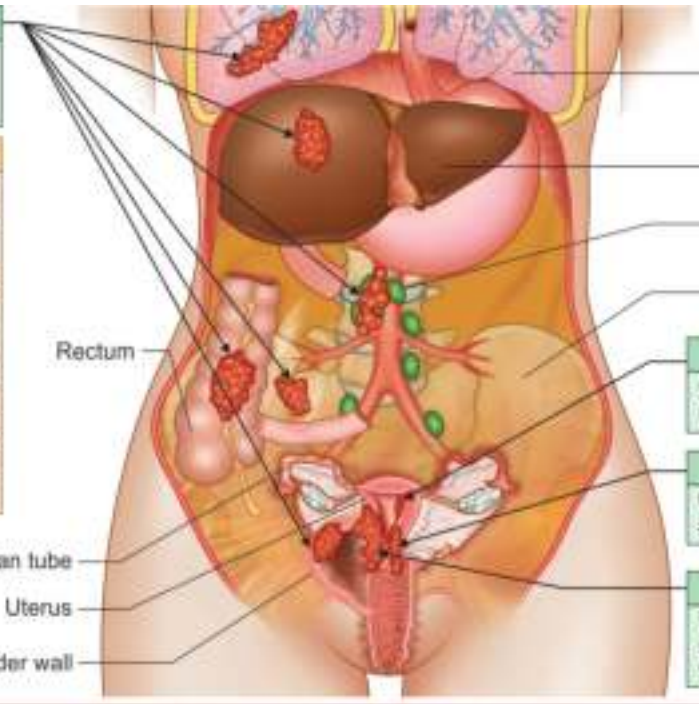
histologic types are similar to typical type 1 endometrioid carcinomas. Histologic variants of type 2 nonendometrioid carcinoma include serous, clear cell, squamous and undifferentiated. There is no distinctive gross appearance to differentiate individual histologic subtypes of endometrial carcinoma. Some clear cell endometrial carcinomas share the features of type 1 endometrioid carcinoma and type 2 nonendometrioid carcinoma.

- Prognostic factors in endometrial carcinoma limited to the uterine corpus include: histologic type, tumor grade, lymphovascular invasion and lymph node involvement.
  - Depth of myometrial invasion by endometrial carcinoma has proven to be an independent predictor of prognosis in early-stage endometrial carcinoma. Increasing depth of myometrial invasion (inner third, middle third, inner third) is associated with a greater probability of lymph node metastases and mortality from tumor.
  - FIGO divides depth of myometrial invasion by endometrial carcinoma into halves. Ideally, total width of the myometrium should be measured and reported in addition to the measurement of the thickness of tumor invasion. Determining the depth of myometrial invasion by endometrial carcinoma may be complicated when foci of adenomyosis are involved.
  - Involvement of the cervix by endometrial carcinoma has adverse effects on prognosis. Vascular invasion is an important predictor of recurrence of the disease and its presence should always be mentioned in the report by pathologist. Metastatic tumors involving endometrium are uncommon. The most common primary sites are breast, stomach, colon and melanoma.
- Total abdominal hysterectomy with bilateral salpingo-oophorectomy is standard treatment of endometrial carcinoma. Regional lymph node dissection is performed in patients with type 1 endometrioid carcinoma, FIGO 2 or 3 high-grade histologic type, tumor >2 cm or with myometrial invasion on imaging or suspicious lymph nodes. Radiation therapy is indicated in patients with FIGO Ib or with local recurrence. Chemotherapy is indicated for high-risk early stage or advanced stage endometrial carcinoma, recurrences and distant metastases.

Type 1 Endometrioid Carcinoma

Type 1 endometrioid carcinoma is a glandular neoplasm displaying a glandular (acinar), papillary or a mixture of two, or partly solid configuration. Type 1 endometrioid carcinoma is considered to be estrogen dependent with a well-defined precursor lesion—atypical endometrial hyperplasia/endometrial intraepithelial neoplasia (AEH/EIN). Continuous unopposed estrogenic stimulation leads to progression of hyperplasia without cytologic atypia to AEH/EIN. Some studies revealed that AEH/EIN emerges as a clonal process that begins as a localized lesion usually in a background of endometrial hyperplasia without cytologic atypia. Risk for type I endometrioid carcinoma is increased associated with hereditary syndromes such as Cowden syndrome and Lynch syndrome (hereditary non-polyposis colon cancer).

Stage IV



Invasion of bladder or rectum or metastasis to
- Bones
- Liver
- Lungs
- Brain (40%)
- Lymph nodes

Endometrial carcinoma: Work up

- **Clinical features:** Abnormal uterine bleeding, vaginal discharge, constitutional symptoms (weight loss, anemia).
- **Laboratory diagnosis:** Papanicolaou smear abnormalities, hysteroscopy, assessment of endometrial thickening, imaging techniques, biochemical and hematological tests. Endometrial tissue sampling, histologic examination (histologic type and tumor grade), immunohistochemistry and molecular testing (TP53 gene alteration is wild type in type 1 endometrioid carcinoma but mutant type in type 2 nonendometrioid carcinoma).

Endometrial carcinoma

Stage I
Confined to corpus (90%)

Stage II
Confined to corpus and cervix (50%)

Stage III
Extends outside uterus but confined to pelvis (30%)

Endometrial carcinoma: Histologic Variants

- **Type 1 endometrioid carcinoma:** It is linked to prolonged unopposed estrogen stimulation in women with prolonged reproductive period. Risk factors leading to hyperestrogenism include obesity, tamoxifen therapy in breast cancer, ovarian cortical hyperplasia, polycystic ovarian syndrome and hormone producing ovarian granulosa cell tumor. This histologic variant shows wild type alterations in TP53 gene. It is associated with good prognosis.
- **Type 2 nonendometrioid carcinoma:** It is not linked to estrogenic stimulation. It most often occurs in elderly women with atrophic endometrium. Histologic variants include papillary serous followed by serous, mucinous, clear cell and small cell. Serous carcinoma is characterized by early alterations mutant type in TP53 gene. Some type 2 nonendometrioid carcinoma behave more aggressively than type 1 endometrioid carcinoma. Clinical stage 1 disease often has extrauterine metastasis at the time of diagnosis.

Type 1 Endometrioid carcinoma: Biomarkers

- **Proteins:** Serum CA-125 and urinary gonadotropin levels.
- **Oncogenes:** K-RAS, HER2/neu, EGFR, PI3KCA and FGFR2.
- **Tumor suppressor genes:** PTEN, TP53 (wild type spontaneous mutation without first being affected by a mutagen), p21 and CDKN2A.
- **Mismatch repair genes:** hMLH1, hMSH2, hMSH6, PMS1 and PMS2.
- **Index of cell proliferation:** Ki-67.
- **Apoptosis related genes:** Proapoptotic BCL-2 associated X protein (BAX) and BCL-2 apoptosis suppressor gene.
- **Receptors status:** ER and PR.
- **Angiogenesis indices:** Microvascular density and VEGFR.
- **Invasion and metastasis:** E-cadherin, P-cadherin and β-catenin, and ploidy and aneuploidy of DNA.

Note: *Alteration in TP53 in type 1 endometrioid carcinoma is wild type spontaneous mutation without first being affected by a mutagen. On the contrary, alterations in TP53 gene in type 2 nonendometrioid carcinoma is mutant type.*

Mode of spread of endometrial carcinoma

Mode of spread	*Organs involved*
1. Local invasion	Fallopian tube, myometrium, cervix, vagina and urinary bladder
2. Tubal spread	Fallopian tube, ovaries and peritoneum
3. Lymphatic route	Pelvic lymph nodes (e.g. internal iliac and para-aortic lymph nodes), but some tumor cells may skip the pelvic lymph nodes; and involve peri-aortic lymph nodes.
4. Hematogenous route	Lungs, liver, bone and brain

Fig. 24.58: Salient features of endometrial carcinoma. It illustrates types of endometrial adenocarcinoma, mode of spread and staging (approximate five-year survival percentage is shown for various stages).

- The degree of cytologic atypia, the amount of nuclear stratification and the extent to which glands coalesce into foci of solid tumor growth increase as the grade increases. Type 1 endometrioid carcinoma can be graded: (a) grade 1 tumor grows in a glandular or papillary pattern with 5% of solid tumor growth, (b) grade 2 tumor contains 5–50% solid tumor growth, and (c) grade 3 tumor shows >50% solid

Table 24.16 Comparison of type 1 endometrioid carcinoma and type 2 nonendometrioid carcinoma

Parameters	Type 1 Endometrioid Carcinoma	Type 2 Nonendometrioid Carcinoma
Clinical settings		
Incidence	85%	15%
Unopposed action of estrogen	Present (elevated estrogen level)	Absent (low estrogen level)
Menopausal status	Premenopausal and perimenopausal obese, hypertensive and diabetic women (second to eighth decade with mean 60 years)	Postmenopausal (thin, normotensive and nondiabetic) women
Precursor lesion	Atypical endometrial hyperplasia	Atrophic endometrium
Histologic features		
Histological subtype	Endometrioid carcinoma resembles normal endometrium	Serous or clear cell carcinoma
Tumor grade	Low-grade tumor	High-grade tumor
Myometrial invasion	Variable, often minimal	Variable, often deep
Clinical course		
Behavior	Indolent behavior	Aggressive behavior
Prognosis	Good	Poor
Molecular genetic alterations		
ER/PR	Positive	Negative
TP53 gene mutation	Present (10%)	Present (90%)
Microsatellite instability (MSI) caused due to defects in DNA mismatch repair genes, mainly MLH1, MSH2, MSH6 and PMS2	Present (20–30%)	Present (11%)
PTEN mutation	Present (34–83%)	Present in subset of tumors
K-RAS mutation	Present	Absent
P13K mutation	Present	Present (subset of tumors)
FGF-2 mutation	Present	Absent
β-catenin mutation	Present	Absent
ARID1A (regulator of chromatin)	Present	Present
FBX W7 (regulator of Myc cyclin E)	Absent	Present
CHD4 (regulator of chromatin)	Absent	Present
Immunohistochemistry		
Markers	**Expression**	**Expression**
ER/PR (estrogen/progesterone receptors)	Positive	Positive (50%)
Ki-67 proliferative marker	Low expression	High expression
p53	Negative/positive expression (patchy/rare weakly cells)	Positive expression (strong diffuse staining)
p16	Negative/positive (staining patchy)	Positive (strong diffuse staining)
HNF-1β	Negative expression	Negative expression
WT1	Negative expression	Negative/positive expression

Both type 1 and type 2 endometrial carcinomas spread by local invasion, lymphatic route and hematogenous route. In addition, spreads by intraperitoneal spread occurs in type 2 endometrial carcinoma.

tumor growth. Areas of squamous or spindle cell differentiation are not counted in the determination of percentage of solid tumor growth.

- Well differentiated endometrioid carcinoma (grade 1) is composed of back-to-back glands in glandular or papillary patterns without intervening fibrovascular

stroma. The glands and papillae (with or without psammoma bodies) are lined by columnar cells with amphophilic to basophilic cytoplasm, and basally located round to oval nuclei with mild pleomorphism, which may contain nucleoli. Stromal foam cells are generally identified in well-differentiated endometrioid carcinoma, especially associated with endometrial hyperplasia. Although the endometrial glands within focus of complex endometrial hyperplasia are irregular and complex in configuration, intervening stroma is present between the glands. This histologic feature is important in distinguishing complex endometrial hyperplasia from well-differentiated endometrioid carcinoma.

- High-grade endometrioid carcinoma (grade 3) with significant solid component displays an increased amount of nuclear cytologic atypia, as demonstrated by pleomorphic, irregular chromatin clumping, and prominent nuclei. The degree of tumor necrosis is usually mild to moderate. Stroma adjacent to the invasive adenocarcinoma exhibits desmoplastic reaction, often with an accompanying lymphocytic infiltrate.
- Histologic variants of type 1 endometrioid carcinoma include villonodular (papillary), secretory, ciliated cell and adenocarcinoma with squamous differentiation.
  - **Villonodular carcinoma:** It is characterized by a papillary architecture with delicate fibrovascular stroma lined by cuboidal to columnar cells with minimal cellular stratification and mild nuclear pleomorphism with indistinct nucleoli. It is important to distinguish this well-differentiated papillary variant of endometrial carcinoma lacking cellular budding and high-grade cytologic nuclear atypia from serous carcinoma, which is often papillary but displays grade 3 nuclear cytologic atypia with vesicular nuclei, prominent nucleoli and necrosis.
  - **Secretory carcinoma:** It is composed of well-differentiated endometrial glands, which resemble secretory phase of endometrium with prominent vacuoles in subnuclear or supranuclear region of columnar cells and intraluminal secretions.
  - **Ciliated cell carcinoma:** It is composed of neoplastic glands lined by columnar cells showing mild to moderate nuclear cytologic atypia.
  - **Endometrioid carcinoma with squamoid differentiation:** It is composed of polygonal cells with abundant eosinophilic cytoplasm forming a nodular structure between neoplastic endometrial glands.
  - **Mucinous carcinoma:** It is generally well-differentiated low-grade tumor and characterized by columnar cells with basally located nuclei and mucin rich cytoplasm.

Etiopathogenesis

- **Hormonal imbalance:** Type 1 endometrioid carcinoma occurs due to prolonged unopposed estrogenic stimulation in women with prolonged reproductive period (early menarche and late menopause), infertile women, or estrogen hormonal replacement therapy in the setting of endometrial hyperplasia in obese and diabetic premenopausal or perimenopausal women in 85% of cases. Risk of type 1 endometrioid carcinoma is increased in women with estrogen-producing tumors (e.g. granulosa cell tumors of ovary) and familial endometrial carcinoma. Light microscopy shows well differentiated endometrial adenocarcinoma. It is associated with relatively good prognosis.
- **Constitutional factors:** Obesity, like estrogen replacement therapy is a well-defined risk factor for type 1 endometrioid carcinoma. In obese women, adipose tissue converts androgens into estrogens, fueling the proliferation of endometrial tissue. There is lower concentrations of sex hormone-binding globulins in obese women. Diabetes mellitus and hypertension have been reportedly associated with an increased risk of type 1 endometrioid carcinoma.
- **Dietary factors:** Endometrial carcinoma risk is correlated with sedentary lifestyle and total caloric intake, total protein intake, and frequency of consumption of oils, fats, milk and eggs. These factors are major determinants of obesity. A recent study suggests that physical activity decreases the risk of endometrial carcinoma independent of body weight.

Molecular Genetic Alterations: Type 1 Endometrioid Carcinoma

Atypical endometrial hyperplasia/endometrial intraepithelial neoplasia (AEH/EIN) contains many genetic alterations in type 1 endometrioid carcinoma, which include PTEN, TP53, microsatellite instability, K-RAS, CTNNB1 and other mutations.

- **PTEN gene mutation:** Recent studies have shown that most frequent altered gene implicated in the development of endometrioid carcinoma is the PTEN tumor suppressor gene located on chromosome 10q23.3 in 30–50% of cases. PTEN protein negatively regulates the PI3K-AKT signaling. PTEN encodes a dual-specificity phosphatase. The primary target is the lipid molecule phosphatidylinositol-3,4,5-triphosphate (PIP3) that regulates the cell cycle and survival through signal transduction pathway.
- **TP53 gene mutation:** TP53 gene provides instructions for making a DNA-binding phosphoprotein called tumor suppressor protein p53. This protein acts as a tumor suppressor, which means that it regulates cell division by keeping cells from growing and dividing too fast or in an uncontrolled way. Mutation of TP53 is demonstrated in 10% of type 1 endometrioid carcinomas mostly in grade 3 tumors and

occasionally in grade 2 tumors and absent in grade 1 tumor. This finding suggests that TP53 gene is involved in progression of tumor rather than initiation of type 1 endometrioid carcinoma.

- **Microsatellite instability:** Another molecular genetic alteration in type 1 endometrioid carcinoma is the molecular phenotype called microsatellite instability.
  - Microsatellite instability refers to alterations in the length of short, repetitive DNA sequences called microsatellites, in tumors when compared to DNA prepared from the same patient's normal tissue.
  - Microsatellite instability has been demonstrated in hereditary nonpolyposis colorectal cancer (HNPCC), or Lynch syndrome. Lynch syndrome is characterized by development of adenocarcinoma of the endometrium, colon, and breast. Endometrial carcinoma may develop in these patients before gastrointestinal malignancies.
  - Strong family history in women >50 years of age should prompt investigation for mismatch repair defects.
  - Microsatellite instability is also demonstrated in 20% of sporadic endometrial carcinomas and complex atypical hyperplasia.
  - Unlike the familial cases, which occur due to germline mutations in one of the DNA mismatch repair genes (MSH2, MLH1, MSH6 or PMS2), microsatellite instability in the sporadic cases is most commonly due to inactivation of MLH1 gene by promoter hypermethylation.
- **K-RAS proto-oncogene mutation:** Normally, K-RAS proto-oncogene encodes a guanine nucleotide-binding protein, that plays a role in the regulation of cell growth and differentiation by transducing signals from activated transmembrane receptors. K-RAS proto-oncogene mutation has been demonstrated in all grades of type 1 endometrioid carcinoma and complex atypical complex hyperplasia of endometrium.
- **FGFR2 (fibroblast growth factor receptor 2) mutation:** Recently, mutation in FGFR2 has been demonstrated in type 1 endometrioid carcinoma.
- **ARIDIA (regulator of chromatin) gene mutation:** ARIDIA gene encodes ARIDIA, a member of the SW1/SNF chromatin remodeling complex. Mutation of ARIDIA gene induces changes in expression of multiple gene (CDKNIA, SMAD3, and PIK3IPI) via chromatin remodeling dysfunction in association with p13K/AKT pathway contributes in the pathogenesis of type 2 serous endometrial carcinoma as well as type 1 endometrioid carcinoma.
- **Amplification of other oncogenes:** Amplification of other genes such as EGFR, HER2/neu, c-Myc, BCL-2 and CFMS have been demonstrated in type 1 endometrioid carcinoma. Further studies on these genes are required to determine their role in the pathogenesis of endometrial carcinoma.

Clinical Features

Initially, patient with type 1 endometrioid carcinoma may be asymptomatic. Later, patient presents with abnormal dysfunctional or postmenopausal uterine bleeding per vagina, pelvic pain, symptoms related to compression effects of tumor on adjacent structures, abnormal bloating, dyspareunia, dysuria, anorexia, malaise and fatigue. The patient should be evaluated by direct endometrial sampling and cytologic screening.

Surgical Pathology: Type 1 Endometrioid Carcinoma

Gross Morphology

- Gross morphology of type 1 endometrioid carcinoma is similar to the various other types of endometrial carcinoma with the exception of serous endometrial carcinoma or malignant mesodermal mixed tumors.
- Uterine endometrial surface is shaggy in type 1 endometrioid carcinoma. Tumor is uniformly exophytic polypoid even when deeply invasive. Tumor may be focal or diffuse. At times, tumor may be composed of separate polypoid masses. Exophytic polypoid growth protrudes within the uterine cavity (Fig. 24.59).
- Necrosis is present in poorly differentiated or ulcerated tumor but absent in well differentiated tumor. Invasive type 1 endometrioid carcinoma extending through the myometrium into the serosa may result in uterus enlargement. Myometrial invasion usually appears as well-demarcated, gray-white, firm in consistency, with linear extension of the tumor beneath an exophytic mass.
- Extension of the tumor in lower uterine segment is common. Involvement of the uterine cervix occurs in 20% of cases. Type 1 endometrioid carcinoma may manifest different form of myometrial invasion. Tumor can invade myometrium diffusely as clusters, masses, cords or individual cells or deeply invasive involving serosa.

Light Microscopy

- Type 1 endometrioid carcinoma is determined by the histologic appearance of the tumor. It is based on the architectural pattern, FIGO nuclear grade or both. The architectural grade is determined by the extent of which the tumor is composed of solid masses of neoplastic cells as compared with well-formed glandular structures.
- Nuclear grade is determined by the variation in nuclear size and shape, chromatin distribution and the size of the nucleoli. Architectural and nuclear grading of type 1 endometrioid carcinoma is given in Table 24.17.
- Mitotic activity is an independent histologic variable. It is usually increased with increasing nuclear grade.
  - **Well-differentiated endometrioid carcinoma (FIGO grade 1):** Tumor is composed of well formed, closely packed glandular structures with cytologic atypia (nuclei oval, mildly enlarged with evenly dispersed chromatin) that bear resemblance to endometrial glands, hence known as endometrioid adenocarcinoma. Not more than 5% of the tumor is composed of solid masses (Fig. 24.60).
  - **Moderately-differentiated endometrioid carcinoma (FIGO grade 2):** Tumor is composed of nuclear features in between grade 1 and grade 3 with 6–50% of the tumor composed of solid masses.

- **Poorly-differentiated endometrioid carcinoma (FIGO grade 3):** Tumor is composed cells with pleomorphic and enlarged nuclei with irregular coarse chromatin and prominent eosinophilic nucleoli. More than 50% of the tumor is composed of solid masses.

Immunohistochemistry Technique

- Neoplastic cells of type 1 endometrioid carcinoma are immunoreactive to EMA, CA 125, Ber EP4, B72.3, CK7, ER/PR, BAX8, PTEN and p53.
- CA 125 is a cell surface glycoprotein originally identified in mucinous epithelial ovarian tumors. It is also expressed in adenocarcinoma of endometrium; cancers of gastrointestinal tract, thyroid and breast.

Markers	Expression
EMA	Positive
CA 125	Positive
Ber EP4	Positive
B72.3	Positive
CK7	Positive
ER/PR	Positive (>90%)
PAX8	Positive
PTEN	Positive
p53	Positive

Mode of Spread

Type 1 endometrioid carcinoma spreads by direct extension to contiguous organs and lymphovascular invasion.

- Lymphatic metastasis is more common than via hematogenous route.
- But the lung metastasis without mediastinal lymph nodes involvement suggests that the hematogenous spread may occur early in the course of the disease.
- Type 1 endometrioid carcinoma tends to spread to the pelvic lymph nodes before involvement of the para-aortic lymph nodes.

Treatment

Type 1 endometrioid carcinoma is treated by hysterectomy and bilateral salpingo-oophorectomy; radiotherapy and chemotherapy.

Type 2 Nonendometrioid Carcinoma

Aggressive type 2 nonendometrioid carcinoma accounts for 15% of overall cases, which affects multiparous and nonobese, thin and slim, normotensive women with

Table 24.17 Architectural and nuclear grading of type 1 endometrioid carcinoma

Grade of Tumor	Solid Component % in Type 1 Endometroid Carcinoma
Architectural grading of type 1 endometrioid carcinoma	
Grade 1	Not more than 5% of the tumor is composed of solid masses
Grade 2	6–50% of the tumor is composed of solid masses
Grade 3	More than 50% of the tumor is composed of solid masses
Nuclear grading of type 1 endometrioid carcinoma	
Grade 1	Nuclei are oval, mildly enlarged with evenly dispersed chromatin
Grade 2	Nuclei have features in between grade 1 and grade 3
Grade 3	Nuclei are pleomorphic and enlarged with irregular coarse chromatin and prominent eosinophilic nucleoli

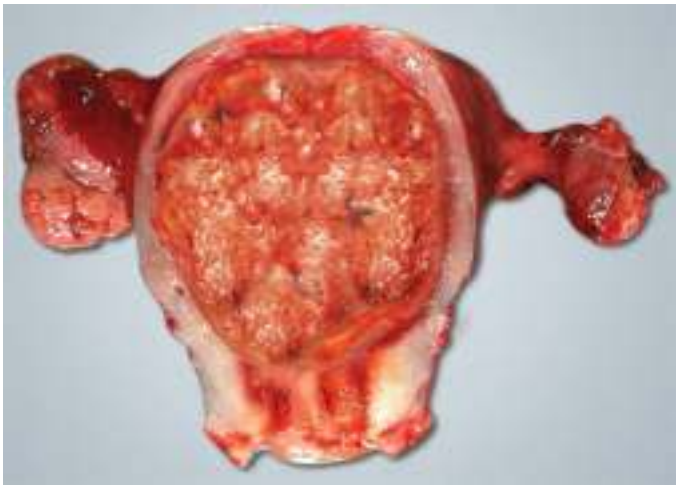


Fig. 24.59: Type 1 endometrioid carcinoma. The uterus is not enlarged, but there is an irregular mass in the upper fundus that proved to be endometrial adenocarcinoma on biopsy. Such carcinomas are more likely to occur in postmenopausal women. Thus, any postmenopausal bleeding should make you suspect that this lesion may be present.

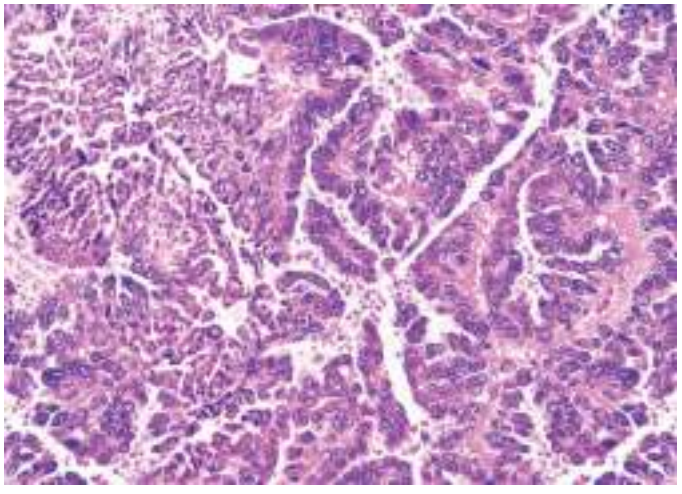

Fig. 24.60: Type 1 endometrioid carcinoma. It is invading into the smooth muscle bundles of the myometrial wall of the uterus. This neoplasm has a higher stage than a neoplasm that is just confined to the endometrium or is superficially invasive (400X).

precursor atrophic endometrium and associated with poor prognosis of five years survival. Tumor occurs disproportionately African-American women. TP53 gene mutation has been identified in the patients. Histologic variants of aggressive type 2 nonendometrioid carcinoma include serous, clear cell, squamous and undifferentiated. There is no distinctive gross appearance to differentiate individual histologic subtypes of endometrial carcinoma.

- **Serous endometrial carcinoma:** It is composed of fibrovascular papillae lined by vesicular nuclei with prominent eosinophilic nucleoli. Small clusters of cells that have separated from the papillae with fibrovascular core are referred as cellular budding. Serous endometrial carcinoma can also demonstrate psammoma bodies in 33% of cases, which may also be found in the villonodular variant of endometrioid carcinoma.
- **Clear cell endometrial carcinoma:** It occurs almost exclusively in postmenopausal women associated with poor prognosis. Although there are no macroscopic features, there are four histologic growth patterns in decreasing frequency: papillary, tubulocystic, glandular and solid. Most tumors display two or more patterns, as well as a mixture of cell types. Papillary pattern of clear cell endometrial carcinoma demonstrates complex papillae with fibrovascular cores lined by one to multiple layers of clear cells. Hobnail cells protrude into a cystic space. Clear cell endometrial carcinoma may exhibit a solid pattern consisting of sheets of clear cells separated focally by thin fibrous bands.
- **Squamous cell endometrial carcinoma:** It is composed of cells with eosinophilic cytoplasm and marked nuclear atypia, intercellular bridges and keratin pearls.
- **Undifferentiated endometrial carcinoma:** It is grade 3 tumor, which lacks glandular or squamous differentiation.

Molecular Genetic Alterations: Type 2 Nonendometrioid Carcinoma

- Compared to type 1 endometrioid carcinoma, relatively little is known about type 2 nonendometrioid carcinoma of endometrium at the molecular level, because of its relative infrequency.
- TP53 gene is a tumor suppressor gene, which encodes p53 protein, that regulates cell division by keeping cells from growing and proliferating too fast or in an uncontrolled way. Mutation in TP53 gene is demonstrated in type 2 nonendometrioid carcinoma in 90% of cases. It has been observed that intense, diffuse immunohistochemical staining for p53 correlates well with TP53 gene mutation. These findings indicate that in type 2 nonendometrioid carcinoma. TP53 gene mutations occur relatively early and its central role in the pathogenesis in this tumor type. It is associated with aggressive behavior. It is worth mentioning that mutation in p53 gene is also demonstrated in grade 3 of type 1 endometrioid carcinoma.
- Recent studies have suggested that mutations in P13K/PTEN/AKT pathway participate in pathogenesis of a subset of type 2 nonendometrioid carcinoma.
- ARIDIA (regulator of chromatin) gene encodes ARIDIA, a member of the SW1/SNF chromatin remodeling complex. Mutation of AIDIA gene induces changes in expression of multiple gene (CDKNIA, SMAD3, and PIK3IPI) via chromatin remodeling dysfunction in association with p13K/AKT pathway contributes in the pathogenesis of type 2 nonendometrioid carcinoma as well as type 1 endometrioid carcinoma.

Clinical Features

Patient presents with abnormal vaginal bleeding. It resembles ovarian serous carcinoma. It spreads throughout abdomen in a similar manner. It metastasizes to urinary bladder simulating a urinary bladder neoplasm.

Surgical Pathology: Type 2 Nonendometrioid Carcinoma

Gross Morphology

Uterus is small and atrophic for high-grade tumor serous carcinoma of endometrium. Generally, the tumor is exophytic and has a papillary appearance. The depth of the tumor invasion is difficult to assess. Tumor may be benign-appearing polyp in hysterectomy specimen. Endocervical involvement can be demonstrated in 25% of cases. Drop metastasis to vagina is common. Transtubal spread is common, that may create ovarian implants and omental tumor nodules.

Light Microscopy

- The cytologic features of type 2 nonendometrioid carcinoma of endometrium are quite varied. Tumor exhibits well-formed thick or thin papillary pattern predominantly; however, glandular and solid pattern may occur.
- Type 2 nonendometrioid carcinoma originally was considered as having thick, short papillae, but subsequent studies revealed that thin papillae may be present in 50% of cases. Tumor cells covering the papillae and lining the glands form small papillary tufts, which may be detached and float freely in the spaces between the papillae and in glandular lumens.
- Tumor is composed of polyhedral cells with clear or eosinophilic cytoplasm, but hobnail cells are among these polyhedral cells are frequently observed.
- In histopathology, hobnail cell has a bulbous nucleus and nuclear projections into the cytoplasm.
- Marked nuclear atypia is always present and required for a tumor to qualify for type 2 nonendometrioid carcinoma. Thus, type 2 nonendometrioid carcinoma of endometrium is characterized by the discordance between its architecture, which appears well-differentiated (papillary or glandular pattern) and its nuclear morphology, which is high-grade 3

nuclei. Many tumor cells are highly pleomorphic with marked nuclear atypia, hyperchromatic nuclei and macronucleoli (Fig. 24.61).
- Multinucleated giant cells, giant nuclei and bizarre forms are demonstrated in the 50% of cases.
- Lobulated nuclei with smudged chromatin, numerous abnormal mitoses and psammoma bodies are encountered. Nests of tumor cells within vascular spaces are usually demonstrated.
- Tumor is considered high-grade and is not graded using FIGO. Tumor has prominent myometrial invasion. Abrupt transition from normal to type 2 nonendometrioid carcinoma is common.
- The adjacent endometrium in type 2 nonendometrioid carcinoma is atrophic in almost all cases.

Immunohistochemistry Technique

Neoplastic cells of type 2 nonendometrioid carcinoma are immunoreactive with p53, CK7, CA 125, Ki-67, vimentin, PAX8, HER2/neu, EGFR, ER/PR, CEA and CK20.

Markers	Expression
p53	Positive
CK7	Positive
CA 125	Positive
Ki-67	Positive
Vimentin	Positive
PAX8	Positive
HER2/neu	Positive
EGFR	Positive
ER/PR	Positive/ Negative
CEA	Negative
CK20	Negative

Mode of Spread

Type 2 nonendometrioid carcinoma has a propensity for myometrial and lymphatic invasion. The hysterectomy specimens often demonstrate neoplastic cells in lymphatics within the myometrium, cervix, fallopian tube, broad ligament and ovarian hilus in the absence of gross tumor in these sites. Serous carcinoma involves peritoneal surfaces in the abdomen and pelvis in the early course of disease. In addition to intraperitoneal spread, serous carcinoma can metastasize to the liver, brain and skin.

Prognosis

- Current approach of management of type 2 nonendometrioid carcinoma is hysterectomy and bilateral salpingo-oophorectomy along with omentectomy.
- Patients receiving chemotherapy and radiotherapy are associated with favorable prognosis.
- Poor prognostic factors include age more than 60 years, lymphovascular invasion, myometrial invasion, stage III and stage IV.
- In summary, it is essential for patients with serous carcinoma to be carefully staged as there may be presence of extrauterine disease even if there is no or minimal invasion of the myometrium.
- Prognosis is excellent in the absence of extrauterine disease. International Federation of Gynecology and Obstetrics Staging of Endometrial Carcinoma (2019) is given in Table 24.18.

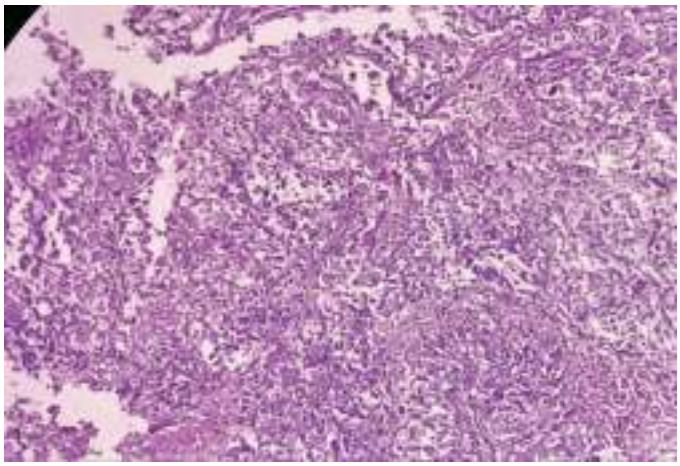

Fig. 24.61: Serous variant of type 2 nonendometrioid carcinoma. Tumor is composed of polyhedral cells with clear or eosinophilic cytoplasm, but hobnail cells are among these polyhedral cells are frequently observed. In histopathology, hobnail cell has a bulbous nucleus and nuclear projections into the cytoplasm. Marked nuclear atypia is always present and required for a tumor to qualify for serous carcinoma. Thus, serous variant of type 2 nonendometrioid carcinoma is characterized by the discordance between its architecture, which appears well-differentiated (papillary or glandular pattern) and its nuclear morphology, which is high-grade 3 nuclei. Many tumor cells are highly pleomorphic with marked nuclear atypia, hyperchromatic nuclei and macronucleoli (400X).

Clinical Pearls: Protocols for Reporting Endometrial Carcinoma on Resection Specimens

- Specimen (endometrial biopsy or endometrial curettings or tumor resection with no residual tumor or hysterectomy-specimen)
- Lymph node sampling
- Specimen integrity
- Tumor site and size
- Histology type: Type 1 endometrioid carcinoma, type 2 nonendometrioid carcinoma
- Histologic FIGO grading system on percentage of solid component in type 1 endometrioid carcinoma (grade 1: ≤5% tumor growth, grade 2:5–50% tumor growth, grade 3: >50% tumor growth)
- Myometrial invasion
- Serosal involvement
- Adnexal involvement
- Involvement of the cervix
- Extent of involvement of other organs
- Lymphovascular invasion
- Optional protocols include peritoneal fluid, additional pathologic findings, ancillary studies (ER/PR, HER2/neu, ploidy) and clinical history.

Table 24.18 International Federation of Gynecology and Obstetrics Staging of Endometrial Carcinoma (2019)

Stage	Endometrial Carcinoma
Stage I	Confined to the uterine corpus
Stage IA	Limited to endometrium or involves less than half of the myometrium
Stage IB	Invasion of half or more of the myometrium
Stage II	Invasion of the cervical stroma but no extension outside the uterus
Stage III	Local and/or regional spread of the tumor
Stage IIIA	Invasion of serosa, adnexa, or both (direct extension or metastasis)
Stage IIIB	Metastases or direct spread to the vagina and/or spread to the parametria
Stage IIIC	Metastases to pelvic or para-aortic lymph nodes or to both
Stage IIIC1	Metastases to pelvic lymph nodes
Stage IIIC2	Metastases to para-aortic lymph nodes, with or without metastases to pelvic lymph nodes
Stage IV	Involvement of the bladder and/or intestinal mucosa and/or distant metastases
Stage IVA	Invasion of the bladder, intestinal mucosa, or both
Stage IVB	Distant metastases, including metastases to the inguinal lymph nodes, lungs, liver, or bone and intraperitoneal disease

1. Endometrial cancer is usually surgically staged. Ideally, the thickness of the myometrium should be measured along with depth of tumor invasion.

2. For all but stage IVB, grade (G) indicates percentage of tumor with a nonsquamous or nonmorular solid growth pattern:

- *G1: ≤ 5%*
- *G2: 6–50%*
- *G3: > 50%*

3. Nuclear atypia excessive for the grade raises the grade of a G1 or G2 tumor by 1. In serous adenocarcinomas, clear cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence. Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

4. Adapted from International Federation of Gynecology and Obstetrics (FIGO) 2019.

ENDOMETRIAL STROMAL TUMORS

Endometrial stromal tumor is rare low- to high-grade tumors. Low-grade endometrial stromal tumor invades extensively through the lymphatics of the myometrium. The tumor cells are bland and showing few mitoses. High-grade endometrial stromal sarcoma shows a vascular supporting framework with spindle-shaped neoplastic cells concentrically arranged around blood vessels. These are much rarer than leiomyosarcomas. It difficult to separate these tumors from uterine leiomyosarcoma. Classification of endometrial stromal tumors is given in Table 24.19.

Table 24.19 Classification of endometrial stromal tumors

Features	Endometrial Stromal Nodule	Endometrial Stromal Sarcoma	Undifferentiated Endometrial Sarcoma (Monomorphic)	Undifferentiated Endometrial Sarcoma (Polymorphic)
Category	Benign tumor	Malignant tumor low-grade	Malignant tumor high-grade	Malignant tumor high-grade
Tumor margin	Well circumscribed tumor	Invasive tumor	Invasive tumor	Invasive tumor
Nuclear atypia	Minimal	Minimal	Moderate to marked	Marked
Nuclear pleomorphism	Minimal	Minimal	Minimal to moderate	Marked
Mitotic activity	<3 mitoses/10 HPF	<3 mitoses/10 HPF	>10 mitoses/10 HPF	>10 mitoses/10 HPF

Pathology Pearls: Endometrial Stromal Tumors	
Immunohistochemistry Technique	
Endometrial stromal tumors of the uterus (endometrial stromal nodule and endometrial stromal sarcoma) are mentioned below.	
Markers	**Expression**
▪ CD10	▪ Positive
▪ ER/PR	▪ Positive
▪ JAZFI-JJAZ1 gene fusion	▪ Positive (50%)
▪ Smooth muscle cell actin (SMA) also known as α-actin	▪ Negative/positive
▪ Desmin	▪ Negative/positive
▪ h-caldesmon (encoded by CALD-1 gene) contractile apparatus associated protein	▪ Negative

MIXED MÜLLERIAN TUMOR

Mixed Müllerian tumor (carcinosarcoma) is a highly malignant mixed tumor comprising of malignant epithelial and stromal components. It affects post-menopausal women. Mixed Müllerian tumor is derived from multipotential stromal cells. Patient presents with bleeding per vagina.

Clinical Features

Patient presents with bleeding per vagina. On per vaginal examination, tumor is soft, bulky and fleshy protruding through the cervix into the vagina.

Surgical Pathology: Mixed Müllerian Tumor
Gross Morphology
Mixed Müllerian tumor is soft and fleshy. Cut surface shows areas of hemorrhage and necrosis.
Light Microscopy
Mixed Müllerian tumor is composed of malignant glandular and stromal components. Sarcomatous element can be homogenous nonspecific malignant stroma or heterologous malignant elements of a different tissues element particularly cartilage.

Prognosis

Tumor usually metastasizes as adenocarcinoma associated with highly aggressive course. Prognosis depends on the stage of the disease. Five-year disease-free is demonstrated in 55% of cases. In stage IV, patient develops extrapelvic disease associated with fatal outcome.

DISORDERS OF UTERINE MYOMETRIUM

NEOPLASTIC DISORDERS OF UTERINE MYOMETRIUM

Smooth muscle cell tumors of the uterus are leiomyomas (most common) and leiomyosarcomas. Recent 2020 WHO classification of mesenchymal tumors specific to uterus is given in Table 24.20.

LEIOMYOMA (FIBROID/FIBROMYOMA/MYOMA)

Leiomyomas are most common benign tumors of smooth muscle origin, also known as fibroids, which usually occur in the uterine corpus (intramural, submucous and subserous regions). These may also arise in cervix or uterine ligaments. Leiomyomas most often occur during reproductive period and most tumors

Table 24.20 Recent 2020 WHO classification of mesenchymal tumors specific to uterus

Mesenchymal Tumors Specific to Uterus

regress after the menopause. Leiomyomas can cause painful menstruation and contribute to infertility. The tumors are estrogen-sensitive. Estrogen promotes the growth of leiomyomas, although it does not initiate them. Both estrogen and progestin receptors are present in leiomyomas. Elevated estrogen levels may cause leiomyoma's enlargement during first trimester of pregnancy.

Clinical Features

In most instances, leiomyomas are asymptomatic and discovered by gynecologists during routine pelvic examination. About 25% of patients are symptomatic. Symptoms depend on size and location of leiomyoma. Menorrhagia and pelvic pain are observed in 33% of patients. Intramural large leiomyoma may compress the urinary bladder and rectum; resulting in feeling of heaviness, pain, incontinence of urine and urgency of defecation. Subserosal leiomyomas undergo torsion due to twisting of pedicle, and detachment resulting in pain and signs of peritonitis. Submucosal leiomyoma is pedunculated tumor, which increases the endometrial surface area and the patient presents with excessive uterine bleeding per vagina.

Surgical Pathology: Leiomyoma

Gross Morphology

- Leiomyomas are discrete, firm, pale gray, sharply circumscribed and varying in size without encapsulation. Cut section reveals whorled pattern reflecting the fact that these are composed of smooth muscle bundles.
- Most leiomyomas are present within wall (intramural), but some are pedunculated and present in submucosal and subserosal region (Fig. 24.62).
- Secondary changes in large leiomyomas are yellow-brown to red softening (cystic degeneration), atrophy, hyaline degeneration, cystic degeneration, fatty change, dystrophic calcification, red degeneration, and chondroid/osteoid metaplasia (Fig. 24.63).

Light Microscopy

Histologic variants of uterine leiomyoma are given in Table 24.21. Leiomyoma composed of whorled bundles of smooth muscle cells that resemble the uninvolved myometrium. Individual smooth muscle cells are uniform in size and shape containing oval nucleus and long, slender bipolar cytoplasmic processes. Mitotic figures are sparse. Tumor cells are arranged in whorled fashion (Fig. 24.64).

- **Cellular leiomyoma:** It is also known as apoleptic leiomyoma shows areas of hemorrhage. It may rupture resulting in hemoperitoneum. Cellular leiomyoma occurs in pregnant women or young females on oral contraceptives.
- **Symplastic (bizarre) leiomyoma:** It is also known as bizarre leiomyoma. It is composed of scattered pleomorphic cells with irregular hyperchromatic nuclei, tumor giant cells with a low mitotic index.
- **Lipoleiomyoma:** It refers to classic leiomyoma which contains islands of mature adipocytes.
- **Epithelioid leiomyoma:** It is composed of predominantly epithelioid cells with clear to eosinophilic cytoplasm and nuclei with fine chromatin.
- **Benign metastasizing leiomyoma:** It is invading blood vessels and metastasizing to lungs.
- **Disseminated peritoneal leiomyomatosis:** It leads to formation of small nodules on the peritoneum. The tumor is considered benign despite its unusual behavior.

Immunohistochemistry Technique

Neoplastic cells of leiomyoma are immunoreactive SMA, desmin, MSA, h-caldesmon and SMMHC, calponin, ER/PR.

Markers	Expression
▪ Smooth muscle cell actin (SMA)	▪ Positive
▪ Desmin (intermediate filament)	▪ Positive
▪ Muscle-specific actin (MSA)	▪ Positive
▪ h-caldesmon (encoded by CALD-1 gene) contractile apparatus associated protein	▪ Positive

▪ Smooth muscle myosin heavy chain (SMMHC) contractile apparatus associated protein	▪ Positive
▪ Calponin (contractile apparatus associated protein)	▪ Positive
▪ Estrogen/progesterone (ER/PR) receptors	▪ Positive

Molecular Genetic Alterations

Leiomyomas show clonal abnormalities of 12q/7q and 6p resulting in rearrangement of genes.

Fig. 24.62: Leiomyomas of uterus. Leiomyoma is a benign mesenchymal tumor derived from smooth muscle and located in the uterus: intramural, submucosal and subserosal. These are most often multiple, well circumscribed and nonencapsulated. Cut surface of leiomyomas in uterus reveals white or tan-white whorled, firm and bulging above surface.

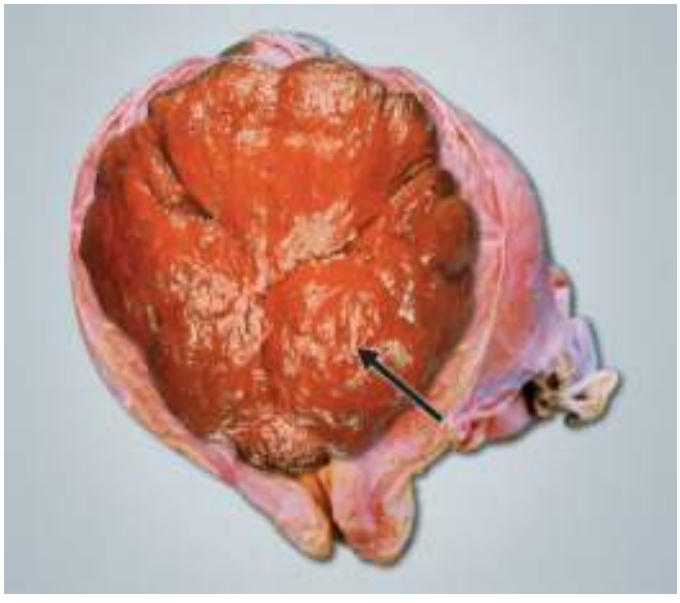

Fig. 24.63: Red degeneration in leiomyoma. Tumor shows red degeneration giving red meat appearance (arrow).

Diagnosis

Leiomyoma can be established by resection of whole uterus (hysterectomy), or resection of the leiomyoma if accessible or curetting of submucosal leiomyoma or resection of subserosal leiomyoma.

Prognostic Factors

Uterine leiomyoma may recur especially after myomectomy. Fumarate hydratase deficient leiomyoma recurs more frequently.

SMOOTH MUSCLE TUMOR OF UNCERTAIN MALIGNANT POTENTIAL (STUMP)

According to World Health Organization (WHO) classification of smooth muscle tumors, uterine smooth muscle tumor of uncertain malignant potential (STUMP) is a rare tumor and regarded as sub-classification in

Table 24.21 Histologic variants of uterine leiomyoma

Epithelioid leiomyoma
Myxoid leiomyoma
Dissecting (cotyledon-like) leiomyoma
Diffuse leiomyomatosis leiomyoma
Intravenous leiomyoma
Metastasizing leiomyoma

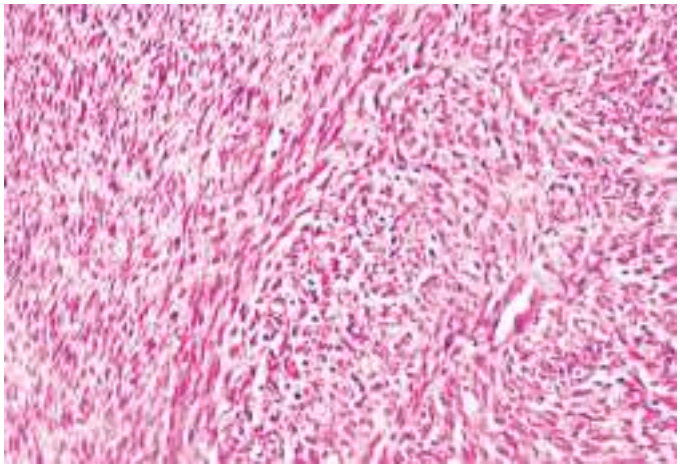

Fig. 24.64: Leiomyoma. The microscopic appearance of a benign leiomyoma. Normal myometrium is at the left, and the neoplasm is well-differentiated so that the leiomyoma at the right hardly appears different. Bundles of smooth muscle are interlacing in the tumor mass (400X).

Table 24.22 Diagnostic criteria for smooth muscle tumor of uncertain malignant potential (STUMP)

Tumor Cell Necrosis	Cellular Atypia (++/+++)	Mitosis	Recurrence Rate
Absent	Focal/diffuse	<10/10 HPF	13%
Absent	Diffuse	<10/10 HPF	11%
Present	Absent	<10/10 HPF	27%
Absent	Absent	>10/10 HPF	Zero

uterine smooth muscle tumors between benign and malignant criteria. Diagnostic criteria of smooth muscle tumor of uncertain malignant potential (STUMP) are given in Table 24.22.

- STUMPs are morphologically heterogenous and diagnostically requiring generous sampling of myometrial growth for histologic examination.
- STUMPs usually occur in women of reproductive age or postmenopausal women in the myometrium.
- Recurrence rate is 7–30% after surgery. Epithelioid and myxoid STUMPs may be more likely to recur after surgical resection. Median survival of patients is 5.5 years for recurrent STUMPs.
- Surveillance of STUMPs is warranted every six months for five years and then yearly.

LEIOMYOSARCOMA

Leiomyosarcoma is a highly malignant tumor of smooth muscle cell origin *de novo*, and unrelated to pre-existing leiomyoma. Single best criterion for predicting the behavior of smooth muscle tumors of uterus is mitotic activity.

Surgical Pathology: Uterine Leiomyosarcoma

Gross Morphology

- One should suspect uterine conventional leiomyosarcoma, if an apparent smooth muscle tumor is soft with irregular borders and areas of necrosis on gross examination.
- Tumor is bulky and fleshy invading into myometrial wall or polypoid tumor projecting into lumen.
- On cut section, tumor is not bulging above the surface. Tumor is invasive with infiltrative growth. Areas of hemorrhage necrosis are present (Fig. 24.65).

Light Microscopy

- Conventional leiomyosarcoma is composed of spindled/fascicular cells resembling smooth muscle with moderate to marked pleomorphism.
- Diagnostic criteria of leiomyosarcoma include following features on light microscopy: (a) 10 or more mitoses per 10 high power fields (HPF); (b) 5 or more mitoses per 10 HPF, with nuclear atypia and necrosis; and (c) myxoid and epithelioid smooth muscle tumors with 5 or more mitoses per 10 HPF (Fig. 24.66A and B).
- Some tumors that meet some, but not all, of the diagnostic criteria for leiomyosarcoma are considered 'STUMP' (smooth muscle tumors of uncertain malignant potential).
- Comparison of leiomyoma and leiomyosarcoma is given in Table 24.23. Histologic criteria for the diagnosis of uterine smooth muscle tumors are given in Table 24.24. Histologic features for the differential diagnosis between ischemic necrosis and tumor cell necrosis in leiomyosarcoma are given in Table 24.25.

Immunohistochemistry Technique

Neoplastic cells of leiomyosarcoma are immunoreactive with SMA, desmin, MSA, h-caldesmon, SMMHC, calponin and ER/PR.

Markers	Expression
Smooth muscle actin (SMA)	Positive
Desmin (intermediate filament)	Positive
Muscle-specific actin (MSA)	Positive
h-caldesmon (encoded by CALD-1 gene) contractile apparatus associated protein	Positive
Smooth muscle myosin heavy chain (SMMHC) contractile apparatus associated protein	Positive
Calponin (contractile apparatus associated protein)	Positive
Estrogen/progesterone (ER/PR) receptors	Positive

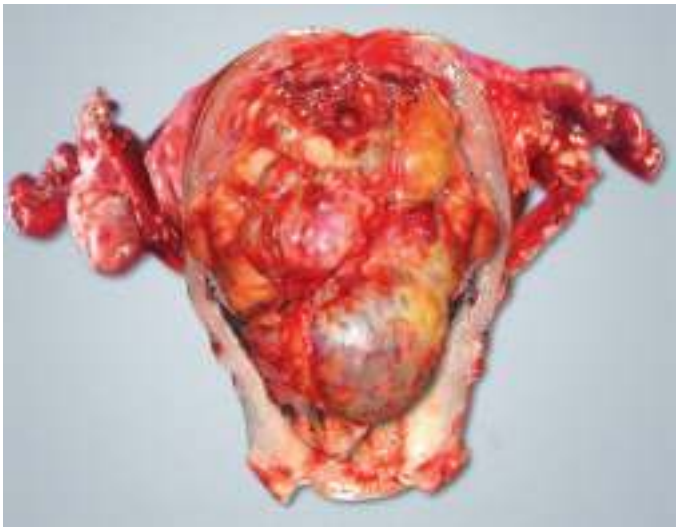

Fig. 24.65: Leiomyosarcoma of the uterus. The uterus is expanded by a massive, fleshy, partly necrotic and hemorrhagic-looking malignant tumor.

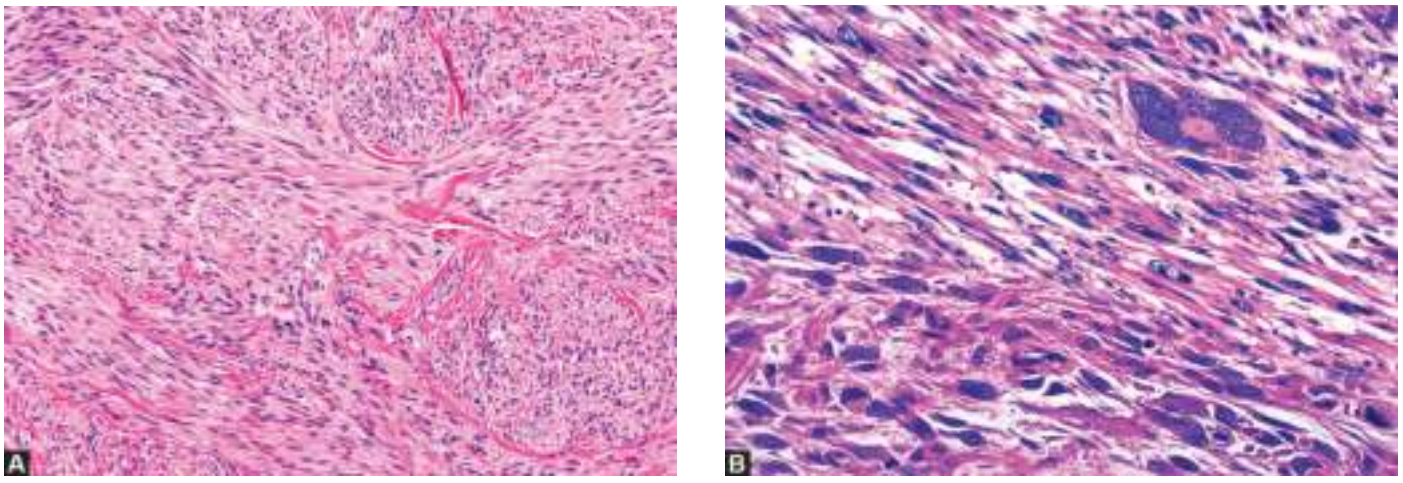

Fig. 24.66A and B: Leiomyosarcoma of uterus. As with sarcomas in general, leiomyosarcomas have spindle cells. Several mitoses are seen here, just in this one high power field (400X).

Table 24.23 Comparison of uterine leiomyoma and leiomyosarcoma

Feature	Leiomyoma	Leiomyosarcoma
Gross morphology		
Number	Usually multiple	Usually solitary (50–70%)
Size	Large tumor 3–5 cm size	Large tumor 5–10 cm size or larger size
Consistency	Firm tumor	Soft tumor
Cut surface	White color with whirling appearance	Yellow to tan with fleshy appearance
Hemorrhage and necrosis	Infrequent	Frequent
Histologic examination		
Hemorrhage and necrosis	Infrequent	Frequent
Mitoses	Mitoses <5/10 HPF	Mitoses ≥10/10 HPF
Immunohistochemistry technique		
SMA (smooth muscle actin)	Positive	Positive
Desmin	Positive	Positive
Caldesmon	Positive	Positive/negative
p16	Negative	Positive
PR	Positive	Negative
MIB-1	Negative	Positive
PHH3 (phosphohistone H3)	Negative	Positive

Mitotically active leiomyoma mitosis ≥5/10 HPF.
Atypical leiomyoma with low risk of recurrence shows diffuse moderate to severe atypia mitoses <5/10 HPF.
STUMP shows tumor necrosis diffuse severe atypia and mitoses 5–9/10 HPF.

Molecular Genetic Alterations

Complex numerical and structural chromosomal aberrations suggesting that chromosomal instability is the hallmark of uterine smooth muscle tumors. Mutations of TP53 (33%), TRRX (26%), and MED12 (21%) genes have been demonstrated in uterine leiomyosarcoma.

Mode of Spread

Leiomyosarcoma of uterus spreads by local invasion and via hematogenous route to most commonly to lungs, liver, brain and bone. Other rare metastatic sites have been reported including pancreas, skull, adrenal glands, heart, bile duct, bowel, breast, orbit and gingiva. It rarely spreads via lymphatic route to the lymph nodes.

Table 24.24 Histologic criteria for the diagnosis of uterine smooth muscle tumors

Uterine Smooth Muscle Tumor	Tumor Necrosis	Cellular Atypia	Mitotic Figures/10 HPF
Leiomyoma	Absent	None to mild	<5/10 HPF
Leiomyosarcoma	Present	Present	≥10/HPF
Atypical leiomyoma	Absent	Focal moderate to severe atypia	<5/10 HPF
Mitotically active leiomyoma with low risk of recurrence	Absent	Focal moderate to severe atypia	<5/10 HPF
STUMP (smooth muscle tumors of uncertain malignant potential)	▪ Absent ▪ Absent ▪ Absent	▪ None to mild atypia (rule out infarcted leiomyoma) ▪ Focal moderate to severe atypia ▪ Diffuse moderate to severe atypia	▪ <10/10 HPF ▪ 5/10 HPF ▪ 5–9/10 HPF

Table 24.25 Histologic features for the differential diagnosis between ischemic necrosis and tumor cell necrosis in leiomyosarcoma

Gross Morphologic and Histologic Features	Ischemic Necrosis	Tumor Necrosis
Necrotic tumor	No cell shadow (cellular outlines and details lost)	Shadows of necrotic cells
Transition between vital and necrotic area	Zone of granulation tissue in older necrosis	Abrupt
Hemorrhage and inflammation	Usual	Unusual

DISORDERS OF FALLOPIAN TUBES

FALLOPIAN TUBES: ANATOMY

Fallopian tube consists of interstitial portion (uterine end), isthmus, ampulla (wider portion) and infundibulum and opens as finger-like projections (towards ovary). Salpingitis can predispose to ectopic pregnancy.

INFLAMMATORY DISORDERS OF FALLOPIAN TUBES

ACUTE SALPINGITIS

Acute salpingitis is most often associated with inflammation of endometrium, ovaries and pelvic inflammatory disease in young- to middle-aged women. In some cases, acute salpingitis occurs due to abortion, puerperal sepsis, trauma and surgical manipulation.

- Acute salpingitis is caused by *Escherichia coli*, *Neisseria gonorrhoeae* (gram-negative diplococci), *Chlamydia trachomatis*, and Mycoplasma, Staphylococcus and streptococci organisms resulting in suppuration.
- Damage to the fallopian tube resulting from acute salpingitis may lead to infertility. Antibiotic therapy resolves inflammation of acute cervicitis. If resolution of the acute inflammation does not occur, chronic salpingitis follows with formation of tubo-ovarian mass.

Surgical Pathology: Acute Salpingitis

Gross Morphology

Bilateral fallopian tubes are congested, edematous and lumen filled with purulent exudates (pyosalpinx).

Light Microscopy

Fallopian tube epithelium shows marked infiltration by numerous neutrophils with congestion and edema (Fig. 24.67).

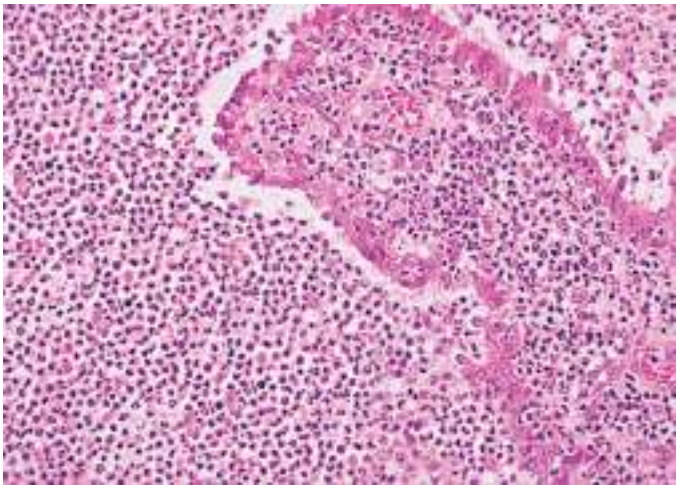

Fig. 24.67: Acute salpingitis. A remnant of tubal epithelium is seen here surrounded and infiltrated by numerous neutrophils. This is acute salpingitis. *Neisseria gonorrhoeae* was cultured (400X).

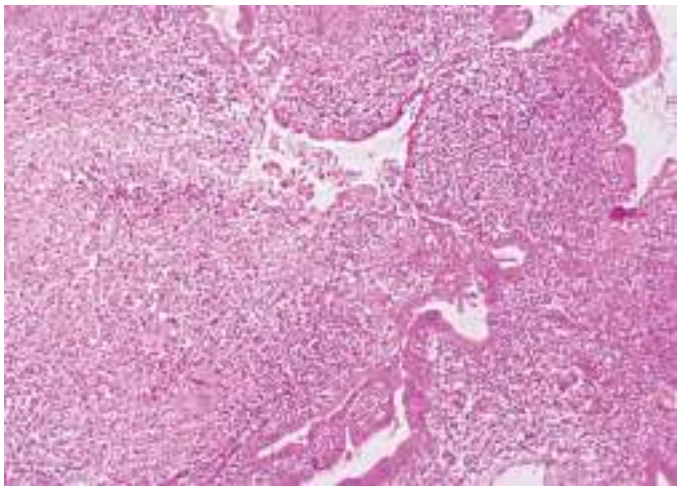

Fig. 24.68: Tubercular salpingitis. It shows large number of epithelioid cell granulomas, Langhans giant cells and caseous material. In the background, tubal wall is infiltrated by lymphocytes, macrophages and plasma cells (100X).

CHRONIC SALPINGITIS

Chronic salpingitis is characterized by presence of plasma cells and lymphocytes in the submucosa with or without foamy histiocytes and granulomas. Plicae are fibrotic, fused, short and thick.

- Repeated attacks by organisms cause chronic salpingitis with formation of violin string adhesion. Hydrosalpinx may be end stage of chronic salpingitis characterized by thin wall with a few plicae and lumen filled with clear fluid. Numerous adhesions occur on the serosal surface.
- Granulomatous salpingitis may be caused in the settings of tuberculosis, sarcoidosis, Crohn's disease and fungal infections. Tubercular salpingitis occurs as a result of extension of tubercular infection from endometrium. Spread of tubercular infection through intraluminal route causes adhesions of lining epithelium resulting in infertility. Tuberculous salpingitis shows epithelioid cell granulomas, Langhans' giant cells and caseous necrosis (Fig. 24.68).

Surgical Pathology: Chronic Salpingitis
Gross Morphology
Fallopian tube is most often enlarged, fibrotic, disordered and adhered to the ovary and surrounding structures.
Light Microscopy
Plicae of fallopian tube show infiltration by lymphocytes and plasma cells. Fusion of plicae may lead to formation of follicle-like spaces known as salpingitis follicularis.

SALPINGITIS ISTHMICA NODOSA

Salpingitis isthmica nodosa is characterized by outpouching of follopian tube epithelium into tubal wall. In severe cases, lumen may be completely obstructed. It ocurs in African Americans and Caucasians, and involves both tubes in 85% of cases. Salpingitis isthmica nodosa is most often associated with ectopic pregnancy and infertility in young women. It may lead to ectopic pregnancy. Its pathogenesis is not clear.

Surgical Pathology: Salpingitis Isthmica Nodosa
Gross Morphology
Fallopian tubal wall shows a yellow-white nodule in the isthmus region measuring 1–2 cm in diameter. Bilateral fallopian tubes are involved in 85% of cases.
Light Microscopy
▪ Fallopian tubal lesion consists of outpouchings of tubal epithelium surrounded by a thickened wall of smooth muscle. ▪ Glands may be cystically dilated and are true diverticula that communicate with tubal lumen.

NON-NEOPLASTIC DISORDERS OF FALLOPIAN TUBES

TUBAL ENDOMETRIOSIS

Presence of normal endometrial glands and stroma in fallopian tubes outside uterine cavity is known as endometriosis. Fallopian tubes are most frequently involved due to endometriosis in 1–2% women during reproductive period. It is an important cause of infertility. Endometriosis regresses after menopause. It is described in details in placental and pregnancy associated disorders in this chapter.

Surgical Pathology: Tubal Endometriosis
Gross Morphology
Fallopian tube endometriosis consists of dark brown chocolate-colored serosal nodules.
Light Microscopy
Fallopian tube shows presence of endometrial glands surrounded by endometrial stroma associated with hemosiderin-laden macrophages and chronic inflammatory cells.

TUBAL ECTOPIC PREGNANCY

Ampulla of the fallopian tube is the most common site of ectopic pregnancy. It is described in details in placental and pregnancy associated disorders. Risk factors for tubal ectopic pregnancy include salpingitis, prior ectopic pregnancy, salpingitis isthmica nodosa, congenital tubal anomalies and endometriosis.

- The classic clinical triad is pain abdomen, amenorrhea and vaginal bleeding in 50% of cases. On clinical examination, palpable adnexal mass and abdominal tenderness are demonstrated in many patients.

- Rupture of tubal ectopic pregnancy products lead to hypotensive shock. Fallopian tube shows dilatation, hemorrhagic, chorionic villi with or without embryo.
- Fallopian tubal mucosa or wall shows products of gestation (chorionic villi or trophoblast). Tubal pregnancy is given in details under pregnancy associated disorders in this chapter.

NEOPLASTIC DISORDERS OF FALLOPIAN TUBES

ADENOMATOID TUMOR OF FALLOPIAN TUBES

Adenomatoid tumor is the most common benign tumor of the fallopian tubes. It is derived from mesothelium.

Surgical Pathology: Adenomatoid Tumor of Fallopian Tube
Gross Morphology
Tumor is well circumscribed and white tan-colored seen in tubal wall.
Light Microscopy
Tumor shows slit-like spaces lined by single layer of flattened cuboidal cells (Fig. 24.69).
Immunohistochemistry Technique
Tumor cells are positive for expression of cytokeratin, calretinin, EMA and vimentin. These cells are negative for factor VIII-related antigen and CD31, a profile indicating a mesothelial origin rather from vascular endothelium.

Markers	Expression
Cytokeratin	Positive
Calretinin	Positive
Epithelial membrane antigen (EMA)	Positive
Vimentin	Positive
Factor VIII-related antigen and CD31	Positive

ADENOCARCINOMA OF FALLOPIAN TUBES

Primary adenocarcinoma of fallopian tube is extremely rare, and associated with BRCA gene mutation. In the vast majority of cases, bulky tumor extending from the ovary or endometrium involves fallopian tube. There may be a watery secretion resulting in serous discharge per vagina.

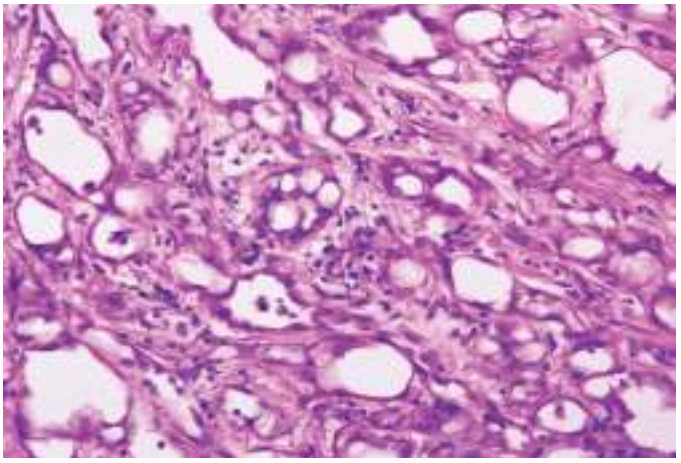

Fig. 24.69: Adenomatoid tumor of the fallopian tube. It shows slit-like spaces lined by single layer of flattened cuboidal cells (400X).

DISORDERS OF OVARIES

OVARIES: OVERVIEW

The ovaries are paired intraperitoneal gonads in the abdomen. These play a fundamental role in reproduction as well as the production of hormones.

- Granulosa cells and theca cells present in the ovary synthesize estrogen and progesterone.
- Graafian follicles mature during the proliferative phase of menstrual cycle. Once the dominant graafian follicle matures and luteinizing hormone surges, the oocyte will be expelled and begin its journey through the fallopian tubes and into the uterus.
- The corpus luteum functions as a temporary endocrine organ, that synthesizes progesterone along with smaller amounts of inhibin A and estradiol, which protects the oocyte and allows time for union of spermatozoa and ovum and implantation before menstruation.
- If fertilization takes place, the newly formed blastocyst synthesizes human chorionic gonadotropin hormone, which transmits signals to the corpus luteum to continue synthesizing progesterone. This function is now taken over by the placenta once it has matured.
- If fertilization does not occur, then the corpus luteum will degenerate and become corpus albicans, and the withdrawal of progesterone will initiate the process of menstruation.

INFLAMMATORY DISORDERS OF OVARIES

Inflammatory disorders of ovaries include acute oophoritis, autoimmune oophoritis and noninfectious granulomatous oophoritis (Table 24.26).

Table 24.26 Inflammatory disorders of ovaries

Characteristics	Acute Oophoritis	Autoimmune Oophoritis	Noninfectious Granulomatous Oophoritis
Underlying causes	▪ Salpingitis ▪ Systemic infections ▪ Tubo-ovarian abscess ▪ Ascending pelvic inflammatory disease	▪ Oligomenorrhea ▪ Infertility	▪ Sarcoidosis ▪ Foreign body granulomas following pelvic or abdominal surgery
Histologic features	Polymorphonuclear infiltration in ovaries	Lymphocytes and plasma cells infiltration in developing follicles (ovaries normal size)	Granulomatous inflammation
Clinical course	Subsequent fibrosis, scarring from pelvic inflammatory disease leading to infertility	Premature ovarian failure and premature menopause	Incidental finding

ACUTE OOPHORITIS

In most cases, inflammation of ovaries is caused by a bacterial infection spreading from the vagina or cervix and fallopian tubes. Pelvic inflammatory disease is often caused by more than one type of bacterium, which involves internal reproductive organs. Patient presents with pain in lower abdomen and pelvis and discharge per vagina. Acute oophoritis is characterized by infiltration by polymorphonuclear cells. Subsequent fibrosis, and scarring from pelvic inflammatory disease leading to infertility.

AUTOIMMUNE OOPHORITIS

Autoimmune oophoritis is associated with oligomenorrhea and infertility. Ovaries are of normal size, which show lymphocytes and plasma cells infiltration in developing graafian follicles. Women develop premature ovarian failure and premature menopause.

NONINFECTIOUS GRANULOMATOUS OOPHORITIS

Noninfectious granulomatous oophoritis is seen as incidental finding secondary to sarcoidosis and following pelvic or abdominal surgery. Ovaries show granulomas. Women with noninfectious granulomatous oophoritis are asymptomatic.

OVARIAN CYSTS

During the proliferative phase of the menstrual cycle, many graafian follicles are released, but only one reaches maturity progressing to development of corpus luteum. It eventually undergoes degeneration during the menstrual cycle. There are two types of functional ovarian cysts (follicular and luteal cysts): small non-neoplastic sacs containing fluid or semisolid material. These cysts require thorough investigation as possible sites of malignant change. Salient features of ovarian cysts are given in Table 24.27.

FOLLICULAR CYST

Follicular cyst occurs in the first 2 weeks of the menstrual cycle during prepubescent or reproductive age group. When the graafian follicle fails to rupture, it continues to grow and resulting in follicular cyst. It is sometimes associated with hyperestrinism and endometrial hyperplasia.

Clinical Features

Patient presents with abdominal mass, rupture. Follicular cysts may be associated with polycystic ovarian syndrome or McCune-Albright syndrome.

Surgical Pathology: Follicular Cyst in Ovary
Gross Morphology
Follicular cyst is unilateral measuring 2.5–10 cm in diameter. Normal follicle measures up to 1 cm. Follicular cyst contains serosanguineous fluid.
Light Microscopy
Follicular cyst is lined by inner granulosa cells and outer theca cells.

CORPUS LUTEAL CYST

Corpus luteal cyst occurs in the second half of the menstrual cycle during reproductive age group. Hemorrhage into a persistent mature corpus luteum results in formation of corpus luteal cyst. Woman with corpus luteal cyst is usually associated with menstrual irregularity, occasionally with intraperitoneal hemorrhage. Corpus luteal cyst measures >3 cm in diameter and contains hemorrhagic fluid. Corpus luteal cyst shows granulosa cells interspersed with peripheral theca cells similar to normal corpus luteum.

POLYCYSTIC OVARY SYNDROME (STEIN-LEVENTHAL SYNDROME)

Polycystic ovary syndrome (Stein-Leventhal syndrome) is a disorder in which ovaries produce an abnormal

Table 24.27 Salient features of ovarian cysts

Ovarian Cyst	Age Group	Gross Morphology and Histologic Features	Clinical Features
Follicular cysts	Prepubertal and reproductive period	Unilateral cyst 2.5–10 cm with sanguineous fluid; and lined by inner granulosa cells and outer theca cells	Abdominal mass, rupture, may be associated with polycystic ovarian syndrome or McCune-Albright cyst
Corpus luteal cysts	Reproductive period	Cyst >3 cm size with hemorrhagic fluid, composed of granulosa cells interspersed with peripheral theca cells similar to corpus luteum	Menstrual cycle abnormalities, occasional intraperitoneal hemorrhage
Polycystic ovarian syndrome	20–30 years	Ovaries enlarged, thickened, collagenized cortical surface containing multiple uniform graafian follicles, absence of corpus luteum indicating infrequent ovulation	Anovulation, infertility, hirsutism, increased incidence of endometrial hyperplasia and endometrioid carcinoma
Surface epithelial inclusion cysts	Reproductive period	Surface epithelial inclusion cysts 1 cm size formed due to invagination of ovarian surface epithelium secondary to rupture with ovulation; lined by single layer of cuboidal or columnar cells, psammoma bodies may be present	Surface inclusion cyst may be precursor of benign, borderline and low-grade epithelial neoplasms
Paraovarian or paratubal cysts	Reproductive period	Cysts present in hilar region of ovary derived from Wolffian duct lined by simple or stratified epithelium and Müllerian ducts lined by columnar epithelium and nonciliated cells similar to surface inclusion cyst	Asymptomatic
Endometriosis (endometrial glands and stroma outside uterus most often in ovary)	Reproductive period	Chocolate cysts in ovarian cortex filled with thick brown fluid resembling chocolate syrup; presence of endometrial glands, hemosiderin-laden macrophages, fibroblasts and inflammation simulating malignancy	Menstrual cycle associated with pain and infertility
Theca luteal cysts (formed due to gonadotropin stimulation)	Cysts formed in hydatidiform mole and choriocarcinoma cases	Theca luteal cysts small size, lined by luteinized theca cells	Women with hydatidiform mole and choriocarcinoma develop theca luteal cysts

amount of androgens, male sex hormones that are usually present in women in small amounts. Polycystic ovaries, hormonal imbalance and irregular menstrual periods are signs and symptoms of polycystic ovary syndrome. Clinical manifestations of polycystic ovary syndrome (Stein-Leventhal syndrome) are related to excess synthesis of androgenic hormones (amenorrhea or oligomenorrhea), persistent anovulation (important cause of infertility), and small subcapsular cysts in ovaries, obesity, and hirsutism in young women of 20–30 years of age group.

Pathogenesis

Patient synthesizes excess of luteinizing hormone (LH) and androgens. Increased synthesis of androgens occurs by two mechanisms: LH may stimulate follicular theca-lutein cells, with consequent increased synthesis of androgens. Hyperinsulinemia in insulin resistance diabetes mellitus may lead to increased ovarian androgen production, which then may cause increased LH synthesis.

Complications

Women develop anovulation, irregular menstrual cycles, infertility and hirsutism. Unopposed acyclic estrogen synthesis in women with polycystic ovary syndrome (Stein-Leventhal syndrome) leads to increased incidence of endometrial hyperplasia and/or adenocarcinoma.

Surgical Pathology: Polycystic Ovary Syndrome (Stein-Leventhal Syndrome)

Gross Morphology

- Both ovaries are enlarged. Cut section reveals thickened collagenized cortex surface.
- Numerous cysts in ovaries measuring 2–8 mm in diameter are arranged peripherally around a dense core of stroma.

Light Microscopy

- Ovaries show multiple uniform graafian follicles lined by granulosa cells and absence of corpus lutea (indicating infrequent ovulation).
- Ovaries show marked thickened ovarian capsule and cortical stromal fibrosis with islands of focal luteinization.

SURFACE EPITHELIAL INCLUSION CYSTS

Surface epithelial inclusion cysts in ovaries are seen during reproductive period. These are formed as a result of repeated invaginations of ovarian epithelium secondary to rupture with ovulation. These surface epithelial inclusion cysts may be precursor of benign, borderline and low-grade serous epithelial neoplasms.

Surgical Pathology: Surface Epithelial Inclusion Cysts in Ovaries

Gross Morphology

Surface epithelial inclusion cysts are less than 1 cm in diameter.

Light Microscopy

- Surface epithelial inclusion cysts are lined by single layer of cuboidal or columnar cells.
- Psammoma bodies may be present. Paramesonephric cysts are lined by columnar epithelium with mixture of ciliated and nonciliated cells similar to epithelial inclusion cysts.

PARAOVARIAN OR PARATUBAL CYSTS

Paraovarian or paratubal cysts are formed during reproductive age group. Cysts are derived from mesonephric (Wolffian) or paramesonephric (Müllerian) ducts and found in the hilar region of the ovary. Women are asymptomatic.

Surgical Pathology: Paraovarian or Paratubal Cysts

Gross Morphology

Paraovarian or paratubal cysts are of small size.

Light Microscopy

Mesonephric cysts are lined by simple or stratified epithelium with prominent muscular walls. Paramesonephric cysts are lined by columnar epithelium with mixture of ciliated and nonciliated cells similar to epithelial inclusion cysts.

ENDOMETRIOSIS (CHOCOLATE CYSTS)

Endometriosis represents endometrial glands and stroma outside uterus during reproductive period. The ovary is the most frequent site of endometriosis. Hemorrhage into endometriosis focus results in formation of blood-filled cysts on the ovary termed chocolate cysts. Endometriosis is associated with pain during menstrual cycle. It is frequent cause of infertility.

Surgical Pathology: Paraovarian or Paratubal Cysts in Ovaries

Gross Morphology

Ovaries show thickened cortex, surface adhesion. Cysts are filled with thick brown fluid resembling chocolate syrup, the so-called chocolate cysts.

Light Microscopy

Endometrial glands and stroma associated with hemosiderin-laden macrophages and fibroblasts. These cysts may contain atypical cytologic features and acute inflammation raising suspicious of malignancy.

THECA LUTEAL CYSTS

Theca luteal cysts in ovaries are most often multiple and bilateral. These are lined by luteinized theca cells. Theca luteal cysts are formed due to gonadotropin stimulation in patients associated with choriocarcinoma and hydatidiform mole. Ovaries contain multiple small cysts of variable diameter. Theca luteal cysts are lined by luteinized theca cells.

NEOPLASTIC DISORDERS OF OVARY

Ovarian cancer is the second most common malignancy of the genital tract and most common cause of death due to late diagnosis.

- Most of the ovarian tumors are of epithelial origin, which occur after the age of 35 years with increasing incidence as age advances.
- Approximately 3% of ovarian tumors occur before 35 years of age, which are mostly nonepithelial in origin as germ cell tumors.
- Primary ovarian tumors are classified according to recent 2020 World Health Organization (WHO) classification, which divides primary tumors into three main groups based on line of differentiation—surface epithelial-stromal tumors (Müllerian epithelium), germ cell tumors (ovum), and sex cord-stromal tumors (Fig. 24.70). Recent 2020 WHO classification of tumors of the ovary is given in Table 24.28. Most common histologic subtypes of surface

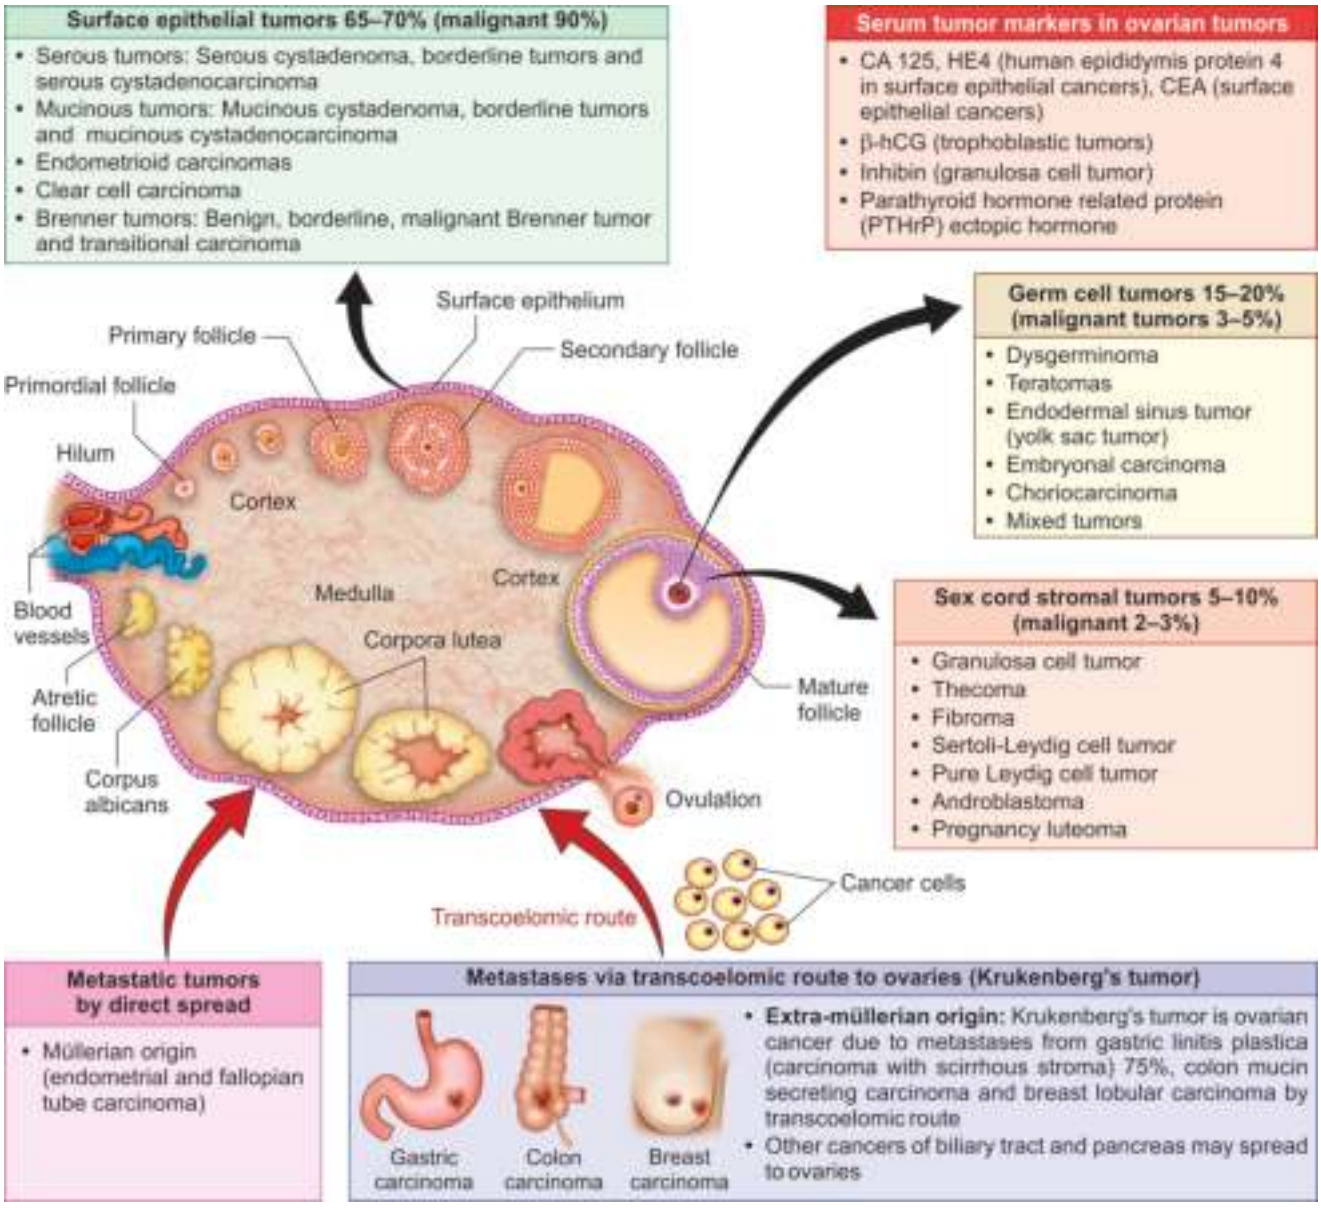

Fig. 24.70: Classification of ovarian tumors.

epithelial carcinomas of ovary are given in Table 24.29. Differentiating features of benign and malignant ovarian tumors are given in Table 24.30. Salient features of ovarian masses are given in Table 24.31.

KRUKENBERG TUMOR (METASTATIC TUMOR)

Krukenberg tumor is the metastatic carcinoma of ovaries. The gastric mucin secreting adenocarcinoma is the primary site in 75% of cases, followed by colon mucin secreting adenocarcinoma and lobular carcinoma of breast. Metastases to ovary(ies) occur by transcoelomic spread. One should suspect metastatic carcinoma involving bilateral ovaries with multiple nodules.

Surgical Pathology: Krukenberg Tumor

Gross Morphology

Tumor shows multiple solid nodules. Cut surface shows gray white, gelatinous, areas of extensive necrosis and cystic spaces (Fig. 24.71).

Light Microscopy

Krukenberg tumor is characterized by ovarian metastases, in which the tumor shows nests of mucin-filled signet ring epithelial cells with eccentric nuclei within a cellular stroma derived from the ovary (Fig. 24.72).

Immunohistochemistry Technique

- Metastatic gastric mucin secreting carcinoma to ovary is immunoreactive with cytokeratin, epithelial membrane antigen (EMA), carcinoembryonic antigen (CEA).

- Metastatic colon mucin secreting carcinoma to ovary is immunoactive with CK20, CDX2, MUC1, CEA, β-catenin, SAT2 and p53.
- Breast lobular carcinoma metastasizing to ovary is immunoreactive with estrogen receptor/progesterone receptor (ER/PR). It is negative for E-cadherin and HER2/neu.

Markers	Expression
Metastatic gastric carcinoma to ovaries	
▪ Cytokeratin	▪ Positive
▪ CEA	▪ Positive
▪ EMA	▪ Positive
Metastatic colon carcinoma to ovaries	
▪ CK20	▪ Positive
▪ CDX2	▪ Positive
▪ MUC1	▪ Positive
▪ CEA	▪ Positive
▪ β-catenin	▪ Positive
▪ SAT2	▪ Positive
▪ p53	▪ Positive
Metastatic lobular carcinoma of breast to ovaries	
▪ ER/PR	▪ Positive
▪ E-cadherin	▪ Negative/decreased expression
▪ HER2/neu	▪ Negative/decreased expression

Table 24.28 Recent 2020 WHO classification of tumors of the ovary

Surface Epithelial Tumors	
Serous tumors	▪ Serous cystadenoma, NOS • Serous surface papilloma • Serous adenofibroma, NOS • Serous cystadenofibroma, NOS ▪ Serous borderline tumor, NOS ▪ Serous borderline tumor, micropapillary variant ▪ Serous cystadenocarcinoma • Low-grade serous cystadenocarcinoma • High-grade serous cystadenocarcinoma
Mucinous tumors	▪ Mucinous cystadenoma, NOS ▪ Mucinous adenofibroma, NOS ▪ Mucinous borderline tumor ▪ Mucinous adenocarcinoma
Endometrioid tumors	▪ Endometrioid cystadenoma, NOS ▪ Endometrioid adenofibroma, NOS ▪ Endometrioid tumor, borderline ▪ Endometrioid adenocarcinoma, NOS ▪ Seromucinous carcinoma
Clear cell carcinoma	▪ Clear cell cystadenoma ▪ Clear cell cystadenofibroma ▪ Clear cell borderline tumor ▪ Clear cell adenocarcinoma, NOS
Seromucinous tumors	▪ Seromucinous cystadenoma ▪ Seromucinous adenofibroma ▪ Seromucinous borderline tumor
Brenner tumors	▪ Brenner tumor, NOS ▪ Brenner tumor, borderline malignant ▪ Brenner tumor, malignant
Other carcinomas	▪ Mesonephric-like adenocarcinoma ▪ Carcinoma, undifferentiated, NOS ▪ Dedifferentiated carcinoma ▪ Carcinosarcoma, NOS ▪ Mixed cell adenocarcinoma
Sex Cord-stromal Tumors	
Pure stromal tumors	▪ Fibroma, NOS ▪ Cellular fibroma
	▪ Thecoma, NOS ▪ Thecoma luteinized ▪ Sclerosing stromal tumor ▪ Microcystic stromal tumor ▪ Signet-ring stromal tumor ▪ Leydig cell tumor of the ovary, NOS ▪ Steroid cell tumor, malignant ▪ Fibrosarcoma
Pure sex cord tumors	▪ Adult granulosa cell tumor ▪ Granulosa cell tumor, juvenile ▪ Sertoli cell tumor, NOS ▪ Sex cord tumor with annular tubules
Mixed sex cord-stromal tumors	▪ Sertoli-Leydig cell tumor, NOS ▪ Sertoli-Leydig cell tumor, well-differentiated ▪ Sertoli-Leydig cell tumor, moderately differentiated ▪ Sertoli-Leydig cell tumor, poorly-differentiated ▪ Sertoli-Leydig cell tumor, retiform ▪ Sex cord tumor, NOS ▪ Gynandroblastoma
Germ Cell Tumors	
Germ cell tumors examples	▪ Teratoma ▪ Immature teratoma, NOS ▪ Dysgerminoma ▪ Yolk sac tumor, NOS ▪ Embryonal carcinoma, NOS ▪ Choriocarcinoma, NOS ▪ Mixed germ cell tumor
Monodermal teratomas and somatic-type tumors arising from a dermoid cyst	▪ Struma ovarii, NOS ▪ Struma ovarii, malignant ▪ Struma carcinoid tumor ▪ Teratoma with malignant transformation ▪ Mature cystic teratoma, NOS ▪ Immature teratoma, NOS
Germ cell-sex cord-stromal tumors	▪ Gonadoblastoma • Dissecting gonadoblastoma • Undifferentiated gonadal tissue ▪ Mixed germ cell-sex cord-stromal tumor, NOS

Table 24.29 Most common histologic subtypes of surface epithelial carcinomas of ovary

Ovarian Carcinoma Subtype	Frequency (%)	Morphologic Features of Well Differentiated Ovarian Carcinoma
Serous cystadenocarcinoma	50%	Tumor is composed of columnar cells with a prominent ciliated border that often form finger-like projections around fibrovascular core (papillae) within the inner lining of cysts filled with serous fluid
Endometrioid carcinoma	25–30%	Tumor is composed of glandular structures lined by low columnar cells that may be filled with bloody material
Mucinous cystadenocarcinoma	10–15%	Tumor is composed of columnar cells with clear mucus pushing cell nucleus toward basal pole, typically forming complex cystic structures
Clear cell carcinoma	5%	Tumor is composed of low columnar to cuboidal cells with clear cytoplasm and hobnail appearance, often forms small glandular structure or solid nests
Other tumors	<5%	Heterogenous group that includes ovarian tumor so poorly differentiated that their exact lineage cannot be determined as well as rare subtypes such as tumors showing features of transitional epithelium (malignant Brenner tumor) and others

Table 24.30 Differentiating features of benign and malignant ovarian tumors

Characteristics	Benign Ovarian Tumors	Malignant Ovarian Tumors
Clinical examination		
Mobility of tumor	Mobile	Immobile and fixed
Consistency	Cystic tumor	Solid and cystic tumor
Laterality of tumor	Unilateral tumor	Bilateral tumors
Vaginal examination	Smooth tumor on per vagina examination	Nodular tumor on per vagina examination
Intraoperative findings		
Imaging technique findings	Unilateral cyst with intact capsule	Ovarian capsule breached
Size	Most often, 10 cm size	Size varies
Septate	Septate <3 mm in thickness	Multiple septate >3 mm in thickness
Calcification	Present in benign cystic teratoma	Absent
Omental involvement	Absent	Present
Ascites	Absent (present in fibroma presenting as Meig's syndrome)	Present

Table 24.31 Salient features of ovarian masses

Ovarian Tumors	Clinical Manifestations	Tumor Markers	Facts
Germ cell tumors	▪ Young women ▪ Pain in adnexa ▪ Complex cystic mass	▪ LDH ▪ β-hCG ▪ AFP (α-fetoproteins)	Dysgerminoma most common malignant tumor
Surface epithelial tumors	▪ Postmenopausal women ▪ Distended abdomen ▪ Adnexal mass/pain ▪ Weight loss	▪ CA 125 ▪ CEA (carcinoembryonic antigen)	▪ Most common ovarian cancer ▪ Most common subtype (serous cystadenocarcinoma)
Granulosa-theca cell tumors	▪ Postmenopausal women ▪ Postmenopausal bleeding	Estrogen	Synthesizes estrogen resulting in endometrial hyperplasia
Sertoli-Leydig cell tumors	Women with masculinization features (deepening of voice and more hair on body)	Testosterone	Synthesizes testosterone
Krukenberg tumors	▪ History of gastric ulcer with worsening epigastric pain ▪ Breast lump	CEA (carcinoembryonic antigen)	Mucin secreting adenocarcinoma from stomach but with metastasis to ovaries

Serum CA 125 is elevated in ovarian cancer and also elevated in cirrhosis, endometriosis, peritonitis and pancreatitis. Ultrasonography is preformed to confirm ovarian mass. Serum tumor markers and histologic examination of biopsy are needed to establish diagnosis. Salpingo-oophorectomy is performed during childbearing women. In postmenopausal women, abdominal hysterectomy with bilateral salpingo-oophorectomy is done.

Fig. 24.71: Krukenberg's tumor: Both ovaries show involvement as a result of metastases from primary carcinomas of stomach or colon or breast (arrows).

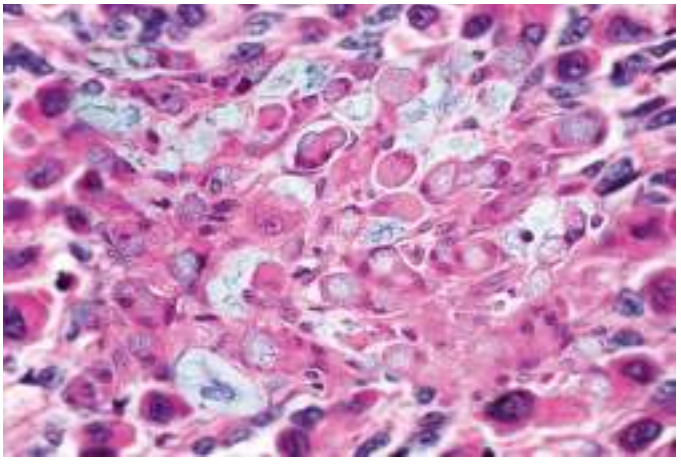

Fig. 24.72: Krukenberg's tumor. It shows nests of mucin-filled signet ring epithelial cells with eccentric nuclei within a cellular stroma (400X).

SURFACE EPITHELIAL TUMORS OF OVARY

Primary surface epithelial tumors account for 65–70% of all ovarian tumors, which include serous, mucinous, endometrioid, clear cell, and transitional (Brenner) tumors.

- **Histogenesis:** During embryonic life, the coelomic cavity is lined by a mesothelium. This mesothelium gives rise to Müllerian ducts, from which uterus, fallopian tubes, and vagina originate. Pluripotency of the ovarian surface epithelium accounts for the spectrum of histologic tumor variants seen in this location.
- **Differentiation of surface epithelium:** Surface epithelium has potential to differentiate to ciliated columnar epithelium resembling tubal epithelium, tall mucus-secreting nonciliated epithelium resembling endocervix, uterine endometrial glands and transitional epithelium resembling urinary bladder. Surface epithelium of ovary has potential to differentiate into various surface epithelial tumors (Table 24.32). Classification of ovarian surface epithelial tumors based on their malignant potential is given in Table 24.33. Risk factors for surface epithelial tumors of ovary are given in Table 24.34. Risk factors for familial ovarian carcinoma are given in Table 24.35. Molecular genetic alterations associated with sporadic (nonfamilial) ovarian carcinomas are given in Table 24.36.

Table 24.32 Surface epithelium of ovary has potential to differentiate into various surface epithelial tumors

Lining Epithelium	Similar to Epithelial Lining and Examples of Ovarian Tumors	Examples of Ovarian Tumors
Ciliated columnar epithelium	Fallopian tube	Serous tumors
Tall mucus-secreting nonciliated epithelium	Endocervix	Mucinous tumors
Epithelium similar to uterine endometrial glands	▪ Uterine endometrial glands ▪ Uterine endometrial glands during pregnancy	▪ Endometrioid tumors ▪ Clear cell tumors (glycogen rich)
Transitional epithelium	Urinary bladder	Brenner tumors

Table 24.33 Classification of ovarian surface epithelial tumors based on their malignant potential

Nature	Features
Benign surface epithelial tumors	▪ Surface epithelial benign tumors include serous cystadenoma, mucinous cystadenoma and Brenner tumors. Serous tumors account for approximately 20% of all ovarian tumors. Serous epithelial tumors are most often bilateral and are more common than mucinous tumors ▪ Fluid-filled cysts lined by single layer of neoplastic epithelium supported by a fibrovascular wall; without invasion or metastatic ability
Borderline surface epithelial tumor or low malignant potential	Approximately 10% of ovarian surface epithelial tumors are borderline malignant, which show varying degree of nuclear atypia and increased mitotic activity. Neoplastic cells form complex structures such as '**papillae**' compared to carcinomas, without or reduced invasive ability. These remain confined to the ovary. Rarely, these may metastasize to peritoneum ▪ Serous borderline tumors most often occur in 20–50 years of age group. Cells may shed from the surface and implant on peritoneum, possibly reflecting multifocal origin. S-100 protein is positive in particularly borderline tumors ▪ Mucinous borderline tumors most often occur in younger women. Hart Norris criteria of borderline mucinous tumor include atypical epithelial cells >4 layers thick, are showing pleomorphism and arranged in cribriform pattern. There is lack of fibrovascular cores in these tumors ▪ Borderline endometrioid tumors exhibit well differentiated adenocarcinoma with lack of stromal invasion ▪ Borderline Brenner tumor is composed of cysts and papillae. These papillae are projecting in cystic spaces and lined by stratified lining. Stromal invasion is absent
Invasive surface epithelial carcinomas	Well differentiated malignant surface epithelial tumors tend to be associated with early stage disease. Mucinous and endometrial tumors have better prognosis than serous cystadenocarcinomas. Serous epithelial tumors are most often bilateral with malignant potential in 30% of patients ▪ Low-grade invasive surface epithelial carcinomas of ovary retain the ability to form organized structures such as gonads or papillae; neoplastic cells are abnormal, but similarities with their normal counterparts are readily apparent, mild nuclear polymorphism ▪ High-grade invasive surface epithelial carcinomas of ovary tend to form solid sheets with no organization; cellular features seen in the benign counterparts of these tumors, such as secretions and others, are not readily apparent, marked nuclear polymorphism

Table 24.34 Risk factors for surface epithelial tumors of ovary

Risk Factors	Characteristics
Age group	As a group, younger patients have a better outcome due to occurrence of higher percentage of borderline, well differentiated, and stage I tumors in this age group
Nulliparity	It is dangerous because repeated disruption and repair of the epithelial surface. It occurs during normal cyclic ovulation in nulliparous. Conversely, suppression of ovulation in multiparous women is protective due to repeated pregnancy, lactation and oral contraceptive pills
Long fertile period	Early menarche (>12 years age), late menopause and long-term estrogen replacement therapy increase risk of ovarian cancer
Family history	BRCA1 is implicated in cancers of breast and ovary. If mother had ovarian cancer then daughter is at increased risk of developing cancer of breast and ovary

Contd...

Table 24.34 Risk factors for surface epithelial tumors of ovary (*Contd...*)

Risk Factors	Characteristics
Gonadal dysgenesis	Patient develops ovarian childhood malignancies and rarely gonadoblastoma
Superovulation therapy for infertility treatment	It may also be a predisposing factor (controversial)
BRCA1 tumor suppressor gene	Mutation of BRCA1 has been implicated in familial cancers of ovary (50%) and breast. These patients tend to develop ovarian cancer considerably earlier than women who have sporadic ovarian cancer
ERBB2 (HER2/neu)	Gene amplification of ERBB2 (HER2/neu) is demonstrated by immunohistochemistry technique (monoclonal antibody) on the cell membrane or using fluorescent *in situ* hybridization. Mutation of ERBB2 (HER2/neu) is observed in 30% of ovarian cancers. Herceptin is administered to treat ovarian cancers
SMADA4 tumor suppressor gene	Mutation of DPC4 (deletion) has been demonstrated in 55% of pancreatic carcinoma and rarely seen in cancers of breast and ovaries
DNA mismatch repair genes inactivation	There is increased risk for development of carcinoma of endometrium (first most common cancer), right colon and ovary in patients with hereditary nonpolyposis colon cancer (Lynch syndrome)

Definite risk factors can be identified only in minority of cases and include ovarian dysgenesis, family cancer syndrome, and BRCA1 and BRCA2 gene mutations linked with an increased incidence of breast cancer

Table 24.35 Risk factors for familial ovarian carinoma

Family History of Carcinoma	Additional Risk Factor	Gene Mutation
First-degree relative with ovarian carcinoma	History of infertility	BRCA2 tumor suppressor gene
Second-degree relative with ovarian carcinoma	Nulliparity (no history of pregnancies)	BRCA1 tumor suppressor gene
Two or more relatives with ovarian carcinoma	Long fertile period (early menarche and late menopause)	SMADA4 tumor suppressor gene
Hereditary breast-ovarian carcinoma (HBOC) syndrome	North American/European women	ERBB2 (HER2/neu)
Hereditary nonpolyposis colorectal carcinoma (HNPCC)	▪ Gonadal dysgenesis ▪ Superovulation therapy for infertility treatment ▪ Exposure to talc	DNA mismatch repair genes inactivation

Table 24.36 Molecular genetic alterations associated with sporadic (nonfamilial) ovarian carcinomas

Category	Gene and Chromosome Alterations	Comment
Oncogenes	▪ HER2/neu	▪ Receptor tyrosine kinase; overexpression is associated with poor prognosis and therapeutic response
	▪ K-RAS, H-RAS, BRAF	▪ Mutations in K-RAS, H-RAS and BRAF genes are frequent in serous and mucinous ovarian low-grade carcinomas and tumors of low malignant potential
	▪ AKT2	▪ Member of a subfamily of protein-serine/threonine kinases is linked to ovarian cancer
	▪ Cyclin E	▪ Overexpression in ovarian carcinoma has been associated with poor prognosis
Tumor suppressor genes	▪ TP53	▪ Regulator of cell cycle progression and apoptosis. TP53 gene mutation is linked to ovarian cancer
	▪ PTEN	▪ PTEN gene results in part, in inhibition of cell death; it is mutated in a significant proportion of endometrioid ovarian carcinomas
	▪ BAF250α	▪ Component of the SW1-SNF chromatic remodeling complex. BAF250α gene mutation is linked to ovarian carcinoma

Contd...

Table 24.36 Molecular genetic alterations associated with sporadic (nonfamilial) ovarian carcinomas (*Contd...*)

Category	Gene and Chromosome Alterations	Comment
	▪ NOEY2	▪ Induces p21 and downregulates cyclin D. NOEY2 gene mutation is linked to ovarian cancer
	▪ SPARC2	▪ Encodes a calcium binding matrix protein that contributes to cell adhesion. SPARC2 gene mutation is linked to ovarian cancer
	▪ DOC-2	▪ Binds GRB-2 upstream of RAS. DOC-2 gene mutation is linked to ovarian cancer
Chromosomes with frequent losses of heterozygosity	Chromosomes: 3p, 6p, 6q, 9p, 1p, 11q, 13q, 17p, 17q, 19q, 22q, Xp, Xq	Multiple candidate tumor suppressor genes have been reported on these chromosomes, but their role in ovarian carcinogenesis is unclear
Altered signal transduction pathways	▪ PIK3CA	▪ Amplification and overexpression of PIK3CA has been demonstrated in ovarian sporadic cancer
	▪ Wnt/β-catenin	▪ The Wnt/β-catenin pathway plays critical roles in regulating embryonic development and physiological processes. In the absence of Wnt/β-catenin ligands, β-catenin is degraded by a destruction complex. Aberrant activation of Wnt pathway has been reported in ovarian sporadic cancer. Aberrant activation of Wnt pathway leads to hyperactivity of β-catenin, which interacts with TCF/LEF transcription factors to regulate target gene expression
	▪ EGFR (tyrosine kinase activity)	▪ EGFR plays a major role in the etiology and progression of many carcinomas, including epithelial ovarian cancer

Mode of Spread of Surface Epithelial Carcinomas of Ovary

Surface epithelial ovarian carcinomas initially spread by direct seeding of the peritoneal surfaces, and is found on the underside of the diaphragm, paracolic gutters, urinary bladder, cul-de-sac, surface of liver, mesentery and serosa of large and small bowel, omentum, uterus and para-aortic and pelvic lymph nodes. Mode of spread of surface epithelial carcinomas of ovary is shown in Fig. 24.73 and Table 24.37.

Clinical Course of Surface Epithelial Tumors of Ovary

- **Benign surface epithelial tumors:** These constitute 80% of ovarian tumors during reproductive period. Most ovarian tumors are benign and nonfunctional and do not produce clinical effects until they have grown to a large size and present with increasing mass or girth.
- **Malignant surface epithelial tumors:** These tumors affect elderly women (40–65 years), which rapidly spread outside the ovary by local extension or surface seeding and occasionally through lymphatic route and hematogenous route involving extra-abdominal organs such as lung at the time of diagnosis. Patient presents with abdominal mass, ascites, cachexia, and pleural effusion, signs of increased pressure on neighboring organs such as urinary frequency, constipation, torsion, feminizing or masculinizing effects. These tumors often have poor prognosis.

Role of Immunohistochemistry Technique in Primary Surface Epithelial Tumors of Ovary and Krukenberg Tumor of Ovary

Immunohistochemistry aids in differentiating primary surface epithelial tumors and metastatic tumors to ovary (Krukenberg tumor). Most common panel of immunohistochemical markers is used to differentiate primary surface epithelial tumors from metastatic tumors to ovary. These markers are CK7, CK20, CEA, CA 125, ER, WT1 and S-100 protein.

- **CK7 marker:** It is the most helpful in differentiating primary surface epithelial cystadenocarcinoma and metastatic colorectal carcinoma to ovary. CK7 is positive in primary adenocarcinoma of ovary in 96% of cases.
- **CK7, CK20 and CEA:** These aid in differentiating primary surface serous cystadenocarcinoma from primary mucinous carcinoma of ovary. These immunohistochemical markers are less helpful in differentiating primary surface adenocarcinoma form colorectal adenocarcinoma metastasizing to ovaries.
- **S-100 protein:** It is positive in borderline serous epithelial tumors of ovary.
- **WT1 marker:** It stains diffusely in most primary serous epithelial adenocarcinomas within the female genital tract.
- **PAX2 marker:** It is positive in primary serous cystadenocarcinomas of ovary.
- **SMO47 marker:** It is used to establish origin of cystadenocarcinoma from ovary. It is strongly expressed in most primary serous cystadenocarcinomas of ovary. SMO47 is not expressed in primary mucinous cystadenocarcinomas.

- **Anti-MUC16 (OC125):** Anti-MUC16 (OC125) monoclonal antibody recognizes an epitope on a molecule called cancer antigen 125 (CA 125). The human cancer antigen 125 (CA 125) plays an important role in the pathogenesis of ovarian surface epithelial carcinoma. Hence, it shows overexpression in the primary ovarian surface epithelial cancer cells.

Markers	Expression	Ovarian Surface Epithelial Tumor
▪ CA 125 (anti-MUC16 (OC125)	▪ Positive	▪ Mucinous cystadenocarcinoma ▪ Cervical carcinoma ▪ Endometrial carcinoma ▪ Breast carcinoma ▪ Thyroid carcinoma ▪ GIT carcinoma
▪ ER/PR	▪ Positive	▪ Surface epithelial tumors
▪ S-100 protein	▪ Positive	▪ Borderline serous surface epithelial tumors
▪ CK7	▪ Positive	▪ Serous cystadenocarcinoma
▪ CK20	▪ Positive	▪ Serous cystadenocarcinoma
▪ CEA	▪ Positive	▪ Serous cystadenocarcinoma
▪ WT1	▪ Positive (diffuse staining)	▪ Serous cystadenocarcinoma
▪ PAX2	▪ Positive (strong staining in most tumors)	▪ Serous cystadenocarcinoma
▪ SMO47	▪ Positive (useful marker in ascertaining the female genital tract tumor)	▪ Serous cystadenocarcinoma
▪ CK7, CK20, CEA	▪ Negative	▪ Mucinous cystadenocarcinoma

CA 125 is also positive in cervical carcinoma, endometrial carcinoma, breast carcinoma, thyroid carcinoma, gastric carcinoma and colon carcinoma. CEA: Carcinoembryonic antigen; ER: Estrogen receptor; PR: Progesterone receptor.

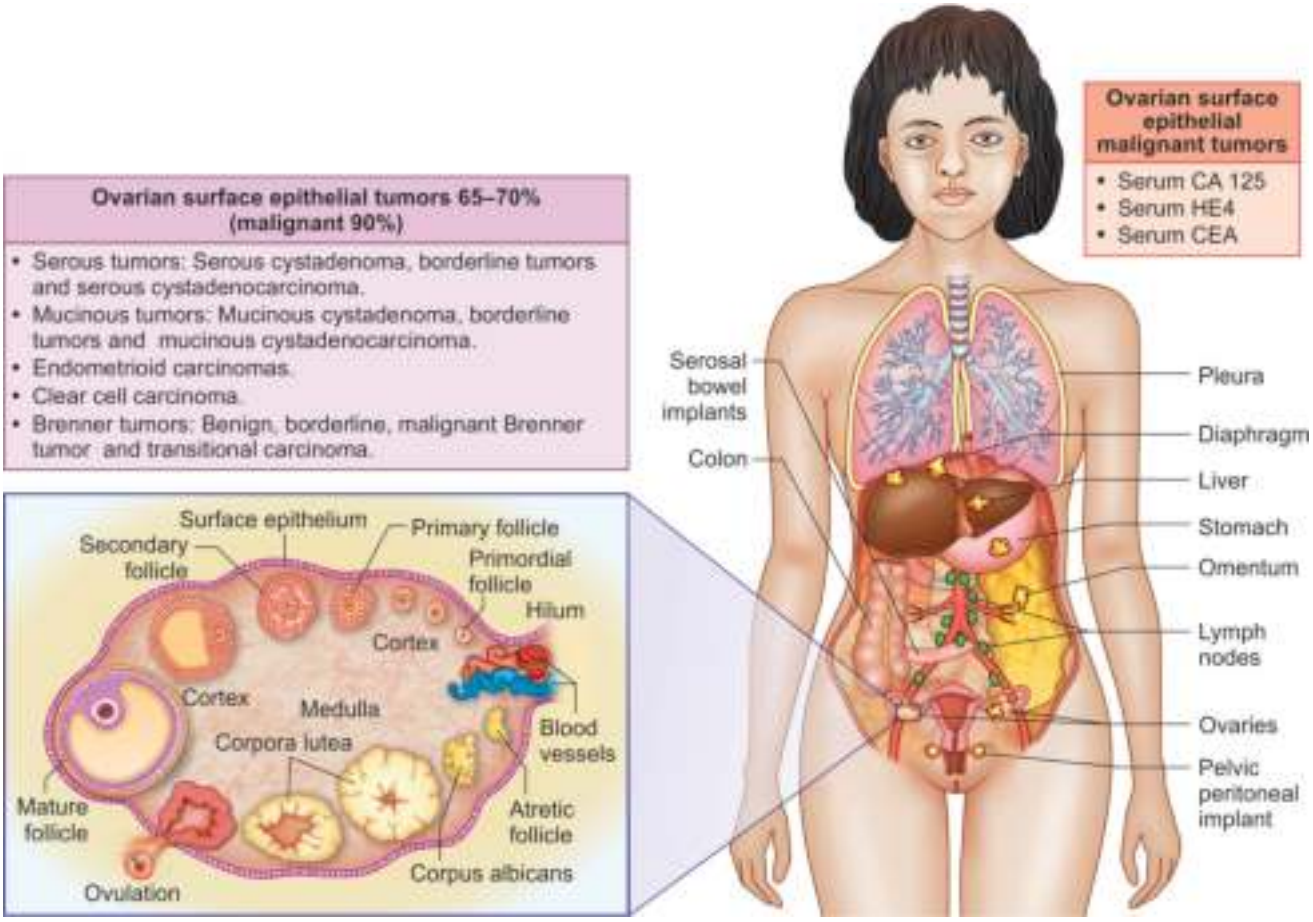

Fig. 24.73: Metastases of surface epithelial ovarian carcinoma to various organs.

Table 24.37 Mode of spread of surface epithelial carcinomas of ovary

Surface Epithelial Carcinoma of Ovary	Metastases to Organs
Direct extension of tumor	
Serous cystadenocarcinoma or mucinous cystadenocarcinoma or endometrioid carcinoma	▪ Omentum or pelvic peritoneum ▪ Serosa of the uterine corpus ▪ Fallopian tube ▪ Ovary (autoimplants) and opposite ovary ▪ GIT (serosa of stomach, sigmoid colon, cecum) ▪ Liver, spleen due to spread from peritoneum ▪ Widespread peritoneal cavity covered by tumor implants
Borderline serous tumors	▪ Peritoneal implants (16–47%) ▪ Psammoma bodies more numerous in noninvasive carcinoma than invasive peritoneal implants
Peritoneal dissemination	
Serous cystadenocarcinoma	Peritoneal involvement most common resulting in ascites
Mucinous cystadenocarcinoma	Peritoneal involvement less common
Endometrioid carcinoma	Peritoneal involvement less common
Lymphatic route	
Papillary serous cystadenocarcinoma	▪ Most common spread by lymphatic route ▪ Contralateral ovary ▪ Lymph nodes (para-aortic, pelvic, hepatic groups) ▪ Omentum peritoneal cavity ▪ An umbilical metastasis ('Sister Joseph's nodule') may be the first manifestation of the disease
Mucinous cystadenocarcinoma	Rarely spreads by lymphatic route
Hematogenous route	
Papillary serous cystadenocarcinoma	▪ Lungs ▪ Pleural cavity results in pleural effusion

Serous and mucinous cystadenocarcinoma and endometrioid carcinoma: These metastasize to pleura, diaphragm, lymph nodes, liver, stomach, omentum, serosa of bowel, pelvic peritoneal implant and opposite ovary. Mucinous and endometrioid ovarian carcinomas: These have less tendency to early and widespread peritoneal involvement in comparison to serous cystadenocarcinoma. Serous cystadenocarcinoma: It most often spreads by lymphatic route. Mucinous cystadenocarcinoma: It rarely spreads by lymphatic route.

SEROUS SURFACE EPITHELIAL TUMORS

Serous surface epithelial tumors account for approximately 20% of all ovarian tumors. Serous surface epithelial tumors of ovary are more common than mucinous tumors. These are most often bilateral with malignant potential in 30% of patients. These occur in women during reproductive age group (20–50 years). On the other hand, mucinous surface epithelial tumors are most often unilateral, therefore, mucinous surface epithelial tumors have better prognosis than serous surface epithelial tumors with bilateral involvement.

- Histologic types include serous cystadenoma, borderline tumor and serous cystadenocarcinoma. The tumor cells from serous borderline tumor may shed from the surface and implant on peritoneum, possibly reflecting multifocal origins, which show positivity for **S-100**. On electron microscopy, cilia are often found in ovarian benign and borderline tumors, but usually absent in serous cystadenocarcinomas.
- The neoplastic cells of serous surface epithelial tumors are always reactive to cytokeratins (CK7+/CK20), also express **EMA** and **CK18**. **S-100 protein** is positive in particularly borderline tumors. **WT1** stains diffusely most ovarian serous carcinomas ascertaining the site of origin of serous cystadenocarcinomas, within the female genital tract. **PAX8** is commonly positive in serous surface epithelial tumors of the ovary. Various monoclonal antibodies have been produced against surface epithelial (mainly serous) ovarian adenocarcinomas such as **CA 125** and **SMO47**.

Serous Cystadenoma of Ovary

Serous cystadenomas are most common ovarian tumors, and account for 66% of benign ovarian epithelial tumors, which occur in adult women in all age groups with mean of 40–60 years of age. Tumor measuring 1–3 cm is usually incidental finding. Large tumor produces nonspecific pelvic pain, discomfort and symptomatic pelvic mass. Patient is treated by unilateral salpingo-oophorectomy or ovarian cystectomy.

Surgical Pathology: Serous Cystadenoma of Ovary

Gross Morphology

- Serous cystadenomas of ovary are unilateral in majority of women and bilateral in 10–20% of cases.
- Tumor may be unilocular or multilocular cysts measuring 10–15 cm and filled with clear serous fluid.
- Cyst is either covered by smooth glistening capsule or partly by papillary excrescences (Fig. 24.74A and B).

Light Microscopy

- Serous cystadenoma of ovary is composed of fibrovascular core lined by pseudostratified single layer ciliated tall columnar epithelium similar to seen in fallopian tube epithelium, with round nuclei without atypia and mitoses. The columnar cells lining cyst contain mucin.
- There is presence of psammoma bodies with concentric layers of calcification (calcification of necrotic cells) in the fibrovascular core in 30% of cases. It has been suggested that a serous cystadenoma can be diagnosed only if the tumor measures more than one centimeter in diameter.
- A recent study indicates that the cells lining the cysts in most serous cystadenomas are polyclonal and therefore, non-neoplastic (Fig. 24.74C).

Immunohistochemistry Technique

Serous cystadenoma of ovary shows positivity for p16 epithelial marker.

Borderline Serous Tumor of Ovary

Approximately 10% of ovarian surface epithelial tumors are borderline low malignant potential. These tumors are predominantly cystic and seen in perimenopausal women. Borderline serous tumor remains confined to the ovary. Rarely, tumor cells may shed from the ovarian surface and implant on peritoneum, possibly reflecting multifocal origin.

Surgical Pathology: Borderline Serous Tumor of Ovary

Gross Morphology

- Borderline serous tumor of ovary tends to have fine, friable, and exuberant papillary projections on the internal and external surfaces of the cyst in 70% of tumors in contrast to the smooth-walled cysts of serous cystadenoma.
- Noninvasive desmoplastic implants are firm in consistency and are covered by an inflammatory exudate in 20% of cases.
- Thorough sampling of the primary tumor for histologic examination is essential to rule out tumor invasion.
- Recent data suggests that at least two sections per centimeter are required to confidently exclude tumor invasion.

Light Microscopy

- Borderline serous tumor is of ovary composed of extensive epithelial stratification, tufting (budding), and detachment of individual tumor cells and cell clusters in addition to small or large papillary branching.
- Stratification and tufting in at least 10% of the tumor warrant the diagnosis of borderline serous tumor.
- The cells in borderline serous tumor show features of epithelial and occasionally mesothelial differentiation.
- Ciliated cells resembling fallopian tubes are demonstrated in 33% of cases. The nuclei resemble those present in serous cystadenoma with slight nuclear atypia. The nuclei are ovoid or round with fine chromatin and nucleoli and basal located. Mitoses rarely exceed 4/10 high power fields.
- Psammoma bodies are demonstrated in ≤50% of cases.
- Autoimplants are demonstrated on the ovarian surface and inbetween exophytic surface papillae. Autoimplants range from 0.1 to 2.5 cm in size in 66% of cases (Fig. 24.75).

Immunohistochemistry Technique

S-100 protein is positive in borderline serous tumors.

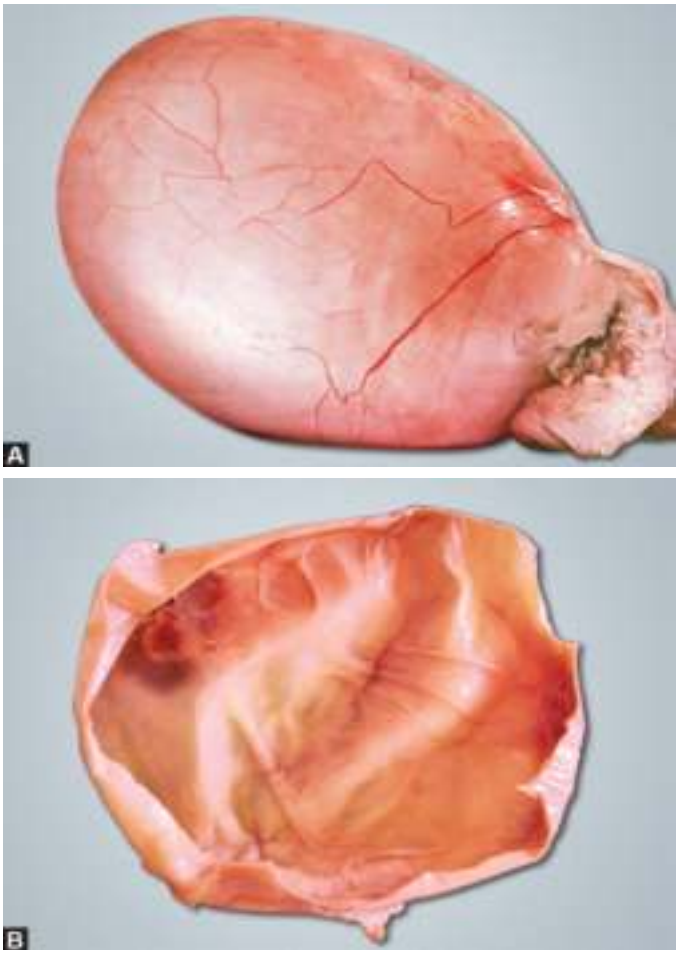

Fig. 24.74: (A) Serous cystadenoma, (B) cut opened unilocular, thin-walled cyst was containing clear fluid.

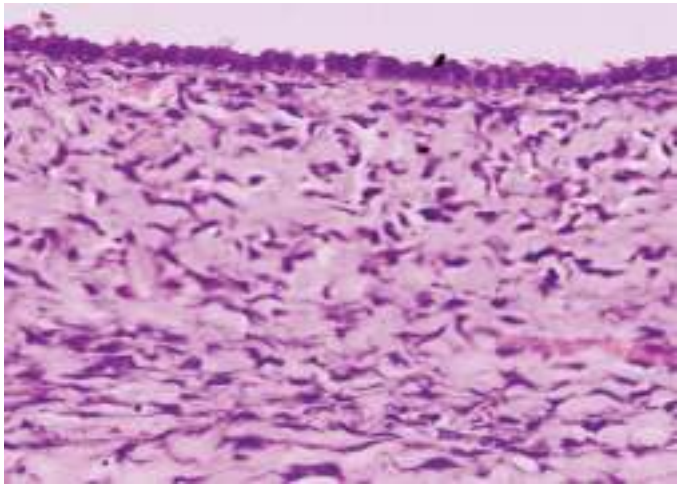

Fig. 24.74C: Serous cystadenoma of ovary. Tumor is composed of fibrovascular core lined by single layer ciliated tall columnar epithelium similar to fallopian tube epithelium, without atypia (100X).

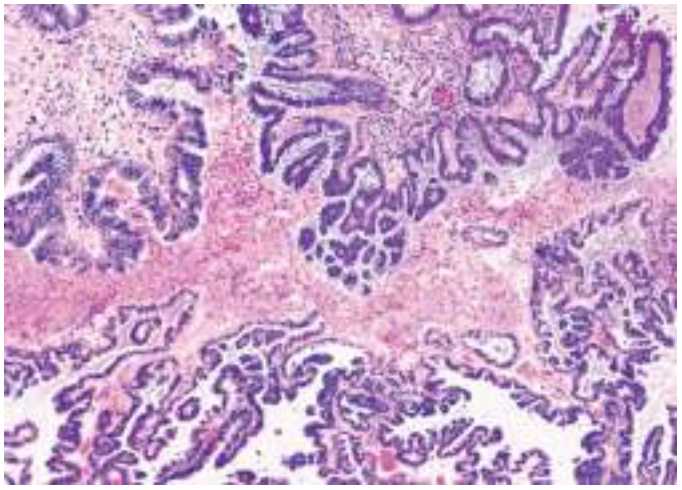

Fig. 24.75: Serous borderline tumor. Tumor shows nuclear atypia and increased mitotic activity. It is confined to be ovary (100X).

Serous Cystadenocarcinoma of Ovary

Serous cystadenocarcinoma accounts for approximately 50% of ovarian carcinomas, which is most often bilateral, solid and cystic ovarian masses. The diagnostic criteria of malignancy are stromal invasion.

- Presence of psammoma bodies in a patient with ascites is most compatible with the diagnosis of papillary serous cystadenocarcinoma of the ovary.
- Tumor most often occurs in the sixth and seventh decades of life. Patient undergoes rapid deterioration associated with fatal outcome.
- Patient presents with abdominal pain and distension due to ascites or bulky abdominal tumor, dysuria and bleeding per vagina.
- Peritoneal carcinomatosis is most demonstrated due to serous cystadenocarcinoma of ovary.
- During surgery, one can find advanced stage disease (stage II or III) of serous cystadenocarcinoma with seeding of surfaces of pelvic and abdominal peritoneum and bowel in majority of cases.

Surgical Pathology: Serous Cystadenocarcinoma of Ovary

Gross Morphology

- Serous cystadenocarcinomas of ovary range from microscopic to 20 cm in diameter. Tumor is typically multilocular with both solid and cystic elements. Tumor has soft, friable papillary projections filling the cavity.
- Stromal invasion by tumor and foci of necrosis are present.
- The multilocular cycts contain serous, turbid or hemorrhagic fluid. Solid areas of the tumor are pink to gray and soft to firm in consistency. Hemorrhage and necrosis are present.
- The outgrowth of tumor cells through the capsule of the tumor is an ominous sign.
- Omental metastases are characterized by firm nodules of variable size with gray-white surfaces. On gross examination, omentum contains microscopic tumor in 20% of cases (Fig. 24.76A).

Light Microscopy

- Serous cystadenocarcinoma of ovary displays complex multilayered papillary and solid patterns, marked cytologic atypia and psammoma bodies.
- Frequently, tumor displays lace-like pattern is characterized by extensive bridging and coalescence of papillae resulting in slit-like spaces. Areas of solid growth, glandular and cribriform patterns are commonly demonstrated.
- Neoplastic cells may be small and uniform focally contain pleomorphic nuclei with obvious malignant features, numerous mitoses and abnormal mitoses invading the stroma.
- There is presence of focal areas with papillary or glandular architecture that establish the diagnosis.
- The presence of tumor nodules on the peritoneum and ascites fluid that contains tumor cells is other sign of malignancy.
- Glandular tissue may be present. Tumor could be demonstrated at any stage of differentiation (Figs 24.76B and 24.77).

Immunohistochemistry Technique

Panel of immunohistochemical markers applied to paraffin-embedded sections of serous cystadenocarcinoma of ovary includes CA 125, CK7, CK20, SMO47, B72.3, CEA, Ber-EP4, PAX8, placental alkaline phosphatase (PLAP), hormone receptors (ER/PR) and WT1 (*see* Table 24.20).

Markers	Expression
CA 125	Positive
CK7	Positive
CK20	Positive
SMO47	Positive
B72.3 (anti-TAG72)	Positive
CEA	Positive
Ber-EP4	Positive
PAX8	Positive
PLAP	Positive
ER/PR	Positive
WT1	Positive
BRCA1	Positive (high-grade tumor)
p53	Positive (high-grade tumor) and negative (low-grade tumor)
p16	Positive (diffuse staining)

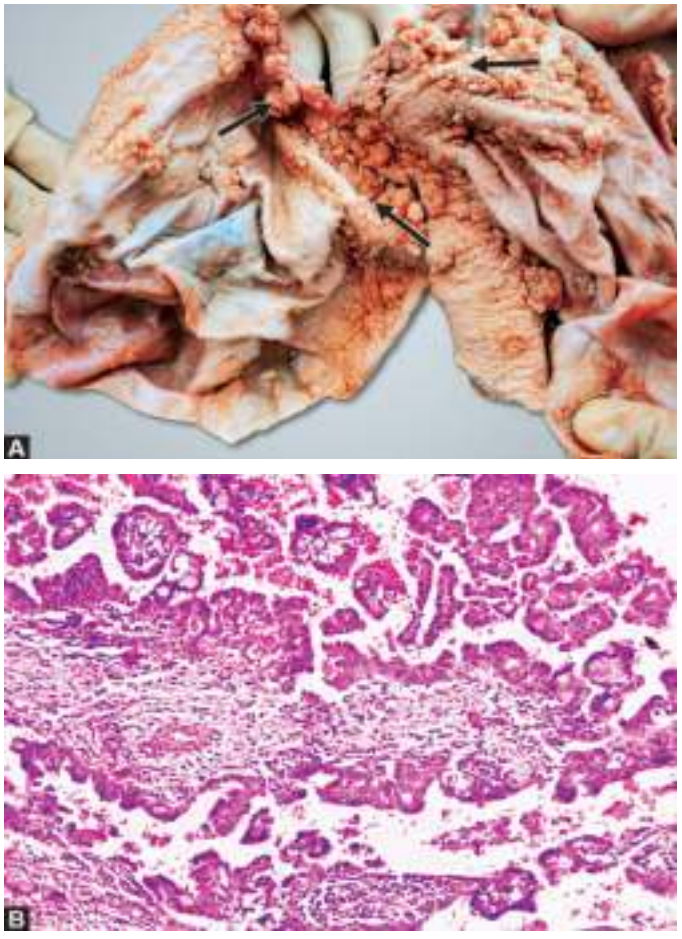

Fig. 24.76: (A) Papillary serous cystadenocarcinoma of the ovary. Note the papillary projections in the lumen of the cyst, and also on its surface. In a benign papillary cystadenoma, the papillae are present only on the inner surface of the cyst (arrows). (B) Papillary serous cystadenocarcinoma of the ovary. The tumor is composed of multilayered cells with solid papillae formation, cytologic atypia and psammoma bodies. Stromal invasion by tumor cells is evident (100X).

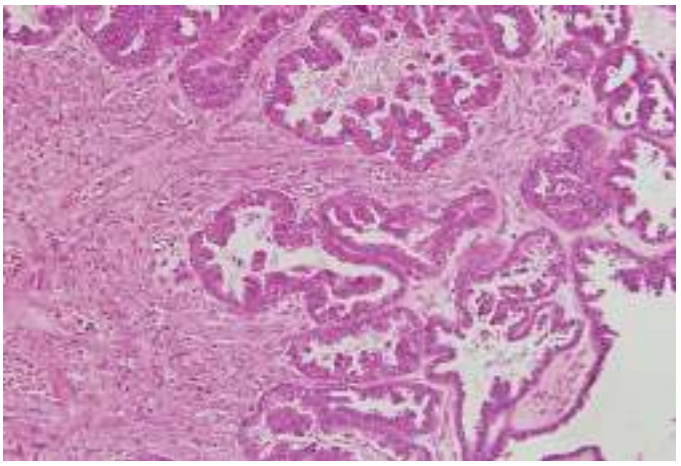

Fig. 24.77: Papillary serous cystadenocarcinoma of the ovary. The tumor is composed of multilayered cells with solid papillae formation, cytologic atypia and psammoma bodies. Stromal invasion by tumor cells is evident (400X).

MUCINOUS SURFACE EPITHELIAL TUMORS

Mucinous surface epithelial tumors of ovary are less common than serous tumors, which constitute 25% of all ovarian tumors. These are more often unilateral in 80% and bilateral in 20% of cases. Mucinous surface epithelial tumors are larger and usually multilocular filled with viscous mucus, which occur in middle-aged women. Like serous tumors, mucinous surface epithelial tumors can be classified as benign mucinous cystadenoma (80%), borderline mucinous tumor (10–15%) and mucinous cystadenocarcinoma (5–10%), and may be lined by endocervical or intestinal type of epithelium. Mucinous cystadenoma and borderline mucinous tumor are noninvasive; and mucinous cystadenocarcinoma is invasive tumor of ovary.

Mucinous Cystadenoma of Ovary

Mucinous cystadenoma of ovary can reach a very large size. Over 80% of mucinous cystadenomas are of intestinal type. Tumor is multilocular cystic tumor ranging from a few cm to 30 cm with a mean of 10 cm filled with viscous gelatinous material. It is most often unilateral in 75%, but bilateral in 25% of cases. It may undergo torsion, rupture, and transformation to borderline mucinous tumor or mucinous cystadenocarcinoma. Surgical excision of mucinous cystadenoma of ovary cures the patient.

Surgical Pathology: Mucinous Cystadenoma of Ovary

Gross Morphology

- Mucinous cystadenoma of ovary has a thick white capsule with smooth surface. Cut surface reveals large multilocular cyst.
- Cut surface shows multiple cystic spaces filled with viscous mucus. In a few cases, it may reach truly massive proportion, exceeding 50 cm in diameter (Fig. 24.78).

Light Microscopy

- Majority of mucinous cystadenomas of ovary are composed of glands and cysts lined by simple nonstratified mucinous epithelium resembling intestinal epithelium containing goblet cells or gastric foveolar-type epithelium with apical vacuolation.
- Tumors predominantly composed of mucinous cystadenoma with <10% of borderline features is diagnosed as mucinous cystadenoma with focal proliferation or focal atypia.
- The majority of tumors contain calcification. Muciphages, luteinized stromal cells and pseudoxanthoma cells are present in 40–50% of cases.
- Dissection of acellular mucin in the stroma of tumor is referred to as '**pseudomyxoma ovarii**' in 10% of cases.
- Multinucleated giant cells may be present in 10% of cases.
- Some mucinous cystadenomas can be admixed with Brenner tumor component. Histology of mucinous cystadenoma of ovary is shown in Fig. 24.79.

Borderline Mucinous Tumor of Ovary

Borderline mucinous tumor of ovary is analogous to borderline serous tumor. Most recent studies established 100% survival in these patients. It is important to rule out metastatic ovarian carcinomas arising from biliary tract, pancreas and cervix.

Surgical Pathology: Borderline Mucinous Tumor of Ovary

Gross Morphology

- Borderline mucinous tumor of ovary is large multicystic tumor with a smooth capsule and usually unilateral.
- Tumor measures 20–22 cm in diameter. Cut surface reveals multilocular tumor filled with mucinous material.

Light Microscopy

Mucinous borderline tumor of ovary is lined by stratified, proliferative gastrointestinal-type mucinous epithelium exhibiting tufted and villonodular or papillary intraglandular growth with mild to moderate nuclear atypia with mitotic activity confined to epithelium; and by definition, stromal invasion by tumor cells absent (Fig. 24.80).

Mucinous Cystadenocarcinoma of Ovary

Mucinous cystadenocarcinoma of ovary accounts for 10% of malignant ovarian tumors. It occurs most often unilateral, and multilocular cysts.

- Largest tumor measures 25 cm. Thin-walled tumor is containing mucinous fluid. Tumor most often occurs in perimenopausal women.
- Approximately 5% of women with mucinous cystadenocarcinomas of ovary present with pseudomyxoma peritonei, known as 'jelly belly', is a condition characterized by filling of peritoneal cavity with pool of mucin due to peritoneal tumor implants.

Fig. 24.78: Mucinous cystadenoma of the ovary. Tumor shows multiple cystic spaces filled with viscous mucus.

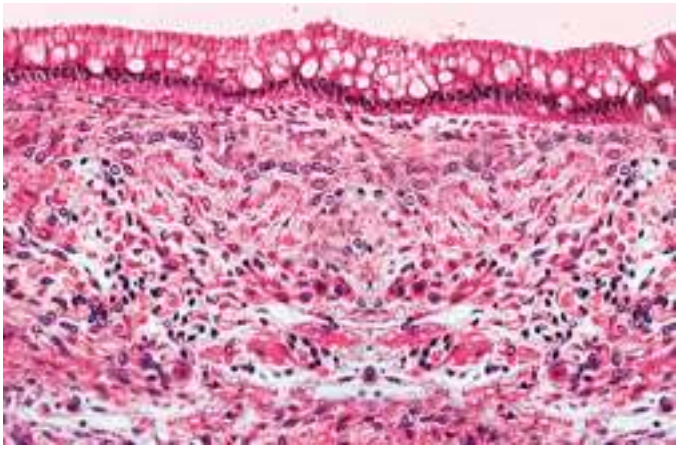

Fig. 24.79: Mucinous cystadenoma of the ovary. Tumor is composed of glands and cysts lined by simple nonstratified mucinous epithelium resembling intestinal epithelium containing goblet cells or gastric foveolar-type epithelium with apical vacuolation. Tumor composed predominantly of mucinous cystadenoma with <10% of borderline features is diagnosed as mucinous cystadenoma with focal proliferation or focal atypia (100X).

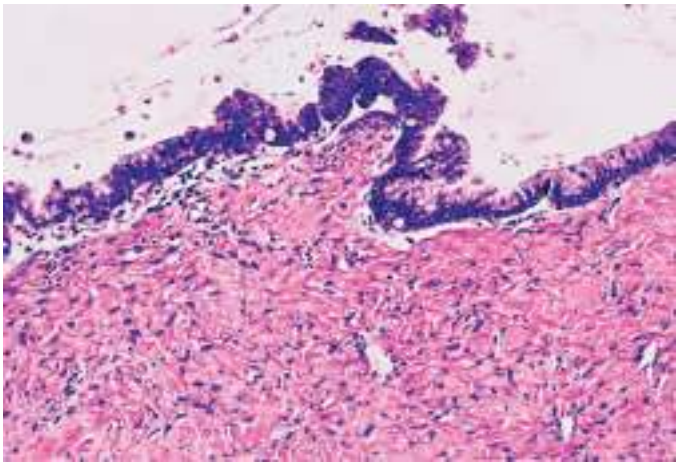

Fig. 24.80: Mucinous borderline tumor of ovary. Tumor is showing varying degree of nuclear atypia and increased mitotic activity confined to epithelium. There is no invasion of stroma by tumor cells (100X).

- Most mucinous cystadenocarcinomas associated with pseudomyxoma peritonei are metastatic in origin. It is worth mentioning that pseudomyxoma peritonei may also occur in mucocele of appendix. Accumulated mucinous contents may cause intestinal adhesions resulting in fatal outcome.
- Mucinous cystadenocarcinomas rarely spread via lymphatic route. These are clinically silent; hence the majority of patients have advanced metastatic disease at diagnosis.

Molecular Genetic Alterations: Mucinous Cystadenocarcinoma of Ovary

- K-RAS mutations have been detected in mucinous cystadenocarcinomas, adjacent mucinous cystadenoma and borderline mucinous tumor of ovary.
- Ovarian mucinous cystadenomas express several mucin genes (MUC2, MUC3 and MUC17), these are characteristic of mucinous carcinomas irrespective of their tissues of origin.
- Because primary ovarian mucinous cyst adenocarcinomas often display intestinal-type of differentiation, these express homeobox transcription factors CDX1, CDX2 and LGALS4 (galectin 4), which encode an intestinal cell surface adhesion molecule that is overexpressed in intestinal carcinomas.
- Galectin 4 (LGALS4) is not expressed by normal ovarian surface epithelium, but it is overexpressed in mucinous cystadenoma, borderline mucinous tumor and mucinous cystadenocarcinoma.

Surgical Pathology: Mucinous Cystadenocarcinoma of Ovary

Gross Morphology

Mucinous cystadenocarcinoma of ovary is large unilateral multilocular tumor with smooth white capsule. Cut surface shows multiple cystic spaces filled with mucinous fluid. Tumor may contain solid areas and foci of necrosis and hemorrhage (Fig. 24.81).

Light Microscopy

Frank stromal invasion by tumor cells of mucinous cystadenocarcinoma is demonstrated in histological sections. Two patterns of invasion are recognized—expansile and destructive.

- **Expansile pattern of invasion:** Tumor shows multilayered atypical epithelial cells arranged in crowded glandular fashion, a little stroma and sometimes a cribriform architecture.
- **Destructive pattern of invasion:** Tumor shows single gland or individual atypical cells invading >3 mm in two linear dimensions or >10 mm in 2 areas (Fig. 24.82A and B). Mucinous cystadenocarcinoma of ovary should be differentiated from metastatic colorectal adenocarcinoma metastasizing to ovaries.

Immunohistochemistry Technique

Ovarian mucinous cystadenocarcinomas show positivity with CA 125, CK7 and CEA. Metastatic colorectal adenocarcinomas show positivity with CK20 and CEA.

Markers	Expression
▪ CA 125	▪ Positive
▪ CK7	▪ Positive
▪ Carcinoembryonic antigen (CEA)	▪ Positive
▪ CD29	▪ Negative/positive (focal staining)
▪ CDX2	▪ Negative/positive (focal staining)

Clinical Course and Treatment

Patients with stage I mucinous cystadenocarcinoma displays expansile invasive growth have survival in 90%

Fig. 24.81: Mucinous cystadenocarcinoma of ovary. Cut surface of tumor shows multilocular cysts containing mucinous material. Solid areas are malignant.

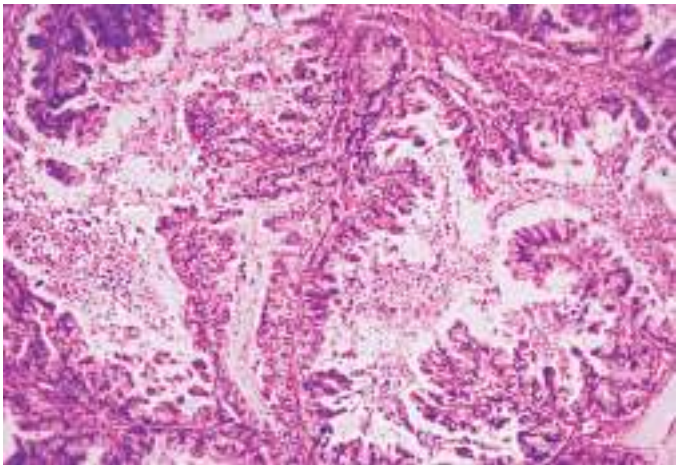

Fig. 24.82A: Mucinous cystadenocarcinoma of ovary. Tumor is multilayered atypical epithelial cells arranged in crowded glandular fashion, a little stroma and sometimes a cribriform architecture (400X).

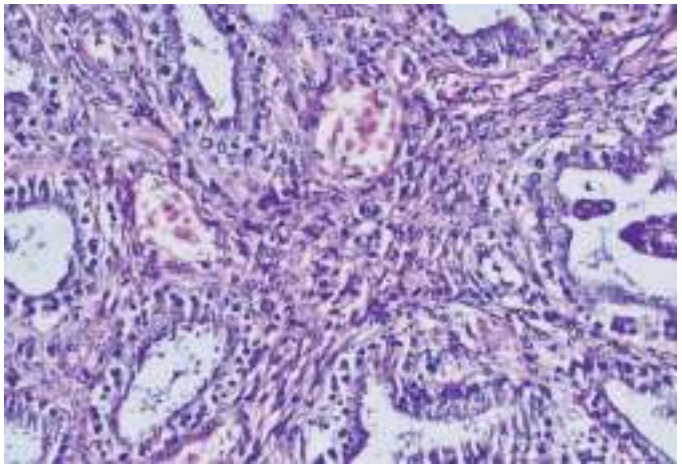

Fig. 24.82B: Mucinous cystadenocarcinoma of ovary. Tumor is composed of cystic spaces lined by atypical tall columnar cells with abundant intracytoplasmic mucin. The tumor cells are arranged in round or crowded glandular fashin with little stroma. Tumor cells exhibit stratification. Tufting and papillary formation with variable cytologic atypia. Tumor demonstrates both intracellular and extracellular mucin (400X).

of cases. Patients are treated with platinum-paclitaxel. Advanced disease is associated with fatal outcome.

Pathology Pearls: Metastatic Mucinous Carcinoma to Ovaries

- Metastatic mucinous carcinomas most often involve bilateral ovaries.
- Metastatic deposits are demonstrated on the ovarian surface and superficial cortex in a nodular or infiltrative haphazard pattern of stromal invasion.
- Some metastatic mucinous carcinomas are derived from the colorectum, pancreatobiliary tract, appendix and endocervix.
- Sometimes, metastatic mucinous carcinomas present in the ovary may resemble occult primary.
- Immunohistochemistry technique plays an important role in diagnosing primary and metastatic mucinous carcinomas.
- Distinction between primary and secondary colorectal mucinous carcinomas in the ovary is given in Table 24.38.

ENDOMETRIOID ADENOCARCINOMA

Endometrioid adenocarcinoma of ovary histologically resembles well differentiated carcinoma of endometrium. Majority of endometrioid tumors of the ovary are carcinomas. Squamous differentiation may be demonstrated in all types of endometrioid tumors.

Table 24.38 Distinction between primary and secondary colorectal mucinous carcinomas in the ovary

Feature	Primary Mucinous Carcinoma of Ovary	Metastatic Mucinous Colorectal Carcinoma in Ovary
Extraovarian disease	Usually absent (stage 1)	Often present (implants on peritoneum and omentum)
Gross morphology		
Ovary involvement	Unilateral (95%)	Bilateral (65%)
▪ Size of tumor ▪ Capsule ▪ Cut surface ▪ Presence of tumor	▪ Large tumor (mean 21 cm) ▪ Smooth capsule ▪ Multicystic tumor with solid foci ▪ Within ovarian stroma	▪ Small tumor (mean 2–18 cm) ▪ Smooth capsule ▪ Nodular to multicystic tumor ▪ On surface, superficial cortex and within ovarian stroma
Histologic features		
Tumor cells arrangement	▪ Well differentiated mucinous carcinoma forming crowded glandular/ cribriform pattern with little stroma ▪ Destructive pattern shows single gland or individual atypical cells	▪ Mucinous epithelium forming glandular pattern with nuclear atypia ▪ Garland pattern of glands lining cystic spaces, which contain dirty necrosis (abundant karyorrhectic debris)
Immunohistochemistry		
Immunohistochemistry is a diagnostic tool to establish diagnosis		
Markers	**Expression**	**Markers** / **Expression**
Primary mucinous cystadenocarcinoma of ovary

- Endometrioid adenocarcinoma of ovary is a surface epithelial tumor arising from the coelomic epithelium, which constitutes 10% of the malignant ovarian tumors affecting perimenopausal age group. Approximately 10–20% of cases are associated with endometriosis and endometrial carcinoma. Benign endometrioid tumors (adenofibromas/cystadenofibromas) are rare.
- Endometrioid adenocarcinoma of ovary is composed of endometrial glands arranged in fibrous stroma, which is distinguished from endometriosis by lack of associated endometrial stroma and hemosiderin-laden macrophages.

Molecular Genetic Alterations

Molecular genetic studies have revealed that endometrioid carcinoma of ovary have similarities with, and differences from their uterine endometrioid carcinomas. Both ovarian and uterine endometrioid carcinomas demonstrate mutations in PTEN, PIK3CA and CTNNB1 genes. Primary ovarian endometrioid carcinoma demonstrates mutations in PTEN, PIK3CA, CTNNB1, TP53 and mismatch repair genes.

Molecular Genetic Alterations: Endometrioid Carcinoma of Ovary

- PTEN gene mutation
- PIK3CA gene mutation
- Mismatch repair gene mutation
- TP53 gene mutation (high-grade tumor)
- CTNNB-1 gene mutation (low-grade tumor showing squamous differentiation)

Clinical Features

Ovarian endometrioid adenocarcinoma affects women in fifth to sixth decades of life. Patient presents with abdominal distension and pain in pelvic and abdomen; and abnormal vaginal bleeding.

Surgical Pathology: Endometrioid Adenocarcinoma of Ovary

Gross Morphology

Endometrioid adenocarcinoma of ovary has an outer smooth surface. Cut surface reveals solid and cystic areas in contrast to serous and mucinous tumors. Cystic areas are filled with friable soft masses and hemorrhagic greenish turbid fluid. Less, commonly, the tumor is solid with extensive hemorrhage and necrosis. Tumors arising in endometriotic cyst may display cysts with chocolate-colored fluid. Visible papillary formations are usually absent or inconspicuous. It is mostly unilocular cystic tumor containing turbid brown fluid.

Light Microscopy

- Endometrioid adenocarcinoma of ovary resembles endometrial adenocarcinoma.
- Endometrioid adenocarcinoma of ovary has destructive infiltrative growth pattern. Most tumors are well differentiated, with or without papillary formations.
- Tumor is composed of angulated glands with and infiltrative pattern, jagged irregularly spaced and unevenly shaped nests and solid sheets.
- Presence of confluent glandular proliferation exceeding 5 mm (the limit of microinvasion) is termed 'expansile invasion'.
- Some tumors may show squamous cell differentiation in 50% of cases. Mitotic figures are commonly demonstrated. Histology of ovarian endometrioid adenocarcinoma is shown in Fig. 24.83. FIGO grading system for endometrioid adenocarcinoma of ovary is given in Table 24.39. Similarly, some tumors have foci resembling serous or mucinous carcinomas. Comparison of serous and mucinous and endometrioid carcinomas is given in Table 24.40.

Histochemistry

Mucin present within lumen or surface epithelium is demonstrated by mucicarmine.

Immunohistochemistry Technique	
Neoplastic cells of endometrioid carcinoma show positivity for hormone receptors (ER/PR).	
Marker	**Expression**
Estrogen/progesterone (ER/PR) receptors	Positive (>90%)

CLEAR CELL CARCINOMA OF OVARY

Clear cell carcinoma of ovary (mesonephroid tumor) is the least common tumor. The mean age of patients is between 50 and 55 years. These have strong association of clear cell carcinoma of ovary to ovarian endometriosis (70%) and endometrioid adenocarcinomas. Majority of clear cell tumors of ovary are frank high-grade adenocarcinomas associated with venous thromboembolism (15–45%) and paraneoplastic hypercalcemia.

Prognostic Factors

Staging is the only single prognostic factor for clear cell carcinoma of ovary. Tumor is confined to the pelvis and associated with better prognosis than high-grade serous cystadenocarcinoma of ovary. Advanced stage disease is associated with worse prognosis. Clear cell carcinoma associated with mutation in GPC3 gene located on Xp26 encoding glypican 3 is associated with poor prognosis. Approximately 50% cases have 5-year survival rate, when the tumor is confined to the ovaries.

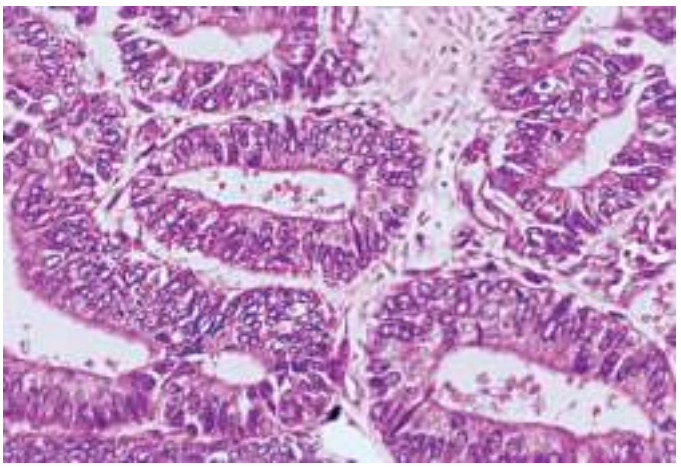

Fig. 24.83: Endometrioid adenocarcinoma of ovary. Tumor is composed of angulated glands with and infiltrative pattern, jagged irregularly spaced and unevenly shaped nests and solid sheets. Presence of confluent glandular proliferation exceeding 5 mm (the limit of microinvasion) is termed 'expansile invasion' (400X).

Table 24.39 FIGO grading system for endometrioid adenocarcinoma of ovary

Grade	Differentiation	Growth Pattern	Histologic Features
Grade 1	Well differentiated tumor	<5% solid growth pattern	Well formed glandular structures
Grade 2	Moderately differentiated tumor	6–50% solid growth	More complex glandular architecture with increased stratification
Grade 3	Poorly differentiated tumor	>50% sold growth	Poorly formed glands with large sheets of cells

Table 24.40 Comparison of primary endometrioid adenocarcinoma, mucinous cystadenocarcinoma and serous cystadenocarcinoma of ovary

Characteristics	Endometrioid Adenocarcinoma	Mucinous Cystadenocarcinoma	Serous Cystadenocarcinoma
Age group	Perimenopausal women	Middle adult age	Reproductive age
Relative frequency	10–25%	5–15% (less common)	60–80% (more common)
Ovary involvement	Bilateral 15–30%	Often unilateral (10–20%)	Often bilateral (30–50%)
Tumor	Solid or cystic	Multilocular cysts	Unilocular cyst
Size	Moderate	Often large size	Moderate size
Fluid content	Hemorrhagic fluid	Mucinous fluid	Serous fluid
Coexistent endometrial hyperplasia, or carcinoma	15–30% of cases associated with endometriosis	Exceptional case	Exceptional case
Torsion	Absent	Absent	Common
Pseudomyxoma peritonei	Absent	Most often present	Absent
Lining epithelium	Columnar, with centrally located nucleus	Columnar, with basally located nucleus	Cuboidal
Mucin	Mucin present in luminal border	Abundant mucin present in cytoplasm	Present only in luminal border
Squamous metaplasia	50% of cases	Exceptional case	Exceptional case
Cilia	Present in rare case	Absent	Frequent
Psammoma bodies	Exceptional case	Exceptional case	30%

Fig. 24.84: Clear cell carcinoma of ovary. Cut surface of tumor shows solid and cystic spongy areas giving honeycomb appearance.

Clinical Features

Patient presents with pelvic or abdominal mass. Clear cell carcinoma of ovary is frequently associated with ovarian or pelvic endometriosis, paraneoplastic hypercalcemia and venous thromboembolism.

Surgical Pathology: Clear Cell Carcinoma of Ovary

Gross Morphology

- Clear cell carcinoma of ovary is usually unilateral with size up to 30 cm (mean 13–15 cm).
- On cut surface, tumor exhibits a combination of solid white-tan to yellowish and thick-walled cystic spongy areas giving honeycomb appearance.
- Multiple yellow fleshy nodules are protruding in the lumen of the cyst reflecting focus of malignant transformation.
- These nodules may be lined by an endometriotic cyst, which typically contains chocolate brown fluid (Fig. 24.84).

Light Microscopy

- Clear cell carcinoma of ovary displays different histologic patterns: tubulocystic, papillary and solid.
- Cystic tumors exhibit small, regular and frequently hyalinized papillae, whereas tubulocystic pattern tumor tends to dominate in the adenofibromatous tumors.
- Tubulocystic pattern of tumor is characterized by varying size tubules and cysts. Cystic variant is more frequently associated with endometriosis. These two variants arise along different pathways.
- Solid pattern of tumor is composed of polygonal to cuboidal and flattened cells with clear slightly granular cytoplasm containing glycogen, mucin, and fat giving signet ring appearance. Some of the nuclei protrude into the lumina, resulting in hobnail configuration. These cells are arranged in solid sheets, tubular and papillary fashion separated by delicate fibrovascular septae or dense fibrotic stroma. The cores of the papillae often exhibit prominent eosinophilic hyalinized bodies (PAS positive) and lack epithelial stratification. In cystic areas, it shows neoplastic cells lining the spaces. Nuclear grade is nearly always regardless of the grading system. Mitotic activity tends to be low exceeding 10/10 HPF (Fig. 24.85).

Histochemistry

Cells may exhibit positivity with periodic acid–Schiff (PAS), diastase-resistant hyaline globules.

Immunohistochemistry Technique

Neoplastic cells of clear cell carcinoma show positivity for HNF-1β, CA 125, CEA, EMA, PAX8, CK7, CAM 5.2, CD15 (LeuM1), vimentin, BCL-2, OC125 and hormone receptors (ER/PR).

Markers	Expression	Markers	Expression
▪ HNF-1β	▪ Positive	▪ CD15 (LeuM1)	▪ Positive
▪ CA 125	▪ Positive	▪ B72.3	▪ Positive
▪ CEA	▪ Positive	▪ Vimentin	▪ Positive
▪ EMA	▪ Positive	▪ BCL-2	▪ Positive
▪ PAX8	▪ Positive	▪ OC125	▪ Positive
▪ CK7	▪ Positive	▪ ER/PR	▪ Negative
▪ CAM 5.2	▪ Positive		

Clinical Course and Treatment

Comprehensive surgical staging is essential in the early stage of clear cell carcinoma. Patient is treated by bilateral salpingo-oophorectomy, total hysterectomy, and lymph node dissection. Advanced disease is treated with paclitaxel plus carboplatin chemotherapy. Clear cell carcinoma is resistant to platinum-based chemotherapy, making metastatic disease difficult to treat.

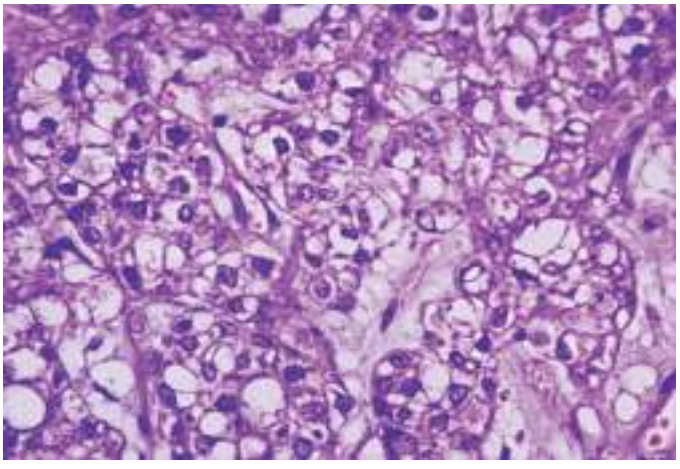

Fig. 24.85: Clear cell carcinoma of ovary. It shows large tumor cells with clear cytoplasm arranged in solid sheets, tubular and papillary fashion (400X).

BRENNER TUMOR OF OVARY

Brenner tumors account 10% of ovarian surface epithelial neoplasms and 1–2% of all ovarian tumors. Nearly all Brenner tumors are benign and uncommon include borderline and malignant forms. Brenner tumor occurs in premenopausal (70%) and postmenopausal (0–1%) women. Some cases are accompanied by signs of hyperestrinism, such as uterine bleeding from endometrial hyperplasia in the postmenopausal women.

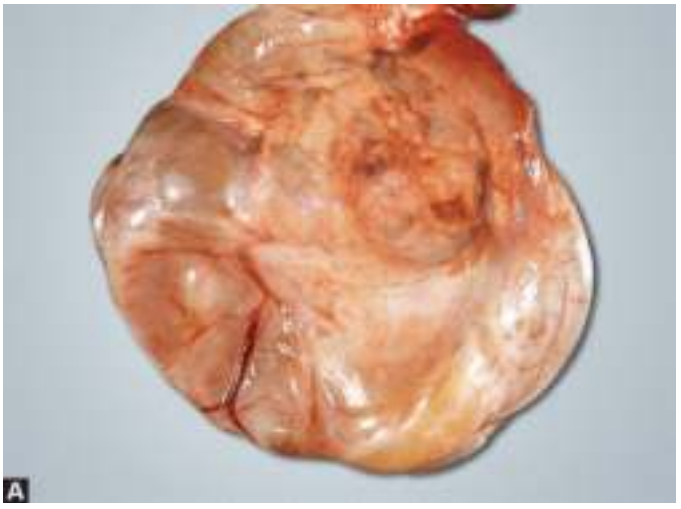
Surgical Pathology: Brenner Tumor of Ovary

Gross Morphology

Brenner tumor of ovary is encapsulated with solid consistency variable in size usually unilateral, firm, white or yellowish resembling fibroma but contain small cystic areas filled with opaque, viscous, yellowish-brown fluid (Fig. 24.86A and B).

Light Microscopy

- **Benign Brenner tumor:** Tumor is composed of uniform population of stratified transitional cells with sharp outlines, ovoid nuclei displaying longitudinal groove (**coffee bean appearance**) arranged in well-formed solid nests, resembling transitional epithelium of urinary bladder. Tumor cells are surrounded by abundant dense, fibrous stroma. Most often, mucinous glands are present in the center and scattered throughout the dense fibrous stroma, resembling that of an ovary. Such neoplasm may have hormonal activity.
- **Borderline Brenner tumor:** This variant has low malignant potential. Tumor is composed of cysts and papillae. These papillae are projecting in cystic spaces and lined by stratified lining. Stromal invasion by tumor cells is absent.
- **Malignant Brenner tumor:** Tumor is composed of atypical large pleomorphic cells arranged in large nests with irregular borders. Stromal invasion by tumor cells is present.
- **Transitional cell carcinoma:** Tumor closely resembles transitional cell carcinoma of urinary bladder with same grading (Fig. 24.87).



Histochemistry

The tumor cells of Brenner tumor of ovary may contain glycogen, mucin, and lipid. Lipid is present in larger amounts in the stromal cells in the cases accompanied by hyperestrinism.

Immunohistochemistry Technique

The tumor cells of Brenner tumor of ovary are reactive to cytokeratin, EMA, CEA (the latter also present in the lumen of the cysts), CA 19-9, uroplakin III and thrombomodulin.

Markers	Expression
▪ Cytokeratin	▪ Positive
▪ EMA	▪ Positive
▪ CEA	▪ Positive
▪ CA 19-9	▪ Positive
▪ Uroplakin III	▪ Positive
▪ Thrombomodulin	▪ Positive

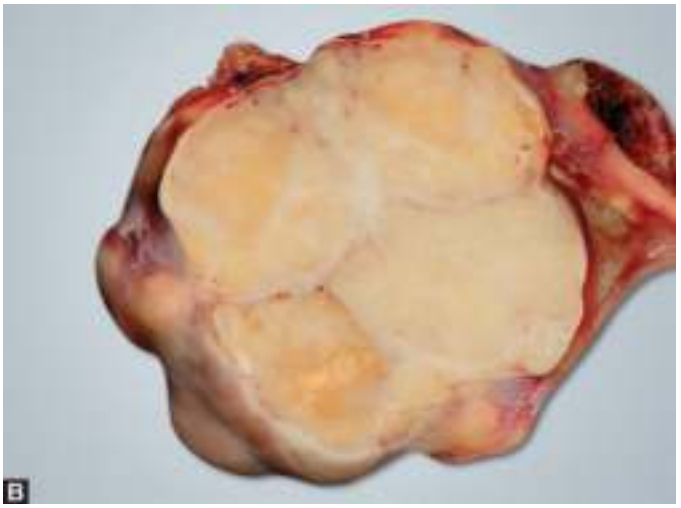


Fig. 24.86A and B: Brenner tumor of ovary. (A) Tumor is encapsulated solid tumor, (B) cut surface is white or yellow with firm consistency.

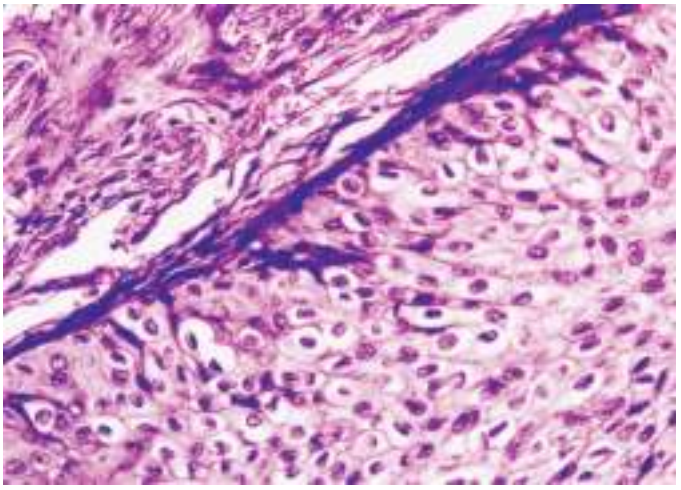

Fig. 24.87: Benign Brenner tumor of ovary. It shows solid and cystic nests of epithelial cells with oval nuclei, small nucleoli in a fibrous stroma. Many of these cells exhibit longitudinal grooves (400X).

Table 24.41 Recent 2020 World Health Organization of germ cell tumors of the ovary

Germ Cell Tumors
▪ Dysgerminoma • Classic dysgerminoma • Dysgerminoma with syncytiotrophoblastic cells • Dysgerminoma with yolk sac element • Anaplastic dysgerminoma
▪ Yolk sac tumor (endodermal sinus tumor) (extraembryonic differentiation) • Polyvesicular vitelline yolk sac tumor • Hepatoid yolk sac tumor • Glandular yolk sac tumor
▪ Choriocarcinoma (extraembryonic differentiation)
▪ Embryonal carcinoma (embryonic differentiation)
▪ Teratoma • Teratoma (embryonic differentiation) • Mature cystic teratoma (dermoid cyst) • Mature solid teratoma with malignant transformation • Immature teratoma • Monodermal and highly specialized types ◆ Struma ovarii (with thyroid tissue) ◆ Carcinoid tumor (e.g. insular, trabecular, stromal carcinoid, mucinous carcinoid)
▪ Polyembryoma
▪ Neuroectodermal tumors
Germ Cell-Sex Cord-Stromal Derivatives
▪ Gonadoblastoma with dysgerminoma and other germ cell tumors
▪ Germ cell-sex cord-stromal tumor with dysgerminoma and other germ cell tumors

Contd...

Clinical Course and Treatment

Benign and borderline Brenner tumors of ovary have a benign clinical course. Complete excision (unilateral oophorectomy, bilateral oophorectomy or total hysterectomy) is curative. About 80% of malignant Brenner tumors are in stage I and have an excellent prognosis after surgery.

GERM CELL TUMORS OF OVARY

Germ cell tumors constitute approximately 25% of all ovarian tumors, which are the most common tumors in children, accounting for 60–70% of all ovarian tumors in these age groups especially mature cystic teratomas.

- Germ cell tumors of ovary include dysgerminoma, germ cell tumors with embryonic differentiation (embryonal carcinoma, teratoma) and extraembryonic differentiation (yolk sac tumor, choriocarcinoma).
- There may be mixed germ cell tumor (dysgerminoma + benign cystic teratoma). Except mature cystic teratomas, the proportion of malignant germ cell tumors (especially immature teratomas, yolk sac tumors, and dysgerminomas) is much greater than in adults. Recent 2020 WHO of germ cell tumors of the ovary is given in Table 24.41.

DYSGERMINOMA OF OVARY

Dysgerminoma of ovary is composed of germ cells that exhibit morphologic, structural and histochemical similarity to primordial germ cell. The germ cells are considered to be arrested at an early and sexually stage of differentiation. Tumor is analogous to testicular seminoma. Dysgerminoma accounts for 50% of germ cell tumors and 2% of all ovarian tumors and affects 10–30 years of age group especially second and third decades. Dysgerminoma is extremely radiosensitive, and most often unilateral in 80–90% of cases. Incidence is more in Turner's syndrome, gonadal dysgenesis and pseudohermaphroditism.

Clinical Features

Patient presents with abdominal/pelvic pain followed by an abdominal mass, fever, vaginal bleeding and occasionally ascites. Dysgerminoma is usually unilateral, and may be bilateral in 10–20% of cases.

Surgical Pathology: Dysgerminoma of Ovary

Gross Morphology

- Dysgerminoma affects right ovary (50%), left ovary (35%) and bilateral (15%). There is increased prevalence of bilateral dysgerminomas associated with gonadoblastoma.
- Pure dysgerminoma is a solid tumor, round, oval or lobulated with a smooth glistening fibrous capsule ranging from a few centimeters in diameter to large size measuring 50 cm, which fills the pelvic and abdominal cavities. Tumors weighing 5 kg have been documented. The capsule is usually intact, but may be ruptured in case of large tumor.
- The consistency of dysgerminoma varies from firm and rubbery in small tumors and soft in large tumor. On cut surface, tumor is solid and varying from gray-pink to light tan.
- Cut surface of large tumor shows red brown or yellow discoloration due to hemorrhage and necrosis.
- The presence of cystic areas on cut surface suggests the possibility of teratoma component (mixed germ cell tumor). It is important to do extensive sampling of the tumor (Fig. 24.88).

Light Microscopy

Like testicular seminoma, ovarian dysgerminoma may exhibit following histologic variants described as under.

- **Classic dysgerminoma:** Tumor is composed of large nests of monotonously uniform round or oval cells with centrally located deeply staining nuclei with finely granular chromatin and prominent eosinophilic 1–2 nucleoli, and abundant clear glycogen-filled cytoplasm. Tumor cells are separated by fibrous septa ranging from fine, delicate fibrovascular network to densely hyalinized stroma containing mostly T cells and granulomas (Fig. 24.89).
- **Dysgerminoma with syncytiotrophoblastic element:** Tumor is composed of scattered hCG positive syncytiotrophoblastic cells around proximity to blood vessels or to hemorrhagic foci in 6–8% of tumors. It may be accompanied by serum elevation of hCG and tissue immunoreactivity for this marker. The syncytiotrophoblastic giant cells may form large syncytial mass resembling the syncytiotrophoblast element of choriocarcinoma, but may differ from choriocarcinoma because there is no cytotrophoblast. Presence of choriocarcinoma in association with dysgerminoma is not frequent. There is no evidence that dysgerminoma with syncytiotrophoblastic element is associated with worse prognosis.
- **Dysgerminoma with yolk sac tumor:** Pure dysgerminoma is not associated with elevated levels of serum α-fetoprotein (AFT). The presence of elevated levels of AFT indicates that dysgerminoma contains primary yolk sac tumor or its metastases.
- **Anaplastic dysgerminoma:** Tumor shows increased mitotic activity over 30 mitoses/10 high power fields. This variant is reactive for keratin.

Histochemistry

- The cytoplasm of the tumor cells contains glycogen, which can be demonstrated with the periodic acid–Schiff (PAS) reaction and is removed by diastase digestion. The amount of glycogen in tumor cells is variable, and the glycogen is lost during prolonged fixation with formalin. Hence, PAS reaction may be vary from strong to weak.
- Presence of lipid in tumor cells can be demonstrated in the cytoplasm of tumor cells in frozen tissue stained by Sudan III, Sudan IV, Sudan black and Oil red O stains.

Immunohistochemistry Technique

Neoplastic cells of dysgerminoma are positive for placental alkaline phosphatase (PLAP), CD117, SALL4, D2–40, PAS and OCT4 (POU5F1). SALL4 is highly sensitive and specific for primitive germ cell tumors, including dysgerminoma.

Markers	Expression
PLAP	Positive
CD117(c-KIT)	Positive
SALL4	Positive (nuclear staining)
D2–40 (podoplanin)	Positive (membrane staining)
PAS	Positive
OCT4 (POU5F1)	Positive (nuclear staining)
CAM 5.2	Negative
AE1/3	Negative
EMA	Negative

Molecular Genetic Alterations

Neoplastic cells of dysgerminoma of ovary contain double the amount of DNA in the nuclei as compared to normal somatic cells. Isochromosome 12 has been demonstrated in dysgerminoma as well as seminoma.

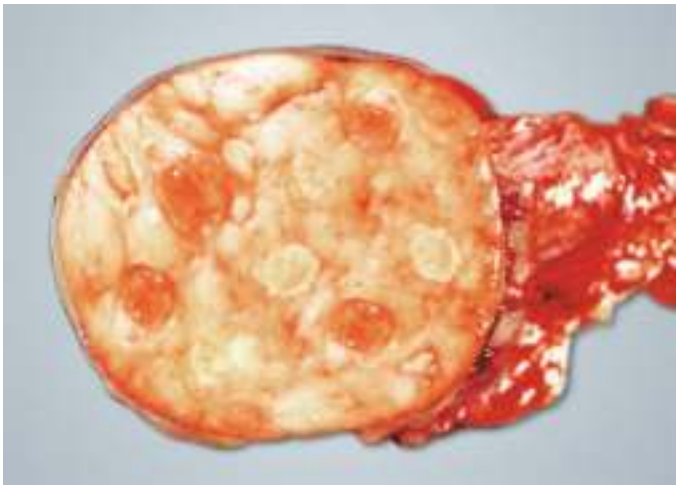

Fig. 24.88: Dysgerminoma of ovary. The tumor has a cream colored, fleshy appearance on its cut surface, with some areas of hemorrhage. This tumor has the same microscopic appearances as a seminoma of the testis.

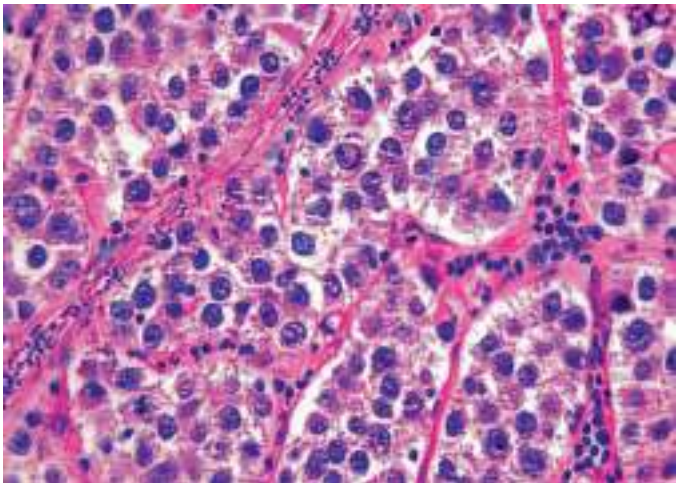

Fig. 24.89: Dysgerminoma of ovary. Tumor is composed of large nests of monotonously uniform round or oval cells with centrally located deeply staining nuclei with finely granular chromatin and prominent eosinophilic 1–2 nucleoli, and abundant clear glycogen-filled cytoplasm. These tumor cells are separated by fibrous septa ranging from fine, delicate fibrovascular network to densely hyalinized stroma containing mostly T cells (400X).

Clinical Course

Dysgerminoma is a rapidly growing malignant tumor capable of local invasion and late metastases. But metastases do not occur in the early course of disease.

- Dysgerminoma usually metastasizes more commonly in the contralateral ovary, retroperitoneal nodes, and peritoneal cavity.
  - Small tumor is freely mobile, and its capsule is usually intact.
  - Large tumor is adherent to surrounding structures. Such tumor may rupture either spontaneously or at operation resulting in spillage of the tumor contents on peritoneum. Involvement of peritoneum is associated with poor survival rate.
- Dysgerminoma can spread via lymphatic route to lymph nodes in the vicinity of the iliac arteries and terminal part of the abdominal aorta, and then to mediastinal and supraclavicular region.
- Dysgerminoma can spread via hematogenous route to liver, lungs and bones. Metastatic tumor showing marked atypia, high mitotic activity and small amounts of stroma with scant lymphocytic infiltration tend to be more aggressive. Primary tumor and its metastases can be demonstrated by CT scan and MRI. Elevated LDH (isoenzyme 1) can be used as serum tumor marker in 95% of cases.

Treatment

Dysgerminoma is extremely responsive to radiotherapy and chemotherapy (cisplatin, etoposide and bleomycin). Prognosis is excellent in 95% of stage I cases, if tumor is unilateral and salpingo-oophorectomy is done. Unfavorable prognostic factors include adhesion of large tumor and presence of metastases.

YOLK SAC TUMOR OF OVARY

Yolk sac tumor of ovary is highly malignant germ cell tumor with extraembryonic differentiation. It is also known as endodermal sinus tumor analogous to endodermal sinus tumor of the testis.

- It is thought to arise from the undifferentiated and multipotential embryonal carcinoma by selective differentiation toward yolk sac or villetine structures, in the same way as nongestational choriocarcinoma differentiates into trophoblastic structures.
- Tumor histologically resembles mesenchyme of the primitive yolk sac. When examined under electronic microscope, the cell of the yolk sac tumor resembles those of the normal human yolk sac.
- Yolk sac tumor of the ovary most often affects children and young women under 30 years of age. It is most commonly encountered in the second and third decades followed by first and fourth decades. It has also been reported in the elderly women.
- Tumor produces α-fetoprotein (AFP). Its detection in the blood is useful both for diagnosis of yolk sac tumor and for monitoring the effectiveness of therapy. Disorders associated with increased AFP levels are given in Table 24.42.

Table 24.42 Disorders associated with increased α-fetoprotein (AFP) levels

Yolk sac tumors of gonads
Pregnancy
Hepatocellular carcinoma
Hepatoblastoma
Cirrhosis
Massive hepatocellular necrosis with regeneration
Chronic hepatitis

Clinical Features

Patient presents with abdominal enlargement and pain abdomen due to rapidly growing pelvic mass. Occasionally, patient may present with acute severe pain abdomen, that simulates ruptured ectopic pregnancy and acute appendicitis. On clinical examination, a tumor mass is usually palpable of considerable size. Untreated cases have poor prognosis with two years survival.

Surgical Pathology: Yolk Sac Tumor of Ovary

Gross Morphology

- Yolk sac tumor of ovary is almost always unilateral. Bilateral involvement of ovaries is a manifestation of metastatic spread of tumor. The tumor is large partly cystic varying in size from 3 to 30 cm in diameter. Most tumors measure >10 cm in diameter and weighs 500 g–5 kg. External surface of tumor is smooth and glistening.
- Tumor is usually encapsulated, round, oval or globular; firm, smooth, or somewhat lobulated.
- Cut surface of tumor shows variegated appearance, partially cystic areas containing gelatinous material, and solid area often containing large foci of hemorrhage and necrosis (grayish brown).

Light Microscopy

- Yolk sac tumor of ovary shows a network of embryonal cells (large cells with prominent nuclei and mitotic activity) and connective tissue structures arranged around blood vessels as the endodermal sinus of rat placenta 'Schiller-Düval bodies' (resembling glomerulus-like structures), which are hallmark of yolk sac tumor.

- Schiller-Düval bodies contain central tissue core containing a longitudinal vessel surrounded by epithelial-like cells into the surrounding capsular sinusoid space. Intracellular and extracellular hyaline globules/droplets (PAS positive) are present in all tumors.
- All the histologic patterns of yolk sac tumor can be observed in the same yolk sac tumor or one or two predominate, which include: (a) microcystic or reticular lined by flat, pleomorphic hyperchromatic nuclei, (b) endodermal sinus, (c) solid, (d) alveolar-glandular, (e) polyvesicular vitelline, (f) myxomatous, (g) papillary, (h) macrocystic, (i) hepatoid, and (j) glandular or primitive endodermal (intestinal). Histology of yolk sac tumor is shown in Fig. 24.90A and B.

Immunohistochemistry Technique

Neoplastic cells of yolk sac tumor of ovary show positive for placental alkaline phosphatase (PLAP), SALL4, CAM 5.2, AE1/AE3, α-fetoproteins (AFP), α_1-antitrypsin, and negative for CD117 (c-KIT) and D2–40 (podoplanin).

Markers	Expression
PLAP	Positive
SALL4	Positive
CAM 5.2	Positive
AE1/AE3	Positive
α-Fetoproteins	Positive (not specific marker)
α_1-Antitrypsin	Positive
CD117	Negative
D2–40	Negative

Clinical Course

Yolk sac tumor is a highly malignant tumor. It metastasizes early and invades the surrounding structures.

- Local invasion and intra-coelomic spread of tumor frequently results in extensive involvement of the abdominal cavity.
- Tumor metastasizes first via lymphatic route to para-aortic lymph nodes and then mediastinal and supraclavicular lymph nodes.
- Tumor later spreads via hematogenous route to lungs, liver and other organs.

Treatment

Patients are treated with conservative surgery (unilateral salpingo-oophorectomy) and adjuvant multiagent combination chemotherapy. Recurrence is common even after surgical excision of the tumor.

- Serum AFP analysis is useful in diagnosing and monitoring of yolk sac tumor to therapeutic response.
- Serum α_1-antitrypsin can be used to monitor therapeutic response of tumor, but it is inferior to serum AFP.

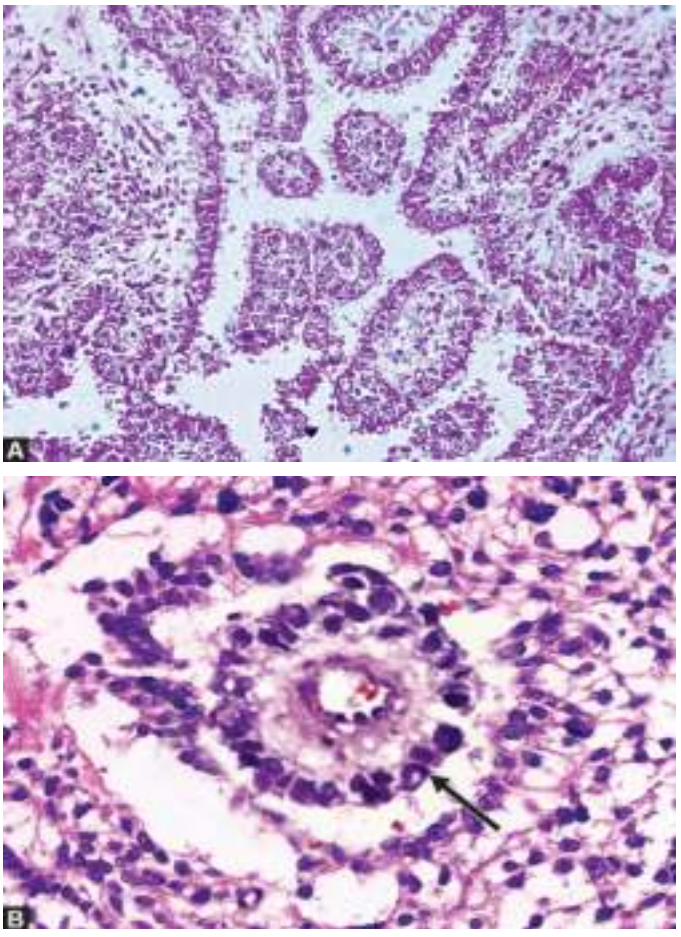

Fig. 24.90: Yolk sac tumor of ovary. (A) The endodermal sinus pattern of yolk sac tumor is characterized by the presence of irregular interconnecting labyrinthine-like spaces and Schiller-Düval bodies, several of which are nicely illustrated (200X), (B) tumor is showing Schiller-Düval bodies (arrow) (400X).

EMBRYONAL CARCINOMA OF OVARY

Embryonal carcinoma of ovary is highly malignant and least differentiated germ cell tumor. Embryonal carcinoma usually affects children and young women (mean age 15 years).

- Tumor may differentiate either to somatic (teratomatous tumors of various degrees of differentiation) or extraembryonal structures, forming yolk sac or vitelline (yolk sac tumor) or trophoblastic elements (choriocarcinoma).
- Tumor is considered to be homologous with its testicular counterpart. It is usually combined with other germ cell tumor component, most frequently yolk sac tumor and forms a part of mixed germ cell tumor. Tumor has been observed in association with gonadoblastoma.
- At surgery, there is extension of embryonal carcinoma of ovary beyond the ovary in 40% of cases. Tumor is generally large with a median diameter of 17 cm.

Clinical Features

Patient presents with ovarian mass (average 17 cm), precocious puberty (47%), vaginal bleeding (33%), amenorrhea (7%) and hirsutism. Embryonal carcinoma of ovary may synthesize AFP, even when it is not combined with yolk sac tumor, but the serum AFP levels are slightly raised. When embryonal carcinoma contains syncytiotrophoblastic element, it is usually combined with choriocarcinoma, which synthesizes hCG and associated with precocious puberty. A positive pregnancy test is present in almost all such patients due to high serum hCG and its excretion in urine.

Surgical Pathology: Embryonal Carcinoma of Ovary

Gross Morphology

- Because embryonal carcinoma is most often a component of mixed germ cell tumor.
- The gross appearance of the tumor varies to the type and amount of the different components present in the tumor.
- Median diameter of tumor is 17 cm. External surface is smooth and glistening.
- Cut surface of tumor is predominantly solid gray-white, granular and variegated, with extensive areas of necrosis and hemorrhage in large tumor.
- The tumor is variably demarcated from surrounding ovary and structures (Fig. 24.91).

Light Microscopy

- **Primitive and undifferentiated embryonal carcinoma:** Embryonal carcinoma has a similar morphology to the embryonal carcinoma of the adult testis.
  - In its most primitive and undifferentiated form, tumor is composed of solid aggregates of epithelial-like, medium to large polygonal or ovoid cells with prominent vesicular centrally located hyperchromatic nuclei and numerous nucleoli; and pale eosinophilic granular cytoplasm, frequently forming syncytial arrangement and occasionally forming glandular and papillary structures.
  - Mitotic activity is usually brisk. Abnormal mitoses are frequently demonstrated. Pleomorphism is usually marked. Scattered giant cells and multinucleated giant cells are present.
- **Moderately differentiated embryonal carcinoma:** In moderately differentiated embryonal carcinoma, the tumor cells are arranged in solid sheets.
  - Tumor cells tend to line clefts and spaces and form papillary structures. Tumor cells appear more like epithelial cell-like than those of more primitive undifferentiated type. These papillae must be differentiated from perivascular formation demonstrated in yolk sac tumor. Very primitive mesenchymal tissue may be present in conjunction with the epithelial-like component.
  - Tumor cells are cuboidal or columnar in shape tend to form glandular differentiation, but lacking true gland formation.
  - Syncytiotrophoblastic element immediately adjacent to aggregates of embryonal carcinoma cells or lying isolated in the stroma are frequently demonstrated.
  - Areas of hemorrhage and necrosis are usually seen. Tumor cells are immunoreactive for hCG. Embryonal carcinomas largely composed of embryoid bodies are referred to as 'polyembryomas' (Fig. 24.92).

Immunohistochemistry Technique

Neoplastic cells of embryonic cell carcinoma are positive for placental alkaline phosphatase (PLAP), OCT4 (POU5F1), SALL4 and CD30. These demonstrate variable staining for D2–40 (podoplanin) and negative staining for CD117 (c-KIT).

Markers	Expression
▪ PLAP	▪ Positive
▪ OCT4 (POU5F1)	▪ Positive (consistent staining)
▪ SALL4	▪ Positive (nuclear staining)
▪ CD30	▪ Positive
▪ D2–40 (podoplanin)	▪ Positive/negative
▪ CD117 (c-KIT)	▪ Negative

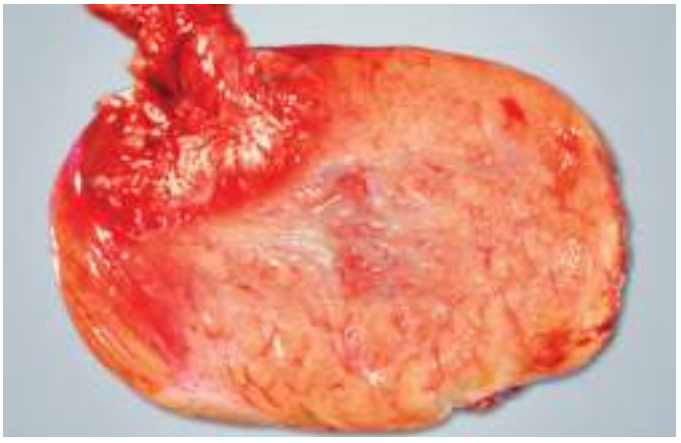

Fig. 24.91: Embryonal carcinoma of ovary. Cut surface shows variegated appearance with extensive areas of hemorrhage and necrosis.

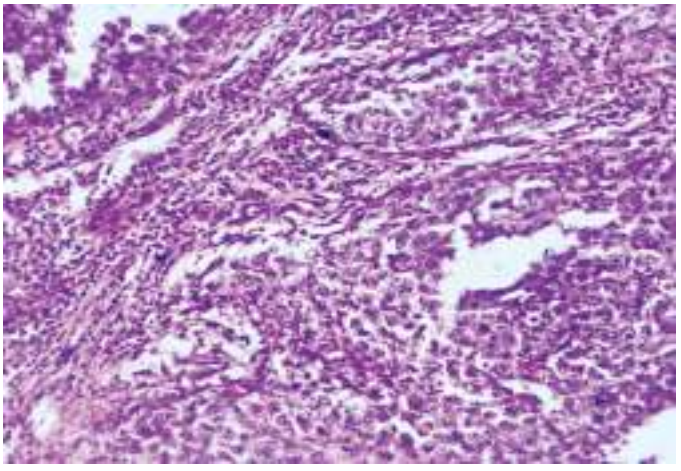

Fig. 24.92: Embryonal carcinoma of ovary. Tumor is composed of solid sheets of large anaplastic cells with hyperchromatic nuclei (400X).

Serum Tumor Markers

Serum α-fetoprotein level is often elevated as a result of its association with yolk sac tumor. Serum human chorionic gonadotropin (hCG) level is invariably high.

Clinical Course

Embryonal carcinoma of ovary is highly malignant tumor, which spreads by direct invasion into the peritoneal cavity, via lymphatic route to lymph nodes in the vicinity of the common iliac arteries and terminal part of the abdominal aorta, and then to mediastinal and supraclavicular region. Tumor can spread via hematogenous route to liver, lungs and bones.

Treatment

Patient with embryonal carcinoma of ovary is treated by unilateral salpingo-oophorectomy and combination chemotherapy (bleomycin, vinblastine and cisplatin).

CHORIOCARCINOMA OF OVARY

Choriocarcinoma of ovary is a rare malignant germ cell tumor with extraembryonic differentiation, which may be divided into two groups: (a) gestational choriocarcinoma and (b) nongestational choriocarcinoma, *de novo* (98%). Tumor is differentiating in the direction of trophoblastic elements, usually admixed with other neoplastic germ cell elements, which mimics the epithelial covering of placental villi (cytotrophoblast and syncytiotrophoblast). Most choriocarcinomas occur in combination with other germ cell tumors. Pure ovarian choriocarcinomas are rare.

Histogenesis

Choriocarcinoma of the ovary may arise in the three different ways: (a) germ cell tumor is differentiating in the direction of trophoblastic elements, and usually admixed with other neoplastic germ cell elements, (b) primary gestational choriocarcinoma is associated with ovarian pregnancy, and (c) as metastatic choriocarcinoma is derived from a primary gestational choriocarcinoma in other parts of female genital tract mainly in the uterus.

Clinical Features

Clinical findings in patient with ovarian nongestational choriocarcinoma are similar to those present in other malignant ovarian germ cell tumors, except that clinical manifestations are modified by the endocrine activity of the tumor, which synthesizes hCG.

- The endocrine effect is observed in prepubertal girls, who present with precocious sexual development, rapid breast enlargement growth of pubic and axillary hair, and menstrual irregularities. Occasionally, patient presents with symptoms of thyrotoxicosis.

Table 24.43 Elevated human choriogonadotropin (β-hCG) in various disorders

Choriocarcinoma of gonads and extragonadal regions
Embryonal carcinoma of the ovary
Hydatidiform mole (molar pregnancy)
Seminoma with syncytiotrophoblastic element
Dysgerminoma with syncytiotrophoblastic element

- Women of reproductive age may present with metastasis in lung, liver and brain.
- In some cases, choriocarcinoma of ovary becomes evident 10 or more years after the last pregnancy.

Serum and Urine Marker

Choriocarcinoma of ovary synthesizes human chorionic gonadotropin (hCG). There is increased hCG in serum and urine in these women. Elevated human choriogonadotropin (β-hCG) in various disorders is given in Table 24.43.

Surgical Pathology: Choriocarcinoma of Ovary

Gross Morphology

Ovarian pure choriocarcinoma is large, unilateral, solid, gray-white and hemorrhagic. Necrosis may be evident. Because most of the tumors are composed of combination of neoplastic cytotrophoblastic and syncytiotrophoblastic elements, the gross appearance tend to be vary according to the neoplastic elements present in the tumor (Fig. 24.93).

Light Microscopy

- Choriocarcinoma of ovary shows an admixture of malignant cytotrophoblastic and syncytiotrophoblastic elements.
- Cytotrophoblastic component is composed of medium-sized polygonal, round or oval cells with clear cytoplasm and sharp borders. Some tumor cells contain centrally placed nuclei, whereas other cells have large vesicular nuclei with nucleoli showing brisk mitotic activity. Cytotrophoblastic cells are usually dispersed centrally in tumor mass, and surrounded by syncytiotrophoblastic element.
- Syncytiotrophoblastic element is composed of large basophilic, vacuolated cells with irregular outlines and multiple hyperchromatic nuclei varying in size and shape.
- Cells of syncytiotrophoblastic element of choriocarcinoma are nondividing, which synthesize hCG, which accounts for the frequent finding of a positive pregnancy test result (Fig. 24.94).

Immunohistochemistry Technique

Tumor cells of choriocarcinoma show positivity for CAM 5.2, β-hCG (most specific marker), inhibin, human placental lactogen (hPL) and cytokeratin 7 (CK7). These cells show variable staining for SALL4 and placental alkaline phosphatase (PLAP).

Markers	Expression
▪ CAM 5.2	▪ Positive
▪ β-hCG	▪ Positive
▪ Inhibin	▪ Positive
▪ Human placental lactogen (hPL)	▪ Positive
▪ CK7	▪ Positive
▪ LK26 (folate binding protein)	▪ Positive
▪ SALL4	▪ Positive/negative (nuclear staining)
▪ PLAP	▪ Positive/negative
▪ CD117 (c-KIT)	▪ Negative
▪ OCT4 (POU5F1)	▪ Negative
▪ D2–40 (podoplanin)	▪ Negative

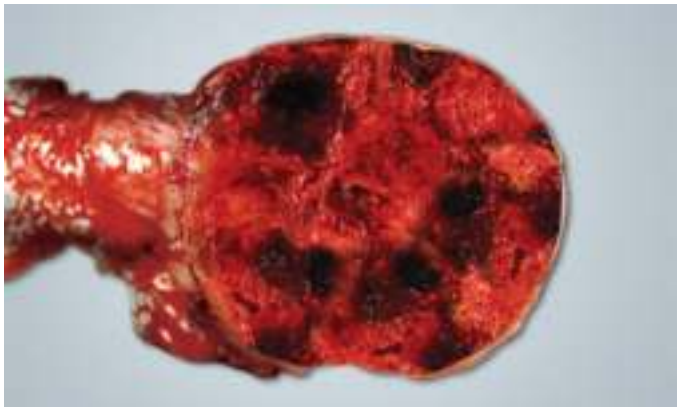

Fig. 24.93: Choriocarcinoma. The testis is replaced by a bloody bulging mass. More typically, choriocarcinoma tends to be somewhat smaller, and may not significantly distort the ovary.

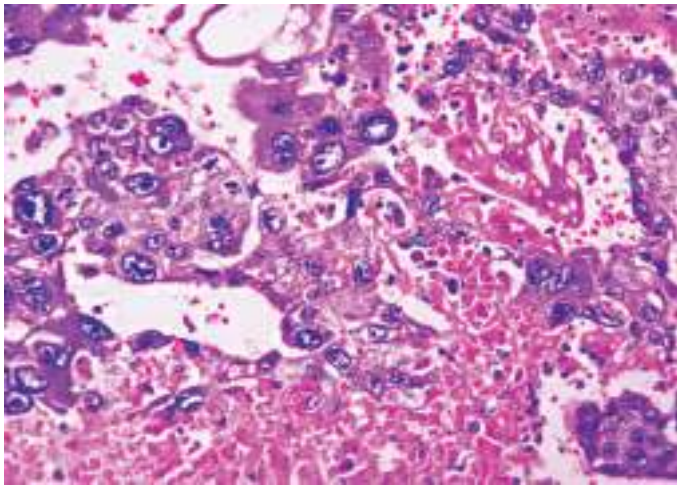

Fig. 24.94: Choriocarcinoma of the ovary. Tumor is composed of multinucleated syncytiotrophoblastic and cytotrophoblastic cells. The multinucleated syncytiotrophoblasts have voluminous eosinophilic cytoplasm and large darkly staining irregular nuclei with prominent nucleoli. The smaller mononuclear cytotrophoblasts are fairly uniform in size with amphophilic cytoplasm and distinct cellular outlines resembling to the tumor cells of solid yolk sac tumor (400X).

Clinical Course

Nongestational ovarian choriocarcinoma is a highly malignant germ cell tumor. It spreads by direct invasion in the surrounding structures throughout abdominal cavity, via lymphatic route to lymph nodes and via hematogenous route to distant organs. Sometimes, hematogenous spread of tumor is less evident.

Treatment

Treatment of choriocarcinoma of ovary has been revolutionized by the administration of combined chemotherapy containing cisplatin, etoposide and bleomycin with marked improvement in prognosis and survival. On the other hand, gestational choriocarcinoma is responsive to chemotherapy with better prognosis and survival.

TERATOMA OF OVARY

Teratomas of ovary demonstrate tissue elements derived from two or three embryonic layers. These tumors are observed in distinct forms: mature cystic teratoma, mature solid teratoma, immature teratoma and monodermal specialized teratomas (struma ovarii, carcinoid tumor, and teratoma with malignant transformation). Most teratomas (95%) are mature cystic teratomas also known as dermoid cysts.

Mature Cystic Teratoma of Ovary

Mature cystic teratoma of ovary is also known as dermoid cyst. Mature cystic teratomas constitute 95% of germ cell tumors and 20% of all ovarian neoplasms, which most often occur in young women during reproductive period. Dermoid cyst is usually unilateral in 75% and bilateral in 25% of cases.

- **Origin:** Mature cystic teratoma arises from haploid fertilized germ cell (? ovum after 1st meiotic division). It is considered that haploid (post-meiotic) germ cells autofertilize, yielding diploid tumor cells that are genetically female (46XX). The radiographic calcifications are highly suggestive of mature cystic teratoma of ovary, i.e. dermoid cyst.
- **Malignant transformation:** An element of mature cystic teratoma may undergo malignant transformation in about 1% of cases, usually squamous cell carcinoma (most common), followed by carcinoid tumor, adenocarcinoma, thyroid carcinoma, melanoma, osteosarcoma, carcinosarcoma, and glioblastoma multiforme. Malignant transformation in mature cystic teratoma is accompanied by complex chromosomal aberrations. Teratomas are graded I, II and III based on the presence of immature neuroepithelium in the tumor.

- **Karyotyping by banding technique:** Mature cystic teratomas of ovary show 46XX chromosomal patterns. Some believe that these tumors arise from an ovum after first meiotic division.
- **Clinical features:** Patient presents with constant slight to moderate abdominal pain (50%), abdominal freely mobile mass and abnormal uterine bleeding. Dermoid cysts most often undergo torsion and subsequent hemorrhagic infarction resulting in abdominal pain.

Surgical Pathology: Mature Cystic Teratoma of Ovary

Gross Morphology

- Mature cystic teratoma of ovary (i.e. dermoid cyst) is usually unilateral, however, bilateral tumors occur in 15% of cases. Tumor varies to several kilograms, which is usually freely mobile, but occasionally form adhesions to surrounding structures due to leakage of the tumor contents. Tumor is round, oval or globular with a smooth, gray-white and glistening surface. Tumor is soft and fluctuant with hard and soft areas.
- Cut surface shows a cavity filled with hair and fatty material similar to sebum surrounded by a firm capsule of normal varying thickness.
  - Tumor is usually unilocular but may be multilocular. Several dermoid cysts may be present in the same ovary.
  - Originating from the cyst wall and projecting into the tumor cavity from a small to large solid and cystic nodule termed Rokitansky or dermoid protuberance. Hair present in the tumor cavity originates from this dermoid protuberance, when bone or teeth are present.
  - Well-formed teeth are present in 31% of mature cystic teratomas.
  - Sometimes, phalanges, long bones or other bones may be occasionally demonstrated in these tumors, and these tumors are termed '**fetiform teratomas**'. Gross morphology of mature cystic teratoma of ovary is shown in Fig. 24.95.

Light Microscopy

- Outer surface of wall of mature cystic teratoma is composed of ovarian hyalinized stroma.
- The cavity of the dermoid cyst wall is lined by skin, and cutaneous structures. The skin is composed of keratinized squamous epithelium and contains sebaceous and eccrine glands associated with adipose tissue. Cyst contains hair and other dermal appendages.
- Some tumors may demonstrate lipogranulomatous, fat necrosis-like, sieve-like or pneumatosis cystoides-like pattern.
- Occasional dermoid cyst wall may be lined by bronchial or gastrointestinal cuboidal or columnar epithelium. Squamous epithelium may be present in the region of Rokitansky or dermoid protuberance.
- Due to desquamation of lining, foreign body giant cell reaction may be demonstrated. Foreign body giant cell reaction may occur when the contents of the dermoid cysts are spilled resulting in formation of adhesions.
- Area around Rokitansky or dermoid protuberance may contain tissues derived from the three germ layers: ectodermal structures (100%), mesodermal structures (90%) and endodermal structures (70%).
  - Structures derived from ectoderm are squamous epithelium, other skin derivatives, brain tissue, neural tissue, retina, choroid plexus and ganglia.
  - Mesodermal tissue is represented cartilage, bone, smooth muscle, adipose tissue and fibrous tissue.
  - Endoderm derived structures include gastrointestinal and bronchial epithelial lining and glands, thyroid tissue, salivary gland tissue.
  - These structures may be scattered diffusely, and these do not show the orderly haphazard arrangement that is seen in immature teratoma. Histology of mature cystic teratoma of ovary is shown in Fig. 24.96.

Fig. 24.95: Mature cystic teratoma of ovary. Cut surface of cavity shows hair and teeth surrounded by a firm capsule.

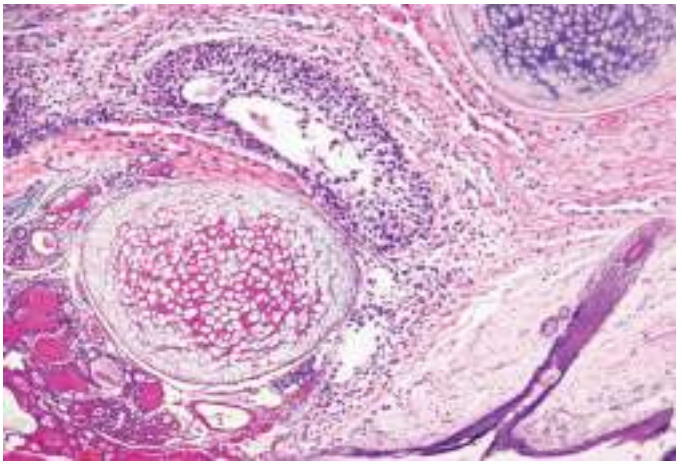

Fig. 24.96: Mature cystic teratoma of ovary. Outer surface of wall of mature cystic teratoma is composed of ovarian hyalinized stroma. The cavity of the dermoid cyst wall is lined by skin, and cutaneous structures. The skin is composed of keratinized squamous epithelium and contains sebaceous and eccrine glands associated with adipose tissue. Some tumors may demonstrate lipogranulomatous, fat necrosis-like, sieve-like or pneumatosis cystoides-like pattern. Cyst contains hair and other dermal appendages (400X).

Clinical Course: Mature Cystic Teratoma of Ovary

Treatment of choice for uncomplicated mature cystic teratoma in young women is excision of the tumor with conservative of the ovary is possible. Local recurrence after conservative treatment for mature cystic teratoma is uncommon and occurs in less than 1% of cases. Mature cystic teratoma of the ovary may be associated many complications: (a) torsion, (b) rupture, (c) infection, (d) autoimmune hemolytic anemia, and (e) development of cancer.

- **Torsion:** Torsion is the most frequent complication of mature cystic teratoma of ovary especially during pregnancy (20–40%) and puerperium (1–10%). Torsion of dermoid cyst during pregnancy has considerable clinical significance. Torsion of dermoid cyst tends to rupture. Patient presents with severe acute abdominal pain, and the condition is an acute emergency. Excision of the affected ovary or salpingo-oophorectomy is treatment of choice.
- **Rupture:** Immediate result of the rupture of dermoid cyst is hemorrhage and shock. Rupture of the tumor into the peritoneal cavity leads to chemical peritonitis as a result of spillage of dermoid cyst contents, which leads to granulomatous reaction and formation of dense adhesions throughout the peritoneum. Glial implants may be demonstrated on the peritoneum as a result of spillage of neuroglial tissue. Rupture of the tumor may involve urinary bladder and rectum.
- **Infections:** Patient with mature cystic teratoma is prone to infections due to coliform organisms and *Salmonella typhi*.

Mature Solid Teratoma of Ovary

Mature solid teratoma of ovary is a rare ovarian neoplasm affecting young women, predominantly in the second decade.

- Structures in mature solid teratoma are derived from all germ cell layers unlike dermoid cyst that mainly composed of structures derived from ectoderm.
- Mature solid teratoma is difficult to differentiate from malignant immature teratoma. The prognosis is excellent, even if peritoneal implants are present.
- The tumor shows 46XX chromosomal patterns by karyotyping banding technique.
- Some believe that mature solid teratoma arises from an ovum after first meiotic division.

Surgical Pathology: Mature Solid Teratoma of Ovary

Gross Morphology

Mature solid teratoma of ovary is usually large solid tumor, but multiple small cystic areas also are present. Tumor is usually unilateral in all cases (Fig. 24.97).

Light Microscopy

- Mature solid teratoma is composed entirely of mature tissues derived from all three germ layers arranged in an orderly manner resembling mature cystic teratoma except that the tumor is solid.
- Mature tissues derived from three germ cell layers such as skin, hair, sebaceous gland, teeth, neural and retinal tissues, cartilage, bone, muscle, hemopoietic tissue, bronchial glands, gastrointestinal tract mucosa, salivary tissue, thyroid tissue and pancreatic tissue.
- Occasionally, mature solid teratoma may be associated with peritoneal implants composed of mature glial tissue.

Immunohistochemistry Technique

Staining for glial fibrillary acidic protein (GFAP) is helpful in the identification of mature and immature glial tissues. Drawback is that GFAP is also detectable in chondrocytes. Immature and mature neural tissues are reactive for long-chain polysialic acid moiety of the neural cell adhesion molecule (NCAM).

Markers	Expression
▪ GFAP	▪ Positive
▪ NCAM	▪ Positive

Clinical Course and Treatment

Because mature solid teratoma is unilateral tumor, oophorectomy or unilateral salpingo-oophorectomy is the treatment of choice associated with complete cure.

Immature Teratoma of Ovary

Immature teratoma of ovary is an aggressive rapidly growing malignant tumor. Tumor is composed of tissues derived from the three germ cell layers: ectoderm, mesoderm and endoderm in contrast to the mature cystic teratoma of ovary.

- Mature tissues are frequently present in immature teratoma of ovary. In these cases, immature teratoma should be differentiated from a mature cystic teratoma with malignant transformation.
- Tumor most often occurs in children and adolescents age group under 20 years of age (average 18 years).

Fig. 24.97: Mature solid teratoma of ovary. Cut surface shows variegated appearance with solid and cystic areas.

Clinical Features

Patient is usually asymptomatic until immature teratoma of ovary attains a considerable size. Patient presents with pelvic or abdominal mass as a result of pressure on surrounding tissues, abdominal heaviness and dull pain abdomen. Tumor may undergo torsion and cause acute abdominal pain.

Surgical Pathology: Immature Teratoma of Ovary

Gross Morphology

- Immature teratoma of ovary is composed of immature and mature tissues derived from all three germ cell layers: ectoderm, mesoderm and endoderm.
- Ectoderm-derived tissues are ciliated epithelium and occasionally gastrointestinal or renal epithelium.
- All the tissues derived from three germ cell layers in immature teratoma of ovary are varying from embryonic to mature tissue, arranged haphazardly throughout the tumor so differ from the orderly organized arrangement of the tissues in mature cystic teratoma.
- Immature teratoma may be combined with other germ cell tumor elements such as dysgerminoma, yolk sac tumor, embryonal carcinoma, choriocarcinoma and polyembryoma.
- Therefore, it is important to do thorough sampling of the tumor. Immature teratoma is solid bulky with smooth external surface.
- Capsular penetration by the tumor is usual. Cut surface is solid with multiple minute cysts, or predominantly cystic. Hair, bone, cartilage and calcification may be demonstrated.

Light Microscopy

- Immature teratoma is composed of a mixture of embryonal and adult tissues derived from all three germ cell layers, regardless of its gross appearance, which are most often primitive neural elements, but mesodermal elements are also common.
- Some tumors are predominantly composed of endodermal derivatives, including esophagus, liver, and intestinal structures.
- Embryonal component of the tumor resembles tissues from an embryo or fetus than an adult. Immature cartilage, glands, bone, muscle, neural rosettes are present (Fig. 24.98).

Immunohistochemistry Technique

Staining for GFAP is helpful in the identification of mature and immature glial tissues. Drawback suggests that GFAP is also detectable in chondrocytes. Immature and mature neural tissues are reactive for long-chain polysialic acid moiety of the NCAM.

Markers	Expression
▪ GFAP	▪ Positive
▪ NCAM	▪ Positive

Clinical Course

Immature teratoma of ovary is malignant tumor, that tends to grow rapidly and penetrates capsule and invades surrounding structures resulting in formation of adhesions. It spreads throughout the peritoneal cavity.

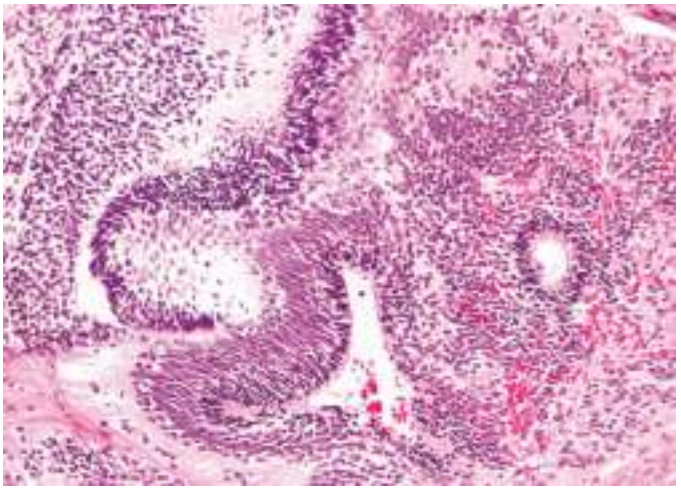

Fig. 24.98: Immature teratoma of ovary. Tumor is composed of a mixture of embryonal and adult tissues derived from all three germ layers, regardless of its gross appearance, which are most often primitive neural elements, but mesodermal elements are also common (400X).

- Tumor spreads via lymphatic route to retroperitoneal lymph nodes, para-aortic lymph nodes and more distant lymph nodes; and via hematogenous route to lungs, liver and other organs.
- Prognosis depends on grade of immature teratoma of ovary. Histologic features of the tumor affect prognosis. Very immature and poorly differentiated tumors are associated with poor prognosis. Immature teratoma consisting of mature and better differentiated components is associated with more favorable prognosis. Prognosis is poor except for stage I disease.
- Recurrence occurs within two years of excision. Chemotherapy in low-grade tumor may induce maturation of the immature elements. The risk for extraovarian spread depends on the amount of immature tissue present.

Treatment

Treatment for immature teratoma of ovary includes surgery and chemotherapy. Grade I immature teratoma limited to ovary or fallopian tube is treated by surgery. Pure ovarian immature teratoma is a potentially curable disease.

Struma Ovarii (Monodermal Teratoma)

Thyroid tissue is a relatively frequent constituent of mature cystic teratoma demonstrated in 5–20% of cases. Struma ovarii is a monodermal (specialized) teratoma composed of functional ectopic thyroid tissue. Tumor is most often unilateral tumors and bilateral in a few cases. The term 'struma ovarii' should be reserved for tumors composed of entirely or predominantly

thyroid tissue. Struma ovarii accounts for 3% of ovarian teratomas during reproductive period.

Clinical Features

Patient may present with features of hyperthyroidism due to thyroxine production by the tumor.

- Tumor has a benign course (95%), but may transform to papillary thyroid carcinoma in 5% of cases.
- BRAF gene mutations and RET/PTC rearrangements have been demonstrated in papillary carcinoma.
- Papillary thyroid carcinoma arising in struma ovarii invades peritoneum and metastasize via lymphatic route to para-aortic lymph nodes and other lymph nodes; and via hematogenous route to lungs and bones.
- These patients are treated by oophorectomy and thyroidectomy with administration of radioactive iodine (^{131}I).
- Long-term follow-up with serum thyroglobulin measurements are essential in these cases. Another complication of struma ovarii is the presence of ascites associated with pleural effusion producing 'Meig syndrome' even in benign tumor.

Treatment

Most cases are treated by excision of ovary or unilateral salpingo-oophorectomy.

Surgical Pathology: Struma Ovarii

Gross Morphology

- Struma ovarii tumor varies in size and measures less than 10% cm. The surface is usually smooth.
- Cut surface resembles a mature cystic teratoma. Cut surface of the tumor may be composed of light tan, glistening thyroid tissue. Hemorrhage, necrosis and foci of fibrosis may be present.
- Solid tumors with small amounts of colloid appear less glistening and more fleshy appearance. Some tumors may be cystic.

Light Microscopy

- Struma ovarii is composed of mature thyroid follicles of variable size lined by a single layer of columnar or flattened epithelium.
- The follicular acini contain eosinophilic, PAS positive colloid material. The intensity of the PAS staining may vary. Follicular acini are of variable size and containing colloid material.
- Sometimes, tumor may demonstrate papillary projections and resemble adenomatous goiter.
- Presence of marked crowded thyroid follicles without features of malignancy is designated as 'proliferative struma ovarii'.
- Struma ovarii showing features of Hashimoto's thyroiditis has also been reported (Fig. 24.99).

Immunohistochemistry Technique

Immunohistochemical studies for TTF-1 and thyroid hormones have established thyroid tissue in nature of this lesion.

Markers	Expression
Thyroid transcription factor 1 (TTF-1)	Positive
Thyroglobulin	Positive
Epithelial membrane antigen (EMA)	Positive

Carcinoid Tumor of Ovary

Carcinoid tumor of ovary is monodermal specialized functional monodermal teratoma, which may be primary or metastatic. Primary carcinoid tumors are divided into four categories in decreased frequency: insular (most common), trabecular, stromal and mucinous. Insular carcinoid tumor is considered to be of midgut derivation, which originates in association with gastrointestinal or respiratory epithelium in a mature cystic teratoma.

- About 40% of carcinoid tumor occur in pure form and remaining 60% are combined. Most patients are perimenopausal or menopausal women in the age group ranging from 30 to 80 years.
- About 33% of patients are associated with carcinoid syndrome due to synthesis of 5-HT (5-hydroxytryptamine). This is in contrast to intestinal carcinoids, which are associated with carcinoid syndrome only when there is metastatic spread to the liver. The reason for this difference is that the blood flow from the ovary is directly drained into the systemic circulation without reaching through the liver, which inactivates the serotonin synthesized by the tumor.

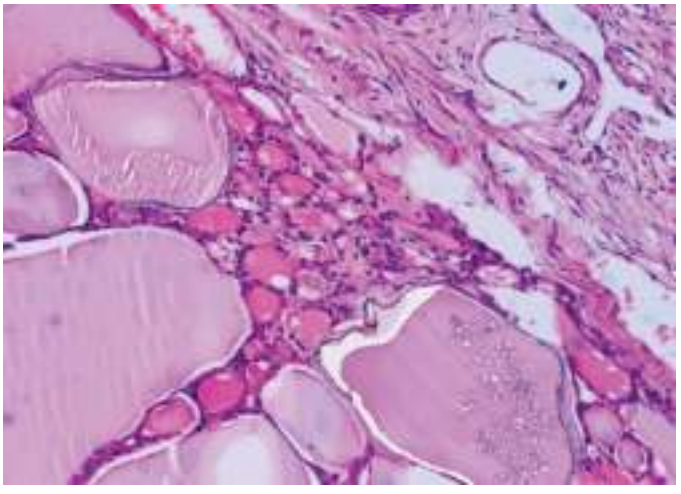

Fig. 24.99: Struma ovarii. Struma ovarii is composed of mature thyroifollicles of variable size lined by a single layer of columnar or flattened epithelium. The follicular acini contain eosinophilic colloid material (400X).

- The presence or absence of symptoms of carcinoid syndrome is also dependent on the number of tumor cells synthesizing 5-HT (5-hydroxytryptamine).
- Excision of carcinoid tumor is associated with rapid complete remission of the clinical symptoms of carcinoid syndrome, disappearance of 5-hydroxy-indoleacetic acid (5-HIAA) from the urine and marked decrease of serum serotonin.
- Analysis of serum serotonin and urinary 5-hydroxy-indoleacetic acid (**5-HIAA**) may be used to monitor the activity of the tumor and response to therapy.

Surgical Pathology: Carcinoid Tumor of Ovary

Gross Morphology

- Carcinoid tumor is solid and smooth on external surface. It varies in size from microscopic to 20 cm with mean 10 cm.
- Primary carcinoid is always unilateral, and may be associated with mature cystic teratoma in contralateral ovary.
- But metastatic intestinal tumor involves both ovaries. Cut surface is predominantly solid, firm, tan to yellow, homogeneous with a few cystic spaces.

Light Microscopy

- Carcinoid tumor of ovary is composed of numerous small acini and solid nests of uniform polygonal cells with abundant basophilic or amphophilic cytoplasm and round to oval hyperchromatic nuclei.
- Cytoplasm of tumor cells may contain red, brown, or orange argentaffin or argyrophil granules, which have property to reduce silver salts.
- Mitotic activity is low.
- Rarely, mixed tumor may occur, that is composed of struma ovarii and carcinoid tumor. Histology of carcinoid tumor of ovary is shown in Fig. 24.100.

Electron Microscopy

Tumor cells of insular carcinoid tumor contain abundant neurosecretory granules. Tumor cells exhibit marked variation in size and shape, being round, oval or elongated.

Immunohistochemistry Technique

Neoplastic cells of carcinoid tumor of ovary are immunoreactive to chromogranin, synaptophysin, neuron-specific enolase and 5-HT.

Markers	Expression
Chromogranin	Positive (diffuse and strong staining)
Synaptophysin	Positive (diffuse and strong staining)
Neuron-specific enolase (NSE)	Positive
Serotonin (5-hydroxytryptamine, i.e. 5-HT)	Positive

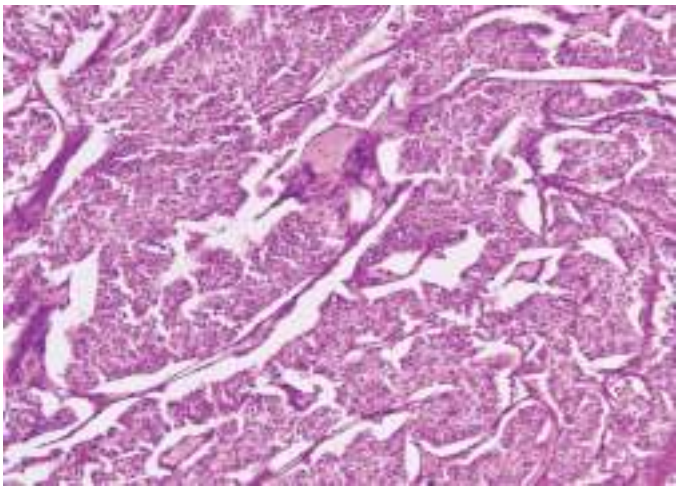

Fig. 24.100: Carcinoid of the ovary. Tumor is composed of numerous small acini and solid nests of uniform polygonal cells with abundant basophilic or amphophilic cytoplasm with round to oval hyperchromatic nuclei. Mitotic activity is low (400X).

POLYEMBRYOMA OF OVARY

Polyembryoma is rare but highly malignant ovarian neoplasm. Tumor is composed of numerous embryoid bodies resembling morphologically normal presomite embryo. It is most often a component of mixed germ cell tumor of ovary.

Surgical Pathology: Polyembryoma of Ovary

Gross Morphology

- Tumor is usually unilateral and solid areas of hemorrhage and necrosis. Gross morphology is similar to those seen in malignant germ cell tumors.
- Tumor varies in size from 9/5 cm to large tumor almost filling whole abdominal cavity and invading surrounding tissue.

Light Microscopy

- Tumor is composed of embryoid bodies and better-differentiated.
- Embryoid bodies are composed of embryonic discs lined by endoderm on one side, ectoderm on opposite side and associated with yolk sac and amniotic cavities.

Clinical Course

Polyembryoma of ovary is a highly malignant germ cell tumor. It spreads by direct invasion in surrounding structures, via lymphatic route to various lymph nodes and via hematogenous route to distant organs.

Treatment

Patient with polyembryoma of ovary is treated by surgical excision and combination chemotherapy.

MIXED GERM CELL TUMORS OF OVARY

Mixed germ cell tumors of ovary constitute 10% of germ cell tumors. Most common combination is dysgerminoma and yolk sac tumor, although any combination may occur.

SEX CORD-STROMAL TUMORS OF OVARY

Sex cord-stromal tumors of ovary constitute 10–25% of cases, which are derived from ovarian sex cords of embryonic gonads. Recent 2020 WHO classification of sex cord-stromal tumors of ovary is given in Table 24.44.

- Sex cord-stromal tumors of ovary may be divided into two broad groups: (a) estrogen producing granulosa cell tumor and the coma and (b) androgen producing Sertoli-Leydig cell tumors, hilus cell tumors and lipid cell tumors. Except fibromas, all these tumors are endocrinologically functional.
- Most sex cord-stromal tumors of ovary are benign. Approximately 25% of all granulosa cell tumors are prone to recur or metastasize during 10-year period after diagnosis and are considered low-grade malignant. Highly malignant tumors are extremely rare.

Table 24.44 Recent 2020 WHO classification of sex cord-stromal tumors of ovary

Granulosa-Stromal Tumors
- Granulosa cell tumor
  - Granulosa cell tumor (adult type)
  - Granulosa cell tumor (juvenile type)
- Tumors of thecoma-fibroma group
  - Typical thecoma
  - Luteinized thecoma
  - Thecoma associated with sclerosing peritonitis
  - Unclassified thecoma
  - Fibroma
  - Cellular fibroma
  - Fibrosarcoma
  - Sclerosing stromal tumor
  - Signet cell-stromal tumor
  - Microcystic stromal tumor

Sertoli-Stromal Tumors
- Sertoli cell tumor
- Leydig cell tumor
- Sertoli-Leydig cell tumors
  - Sertoli-Leydig cell tumor well differentiated
  - Sertoli-Leydig cell tumor intermediate differentiation
  - Sertoli-Leydig cell tumor poorly differentiated
  - Sertoli-Leydig cell tumor with heterologous elements
  - Retiform Sertoli-Leydig cell tumor

Gynandroblastoma (Specify Components)

Sex Cord Tumor with Annular Tubules

Unclassified Tumors

GRANULOSA CELL TUMOR OF OVARY

Granulosa cell tumor is potentially malignant ovarian tumor associated with estrogen production, which is derived from sex cord-stromal cells.

- Approximately 75% of granulosa cell tumors of ovary secrete estrogens, which also synthesize weak androgens.
- Excess of estrogen causes endometrial hyperplasia (most common finding) that may progress to endometrial adenocarcinoma if the functioning granulosa cell tumor remains undetected in adult women.
- Most adult granulosa cell tumors of ovary occur in postmenopausal women and associated with endometrial hyperplasia or endometrial carcinoma or fibrocystic disease of breast.
- Juvenile granulosa cell tumor of ovary affecting children and young women results in excess estrogens and isosexual precocious puberty. Flow cytometry reveals greater percentage of aneuploidy in juvenile than adult granulosa cell tumor variants, but without prognostic significance.

Chromosomal Aberrations

Granulosa cell tumor of ovary shows consistent trisomy of chromosome 12. Trisomy of chromosomes 14 and 22 has also been demonstrated. All adult granulosa cell tumors show characteristic somatic mutation in the FOXL2 gene. Flow cytometry reveals DNA polyploidy.

Clinical Features

Adult woman with granulosa cell tumor of ovary presents with abnormal uterine bleeding or postmenopausal bleeding increased abdominal size with abdominal pain and increase in abdominal girth.

Surgical Pathology: Granulosa Cell Tumors of Ovary

Gross Morphology

Granulosa cell tumor of ovary is unilateral solid tumor, microscopic size to large solid, cystic encapsulated masses, usually not firm as fibromas and thecomas (Fig. 24.101).

Light Microscopy

- Granulosa cell tumor of ovary is composed of small cuboidal to polygonal, deeply staining granulosa cells arranged in sheets and strands.
- 'Call-Exner bodies' are formed by tumor cells forming rosette-like structures (small follicles) filled with eosinophilic secretion arranged in a circular pattern resembling an ovarian immature follicle.
- Another variant is luteinized granulosa cell tumor comprised of plump granulosa theca cells with ample cytoplasm.

- Granulosa cell tumor chiefly composed of theca cell is almost never malignant (Fig. 24.102). Differentiating features of adult and juvenile granulosa cell tumors are given in Table 24.45.
  - **Adult granulosa cell tumor of ovary:** Tumor is composed of uniform cells with scant cytoplasm and pale grooved nuclei; low mitotic count, occasional **Call-Exner bodies** and **mature follicles**.
  - **Juvenile granulosa cell tumor of ovary:** Tumor is composed of pleomorphic cells with hyperchromatic ungrooved nuclei, high mitotic count and immature follicles. Call-Exner bodies are rarely demonstrated.

Differential Diagnosis

Adult granulosa cell tumor should be differentiated from endometrioid adenocarcinoma, poorly differentiated ovarian carcinoma, thecoma, cellular fibroma, small cell carcinoma of ovary, endometrioid stromal sarcoma, stromal tumor with minor-sex cord elements and yolk sac tumor.

Immunohistochemistry Technique

Neoplastic cells of granulosa cell tumor of ovary show positivity for CD99, inhibin, calretinin, melan-A (MART-1, clone A103), ER/PR, vimentin, desmoplakin, follicle regulatory proteins and S-100 protein.

Markers	Expression
▪ CD99	▪ Positive
▪ Inhibin	▪ Positive (except fibroma)
▪ Calretinin	▪ Positive (most sensitive marker than inhibin)
▪ Melan-A (MART-1, clone A103)	▪ Positive
▪ Estrogen/progesterone (ER/PR) receptors	▪ Positive
▪ Vimentin	▪ Positive (50%)
▪ Desmoplakin	▪ Positive (50%)
▪ Follicle regulatory proteins	▪ Positive (50%)
▪ S-100 protein	▪ Positive (50%)

Fig. 24.101: Granulosa cell tumor of ovary. These tumors are usually yellow. Positive diagnosis depends on the microscopic appearances. They sometimes secrete estrogen.

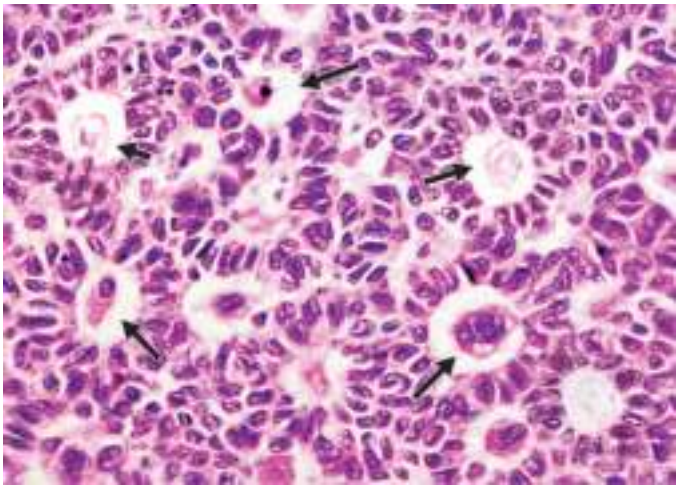

Fig. 24.102: Granulosa cell tumor of ovary. Tumor is composed of small cuboidal to polygonal, deeply staining granulosa cells arranged in sheets and strands. Call-Exner bodies are formed by tumor cells forming rossette-like structures (small follicles) filled with eosinophilic secretion arranged in a circular pattern resembling an ovarian immature follicle (arrows) (400X).

Table 24.45 Differentiating features of adult and juvenile granulosa cell tumors of ovary

Feature	Adult Granulosa Cell Tumor of Ovary	Juvenile Granulosa Cell Tumor of Ovary
Age group	<30 years	Mostly postmenopausal (all ages)
Behavior	Occasionally malignant often with protracted course	Rarely malignant
Estrogenic	Never estrogenic	Usually estrogenic
Luteinization	Infrequent	Frequent
Serum calcium	Present (common)	Absent
Thecoma component	Fibrothecoma component common	Thecomatous component common
Mucinous epithelium	Present but rare	Absent
Cell and nuclear morphology	Nuclei pale and often grooved	Pleomorphic cells with hyperchromatic ungrooved nuclei
Mitoses	Variable	Numerous
Follicles	Mature follicles	Immature follicles
Call-Exner bodies	Occasional	Rare
Cytoplasm	Scanty	Scanty to abundant

Clinical Course

It is difficult to predict biologic behavior on histologic evaluation of granulosa cell tumors. Granulosa cell tumors of ovary are potentially malignant, which may recur or metastasize in 25% of cases during 10-year period after diagnosis. 10-year survival is in 85% of cases.

THECOMA OF OVARY

Thecoma is a benign functional ovarian tumor, which occasionally synthesizes estrogens. It most often affects 30–50 years of women. In most cases, tumor produces signs of estrogen synthesis. The tumor is unilateral in 90% and bilateral in 10% of cases. Thecomas are almost always benign. Some tumors in young women are heavily calcified.

Surgical Pathology: Thecoma of Ovary

Gross Morphology

- Thecomas are solid tumors of 5–10 cm in diameter. These tumors are spherical, gray-white encapsulated tumors, covered by glistening intact ovarian serosa.
- Cut surface appears yellow due to presence many lipid-laden theca cells. Pure thecomas are rare.
- Many tumors contain a mixture of fibroma and thecoma components, hence called fibroma–thecoma (Fig. 24.103).

Light Microscopy

- Thecoma is composed of round lipid-containing theca cells in addition to fibroblasts.
- Theca cells contain fat and synthesize estrogens.
- Bands of hyalinized collagen separate nests of theca cells.

Histochemistry

- Lipids in theca cells may be demonstrated by frozen section technique. Tissue sections are stained with fat stains such as Sudan III, Sudan IV, Sudan black and Oil red O.
- Silver stains demonstrate reticulin fibers surrounding individual cells (as opposed to granulosa cell tumor, in which the reticulin surrounds clusters of cells).

FIBROMA OF OVARY

Fibroma is most common benign ovarian stromal tumor, which occurs at all ages, with a peak in the perimenopausal period, and is virtually always benign. Cytogenetic analysis demonstrates trisomy of chromosome 12 in fibroma of ovary.

Clinical Features

Fibroma may be associated with **Meigs' syndrome**, a triad of ovarian fibroma >8.0 cm in size, ascites, and hydrothorax in 40% of cases. Rarely, it may undergo malignant change and present as fibrosarcoma.

Fig. 24.103: Thecoma of ovary. This is distinguished from fibroma by the presence of lipid, which gives it a yellow color.

Fig. 24.104: Fibroma of ovary. The cut surface of the tumor shows a homogeneous white appearance with hemorrhage and necrosis.

Surgical Pathology: Fibroma of Ovary

Gross Morphology

The tumor is solid, firm, and gray-white. There is absence of hemorrhage and necrosis (Fig. 24.104).

Light Microscopy

- Tumor cells of fibroma resemble the stroma of the normal ovarian cortex.
- Fibroma is composed of well-differentiated bundles of spindle-shaped fibroblasts and variable amounts of collagen (Fig. 24.105). Distinction between thecoma and fibroma of ovary is given in Table 24.46.

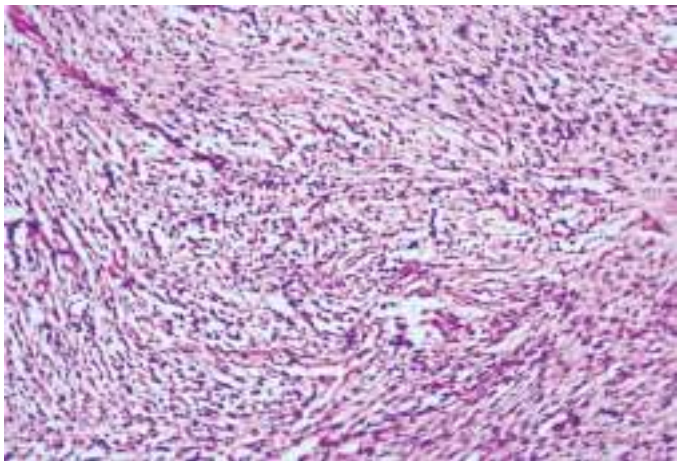

Fig. 24.105: Fibroma of ovary. Tumor is composed of well-differentiated bundles of spindle-shaped fibroblasts and variable amounts of collagen (400X).

SERTOLI-LEYDIG CELL TUMORS OF OVARY

Sertoli-Leydig cell tumor is a rare mesenchymal neoplasm of the ovary of low malignant potential, which resembles the embryonic testis.

- Tumor usually occurs in young women of childbearing age. However, it can affect all ages.
- Tumor is androgen (dehydroepiandrosterone) secreting tumor associated with virilism (masculinization). Due to excess of androgens, approximately 50% of patients initially present with breast atrophy, amenorrhea, and loss of hip fat followed by hirsutism, male escutcheon, enlarged clitoris, and deepened voice.

PURE LEYDIG CELL TUMOR OF OVARY

Pure Leydig cell tumor is a benign tumor present in the hilus or the ovary. It may synthesize androgens. Due to excess androgens, patient presents with masculinization, hirsutism, voice changes, and clitoris enlargement. There is increased excretion of 17-ketosteroid unresponsive to cortisone suppression. Surgical excision of tumor cures the patient.

Surgical Pathology: Pure Leydig Cell Tumor of Ovary

Gross Morphology

Pure Leydig cell tumor is small yellow-colored, unilateral less than 3 cm in diameter.

Light Microscopy

Pure Leydig cell tumor is composed large lipid-laden cells with distinct borders. A typical cytoplasmic structure characteristic of Leydig cells (Reinke crystalloid) is usually present.

ANDROBLASTOMA OF OVARY

Androblastoma is unilateral ovarian tumor, which affects all ages but peak incidence in second and third decades, which has masculinization effect or defeminization effect. This is biphasic tumor, which contains cells resembling testicular Sertoli and Leydig cells interspersed with stroma. Tumor constitutes <5% of cases.

Clinical Features

Androblastoma of ovary synthesizes androgens, which causes atrophy of breasts and external genitalia, amenorrhea, infertility, deepening of voice, male distribution of hair on face and chest; and hypertrophy of clitoris.

Surgical Pathology: Androblastoma of Ovary

Gross Morphology

Androblastoma is unilateral small tumor and resembles granulosa theca cell tumor. Cut surface is gray to golden brown.

Light Microscopy

- Tumor is a well-differentiated tumor composed of Sertoli cells or Leydig cells interspersed with stroma. Intermediate differentiated tumor is composed of immature tubules and large eosinophilic Leydig cells.
- Poorly differentiated tumor shows sarcomatous pattern, disorderly disposition of epithelial cell cords and absence of Leydig cells.
- Heterologous elements like mucinous glands, bone and cartilage are present.

Table 24.46 Distinction between thecoma and fibroma of ovary

Feature	Thecoma of Ovary	Fibroma of Ovary
Age group	Mean age 63 years	<30 years
Function	Typically, estrogenic	Absent
Gross morphology variegation	No	No
Pseudolobulation	Rare	Rare
Prominent ectatic blood vessels	Rare	Rare
Two-cell type	Only in luteinized form	Absent
Hyaline plaques	Common	Common
Clinical behavior	Almost always benign	Almost always benign

GONADOBLASTOMA OF OVARY

Gonadoblastoma is an uncommon ovarian tumor, which occurs in persons with abnormal sexual development and in gonads of indeterminate nature. Approximately 80% of patients are phenotypic females and 20% are phenotypic males with undescended testicles and female internal secondary organs.

Surgical Pathology: Gonadoblastoma of Ovary
Light Microscopy
Tumor is composed of mixture of germ cells and sex cord derivatives resemble immature Sertoli and granulosa cells. A co-existent dysgerminoma occurs in 50% of cases.

PREGNANCY LUTEOMA OF OVARY

Ovary during pregnancy may exhibit nodular proliferation of theca cells, in response to gonadotrophins. Rarely a frank tumor may develop termed pregnancy luteoma that resembles corpus luteum of pregnancy.

- Pregnancy luteoma has been associated with virilization in pregnancy patients and in their respective female infants.
- Pregnancy luteoma should be differentiated from functional luteal cysts (regress in 4–6 weeks), follicular cyst, corpus luteal cysts and theca lutein cyst, subserous leiomyoma, extrauterine pregnancy, hydrosalpinx, appendicular mass, tubercular abdomen, hydatid cyst, and ascites.

LABORATORY DIAGNOSIS OF OVARIAN TUMORS

No high risk groups of ovarian tumors can be identified for whom screening might be appropriate with the rare exception of families with hereditary ovarian cancer. No screening methods have proven to be effective at this time-trials examining screening based upon physical examination, ultrasound imaging, and biomarker serum CA 125 analysis had been unreliable, and productive of a high rate of false positives. The routine Papanicolaou smear is not effective for ovarian cancer screening.

CLINICAL FEATURES

Ovarian tumors are mainly asymptomatic. About 25% of ovarian neoplasms are malignant. Adnexal tumor over 6 cm; if persisting/increasing in size in a postmenopausal woman, ovarian tumor be suspected.

- Benign ovarian tumor is usually slow-growing, unilateral, cystic-free mobile. A solid/cystic, bilateral, rapidly growing tumor associated with pressure symptoms especially in postmenopausal woman is very likely to be malignant.

Table 24.47 Serological markers in ovarian malignant tumors in clinical practice

Serum CA 125: It is a glycoprotein often produced by surface epithelial ovarian tumors. It may help characterize ovarian masses and monitor the extent of disease
Estrogen levels: These are increased in thecomas and granulosa cell tumors
Androgen levels: These are increased in Sertoli-Leydig and hilar tumors
α-Fetoprotein levels: These are demonstrated in yolk sac tumors
Human chorionic gonadotropin β (hCG-β) levels: These are increased in choriocarcinomas

- In hormones producing tumors; clinical history, vaginal cytology, endometrial histology, estimation of hormone levels in blood and urine are significant. Physical examination and clinical examination of the vagina and rectum can detect most important ovarian masses.
- Radiograph has diagnostic utility to demonstrate calcification in cases of dermoid cyst and serous cystadenoma of ovary.

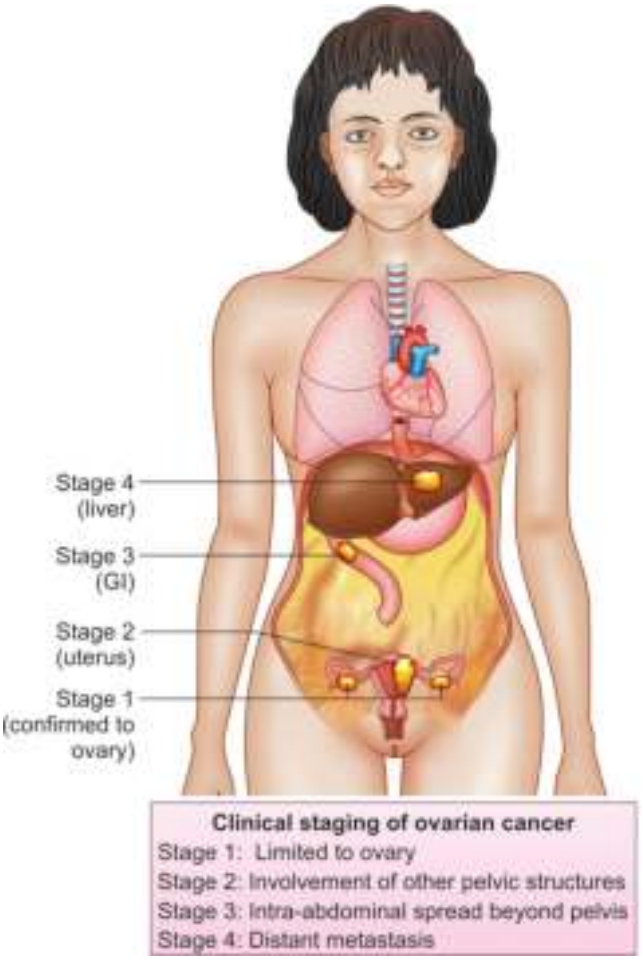

Fig. 24.106: Staging of ovarian cancers.

- Pelvic ultrasound can be very valuable in determining the characteristics of ovarian and other pelvic masses. Ascitic fluid cytology is done to demonstrate malignant cells of ovarian malignant tumors.
- Serological markers in ovarian malignant tumors in clinical practice are given in Table 24.47.

HISTOLOGIC EXAMINATION

A tissue sample is necessary to make an unequivocal diagnosis, this may be obtained by exploratory laparotomy (surgical incision of the abdominal wall to examine the contents of the peritoneal cavity) or laparoscopy. Surgeons take care to avoid rupture of ovarian masses when a diagnosis of cancer is suspected, so as not to spread the disease.

STAGING SYSTEM

Staging is a clinical exercise that classifies tumors according to their size, invasiveness and spread. Tumors are staged according to the TNM system (T: Tumor size, N: Lymph node involvement, M: Metastases to distant organs). Schemes for TNM classification vary according to tumor type and organ involved. Grading classifies tumor according to their light microscopic characteristics (Fig. 24.106 and Table 24.48).

Table 24.48 Stages of ovarian cancers

Stage	Extent of Ovarian Growth
Stage 1	Growth limited to ovaries
Stage 2	Growth in one or both ovaries with pelvic extension
Stage 3	Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes or superficial liver metastases
Stage 4	Growth involving one or both ovaries with distant metastases, if a pleural effusion is present there must be positive cytology; parenchymal (internal) liver metastases—stage 4

GESTATIONAL TROPHOBLASTIC NEOPLASTIC DISORDERS AND RELATED TUMOR-LIKE LESIONS

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease with abnormal chorionic villi (hydatidiform mole) is characterized by a spectrum of villous populations ranging from normal size to substantial enlargement, irregular contours and mild, focal trophoblastic hyperplasia.

- Gestational trophoblastic disease includes hydatidiform mole (complete, partial and invasive), benign tumor-like diseases of the trophoblast (placental site nodule) and choriocarcinoma, latter being the only malignant tumor, but responsive to chemotherapy. Revised 2020 WHO of gestational trophoblastic disease is given in Table 24.49.
- Immunohistochemical analysis of placental site nodule, placental site trophoblastic tumor, epithelioid trophoblastic tumor and choriocarcinoma is given in Table 24.50.
- Hydatidiform mole represents abnormal placenta during pregnancies, which results from faulty fertilization. It is characterized by cystic swelling of the chorionic villi and accompanied by variable trophoblastic proliferation. It occurs in two variants: complete, partial and invasive hydatidiform moles. Invasion of hydatidiform mole into myometrium is termed invasive hydatidiform mole.
- Complete and partial hydatidiform moles are shown in Fig. 24.107. Comparison of complete and partial hydatidiform moles is given in Table 24.51.

Table 24.49 Revised 2020 WHO of gestational trophoblastic disease

- **Hydatidiform Moles (Abnormally Formed Placentas during Pregnancy)**
  - Complete mole
  - Partial mole
  - Invasive mole
- **Gestational Trophoblastic Neoplastic Disorders**
  - Choriocarcinoma
  - Placental site trophoblastic tumor (PSTT)
  - Epithelioid trophoblastic tumor (ETT)
- **Trophoblastic Tumor-like Benign Lesions**
  - Exaggerated placental site/reaction
  - Placental site nodule
- **Abnormal (Nonmolar) Villous Lesions**

HYDATIDIFORM MOLE

Hydatidiform mole is characterized by proliferation of villous trophoblast with cystic 'swollen' villi. Macroscopically, these can be visible during second trimester of pregnancy, as clusters of vesicles similar to small grapes developed from the transformation of chorionic villi.

- Complete hydatidiform mole differs from partial hydatidiform mole in cytogenetic and histologic appearance. Important is a complete lack of embryonic/fetal tissue in complete hydatidiform

Table 24.50 Immunohistochemical markers of placental site nodule, placental site trophoblastic tumor, epithelioid trophoblastic tumor and choriocarcinoma

Immunohistochemical Markers	Placental Site Nodule	Placental Site Trophoblastic Tumor	Epithelioid Trophoblastic Tumor	Choriocarcinoma
Mel-Cam (CD146) membranous staining	Positive (0–2%)	Positive (75–100%)	Positive (0–2%)	Positive (6–75%)
HPL (human placental lactogen)	Positive (0–2%)	Positive (25–75%)	Positive (0–2%)	Positive staining in intermediate trophoblastic and syncytiotrophoblastic elements
β-hCG	Positive (0–25%)	Positive (0–25%)	Positive (0–25%)	Positive staining in syncytiotrophoblastic element
p53	Positive (>50–75%)	Negative	Positive (<25–75%)	Positive (<25%)
Ki-67 (MIB-1)	Positive (3–10%)	Positive (>10%)	Positive (>10%)	Positive (49–89%)
Cyclin E	Focal staining	Negative	>50%	Negative

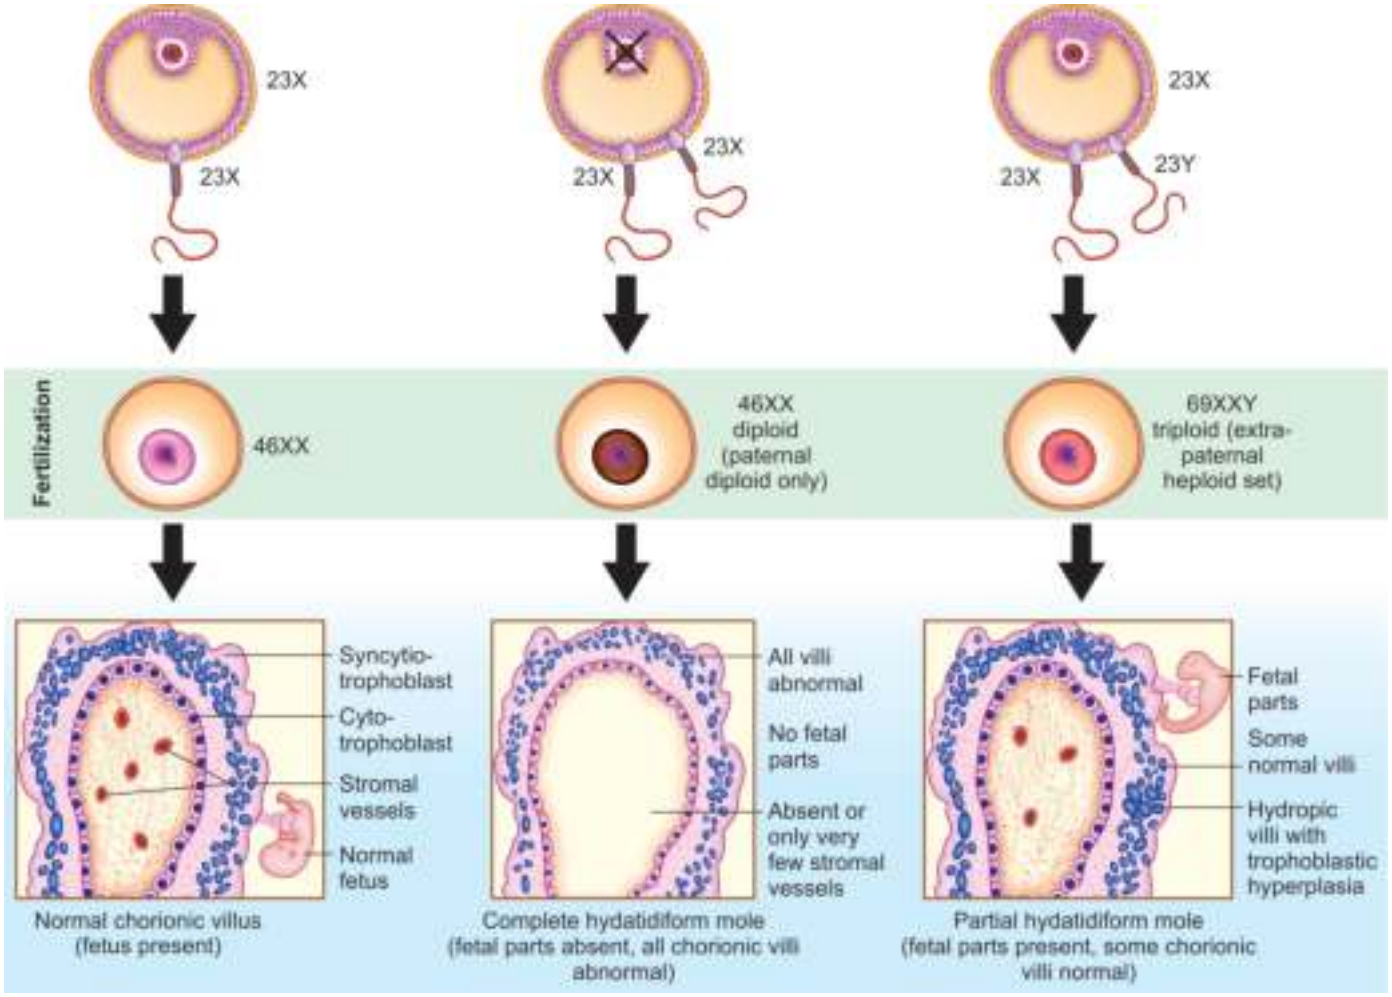

Fig. 24.107: Complete and partial hydatidiform moles. Complete hydatidiform moles result from androgenesis due to fertilization of an empty ovum (lacking functional maternal chromosomes) by one spermatozoon that goes duplication thus resulting in a 46XX karyotype in 90% of cases. Therefore, all the chromosomes are of paternal origin (paternal androgenesis). Fetal parts are absent. All chorionic villi are abnormal. Partial moles result from fertilization of a normal ovum (23X) by two normal spermatozoa each carrying 23 chromosomes—a process called dispermy triploidy. The zygote is triploid (69XXY or 69XYY) with two sets of paternal chromosomes and one set of maternal chromosome or rarely tetraploidy. Ratio of paternal to maternal chromosomes is 2:1. Fetal parts and some chorionic villi are present.

Table 24.51 Comparison of complete and partial hydatidiform moles

Features	Complete Hydatidiform Mole	Partial Hydatidiform Mole
Normal chorionic villi	Absent	May be present
Edema in chorionic villi	All chorionic villi edematous	Some chorionic villi edematous
Capillaries in the chorionic villi	Few or no fetal RBCs in chorionic villi	Many fetal RBCs in chorionic villi
Trophoblastic hyperplasia	Diffuse and marked	Focal (minimal to moderate)
Embryo (fetal parts)	No cord, amnion or fetus	Abnormal fetus (may be present) is viable for a few weeks
Gestational age	8–16 weeks	10–26 weeks
Cytogenetics	46XX/46XY (diploid)	Triploid 69XXX, tetraploid 92XXXY
Chromosomal pattern	Paternal chromosome only	Maternal and paternal chromosomes
Serum β-hCG	Markedly increased	Mild to moderately increased
Tissue β-hCG	Strong positivity	Mild positivity
Pathogenesis	Fertilization of empty egg by one or two sperms: No maternal DNA	Fertilization of ovum by one or two sperms: Paternal and maternal DNA
Ultrasonography finding	Snow storm sign, uterus large for duration of pregnancy	Uterus small for fetus during pregnancy
p57 staining in cytotrophoblastic and villus stromal cells	Low or absent staining	Diffuse staining
Risk of development of gestational trophoblastic disease	≤30%	5%
Malignant transformation	Choriocarcinoma (2%)	Choriocarcinoma minimal risk

mole and presence of embryonic tissue in partial hydatidiform mole.

- An important marker that aids in diagnosis of the complete hydatidiform mole is the absence of p57 in immunohistochemistry. This p57 marker is a paternal imprint inhibitor gene, so its expression implies the maternal contribution. In brief, the absence of p57 expression supports the diagnosis of complete hydatidiform mole.
- Invasive hydatidiform mole is defined as molar gestation invading myometrium or uterine blood vessels.
- Patient presents with vaginal bleeding and presistent elevation of human choriogonadotropin hormone (hCG). Extrauterine spread to lungs, vagina, vulva and broad ligament is observed in 20–40% cases.

COMPLETE HYDATIDIFORM MOLE

Complete hydatidiform mole is a proliferative disorder of the placenta resulting in hydropic change and trophoblastic hyperplasia without development of embryo. Ultrasonography demonstrates characteristic 'snowstorm appearance'. Patient typically presents with vaginal bleeding or a missed abortion.

- In complete hydatidiform mole, molar changes occur as early as in 4th week but most cases present in 4–5th months of pregnancy. Since the embryo dies at a very early stage, fetal parts are absent. Chorionic villi show florid trophoblastic proliferation and hydropic change.
- Complete hydatidiform mole resembles bunches of grapes, exhibits **diploidy (46XX karyotype)** and shows only paternal chromosomes. Ratio of paternal to maternal chromosomes is 2:0. It most often affects young females 40 years of low socioeconomic group.
- Most molar pregnancies are diagnosed by ultrasound in the early stages of pregnancy. Molar pregnancies can be completely evacuated by curettage. Complete hydatidiform mole becomes locally invasive in 15–20% of cases. Malignant transformation (choriocarcinoma) develops in about 2% of cases.

Pathogenesis

Complete hydatidiform mole results from androgenesis due to fertilization of an empty ovum (lacking functional maternal chromosomes) by one spermatozoon that goes duplication thus resulting in a 46XX karyotype in 90% of cases. Fertilization of the empty ovum occurs by two spermatozoa (dispermy) results in a 46XY phenotype in 10% of cases. Therefore, all the chromosomes are of paternal origin (paternal androgenesis).

Clinical Features

Patient presents with history of amenorrhea of less than 24 weeks of gestation, passage of grape-like structures (vesicles) per vagina, abdominal pain, and hyperemesis.

- Complete hydatidiform mole can be mistaken for a normal pregnancy, but the uterus is often too large for the supposed state of gestation.
- There is increase in serum hCG levels after 14th week, as opposed to the drop typically seen in the course of normal gestation.
- Hyperstimulation of ovaries by human chorionic gonadotropin (hCG) synthesis is responsible for bilateral ovarian luteal cysts associated with trophoblastic tumors.
- Normal trophoblastic tissue synthesizes β-hCG, estrogen, progesterone and TSH-like hormones. Excess of TSH production causes hyperthyroidism in 2% of cases.

Complications

Complications of complete hydatidiform mole include hemorrhage, anemia, uterine sepsis, uterine perforation during suction curettage, choriocarcinoma, and disseminated intravascular coagulation (DIC).

- Perforation of the uterus during suction curettage sometimes occurs due to large and boggy uterus. If uterine perforation is observed, the suction procedure should be completed under laparoscopic guidance.
- Hemorrhage is a frequent complication during the evacuation of a molar pregnancy.
- For this reason, intravenous oxytocin should be started at the initiation of the suctioning. If a molar pregnancy is not completely treated, it can cause a range of serious complications such as gestational trophoblastic disease (GTD) including persistent gestational trophoblastic disease such as persistent growth of the placental tissue and invasive mole invading uterine wall.

Surgical Pathology: Complete Hydatidiform Mole

Gross Morphology

- Grossly bulky tissue with hydropic changes in all chorionic villi resemble 'bunch of grapes' pearly white, semitransparent vesicles of variable size measuring a few mm to 2–3 cm. The total weight of bunch of grapes is usually over 200 g in complete hydatidiform mole.
- Normal placental structures or fetal parts are absent. Early complete hydatidiform mole may not demonstrate evidence of abnormal chorionic villi (Fig. 24.108).

Light Microscopy

- In complete hydatidiform mole, chronic villi show diffuse enlargement with marked hydropic changes and irregular scalloped borders.
- Hydropic change in chorionic villi occurs due to abnormal angiogenesis and decreased blood vessels in the chorionic villi resulting in lack of vascular drainage and accumulation of fluid, which show variable degrees of trophoblastic hyperplasia usually in a circumferential pattern.
- Remarkable cytologic atypia is almost always present in chorionic villi. Mitoses are common.
- The blood vessels are absent or inadequate in loose edematous myxomatous stroma.
- Stromal mucin and stromal nuclear debris (apoptosis), appear very early and represent a diagnostic clue. Histology of complete hydatidiform mole is shown in Fig. 24.109.

Molecular Genetic Alterations

Ploidy analysis is a useful adjunct in diagnosis of complete hydatidiform mole. Novel missense NLRP7 gene mutation located on chromosome 19q has been identified in cases of familial clusters of biparental complete hydatidiform moles.

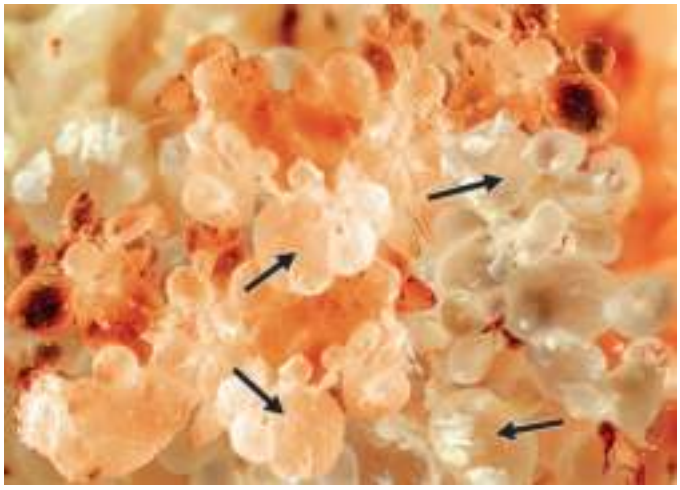

Fig. 24.108: Complete hydatidiform mole. Uterine cavity is occupied by a mass of abnormal chorionic villi resembling a bunch of grapes. Each villus is distended by fluid to reach a diameter of about 1–3 mm. No fetus is present (arrows).

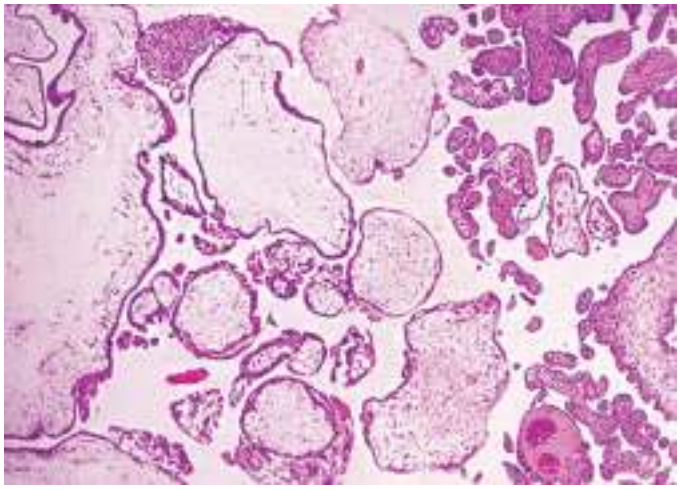

Fig. 24.109: Complete hydatidiform mole. Histologic examination shows fluid-filled, avascular villi with overlying hyperplastic trophoblast that shows cellular atypia (100X).

Laboratory Diagnosis

In complete hydatidiform mole, ultrasonography reveals snowstorm/speckled appearance. Doppler study reveals absent fetal heart sounds. X-ray chest is done to rule out metastatic choriocarcinoma. An hCG level of less than 5 mIU/ml is considered negative for pregnancy, and anything above 25 mIU/ml is considered positive for pregnancy.

- Patient with complete hydatidiform mole shows urinary hCG excretion >100,000 IU/24 hours; and serum hCG of 100,000 mIU/ml is demonstrated in 50% of cases.
- Post-evacuation serum quantitative hCG measurements should be performed every 1–2 weeks until 3 consecutive tests are normal, followed by hCG measurement at 3-month intervals for 6 months. The patient should be followed up by estimation of serum human chorionic gonadotropin up to 2 years to rule out development of choriocarcinoma.

Treatment

Suction and evacuation of complete hydatidiform mole is done. Chemotherapy should be given to the patients, who have persistent uterine bleeding despite curettage, elevated serum hCG levels remain even after 12 weeks of post-evacuation; and choriocarcinoma on endometrial biopsy.

PARTIAL HYDATIDIFORM MOLE

Partial hydatidiform mole exhibits partially formed fetal parts, normal and abnormal hydropic chorionic villi with irregular scalloped borders and variable degree of proliferation. Fetus associated with partial hydatidiform mole usually dies after 10 weeks of gestation followed by abortion of the partial hydatidiform mole shortly thereafter. Partial hydatidiform moles generally do not predispose to choriocarcinoma.

Pathogenesis

Partial hydatidiform mole results from fertilization of a normal ovum (23X) by two normal spermatozoa; each carrying 23 chromosomes—a process called dispermy triploidy. By alternate mechanism, it results from fertilization of a normal ovum (23X) by single spermatozoon that has not undergone meiotic reduction and bears 46 chromosomes. The zygote is triploid (69XXY or 69XYY) with two sets of paternal chromosomes and one set of maternal chromosome or rarely tetraploidy. Ratio of paternal to maternal chromosomes is 2:1.

Surgical Pathology: Partial Hydatidiform Mole

Gross Morphology

In partial hydatidiform mole, immature placental tissue is admixed with vesicles that tend to be smaller and less numerous than those of a complete hydatidiform mole. Fetal parts including nucleated red blood cells in villous capillaries, as well as a gestational sac may be present.

Light Microscopy

- Partial hydatidiform mole is composed of heterogenicity in villus size with discrete populations of chorionic villi ranging from large hydropic villi and small fibrotic villi.
- The enlarged chorionic villi are of irregular shape with scalloped borders and secondary inclusions.
- Chorionic villi show circumferential trophoblastic hyperplasia.
- Presence of at least 3 of these histologic features of partial hydatidiform mole correlates with triploidy on FISH and flow cytometry analysis.

Flow Cytometry

- Flow cytometry can be performed on paraffin-embedded samples to determine ploidy in partial hydatidiform mole.
- Flow cytometry cannot distinguish between maternal or paternal origin of genetic material.
- A triploid karyotype by flow cytometry is consistent with partial hydatidiform mole in conjunction with morphological features.

Molecular Genetic Alterations

In partial hydatidiform mole, testing of both maternal decidua and villous tissue can identify triploid genotype (69XXY or 69XYY) by polymerase chain reaction (PCR). Fluorescence *in situ* hybridization (FISH) uses fluorescently labeled DNA probes targeting regions of various chromosomes, including X and Y. FISH can be used to determine sex chromosome and copy number. It cannot differentiate between maternal and paternal origins of genetic material.

Treatment

Patient of partial hydatidiform mole is treated by evacuation and curettage with follow-up with serum human chorionic gonadotropin (hCG) levels and contraception until undetectable levels. Some patients may require chemotherapy in 1% of cases compared with 14% for complete hydatidiform mole.

INVASIVE HYDATIDIFORM MOLE

Invasive hydatidiform mole is the most common form of persistent or metastatic gestational trophoblastic disease (GTD) after complete or partial hydatidiform mole. It is also termed chorioadenoma destruens. It occurs more frequently than choriocarcinoma.

- Invasive hydatidiform mole is defined as molar gestation invading underlying myometrium. It can spread to extrauterine structures such as parametrium, broad ligament, vagina, vulva and lungs in 20–40% of cases. It may rarely invade paraspinal tissue.
- Patient usually presents with vaginal bleeding and persistent elevation of β-hCG.
- Invasive hydatidiform mole is commonly diagnosed after primary evacuation of complete or partial hydatidiform mole.
- Chemotherapy is highly effective in treating these cases associated with 80% cure rate.

Clinical Features

Invasive hydatidiform mole may cause uterine perforation and embolize to lung, brain, but does not grow there. The hCG-β levels are persistently increased in invasive hydatidiform mole and choriocarcinoma. It responds well to chemotherapy. Normally, serum hCG-β level is 120–160 IU/ml in normal pregnancy after 70–90 days. But in invasive hydatidiform mole, serum hCG-β level is 1000 IU/ml in pregnancy after 70–90 days.

Surgical Pathology: Invasive Hydatidiform Mole

Gross Morphology

In invasive hydatidiform mole, hydropic chorionic villi are observed extending from endometrium to myometrium. Invasive hydatidiform mole in the uterus is commonly seen as an erosive hemorrhagic lesion, that may perforate the uterus (Fig. 24.110).

Light Microscopy

- Invasive hydatidiform mole shows dysmorphic, less hydropic chorionic villi and extravillous trophoblast invading the myometrium and blood vessels.
- Tissue exhibits morphologic characteristics of hydatidiform complete mole (most common) or partial mole are retained in the invasive hydatidiform mole.
- Chorionic villi are less hydropic than complete or partial mole.
- Trophoblastic proliferation with mild to severe dysplasia is usually demonstrated. Metastatic invasive hydatidiform mole is diagnosed by demonstration of dysmorphic chorionic villi in the blood vessels without tissue invasion.
- Since the diagnosis requires the presence of myometrium and blood vessels invaded by chorionic villi, it can be confirmed on histopathologic examination of resected tissue.

Treatment and Prognosis

Patient with invasive hydatidiform mole has a good prognosis even when it has spread to extrauterine sites. Patient should be treated with eight cycles of two weekly methotrexate and followed up for one year.

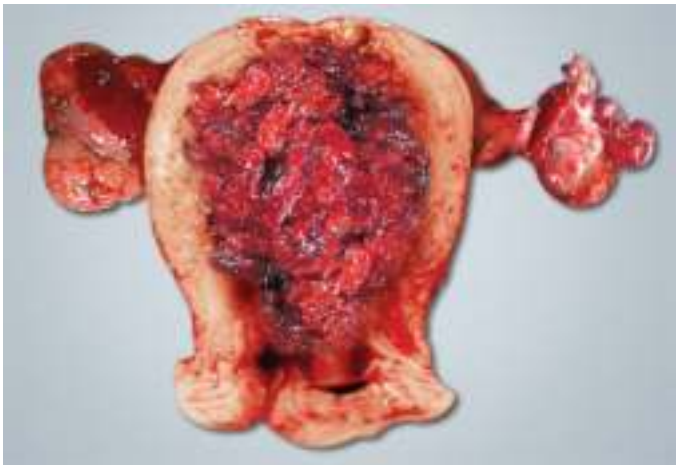

Fig. 24.110: Invasive hydatidiform mole. It is invading myometrium.

GESTATIONAL TROPHOBLASTIC NEOPLASTIC DISORDERS

GESTATIONAL CHORIOCARCINOMA

Gestational choriocarcinoma lacks chorionic villi. It is highly invasive epithelial malignant tumor of trophoblast, which shows widespread metastases.

- Tumor is derived from hydatidiform mole (50% of cases), previous abortion (25%), normal pregnancy (22%), and ectopic pregnancy in 1 of 30,000 pregnancies.
- Tumor occurs more often in Asian women especially younger than 20 and older than 40 years. Very young and older women (<20 and >40 years) are most commonly affected.

Clinical Features

Patient presents with irregular bloody, foul smelling discharge per vagina, fever, cachexia with raised serum hCG level. Rapidly growing tumor causes ischemic necrosis, hemorrhage and secondary infection. Presence of infection reveals foul smell discharge per vagina.

Surgical Pathology: Gestational Choriocarcinoma

Gross Morphology

Gestational choriocarcinoma is soft, fleshy, yellow white, large pale areas, ischemia, necrosis, foci of cystic softening with extensive hemorrhage. It does not classically produce a large bulky mass (Fig. 24.111).

Light Microscopy

Gestational choriocarcinoma is composed of abnormal proliferation of syncytiotrophoblast and cytotrophoblast. It does not form chorionic villi. Areas of hemorrhage and necrosis are present (Fig. 24.112).

Immunohistochemistry Technique	
Neoplastic cells of gestational choriocarcinoma are immunoreactive to β-hCG, CD10, inhibin, CD146, p63, Ki-67 (MIB-1), HPL, Mel-Cam (CD146), p53.	
Markers	**Expression**
▪ β-hCG	▪ Positive (100%)
▪ CD10	▪ Positive (100%)
▪ Inhibin	▪ Positive (85%)
▪ CD146	▪ Positive (70%)
▪ p63	▪ Positive (70%)
▪ Ki-67 (MIB-1)	▪ Positive (49–89%)
▪ HPL (human placental lactogen)	▪ Positive (45%)
▪ Mel-Cam (CD146)	▪ Positive (6–75%)
▪ p53	▪ Positive (<25%)
▪ p16	▪ Negative
▪ Pan cytokeratin (CK5/CK6) AE1/AE3	▪ Negative
▪ CEA	▪ Negative

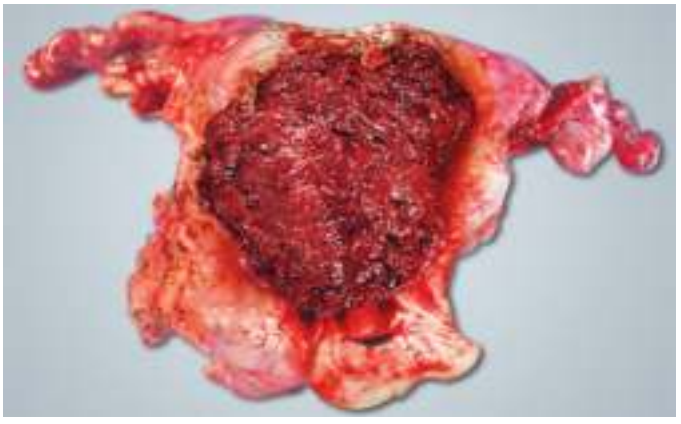

Fig. 24.111: Gestational choriocarcinoma. It shows soft and fleshy tumor with extensive hemorrhage and necrosis.

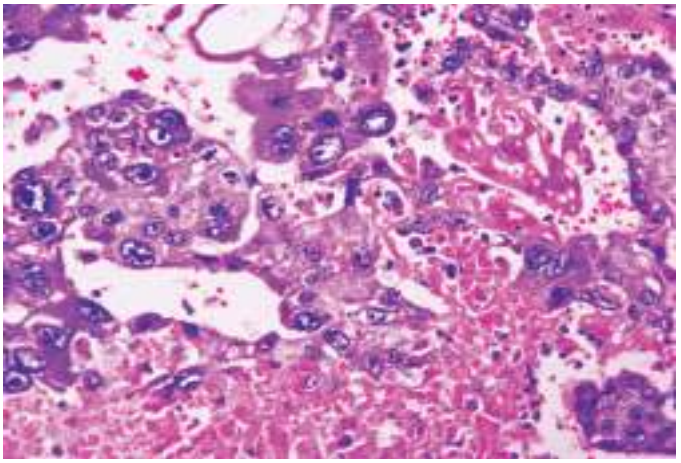

Fig. 24.112: Gestational choriocarcinoma. Tumor is composed of multinucleated syncytiotrophoblastic and cytotrophoblastic cells. The multinucleated syncytiotrophoblasts have voluminous eosinophilic cytoplasm and large darkly staining irregular nuclei with prominent nucleoli. The smaller mononuclear cytotrophoblasts are fairly uniform in size with amphophilic cytoplasm and distinct cellular outlines resembling to the tumor cells of solid yolk sac tumor (400X).

Mode of Spread

The gestational choriocarcinoma invades the underlying myometrium, extends uterine to serosa, lymphatic channels and blood vessels. It is associated with extensive hemorrhage and necrosis. In fatal cases, metastases are seen in lung (50%), vagina (30%) brain, bone marrow, liver, kidney and other organs. In occasional case, primary tumor has undergone total necrosis, while the patient has clinical features due to metastases.

Prognosis and Treatment

Gestational choriocarcinoma is treated by evacuation of uterine contents, surgery and chemotherapy. Tumor is highly responsive to chemotherapy regimens, such as EMA/CO (methotrexate, actinomycin D, cyclophosphamide, vincristine and etoposide).

- Tumor arising from the placenta carries paternal gene that are foreign to the host.
- In contrast, tumor arising from the host's own germ cells has the same genes as the host. This accounts for the fact that gestational choriocarcinomas are readily curable with chemotherapy. It probably stimulates the host immune system in the defense against the choriocarcinoma cancer stem cells (CSCs).
- On the other hand, germ cell choriocarcinomas are incurable. Prognosis is very good with 100% cure rate/remission.

PLACENTAL SITE TROPHOBLASTIC TUMOR

Placental site trophoblastic tumor (PSTT) originates from the intermediate trophoblastic cells of the implantation site. It usually occurs in multiparous women, and sometimes long after the last known pregnancy.

- Usual location of PSTT is in the uterine fundus, where it invades the myometrium and serous coat. It is preceded by normal pregnancy in 50% of cases. Spontaneous abortion can occur with increased serum hCG level. Serum levels of hCG are generally low.
- PSTT is composed of intermediate trophoblastic cells that display a marked propensity to invade blood vessels. Vascular invasion is associated with fibrin deposition.
- PSTT is cured by curettage alone. PSTT may undergo malignant transformation in 10–15% of cases.
- The diagnosis of placental site trophoblastic tumors, particularly the distinction between placental site tumor from an exaggerated placental site can be difficult. Mel-Cam (also known as CD146 and MUC18) is recently recognized cell adhesion molecule belonging to the immunoglobulin gene superfamily that specifically identifies intermediate trophoblast. A double-staining technique using MIB-1 antibody determines the Ki-67 proliferative index in Mel-Cam

defined intermediate trophoblast is a useful technique in the diagnosis of exaggerated PSTT.

Clinical Features

Patient with placental site trophoblastic tumor can present with either amenorrhea or abnormal bleeding per vagina, often accompanied by uterine enlargement. When uterine enlargement ceases the diagnosis of missed abortion is sometimes made. About 66% of cases follow a full term pregnancy and are in stage I. Recurrence or metastases occurs in 25–30% of cases.

Surgical Pathology: Placental Site Trophoblastic Tumor

Gross Morphology

- Placental site trophoblastic tumor (PSTT) is well circumscribed nodular mass up to 10 cm projecting into uterine cavity or predominantly involving the myometrium.
- Cut surface is usually solid, fleshy and white-tan to light yellow, containing only focal areas of hemorrhage or necrosis if present.
- Deep myometrial invasion is observed in 50% of cases, which frequently extends into the uterine serosa (18%) and rarely adnexal structures and broad ligament.

Light Microscopy

- PSTT has infiltrative growth pattern, which consists of sheets of large, polyhedral to round intermediate trophoblastic mononuclear cells and scattered multinucleated cells.
- At the periphery, trophoblast cells invade singly or in cords and nests in the myometrium by separating individual muscle fibers or groups of muscle fibers. Vascular invasion is commonly seen.
- Most PSTTs have a low mitotic count 2–4 mitoses per high power fields.
- Decidua or Arias-Stella reaction my be present in the adjacent uninvolved endometrium. Chorionic villi are never identified.

Immunohistochemistry Technique

PSTT is immunoreactive to Mel-Cam (CD146), human placental lactogen (HPL), β-hCG, Ki-67 (MIB-1), p63.

Markers	Expression
▪ Mel-Cam (CD146)	▪ Positive membranous staining (75–100%)
▪ Human placental lactogen (HPL)	▪ Positive (25–75%)
▪ β-hCG	▪ Positive (>10%)
▪ Ki-67 (MIB-1)	▪ Positive
▪ p63	▪ Negative

Prognosis

Prognosis is poor, if the tumor develops after 4 years interval from prior pregnancy. In 10% of cases, widespread metastases are seen. ETT behaves in a benign fashion in two-thirds of cases. It may recur and metastasize in one-third of cases.

EPITHELIOID TROPHOBLASTIC TUMOR

Epithelioid trophoblastic tumor (ETT) is a rare trophoblastic tumor composed of chorionic-type intermediate trophoblast. ETT originates in the uterine corpus, lower uterine segment, or endocervix and grows in a nodular expansive manner.

Surgical Pathology: Epithelioid Trophoblastic Tumor

Light Microscopy

- Histologically, epithelioid trophoblastic tumor (ETT) resembles a carcinoma. It is composed of cells with distinct borders and abundant eosinophilic to vacuolated cytoplasm.
- Histologic hallmark of ETT is the presence of multifocal necrosis with accumulation of a fibrinoid eosinophilic material.
- Another key feature is that the neoplastic cells may displace the endometrial and endocervical epithelium.

Immunohistochemistry Technique

Neoplastic cells of epithelioid trophoblastic tumor are immunoreactive to p53, cyclin E, Ki-67 (MIB-1), HPL (human placental lactogen) and β-hCG.

Markers	Expression
▪ p53	▪ Positive (<25–75%)
▪ Cyclin E	▪ >50%
▪ Ki-67 (MIB-1)	▪ Positive (>10%)
▪ Mel-Cam (CD146)	▪ Positive (0–2%) membranous staining
▪ Human placental lactogen (HPL)	▪ Positive (0–2%)
▪ β-hCG	▪ Positive (0–25%)

PREGNANCY ASSOCIATED NON-NEOPLASTIC DISORDERS

TOXEMIA OF PREGNANCY

Toxemia of pregnancy most often occurs during third trimester in women with first pregnancy. It most often affects kidneys, liver and brain (hemorrhages) in acute toxemia of pregnancy. Patient develops puffiness on face, pitting edema and convulsions in true eclampsia. It usually begins insidiously after the 20th week of pregnancy. Toxemia of pregnancy exists in two forms: pre-eclampsia and eclampsia.

- Pre-eclampsia is defined as a previously normotensive pregnant woman whose blood pressure reaches 140/90 mm Hg or greater after 20 weeks gestation on at least two occasions (pregnancy-induced

hypertension). The addition of proteinuria (≥1+ on urine dipstick confirmed by a 24-hour collection ≥300 mg of protein) indicates that pre-eclampsia has occurred.

- Eclampsia of pregnancy indicates one or more of the following: blood pressure systolic >160 or diastolic >100 mm Hg, proteinuria >5 g/24 hours or ≥3+ proteinuria or two dipstick evaluations at least 4-hour apart; headache; visual disturbances, epigastric or right upper quadrant pain; oliguria, thrombocytopenia, and/or elevation of hepatocellular enzymes, fetal growth restriction, and/or pulmonary edema.
  - Hemolysis elevated liver enzymes, low platelet count syndrome is a form of severe eclampsia before the 37th week of pregnancy with a specific triad finding including hemolysis, elevated hepatocellular enzymes, and thrombocytopenia. Convulsions, signify the onset of eclampsia of pregnancy.
  - Eclampsia of pregnancy adversely affects kidneys, liver (subcapsular hemorrhages and periportal necrosis), and brain (hemorrhages). Patient may also develop placental infarcts.
  - Delivery of the platient is the only effective medical intervention. The definitive therapy is the removal of the placenta, hopefully by normal delivery (Table 24.52 and Fig. 24.113).

Table 24.52 Differences between pre-eclampsia (mild) and eclampsia (severe) of pregnancy

Parameters	Pre-eclampsia of Pregnancy	Eclampsia of Pregnancy
Blood pressure	140/90	>160/110 mm Hg
Proteinuria	Traces to mild	Moderate to marked proteinuria
Urine output	Normal	Oliguria
Headache	Absent	Present
Cerebral and visual disturbances	Absent	Present
Upper abdominal pain	Absent	Present
Convulsions	Absent	Present
Serum creatinine	Normal range	Elevated
Thrombocytopenia	Absent	Present
Pulmonary edema	Absent	Present
Fetal growth retardation	Absent	Present

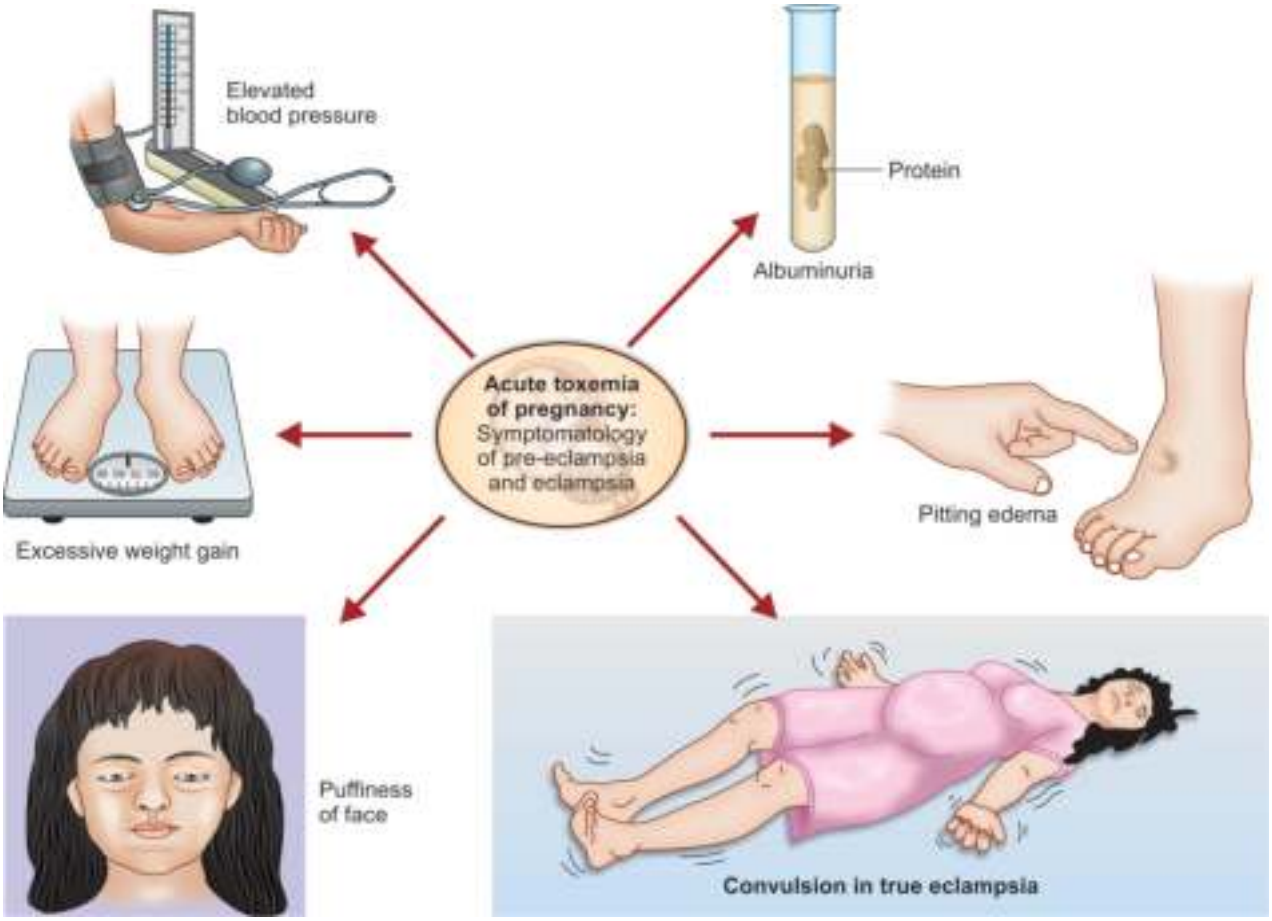

Fig. 24.113: Toxemia of pregnancy: Clinical manifestations in pre-eclampsia and eclampsia of pregnancy.

ETIOPATHOGENESIS

The spiral arteries that supply maternal blood flow to the placenta normally expand to accommodate the growing placentofetal unit, which usually occurs due to trophoblastic remodeling of spiral arteries. Failure to expand spiral arteries results in decidual vasculopathy, reduced maternal blood flow, placental ischemia, and toxemia of pregnancy.

- Ischemic placenta synthesizes soluble factors resulting in generalized maternal dysfunction. The soluble factors synthesized by ischemic placenta act by neutralizing the angiogenic and vasodilatory effects of vascular endothelial growth factor and placental growth factor produced by placenta.
- Two types of abnormal placentas are associated with pre-eclampsia of pregnancy.
- Small placenta with decidual vasculopathy and thin umbilical cord is most common cause of maternal vascular perfusion. Less common is the large placenta associated with diabetes mellitus, placental hydrops, multiple gestation and hydatidiform mole.

CLINICAL FEATURES

As the disease progresses the diastolic pressure persistently exceeds 110 mm Hg. Proteinuria is ≥3 g per day, and renal function declines. It is complicated by convulsions, and disseminated intravascular coagulation the term eclampsia is applied, that can be fatal. Disseminated intravascular coagulation (DIC) is characterized by formation of fibrin thrombi in the liver, brain, and kidneys. Patient may develop subcapsular hemorrhage in the liver.

ECTOPIC PREGNANCY

Ectopic pregnancy is defined as implantation (gestation) of the fertilized ovum outside the normal uterine cavity. Ectopic pregnancy is usually discovered early in a suspected pregnancy when ultrasound examination reveals the uterus to be empty. Ampulla of the fallopian tube is the most common site of ectopic pregnancy. The classic clinical triad of ectopic pregnany is pain abdomen, amenorrhea and vaginal bleeding in 50% of cases. On clinical examination, palpable adnexal mass and abdominal tenderness are demonstrated in many patients. Rupture of tubal ectopic pregnancy products leads to hypotensive shock.

- **Predisposing factors:** Predisposing factors include pelvic inflammatory disease (15–50%) with chronic salpingitis often gonorrheal infection leading to partial blockage, peritubal adhesions. There has been increased incidence of ectopic pregnancy in women fitted with IUCD (50%) with normal tubes, prior ectopic pregnancy, congenital tubal anomalies and endometriosis.
- **Locations:** Over 95% of ectopic pregnancies occur in the fallopian tube. Ectopic pregnancy in ampullary portion of the fallopian tube is commonest followed by distil/middle-third of tube and isthmus. Other uncommon sites of implantation are ovary, cervix and abdominal cavity.
- **Clinical features:** Patient presents with severe abdominal pain about 6 weeks after previous normal menstrual period. Tubal rupture causes bleeding in tube (hematosalpinx) and pelvis resulting in hypotensive shock. Tubal pregnancy is suspected when a tubal hematoma is present.
- **Tubal changes:** The fertilized ovum implants in tubal wall with minimal decidual reaction. By 12th week of gestation, the trophoblast easily penetrates the mucosa and thin tubal wall resulting in rupture and intratubal as well as intraperitoneal hemorrhage. Less commonly tubal pregnancy may regress spontaneously with resorption of the entire gestation.
- **Ultrasonography:** USG, estimation of blood hCG levels and laparoscopy aid in diagnosis of ectopic tubal pregnancy.

Surgical Pathology: Ectopic Pregnancy in Fallopian Tube
Gross Morphology
Fallopian tube shows dilatation, hemorrhagic, chorionic villi with or without embryo (Fig. 24.114).
Light Microscopy
Fallopian tubal mucosa or wall demonstrates gestation products (chorionic villi or trophoblast) (Fig. 24.115).

Fig. 24.114: Tubal ectopic pregnancy. Cut opened tube demonstrates gestation products.

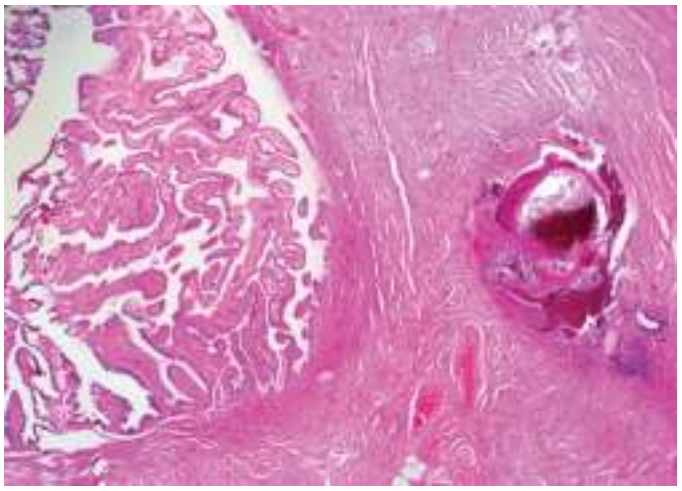

Fig. 24.115: Ectopic tubal pregnancy. A positive pregnancy test (presence of human chorionic gonadotropin), ultrasound, and culdocentesis with presence of blood are helpful in making the diagnosis of ectopic pregnancy. Seen here is tubal epithelium at the right, with rupture site and chorionic villi at the lower left (100X).

THROMBOEMBOLISM

There is increased risk for deep vein thrombosis resulting in pulmonary embolism during pregnancy and postpartum period. The weight of the fetus on femoral vessels slows blood venous return. Hormonal changes and stress precipitates thrombi formation. Thromboplastin released from amniotic fluid results in activation of coagulation system.

- Venous thrombi are present in deep veins in the lower extremities below knee joint (most common in 90%), superior saphenous, ovarian or uterine veins.
- Patient with deep vein thrombosis results in pain and distal edema (Homar's sign). Patient may develop migratory thrombophlebitis and pulmonary embolization. Iliofemoral venous thrombus is formed during puerperium.
- Venous thrombi formed in the lower extremities propagate (extend) toward the heart may cause pulmonary artery embolization.
- Deep vein thrombosis is entirely asymptomatic in 50% of affected patients. It is recognized only after thrombus is embolized.

AMNIOTIC FLUID EMBOLISM

The cause of amniotic fluid embolism is a tear in the placental membranes and rupture of maternal veins. Amniotic fluid embolism is characterized by sudden respiratory difficulty, progressing to shock and often to death. Amniotic fluid embolism and abruptio placentae are well-known causes of disseminated intravascular coagulation (DIC). It is marked by masses of debris and epithelial squamous cells in the maternal pulmonary microcirculation. Amniotic fluid embolism should not be confused with the amniotic fluid aspiration syndrome seen in neonates.

Amniotic Fluid Aspiration Syndrome in Newborn

Amniotic fluid aspiration syndrome in newborn characterized by squamous epithelial cells of amniotic fluid origin in fetal terminal air spaces and major bronchi.

GESTATIONAL DIABETES MELLITUS

Pregnancy associated transient diabetes mellitus is known as gestational diabetes mellitus. Gestational diabetes mellitus is usually identified in the 24–28 weeks of gestation. A woman, who develops gestational diabetes mellitus, has high risk for development of type 2 diabetes mellitus later in life.

- During pregnancy, anti-insulin hormones are synthesized by placenta such as estrogen, prolactin, human chorionic somatomammotropin, cortisol, and progesterone. Human chorionic somatomammotropin regulates carbohydrate and protein metabolism of the mother to ensure delivery to the fetus of glucose for energy and protein for fetal growth.
- Gestational diabetes mellitus is diagnosed with a glucose tolerance test, in which the woman drinks 50 glucose. Blood glucose level after an hour >140 mg/dl is considered positive. The confirmatory test is a 3-hour, 100 glucose tolerance test in which the blood glucose values are set at highest sensitivity. Urine analysis is done for sugar.
- Due to increased fetal birth weight in gestational diabetes mellitus, there is increased indication of cesarean section. There is increased fetal birth weight, brachial plexus injuries, and neonatal respiratory distress syndrome (hyaline membrane disease).
- During intrauterine life in diabetic mothers, fetus develops pancreatic β cell hyperplasia in response to hyperglycemia and increased demand of insulin during early gestation. Pancreatic β cells, which may secrete insulin autonomously and cause hypoglycemia at birth.

SHEEHAN'S SYNDROME

During postpartum period, woman may develop postpartum pituitary gland necrosis, which is characterized by hypopituitarism caused by obstetric blood loss, hypovolemic shock with resultant ischemia of anterior pituitary during delivery and over weeks and months after childbirth (Fig. 24.116).

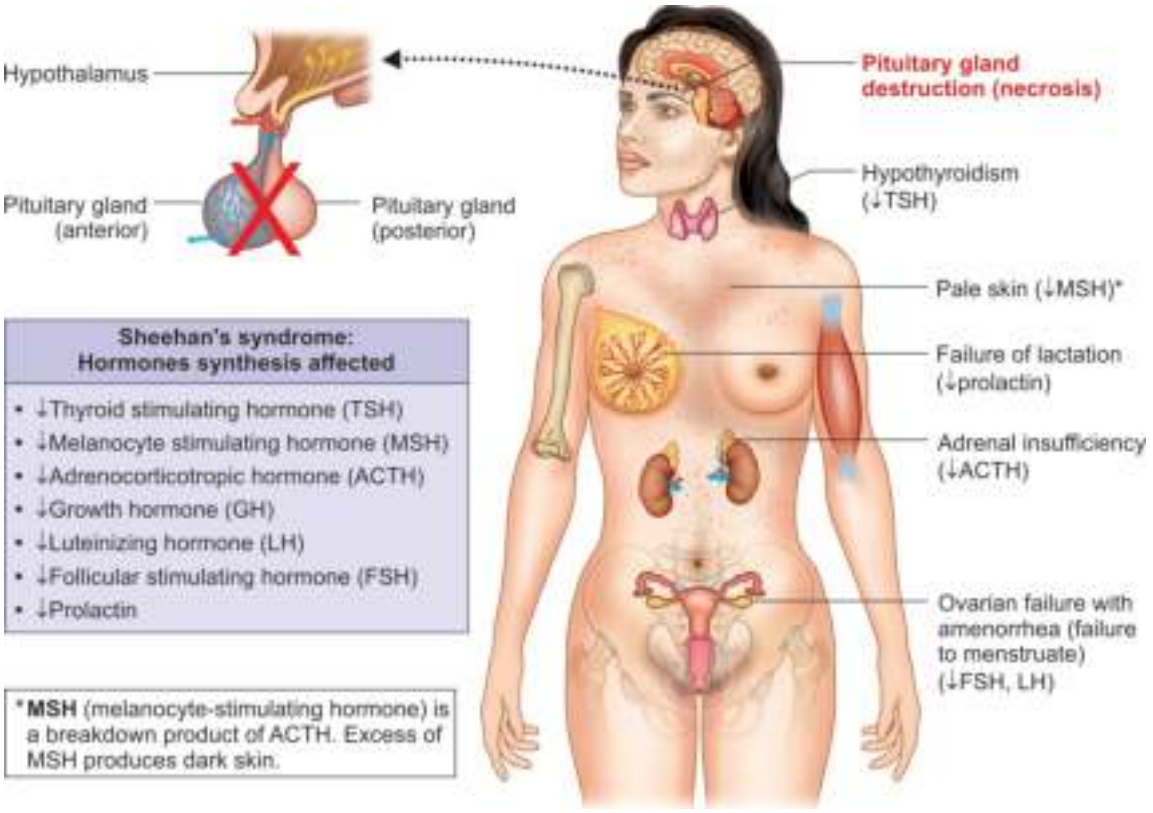

Fig. 24.116: Sheehan's syndrome. It is caused by hemorrhagic destruction of the pituitary in pregnancy.

PLACENTAL DISORDERS

PLACENTAL MALPERFUSION

Placental malperfusion refers to chronic perfusion ischemia resulting from maternal vascular diseases such as pre-eclampsia, eclampsia, chronic hypertension, diabetes mellitus, systemic lupus erythematosus, antiphospholipid syndrome, thrombophilia and cocaine drug. Histologic examination of placenta shows infarcts of usual type.

LONG OR SHORT UMBILICAL CORD

Length of the umbilical cord should be documented in pathology reports. The mean length of umbilical cord is 50–60 cm. A long umbilical cord more than 70 cm is prone to knots, torsion, prolapse, enlargement and compression, which my result in decreased blood flow and increased morbidity and mortality of the fetus. Conversely, a short umbilical cord is defined as measuring <32 cm, which is associated with restricted fetal movements.

VELAMENTOUS INSERTION AND VASA PREVIA

Normally, the umbilical cord insertion is located centrally or near the center of the placental disc. Marginal insertion refers to an umbilical cord that inserts within <2 cm from the disc margin. A velamentous umbilical cord inserts into the fetal membranes, so that the blood vessels travelling through the membranes are susceptible to compression, thrombosis, and rupture.

- Velamentous umbilical cord insertion can cause vasa previa, in which the umbilical cord blood vessels within the membrane present before the fetus during delivery and may undergo rupture resulting in catastrophic fetal hemorrhage.
- It is important to measure the sample of any membranous blood vessels to check for thrombosis, inflammation or necrosis.

OLIGOHYDRAMNIOS

Oligohydramnios is defined as an abnormally reduced volume of amniotic fluid. The reduced available space results in fetal deformities as well as compression of the umbilical cord.

CHORIOAMNIONITIS

Chorioamnionitis results from infectious organisms travelling through the birth canal (vagina or cervix) to the amniotic cavity, which often follows premature rupture of membranes. It can have devastating consequences for both the mother and the fetus. Maternal

neutrophils migrate from the decidua to the chorion and later into the amniotic membrane. Fetal neutrophils migrate from chorionic blood vessels to amnion and from the umbilical cord and blood vessels as well (funisitis).

- Staging and grading of chorioamnionitis is based on assessment of both maternal and fetal responses.
- In full term pregnancy, chorioamnionitis usually follows rupture of the membranes. In preterm pregnancies, chorioamnionitis predisposes to premature rupture of the membranes and various fetal complications. Group B streptococci are the most frequent etiological organisms of severe fetal/neonatal sepsis.
- Clinical diagnostic criteria for chorioamnionitis include maternal fever during labor, leukocytosis, uterine tenderness, and maternal or fetal tachycardia (Fig. 24.117).

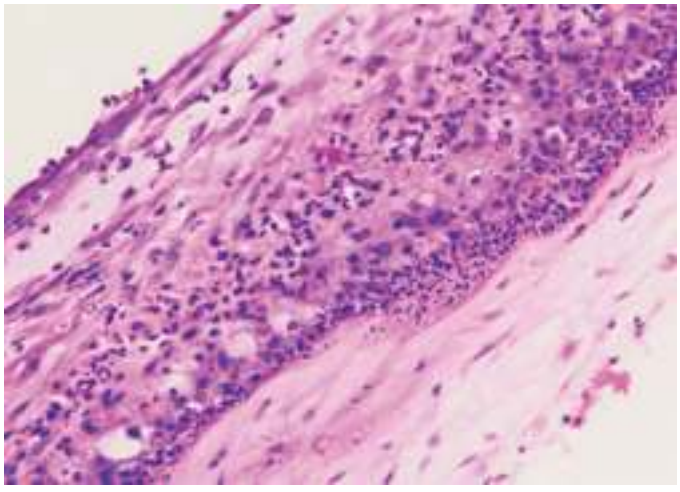

Fig. 24.117: Chorioamnionitis (400X).

ABNORMALITIES OF PLACENTAL ATTACHMENT

Abnormal adherence of the placenta to the uterine wall is categorized according to the depth of chorionic villous invasion into the myometrium.

ABRUPTIO PLACENTAE

Abruptio placentae is premature separation of the placenta and an important cause of antepartum bleeding and fetal death. It is often associated with ectopic tubal pregnancy and disseminated intravascular coagulation.

PLACENTA ACCRETA

Placenta accreta is an abnormal adherence of the placenta to the underlying uterine wall without further invasion; the decidual layer is defective. It most often occurs in inflamed endometrium and old scars from prior cesarean sections or other surgery. Most patients have a normal pregnancy and delivery. Impaired placental separation leads to severe bleeding in the third trimester before delivery.

PLACENTA INCRETA

Placenta increta defines chorionic villi invading the underlying myometrium.

PLACENTA PERCRETA

Placenta percreta refers to penetration of placental villi into full thickness of the uterine wall.

PLACENTA PREVIA

Placenta previa is an attachment of the placenta to the lower uterine segment, partially or completely covering the cervical os. This may coexist with placenta accreta. It is often manifested by bleeding.

FEMALE BREASTS

FEMALE BREASTS: OVERVIEW

EMBRYOLOGY OF FEMALE BREASTS

Each breast is a group of large glands derived from epidermis, which lies in a network of fascia derived from the dermis and the superficial fascia at the ventral surface of the thorax.

- Breast development begins in the 6th week of fetus development.
- Mammary gland originates from milk streaks, bilateral ectodermal thickenings that extend from the axilla to the groin.
- The ectoderm invaginates into the surrounding mesenchyme.

ANATOMY AND PHYSIOLOGY OF FEMALE BREASTS

The female breasts are modified sweat glands, which develop from the milk line. At birth there is no difference between male and female breasts. Pubertal growth of breasts occurs due to glandular and fibrofatty proliferation. The amount of fibroglandular tissue decreases with age. Multiple hormonal stimulation significantly increases the volume of the breast tissue during pregnancy (Fig. 25.1).

Structure of Female Breasts

Each female breast is composed of 15–20 lobes interspersed with adipose tissue and connective tissue arranged in radial fashion extending from the nipple. The nipple is situated in the center of a darker area of skin called the areola. The areola contains small glands, called Montgomery glands, which lubricate the nipple during breastfeeding. There are no muscles in the breasts, but the pectoral muscles lie under each breast and cover the ribs. Structure of female breast is shown in Fig. 25.2.

Terminal Duct Lobular Unit

The lobules of each female breast consist of acini or glands lined by an outer myoepithelial cells and inner secretory cells, also known as luminal cells. Each lobe of the breast has one unique functional terminal duct lobular unit (TDLU), which drains via a branching duct system, i.e. intralobular ducts, interlobular ducts and lactiferous sinuses outside through the nipple. Duct system carries milk to the nipples. Each duct acinus has a lining epithelium surrounded by a thin myoepithelial cell layer responsive to oxytocin, the hormone that stimulates lactation.

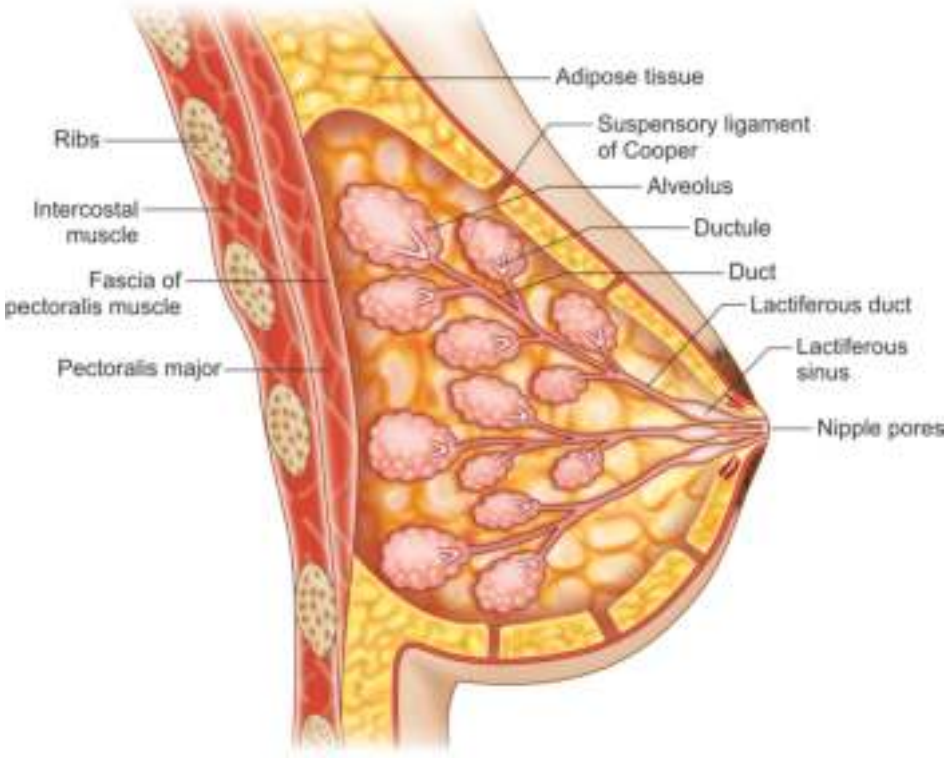

Fig. 25.1: Structure of the adult female breast showing major components and their functions.

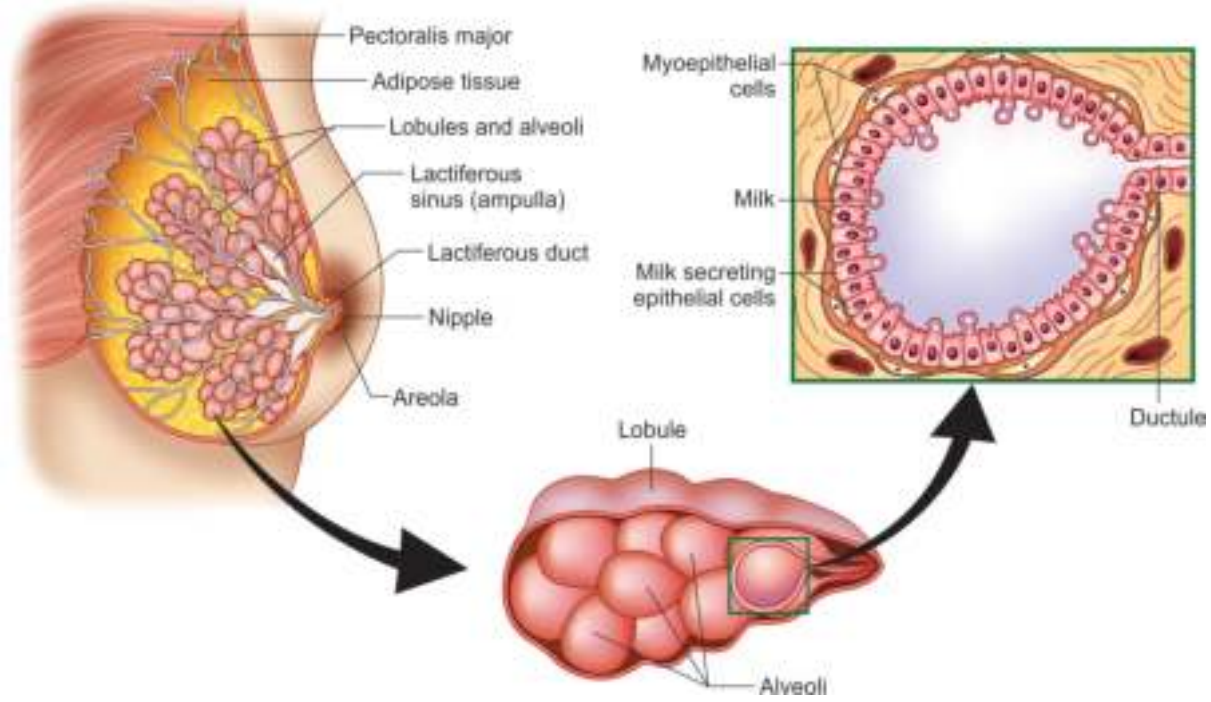

Fig. 25.2: Structure of female breast. Each lobe of the breast has one unique terminal duct lobular unit (functional unit), which drains via a branching duct system, i.e. intralobular ducts, interlobular ducts and lactiferous sinuses outside through the nipple. Duct system carries milk to the nipples. Each duct has a lining epithelium surrounded by a thin myoepithelial cell layer responsive to oxytocin, the hormone that stimulates lactation.

- During 30 weeks of pregnancy, each breast shows controlled proliferation of lobular acini lined by cells containing secretory vacuoles and secretions in their lumina. Breast milk comprises casein, α-lactalbumin and milk fat globule derived from the luminal surface of ductal cells.
- The acinus is lined by epithelial cells surrounded by myoepithelial cells and the basement membrane. Myoepithelial cells may function as a guardian of breast tissue integrity by maintaining its intergrity. Myoepithelial cells suppress stromal invasion by breast ductal/lobular carcinoma tumor cells by the synthesis of various anti-angiogenic and anti-invasive factors.
- Benign breast diseases and carcinomas arise in the terminal duct lobular unit (TDLU).
- Myoepithelial cells are smooth muscle cell-like cells present in the glandular epithelium as a thin layer above the basement membrane and beneath the luminal cells of breast. Myoepithelial cell layer is intact in normal breast and ductal carcinoma *in situ* (DCIS); but absent in invasive ductal carcinoma. Microglandular adenosis lacks myoepithelial cells. Panel of immunohistochemical markers is used on paraffin-embedded tissue section of breast lesions to demonstrate myoepithelial cells in breast.
  - Myoepithelial cells contain microfilaments and smooth muscle-specific cytoskeletal proteins such as α-actin and myosin that are responsible for the contractile phenotype mediated by oxytocin during lactation. Smooth muscle actin (α-actin), calponin, smooth muscle myosin heavy chain (SMMHC) and p63 are usual immunomarkers for myoepithelial cells.
  - Other immunomarkers are CK14 (HMWCK), S-100 protein, glial fibrillary acidic protein (GFAP) and CD10. Panel of immunohistochemical markers is used to demonstrate myoepithelial cells is given in Table 25.1.

Table 25.1 Panel of immunohistochemical markers is used to demonstrate myoepithelial cells

Markers	Expression
Smooth muscle actin (α-actin)	Positive
Calponin	Positive
Smooth muscle myosin heavy chain (SMMHC)	Positive
p53	Positive
CK14 (HMWCK)	Positive
S-100 protein	Positive
Glial fibrillary acidic protein (GFAP)	Positive
CD10	Positive

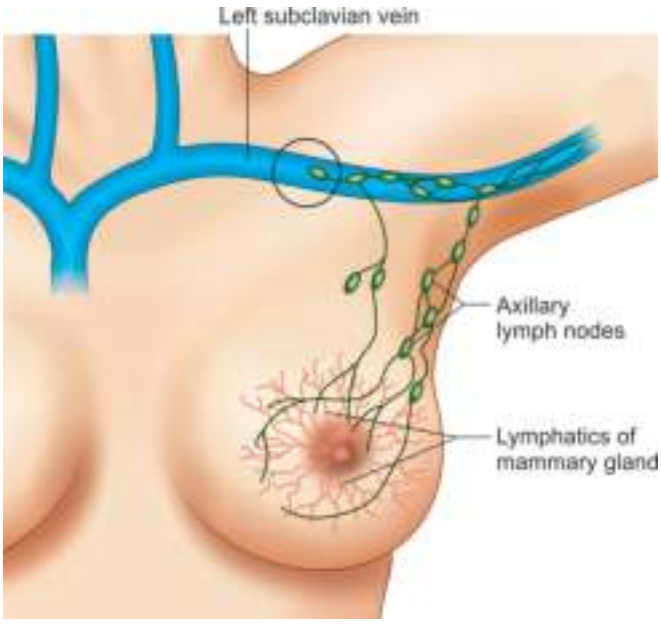

Fig. 25.3: Indicate a chain of the lymph nodes near the axilla and breast. Another point of contact between the two circulations (lymphatic and venous circulation).

Blood Supply of Female Breasts

The vascular supply of the breast is from internal mammary and lateral thoracic artery. There is communication between lymphatic and venous drainage in subclavicular region (Fig. 25.3).

Lymphatic Drainage of Female Breasts

The breast has extensive lymphatic drainage and lymph node groups: axillary nodes and internal thoracic lymph nodes. Approximately 75% of the lymphatic drainage occurs to the axillary lymph nodes. So, there is greater frequency of breast carcinoma metastases to axillary lymph nodes. Approximately 25% of lymphatic drainage from inner quadrants of breast is drained to internal mammary (parasternal) lymph nodes and skin lymphatic channels. To a lesser extent, lymph is also drained to lymph nodes adjacent to the vertebra.

There are five groups of breast lymph nodes:

1. **Central axillary lymph nodes:** These lymph nodes are located higher up in the middle of the axilla, over the ribs and serratus anterior muscle. These lymph nodes receive lymph from the other three groups of pectoral, subscapular and lateral lymph nodes.
2. **Pectoral (anterior) lymph nodes:** These lymph nodes are located along the lateral edge of the pectoralis major muscle, just inside the anterior axillary fold.
3. **Subscapular (posterior) lymph nodes:** These lymph nodes are situated along the lateral edge of the scapula, deep in the posterior axillary fold.
4. **Lateral lymph nodes:** These lymph nodes are situated along the humerus inside upper arm.
5. **Apical lymph nodes:** These lymph nodes are situated in the apical region of axilla (Fig. 25.4).

Role of Hormones in Breasts Development

The female breast development depends on a variety of hormones for its normal activity, which exhibits structural and functional variation throughout life, especially during puberty, pregnancy, lactation, normal menstrual cycle, and postmenopausal state.

- **Hormones and breast development:** Breast development and function depend on the ovarian hormones estrogen and progesterone. Hormones reaching breast via blood stream either interact with membrane receptors (prolactin) or nuclear receptors (estrogen). The hormone receptor interaction activates DNA synthesis of transcription factors responsible for proliferation and differentiation of terminal duct lobular unit. Estrogen hormone elongates the ducts and causes them to create side branches. Progesterone hormone increases the number and size of the lobules in order to prepare the breasts for nourishing a baby. Growth hormone, insulin and glucocorticoids also participate in proliferation of breast lobules.
- **Breast changes during pregnancy:** After ovulation, progesterone hormone makes the breasts to grow and blood vessels become filled with blood. At this time, the breasts often become engorged with fluid. Breasts may become tender and swollen. The female breasts during pregnancy undergo lobular hypertrophy; so that lactation can occur due to action of prolactin. Breast histology from a pregnant woman (30 weeks of gestation) shows the lobular acini lined by cells containing secretory vacuoles and filled with pink secretions in their lumens.

BREAST LUMPS AND THEIR ANATOMICAL CORRELATION

Frequency of Breast Lumps

A breast mass in a woman is likely to occur in decreasing frequency due to fibrocystic disease (40%), miscellaneous benign lesions (13%), carcinomas (10%) or fibroadenomas (7%) and no disease (30%). The presence of myoepithelial cells in breast typically indicates a benign disease and useful in diagnosis. The p63 is a reliable marker for myoepithelial cells. Other myoepithelial cell markers include S-100, GFAP (glial fibrillary acidic protein) and α-smooth muscle actin. Structure of the adult female breast shows major components and location of various lesions (Fig. 25.5).

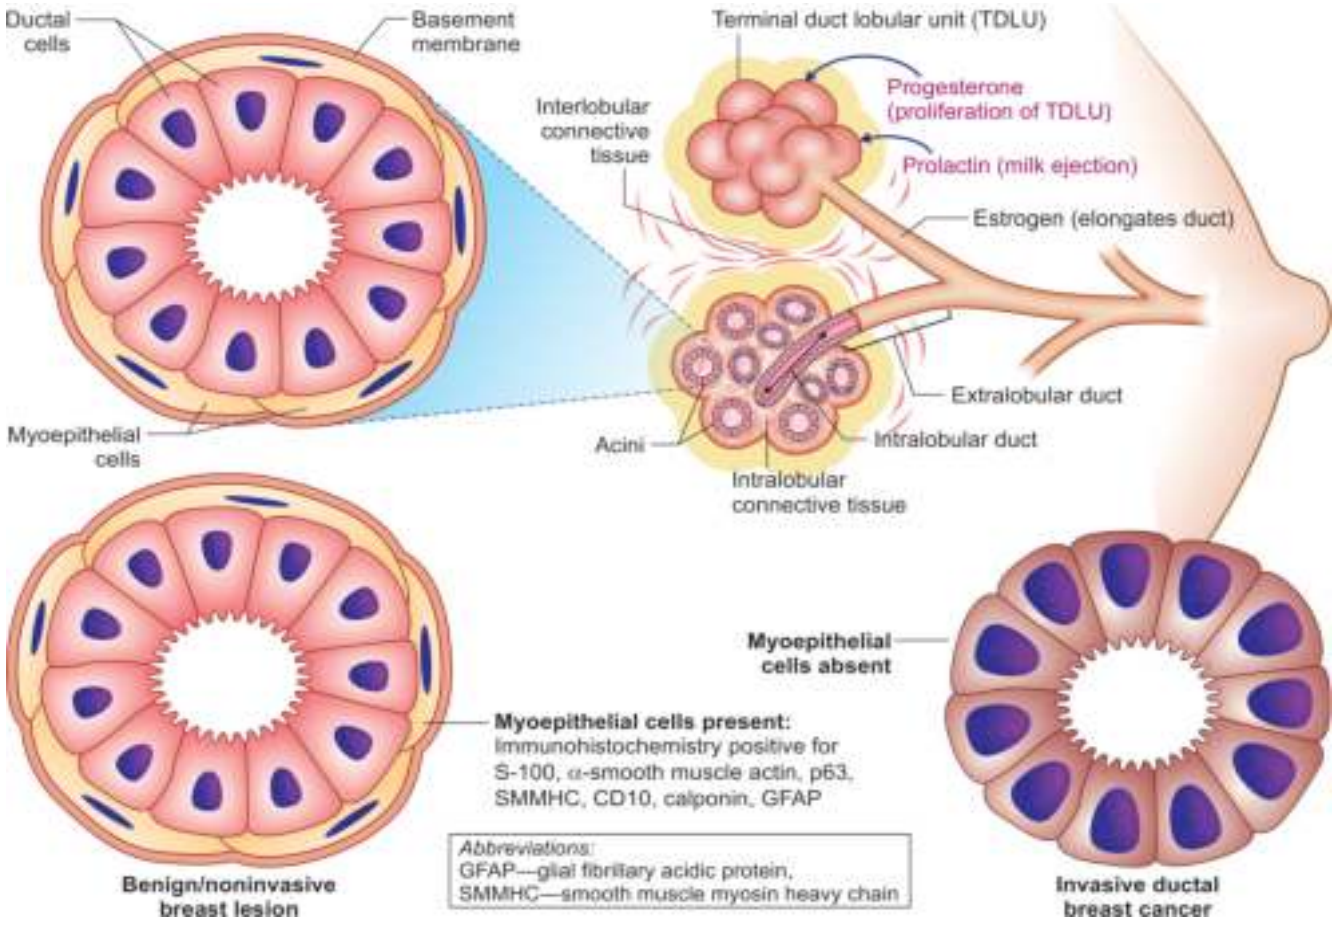

Fig. 25.4: A breast lobule shows the different components. The acinus is lined by epithelial cells surrounded by myoepithelial cells and the basement membrane.

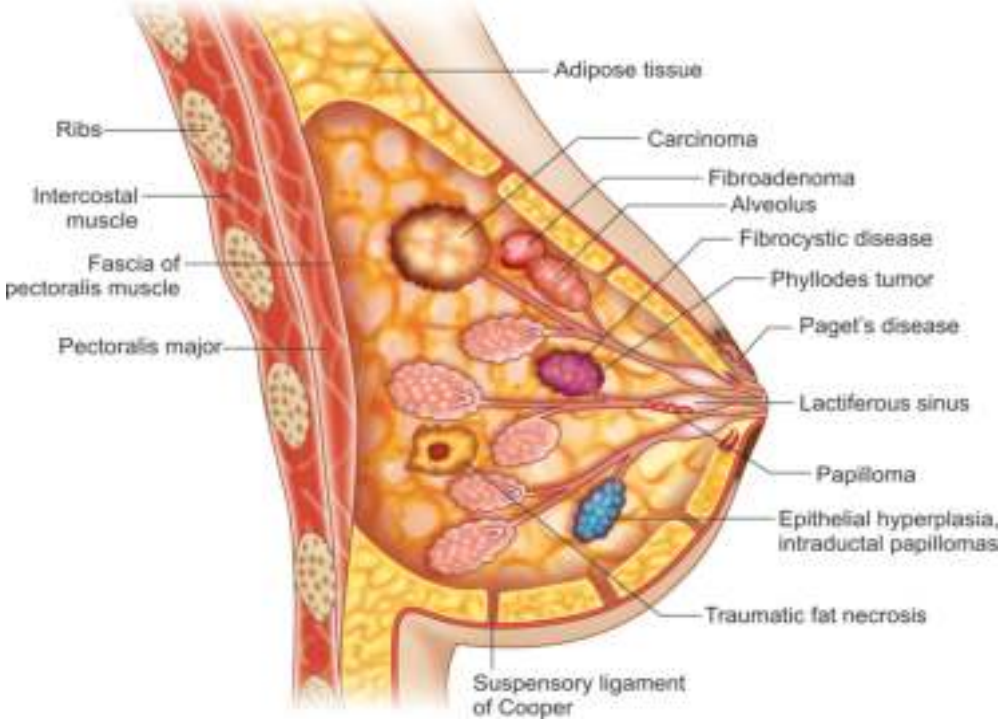

Fig. 25.5: Structure of the adult female breast shows major components and location of various lesions.

Nipple

The nipple may be site for Paget's disease of breast (ductal carcinoma involving nipple skin), nipple adenoma and breast abscess.

Lactiferous Ducts and Sinuses

The lactiferous ducts are the most common site for intraductal papilloma, galactocele (blocked lactiferous duct in a lactating woman), breast abscess, or plasma cell mastitis.

Large Ducts of Female Breasts

Large ducts are the most common site for **fibrocystic disease** and most ductal carcinoma of breast.

Terminal Duct Lobular Unit

The terminal lobules are involved in sclerosing adenosis (variant of fibrocystic change), lobular carcinoma and tubular carcinoma of breast.

Interlobular or Intralobular Stroma of the Breast

Breast stroma can be divided into interlobular and intralobular stroma. Interlobular stroma surrounds large ducts and terminal duct lobular units (TDLUs), and is more collagenous and dense than intralobular connective tissue.

- Interlobular stroma becomes more fatty after puberty; and its increase in volume of this compartment is responsible for majority of breast tissue. **Fibroadenoma** and **phyllodes tumor** are derived from intralobular stroma.
- The breast tumor stroma mainly consists of the basement membrane, fibroblasts, extracellular matrix, immune cells and blood vessels. Although, most host cells in the stroma possesses certain tumor-suppressing abilities. The stroma will change during breast carcinoma and eventually promote growth, invasion and metastasis.

CLINICAL PRESENTATION OF BREAST LUMPS

Women with breast disease most often complains of pain, a palpable lump without a discrete lump and nipple discharge. It is most important to evaluate these women because of the possibility of breast carcinoma.

- Patient with breast carcinoma may present with breast lump, change in the symmetry of the breast, and nipple itching, burning, erosion or retraction, pathological bone fractures and increased serum calcium levels.
- A spontaneous nipple discharge of any kind in a non-breastfeeding and non-lactating women warrants investigation for breast disease (Table 25.2).

Painful Breasts

Tightness, tenderness or sharp pain in one or both breasts can occur not due to underlying disease. Examples include a tight-fitting bra, pregnancy, menstruation, breastfeeding or exercise.

- **Premenopausal women:** These women present with cyclic pain in bilateral breasts, increasing in severity from mid-cycle onwards, and pain improving at menstruation. Women often report fullness,

Table 25.2 Pathological basis of breast signs and symptoms in women

Clinical Presentation	Pathological Correlation	
Breast lump frequency	▪ Fibrocystic disease (40%) ▪ No disease (30%) ▪ Miscellaneous benign lesions (13%)	▪ Breast carcinomas (10%) ▪ Fibroadenomas (7%)
Onset of lump	▪ Fat necrosis-associated with trauma ▪ Fibrocystic disease-associated with menstrual cycle	▪ Duration and rate of growth of lump (fibroadenoma shows slow growth no apparent change in size in 6+ months and rapid growth in breast carcinoma)
Pain and tenderness in breasts	▪ Mastitis (acute or chronic) ▪ Mammary duct ectasia ▪ Breast abscess	▪ Galactocele ▪ Fibrocystic disease (cyclic pain)
Nipple discharge	▪ Milky nipple discharge (galactorrhea) occurs due to increased prolactin level during pregnancy, pituitary adenoma, oral contraceptive therapy, tricyclic antidepressant, methyldopa	▪ Serous/bloody (intraductal papilloma/cancer) ▪ Nipple with rash, eczema-like or blood stained discharge in Paget's disease of nipple (ductal carcinoma involving overlying skin)
Manual examination of breasts	▪ Diffuse: Fibrocystic disease ▪ Discrete: Neoplasm or cyst ▪ Mobile lump: Fibroadenoma	▪ Bulky tumor: Phyllodes tumor and giant fibroadenoma ▪ Immobile lump: Invasive breast carcinoma

Contd...

Table 25.2 Pathological basis of breast signs and symptoms in women (*Contd...*)

Clinical Presentation	Pathological Correlation	
Nipple retraction	▪ Breast carcinomas ▪ Fat necrosis of breast	▪ Inflammatory breast lesions undergoing fibrosis
Skin features	▪ Peau d' orange: Lymphatic blockage by carcinoma cells and puckering ▪ Tethering: Due to invasion of Cooper's ligament in breast cancer	▪ Erythema: Acute mastitis and Paget's disease of nipple
Microcalcifications on mammography	▪ Dystrophic calcification associated with fibrocystic changes such as cysts and adenosis	▪ Carcinoma *in situ* or invasive carcinoma
Metastases	▪ Lymph nodes involvement in axillary and supraclavicular regions ▪ Visceral metastases	▪ Bone pain and pathological fractures occur due to metastases

heaviness, areas of tenderness and increased breast size during 3–7 days before each menstruation.

- **Postmenopausal women:** These women present with continuous localized breast pain not related to menstrual cyclic changes. Approximately 90% of painful breast diseases are benign and 10% of breast carcinomas present with pain.

Breast Lumps

The most common palpable breast lumps are fibrocystic disease, fibroadenoma and invasive breast carcinoma. Premenopausal women most often develop benign palpable masses in 90% and breast carcinoma in 10%. Risk for breast carcinoma increases with advancing age. In clinical practice, Indian women with breast carcinomas report late with evidence of metastases.

Nipple Discharge

Nipple discharge is a part of breast function during pregnancy or breastfeeding. It may also be associated with abnormal response of hormones during menstrual cycle and fibrocystic disease of breast.

- **Milky nipple discharge:** It occurs due to increased prolactin level in pregnant women, oral contraceptive therapy, pituitary adenoma, tricyclic antidepressant and methyldopa.
- **Serous/bloody discharge:** It occurs due to intraductal papilloma or breast carcinoma.
- **Eczema-like lesion with blood stained discharge:** A rash, often eczema-like lesion on the nipple or surrounding area and blood stained discharge from nipple is observed in Paget's disease of breast (ductal carcinoma involving overlying skin).

Nipple Retraction

Indrawing (retraction) of the nipple due to desmoplasia in an underlying advanced scirrhous breast carcinoma is a late feature. Nipple retraction also occurs due to fibrosis in chronic inflammation of the breast.

Overlying Skin Edema of Female Breast

The "**peau d'orange**" (skin edema) appearance of the breast skin occurs due to obstruction of the dermal lymphatics by tumor cells in a case of breast carcinoma.

CLINICAL EXAMINATION OF BREAST LUMPS

Clinician should note these characteristics in women with breast diseases:

- **Location:** Quadrant involved due to breast lump
- **Size:** Dimensions of breast lump
- **Shape:** Lump oval, lobulated or indistinct breast lump
- **Consistency:** Soft, firm or hard breast lump
- **Movable:** Freely movable or fixed breast lump
- **Distinction:** Solitary or multiple breast lumps
- **Nipple:** Displaced or retracted or nipple discharge
- **Skin over the lump:** Erythematous, dimpled or retracted
- **Tenderness:** Presence or absence of tenderness on palpation of breasts
- **Lymphadenopathy:** Lymph nodes palpable or not
- **Distant metastases:** Organs involved, i.e. lungs, liver, bones or brain.

INFLAMMATORY DISORDERS OF BREAST

INFLAMMATORY BREAST DISEASES

Inflammatory breast diseases include acute mastitis, periductal mastitis, mammary duct ectasia, fat necrosis and granulomatous mastitis. Lactational mastitis is common and requires antibiotic therapy. Aspiration is the preferred initial management of lactational breast abscess. Periductal mastitis may be associated with tobacco smoking and requires surgery. Tuberculous mastitis responds to antitubercular treatment.

Pathology Pearls: Inflammatory Disorders of Breast

- Inflammatory diseases of the breast are rare.
- Acute infection occurs only in the lactating breast.
- Periductal mastitis is also known as Zuska's disease (squamous metaplasia of lactiferous ducts).
- Fat necrosis occurs due to trauma to breast especially in obese women.
- Duct ectasia shows many thick-walled dilated ducts filled with yellow-brown cheesy secretions.
- Granulomatous mastitis occurs in systemic granulomatous disease, e.g. tuberculosis, sarcoidosis, Wegener's granulomatosis, fungal infection, breast implants or unknown etiology.
- There is involvement of lobular epithelium of breast.
- Lipogranulomas are caused by rupture of a paraffin-filled polythene sac implanted silicone prosthesis previously as a device for breast augmentation.

ACUTE MASTITIS

Milk stasis is the main predisposing factor for acute mastitis. If disorder is not treated appropriately, breast abscesses can recur, which may be complicated by a fistulous tract. Acute mastitis is caused by *Staphylococcus aureus* that can enter the breast tissue through cracks and fissures in the nipple. Acute mastitis disorder is usually secondary to obstruction of the duct system by inspissated secretions.

Age Group

In acute mastitis, infection of overlying breast skin commonly affects women aged between 18 and 45 years, which may be primary or secondary due to infected sebaceous cyst in overlying skin. Females with pituitary prolactinomas occasionally are associated with galactorrhea.

Clinical Features

In acute mastitis, the breast becomes tense, hot, and very painful. Axillary lymph nodes may become enlarged and tender.

Therapeutic Correlation

Acute mastitis may be treated by mechanical suction, frequent emptying of the breasts, and administration of antibiotics.

PERIDUCTAL MASTITIS

Periductal mastitis is also known as Zuska's disease or squamous metaplasia of lactiferous ducts and characterized by different degrees of periductal inflammation, and periductal fibrosis.

- Periductal mastitis occurs especially in tobacco smokers. Tobacco smoke alters the epithelium of lactiferous sinuses. Keratin is trapped into ducts.
- Nipple inversion occurs due to fibrosis. Recurrences in women with recurrent periductal mastitis are common.

Surgical Pathology: Periductal Mastitis

Light Microscopy

- Histologic examination of biopsy reveals chronic and granulomatous inflammation.
- Foamy histiocytes are typically present within the luminal secretions and within wall of the involved ducts.
- Periductal fibrosis occurs in the late stage.

MAMMARY DUCT ECTASIA

Duct ectasia of major subareolar ducts is characterized by inflammation and dilatation of the major ducts. The ducts are filled with debris, resulting in dilatation, rupture and inflammation. Possible etiological factors of duct ectasia are infections and cigarette smoking.

Clinical Features

Some women present with greenish brown cheesy nipple discharge, slit-like nipple retraction, or palpable lump simulating breast carcinoma that may be hard or doughy. There is no increased risk for breast carcinoma.

Complications

Complications of mammary duct ectasia include breast abscess, fistulous tract and nipple retraction. Associated fibrosis and calcification in mammary duct ectasia simulate breast carcinoma.

Surgical Pathology: Mammary Duct Ectasia

Gross Morphology

- Cut section of mammary duct ectasia lesion shows many thick-walled dilated ducts filled with yellow brown cheesy secretions.

- In women above 50 years of age, frequent incidental pathologic finding is fibrocystic disease in 30–40% of cases in surgically excised breast tissue and in autopsy specimens.

Light Microscopy

Histologic examination shows dilated ducts with fibrosis of wall, inflammatory cell infiltrate with plasma cells, and inspissation of lipid-rich material within duct lumen.

Management

Antibiotics and surgical removal of dilated duct cures these patients with periductal mastitis.

FAT NECROSIS OF BREAST

Fat necrosis of breast most often occurs in women >55 years. It is most common nonsuppurative chronic inflammatory lesion which follows foreign body giant cell reaction and fibrosis due to lipid released from traumatized adipocytes.

Pathogenesis

Trauma to the breast is most common cause of fat necrosis, followed by prior surgical intervention and radiation therapy. Fat necrosis of breast occurs when lipase enzyme breaks down intracellular triglycerides into free fatty acids, which combine with sodium, magnesium or calcium ions to form **soaps** (saponification). The tissue becomes opaque and chalky white due to fat necrosis.

Clinical Features

Patient develops unilateral localized breast mass, which may be painful in acute stage. Clinical examination of affected breast reveals a firm, superficial irregular mass, erythema of the overlying skin, dimpling and nipple retraction, which mimics breast carcinoma.

Radiologic Findings

Fat necrosis of the breast is a challenging diagnosis due to various appearances on mammography, ultrasonography, CT, PET-CT and MRI. Although mammography is more specific in diagnosing the disease. Mammography reveals calcified lesion in the breast.

Surgical Pathology: Fat Necrosis of Breast

Gross Morphology

- Fat necrotic tissue shows chalky white areas of fat saponification. Variegated color and areas of hemorrhage are demonstrated on the cut surface of this lump.
- It is gritty to cut because of the presence of spotty calcification.

Light Microscopy

- In the response to fat necrosis, there is an initial acute inflammatory reaction consisting of necrosis of adipocytes and hemorrhage. It is followed by chronic inflammatory response in which numerous plasma cells are seen.
- Macrophages phagocytose lipid released from adipocytes, forming multinucleated foreign body giant cells, as well as foam cells, also termed '**lipophages**'.
- There is presence of **dystrophic calcification** demonstrated by imaging techniques.
- Fibroblastic proliferation leads to fibrosis resulting in extension into the surrounding tissue. As a result, an irregular, fixed, hard mass may ensue and clinically fat necrosis of breast carcinoma. Thus, the fat necrosis of breast often requires biopsy to establish its benign character.

GRANULOMATOUS MASTITIS

Granulomatous mastitis is a group of immunologic mediated disorder of breast lobules, which leads to alteration in the breast lobular epithelium during lactation in multiparous women.

Etiology

Granulomatous mastitis occurs in systemic granulomatous disease, e.g. tuberculosis, sarcoidosis, Wegener's granulomatosis, fungal infection, breast implants and unknown etiology. There is involvement of breast lobular epithelium.

Surgical Pathology: Granulomatous Mastitis

Light Microscopy

In granulomatous mastitis, breast lobules show granulomas, histiocytes, lymphocytes, plasma cells and giant cells by sparing interlobular stromal region.

- **Breast tuberculosis:** Breast tuberculosis usually occurs due to tubercular lesion extension from rib in females. Patient presents with breast abscess and fever. On cut section, breast abscess contains caseous material. Light microscopy reveals epithelioid cell granulomas, caseous necrosis and Langhans type of giant cells.
- **Sarcoidosis:** Breast sarcoidosis is an idiopathic disorder in which abnormal immune system leads to formation of noncaseating epitheliod cell granulomas and collection of macrophages. These trigger an inflammatory response that causes extensive tissue damage and scarring in the breasts. **Kveim test** is performed by intracutaneous injection of saline suspension of human sarcoidal spleen or lymph nodes, which induces appearance of erythematous nodules.
- **Wegener's granulomatosis:** It is a systemic necrotizing granulomatous vasculitis of unknown etiology or due to inhalation of some infectious agents. Antineutrophil cytoplasmic antibodies (c-ANCA type) play a pivotal role in its pathogenesis. Immune complexes formed are deposited in small vessels resulting in necrotizing vasculitis.

SILICONE BREAST IMPLANTS

Silicone breast implants are used for cosmetic augmentation. Silicone is a polymer of silica, O_2 and

hydrogen. Due to leakage of silicone implants, chronic inflammation takes place. Lipogranulomas are caused by rupture of a paraffin-filled polythene sac implanted prosthesis previously as a device for breast augmentation. This is a very old-fashioned type of breast implantation used for cosmetic augmentation.

SCLEROSING LYMPHOCYTIC LOBULITIS

Sclerosing lymphocytic lobulitis is also known as lymphocytic mastopathy, which most often occurs in women with type I diabetes mellitus or autoimmune thyroid diseases. It is considered to be an autoimmune disorder. Patient presents with hard palpable lumps. It is difficult to obtain breast tissue with needle biopsy due to presence of dense collagenous stroma. Sclerosing lymphocytic lobulitis should be differentiated from breast carcinoma.

DIABETIC MASTOPATHY

Diabetic mastopathy is uncommon complication of diabetes mellitus characterized by painless breast lump mistaken for breast carcinoma.

Surgical Pathology: Diabetic Mastopathy
Light Microscopy
Histologic examination shows keloid-like fibrosis, lymphocytic ductitis, lymphocytic lobulitis and lymphocytic vasculitis.

FIBROCYSTIC DISEASE OF BREAST

FIBROCYSTIC DISEASE OF BREAST: OVERVIEW

Fibrocystic disease is the most common benign disorder of the female breasts. It is caused by abnormal response of breast to ovarian hormones. Patient develops painful multifocal lumps in both breasts. The frequency of fibrocystic disease of breast decreases progressively after menopause.

Although it is a benign condition, the gross and mammographic appearance may mimic breast carcinoma, and is often difficult to distinguish from breast carcinoma on frozen section (Fig. 25.6).

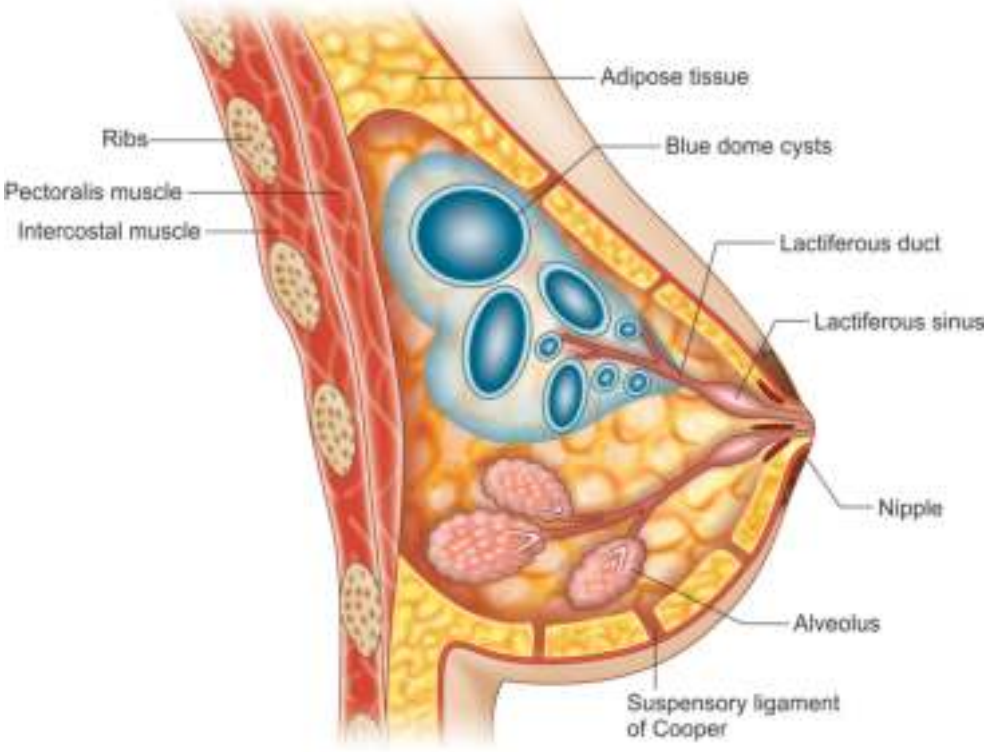

Fig. 25.6: Fibrocystic disease of breast. Structure of the adult female breast shows fibrocystic disease in 45-year-old woman showing one large cyst and multiple smaller ones, with areas of fibrosis.

Pathology Pearls: Fibrocystic Disease of Breast

- Fibrocystic disease of breast is caused by abnormal response of breast to ovarian hormones.
- Fibrocystic changes occur in glands and stroma, which include fibrosis, duct ectasia, apocrine metaplasia, duct hyperplasia and sclerosing adenosis.
- There is increased risk for development of breast carcinoma related to the presence of atypical hyperplasia of the glands.
- Sclerosing adenosis can be clinically and radiologically confused with breast carcinoma.

Fibrocystic disease of breast affects women in 20–50 years of age. About 10% of women have clinically evident disease. It is uncommon before adolescence or after menopause. Approximately 60–90% of breasts show fibrocystic disease at autopsy.

- **Etiopathogenesis:** It is postulated that fibrocystic disease of breast occurs due to hormonal imbalance, i.e. increased uncontrolled response of estrogens on terminal duct lobular unit (TDLU) or to decreased progesterone activity. This hormonal imbalance occurs in functional ovarian granulosa cell tumors and anovulatory cycles. Environmental toxins inhibiting cyclic guanosine monophosphate enzymes by methylxanthines (e.g. caffeine, tea, chocolate), tyramine (e.g. cheese, wine, nuts) and tobacco smoking may also cause fibrocystic disease of breast.
- **Clinical features:** Patient presents with bilateral breast palpable lumps (irregular nodularity) with mid-cyclic tenderness varying during the menstrual cycle. Pain is present in the upper outer quadrant of bilateral breasts. Occasionally, there is history of greenish brown to black nipple discharge containing fat, proteins, ductal cells and erythrocytes.

Surgical Pathology: Fibrocystic Disease of Breast

Gross Morphology

- Cut surface of lesion is firm grey white fibrous tissue.
- Some cysts may be quite large, which undergo hemorrhage into the cyst fluid called blue domed cysts.
- These cysts vary in size during the menstrual cycle.
- These are most often enlarged and tender one week before menstruation.

Light Microscopy

- Fibrocystic changes occur in glands and stroma, which include fibrosis, duct ectasia, apocrine metaplasia, duct hyperplasia and sclerosing adenosis.
- Histologic examination shows cystic dilatation of the terminal ducts and increased surrounding collagen fibers.
- Fibrocystic disease of breast changes may be nonproliferative or proliferative.

FIBROCYSTIC DISEASE OF BREAST: HISTOPATHOLOGIC CHANGES

NONPROLIFERATIVE CHANGES IN BREASTS

Nonproliferative changes in fibrocystic disease of breast include dense fibrous stroma encompassing a number of variable size cystic dilatation of the terminal duct lobular unit (duct ectasia) and mild hyperplasia. Alteration in epithelial lining of ducts is termed 'apocrine metaplasia'.

- Apocrine cells are large and more eosinophilic than that usually line the ducts and resemble apocrine sweat gland epithelium.
- On clinical examination, the breasts are lumpy. In fibrocystic disease of breast, there is no risk for breast carcinoma (Figs 25.7 to 25.11).

PROLIFERATIVE CHANGES IN BREASTS

Proliferative changes in fibrocystic disease of breast are associated with epithelial hyperplasia of ducts and lobules, with or without features of atypia, and sclerosing adenosis. Atypical hyperplasia of ducts and lobules is associated with a five-fold increase in the risk of breast ductal carcinoma. When proliferative changes in fibrocystic disease of breast are associated with a family history of breast carcinoma; the risk of breast carcinoma is ten-fold.

- **Inflammation and fibrosis:** Rupture of the cysts with extravasation of fluid in the stroma results in inflammation and fibrosis. Dense fibrous interlobular stroma expands into the lobules, and replaces the loose intralobular connective tissue. Strands of fibrous tissue constrict the ducts, so that the normal secretions cannot pass out. Terminal ducts become dilated and filled with secretions.
- **Duct ectasia:** Paste-like material in subareolar ducts produces sticky purulent discharge that may be white, gray, brown, green or bloody, which is caused by stagnation of cellular debris and secretions in the ducts. Cysts filled with bluish fluid are known as 'blue dome cysts' when examined through the cyst wall. Histologic examination shows cysts lined by uniform benign cuboidal to columnar epithelial cells of variable height with microcalcifications in their lumen. These blue dome cysts do not have malignant potential. Clinical examination of the breasts reveals cystic feel on palpation.
- **Apocrine metaplasia:** The cells lining large cysts undergo metaplastic change consisting of tall, pink, columnar benign epithelial cells with small nuclei and brightly eosinophilic cytoplasm. Chromosomal abnormalities in apocrine epithelium suggest possible precursor of apocrine carcinoma.

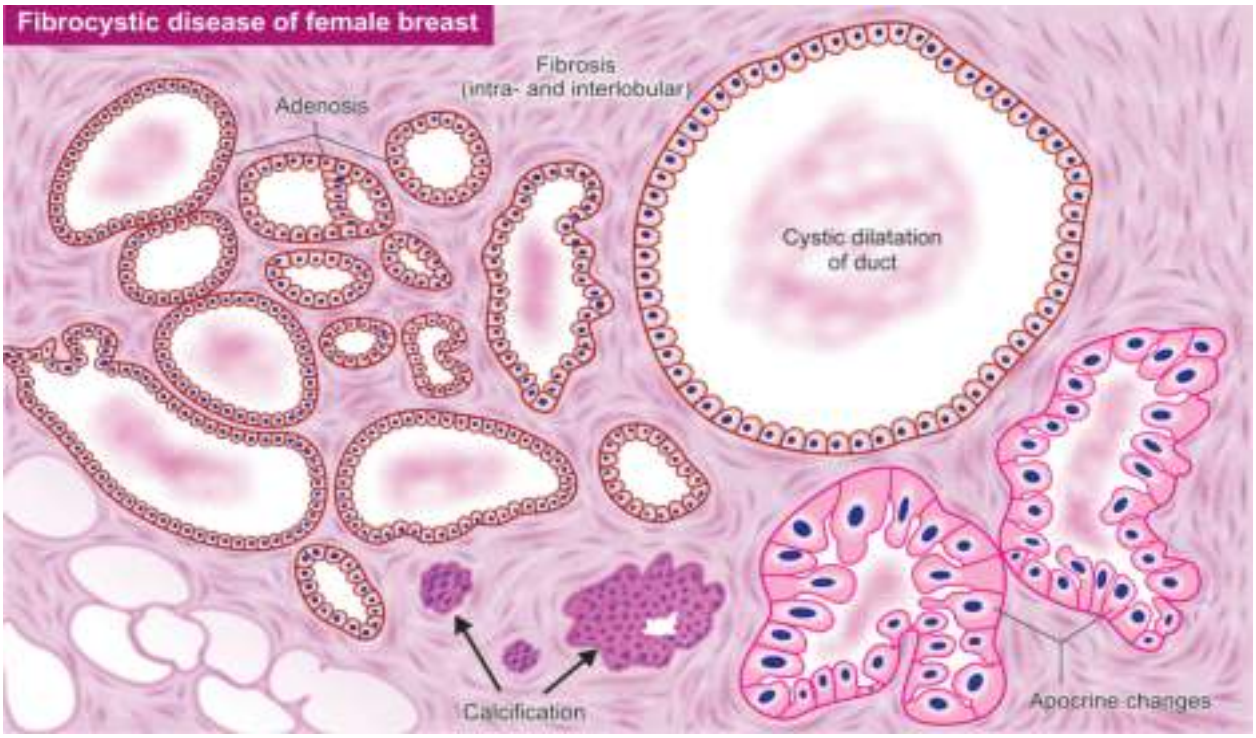

Fig. 25.7: Structure of the adult female breast shows fibrocystic disease (e.g. cystic dilatation of ducts, apocrine change, fibrosis and sclerosing adenosis). In sclerosing adenosis, there are glandular structures with intervening cords of cells in a fibrous stroma. Areas of calcification (arrows) are also present; these would render the lesion visible on mammography.

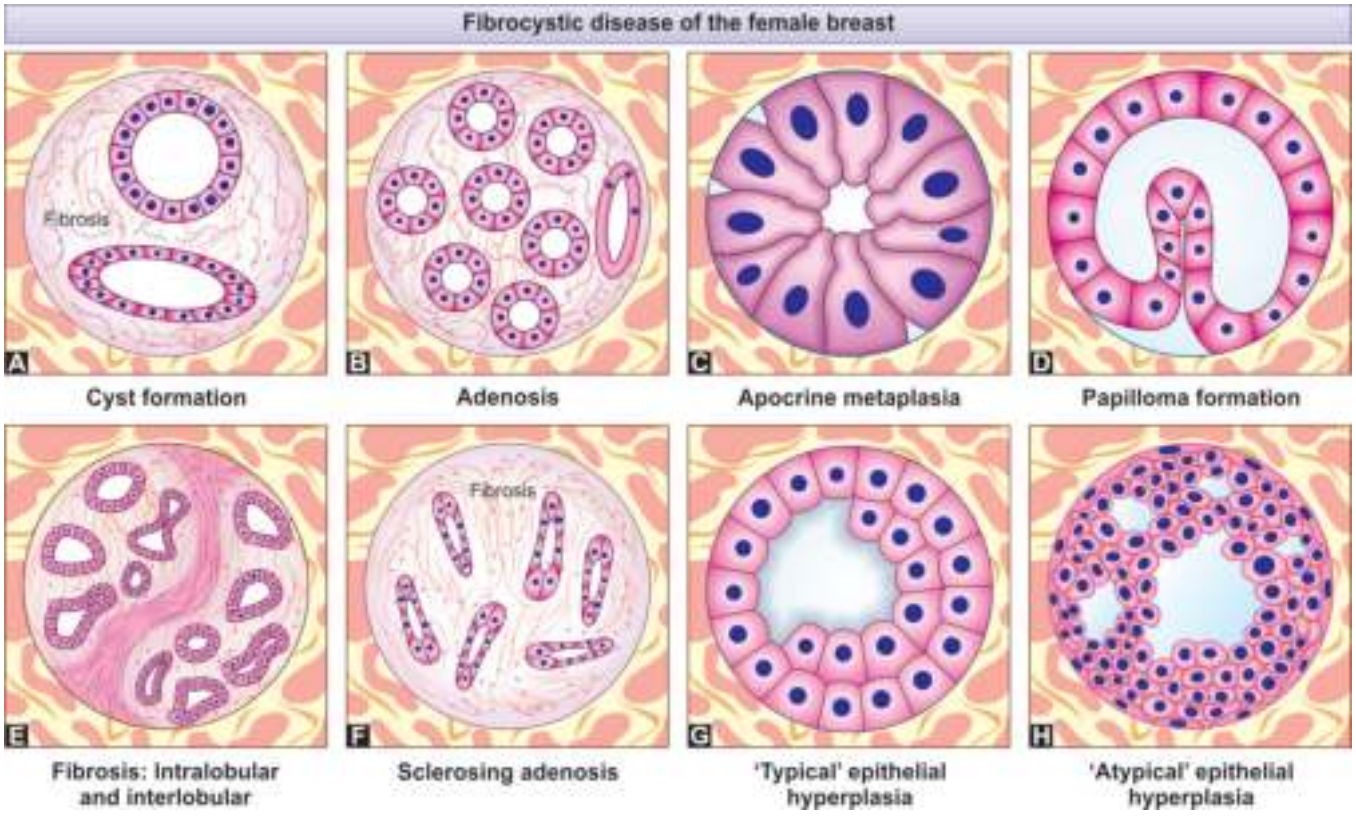

Fig. 25.8: Fibrocystic disease of breast. It shows (A) cyst formation, (B) adenosis, (C) apocrine metaplasia, (D) papilloma formation, (E) fibrosis (intralobular and interlobular), (F) sclerosing adenosis, (G) typical epithelial hyperplasia, and (H) atypical epithelial hyperplasia. In epithelial hyperplasia, the duct lumen is filled by hyperplastic epithelium. In atypical hyperplasia, there is increased risk of development of breast cancer.

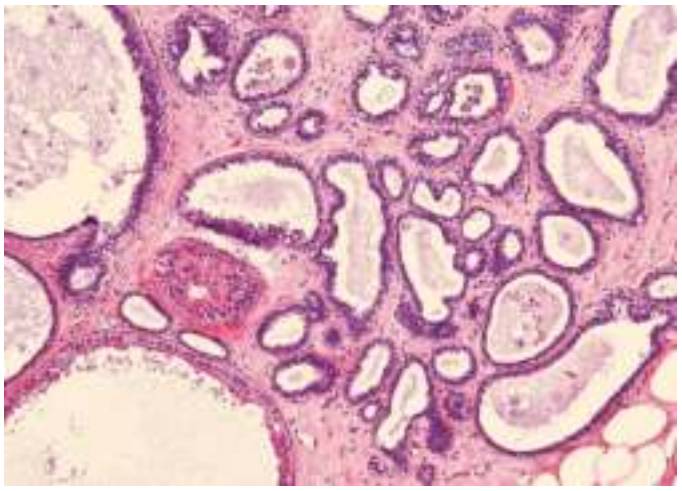

Fig. 25.9A: Spectrum of morphological changes in fibrocystic disease of breast shows duct dilatation, adenosis, fibrosis (intralobular and interlobular), and apocrine change (400X).

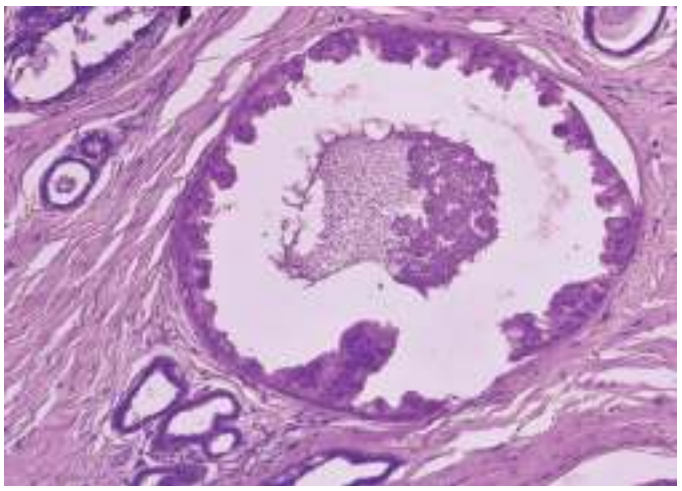

Fig. 25.9B: Apocrine metaplasia in fibrocystic disease of breast. It is characterized by enlarged ductal and lobular epithelial cells with apical sprouting, abundant granular eosinophilic cytoplasm, round nuclei of variable size with vesicular chromatin and prominent nuclei (400X).

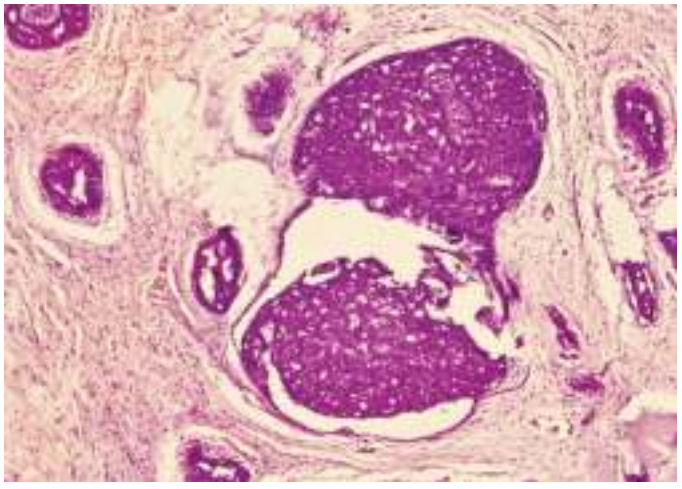

Fig. 25.10: Fibrocystic disease of breast. It shows typical ductal hyperplasia.

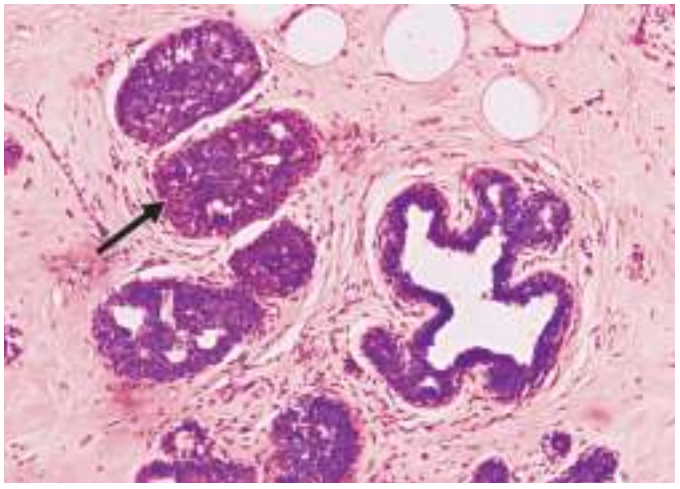

Fig. 25.11: Fibrocystic disease of breast. It shows atypical ductal hyperplasia (arrow) (100X).

- **Sclerosing adenosis:** Sclerosing adenosis associated with fibrosis of the intralobular stroma results in compression of the epithelial structures to give a pseudoinfiltrative growth pattern. The number of acini per terminal duct lobular unit (TDLU) in sclerosing adenosis is more than double the normal found in normal breast lobules. Tubules are lined by two layers of epithelial cells giving lobular configuration. There is more often presence of numerous microcalcifications. Sclerosing adenosis lesion in breast has become significant in modern clinical practice, as sclerosing adenosis in breast can be confused with breast carcinoma on mammographic screening.
- **Ductal epithelial hyperplasia:** As the ducts are estrogen sensitive, florid ductal epithelial hyperplasia occurs within areas of fibrocystic changes. The epithelial lining of ductal cells are multilayered, filling and expanding the ducts or acini. There is a slightly increased risk (1.5–2 times) for breast carcinoma.
- **Atypical ductal hyperplasia:** It occurs in ducts and lobules lined by multilayered pleomorphic atypical cells with hyperchromatic nuclei resembling ductal carcinoma *in situ* (DCIS) or lobular carcinoma *in situ* (LCIS). These atypical cells do not fill the entire lumen of ducts or lobules. The atypical ductal hyperplasia is indicative of an increased risk for subsequent breast carcinoma (Table 25.3).

FIBROCYSTIC DISEASE OF BREAST: DIAGNOSIS

Since the introduction of mammographic and ultrasound imaging of the breast, this condition can be diagnosed without performing surgical excision.

Table 25.3 Comparison of histologic features of ductal hyperplasia and ductal carcinoma *in situ* (DCIS)

Histologic Features	Ductal Hyperplasia (Usual Type)	Atypical Hyperplasia/DCIS (Low Nuclear Grade)
Size	Variable size, rarely extensive when associated with papilloma or radical scar	May be extensive, rarely <3 mm
Cellular composition	Epithelial cells along with spindle cells, lymphocytes, macrophages. Myoepithelial cell hyperplasia around periphery	Single cell population. Absence of spindle cells. Myoepithelial cells around periphery
Architecture	Variable	Well-developed micropapillary, cribriform or solid patterns
Lumina	Lumina irregular often ill-defined slit-like spaces common	Lumina well-delineated, regular, punched out in cribriform pattern
Cell orientation	Streaming pattern with long axis of nuclei arranged parallel to direction of cellular bridges, which often have a 'tapering appearance	Micropapillary structures with indiscernible fibrovascular cores or smooth, well-delineated geometric spaces. Cell bridges 'rigid' in cribriform type with nuclei oriented towards the luminal type
Nuclear spacing	Uneven nuclear spacing	Even nuclear spacing
Epithelial cell character	Small ovoid with variation in shape	Small uniform monotonous appearance
Nucleoli	Indistinct	Single small
Mitoses	Infrequent	Infrequent, abnormal form
Necrosis	Rare	If present, confined to small particulate debris in cribriform and/or luminal spaces

Ultrasonography is done to distinguish cystic fluid filled lesions in fibrocystic disease of breast from solid lumps. Fine needle aspiration cytology of bloody aspirate is done to rule out malignant change. Histologic examination distinguishes benign from malignant changes in fibrocystic disease of breast.

REVISED 2019 WHO CLASSIFICATION OF BREAST TUMORS

The classification of breast tumors continues to evolve with integration of new knowledge from research rapidly translated into the clinical practice. The 2019 WHO of breast tumors series' 5th edition is an update of the 4th edition breast tumors volume published in 2012. Major changes have been updated within the new 2019 WHO classification of breast tumors. Revised 2019 WHO classification of breast tumors is given in Table 25.4.

STROMAL TUMORS OF BREAST

FIBROADENOMA OF BREAST

Fibroadenoma is the most common benign tumor of the breast derived from intralobular stroma (Fig. 25.12), which affects females <25 years of age. In some teenagers, it may reach enormous size (10–15 cm), so-called juvenile giant fibroadenoma. Complex fibroadenoma is associated with increased risk for subsequent breast carcinoma.

Pathogenesis

Proliferation of intralobular stroma of breast leads to compression of the ducts. Intralobular stroma also synthesizes growth factors, which may stimulate proliferation of ducts. The basis of ductal proliferation is not clear; perhaps the neoplastic stromal cells secrete growth factors that induce proliferation of epithelial cells. Fibroadenoma develops in 50% of women, who receive cyclosporine after renal transplantation due to synthesis of growth factor by intralobular stroma of breast.

Molecular Genetic Alterations

Molecular technique reveals that the stromal cells are monoclonal and representing the neoplastic element of fibroadenoma of breast.

Clinical Features

Patient presents with solitary, well-circumscribed, firm rubbery and painless lump most often in the upper

Table 25.4 Revised 2019 WHO classification of breast tumors

Epithelial Tumors	
Benign tumors	▪ Tubular adenoma ▪ Lactating adenoma ▪ Apocrine adenoma ▪ Ductal adenoma ▪ Pleomorphic adenoma
Malignant tumors	▪ Ductal carcinoma *in situ* or invasive (NOS) ▪ Lobular carcinoma (*in situ* or invasive) ▪ Inflammatory carcinoma ▪ Medullary carcinoma ▪ Colloid (mucinous) carcinoma ▪ Tubular carcinoma ▪ Cribriform carcinoma (*in situ* or invasive) ▪ Papillary carcinoma ▪ Micropapillary carcinoma ▪ Scretory carcinoma ▪ Metaplastic carcinoma shows chondroid or bone formation or squamous differentiation ▪ Apocrine carcinoma ▪ Lipid-rich carcinoma ▪ Adenoid cystic carcinoma ▪ Sebaceous carcinoma ▪ Paget's disease of breast
Proliferative lesion	Ductal hyperplasia (typical or atypical)
Stromal Tumors	
Benign and malignant tumors	▪ Biphasic stromal benign tumors • Fibroadenoma • Phyllodes tumor • Periductal stromal tumor ▪ Pure stromal benign tumor • Pseudoangiomatous stromal hyperplasia • Nodular fasciitis • Fibromatosis ▪ Malignant stromal tumor with predominant myofibroblastic differentiation ▪ Malignant stromal tumor with predominant fibroblastic differentiation ▪ Lipoma ▪ Liposarcoma ▪ Leiomyoma ▪ Leiomyosarcoma ▪ Neural origin tumors • Granular cell tumor • Neurofibroma • Schwannoma ▪ Vascular lesions/tumors • Angioma • Angiomatosis • Angiosarcomas (primary, post-irradiation, post-radical mastectomy)
Lymphoid Neoplasm	
NHL	Diffuse large B cell lymphoma (DLBCL)
Metastatic Tumors	
Malignant tumors	Malignant melanoma and gastrointestinal carcinoma

Contd...

In clinical practice, breast tumors include fibroadenoma, phyllodes tumor, invasive ductal carcinoma (70–75%), invasive lobular carcinoma (5–14%), medullary carcinoma, mucinous (colloid) carcinoma, Paget's disease of nipple, papillary carcinoma, and tubular carcinoma.

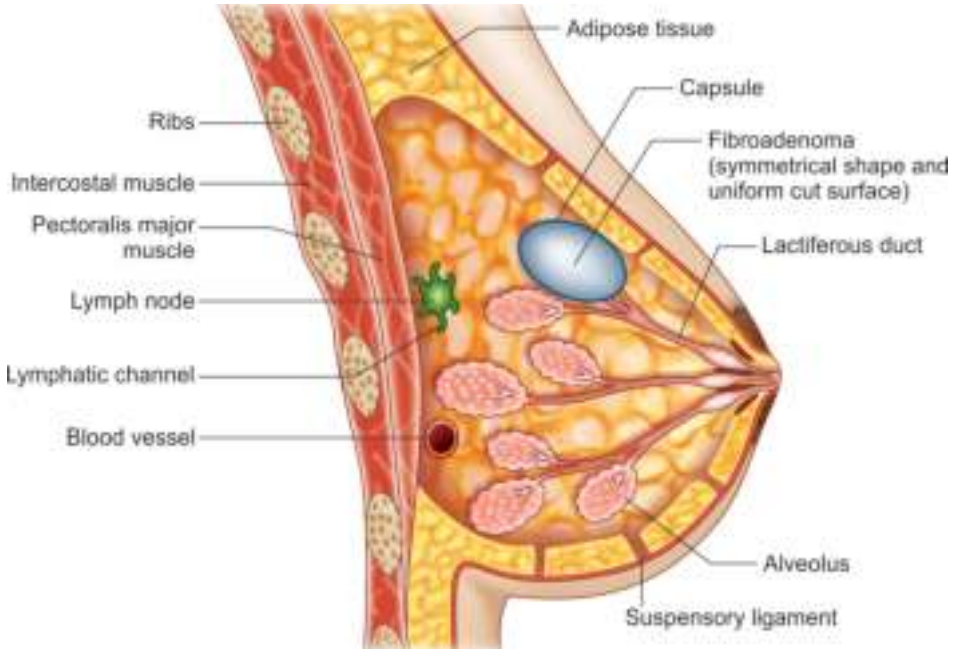

Fig. 25.12: Structure of the adult female breast shows fibroadenoma (well circumscribed tumor) in young female.

outer quadrant. However, fibroadenoma may be present in any quadrant of breast. Multiple or bilateral fibroadenomas may be observed in 10–15% of patients. There is no dimpling or retraction of overlying skin.

During menstrual cycle, pregnancy and lactation, fibroadenoma may undergo transient enlargement associated with pain in response to increase in estrogen/progesterone levels. Fibroadenoma of breast may regress and calcify after menopause.

Surgical Pathology: Fibroadenoma of Breast

Gross Morphology

- Fibroadenoma is delineated from adjacent breast tissue.
- Cut surface is gray white, smooth, firm with rubbery consistency.
- Tumor most often varies in size 1–3 cm in diameter, but may grow larger. Rarely tumors growing >10 cm in diameter are called giant fibroadenoma (Fig. 25.13A and B).

Light Microscopy

- Fibroadenoma of breast shows proliferation and expansion of the stroma is of usually low cellularity.
- The ductal element sometimes forms an intracanalicular pattern with a leaf-like pattern (Figs 25.14 to 25.16). Delicate loose fibrous stroma encloses the epithelial component consisting of gland-like or duct-like spaces lined by cuboidal or columnar cells. The stromal cells of loose fibrous stroma are neoplastic, and the epithelial cells lining ducts to be reactive.
- Tumor shows biphasic patterns: intracanalicular and pericanalicular patterns.
  - **Intracanalicular pattern:** Excessive proliferation of intralobular stroma compressing and distorting glands (ducts) and forming slit-like spaces is known intracanalicular pattern with a leaf-like pattern.
  - **Pericanalicular pattern:** The glands (ducts) retain round shape. Because ducts are not compressed by fibrosis resulting in pericanalicular pattern.

Treatment

Treatment of fibroadenoma of breast depends on severity of disease, which may include monitoring for changes in the size and biopsy evaluation. Fibroadenoma is treated by surgical excision.

GIANT JUVENILE FIBROADENOMA OF BREAST

Giant juvenile fibroadenoma is considered >5 cm, 500 g and replacing 80% of the breast in young girls between the ages of 10 and 18 years. It is characterized by massive and rapid enlargement of a rubbery mobile and a non-tender breast lump. The etiology is not well understood and believed to be an increased sensitivity to normal estrogen level.

- Differentiating giant juvenile fibroadenoma from phyllodes tumor may be difficult with histopathology.
- Surgical excision is highly recommended to establish the diagnosis. Patient is managed by surgical excision with conservation of normal breast tissue, nipple and the areola.
- Hematoxylin and eosin stained section from giant juvenile fibroadenoma tumor shows biphasic proliferation of fibroblastic elements with no cytologic atypia. Clinical photograph of giant juvenile fibroadenoma is shown in Fig. 25.17.

PHYLLODES TUMOR OF BREAST

Phyllodes tumor is a large fleshy bulky tumor measuring 10–15 cm distorting the breast, and overlying skin ulceration and related to fibroadenomas. Phyllodes tumor of breast is more cellular than fibroadenoma.

The distinction of phyllodes tumor from fibroadenoma is made not on the size, but on the histologic and cytologic characteristics of the stromal component.

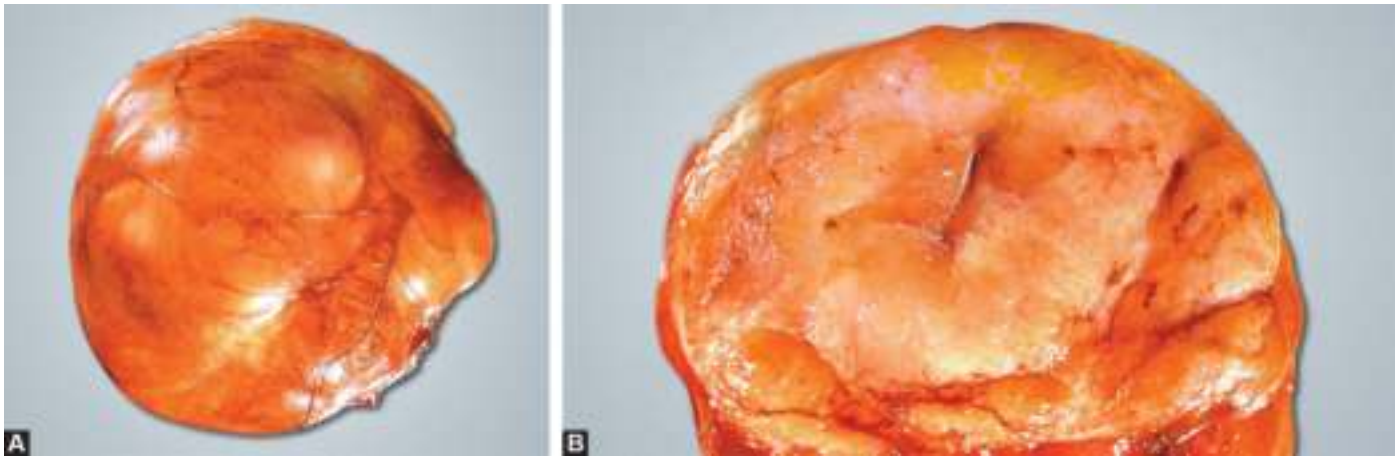

Fig. 25.13A and B: (A) Fibroadenoma—this well circumscribed mobile lump was removed surgically, (B) cut surface of fibroadenoma shows lobulated appearance of tumor bulging outwards, gray white, smooth, firm with rubbery consistency. Most often varies in size from 1 to 3 cm in diameter.

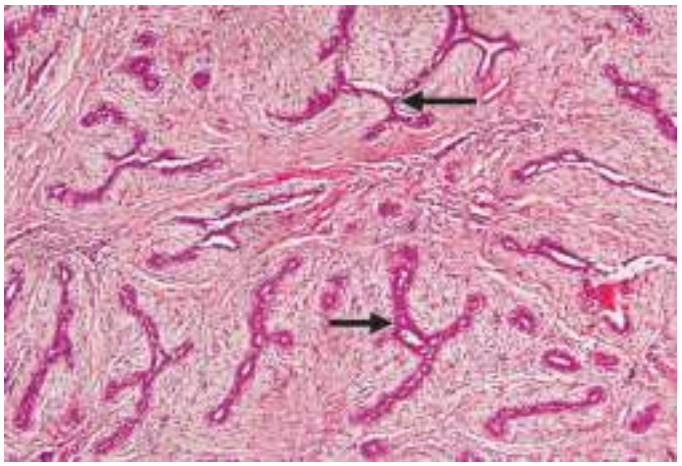

Fig. 25.14: Fibroadenoma breast with intracanalicular pattern. Light microscopy shows intracanalicular pattern. Glands are compressed cords to form slit-like spaces in fibrotic stroma (arrows) (100X).

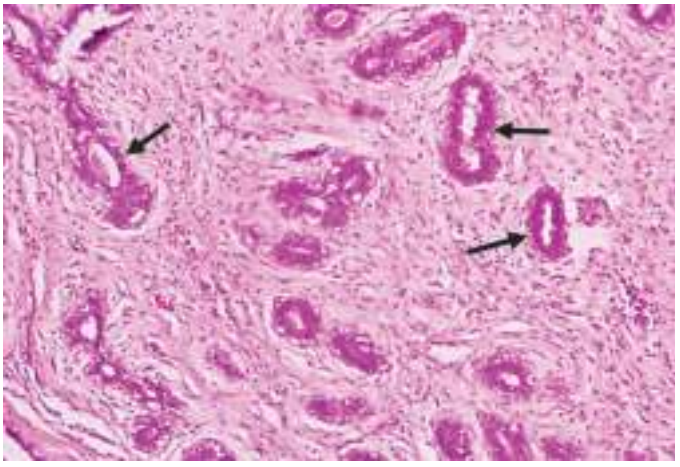

Fig. 25.15: Fibroadenoma breast with pericanalicular pattern—the glands (ducts) retain round shape. Because ducts are not compressed by fibrosis result in 'pericanalicular pattern' (arrows) (100X).

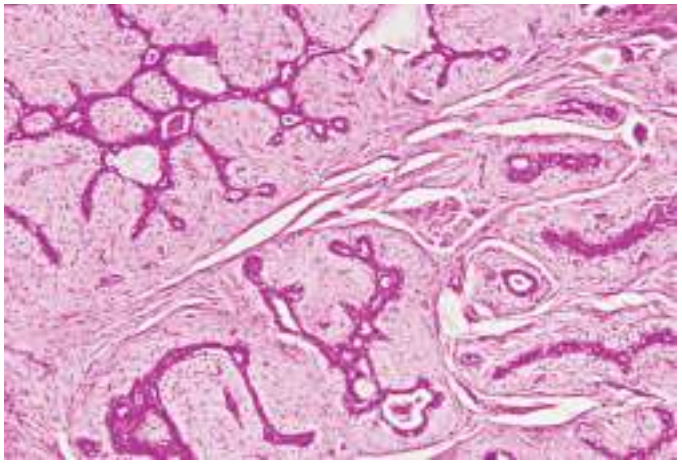

Fig. 25.16: Fibroadenoma. It shows intracanalicular and pericanalicular patterns. Glands compressed by stroma result in slit-like spaces known as intracanalicular pattern. Ducts not compressed by stroma have round shape known as pericanalicular pattern (100X).

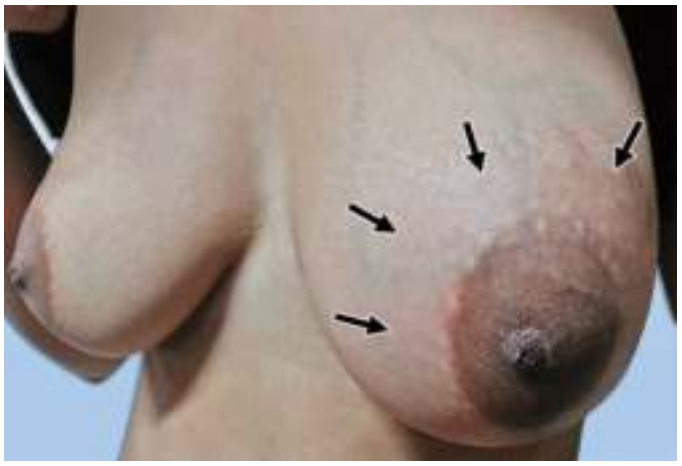

Fig. 25.17: Clinical photograph of giant juvenile fibroadenoma. A 16-year-old girl presented with rapid large lump in the left breast. Clinical examination of breasts revealed a mobile large lump in left breast measuring >5 cm in size stretching the overlying skin and dilatation of superficial veins. Lumpectomy was done. Histologic examination revealed features of fibroadenoma (arrows). (*Courtesy:* Dr. Permeet Kaur Bagga, Senior Professor and Head, Department of Pathology, Govt. Medical College, Amritsar.)

Origin of Tumor

Phyllodes tumor of the breast arises from intralobular stromal cells of the breast, not the ducts or glands. It is most often low-grade neoplasm accompanied by a benign growth of ductal structures. Phyllodes tumor of breast may be benign, intermediate and malignant. Most phyllodes tumors are benign and only a small number are malignant.

Age Group

Phyllodes tumor of breast most often occurs in older age group. It may affect 30–70 years aged women.

Clinical Features

Patient presents with bulky lump distorting the breast with overlying skin ulceration.

Surgical Pathology: Phyllodes Tumor of Breast

Gross Morphology

- Like fibroadenoma, benign phyllodes tumor is sharply circumscribed, lobulated large size tumor measuring 10–15 cm. Cut surface is firm, glistening, and grayish white with cystic spaces containing leaf-like extensions.
- Benign phyllodes tumor has pushing margin.
- Malignant phyllodes tumor has infiltrating margin. Tumor is poorly circumscribed with invasion into the surrounding breast tissue (Figs 25.18 and 25.19).

Light Microscopy

Following histologic features may help to differentiate benign phyllodes tumor from malignant phyllodes tumor, which include cellularity, margin of tumor, mitoses and heterologous elements.

- **Benign phyllodes tumor of breast:** Tumor comprises highly cellular myxoid stroma projecting into the ducts lined by benign epithelial cells, creating the leaf-like pattern (Greek word phyllodes meaning leaf-like clefts and slits) and presence of <5 mitoses per 10 high power field (HPF) in the stroma. The stroma is more cellular than a fibroadenoma.
- **Borderline phyllodes tumor of breast:** Histologic examination of tumor shows 5–10 mitoses per 10 HPF.
- **Malignant phyllodes tumor of breast:** A malignant phyllodes tumor has a sarcomatous stroma that predominates over the ductal elements and invades the breast. Tumor has abundant mitotic activity. Stromal component is abundant in comparison to benign duct elements.
  - Light microscopy shows malignant change in the stromal component of tumor, numerous mitoses >10 per 10 HPF in the stroma, hemorrhage and necrosis (Fig. 25.20).
  - Diagnostic features of biphasic neoplasms of breast are given in Table 25.5. Differentiating pathologic features of cellular fibroadenoma and malignant phyllodes tumor are given in Table 25.6.

Biologic Behavior

It is difficult to predict biologic behavior of phyllodes tumor of breast, which may recur locally after incomplete excision. High grade phyllodes tumor may metastasize to lymph nodes or lung in 33% of cases.

Management

Treatment of phyllodes tumor is wide excision of tumor with wide margin of normal surrounding tissue. Inadequate excision of tumor results in recurrences.

JUVENILE PAPILLOMATOSIS OF BREAST

Juvenile papillomatosis is also known as ('Swiss cheese disease') affecting young girls. Patient presents with solitary, unilateral breast lump. Juvenile papillomatosis is often mistaken for a phyllodes tumor clinically. A family history of breast carcinoma has been observed in 30–50% of juvenile papillomatosis. In addition, increased risk for development of breast carcinoma during follow-up of patient diagnosed with juvenile papillomatosis.

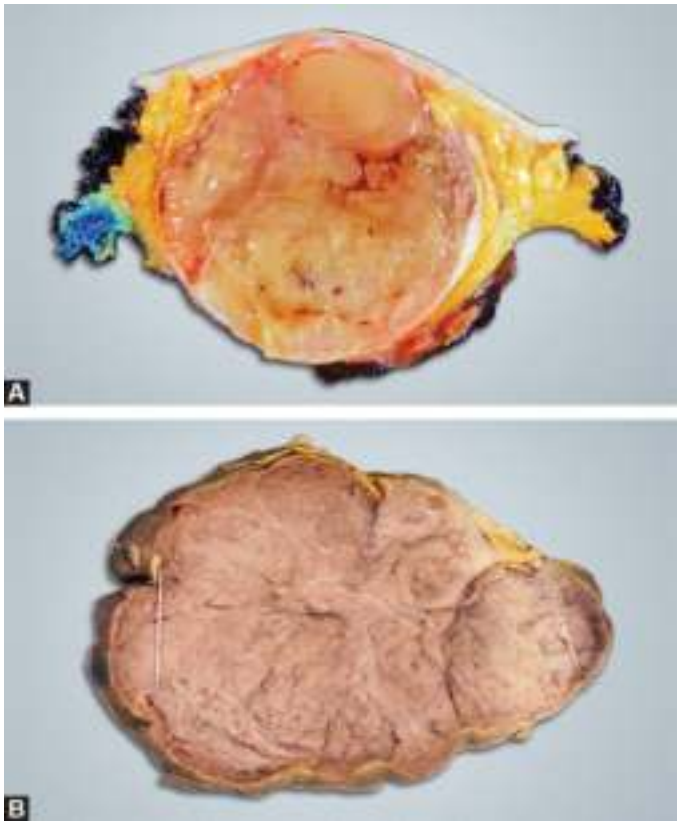

Fig. 25.18A and B: Phyllodes benign tumor. Tumor is large bulky with pushing margin. Cut surface is firm, glistening, and grayish white with cystic spaces containing leaf-like extensions. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru.)

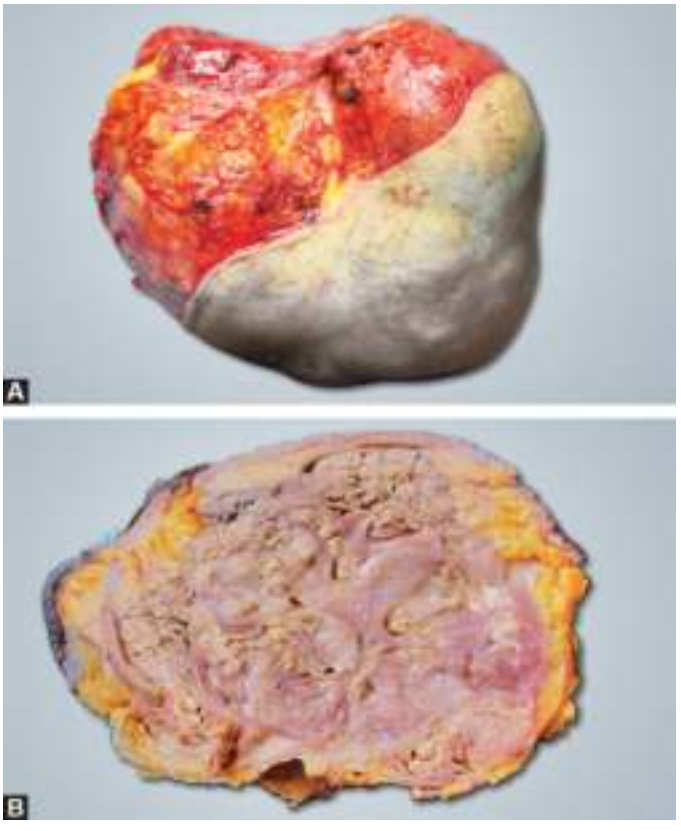

Fig. 25.19A and B: Phyllodes malignant tumor. Tumor is large bulky distorting breast with areas of hemorrhage and necrosis. On right side, surgical excised tumor shows firm, glistening, and grayish white with cystic spaces containing leaf-like extensions. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru.)

Fig. 25.20: Phyllodes tumor—it comprises highly cellular myxoid stroma projecting into the ducts creating the leaf-like pattern (Greek word *phyllodes* meaning leaf-like clefts and slits) and presence of <5 mitoses per 10 HPF in the stroma. The stroma is more cellular than a fibroadenoma (arrows) (400X).

Surgical Pathology: Juvenile Papillomatosis of Breast

Gross Morphology

- Juvenile papillomatosis lesion is circumscribed, but not encapsulated containing large multiple cysts. It strongly resembles fibrocystic disease of the breast.
- Differential diagnosis also pubertal macromastia, and juvenile fibroadenoma of breast.

Light Microscopy

Juvenile papillomatosis shows dilated breast ducts lined by a proliferation of highly atypical-looking epithelium that would be regarded as precancerous in an older woman.

PSEUDOANGIOMATOUS STROMAL HYPERPLASIA

Pseudoangiomatous stromal hyperplasia is a rare benign stromal lesion, which arises from myofibroblast cells lining the slit-like spaces. Lesion is positive for vimentin, actin, CD34 and estrogen receptors (ER).

Table 25.5 Diagnostic features of biphasic neoplasms of breast

Features	Fibroadenoma	Low-grade Phyllodes Tumor	High-grade Phyllodes Tumor
Gross morphology			
Size of the tumor	Variable size	Variable size	Variable size
Margins	Pushing	Pushing	Infiltrative
Cut surface	Gray-white	Gray-white with cystic spaces	Gray-white with cystic spaces
Histologic features			
Cystic spaces	Tubular (pericanalicular) or slit (intracanalicular)-like	Leaf-like cystic spaces	Leaf-like cystic spaces
Stromal cellularity	Variable stromal cellularity	Moderate to high stromal cellularity	Moderate to high stromal cellularity
Stromal overgrowth	Absent	Absent	Present in some cases
Stromal nuclear atypia	Minimal	Mild to moderate	Moderate to severe
Mitotic figures	Variable	<5/10 HPF	>10/10 HPF
Benign heterogenous elements	Rare	Frequent	Frequent

Table 25.6 Differentiating pathologic features of cellular fibroadenoma and malignant phyllodes tumor

Features	Cellular Fibroadenoma	Malignant Phyllodes Tumor
Gross morphology	Well circumscribed without invasion into surrounding breast tissue	Poorly circumscribed with invasion into a surrounding breast tissue
Margins on light microscopy	Well circumscribed margins	More often well circumscribed than infiltrative; adipose tissue infiltration
Nuclear pleomorphism	Absent	Marked
Stromal proliferation/overgrowth	Present	Present
Epithelial lined clefts—epithelium at the age of tissue fragmentation	Usually absent or less prominent	Present
Stromal cellularity	Heterogenous stromal cellularity	Heterogenous; periductal/subepithelial condensation
Mitotic activity	<3/10 HPF	>10/10 HPF

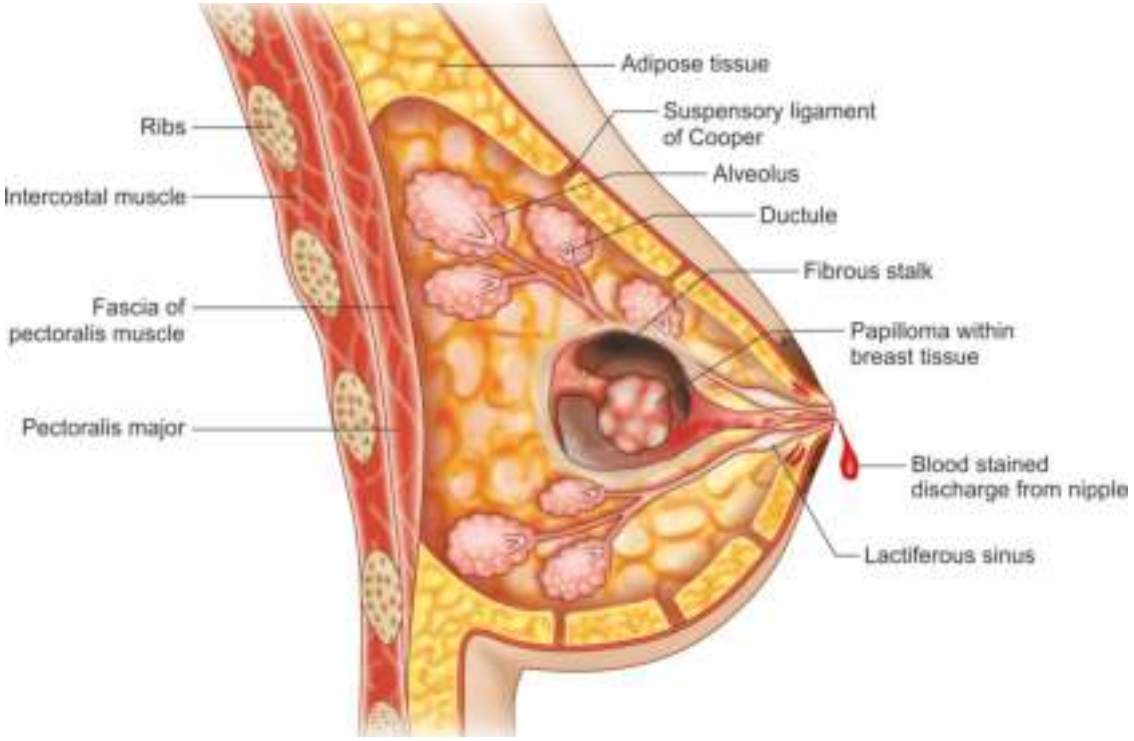

Fig. 25.21: Breast intraductal papilloma has a stalk. Tumor is present within breast substance.

BENIGN EPITHELIAL TUMORS OF BREAST

INTRADUCTAL PAPILLOMA OF BREAST

Intraductal papilloma is a benign proliferative solitary lesion within the subareolar lactiferous duct of female breast, which consists of benign ductal epithelial cell proliferation with branching fibrovascular core and underlying myoepithelial cells. Central intraductal papilloma is well-circumscribed polypoid nodule in a cystically dilated lactiferous duct. Peripheral intraductal papillomas are not grossly visible. Schematic representation of intraductal papilloma of female breast is shown in Fig. 25.21.

Age Group

Intraductal papilloma of breast occurs in the middle-aged (30–50 years) and elderly women.

Pathology Pearls: Intraductal Papilloma of Breast

- Intraductal papilloma of the breast occurs within breast ducts in middle aged and elderly women.
- Patient with central intraductal papilloma within lactiferous duct presents with hemorrhagic or serous nipple discharge, however peripheral tumor lacks nipple discharge.
- There is increased risk for development of cancer in patients with multiple intraductal papillomas.
- Tumor is detected on a mammogram or ultrasound and diagnosed by needle biopsy.
- Tumor is composed of fibrovascular core lined by benign ductal cells and myoepithelial cells.

Clinical Features

Clinical examination may reveal solitary large tumor within large lactiferous duct in the central region or multiple small tumors in the peripheral region of the breast. Patients with large central intraductal papilloma of breast may present with hemorrhagic or serous nipple discharge. Peripheral intraductal papillomas are most often multiple but smaller in size, which do not present with nipple discharge, but can undergo malignant change.

Diagnostic Modalities

Diagnostic modalities of intraductal papilloma of female breast include mammography, biopsy (core needle biopsy, vacuum-assisted biopsy, excisional biopsy), histologic examination and immunohistochemistry.

Surgical Pathology: Intraductal Papilloma of Breast

Gross Morphology

The tumor is tan-pink, friable, usually <1.0 cm in size.

Light Microscopy

- Intraductal papilloma is attached to the wall of the duct by a fibrovascular stalk. It shows multiple branching papillae composed of thin fibrovascular core lined by cuboidal to columnar ductal cells toward lumen and outer myoepithelial cells. Ductal cells may show squamous metaplasia or apocrine change.
- Intraductal papilloma with <3 mm focus of atypical hyperplasia is termed ductal carcinoma *in situ*.

- Myoepithelial cells are demonstrated in intraductal papillomas.
- Intraductal papilloma must be distinguished from papillomatosis, occurring in the peripheral ducts as a component of proliferative fibrocystic change (Fig. 25.22). It should be differentiated from noninvasive papillary carcinoma of breast (Table 25.7).
- Comparative pathologic features among benign intraductal papilloma, atypical papilloma, papilloma with DCIS and papillary DCIS are given in Table 25.8.

Immunohistochemistry Technique

- Myoepithelial cells are smooth muscle-like cells present in the glandular epithelium as a thin layer above the basement membrane and beneath the luminal cells of breast.
- Myoepithelial cell layer is intact in benign (e.g. breast papilloma) and *in situ* breast lesions; but absent in invasive breast carcinoma. Microglandular adenosis lacks myoepithelial cells.
- Panel of markers is used on paraffin-embedded tissue section of breast lesions to demonstrate myoepithelial cells in breast.

Markers	Expression
Smooth muscle actin (α-actin)	Positive
Calponin	Positive
Smooth muscle myosin heavy chain (SMMHC)	Positive
p63	Positive
CK14 (HMWCK)	Positive
S-100 (calcium binding protein)	Positive
Glial fibrillary acidic protein (GFAP)	

TUBULAR ADENOMA OF BREAST

Tubular adenoma of the breast is a benign epithelial tumor predominantly composed of bilayered tubules with sparse intervening stroma. Tubules are lined by an inner layer of epithelial cells and an outer layer of myoepithelial cells. Tumor most often occurs in young women (20–40 years) in the upper outer quadrant of the breast. Patient presents with firm, mobile, well defined and painless breast lump. There is no increased risk for developing subsequent breast carcinoma. Tumor is curable by complete surgical excision.

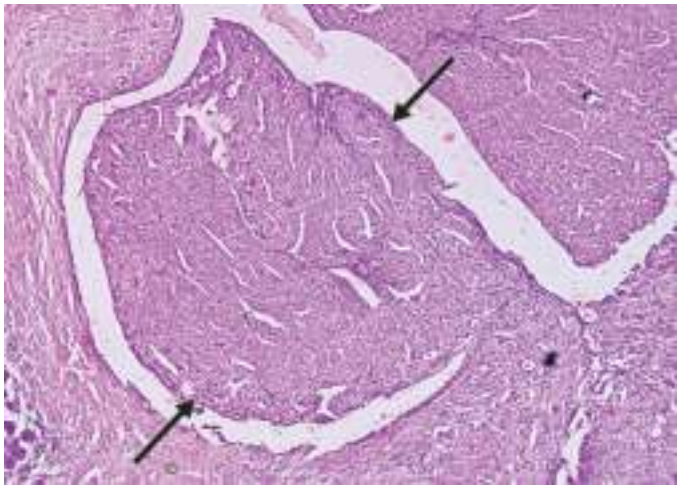

Fig. 25.22: Intraductal papilloma. It shows multiple branching papillae composed of thin fibrovascular core lined by cuboidal to columnar ductal cells toward lumen and outer myoepithelial cells (arrows) (200X).

Surgical Pathology: Tubular Adenoma of Breast

Gross Morphology

Tubular adenoma of breast is well circumscribed mass, sharply demarcated but without capsule.

Light Microscopy

- Tumor is composed of densely packed uniform round tubules lined by luminal cuboidal epithelial and outer myoepithelial cells without cytological atypia.
- There is scant intervening stroma without compression of ducts (Fig. 25.23).

LACTATING ADENOMA OF BREAST

Lactating adenoma of breast may represent the same lesion under different physiologic conditions. Lactating adenoma has been identified in postpartum biopsies that first presented during pregnancy.

- Lactating adenoma predominantly occurs in the breast, however, it may develop in ectopic breast tissue along milk line extending from axilla to vulva.
- Patient presents with painless, soft, palpable, solid mobile and discrete mass. Tumor may be bilateral

Table 25.7 Comparison of intraductal papilloma and noninvasive papillary carcinoma of breast

Parameters	Intraductal Papilloma	Noninvasive Papillary Carcinoma
Cell morphology	Benign cells with normochromatic nuclei	Atypical cells with hyperchromatic nuclei
Myoepithelial cells	Present	Absent
Apocrine change	Present	Absent
Adjacent stroma	Thick prominent stroma	Delicate stroma
Sclerosing adenosis	Unusual finding	Usual finding

Table 25.8 Comparative pathologic features among benign intraductal papilloma, atypical papilloma, papilloma with DCIS and papillary ductal carcinoma *in situ* (DCIS)

Parameters	Benign Intraductal Papilloma	Atypical Papilloma	Papilloma with DCIS	Papillary DCIS
Architectural pattern	Papillary pattern	Architectural pattern of ADH or DCIS (mm in size) or atypical population constitutes 10 to <33% of the lesion	Architectural pattern of ADH or DCIS (>mm in size) or atypical cells involving one-third but <90% of the lesion	Papillary, cribriform, solid or spindle
Fibrovascular core	Present	Present	Present	Present, may be obscured
Cellular components	Epithelial and myoepithelial components present	Epithelial and myoepithelial components may be lost	Epithelial component present, loss of myoepithelial component	Only epithelial component present
Atypia	Present	Present, can be focal	Usually present; variable dregree	Usually present
Necrosis	Absent	Usually absent	May be present	May be present
Cytomorphologic features	Heterogenous	Monotonous	Monotonous	Monotonous
Myoepithelial cell layer	Present	Absent	Usually absent	Usually absent
Immunohistochemistry	CD5, CD6 positive	CD5, CD6 negative	CD5, CD6 negative	CD5, CD6 negative

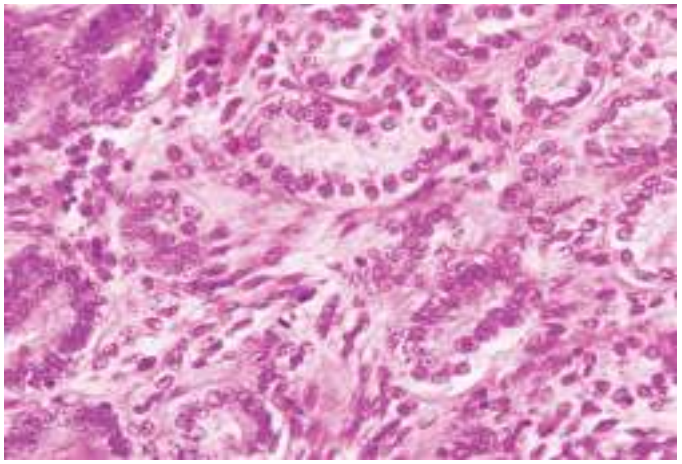

Fig. 25.23: Tubular adenoma. It shows densely packed uniform round tubules lined by luminal cuboidal epithelial and outer myoepithelial cells without cytological atypia. There is scant intervening stroma without compression of ducts (400X).

and multifocal. Infarction of tumor may result in pain, tenderness and rapid enlargement.

- Lactating adenoma of breast is diagnosed by mammography, MRI, fine needle aspiration cytology and histopathologic examination.

Surgical Pathology: Lactating Adenoma of Breast

Gross Morphology

- Lactating adenoma of breast lacks true capsule. It is well circumscribed, lobulated, solitary or multiple firm/rubbery mass.
- Cut surface shows gray-tan appearance. It may have areas of necrosis or infarction.

Light Microscopy

- On histologic examination, tumor is composed of well circumscribed proliferation of hyperplastic closely packed lobules with both epithelial and myoepithelial cell layers separated by thin, delicate connective tissue.
- Glands are lined by actively secreting cuboidal or hobnail-shaped cells with small round nuclei and clear to granular vacuolated cytoplasm. Cells contain nuclei with prominent nucleoli but lack cytologic atypia.
- Tumor resembles pregnancy-like changes, which may resemble fibroadenoma or tubular adenoma with lactational change (Fig. 25.24).

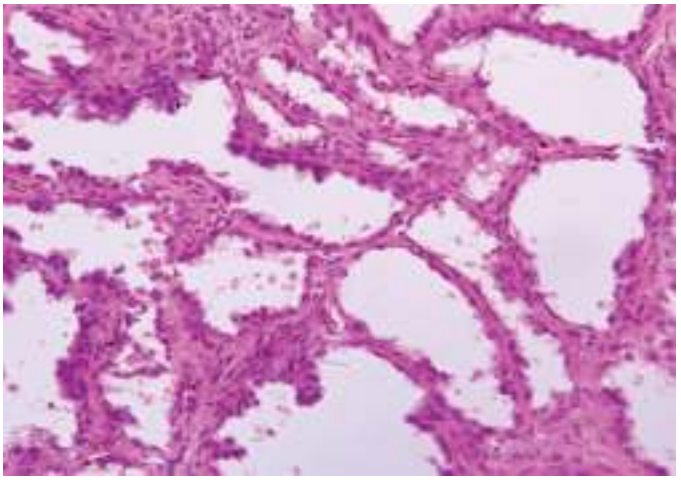

Fig. 25.24: Lactating adenoma of the female breast occurring in pregnancy and lactation. Tumor most often requires biopsy to exclude malignancy. Tumor is composed of mammary ducts lined by epithelial and myoepithelial cells and eosinophilic secretions within the lumen (200X).

COMPLEX FIBROADENOMA OF BREAST

Complex fibroadenoma of breast shows features of fibroadenoma with cysts measuring >3 mm in size, sclerosing adenosis, papillary apocrine change and calcification. Patient presents with round breast lump with distinct borders, mobile and firm or rubbery.

ADENOMA OF THE NIPPLE

Adenoma of the nipple is benign epithelial proliferation arising near the collecting ducts of the nipple.

- Patient presents with serous or bloody nipple discharge or nipple mass or with skin changes such as ulceration and crusting similar to Paget disease of the nipple.
- Initial diagnosis of adenoma of the nipple is established on histologic examination of skin punch biopsy of the nipple.

Surgical Pathology: Adenoma of the Nipple

Gross Morphology

- Adenoma of the nipple is ill-defined.
- Nipple skin shows crusting, erythema, erosion.

Light Microscopy

- In adenoma of breast, adenosis or ducts with usual hyperplasia or papillomatosis are present just below the nipple epidermis associated with collagenous stroma.
- Tumor may demonstrate cysts, focal necrosis associated with ductal hyperplasia or florid ductal hyperplasia, but no cellular atypia.
- Myoepithelial cell layer is intact (Fig. 25.25).

Immunohistochemistry Technique

Myoepithelial cells around duct-like structures are demonstrated by S-100, α-smooth muscle actin (α-SMA), p63 and glial fibrillary acidic protein (GFAP) immunohistochemical markers.

Markers	Expression
S-100	Positive
α-Smooth muscle actin	Positive
p63	Positive
Glial fibrillary acidic protein (GFAP)	Positive

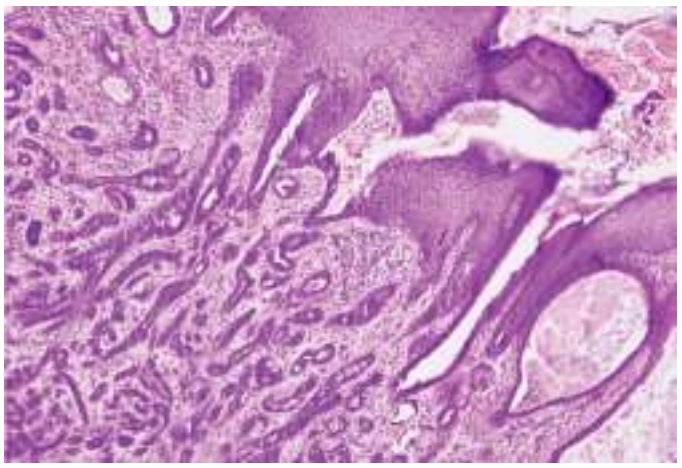

Fig. 25.25: Adenoma of the nipple. It is composed of duct-like structures associated with collagenous stroma (400X).

MALIGNANT EPITHELIAL TUMORS OF BREAST

BREAST CARCINOMA: OVERVIEW

Breast carcinoma is most important disease especially in postmenopausal women and second most frequent cause of death in women. As most breast diseases present as palpable lump, hence it is important to distinguish breast carcinoma from benign breast disease.

- True nature of a breast lump is ascertained by histopathologic examination of many areas of the excised lump. Good idea of nature of breast lump before surgery may be obtained from clinical features (size, texture, relation to adjoining tissues), mammographic examination of the affected breast, and cytologic examination of smears obtained by fine needle aspiration cytology.
- Early detection is the most important factor in breast carcinoma survival. Most important risk factors for breast carcinoma are estrogen stimulation of breasts by ovarian hormones and advancing age. Breast carcinoma occurs due to accumulation of DNA mutations.

Clinical Features

Breast lump is the presenting symptom in 85–90% of patients with breast carcinoma. Approximately 60% of breast masses are discovered by patient on self-examination. Clinical examination of breast is a necessary complement for screening mammography.

Distribution

Most glandular tissue of breast is located in the upper outer quadrant and beneath the nipple. Thus, breast carcinoma is most commonly located in upper outer quadrant. It occurs most commonly in the left breast than right.

Location

Breast carcinoma in decreasing frequency is located in upper outer quadrant (50%), central region beneath nipple (20%), lower outer quadrant (10%), upper inner quadrant (10%) and lower inner quadrant (10%), respectively.

Origin of Tumor

Breast carcinoma arises in the lining cells (epithelium) of the ducts (80–85%) or lobules (10–15%) in the glandular tissue of the breast, i.e. terminal duct lobular unit (TDLU). Initially, breast carcinoma is confined to the

duct or lobule (*in situ*), which has minimal potential to spread. Invasive breast carcinoma has metastatic potential to distant organs. Breast carcinomas are classified according to their site of origin into ductal and lobular. Ductal carcinoma is the most common subtype followed by lobular carcinoma second most common (most often bilateral) with distant metastases. Histologic types and frequency of breast carcinoma are shown in Table 25.9.

- ***In situ* (noninvasive) ductal/lobular carcinoma:** Ductal carcinoma *in situ* and lobular carcinoma *in situ* feature neoplastic cells are confined within the basement membrane of ducts and lobules, respectively. Myoepithelial cells can be demonstrated in ductal carcinoma *in situ* unlike invasive ductal carcinoma of breast.
  - Noninvasive breast carcinomas include ductal carcinoma *in situ*, lobular carcinoma *in situ*, mixed intraductal carcinoma and lobular carcinoma *in situ* and papillary carcinoma and comedocarcinoma (ductal carcinoma *in situ* with central necrosis).
  - Ductal carcinoma *in situ* is detected by screening mammography.
- **Invasive ductal/lobular carcinoma:** When ductal/lobular carcinoma breaches basement membrane and invades the normal breast parenchyma, it is termed invasive breast carcinoma. Lobular carcinomas are usually multifocal in origin.
  - Serum tumor markers for breast carcinoma include CA15.3, CA27.29, BRCA, mammaglobin, PS_2, CEA and gross cystic disease fluid protein 15 (GCDFP-15).
  - CA125 is a cell surface glycoprotein originally identified in mucinous epithelial ovarian tumors, carcinomas of endometrium, gastrointestinal tract, thyroid, and breast (Figs 25.26 and 25.27).

Table 25.9 Histologic types and frequency of breast carcinoma

Histologic Types of Breast Carcinoma	Frequency
Carcinoma *in situ*	
Ductal carcinoma *in situ*	3.6%
Lobular carcinoma *in situ* (LCIS)	1.6%
Intraductal and lobular carcinoma *in situ*	0.2%
Comedocarcinoma with central necrosis	0.3%
Invasive carcinoma	
Ductal carcinoma (not otherwise specified)	70–75%
Lobular carcinoma	5–15%
Ductal and lobular carcinoma	1.6%
Tubular carcinoma	5%
Mucinous (colloid) carcinoma	2–3%
Medullary carcinoma	1–2%
Micropapillary carcinoma	1–2%
Metaplastic carcinoma	1%
Papillary carcinoma	0.8%

Paget's disease constitutes 1.0% of breast cancer. It may be ductal carcinoma in situ or invasive ductal carcinoma involving nipple epidermis.

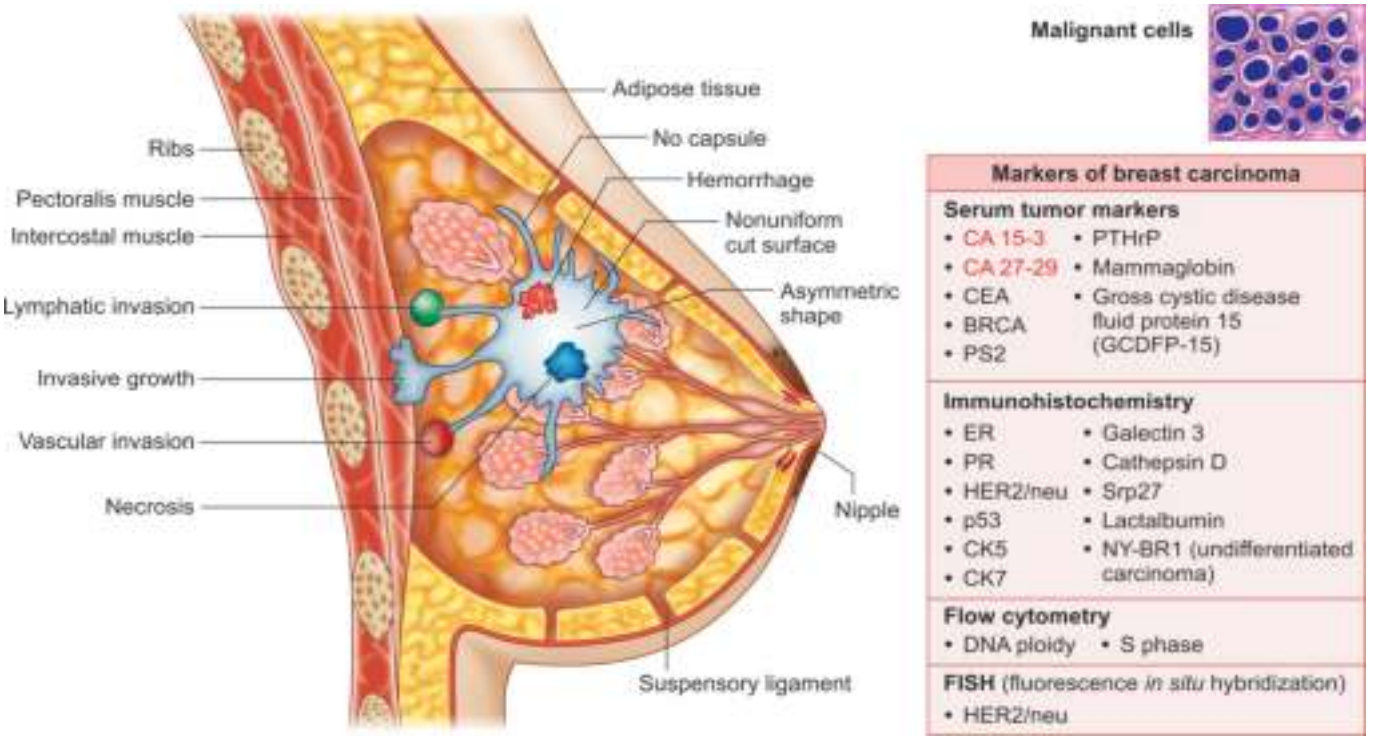

Fig. 25.26: Breast carcinoma shows invasive duct carcinoma with infiltrating margins and areas of hemorrhage and necrosis.

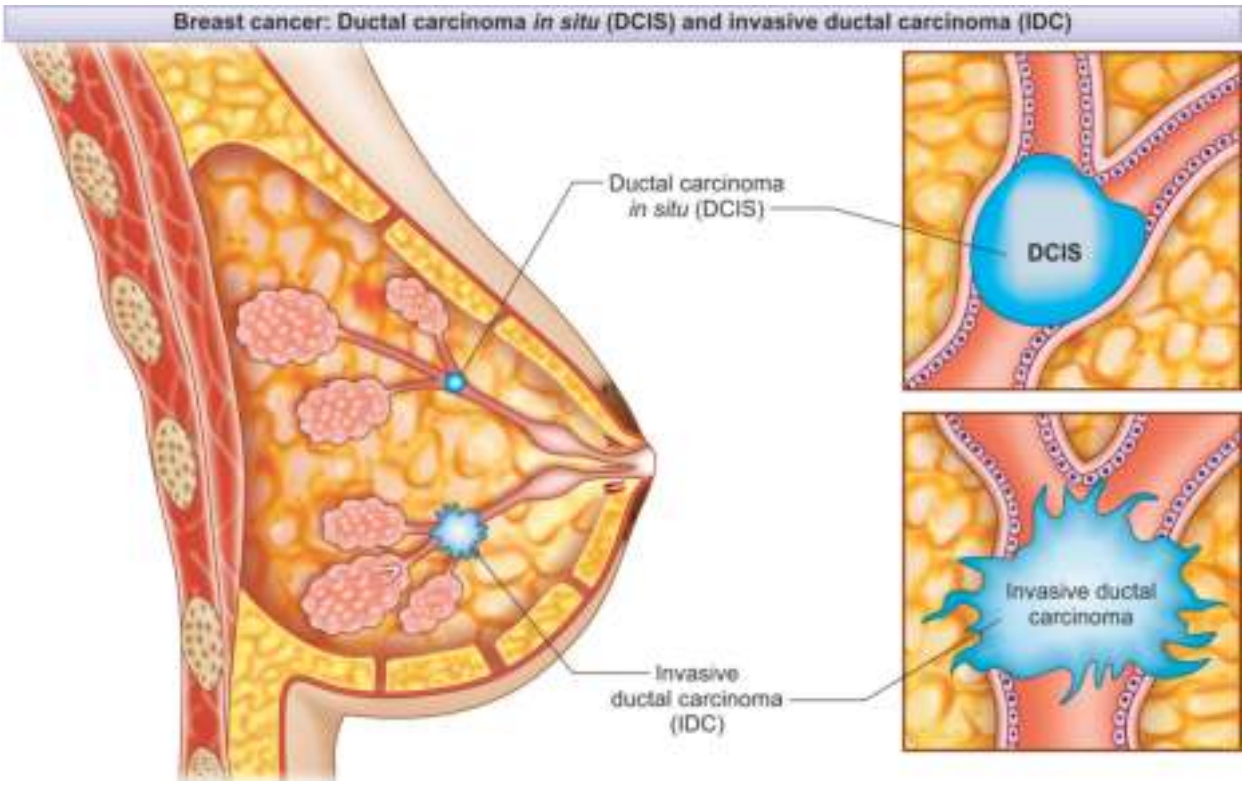

Fig. 25.27: Breast cancer—it shows ductal carcinoma *in situ* in lower inset and invasive ductal carcinoma with infiltrating margins in upper inset.

Pathology Pearls: Myoepithelial Cells

- The acinus is lined by epithelial cells surrounded by myoepithelial cells and the basement membrane.
- On immunohistochemistry, myoepithelial cells show positivity for S-100, α-smooth muscle actin (α-SMA), p63, glial fibrillary acidic protein (GFAP) and keratin 14.
- Myoepithelial cells are most often demonstrated in benign breast tumors and carcinoma *in situ*.

BREAST CARCINOMA: RISK FACTORS

About 50% breast carcinomas develop in women have no identifiable breast carcinoma risk factors other than gender (female) and age (over 40 years). Certain factors increase the risk for breast carcinoma including positive family history, longer reproductive span, nulliparity, obesity after menopause, excessive exposure to estrogens, atypical ductal hyperplasia of breast, radiation exposure, dietary factors, and radical scar in breast.

Incidence of sporadic, familial and hereditary breast carcinomas is given in Table 25.10. Risk for development of invasive carcinoma of breast related to biopsy for histologic findings is given in Table 25.11.

Positive Family History and Breast Carcinoma

Incidence of breast carcinoma is greatly increased in first-degree female relatives of patients (mother, sister,

Table 25.10 Incidence of sporadic, familial and hereditary breast carcinomas

Breast Carcinoma	Incidence	Genes Involved
Sporadic breast carcinoma	65–75%	–
Familial breast carcinoma	20–30%	–
Hereditary breast carcinoma	5–10%	–
▪ BRCA1		45%
▪ BRCA2		35%
▪ TP53 (Li-Fraumeni) syndrome		1%
▪ PTEN (Cowden disease)		<1%
▪ MSH_2/MLH-1 (Muir-Torre syndrome)		<1%
▪ ATM (ataxia-telangiectasia)		<1%
▪ STK-11/4KB1 gene in Peutz-Jeghers syndrome		<1%
▪ Other genes		20%

• Galectin 2		

Table 25.11 Risk of development of invasive carcinoma for breast related to biopsy for histologic findings

Breast Lesion	Clinical Features	Histologic Features	Risk of Breast Carcinoma
Nonproliferative fibrocystic disease	▪ Lumpy bumpy breast ▪ Cyclic breast pain	▪ Cysts formation ▪ Apocrine metaplasia ▪ Fibrosis	No risk
Duct ectasia	Nodule with calcification	Inflammatory breast lesion	No risk
Fat necrosis	Traumatic firm breast lump	▪ Foreign body giant cell reactions ▪ Calcification	No risk
Fibroadenoma	Mobile lump	Stromal-epithelial benign breast neoplasm	No risk
Proliferative fibrocystic disease	▪ Lumpy bumpy breast ▪ Cyclic breast pain ▪ Calcification	▪ Atypical ductal epithelial hyperplasia ▪ Sclerosing adenosis	2-fold (slight risk)
Papilloma	Blood stained nipple discharge in subareolar mass	Epithelial cells lining fibrovascular core	2-fold (slight risk)
Atypical ductal hyperplasia	Mass lesion with or without calcifications	Atypical ductal cells, not enough for ductal carcinoma *in situ*	4-fold (moderate risk)
Ductal carcinoma *in situ*	Breast mass with or without calcifications	▪ Cribriform pattern ▪ Papillary pattern ▪ Solid pattern with atypical nuclei	8-fold (high risk)

or daughter with history of breast carcinoma) at a younger age.

Family members may also transmit the abnormal susceptible gene (autosomal dominant with limited penetrance) without developing breast carcinoma themselves. Approximately 5% of cases are associated with a penetrant dominant genetic predisposition. Prophylactic bilateral mastectomy is performed in familial positive history of breast carcinoma.

BRCA1 Tumor Suppressor Gene Mutation

All women in the family with strong family history of breast carcinoma may have mutation of BRCA1 tumor suppressor gene located on chromosome 17q2, which regulates DNA repair by binding to RAD51, a molecule that mediates DNA double-strand repair breaks.

BRCA1 gene mutation is responsible for 52% familial and rarely sporadic breast carcinomas (medullary carcinoma and metaplastic carcinoma). This is also associated with development of carcinoma of the ovary and prostate.

BRCA2 Tumor Suppressor Gene Mutation

BRCA2 gene is a tumor suppressor gene located on chromosome 13q12–13, which regulates DNA repair by binding to RAD51, a molecule that mediates DNA double-strand repair breaks. BRCA2 gene mutation is responsible for 32% familial breast carcinoma. BRCA2 gene mutation is rarely demonstrated in sporadic breast carcinoma.

TP53 Tumor Suppressor Gene Mutation

TP53 gene is tumor suppressor gene mapped on chromosome **17p13.1**. Approximately 5% of families with breast carcinoma have mutation of TP53 tumor suppressor gene.

Genetic Disorders and Breast Carcinoma

Women with genetic disorders are at increased risk for development of breast carcinoma. These are described as under.

Li-Fraumeni Syndrome

Germline mutations of TP53 tumor suppressor gene cause Li-Fraumeni syndrome. Patients may develop multiple human cancers such as breast carcinoma, leukemia, sarcoma, brain tumors, adrenal tumors, laryngeal and lung carcinoma.

Cowden Disease

PTEN gene is located on chromosome 10q. Phosphatase and tensin homologue are proteins of PTEN gene. Normally, PTEN gene products inhibit AKT/PI3K signaling pathway. PTEN gene mutation leads to Cowden disease, characterized by fibroadenomas, fibrocystic lesions, ductal epithelial hyperplasia, and nipple malformations. There is increased risk for breast carcinoma in Cowden disease.

Inherited Ataxia-telangiectasia

Under physiologic state, ATM gene is a caretaker tumor suppressor gene located on chromosome 11p22.

It downregulates tyrosine kinase activity. Patient with ATM gene mutation has reduced capacity to repair DNA breaks resulting in accumulation of numerous genetic mutations overtime. Patient develops inherited ataxia-telangiectasia characterized by cerebral ataxia, immunodeficiency and dilations of small blood vessels. There is increased risk for breast carcinoma, gastric carcinoma, leukemia and lymphomas in ataxia-telangiectasia.

Age Group

Advancing age is the second most important factor for breast carcinoma. Incidence of breast carcinoma increases with advancing age in women >30 years of age until menopause.

Longer Reproductive Span

Early menarche and late menopause increase duration of reproductive life and associated with increased hormonal activity. Prolonged exposure to endogenous estrogen increases risk for breast carcinoma.

Nulliparous Women

Nulliparous women are at greater risk for breast carcinoma. Women, who had their first child over 30 years of age, are at greater risk. Pregnant women are at lower risk for breast carcinoma.

Age of Women at First Pregnancy

Women, who had their first child over age 30, are at greater risk for breast carcinoma. An early age at birth of a second child further reduces the risk for breast carcinoma.

Obesity after Menopause

Postmenopausal obesity and increased dietary fat increases the risk for breast carcinoma due to aromatization of androstenedione to estrogens in adipose tissue.

Excessive Exposure to Estrogens

Postmenopausal estrogen therapy and oral contraceptive use increase the risk for breast carcinoma. Use of oral contraceptives for >4 years by younger women before their first trimester of pregnancy almost increases risk of breast carcinoma in postmenopausal women.

- Risk for breast carcinoma increases in women, who receive hormonal replacement therapy for a period of 10–15 years. Hormonal replacement therapy increases breast density, which make detection of breast carcinomas more difficult.
- Hormones via blood circulation interact either with nuclear estrogen receptors of breast terminal duct lobular units (TDLUs). The hormone–receptor interactions cause activation of DNA response elements leading to proliferation and differentiation of luminal cells leading to development of breast carcinoma.

Atypical Ductal Hyperplasia of Breast

Presence of atypical changes in ductal epithelium in fibrocystic disease of breast does increase the risk for breast carcinoma.

History of Breast Carcinoma in Opposite Breast

History of breast carcinoma one side of breast is associated with increased incidence of breast carcinoma involving opposite breast.

History of Endometrial Carcinoma

Women with history of endometrial or ovarian carcinoma are at increased risk for breast carcinoma.

Exposure to Diethylstilbestrol

Diethylstilbestrol (DES) was administered to some pregnant women in the United States to prevent miscarriage. Women, who took DES or whose mothers took DES while pregnant with them have a higher risk for getting breast carcinoma.

Radiation Exposure

During Second World War of radiation exposure, risk for breast carcinoma among teenage girls has been observed due to low level ionizing radiation later in life. Women who had prior radiation therapy to the chest or breast region for Hodgkin disease before the age of 30 years have a higher risk for breast carcinoma later in life.

Dietary Factors

Diet high in animal fat increases five times risk for breast carcinoma in the United States than in Japan.

Breastfeeding

Reducing period of breastfeeding increases risk for breast carcinoma.

Longer period of breastfeeding reduces the risk for breast carcinoma. Lactation suppresses ovulation and may trigger terminal differentiation of luminal cells.

Radical Scar in Breast

Radical scar is a benign lesion mimicking breast carcinoma

- There is increased risk for development of breat carcinoma.
- It is believed that most tubular carcinomas of breast arise from radical scar of >1 cm in size.
- Finding of a radical scar on a core biopsy is an indication for resection of the lesion.

MOLECULAR GENETIC ALTERATIONS

Approximately 12% of breast carcinomas occur due to inherited gene mutations. Most of the genes play interrelated roles in maintaining genome integrity (Tables 25.12 and 25.13).

- Loss of genes have been identified in relation to breast carcinoma. Mutations and abnormal amplification of both oncogenes and tumor suppressor genes play key roles in the pathogenesis of tumor initiation and progression. Hereditary syndromes associated with breast carcinoma are given in Table 25.14.
- Sporadic breast carcinomas are associated with estrogen hormone exposure, age of menarche, age of menopause, reproductive history, hormone replacement therapy and breastfeeding. Estrogen has been identified as promoter of breast caracinomas. Estrogen stimulates breast growth during puberty, menstrual cycles and pregnancy, thereby increasing breast cells potential to malignant change.

BRCA1 Tumor Suppressor Gene

BRCA1 is a tumor suppressor gene located on chromosome 17q21.

- **Physiologic state:** BRCA1 regulates DNA repair by binding to RAD51, a molecule that mediates DNA double-strand repair breaks.
- **Pathologic state:** BRCA1 gene mutation is responsible for 52% of familial and 1–2% of all breast caracinomas. Risk is increased in age group by 70 years. Mutation of BRCA1 gene occurs by methylation.

Table 25.12 Oncogenes associated with breast carcinomas

Category	Proto-oncogene	Mode of Activation	Associated Carcinomas
Growth factors			
Fibroblast growth factors	▪ FGF3 ▪ INT2	▪ Amplification ▪ Increased baseline activity	▪ **Breast carcinoma**, osteosarcoma, gastric carcinoma, urinary bladder carcinoma and melanoma ▪ **Breast carcinoma** and melanoma
Growth factor receptors			
EGF receptor	ERBB2 (HER2/neu ERBB2)	Amplification	**Breast carcinoma** (marker of aggressiveness)
Signal transduction proteins			
NOTCH signal transduction	NOTCH 1	Point mutation, translocation	**Breast carcinoma,** leukemia and lymphoma
Cyclin and cyclin-dependent kinase (cell cycle regulators)			
Cyclin-dependent kinase	CCND1 (cyclin D1)	Amplification	**Breast carcinoma,** multiple myeloma and esophageal cancer

Table 25.13 Tumor suppressor gene associated with breast carcinomas

Gene	Proteins	Function	Familial Tumors	Sporadic Carcinomas
Mitotic signaling pathway inhibitors				
PTEN	Phosphatase and tensin homologue	It inhibits AKT/PI3K signaling pathway	*Cowden syndrome* (carcinomas of breast, endometrium and thyroid gland)	Lymphoid neoplasms, carcinomas
Cell cycle progression inhibitors				
CDKN2A	P16/INK4a and P14ARF	P16 inhibits CDK. P14 indirectly activates p53 tumor suppressor gene	Familial melanoma	Breast carcinoma, pancreas carcinoma, and esophagus carcinoma
RB gene	Retinoblastoma protein (locus 13p14) mutation by deletion and nonsense	It codes for pRB protein, master brake on cell cycle. It inhibits G1 to S transition during cell cycle. It inhibits nuclear transcription factor	Retinoblastoma, osteosarcoma	Breast carcinoma, osteosarcoma, colon carcinoma, prostate carcinoma, urinary bladder carcinoma and lung carcinoma
Inhibitors of invasiveness and metastases				
CDH1	E-Cadherin	It participates in cell adhesion. It inhibits cell motility	Gastric carcinoma	Breast lobular carcinoma and gastric carcinoma

There is increased risk of breast and endometrial carcinomas in women on oral contraceptive therapy.

Table 25.14 Hereditary syndromes associated with breast carcinoma

Syndrome	Gene	Inheritance	Carcinomas	Other Features
Breast/ovarian carcinoma syndrome	BRCA1	Autosomal dominant	▪ Breast ▪ Ovary	Absent
Cancer syndrome	BRCA2	Autosomal dominant	▪ Breast ▪ Ovary ▪ Prostate ▪ Pancreas	Fanconi anemia in homozygotes
Li-Fraumeni syndrome	TP53	Autosomal dominant	▪ Breast ▪ Brain ▪ Leukemia ▪ Soft tissue sarcoma	Absent
Cowden syndrome	PTEN	Autosomal dominant	▪ Breast ▪ Ovary ▪ Colon ▪ Thyroid follicular carcinoma	▪ Thyroid adenoma ▪ GI polyps ▪ Leiomyomas
Peutz-Jeghers syndrome	STK-11	Autosomal dominant	▪ GIT ▪ Breast	▪ Hamartomas bowel ▪ Pigmentation buccal mucosa
Ataxia-telangiectasia	ATM	Autosomal dominant	Breast	▪ Leukemia ▪ Lymphoma ▪ Cerebellar ataxia ▪ Telangiectasia ▪ Immune deficiency
Muir-Torre syndrome	MSH-2/ MLH-1	Autosomal dominant	▪ Breast ▪ Colorectal region	Absent
Site specific	CHEK-2	Autosomal dominant	Breast	Low penetration

- BRCA1 gene mutation is rare in sporadic medullary carcinoma and metaplastic carcinoma of breast.
- BRCA1 gene mutation may occur in carcinomas of ovary, male and female breast, prostate, pancreas and fallopian tube; but less than due to BRCA2 gene mutation.

BRCA2 Tumor Suppressor Gene

BRCA2 is a tumor suppressor gene located on chromosome 13q12–13.

- **Physiologic state:** BRCA2 regulates DNA repair by binding to RAD51, a molecule that mediates DNA double-strand repair breaks.
- **Pathologic state:** BRCA2 gene mutation is rare in sporadic cases of breast carcinomas.

BRCA2 gene mutation also occurs in carcinomas of ovary, male and female breasts, prostate, pancreas, stomach, gallbladder, bile duct, pharynx and melanoma.

TP53 Tumor Suppressor Gene

TP53 is tumor suppressor gene located on chromosome 17p13.1.

- **Physiologic state:** TP53 gene product (p53 protein) halts cell cycle in G1 phase by inhibiting nuclear transcription factor, until the DNA is repaired, which activates BAX gene-induced cell suicide (apoptosis). The p53 protein interacts with at least 17 cellular and viral proteins.
- **Pathologic state:** TP53 is responsible for 3% of familial and 20% in sporadic breast carcinomas. There is increased risk for breast carcinoma in 90% of cases by the age of 70 years.

TP53 gene mutations are also demonstrated in cancers of pancreas (50–70%), lung, colon, and breast. TP53 gene mutation also occurs in **Li-Fraumeni syndrome** (breast carcinoma, sarcoma, leukemia, brain tumors and adrenal gland cancer).

CHEK2 Tumor Suppressor Gene

CHEK2 is a tumor suppressor gene located on chromosome 22q12.1.

- **Physiologic state:** CHEK2 protein induces cell cycle arrest and repairs damaged DNA. It activates BRCA1 and p53 tumor suppressors by phosphorylation.
- **Pathologic state:** Gene mutation of CHEK2 is responsible for 5% of familial as well as sporadic breast carcinomas. Due to CHEK2 gene mutation, there is increased risk for breast carcinoma in 10–20% of cases by 70 years of age especially after radiation exposure. It is worth mentioning that CHEK2 gene mutation is

also demonstrated in carcinomas of prostate, thyroid and kidney.

RB Tumor Suppressor Gene

RB is a gatekeeper tumor suppressor gene located on long arm of chromosome 13q14. Normal people have two alleles of the RB gene.

- **Physiologic state:** RB gene codes for pRB protein, master brake of cell cycle. Dephosphorylated pRB protein inhibits cell division. When the pRB gene is phosphorylated, cell division takes place.
- **Pathologic state:** RB gene mutation is demonstrated in breast carcinoma, familial/acquired retinoblastoma, and familial/acquired osteosarcoma. RB gene mutation is also demonstrated in carcinomas of colon, prostate, breast and urinary bladder.

Fibroblast Growth Factor 3 (FGF3)

- **Physiologic state:** FGF3 belongs to growth factor category. Cells have the ability to synthesize the same growth factors to which they are responsive, in generating an autocrine loop.
- **Pathologic state:** Amplification of FGF3 is associated with breast carcinoma, osteosarcoma, gastric carcinoma, urinary bladder carcinoma and melanoma.

INT2 Oncogene

- **Physiologic state:** INT2 belongs to growth factor category. Cells have the ability to synthesize the same growth factors to which they are responsive, generating an autocrine loop.
- **Pathologic state:** Increased baseline activity of INT2 has been demonstrated in breast carcinoma and melanoma.

ERBB2 (HER2/neu) Gene

- **Physiologic state:** Human epidermal growth factor ERBB2 (HER2/neu) belongs to growth factor receptor family, which encodes for an epithelial growth factor receptor on the cell membrane that delivers continuous mitogenic signals to the cells.
- **Pathologic state:** Amplification of ERBB2 (HER2/neu) delivers continuous mitogenic signals to the neoplastic cells of breast carcinoma even in the absence of growth factor in the environment. It is most often observed in ductal carcinoma and rarely in lobular carcinoma of breast.
- **Immunohistochemistry technique:** ERBB2 (HER2/neu) is demonstrated by immunohistochemistry technique on the cell membrane or using fluorescent *in situ* hybridization (FISH). It is marker of breast carcinoma associated with aggressive behavior.

NOTCH1 Gene

- **Physiologic state:** NOTCH 1 gene belongs to NOTCH signal transduction protein category.
- **Pathologic state:** Point mutation or translocation of NOTCH 1 gene is linked to breast carcinoma, leukemia and lymphomas.

RAS (from Rat Sarcoma Virus) Gene

- **Physiologic state:** RAS oncogene activates several intracellular signal transduction pathways and synthesis of transcription factors 'Fos' and 'Jun'.
- **Pathologic state:** RAS gene mutation is demonstrated in breast carcinoma, pancreatic carcinoma, lung carcinoma and colorectal carcinoma.

c-Myc Oncogene (Nuclear Transcription Factor)

- **Physiologic state:** c-Myc is nuclear regulatory protein that controls the expression of several genes.
- **Pathologic state:** Mutation of c-Myc is demonstrated in breast carcinoma, colorectal carcinoma and gastric carcinoma.

BCL-1 Cell Cycle Regulatory Gene

- **Physiologic state:** BCL-1 gene codes for cyclin D1, acts as stimulatory protein of the cell cycle.
- **Pathologic state:** Mutation of BCL-1 gene causes loss of regulation of cell cycle resulting in breast carcinoma.

Cyclins and Cyclin-dependent Kinase

- **Physiologic state:** CCND1 and cyclin D1 are cell cycle regulators.
- **Pathologic state:** CCND1 and cyclin D1 are activated by translocation and amplification. Deregulation of cyclins due to mutation is associated with breast carcinoma.

E-Cadherins

- **Physiologic state:** E-cadherins belong to CDH1 category, which are inhibitors of invasiveness and metastases of breast lobular carcinoma.
- **Pathologic state:** E-cadherins are irreversibly lost in invasive lobular breast carcinoma, but expressed in invasive ductal breast carcinoma. Germline and somatic mutations of E-cadherin also play an important role in the pathogenesis of gastric carcinoma (diffuse type).

PTEN Tumor Suppressor Gene

- **Physiologic state:** PTEN gene is located on chromosome 10q, which inhibits mitogenic signaling pathway.
- **Pathologic state:** PTEN gene mutation is associated with **Cowden disease** characterized by fibroadenoma,

Table 25.15 Molecular subtypes of breast carcinoma on the basis of DNA microarray

Molecular Subgroup and Frequency	Luminal A Breast Carcinoma (50%)	Luminal B Breast Carcinoma (20%)	HER2/neu Enrich Breast Carcinoma (15%)	Triple Negative Basal Type Breast Carcinoma (up to 15% in African Women)
ER	+++	+	–	–
PR	+	+	–	–
HER2/neu	–	–/+	++	–
Proliferation index	Low	Moderate	High	Very high
Distant metastases	Bones, viscera and brain	Bones, viscera and brain	Bones, viscera and brain	Bones, viscera and brain
Gene mutations	GATA-3, LIV-1, CCND-1, FOX-1	–	Amplification of gene located on 17q12	Basal epithelial genes, TP53, BRCA1
Others	CK8/18 (cytokeratin)	CK8/18 (cytokeratin)	Androgen receptors	CK5/6, CK14, vimentin, EGFR, c-KIT
Ki-67	+ (≤10%)	+ (≥30%)	+ High ≥20%	+ (≥20%)
CD20	+	+	+	+
Prognosis	Excellent (recurrence low)	Intermediate (recurrence high)	Poor (recurrence high)	Poor (recurrence high)
Treatment	Hormonal therapy	Hormonal + chemotherapy	Trastuzumab (Herceptin) and anthracyclines	Platinum- and anthracycline-based chemotherapy, PARP inhibitors

PARP: Poly (adenosine diphosphate-ribose) polymerase, ER (estrogen), PR (progesterone).
Histologic variants of luminal A: Low-grade invasive ductal carcinoma (NOS), classic lobular, tubular and cribriform carcinomas.
Histologic variants of luminal B: Invasive ductal carcinoma and micropapillary carcinoma.
Histologic variants of HER2/neu enrich: Invasive ductal carcinoma, NOS (not otherwise specified).
Histologic variants of basal type: Invasive ductal carcinoma, NOS (not otherwise specified), medullary and metaplastic carcinomas.
Patients with breast carcinoma with Ki-67 >20% show poorest prognosis.

fibrocystic disease of breast, ductal epithelial hyperplasia, nipple malformations, breast carcinoma and endometrial carcinoma.

Galectin 3 Encoded by 4GALS3 Gene

- **Physiologic state:** Galectin 3 is a member of lectin family and encoded by LGALS3 gene located on chromosome 14, locus q21–q22. Galectin 3 is expressed in the nucleus, cytoplasm and extracellular space.
- **Pathologic state:** Galectin 3 overexpression promotes neoplastic transformation and the maintenance of transformed phenotypes as well as enhances adhesion of malignant tumor cells to the extracellular matrix in breast carcinoma.

MAJOR MOLECULAR PATHWAYS: EVOLUTION OF BREAST CARCINOMA

Aims of molecular profiling of breast carcinoma to study the patient's risk for stratification, specific treatment modality, reduction therapy-induced toxicity and ensurig high chance of survival.

- In a simplified approach, some authors used ER, PR, ERBB2 (HER2/neu) plus Ki-67 to classify breast carcinoma into four molecular clusters.
- Recently, breast carcinoma is classified based on expression of estrogen (ER), progesterone (PR) and human epidermal growth factor (HER2/neu) markers with or without the addition of molecular gene signatures. Subtypes of breast carcinoma have different biology and prognosis with accumulating evidence of risk factors.
- Proposed molecular subtypes of breast carcinoma on the basis of DNA microarray include as mentioned in Table 25.15.

Molecular Subtypes of Breast Carcinoma

Luminal 'A' Breast Carcinoma

- ER/PR positive
- Ki-67 proliferative activity ≤10%
- Low-grade tumor
- Prognosis good

Luminal 'B' Breast Carcinoma

- ER/PR positive
- ERBB2/HER2/neu expression in some cases
- Ki-67 proliferative activity ≥20%
- Relatively high-grade tumor
- Prognosis is not good.

Triple Negative Basal-like Breast Carcinoma
▪ ER/PR negative ▪ ERBB2/HER2/neu negative ▪ Also called triple negative breast carcinoma (TNBC) ▪ Most BRCA1 breast carcinomas are basal-like TNBC ▪ High-grade tumor ▪ Prognosis worse.
ERBB2/HER2/neu Enriched Breast Carcinoma
▪ ER/PR positive/negative ▪ ERBB2/HER2/neu amplification seen ▪ Most common type of breast carcinoma with germline TP53 gene mutations occurring in Li-Fraumeni syndrome ▪ Ki-67 proliferative activity ≤14% ▪ High-grade tumor ▪ Prognosis poor
Normal Breast-like Breast Carcinoma
▪ ER/PR often negative ▪ ERBB2/HER2/neu often negative ▪ Claudin low breast carcinoma ▪ Low expression of cell to cell junction proteins, i.e. E-cadherin ▪ Tumor showing infiltration by lymphocytes ▪ Prognosis poor

ESTROGEN POSITIVE MOLECULAR PATHWAY (LUMINAL A AND LUMINAL B)

Estrogen (ER) positive breast carcinomas are termed luminal A and luminal B breast carcinomas, which resemble normal breast luminal cells in terms of their mRNA expression regulated by estrogen. Breast carcinoma occurs due to inheritance of germline BRCA2 gene mutation associated with gain of 1q chromosome, loss of 16q. ER positive pathway is the most common molecular pathway, which expresses estrogen receptors (Figs 25.28 and 25.29).

Luminal 'A' Breast Carcinoma

Luminal A breast carcinoma is low-grade tumor with low proliferative activity Ki-67 ≤10% seen in <50% of cases.

- Recurrence rate of breast carcinoma is low.
- Immunohistochemistry shows ER/PR positivity. ERBB2 (HER2/neu) expression is negative.
- Prognosis is excellent, because these patients respond to endocrine therapy, i.e. estrogen blocking drug tamoxifen and aromatase inhibitors.

Luminal 'B' Breast Carcinoma

Luminal B breast carcinoma is relatively high-grade tumor with high proliferative activity Ki-67 ≥30 than luminal A tumor.

- Immunohistochemistry technique reveals low expression of ER/PR in breast carcinoma.

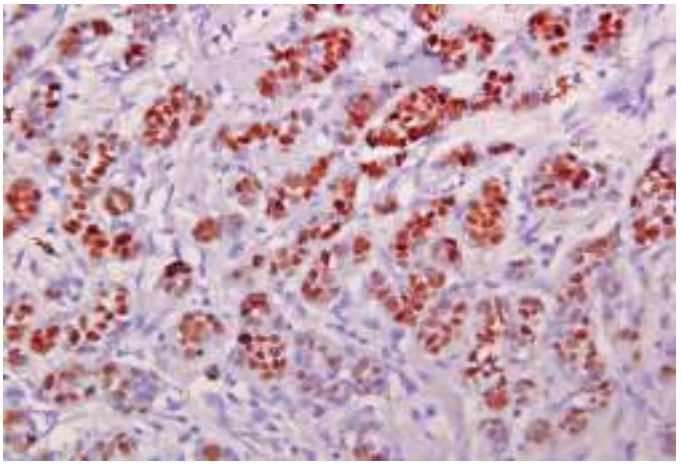

Fig. 25.28: Breast carcinoma—infiltrative duct carcinoma shows estrogen nuclear receptor positivity. Hormone therapy with tamoxifen is used to block the effects of estrogen that may otherwise help breast carcinoma cells to survive and grow. Most women with breast carcinomas expressing estrogen or progesterone benefit from treatment with tamoxifen (400X).

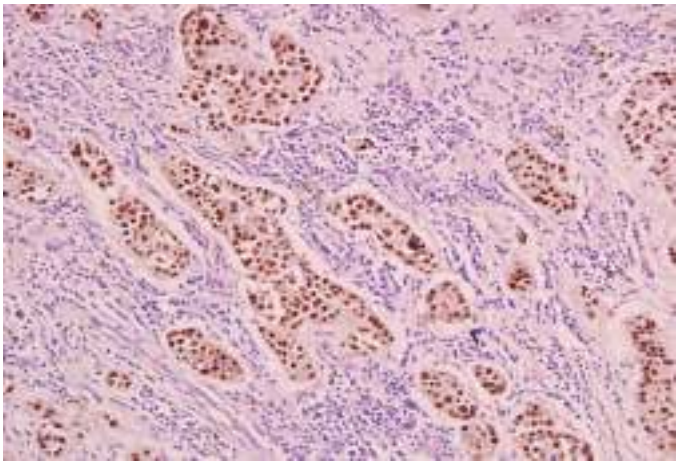

Fig. 25.29: Breast carcinoma—infiltrative duct carcinoma shows progesterone receptor nuclear positivity (100X).

- ERBB2 (HER2/neu) expression in tumor cells may be positive or negative in breast carcinoma.
- Prognosis may not be as good as in luminal A breast carcinoma.

Pathology Pearls: Sequence of Events: Luminal 'B' of Breast Carcinoma
▪ **Development of flat lesion:** Patient develops flat lesion in breast as a result of gain of 1q chromosome and loss of 16q. ▪ **Progression to breast carcinoma:** Due to mutation of PIK3CA gene, flat lesion progresses to atypical hyperplasia of breast, ductal carcinoma *in situ* and invasive breast carcinoma. PIK3CA gene product encodes phosphoinositide-3 kinase (PI3K), major component of signal pathway, down regulating growth factor receptor.

Immunohistochemistry Technique		
▪ Immunohistochemistry technique of luminal type A breast carcinoma shows positivity for ER/PR and cytokeratin (8;18). ▪ Immunohistochemistry technique of luminal type B breast carcinoma shows low expression of ER/PR. Tumor cells are immunoreactive to cytokeratin (8;18).		
Markers	**Luminal type A**	**Luminal type B**
▪ Estrogen receptor (ER)	+++	+
▪ Progesterone receptor (PR)	++	+
▪ HER2/neu	–	–/+
▪ Cytokeratins (8;18)	+	+

HER2/NEU ENRICHED MOLECULAR PATHWAY

HER2/neu is located on chromosome 17q. Amplification of HER2/neu is responsible for 20% cases of breast carcinomas. It is the most common type of breast carcinoma in patient with germline mutations in TP53 gene (Li-Fraumeni syndrome). Patient develops atypical ductal hyperplasia progressing to ductal carcinoma *in situ* resulting in invasive breast carcinoma (Fig. 25.30).

Clinical Course

HER2/neu enriched invasive ductal carcinoma is high-grade tumor with higher proliferative rate and poor prognosis. It most often shows involvement of axillary lymph nodes.

Pathology Pearls: HER2/neu Enriched Molecular Pathway	
Immunohistochemistry Technique	
Immunohistochemistry technique of HER2/neu enriched molecular pathway of breast carcinoma shows HER2/neu positivity. Tumor cells may be ER positive/negative.	
Markers	**Expression**
▪ HER2/neu ▪ Estrogen receptor (ER)	▪ Positive ▪ Positive or negative

Treatment

These patients with HER2/neu enriched invasive ductal carcinoma respond to Herceptin and anthracycline based chemotherapeutic agents.

ER, PR AND HER2/NEU TRIPLE NEGATIVE BASAL-LIKE MOLECULAR PATHWAY

Triple negative molecular basal-like pathway is least understood pathway due to inheritance of BRCA1 gene mutation responsible for 15% of breast carcinomas. These tumors have a basal-like pattern of mRNA expression present in normal myoepithelial cells.

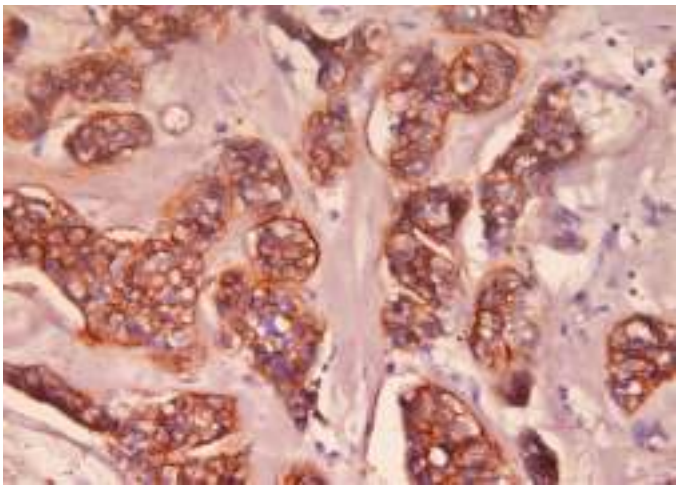

Fig. 25.30: Breast carcinoma. Infiltrative ductal carcinoma of breast shows HER2/neu membrane positivity. These patients are treated with Herceptin (anti-HER2/neu monoclonal antibody) (400X).

- Basal cell type of breast carcinoma has high proliferative rate with positive lymph nodes and high recurrence rate. TP53 gene mutation is very common.
- These breast carcinomas show high expression of basal epithelial genes and TP53 gene mutations, and dysfunctional BRCA1 gene.
- Ki-67 is expressed in <14% cases of triple negative breast carcinomas.
- Triple negative breast carcinomas (TNBCs) are associated with a younger age at clinical presentation, higher-grade tumor and poor prognosis.

Progression of Ductal Carcinoma *in situ* (DCIS) to Invasive Ductal Breast Carcinoma

TP53 gene mutation and inactivation of BRCA1 directly cause ductal carcinoma *in situ* progressing to invasive breast carcinoma. These breast carcinomas are triple negative, i.e. ER/PR and HER2/neu negative.

Treatment

The patients with triple negative breast carcinoma do not respond to endocrine therapy (tamoxifen), aromatase inhibitors or Herceptin. Prognosis is poor. Trials are going onto treat these patients with platinum-based chemotherapy or poly (ADP-ribose) polymerases (PARPs) inhibitors.

NORMAL BREAST-LIKE MOLECULAR PATHWAY

Normal breast-like breast carcinoma lacks the expression of ER, PR and HER2/neu and can also be classified as triple negative but it is not considered to be basal-like breast carcinoma as it is negative for CK5 and EGFR. There are few studies on this subtype and its clinical significance remains under determined.

BREAST CARCINOMA: HISTOLOGIC VARIANTS

More than 90% of breast carcinomas arise in ducts or lobules as carcinoma *in situ* (Figs 25.31 and 25.32). When malignant epithelial cells invade the basement membrane and extends in surrounding tissue, it is known as invasive ductal carcinoma. Ductal carcinoma *in situ* (DCIS) is associated with the development of small calcified deposits in the breast demonstrated by mammography. Differentiating features of invasive ductal carcinoma versus invasive lobular carcinoma of breast are given in Table 25.16.

DUCTAL CARCINOMA: BASIC CONCEPT

Ductal Carcinoma *in situ* of Breast

Ductal carcinoma *in situ* (DCIS) of breast is a neoplastic proliferation of mammary ductal epithelial cells confined to the ductal–lobular system without evidence of invasion through basement membrane into the surrounding stroma. Microcalcification on mammography raises concern and need for obtaining biopsy. Diagnosis is confirmed on histologic examination of tissue obtained via needle core biopsy, lumpectomy or mastectomy.

Ductal carcinoma *in situ* has two histologic variants: comedocarcinoma and noncomedocarcinoma (Table 25.17). Tumors may be low, intermediate and high-grades. Low-grade DCIS shows monomorphic cells looking like normal breast cells with small size nuclei. High-grade DCIS is composed of pleomorphic neoplastic cells with vesicular hyperchromatic nuclei and prominent nucleoli. Intermediate-grade DCIS has intermediate features.

- **Comedocarcinoma:** Comedocarcinoma is high-grade ductal carcinoma *in situ* of breast and composed

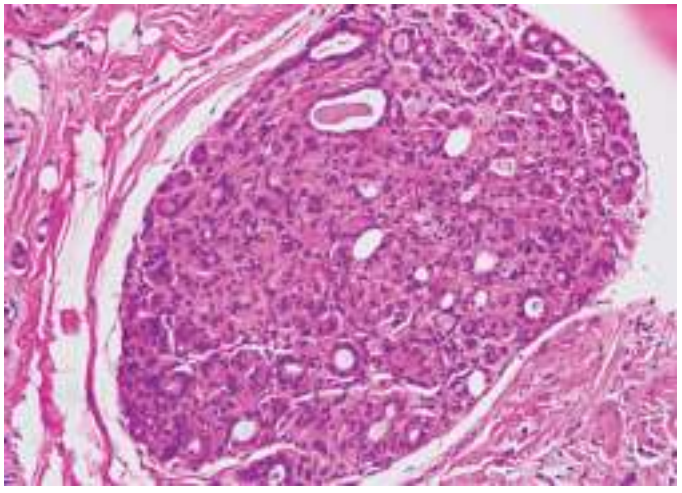

Fig. 25.31: Comedocarcinoma breast. It is high-grade ductal carcinoma *in situ* with highly pleomorphic tumor cells present within and distending the duct space, associated with central comedonecrosis (cheesy material) (400X).

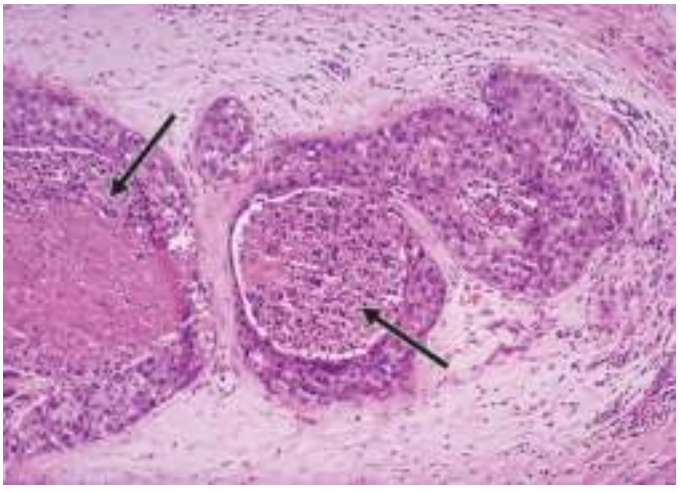

Fig. 25.32: Breast comedocarcinoma. Breast comedocarcinoma is high-grade ductal carcinoma *in situ* (DCIS) that demonstrates comedonecrosis (arrows), which is the central necrosis of cancer cells within involved ducts (400X).

Table 25.16 Differentiating features of invasive ductal carcinoma versus invasive lobular carcinoma of breast

Features	Invasive Ductal Carcinoma	Invasive Lobular Carcinoma
Relative frequency	▪ 80–85% ▪ Usually unifocal involving unilateral breast	▪ <10% ▪ Multifocal and involving bilateral breasts
Pattern of infiltration	Neoplastic cells arranged in nests/sheets	Neoplastic cells arranged in single 'Indian file pattern'/tagetoid pattern
Intervening stroma	Often scant	Extensive
Tubule formation	Present	Absent
Cell size	Moderate to large	Usually small
Signet ring cells	Rare	Frequent
Associated lesions	Ductal carcinoma *in situ*	Lobular carcinoma *in situ*

Presence of in situ component is not essential for diagnosis. Some tumors may show both elements of invasive ductal carcinoma as well as invasive lobular carcinoma.
Mutations in BRCA1 gene located on 17q21 and BRCA2 gene located on 13q12-13 are responsible for familial early onset breast carcinoma.
Patient with HER2/neu oncogene amplification is associated with poor prognosis.

Table 25.17 Comparison of comedocarcinoma and noncomedocarcinoma

Characteristics	Comedocarcinoma	Noncomedocarcinoma
Nuclear grade	High	Low
Estrogen receptor	Negative	Positive
ERBB2/HER2/neu overexpression	Present	Absent
Distribution	Continuous	Multifocal
Necrosis	Persent	Absent
Local recurrence	High	Low
Prognosis	Worse	Favorable

of highly pleomorphic tumor cells present within and distending the duct space, associated with central comedonecrosis (cheesy material), which may show lymph node metastases. The ducts are lined by pleomorphic neoplastic cells with hyperchromatic irregular nuclei, prominent nucleoli and abundant eosinophilic cytoplasm. Tumor cells are arranged in solid pattern with central necrosis in the ducts. The necrotic debris may undergo dystrophic calcification. The tumor cells incite chronic inflammatory cell infiltration and fibroblastic response in the surrounding stroma.

- **Noncomedocarcinoma:** Noncomedocarcinoma of breast is ductal carcinoma *in situ* (DCIS) without central necrosis. Malignant cells have regular outlines and small nuclei in contrast to comedocarcinoma. Tumor cells may be arranged in solid pattern or cribriform (multiple lumens within duct) or micropapillary pattern with delicate fibrovascular cores lined by tumor cells.

Invasive Ductal Carcinoma of Breast

Invasive ductal carcinoma is most common breast carcinoma constituting 65–80% of all breast carcinomas. Tumor breaches basement membrane and invades the normal breast at random. Its precursor lesion is ductal carcinoma *in situ*. Its architecture ranges from tubule formation to solid sheets (Fig. 25.33).

LOBULAR CARCINOMA: BASIC CONCEPT

Lobular carcinoma is most common breast carcinoma in the terminal duct lobular unit (TDLU). Tumor is often bilateral and multifocal in 20–50% of cases. On light microscopy, lobular carcinoma of breast may be classified as *in situ* or invasive types.

Lobular Carcinoma *in situ* (LCIS) of Breast

Lobular carcinoma *in situ* of breast is considerably less common (1%) than ductal carcinoma *in situ* (DCIS). It is characterized by distension of the terminal lobules by small- to intermediate-sized cells with a few mitoses. Approximately untreated 20–30% of cases, patients with lobular carcinoma *in situ* develop invasive lobular carcinoma (Fig. 25.34).

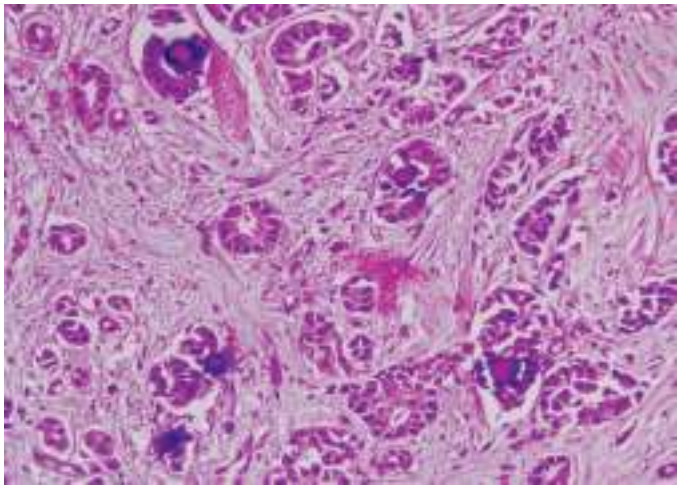

Fig. 25.33: Histgology of breast invasive ductal edenocarcinoma. Tumor is composed of atypical pleomorphic cells with hyperchromatic nuclei and arranged in glandular structures, clusters, and sheets invading surrounding connective tissue stroma of breast and microcalcifications (400X).

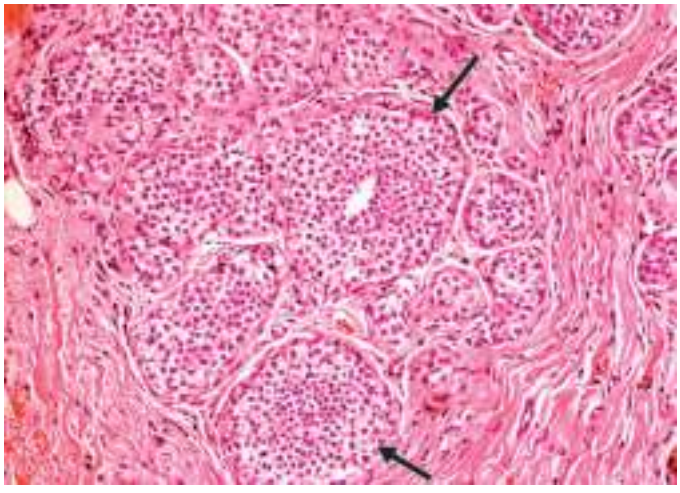

Fig. 25.34: Lobular carcinoma in situ of the breast. Tumor is composed of loosely cohesive uniform population of cells and within the acini (arrows) with indistinct cell borders and pale cytoplasm, small uniform nuclei, evenly distributed chromatin, and inconspicuous nucleoli (400X).

Invasive Lobular Carcinoma of Breast

Invasive lobular carcinoma is less common breast carcinoma constituting 5–10% of cases. Its precursor lesion is lobular carcinoma *in situ*. Although microcalcifications are uncommon, yet mammography detects the lesion. It is luminal A type of breast carcinoma, which shows low proliferative rate. Recurrence rate is low. Immunohistochemistry of invasive lobular carcinoma shows positivity for ER/PR and cytokeratin (8;18). These patients respond to tamoxifen, aromatase inhibitors and Herceptin associated with good prognosis.

Molecular Genetic Alterations

Amplification of ERBB2 (HER2/neu) is rarely detected in noninvasive or invasive lobular carcinoma of breast by immunohistochemistry on the cell membrane or using fluorescent *in situ* hybridization (FISH) technique.

Surgical Pathology: Lobular Carcinoma of Breast

Gross Morphology

Lobular carcinoma *in situ* of breast is rubbery poorly circumscribed, firm to hard tumor or not readily palpable.

Light Microscopy

- Classic variant of invasive lobular carcinoma of breast comprises small- to moderately-sized atypical cells that lack cohesion.
- Neoplastic cells are individually dispersed singly in linear fashion 'single Indian file pattern' through fibrous tissue around preexisting benign ducts.
- Presence of mucin in malignant cells pushes the nucleus against the membrane creating signet ring appearance (Fig. 25.35).

Histologic Variants

Lobular invasive carcinoma of breast shows five histologic types: classic, alveolar (aggregates of more than 20 cells), tubuloalveolar (cells in cords and microtubules), pleomorphic, solid (cells arranged in diffuse sheets) and mixed (70% cells in Indian file pattern) variants.

Immunohistochemistry Technique

Tumor cells show ER, PR and cytokeratin (8;18) positivity in all cases of invasive lobular carcinomas of breast. In addition, a substantial number of these tumors is reactive for CEA.

Markers	Expression
Estrogen receptor (ER)	Positive
Progesterone receptor (PR)	Positive
Cytokeratin (8;18)	Positive
Carcinoembryonic antigen (CEA)	Positive

Clinical Correlation

Patient with invasive lobular carcinoma of breast presents with bilateral multiple breast lumps in 20–50% of cases. Tumor may spread to axillary lymph nodes and distant organs such as lungs, liver, and bone, cerebrospinal fluid, ovaries (Krukenberg tumor) and uterus.

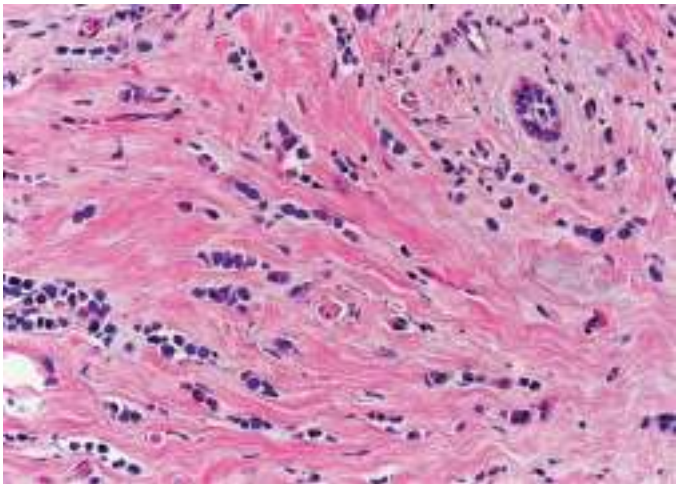

Fig. 25.35: Classic invasive lobular carcinoma of the breast. It shows poorly cohesive uniform round cells infiltrating into surrounding stroma and arranged in rows or in Indian file pattern (400X).

Management

Management of invasive lobular carcinoma of breast depends on stage with treatment similar to that with invasive ductal carcinoma. These patients respond well to tamoxifen, aromatase inhibitors and Herceptin.

INVASIVE DUCTAL CARCINOMA (NOS) OF BREAST

Invasive ductal carcinoma (not otherwise specified) is commonest type of breast carcinoma. Most invasive ductal carcinomas may evoke a dense fibroblastic response (proliferation of fibroblasts producing collagen fibers) in the host tissue that adds to the lesion's bulk.

Tumor replaces normal breast adipose tissue. Prognosis is stage dependent. Tumor has firm to hard in consistency (schirrhous), and chalky white discoloration due to desmoplasia. Nipple retraction due to desmoplasia in an underlying advanced disease is a late feature of invasive ductal carcinoma of breast.

Clinical Features

Patient with invasive ductal carcinoma (NOS) of breast presents with poorly defined solitary, nontender breast lump of variable consistency and mobility with nipple retraction. Tumor is solid or hard, dense and fixed to the underlying tissues or skin due to invasion of breast carcinoma.

Nipple Retraction

A recent nipple retraction suggests breast carcinoma, which causes fibrosis of the whole duct system and pulls

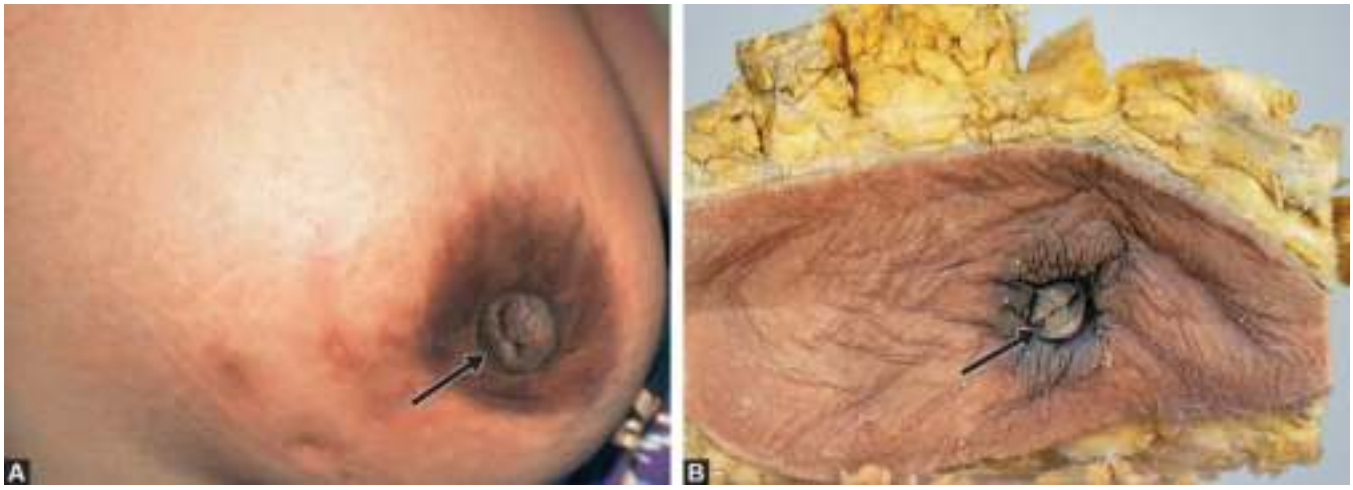

Fig. 25.36: Breast carcinoma. (A) Photograph shows a tumor that has caused nipple retraction (arrow), (B) mastectomy specimen shows nipple retraction (arrow). (*Courtesy*: Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

in the nipple, known as retraction of the nipple. Fibrosis also contracts the suspensory ligament, that pulls the nipple inward is known as dimpling (also called a skin tether) (Fig. 25.36A and B).

Overlying Skin

The '**peau d'orange**' (skin edema) appearance of the breast skin occurs due to obstruction of the dermal lymphatics by breast carcinoma cells (Fig. 25.37).

Surgical Pathology: Invasive Ductal Carcinoma (NOS) of Breast

Gross Morphology

- Tumor is firm to hard, irregular, and fibrous extension into the adjacent breast stroma that create stellate (crab-like) outline measuring 1–4 cm (rarely 4–5 cm).
- Cut section reveals gray chalky white tissue yellow crab-like satellites extending into the yellow fat tissue.
- Skin surface may show retraction of nipple (Fig. 25.38A and B).

Light Microscopy

- Tumor is composed of poorly differentiated pleomorphic neoplastic cells with hyperchromatic nuclei and abundant mitoses.
- Tumor cells are arranged in irregular nests and cords or glandular structures within a dense fibrous stroma.
- Tumor cells invading lymphatic channels, blood vessels and perineural spaces may be seen.
- Microcalcifications may be demonstrated.

Immunohistochemistry Technique

Panel of markers is used on paraffin-embedded tissue sections for invasive ductal carcinoma, which include ER/PR, gross cystic disease fluid protein 15 (GCDFP-15), mammaglobin, HER2/neu, CK7, Ki-67, p53, E-cadherin and N-BRI mentioned below. E-cadherin is expressed by invasive ductal carcinoma. E-cadherin expression is absent in lobular carcinoma of breast.

Markers	Expression
▪ ER/PR	▪ Positive (60–75%)
▪ GCDFP-15	▪ Positive (50%)
▪ Mammaglobin	▪ Positive (50%)
▪ HER2/neu	▪ Positive (10–30%)
▪ CK7	▪ Positive
▪ Ki-67	▪ Positive
▪ p53	▪ Positive
▪ E-cadherin	▪ Positive
▪ NYBRI	▪ Positive (specific in undifferentiated carcinoma)

E-cadherin expression is positive in invasive ductal carcinoma but absent in lobular carcinoma.

Molecular Pathways of Breast Carcinoma

The current molecular classification divides breast carcinoma into five groups as luminal A, luminal B, HER2/neu, basal-like and normal breast-like. The three

Fig. 25.37: Breast carcinoma—peau d'orange appearance and nipple retraction. Peau d' orange appearance occurs due to obstruction of dermal lymphatics by tumor cells.

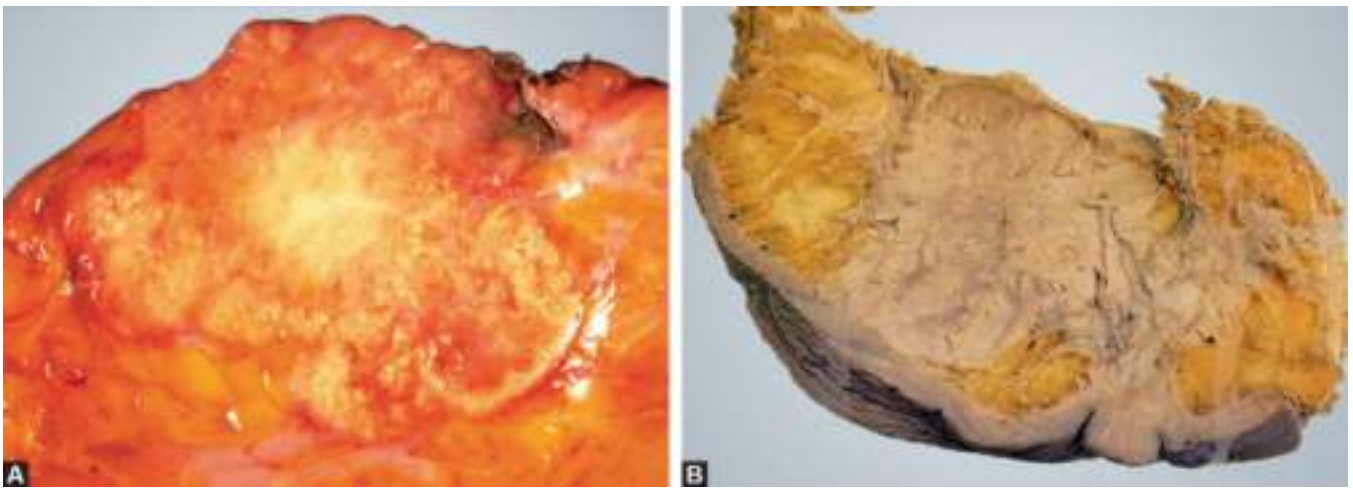

Fig. 25.38A and B: Invasive ductal carcinoma of breast. Cut surface shows gray white tumor with infiltrating margins.

main subtypes of breast carcinoma are: (a) hormone receptor positive breast carcinoma, (b) HER2/neu positive breast carcinoma and (c) triple negative breast carcinoma.

- **Luminal type A breast carcinoma:** It is low-grade breast carcinoma seen in <50% of cases. It shows low proliferative rate (Ki-67 ≤10%). Recurrence rate is low. Prognosis is good.
- **Luminal type B breast carcinoma:** It is relatively high-grade breast carcinoma seen in <15% of cases. It has higher proliferative rate (Ki-67 ≥30%) than luminal A type. Recurrence is high. Prognosis may not be as good as in luminal type A breast carcinoma.
- **HER2/neu enrich breast carcinoma:** It is high-grade breast carcinoma with high proliferative rate Ki-67 seen in <20% of cases. It most often shows involvement of axillary lymph nodes. These patients respond to Herceptin- and anthracycline-based chemotherapeutic agents.
- **Basal-like breast carcinoma:** It is high-grade variant of invasive ductal carcinoma with high proliferative rate with positive lymph nodes. Recurrence rate is high. TP53 gene mutation is very common. It shows dysfunction of BRCA1 gene. Ki-67 is expressed in <14% of cases. On immunohistochemistry, it is triple negative, i.e. ER, PR and HER2/neu negative. These patients do not respond to endocrine therapy (tamoxifen), aromatase inhibitors and Herceptin. Prognosis is poor. Trials are going onto treat these patients with platinum-based chemotherapy or poly ADP-ribose polymerase (PARP) inhibitors.
- **Normal breast-like breast carcinoma:** As it lacks expression of ER, PR and HER2/neu and can also be classified as triple negative but it is not considered to be basal-like breast carcinoma as it is negative for CK5 and EGFR. There are few studies on this subtype and its clinical significance remains undetermined.

Prognostic Implications

Tumor grade, DNA content and proliferative index, and presence of ERBB2 (HER2/neu) amplification also have prognostic implications.

Metastases

Tumor spreads to axillary lymph nodes via lymphatic route and then to lungs, liver and bones via hematogenous route.

Management

Management of invasive ductal carcinoma (NOS) of breast depends on tumor size, grade, metastases status to lymph nodes or distant organs, estrogen and progesterone receptor status. The patients are managed by surgery, irradiation, chemotherapy or tamoxifen or Herceptin.

PAGET'S DISEASE OF BREAST

Paget's disease of breast shows intraepidermal carcinoma cells in overlying epidermis of nipple and areola derived from an intraductal breast carcinoma. Patient presents with eczematous lesion with crusted, eroded surface over nipple and areola. Malignant cells in epidermis are known as '**Paget's cells**'. The tumor is most often poorly circumscribed. Paget's disease of breast is more frequently found in older women (Fig. 25.39A and B). Paget disease of breast is treated by radical mastectomy.

Etiopathogenesis

The synthesis of heregulin-α by keratinocytes, acts via the HER2/neu receptor, may play a role in its pathogenesis of Paget's disease of breast.

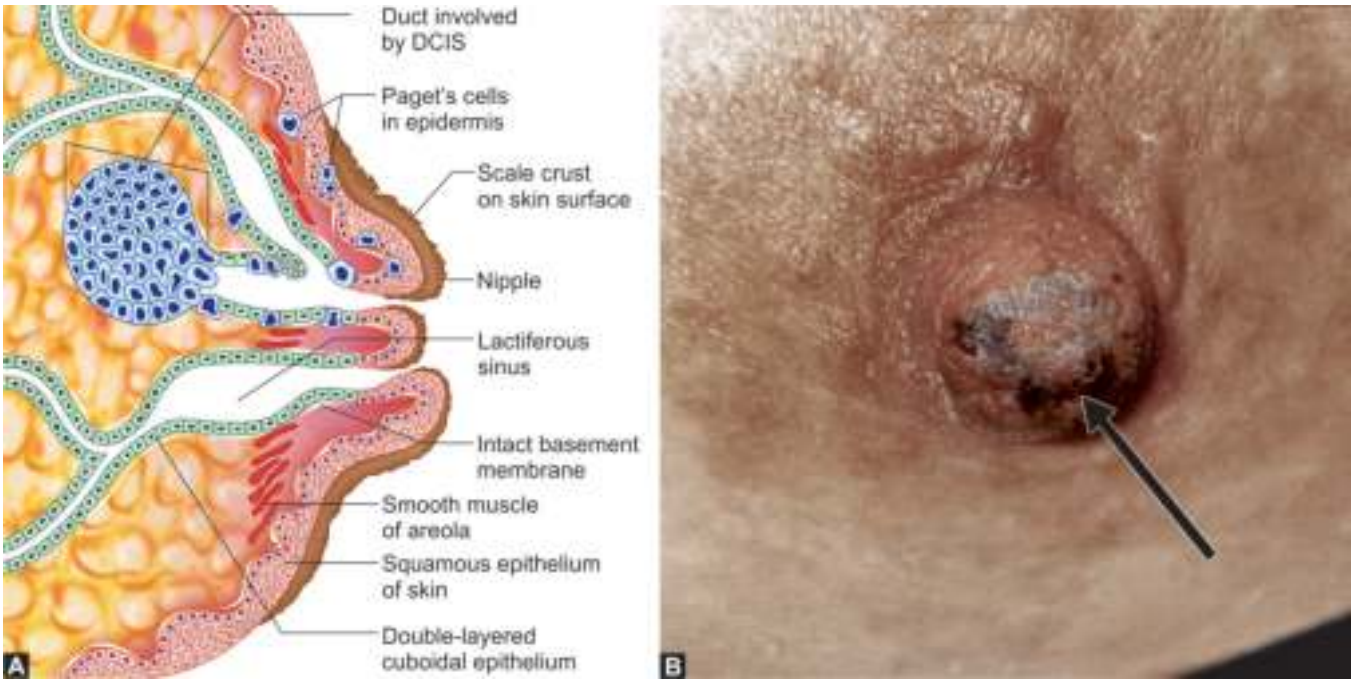

Fig. 25.39: Paget's disease of breast. (A) Structure of the adult female breast shows Paget's disease of the breast. Malignant cells infiltrating overlying epidermis are known as Paget's cells, (B) eczematous lesion with crusted, eroded surface over nipple and areola (arrow).

Molecular Genetic Alterations

Amplification of ERBB2 (HER2/neu) gene is observed in Paget's disease of breast, which encodes an epithelial growth factor receptor (EGFR) on the cell membrane that delivers continuous mitogenic signals to the cell resulting in breast carcinoma, i.e. Paget's disease of breast, even in the absence of growth factor in the environment. HER2/neu is demonstrated by monoclonal antibody on the cell membrane by using fluorescent *in situ* hybridization (FISH) technique.

Clinical Features

Paget's disease of the breast affects the nipple from the start, whereas eczema affects the areolar region first and only rarely affects the nipple skin, which eventually leads to erosion and ulceration of the nipple in elderly women. On clinical examination, a painless mass is palpable in the underlying breast in 50% of cases, and often associated with delay in its diagnosis.

Surgical Pathology: Paget's Disease of Breast

Gross Morphology

Nipple skin in Paget's disease of breast demonstrates scaling crust erythema and exudate resembling eczema. Nipple may show ulceration.

Light Microscopy

- Histologic examination of Paget's disease of breast reveals either *in situ* or invasive ductal carcinoma, which involves overlying epidermis of nipple and areola. The tumor cells in the overlying epidermis are called Paget's cells.
- Paget's cells within the surface epithelium of the nipple and areola are large neoplastic cells with abundant clear cytoplasm and large nuclei with prominent nucleoli, arranged singly or in clusters; represent intraepithelial extension of an underlying ductal carcinoma *in situ* or invasive ductal carcinoma (Fig. 25.40).

Histochemistry

Periodic acid–Schiff (PAS) stain demonstrates mucin within the Paget's cells of Paget's disease of the breast. This is evidence for their origin from an underlying ductal carcinoma.

Immunohistochemistry Technique

By immunohistochemical staining, Paget cells will also be cytokeratin (low molecular weight), HMB-45, CAM 5.2, and epithelial membrane antigen (EMA) positive.

Markers	Expression
▪ Cytokeratin (low MW)	▪ Positive
▪ HMB-45	▪ Positive
▪ CAM 5.2	▪ Positive
▪ Epithelial membrane antigen (EMA)	▪ Positive

Mammography

If Paget's disease of breast is suspected on clinical examination, mammography should be performed to determine if there is an underlying tumor.

Diagnosis

Diagnosis of Paget's disease of breast is established by cytology (e.g. smears from imprint and scrapping) or wedge biopsy of nipple.

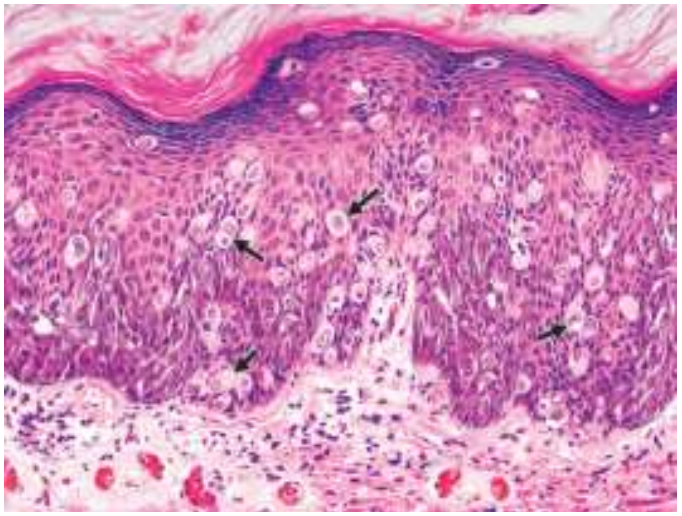

Fig. 25.40: Paget's disease of breast. The tumor cells in the overlying epidermis are called Paget's cells. These are large cells with abundant clear cytoplasm and large nuclei with prominent nucleoli, arranged singly or in clusters; represent intraepithelial extension of an underlying ductal carcinoma *in situ* or invasive ductal carcinoma (arrows) (400X).

Pathology Pearls: Toker Cells Versus Paget Cells in Differential Diagnosis

- Toker cells are epithelial cells with clear cytoplasm most often free of cytologic atypia localized within the nipple epidermis.
- Toker cells normally occur in small number within the nipple epidermis.
- Rarely, Toker cells can be so numerous and atypical as to require a careful distinction from malignant cells of Paget's disease of breast.
- Phenotype markers can be helpful in differential diagnosis.
- On immunohistochemical analysis, Toker cells show positivity for CK7 and ERBB2, while negativity for CD138 and p63.

INFLAMMATORY CARCINOMA OF BREAST

Inflammatory carcinoma of breast shows diffuse erythema and edema (peau d'orange) of the breast skin.

- Rapidly growing breast carcinoma metastasizing in the dermal lymphatic channels results in thickened, erythematous (red), rough, swollen, hot skin as a consequence of inflammatory process.
- Edema (peau d'orange) usually begins in the skin around and beneath the areola, the most dependent area of breast (Fig. 25.41).
- Prognosis is poor in inflammatory breast carcinoma. Patient is treated by chemotherapy followed by surgery and irradiation.

MEDULLARY CARCINOMA OF BREAST

Medullary carcinoma is uncommon breast carcinoma affecting young females. Patient presents with fleshy, bulky tumor measuring 5–10 cm in diameter. It is basal-like subtype of breast carcinoma. It has high proliferative rate with positive lymph nodes. Recurrence rate is high in these patients.

Fig. 25.41: Mastectomy specimen in a case of breast carcinoma. It shows inflammatory carcinoma of breast (arrow).

Molecular Genetic Alterations

BRCA1 gene mutations are observed in some cases. TP53 gene mutation is very common. Ki-67 is expressed in <14% of cases. Amplification of ERBB2 (HER2/neu) is not seen.

Surgical Pathology: Medullary Carcinoma of Breast

Gross Morphology

- The tumor is well circumscribed, with a soft, fleshy and uniform consistency with rounded pushing margins.
- There is no evidence of a fibrous reaction. It most often measures between 1 and 4 cm in diameter.

Light Microscopy

Medullary carcinoma of breast has following diagnostic features based on histology and gross morphology (Fig. 25.42):

- Tumor comprises pleomorphic atypical cells arranged in interconnecting sheets, forming a syncytial network. Cells contain hyperchromatic nuclei with scant to moderate cytoplasm arranged in sheets forming '**syncytial network**'. It shows large bizarre nuclei with high mitotic count.
- The intervening stroma is scant. There is presence of lymphocytes and plasma cells (immune response) around tumor cell groups (and not between individual tumor cells). Foci of necrosis and hemorrhage may be found.

Immunohistochemistry Technique

Medullary carcinoma of breast is triple negative for ER, PR and HER2/neu by immunohistochemistry technique.

Markers	Expression
▪ Estrogen receptor (ER) ▪ Progesterone receptor (PR) ▪ HER2/neu	▪ Negative ▪ Negative ▪ Negative

Treatment

Patients do not respond to tamoxifen, aromatase inhibitors and Herceptin. Trials are going onto treat these patients with platinum-based chemotherapy or PARP inhibitors.

Prognosis

Medullary carcinoma of breast has much better prognosis than usual invasive ductal carcinoma even with lymph node metastases. Approximately 70% of patients have overall 10-year survival.

COLLOID (MUCINOUS) CARCINOMA OF BREAST

Colloid (mucinous) carcinoma of breast is a special type of invasive ductal carcinoma (not otherwise specified). In fact, focal mucin production is quite common in invasive ductal carcinoma (NOS). The mucinous component must comprise >90% of the tumor for diagnosis of colloid carcinoma is made. Colloid carcinoma accounts for 1–4% of breast carcinomas, which features abundant extracellular mucin production and is associated with a favorable prognosis.

Molecular Genetic Alterations

BRCA1 gene mutation is demonstrated in some cases. Amplification of ERBB2 (HER2/neu) is seen in some cases.

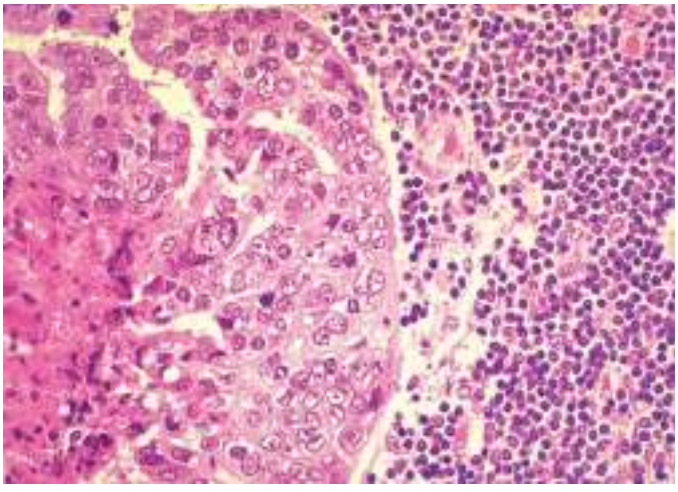

Fig. 25.42: Medullary carcinoma of breast. Carcinoma with medullary features shows a rounded margin and an intense lymphocytic infiltrate at the periphery. The tumor cells form a sheet-like pattern with high degree of nuclear pleomorphism and brisk mitotic activity (400X).

Clinical Features

Colloid carcinoma of breast is uncommon slow-growing neoplasm primarily seen in elderly women as a small well circumscribed mass.

Surgical Pathology: Colloid Carcinoma of Breast
Gross Morphology
▪ Tumor is well circumscribed tumor with soft consistency measuring 1–5 cm in diameter with an average of 2.8 cm. ▪ Cut surface of tumor is completely replaced by glistening gelatinous blue to gray-colored mucoid material (Fig. 25.43).
Light Microscopy
▪ Tumor is composed of small islands or clusters of generally uniform, round epithelial cells (10–20 cells) arranged in trabeculae, nests, sheets or acini with glandular lumen, floating within extensive lakes of extracellular mucin pool synthesized by tumor cells. ▪ Mucin dissects into the surrounding stroma. Tumor contains >90% of mucinous component (Fig. 25.44).
Immunohistochemistry Technique
Most tumors express hormone ER (estrogen receptors) in 80% of cases.

Prognosis

Colloid carcinoma of breast is low-grade malignant tumor with low incidence of metastases. It has better prognosis than conventional invasive ductal carcinoma of breast.

TUBULAR CARCINOMA OF BREAST

Tubular carcinoma of breast accounts for 1–4% of invasive breast carcinomas. A higher frequency (up to 19%) has been reported in small and screen-detected breast carcinomas in whites compared with blacks. It affects younger age at onset (40s). It is luminal type A

Fig. 25.43: Colloid carcinoma of the breast. This sagittal slice of the breast shows that it is completely replaced by mucoid tumor.

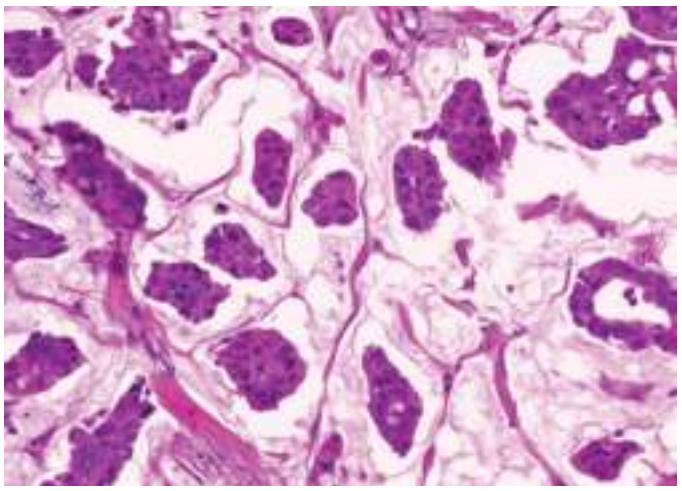

Fig. 25.44: Mucinous/colloid carcinoma of breast. Mucinous carcinoma shows large sheets of low-grade malignant cells present within pools of accumulated extracellular mucinous material (400X).

low-grade invasive ductal cell carcinoma. It shows low proliferative rate. Recurrence rate is low after surgical excision of tumor.

Molecular Genetic Alterations

Amplification of ERBB2 (HER2/neu) is unusual in tubular carcinoma of breast.

Clinical Features

Patient with tubular carcinoma of breast presents with breast lump measuring 2 mm to 1.5 cm in diameter. Most are 1 cm or less, but rarely 2 cm or above is encountered.

Surgical Pathology: Tubular Carcinoma of Breast

Gross Morphology

- The tumor is usually small (<2 cm), firm to hard in consistency, and often detected on mammography.
- There is increased incidence of tubular carcinoma in opposite breast in 10–40% of cases.

Light Microscopy

- Diagnosis of tubular carcinoma of breast is made when 75% of neoplasm shows well-formed small duct structures embedded in cellular stroma.
- Tumor shows bland-looking tumor cells arranged in tubules that possess widely patent lumens lined by low-grade single cell layer.
- Myoepithelial cells are absent, and the malignant tubules are arranged in an irregular stellate pattern.
- The intervening stroma is densely fibrotic. Mitoses are rare.
- Tubular carcinoma may be difficult to defferentiate from sclerosing adenosis or radial scar but generally spread outside the confines of enlarged lobules (Fig. 25.45).
- Distinguishing features of tubular carcinoma, sclerosing adenosis and microglandular adenosis of breast are given in Table 25.18.

Immunohistochemistry Technique

Virtually all tubular carcinomas express ER and PR hormone receptors and **cytokeratin (8;18).**

Markers	Expression
▪ Estrogen (ER)	▪ Positive
▪ Progesterone (PR)	▪ Positive
▪ Cytokeratin (8;18)	▪ Positive

Treatment

Patient presents tubular carcinoma of breast responds to tamoxifen, aromatase inhibitors and Herceptin.

Prognosis

Prognosis of tubular carcinoma of breast is better despite multifocal nature and bilateral involvement. Lymph node metastases are rare.

PAPILLARY CARCINOMA OF BREAST

Papillary carcinoma of breast is a rare subtype of invasive ductal carcinoma (IDC).

- Papillary carcinoma of breast comprises 0.5–0.7% of all invasive breast carcinomas. Tumor has infiltrative papillary growth in women in their sixth to eighth decades of life.
- Approximately 50% of women present with breast lump beneath nipple and bloody nipple discharge.
- Tumors should be graded according to the Nottingham grading system.
- Tumors should be staged according to their pathologic size and lymph node status.
- Poor prognostic factors include old age, advanced pathologic stage and patients without radiation.

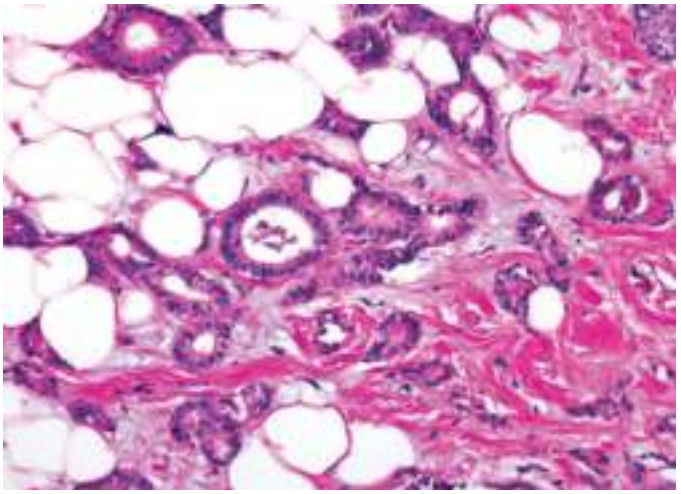

Fig. 25.45: Tubular carcinoma of breast. Tumor is composed of bland-looking tumor cells arranged in tubules that possess widely patent lumens. Myoepithelial cells are absent, and the malignant tubules are arranged in an irregular stellate pattern. The intervening stroma is densely fibrotic (400X).

Table 25.18 Distinguishing features of tubular carcinoma, sclerosing adenosis and microglandular adenosis of breast

Features	Tubular Carcinoma	Sclerosing Adenosis	Microglandular Adenosis
Shape of the lesion	Stellate, irregular	Lobular, round	Irregular
Shape of the glands	Angulated	Round to oval	Round
Luminal contents	Sometimes	Rarely	Frequent 'colloid'
Cell layers	One layer of epithelial cell	Two layers composed of epithelial and myoepithelial components	One layer of epithelial cells
Cell luminal surface	Snouting	Occasional snouting	Smooth
Cytoplasm	Eosinophilic	Inconspicuous	Clear
Stroma	Desmoplastic	Around lobules	Dense collagenous
Basement membrane	Usually none	Present	Prominent

Surgical Pathology: Papillary Carcinoma of Breast

Gross Morphology

- The tumor is usually 2–3 cm in size, and well-circumscribed.
- Cystic tumor contains brown mixture of blood clot and neoplastic tissue.

Light Microscopy

- The tumor is composed of delicate fibrovascular tissue lined by atypical epithelial cells with hyperchromatic nuclei and mitoses forming papillary structures with the absence of an outer myoepithelial cell layer.
- It must be differentiated from intraductal papilloma that is characterized by thick fibrovascular tissue and presence of myoepithelial cells.
- Periphery of the cystic tumor is fibrotic and distinguishing invasion may be difficult unless neoplasm reaches the adipose tissue (Fig. 25.46).

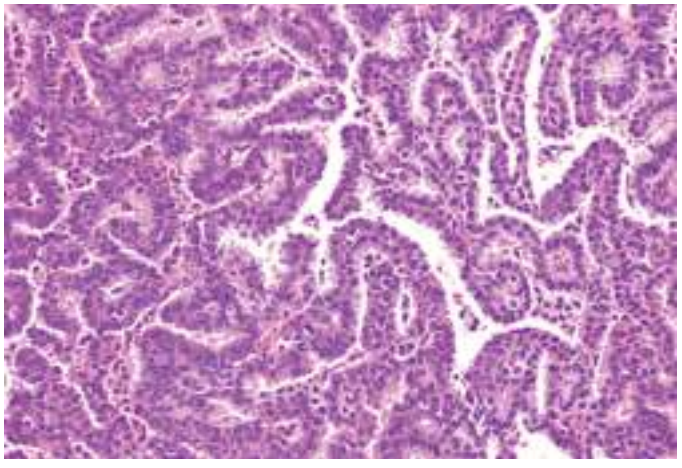

Fig. 25.46: Invasive papillary carcinoma breast. It is comprised of delicate fibrovascular tissue lined by atypical epithelial cells with hyperchromatic nuclei and mitoses forming papillary structures with the absence of an outer myoepithelial cell layer (400X).

INVASIVE MICROPAPILLARY CARCINOMA OF BREAST

Invasive micropapillary carcinoma of breast is luminal type B invasive breast carcinoma, which accounts for seen in <20% of cases. It has higher proliferative rate than luminal type A. Recurrence of tumor after surgery is high. Hormone receptor negativity may explain the more aggressive behavior of invasive micropapillary carcinoma. It should be differentiated from duct papilloma of breast (Table 25.19).

Surgical Pathology: Invasive Micropapillary Carcinoma of Breast

Gross Morphology

- Tumor has no specific gross features.
- Tumor with 75% of micropapillary growth tends to be large (mean 6 cm).
- Tumor has lobulated outline.

Light Microscopy

Invasive micropapillary carcinoma shows rounded groups of tumor cells with a peripheral clear rim and lacks true fibrovascular core (Fig. 25.47).

Immunohistochemistry Technique

Tumor cells may show low expression of ER and PR. Immunohistochemistry shows cytokeratin positivity (8;18).

Markers	Expression
▪ Estrogen receptor (ER)	▪ Negative or low expression
▪ Progesterone receptor (PR)	▪ Negative or low expression
▪ Cytokeratins (8;18)	▪ Positive

Prognosis

Invasive micropapillary carcinoma of breast has aggressive behavior. Prognosis may not be as good as in luminal A breast carcinoma.

Table 25.19 Comparison of intraductal papilloma and noninvasive ductal papillary carcinoma of breast

Parameters	Ductal Papilloma	Noninvasive Ductal Papillary Carcinoma
Cell morphology	Benign cells with normal nuclear chromatin	Atypical cells with hyperchromatic nuclei
Myoepithelial cells	Present	Absent
Apocrine changes	Present	Absent
Surrounding stroma	Thick prominent stroma	Delicate stroma
Sclerosing adenosis	Unusual	Usual

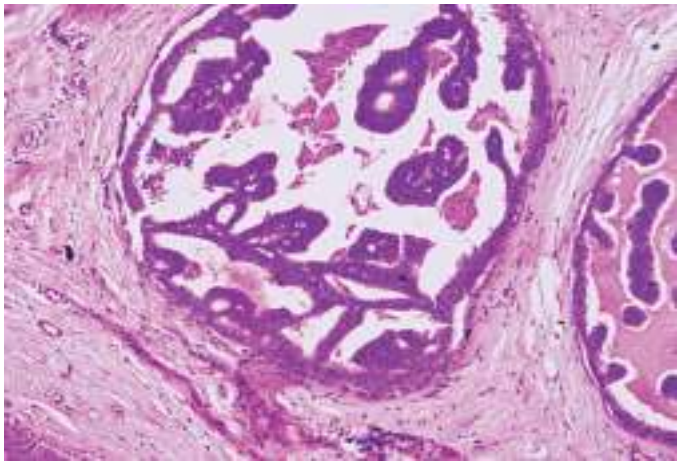

Fig. 25.47: Micropapillary carcinoma of breast. It shows large duct with micropapillary tufts of epithelial cells lacking true fibrovascular core (400X).

Pathology Pearls: Papillary Lesions of Breast

- Papillomas (single or multiple)
- Papilloma with atypical ductal hyperplasia or ductal carcinoma *in situ*
- Solid papillary carcinoma
- Encapsulated papillary carcinoma
- Invasive papillary carcinoma
- Papillomatosis

METAPLASTIC CARCINOMA OF BREAST

Metaplastic carcinoma of the breast is a form of breast carcinoma that shows differentiation towards malignant squamous epithelium, cartilaginous, or bony tissue. This term is used to describe a heterogeneous group of neoplasms. It is also known as carcinosarcoma. It is basal-like subtype of breast carcinoma. It has high proliferative rate with positive lymph nodes. Recurrence rate is high.

Molecular Genetic Alterations

TP53 gene mutation is very common in metaplastic carcinoma of breast. It shows dysfunction of BRCA1 gene. **Ki-67** is expressed in <14% of cases.

Treatment

Patients with metaplastic carcinoma of breast do not respond to tamoxifen, aromatase inhibitors and Herceptin. Trials are going onto treat these patients with platinum-based chemotherapy or poly-ADP ribose polymerase (PARP) inhibitors. PARPs play an important role in various cellular processes such as modulation of chromatin structure, transcription, replication, recombination and DNA repair.

Surgical Pathology: Metaplastic Carcinoma of Breast

Gross Morphology

Metaplastic carcinoma of breast varies in size, i.e. ≤2 cm (31%), 2–5 cm (50%) and ≥5 cm (19%). Cut surface shows variable consistency.

Light Microscopy

- Metaplastic carcinoma of breast has monophasic or biphasic sarcomatoid carcinoma variants.
- Tumor is admixture of malignant epithelial component (adenocarcinoma grade 2 or 3) with malignant mesenchymal elements including cartilage, bone, and myxoid stroma, and/or squamous or spindle cell elements (Figs 25.48 and 25.49).

Immunohistochemistry Technique

Metaplastic carcinoma of breast is '**triple negative**' for ER, PR and HER2/neu. Neoplastic cells show positivity for cytokeratins and vimentin. Spindle cell component is positive for vimentin. Neoplastic cells show positivity for CK903 (HMWCK), p53, CAM 5.2 (most reliable marker), CK7 (most reliable marker) and AE1/AE3 (variable expression).

Markers	Expression
CK903 (HMWCK)	Positive
p53	Positive
CAM 5.2 (most reliable marker)	Positive
CK7 (most reliable marker)	Positive
AE1/AE3 (variable expression)	Positive
ER (estrogen receptor)	Negative
PR (progesterone receptor)	Negative
HER2/neu	Negative

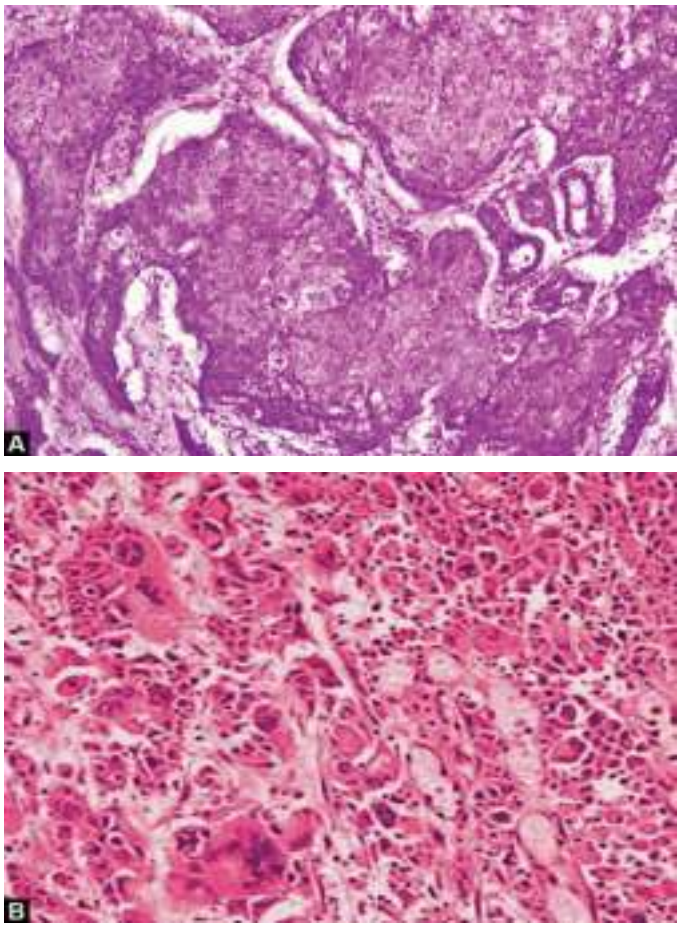

Fig. 25.48: Metaplastic carcinoma of breast with squamous differentiation. (A) Tumor shows mixed squamous cell carcinoma and ductal carcinoma components, (B) the intervening areas show malignant spindle cell proliferation. It is high-grade breast carcinoma with poor prognosis (400X).

APOCRINE CARCINOMA OF BREAST

Apocrine carcinoma of breast consists of tumor cells with apocrine morphology in >90% of neoplastic cells.

Surgical Pathology: Apocrine Carcinoma of Breast
Gross Morphology
▪ Apocrine carcinoma of breast is indistinguishable from invasive ductal carcinoma. ▪ Tumor is often multicentric in breast.
Light Microscopy
Tumor is composed of large cells with well-defined cellular outlines, vesicular nuclei, prominent nucleoli, abundant granular cytoplasm and foci of necrosis (Fig. 25.50).
Electron Microscopy
Tumor contains prominent mitochondria with abnormal cisternae, large membrane bound vesicles and dense cores.

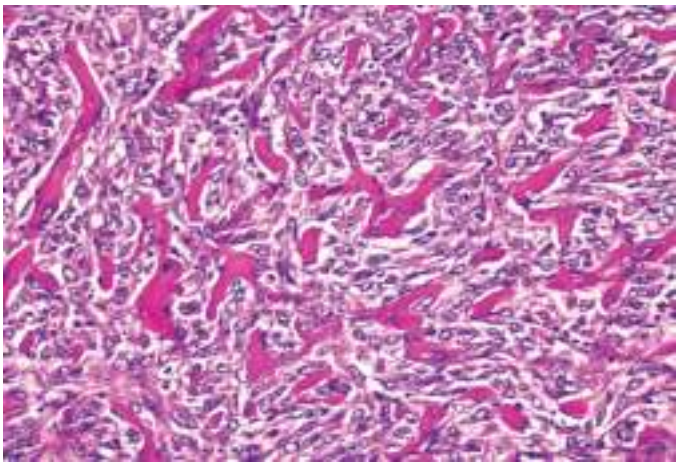

Fig. 25.49A: Metaplastic carcinoma of breast. Tumor is composed of heterogenous malignant mesenchymal components such as osseous element and spindle cells (400X).

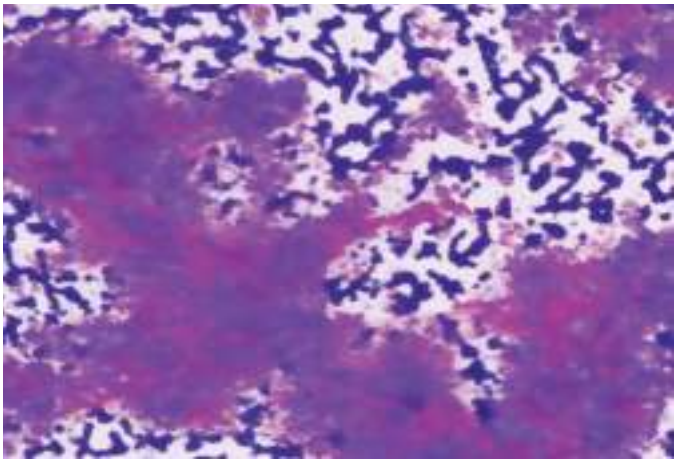

Fig. 25.49B: Breast metaplastic carcinoma with osseous metaplasia. Metaplasia in mammary ductal epithelium and carcinoma is a well-known phenomenon. There seems to be morphological overlap between various components. Smears prepared from fine needle aspiration cytology of breast lump revealed malignant cells and matrix producing metaplastic component. Mastectomy was performed and metaplastic carcinoma of breast with osseous metaplasia (400X).

Prognosis

Apocrine carcinoma of breast has similar prognosis that of infiltrating duct carcinoma (NOS) of similar grade.

SECRETORY CARCINOMA OF BREAST

Originally, secretory carcinoma was named juvenile breast carcinoma. Terminology was changed to secretory carcinoma after the reports of the tumor occurring in the adults of both sexes.

- Tumor size, rates of axillary lymph nodes involvement, stage at presentation, pattern of surgical therapy are similar to invasive ductal carcinoma of breast.
- Tumor is often located in the central region near the areola.

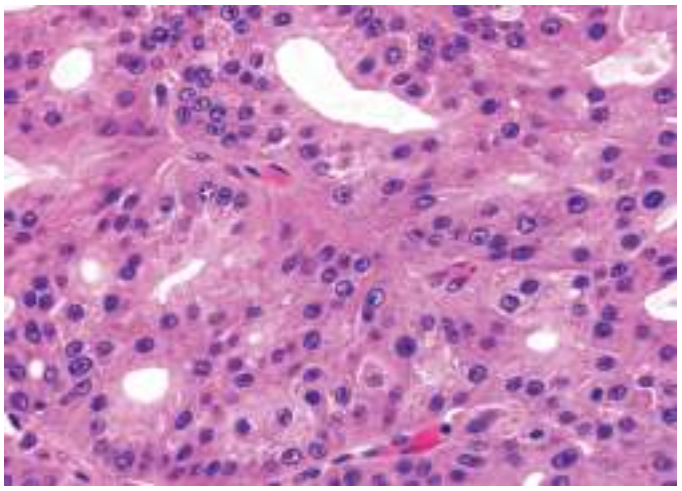

Fig. 25.50: Apocrine breast carcinoma is composed of large cells with well-defined cellular outlines, vesicular nuclei, prominent nucleoli, abundant granular cytoplasm and foci of necrosis (400X).

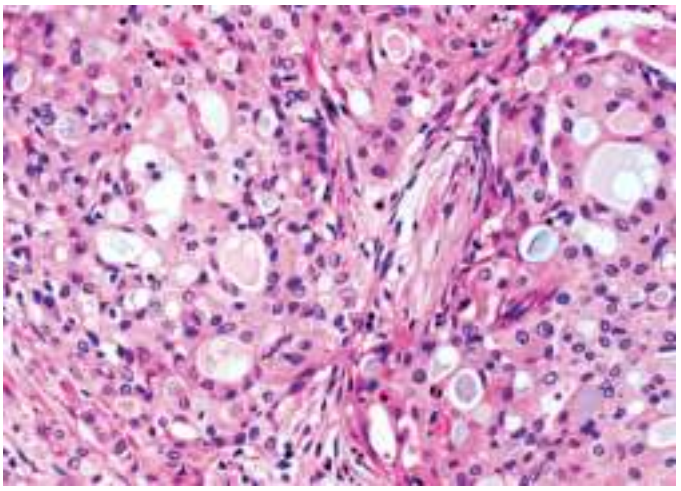

Fig. 25.51: Secretory carcinoma of breast. It mimics lactating breast by forming multiple dilated spaces filled with amorphous eosinophilic secretions. The cystic spaces are lined by cuboidal epithelium with clear or pale cytoplasm (400X).

Clinical Course

Patient with secretory carcinoma of breast has indolent clinical course and excellent prognosis. Five-year survival rate is seen in 87% of cases.

Surgical Pathology: Secretory Carcinoma of Breast

Gross Morphology

- Tumor is small with median size 1.9–2.36 cm, and well circumscribed.
- Tumor is located in the central region near the areola having pushing border but may be infiltrative at periphery.

Light Microscopy

On histologic examination, secretory carcinoma mimics lactating breast.

- Architecture of tumor is most often microcystic, solid or tubular or mixture or all three patterns.
- Tumor cells show low-grade cytologic atypia bland uniform nuclei and low mitotic rate.
- Histologic hallmark of secretory carcinoma of breast is the presence of tumor cells with vacuolated foamy cytoplasm and abundant intracellular and extracellular secretions, which are positive with periodic acid–Schiff (PAS) and diastase resistant (Fig. 25.51).

Histochemistry

Presence of intracellular and extracellular secretions in secretory carcinoma are demonstrated by periodic acid–Schiff (PAS) diastase resistant.

Immunohistochemistry Technique

Tumor cells do not express ER and HER2/neu.

Markers	Expression
▪ Estrogen receptors (ER)	▪ Negative
▪ HER2/neu	▪ Negative
▪ S-100	▪ Positive

Treatment

Surgical treatment of secretory carcinoma of breast and use of antihormonal target therapy are similar to invasive ductal carcinoma.

CRIBRIFORM CARCINOMA OF BREAST

Cribriform carcinoma of breast is luminal A low-grade invasive ductal carcinoma, which shows low proliferative rate. Recurrence rate is low after surgery. These patients respond to endocrine therapy (tamoxifen, aromatase inhibitors and Herceptin). Prognosis is excellent even with nodal metastasis.

Surgical Pathology: Cribriform Carcinoma of Breast

Light Microscopy

- Cribriform carcinoma of breast is a low-grade tumor with cribriform appearance (well-defined spaces formed by arches of cells) similar to ductal carcinoma *in situ* (DCIS) but with large cells, more vesicular nuclei.
- Tumor cells are small, which often have apical snouts, mild/moderate nuclear pleomorphism, which invade stroma.
- Tumor may have predominantly solid appearance.
- It is worth mentioning that pure cribriform pattern is defined as 90% of tumor cribriform appearance. It is also considered 'classic' even if minor component of tubular carcinoma of breast is also present.

Immunohistochemistry Technique

Immunohistochemistry technique shows tumor cells positivity for ER, PR and cytokeratin (8;18).

Markers	Expression
▪ Estrogen receptor (ER)	▪ Positive
▪ Progesterone receptor (PR)	▪ Positive
▪ Cytokeratin (8;18)	▪ Positive

CUTANEOUS ANGIOSARCOMA OF BREAST

Stewart Treves syndrome is also known as cutaneous angiosarcoma, which occurs in long-standing lymphedema.

- Radical mastectomy is performed for treatment of angiosarcoma of breast. Women develop gross lymphedema of the arm, which is a usual consequence of radical mastectomy.
- Occasionally, angiosarcomas arise in the skin and subcutaneous tissue of the grossly edematous arms some years after the surgery.

Surgical Pathology: Cutaneous Angiosarcoma of Breast

Gross Morphology

Angiosarcoma of the breast is seen as a reddish, cavitated hemorrhagic tumor within the subcutaneous mammary tissue.

Light Microscopy

Histologic grades of angiosarcoma of female breast described as under:

- **Low-grade angiosarcoma:** Tumor is composed of predominant freely anastomosing channels. Papillary growth and endothelial tufting is minimal.
- **Intermediate grade angiosarcoma:** Tumor is composed of freely anastomosing vascular channels. Papillary growth and endothelial tufting are present. It may show focal solid areas composed of polygonal and spindle cells.
- **High-grade angiosarcoma:** Tumor is composed of polygonal and spindle cells. Blood lakes and necrosis are common. Vascular channels may be difficult to identify.

Diagnostic features of major histologic types of invasive breast carcinoma are given in Table 25.20.

BREAST CARCINOMA: MODE OF SPREAD, PROGNOSTIC AND PREDICTIVE FACTORS

BREAST CARCINOMA: ROUTES OF METASTASIS

Most breast carcinomas arise from lining epithelium of ducts, which becomes invasive and metastasizes early to axillary lymph nodes, lungs, liver, bones, brain, adrenal glands and ovaries.

Women presenting with an isolated enlarged axillary node must be taken seriously because 33–50% will have occult breast carcinoma. Mode of spread of breast carcinoma by various routes is described as under.

Table 25.20 Diagnostic features of major histologic types of invasive breast carcinoma

Histologic Type	Incidence (%)	Clinical/Gross Findings	Light Microscopy	Prognosis	Typical Biomarkers
Invasive ductal carcinoma, NOS (not otherwise specified)	70–75	Speculated mass, variable	Variable, devoid of special type of histologic features	Variable	Variable
Invasive lobular carcinoma	5–15	Architectural distortion, density (no distinct mass), multifocal/bilateral	Uniform cells, eccentric nuclei, intracytoplasmic lumina, Indian filing, targetoid pattern	Unfavorable	▪ ER (+), PR (+) ▪ HER2/neu (–)
Tubular carcinoma	5	Speculated mass, small size	Angulated tubules with tapered ends, open lumina, dense stroma	Favorable	▪ ER (+), PR (+) ▪ HER2/neu (–)
Mucinous or colloid carcinoma	2–3	Well-circumscribed lobulated mass, gelatinous cut surface	Tumor cells floating in pools of extracellular mucin	Favorable	▪ ER (+), PR (+) ▪ HER2/neu (–)
Medullary carcinoma	1–2	Young women, well-circumscribed mass, no calcifications	Syncytial growth, pushing borders, infiltrated by lymphocytes and plasma cells, high nuclear grade	Favorable (if pure)	Triple negative: ER (–), PR (–) HER2/neu (–); (triple negative)
Micropapillary carcinoma	1–2	Similar to IDC, not otherwise specified (NOS)	Tumor clusters within empty spaces, reverse polarity, no fibrovascular cores	Higher rate of LN metastasis	Variable
Metaplastic carcinoma	<1	Large tumor	Tumor transformation to squamous or mesenchymal (bone, cartilage) elements	Lower LN metastasis; prognosis is very poor	Triple negative: ER (–), PR (–), HER2/neu (–) ER and PR can be positive in glandular elements, coexpression of cytokeratins (5, 6) and vimentin

Local Tumor Invasion Route of Metastasis

Invasive breast carcinoma can infiltrate and cause fixation to adjacent structures. If the tumor is deep, fixation may occur to the pectoralis muscles. If tumor is superficial, the skin may be involved.

- Skin involvement can result in nipple retraction and inversion when the tumor arises near the central zone.
- Invasion and obstruction of small cutaneous lymphatic channels results in edema of the skin giving it the appearance of the surface of an orange peel (**peau d'orange**).
- Once skin fixation occurs, cutaneous ulceration may follow. Breast carcinoma may spread to opposite breast.

Lymphatic Route of Metastasis

Normally lymphatic drainage of breast occurs via axillary and internal mammary nodes. Approximately 75% of breast lymphatic drainage takes place in axillary lymph nodes, while rest 25% via internal mammary lymph nodes adjacent to vertebrae and skin lymphatic channels. That is the reason that occult breast carcinoma presents with isolated axillary lymphadenopathy (Fig. 25.52).

Axillary Lymphatic Drainage

- Axillary group consists of approximately 21 lymph nodes, which lie below the axillary vein. Axillary lymph nodes include anterior, apical, internal (Rotter's nodes), central and lateral lymph nodes.
- Axillary group lymph nodes are divided into three groups in relation to pectoralis minor muscle proceeding from level I (13 nodes) lateral to muscle, level II (5 nodes) behind muscle and level III (3 nodes) medial to pectoralis minor muscle. Level I and level II lymph nodes are removed in the standard axillary dissection of breast carcinoma.

Fig. 25.52: Breast carcinoma—axillary lymph nodes show metastases (arrows).

Sentinel Lymph Node Biopsy

Sentinel lymph nodes are the first group of nodes that drain lymph from the breast to the axilla.

- Sentinel lymph node is usually in level I. It is unusual for breast carcinoma to skip to higher levels of lymph nodes without involving the lower lymph nodes.
- Sentinel lymph node biopsy has been designed for axillary staging in breast carcinoma patients, who have clinically negative lymph nodes. Sentinel lymph node biopsy offers accuracy equivalent to that of axillary lymph node dissection.
- According to the American College of Breast Surgeons (ACBS), lymph node biopsy is suitable for clinically lymph node negative T1–T2 invasive ductal carcinoma of breast.
- Sentinel lymph node demonstration involves injecting radioisotope (technetium-99m sulphur colloid) alone or radioisotope plus a patent blue dye (lymphazurin blue or methylene blue) into the tissues of the breast.
- With sentinel lymph node dissection, 1–3 lymph nodes are removed and tested for nodal metastases with hematoxylin and eosin (H&E) stain and immunohistochemistry.

Lymph Node Skip Metastases

Lymph node skip metastases are seen in <5% of patients breast carcinoma associated with axillary lymph node involvement. It is due to lymphatic drainage from level II to level III under surface of pectoralis minor muscle.

Lymph Node Micrometastases

Micrometastases in lymph node were originally defined as occult metastases <0.2 cm in diameter in patient with breast carcinoma. Nowadays, micrometastasis term also includes presence of disseminated tumor cells in peripheral blood, bone marrow or lymph nodes.

Hematogenous Route of Metastasis

Metastasis occurs as a result of vascular permeation in the region of the breast carcinoma, in areas of lymph node metastases. Neoplastic cells break lymph nodal barriers, invade blood vessels in stroma and enter into systemic circulation.

- Neoplastic cells metastasize through the blood vessels to various distant organs preferentially to the **lung**,

liver and **bones**. Breast carcinoma metastasizing to bones may show either **osteolytic** or **osteoblastic lesions**.

- Patients with breast carcinoma frequently develop metastases to other multiple sites, e.g. adrenal glands, brain, pleura, gastrointestinal tract, peritoneum, skin, spleen, pericardium, ovary, kidney, uterus and heart in decreasing frequency.

Transcoelomic Route of Metastasis

Breast lobular carcinoma spreading to ovaries by transcoelomic route (retrograde lymphatic channels) in elderly women is known as 'Krukenberg tumor'. It is rapidly developing bilateral ovarian metastases from carcinoma of breast, stomach and intestine (Fig. 25.53).

Surgical Pathology: Krukenberg Tumor of Ovary

Gross Morphology

- Tumor is large, solid, lobulated, with smooth surface and freely mobile.
- Cut surface is gray white, gelatinous, areas of hemorrhage and cystic spaces.

Light Microscopy

Tumor shows sheets of malignant epithelial cells in a dense fibromyxomatous stroma.

Immunohistochemistry Technique

Positive immunostains depend on primary tumor. Gastrointestinal carcinomas are positive for CK20 and CDX2. Primary breast carcinoma is positive for GcDFP-15.

BREAST CARCINOMA: PROGNOSTIC AND PREDICTIVE FACTORS

There are a number of pathologic parameters capable of predicting prognosis and guiding new strategies or treatment of cases with breast carcinoma. Prognosis depends on molecular features or histologic type, extent of spread of breast carcinoma (stage) at the time of diagnosis.

Strong independent prognosis factors of breast carcinoma include tumor grade, lymph node status, lymphovascular invasion and tumor size.

Invasiveness of Breast Carcinoma

Breast carcinoma *in situ* (ductal or lobular) has better prognosis after surgery than invasive (ductal or lobular) carcinoma. Exception is comedocarcinoma, a ductal carcinoma *in situ* (DCIS) with central necrosis and lymph node metastases.

Histologic Variant of Breast Carcinoma

Breast carcinomas, i.e. tubular, papillary, mucinous, microinvasive, medullary and adenoid cystic are associated with better prognosis. Patients with scirrhous breast carcinoma, Paget's disease of breast, secretory carcinoma and apocrine carcinoma have poor prognosis.

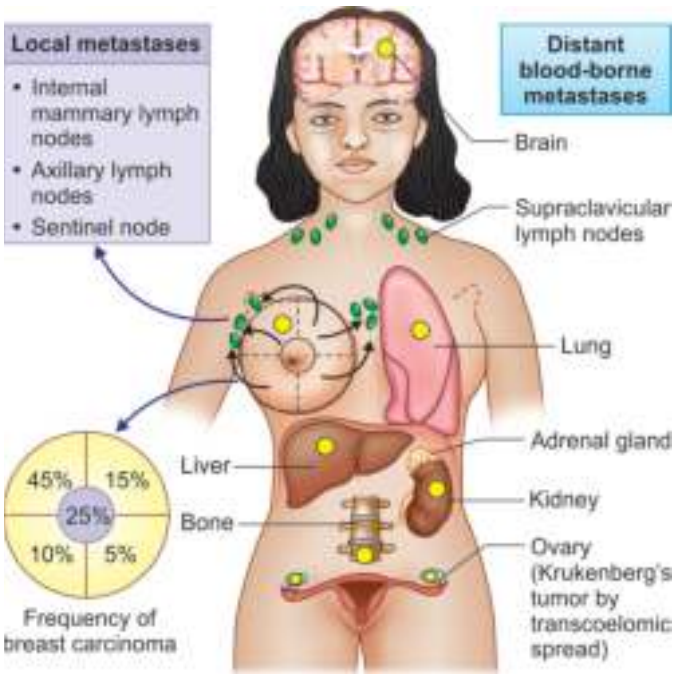

Fig. 25.53: Breast carcinoma—mode of spread of breast cancer. It also shows frequency of breast carcinoma in various quadrants of breast. Breast carcinoma spreads by local invasion, lymphatic, hematogenous and transcoelomic routes.

Distant Metastases of Breast Carcinoma

Breast carcinoma metastases via hematogenous route to lungs, pleura, liver, bones, brain, adrenal glands and ovaries (**Krukenberg tumor**) with fatal outcome.

Status of Axillary Lymph Nodes in Breast Carcinoma

The single best prognostic factor is the presence or absence of axillary nodal metastases in breast carcinoma. There is a direct correlation between survival and the number of axillary lymph nodes involved. Breast carcinoma involving beyond the axillary or internal mammary lymph nodes has a poor prognosis. Breast carcinoma limited to supraclavicular nodes has a good prognosis.

Pathology Pearls: Lymph Nodes Isolation in Mastectomy Specimens

- Lymph nodes should be isolated from mastectomy specimen.
- All the lymph nodes should be examined under microscope to observe number of lymph nodes showing metastatic deposits, size of the metastatic deposit, extracapsular extension and histologic subtype of metastases resembling primary breast carcinoma.

Tumor Size of Breast Carcinoma

Tumor size correlates directly with survival. Patient with smaller tumor <2 cm has better survival rate than with large tumor. Large size breast carcinoma invades locally into adjacent skeletal muscles of breast.

Grading and Staging Systems of Breast Carcinoma

Grading system refers to classification of tumors according to their light microscopic characteristics. Staging system is a clinical exercise that classifies tumors according to their size, invasiveness and spread. Tumors are staged according to the TNM system (T: Tumor size, N: Lymph node involvement, M: Metastases to distant organs). Schemes for TNM classification vary according to tumor type and organ involved (Fig. 25.54).

A grading system (Nottingham modification of the Bloom Richardson Grading System) utilizes histologic characteristics of the breast carcinoma.

- **Basis of Nottingham modification grading system:** It is based on assessment of entire tumor differentiation (e.g. glandular formation), nuclear pleomorphism and frequency of mitotic figures studied in formalin fixed H&E stained sections.
- **Scoring of Nottingham grading system:** For example, a tumor with >75% glandular differentiation would score 1, 10–75% glandular differentiation as score 2, and <10% glandular differentiation would score grade 3. These values are combined and converted into three groups: grade I (scores 3–5), grade II (scores 6–7), and grade III (scores 8 and 9). This histologic grade is often known as Nottingham modification of the Bloom and Richardson grading system (Tables 25.21 to 25.23).

Pathology Pearls: Nottingham Grading System in Breast Carcinoma

High percentage of tubule formation (>75%) would indicate a better prognosis in patient with invasive ductal carcinoma, not otherwise specified (NOS) of breast.

Lymphovascular Invasion of Breast Carcinoma

Invasion of lymphatic channels and blood vessels is demonstrated in 25% of breast carcinoma on light microscopy. These patients have poor prognosis. Breast carcinoma metastasis and its prognostic markers are given in Table 25.24.

Age of the Patient with Breast Carcinoma

Younger women <35 age have a poorer prognosis than older patients with breast carcinoma of equivalent stage.

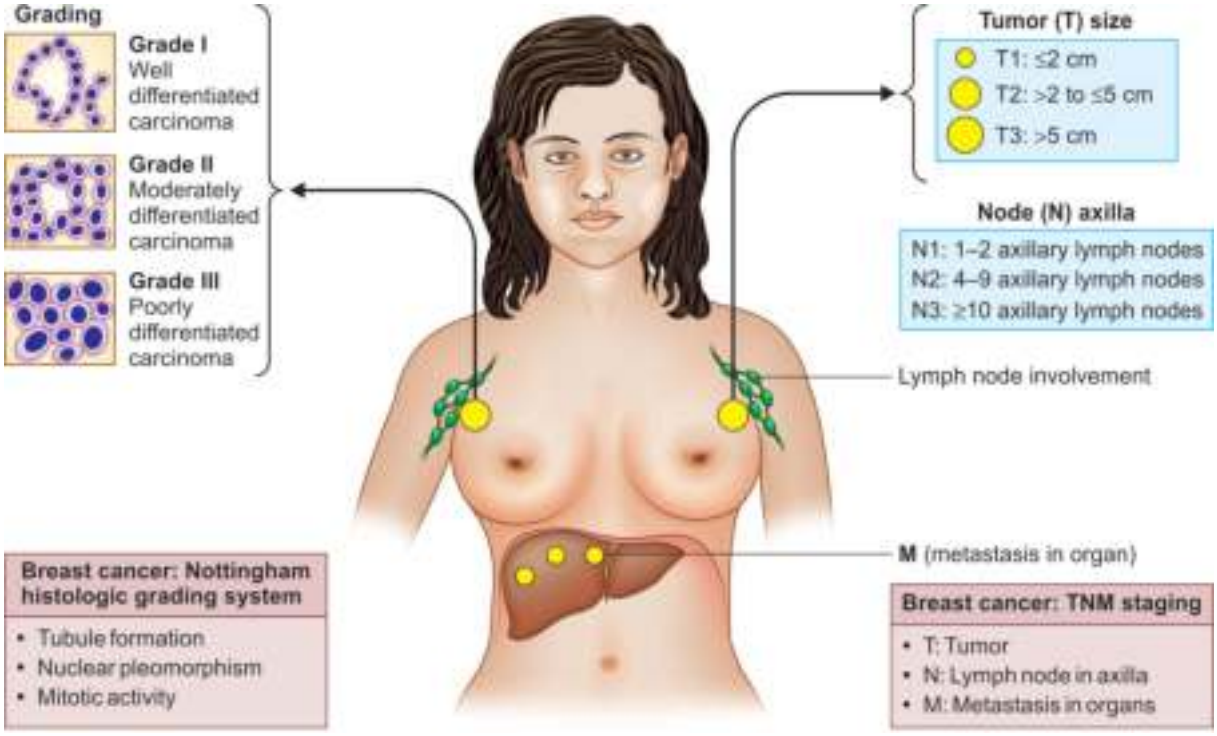

Fig. 25.54: Breast carcinoma shows grading and staging. TNM stands for tumor, lymph node metastases and distant metastases. Grading and staging of breast carcinoma [grading classifies tumors according to their light microscopic characteristics. Staging is a clinical exercise that classifies tumors according to their size, invasiveness and spread. Tumors are staged according to the TNM system (T: Tumor size, N: Lymph node involvement, M: Metastases to distant organs). Schemes for TNM classification vary according to tumor type and organ involved].

Table 25.21 Nottingham modification of the Bloom and Richardson grading system in breast carcinoma

Histology	Characteristics	Scores	Comments
% of tubules formation by tumor cells	▪ >75% ▪ 10–75% ▪ <10%	1 2 3	Based on assessment of entire tumor
Nuclear pleomorphism	▪ Small uniform cells ▪ Moderate increase in size of cells ▪ Marked variation in size of cells	1 2 3	Based on the worst area of tumor
Mitotic count per 10 HPF	▪ ≤6 ▪ 7–13 ▪ ≥14	1 2 3	Mitotic count at the leading edge of tumor growth

The grading is calculated by adding the above scores.

Table 25.22 Correlation of grade and survival rate in breast carcinoma

Grade	Score	Differentiation of Tumor	5-Year Survival (%)	7-Year Survival (%)
1	3 to 5	Well differentiated tumor	95	90
2	6 or 7	Moderately differentiated tumor	75	65
3	8 or 9	Poorly differentiated tumor	50	45

Table 25.23 Staging of breast carcinoma

Stage	Primary Tumor (T)	Positive Axillary Lymph Nodes (N)	Distant Metastases	5-Year Survival
0	▪ DCIS (ductal carcinoma *in situ*) ▪ LCIS (lobular carcinoma *in situ*)	None	None	93%
I	Invasive carcinoma, ≤2 cm	None	None	88%
II	▪ Invasive carcinoma, >2 cm ▪ Invasive carcinoma, <5 cm	▪ 1–3 nodes ▪ 1–3 nodes	None	74–81%
III	▪ Invasive carcinoma, >5 cm ▪ Invasive carcinoma, any size ▪ Invasive carcinoma, attached to skin or chest wall or inflammatory carcinoma	▪ ≥4 nodes ▪ ≥4 nodes ▪ 0–>10 nodes	None None None	41–67%
IV	Any invasive carcinoma ▪ *IVa:* Pectoralis major muscle involvement ▪ *IVb:* Skin involvement: Skin shows ulceration, satellite nodule and peau d' orange ▪ *IVc:* Combination of IVa + IVb ▪ *IVd:* Inflammatory breast carcinoma	Any lymph node status	Present	15%

Markers of Cell Proliferation in Breast Carcinoma

Breast carcinoma with high rate of proliferation of atypical tumor cells in S-phase of cell cycle is associated with local recurrence and associated with fatal outcome in comparison to slow proliferative rate of tumor. S-phase of cell cycle fraction above 5% indicates poor prognosis, which is estimated by the use of monoclonal antibodies such as Ki-67, KiS1, and MIB-1; and identification of proliferating atypical tumor cells by the use of tracers such as bromodeoxyuridine. Measurement of proliferation of tumor cells alone does not give complete information, but prognosis also depends on the metastatic potential of a breast carcinoma.

Table 25.24 Breast carcinoma metastasis and its prognostic markers

Prognostic Markers	Details of Marker	Use in Clinical Practice	Metastatic Determinants
Tumor size	Independent prognostic marker	Established tumor size	▪ Tumor ≤2 cm in diameter has low risk of metastasis ▪ Tumor of 2–5 cm has a high risk of metastasis ▪ Tumor >5 cm has a very high risk of metastasis
Histologic grade	Related to tumor size	Established histologic grade	▪ Grade 1 tumor has a low risk of metastasis ▪ Grade 2 tumor has an intermediate risk of metastasis ▪ Grade 3 has a high risk of metastasis
Axillary lymph node status	Related to tumor size	Established axillary lymph node metastasis	▪ Absence of lymph node metastasis has low risk of metastasis ▪ Presence of lymph node metastasis has high risk of metastasis ▪ Presence of >4 lymph node metastasis has very high risk of metastasis
Angioinvasion	In patient with lymph node negative tumor	Established in patient with lymph node negative tumor	Presence of tumor emboli in >3 blood vessels is associated with metastasis
UPA (urokinase type plasminogen activator) protein and PAI-1 (plasminogen activator inhibitor 1) protein level	Independent prognostic markers	Newly established markers	High protein levels are associated with high risk of metastatic disease
Steroid receptors ER/PR expression	Short-term predictor of metastasis risk (5-year) related to histologic grade of tumor	Established for adjuvant therapy decision	Low steroid receptor (ER/PR) level is associated with metastasis
ERBB2/HER2/neu gene amplification and protein expression	In patient with lymph node positive tumor	Established for adjuvant therapy decision	ERBB2/HER2/neu amplification/overexpression is associated with metastasis
Gene profiling	Currently being analyzed	Analyzed in patient with lymph node negative tumor	▪ A good signature of 70 genes is associated with low risk of metastasis ▪ A poor signature of 70 genes is associated with high risk of metastasis

DNA Content Analysis of Breast Carcinoma

Amount of DNA content in breast carcinoma of atypical tumor cells measured by flow cytometry provides indication of malignant potential. Homogenous population of cells with euploid DNA content is seen in normal or benign cells. Poorly differentiated breast carcinoma shows increased DNA content. Neoplastic atypical cells with aneuploid indicate poor outcome. Diploid tumor has better prognosis than aneuploid tumor.

Internalized Factors Analysis of Breast Carcinoma

Chromosomal aneuploidy and proliferative index parameters determined by flow cytometry or fluorescence *in situ* hybridization (FISH) technique provide data on the aggressiveness of breast carcinoma. Flow cytometry to performed on the atypical cells obtained by fine needle aspiration, excisional biopsy, or resection of breast carcinoma to determine the characteristics of the DNA content. The presence of an increased proliferative rate (high S-phase of cell cycle) and aneuploidy in the flow cytometric pattern of breast carcinoma, suggest a worse prognosis.

Hormone Receptor Status of Breast Carcinoma

The hormone receptor status (estrogen and progesterone) of the breast carcinoma of atypical cells can be useful information for treatment and prognosis. Breast carcinoma with positive estrogen receptor (ER) treated by estrogen receptor blocker (tamoxifen) has better prognosis. In general ER positive breast carcinoma has progesterone positive status. Significance of progesterone status is less well understood.

Amplification of Proto-oncogenes

There is increased expression of oncogenes in breast carcinoma; which include HER2/neu, LGALS3, INT2, and c-Myc.

HER2/neu Proto-oncogene

HER2/neu proto-oncogene encodes for an epithelial growth factor receptor on the cell membrane that stimulates cellular proliferation. Amplification of HER2/neu oncogene is associated with poorly differentiated breast carcinoma (high nuclear grade), metastasizing to lymph nodes, with high rate of recurrence, a small chance of survival and aneuploidy (abnormal number of chromosome).

- **Associated carcinomas:** Amplification of HER2/neu is identified in 10–35% of primary breast carcinoma (high-grade tumors). It has also been demonstrated in carcinomas of the lung, ovary, and stomach.
- **Immunohistochemistry technique:** It is demonstrated as c-erbB2 protein by immunohistochemistry technique on the cell membrane or by analysis of the HER2/neu using fluorescent *in situ* hybridization (FISH). These patients exhibiting HER2/neu gene amplification are treated with monoclonal antibody (Herceptin) that selectively binds to the extracellular domain of the protein.

Galectin 3 Encoded by LGALS3 Proto-oncogene

- **Physiologic state:** Galectin 3 is a member of lectin family and encoded by LGALS3 gene located on chromosome 14, locus q21–q22. Galectin 3 is expressed in the nucleus, cytoplasm and extracellular space.
- **Pathologic state:** Galectin 3 overexpression promotes neoplastic transformation and the maintenance of transformed phenotypes as well as enhances adhesion of tumor cells to the extracellular matrix in breast carcinoma.

Tumor Suppressor Gene Mutations

- **Physiologic state:** RB, TP53 and NM23 are tumor suppressor genes.
- **Pathologic state:** Mutations of RB, TP53 and NM23 genes lead to overexpression of oncogenes resulting in breast carcinoma. These gene mutations are significantly related to poor differentiation, disease recurrence, diminished survival and absence of steroid hormone receptors.
- **Associated carcinomas:** RB tumor suppressor gene mutation is also seen in retinoblastoma, breast carcinoma, osteosarcoma, glioblastoma, urinary bladder carcinoma and small cell lung carcinoma. Inherited TP53 gene mutation is known as Li-Fraumeni syndrome that can increase risk for breast carcinoma, osteosarcoma, leukemia and soft tissue sarcoma. NM3 gene mutation is linked to breast carcinoma metastasis.

Epidermal Growth Factor Receptor (EGFR)

- **Physiologic state:** EGFR is a polypeptide expressed within membrane of breast carcinoma cells. EGFR participates in cell growth.
- **Pathologic state:** Breast carcinoma with overexpression of EGFR is associated with poor survival. There is no role of estrogen receptor blocker (tamoxifen) in these patients.

Alterations in Cell Structure

There is increased expression of **vimentin**, and decreased expression of '**fodrin**' in some cases of breast carcinoma.

Loss of Cell Adhesion Molecules

There is loss of integrin in poorly differentiated ductal carcinoma of breast; and E-cadherin in lobular variant of breast carcinoma in some cases.

Protease (Cathepsin D) Overexpression

- **Physiologic state:** Protease (cathepsin D) is an estrogen-induced acidic lysosomal protease 16 demonstrated in the cytoplasm of nonductal carcinomas of breast. Cathepsin D is also found in the stroma between the cells, which has growth promoting activity and extracellular proteolytic activity.
- **Pathologic state:** Overexpression of cathepsin D is associated with lymph node metastases and poor prognosis in patients with breast carcinoma.

Stress Response Protein 27 (Heat Shock Protein 27)

- **Physiologic state:** Stress response protein 27 (Srp27) is estrogen-related heat shock protein or stress response protein.
- **Pathologic state:** Overexpression of Srp27 is associated with breast carcinoma nodal and widespread hematogenous metastases to distant organs.

Secondary Messenger Systems

- **Physiologic state:** Cyclic AMP binding proteins are the regulatory subunits of a major second messenger system—protein kinase A.
- **Pathologic state:** Cyclic AMP binding proteins are overexpressed in 10–15% of cases. Breast carcinoma expressing high concentration of cyclic AMP is associated with poor outcome.

Prognostic and predictive factors are given in Table 25.25.

Table 25.25 Prognostic and predictive factors of breast carcinoma

Features	Good Prognosis	Poor Prognosis
Age group	30–50	<30 and >50
Diagnosis	Early diagnosis	Late diagnosis
Treatment	Early treatment	Late treatment
Metastases	Absent	Present
Histologic types of breast carcinoma	▪ Ductal carcinoma *in situ* except comedocarcinoma ▪ Low-grade invasive ductal carcinoma (NOS): Luminal type A ▪ Lobular carcinoma *in situ*/invasive: Luminal type A ▪ Tubular carcinoma: Luminal type A ▪ Cribriform carcinoma: Luminal type A ▪ Colloid carcinoma ▪ Papillary carcinoma	▪ Invasive ductal carcinoma of breast ▪ High-grade invasive ductal carcinoma (NOS): It is HER2/neu enrich breast carcinoma. HER2/neu is sensitive to Herceptin. It may be of basal type of breast carcinoma ▪ Paget's disease of breast ▪ Micropapillary carcinoma: Luminal type B ▪ Metaplastic carcinoma: Basal type and luminal type B ▪ Medullary carcinoma: Basal type ▪ Secretory carcinoma
Tumor morphology	▪ <2 cm size ▪ Pushing margin ▪ Absence of necrosis	▪ >2 cm size ▪ Infiltrative margin ▪ Presence of necrosis
Hormonal status	▪ Estrogen positive ▪ Progesterone positive	▪ Estrogen negative ▪ Progesterone negative
C-erbB2	Negative	Positive
p53	Negative	Positive
Srp27	Negative	Positive
Cathepsin D	Negative	Positive
EGFR	Negative	Positive

BREAST LUMPS: LABORATORY DIAGNOSIS

Clinical history includes duration of lump, mode of onset, duration of symptoms, rate of growth, pain in breast, nipple discharge and bone pain.

CLINICAL HISTORY AND EXAMINATION

Nipple, areola, overlying skin, swelling and draining lymph nodes should be examined.

- **Nipple retraction:** Nipple retraction occurs in association with both breast carcinoma and inflammatory lesions in the breast.
- **Skin dimpling or a change in contour:** Skin dimpling is present in a high percentage of patients with breast carcinoma.
- **Nipple and areola eczema:** Paget's disease of breast affects the nipple from the start, whereas eczema affects the areolar region first and only rarely affects the nipple skin, which eventually leads to erosion and ulceration of the nipple in elderly women. Eczema also occurs due to inflammation in the areolar and nipple regions.
- **Peau d'orange skin:** Inflammatory carcinoma of breast is a descriptive term referring to a clinical appearance resembling diffuse acute mastitis, which implies dermal lymphatic channels invasion by underlying usually infiltrating ductal carcinoma.
- **Axillary lymph nodes:** Axillary lymph nodes are palpable in 40% of patients with breast carcinoma.

IMAGING DIAGNOSTIC TECHNIQUES

Radiological investigations done in breast pathology include mammography, nuclear imaging (scintigraphy), Doppler flow studies, thermography, magnetic resonance imaging and positron emission tomography (PET) scan.

Digital Mammography

Screening mammography is done in asymptomatic women, when breast carcinoma is not suspected.

Diagnostic mammography is performed in symptomatic women, when a breast lump or nipple discharge is observed during self-examination by women.

- Digital mammography is screening procedure to detect nonpalpable 2–3 mm breast masses. Most mammographic calcification in benign breast lesions is indeterminate. A few benign lesions such as oil cysts, calcified fibroadenomas and vascular calcification have diagnostic mammographic features. Directional vacuum-assisted core biopsies can remove small benign calcified lesions. BIRADS (breast imaging and radiological analysis data system) is used for reporting digital mammograms (Table 25.26, Figs 25.55 and 25.56).
- Microcalcifications most often occur in ductal carcinoma *in situ* and sclerosing adenosis of breast. The risk of breast carcinoma increases with increase in the number of calcium specks in a cluster.
- Presence of ≥5 tightly clustered microcalcifications within 1 cm area of breast lump is considered a threshold for suspicion of breast cancer. Fibroadenoma shows popcorn calcification.

Table 25.26 BIRADS used for reporting mammograms

Seven Categories	BIRADS is Used for Reporting Mammograms: It has Seven Categories	Management	Likelihood of Breast Carcinoma
0	Incomplete assessment: It needs to additional imaging or prior examinations	Recall for additional imaging and/or await prior examinations	Not applicable
1	Negative assessment	Routine screening	Essentially 0%
2	Benign lesion	Routine screening	Essentially 0%
3	Probably benign lesion	Short interval follow up for 6 months and then continued	>0% and <2%
4	Suspicious lesion	Tissue diagnosis	4a. Low suspicion for malignancy (>2% to <10%) 4b. Moderate suspicion of malignancy (>10% to <50%) 4c. High suspicion of malignancy (>50% to <95%)
5	Highly suspicious of malignancy	Tissue diagnosis	>95%
6	Biopsy proved breast carcinoma	Surgical excision when clinical appropriate	Not applicable

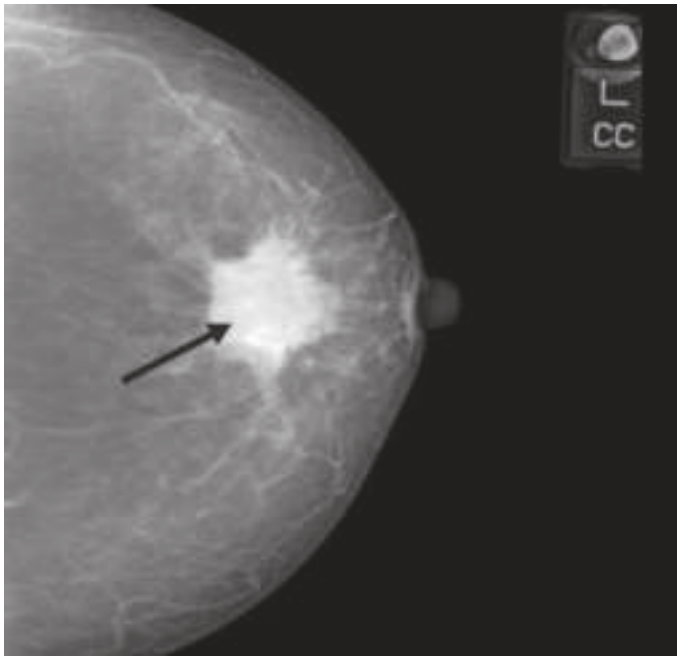

Fig. 25.55: Digital mammogram. It shows breast carcinoma: BIRADS 5 (highly suspicious) (arrow).

Fig. 25.56: Digital mammogram. It shows breast infiltrating carcinoma (biopsy proved breast carcinoma: BIRADS 6) (arrow).

- Mammographic densities are formed due to replacement of adipose tissue with radio-dense tissue. Fibrocystic disease of breast shows rounded densities. Breast carcinomas form irregular masses.
- Approximately 10% of breast carcinomas are not detected by digital mammography.

Xenomammography

Xenomammography is identical with digital mammography except the image produced on xenographic plate rather than a conventional transparency.

- The image produced is positive rather than negative.
- Edge enhancement and wide recording latitude permit details of the soft tissues of the breast, chest wall, and thinner peripheral portions of the breast to be recorded with one exposure.

Magnification Mammography

Magnification mammography enhances the sharpness of details and increases diagnostic accuracy for breast carcinoma.

- Optimum magnification is 1.5 times.
- Margins of breast lumps, degree and specificity of microcalcifications are clearly defined.
- Magnification mammography technique may significantly reduce the number of patients referred for biopsy.

Mammary Ultrasonography

Ultrasonography is the best investigation to differentiate cysts (transparent lesion) from solid lesions such as benign lesions (well demarcated) and breast carcinomas (indistinct outlines). Ultrasonography is also useful for guiding the aspiration of cysts to provide cytologic specimens on fine needle aspiration.

Bone Scan (Bone Scintigraphy)

Bone scan is also known as **bone scintigraphy**, which evaluates breast carcinoma metastases in bone by injecting radioactive substance by intravenous route. After 2–4 hours of absorption of radioactive substance, body scans (films) are taken. This radioactive substance is collected in areas of new bone formation formed by metastases, which appear as dark patches on the film. Any part of the bone may be affected by breast carcinoma.

Computed Tomography Scan

Computed tomography scan can detect breast carcinomas and permit visualization of both axillary and internal mammary lymph nodes. High cost and irradiation exposure are drawbacks of CT scan.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is better for assessing lesions in dense breasts than other methods. MRI is used for evaluation of breast carcinoma, staging of disease (metastases in lungs, bones, liver, brain and ovaries) and detection of silicon prosthesis.

Color Doppler Ultrasonography

Color Doppler ultrasonography serves as a useful imaging modality to evaluate internal structure, blood flow and breast lesions with a hope to differentiate benign nodules from malignant solid masses in breasts. Angiogenesis defined as the emergence of new blood vessels to further growth of the tumor, has stimulated interest in the potential uses of color Doppler ultrasonography in patients with breast carcinoma. Imaging techniques used to detect breast lesions are given in Table 25.27.

Table 25.27 Imaging techniques used to detect breast lesions

Imaging Techniques	Interpretation
Digital mammography: It detects 2–3 mm lesion. BIRADS is used for reporting mammograms. Seven categories are described	▪ Assessment incomplete: 0 ▪ Negative assessment: 1 ▪ Benign lesion assessment: 2 ▪ Probably benign lesion: 3 ▪ Suspicious lesion assessment: 4 ▪ Highly suspicious of malignancy: 5 ▪ Biopsy proved breast carcinoma: 6 **Note:** Popcorn calcification is seen in fibroadenoma. Breast tumor shows ≥5 dense calcified deposits in 1 × 1 cm area is highly suspicious of cancer
Ultrasonography	Ultrasonography detects cysts (transparent lesion), benign lesions (well demarcated) and breast carcinomas (indistinct outlines)
Bone scan (scintigraphy)	Bone scan is used for staging of breast carcinoma
CT scan	Detection of breast carcinoma and involvement of draining axillary and internal mammary lymph nodes
MRI	Evaluation of breast carcinoma and staging disease (metastases in lungs, bones, liver, brain and ovaries)
Color Doppler ultrasonography	Visualization of blood supply to the lump and to distinguish benign nodules from malignant sold masses in breasts.

Positron Emission Tomography Scanning

Positron emission tomography (PET) scanning is the most sensitive and specific imaging modality by using a radioactive substance for studying potential spread of breast cancer.

- At present, its main utility is to detect recurrences of breast carcinoma in scarred breasts.
- PET scanning is also useful in multifocal disease in detecting axillary involvement and equivocal cases of systemic metastases.
- PET scanning also assists in identification of nonaxillary lymph node metastases, i.e. internal mammary or supraclavicular lymph nodes for staging locally advanced and inflammatory breast carcinoma before starting neoadjuvant therapy.

TRIPLE ASSESSMENT OF BREAST LUMPS

Triple assessment in breast cancer is the combination of clinical examination, imaging (e.g. mammography for women aged 35 or over and ultrasonography for women under 35), and fine needle aspiration cytology.

SERUM TUMOR MARKERS

The potential uses of serum tumor markes in breast cancer include aiding early diagnosis determining prognosis, prospectively predicting response or resistance specific therapies surveillance after primary surgery and monitoring therapy in patients with advanced disease. Various serum tumor markers analyzed for breast carcinoma include CA 15-3, CA 27-29. BRCA1, BRCA2, PS2, CEA (carcinoembryonic antigen), PTHrp, GCDFP-15 (gross cystic disease fluid protein 15) and mammaglobin. CA 15-3 is a cell surface glycoprotein demonstrated in breast carcinoma. Serum tumor markers of breast carcinoma are given in Table 25.28.

Table 25.28 Serum tumor markers of breast carcinoma

Markers
CA 15-3
CA 27-29
BRCA1, BRCA2
PS2
Carcinoembryonic antigen (CEA)
PTHrP
Gross cystic disease fluid protein 15 (GCDFP-15)
Mammaglobin

Flow cytometry: DNA ploidy, and S-phase markers.
FISH (fluorescence in situ hybridization): HER2/neu marker.

FINE NEEDLE ASPIRATION CYTOLOGY

Fine needle aspiration cytology (FNAC) is widely used in the diagnosis of breast lumps, which has been reliable, rapid cost effective, complication free and an accurate diagnostic modality for the preoperative evaluation or management of spectrum of benign lesions and malignant tumors. Evaluation of breast lumps involves the rational use of a detailed clinical history, clinical examination imaging modalities and tissue diagnosis.

- Fine needle aspiration cytology is performed using a 23-gauge needle and 10 or 20 ml disposable syringe. Cellular material from brast lump is aspirated into syringe and expelled onto glass slides to prepare smears. All the smears are wet fixed in 95% methanol, and air-dried and stained with two stains, i.e. hematoxylin and eosin (H&E) and Papanicolaou stain. Slides are examined under light microscope by cytopathologist.
- Fibroadenoma can be usually distinguished by invasive ductal carcinoma of breast. Fibroadenoma consists of three components; invasive carcinoma has loosely cohesive and singly dispersed cells with highly atypical morphology. Fine needle aspiration cytology carries high specificity when diagnosing breast malignancy, with a false positive rate of 0–2%. Intraductal papilloma is cytologically distinguishable florid ductal hyperplasia; however, nipple discharge or a mass in the subareolar region may favor the diagnosis of intraductal papilloma. It is difficult to distinguish fibroadenoma from phyllodes tumor of breast on fine needle aspiration cytology, reflecting the fact that these two breast lesions exhibit many overlapping histologic features in common.
- Fine needle aspiration cytology findings in fibroadenoma, fibrocystic disease of breast, ductal carcinoma of breast and medullary carcinoma of breast are shown in Figs 25.57 to 25.60.

BREAST LUMP BIOPSY

Breast lump biopsy is recommended if digital mammogram shows suspicious area in breast. In addition, ultrasound and magnetic resonance imaging (MRI) reveals suspicious area in breast. Biopsy is done if patient has nipple or areolar change including crusting, scaling, dimpling skin or bloody nipple discharge.

- **Tru-cut core needle biopsy:** A small core is removed from the breast mass by means of a cutting needle technique. It is to interpret results on small biopsy measuring 2 cm in length and 1.0 mm wide.
- **Open biopsy:** Open biopsy should be performed only in patients with breast lump, who have been appropriately investigated by imaging, fine needle

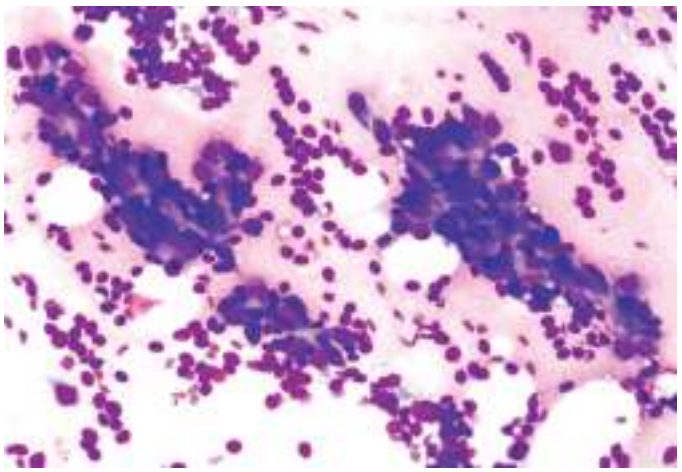

Fig. 25.57: Fibroadenoma of breast—fine needle aspirate smear shows benign ductal cells arranged in clusters. Stromal cells are also seen (400X).

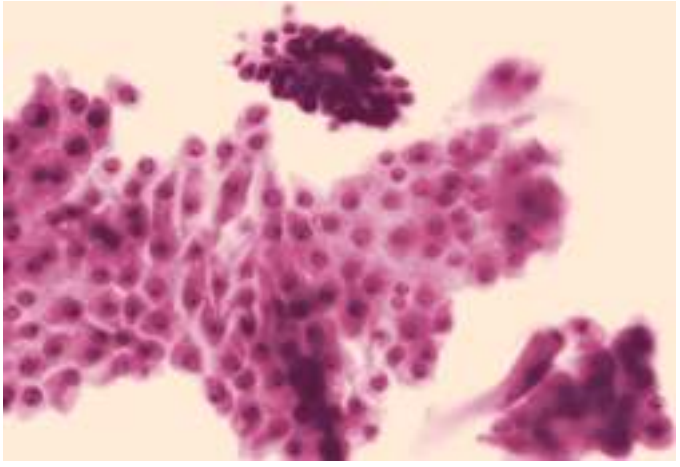

Fig. 25.58: Fibrocystic disease of breast—fine needle aspirate smear shows benign ductal cells arranged in clusters. Apocrine change is seen in the ductal cells (400X).

aspiration cytology, and tru-cut core needle biopsy. The specimen is fixed in 10% buffered formalin to obtain paraffin-embedded sections. Hematoxylin and eosin stained sections are studied by light microscopy. Freshly prepared 2% buffered glutaraldehyde is recommended for fixation of tissues for electron microscopy.

- **Skin biopsy:** Skin biopsy from areola or nipple is important in diagnosing Paget's disease of breast (ductal carcinoma involving epidermis) and inflammatory carcinoma of breast in which dermal lymphatic channels are involved.
- **Sentinel lymph node biopsy:** Sampling of initial lymph node that drains breast carcinoma is done. If sentinel lymph node is negative for metastases, the other lymph nodes in that group are usually negative. If sentinel lymph node is positive for metastases, there is one-third chance that other lymph nodes in the group have metastases.

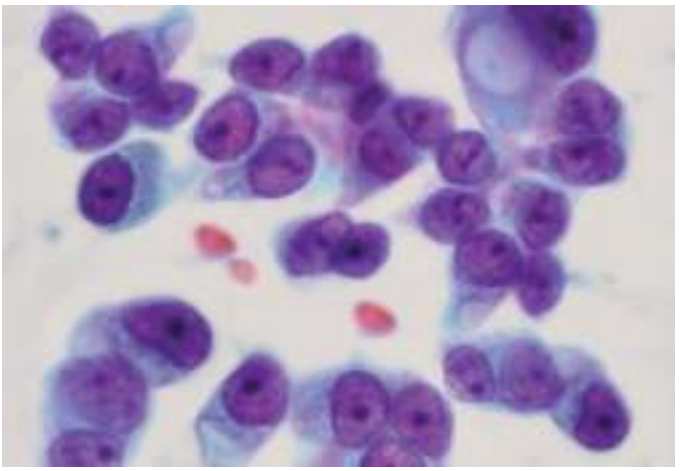

Fig. 25.59: Breast cancer—fine needle aspirate smear shows pleomorphic atypical cells with hyperchromatic nuclei and prominent nucleoli arranged in clusters and dissociated forms (400X).

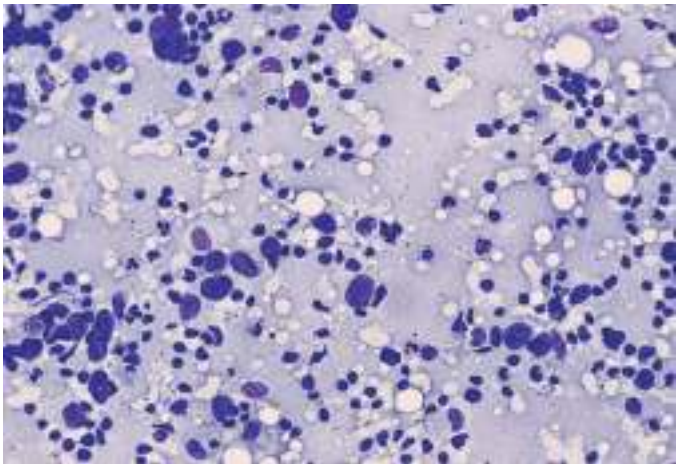

Fig. 25.60: Medullary carcinoma of breast—fine needle aspirate smear shows pleomorphic atypical cells with hyperchromatic nuclei and prominent nucleoli arranged in clusters and dissociated forms. In the background, there is presence of lymphocytes (400X).

FROZEN/CRYOSTAT SECTION TECHNIQUE

Frozen/cryostat section technique is a rapid diagnostic technique before proceeding to definite surgery to confirm breast carcinoma, assessment of margins around tumor, and lymph node involvement. Tissues are quickly frozen, sectioned, mounted on slides, stained with hematoxylin and eosin (H&E) and interpreted within a few minutes, which enable surgeon to take appropriate decisions about the extent of surgery.

Diagnostic difficulties occur in the presence of papillary lesions, sclerosing adenosis, florid adenosis, atypical ductular hyperplasia, fat necrosis, and lobular carcinoma *in situ* (LCIS) cause diagnostic problems on frozen section evaluation. These lesions are best diagnosed with paraffin-embedded sections.

HISTOLOGIC EXAMINATION

Tru-cut core needle biopsy, incisional biopsy, lumpectomy and mastectomy specimens including lymph nodes are fixed in 10% buffered formalin. Sections obtained from paraffin-embedded blocks are stained with hematoxylin and eosin (H&E) studied by light microscopy. The following histologic features of breast tumors are important in deciding course of treatment described as under:

- Size of tumor
- Gross examination of tumor
- Histologic type (*in situ* or invasive)
- Margin of tumor
- Lymph node status (number, size and extracapsular invasion)
- Nottingham modification of Bloom-Richardson (MBR) grade
- Nipple involvement
- Pathologic stage (tumor and lymph node status)
- DNA content
- S-phase fraction
- Immunohistochemistry (ER, PR, ERBB2/HER2/neu).

IMMUNOHISTOCHEMISTRY TECHNIQUE

Immunohistochemistry is a newer technique to detect antigens (markers) by applying monoclonal antibodies in a sample of tissue. It plays an important role in differentiating poorly differentiated carcinoma from lymphoma; and benign lesions from malignant tumors. It is performed for assessment of estrogen receptor (ER), progesterone receptor (PR), HER2/neu for the purpose of therapy of breast carcinoma. Applications of immunohistochemistry in breast carcinoma are given in Table 25.29. Immunoprofile in histologic variants of breast carcinoma is given in Table 25.30.

Estrogen and Progesterone Receptors Analysis

Estrogen and progesterone receptors (ER/PR) are present in normal and neoplastic epithelial cells of breast. It is worth mentioning that carcinomas of ovary and endometrium are also positive for ER/PR.

- ER immunostaining has become a standard protocol in management of breast cancer. In addition, ER/PR immunostaining is performed to predict response to hormonal therapy and identify metastases in lymph nodes and other organs from breast carcinoma.

Table 25.29 Applications of immunohistochemistry in breast carcinoma

Immunomarker	Immunomarker Locations	Features	Applications
E-cadherin	Membranous staining	Adhesion molecule expressed in ducts and lobules of breast	Loss of E-cadherin staining is hallmark of breast *in situ* lobular or invasive lobular carcinoma. E-cadherin staining is negative in breast *in situ* ductal or invasive ductal carcinoma
ER/PR	Nuclear staining	ER/PR expression in normal ductal cells and neoplastic cells of breast	ER/PR expression in breast carcinoma associated with favorable prognosis treated with tamoxifen. ER/PR immunomarkers are used to diagnose metastatic breast cancer
Gross cystic disease fluid protein 15 (GCDFP-15)	Cytoplasmic staining	GCDFP-15 immunomarker for breast and sweat glands showing apocrine differentiation	GCDFP-15 and ER used to detect metastatic breast carcinoma
Mammaglobin	Cytoplasmic staining	Mammaglobin immunomarker for breast and sweat glands showing apocrine differentiation	Mammaglobin more sensitive and less specific than GCDFP-15
HER2/neu	Cytoplasmic staining	HER2/neu is growth factor receptor expressed in neoplastic cells but absent in normal cells	Overexpression of HER2/neu in breast carcinoma associated with poor prognosis. Patients are treated by Herceptin
Myoepithelial cell markers	Variable staining	Smooth muscle actin (α-actin), calponin, smooth muscle myosin heavy chain (SMMHC) and p63 usual immunomarkers for myoepithelial cells. Other immunomarkers are CK14 (HMWCK), S-100 protein, glial fibrillary acidic protein (GFAP) and CD10	Myoepithelial cell layer is intact in benign and *in situ* breast lesions; but absent in invasive breast carcinoma

Microglandular adenosis lacks myoepithelial cells.

Table 25.30 Immunoprofile in histologic variants of breast carcinoma

Immunomarkers	Expression
Breast *in situ* ductal carcinoma/invasive ductal carcinoma (not otherwise specified)	
ER/PR	Positive (65–75%)
GCDFP	Positive (50%)
Mammaglobin	Positive (50%)
HER2/neu	Positive (10–30%)
CK7	Positive
Ki-67	Positive
p53	Positive
E-cadherin	Positive
NY-BR1	Positive (specific marker for undifferentiated breast cancer)
CK20	Negative
Breast *in situ* lobular carcinoma/invasive lobular carcinoma	
GCDFP	Positive (100%)
E-cadherin	Negative
Metaplastic carcinoma of breast	
CK903 (HMWCK)	Positive
p53	Positive
AE1/AE3	Variable
CAM 5.2	Positive (most reliable marker)
CK7	Positive (most reliable marker)
ER/PR	Negative
HER2/neu	Negative
Medullary carcinoma of breast	
ER/PR	Negative
HER2/neu	Negative
Basal-like carcinoma of breast	
ER/PR	Negative
HER2/neu	Negative
Micropapillary carcinoma of breast	
ER/PR	Negative
HER2/neu	Negative

GCDFP (gross cystic disease fluid protein), triple negative, i.e. ER, PR, HER2/neu (medullary carcinoma, basal-like carcinoma, micropapillary carcinoma).

- ER expression correlates better differentiation and favorable predictive factor for treating breast carcinoma with estrogen blocker 'tamoxifen'.
- Risks associated with tamoxifen are endometrial carcinoma and thromboembolism. Tamoxifen is contraindicated in active smokers and previous history of thromboembolism.
- Tamoxifen is administered for five years in cases of ductal carcinoma *in situ* (DCIS) and lobular carcinoma *in situ* (LCIS) for prevention of development of invasive carcinoma of breast.
- While analyzing ER/PR expression in breast carcinoma, percentage of neoplastic cells immunostaining intensity (strong, medium or weak) and internal control tissue should be taken into consideration.
- ER/PR positive breast carcinomas are treated with tamoxifen. Prognosis is excellent in these cases. ER/PR expression and interpretation in breast carcinoma is given in Table 25.31.

HER2/neu Growth Factor Receptor Analysis

HER2/neu is a growth factor receptor, which is absent in normal breast. Due to amplification of HER2/neu, its overexpression is demonstrated in 10–30% of breast carcinomas. HER2/neu positive breast carcinomas are poorly differentiated and associated with poor prognosis.

- HER2/neu positive patients are treated by anti-HER2/neu '**Herceptin**' chemotherapeutic agent.
- On the other hand, well differentiated breast carcinomas are ER/PR positive/HER2/neu negative.
- Triple negative breast carcinomas are medullary carcinoma, basal-like carcinoma and micropapillary carcinoma of breast.
- Analysis of HER2/neu is done by immunohistochemistry, fluorescence *in situ* hybridization (FISH), chromogenic *in situ* hybridization (CISH) and silver *in situ* hybridization technique. Factors adversely affecting analysis of HER2/neu by FISH technique

Table 25.31 ER/PR expression and interpretation in breast carcinoma

ER/PR	Interpretation
≥1% of neoplastic cells showing staining of any intensity	Positive
<1% of cells showing staining of internal control tissue	Negative

While analyzing ER/PR expression, percentage of neoplastic cells immunostaining intensity (strong, medium or weak) and internal control tissue should be taken into consideration.

are prolonged fixation of tissue in formalin for more than one week and insufficient protease treatment of the tissue section.

- Scoring method of HER2/neu expression in breast carcinoma by immunohistochemistry technique is based on the cell membrane staining pattern (Table 25.32). Algorithm of HER2/neu status in diagnosis of breast carcinoma is shown in Fig. 25.61.

E-Cadherin Cell Adhesion Molecule Analysis

E-cadherin is cell adhesion molecule responsible for cell-to-cell adhesion of epithelial cells. E-cadherin requires calcium ions to function. It is expressed in normal breast cells lining the ducts and lobules.

- Main application of E-cadherin immunostaining is to differentiate breast *in situ* ductal carcinoma/invasive ductal carcinoma, atypical ductal hyperplasia from *in situ* lobular carcinoma and invasive lobular carcinoma of breast.
- E-cadherin is expressed in breast *in situ* ductal carcinoma/invasive ductal carcinoma, atypical ductal hyperplasia of breast.
- Loss of E-cadherin immunostaining is a hallmark of breast *in situ* lobular carcinoma and invasive lobular carcinoma of breast. It is worth mentioning that neoplastic cells are discohesive in this histologic variant of breast carcinoma. Application of E-cadherin in normal breast and breast carcinoma is given in Table 25.33.

Gross Cystic Disease Fluid Protein 15 Analysis

Gross cystic disease fluid protein 15 (GCDFP-15) is a cytoplasmic immunomarker for breast and sweat glands showing apocrine cell differentiation. GCDFP-15

Table 25.32 Scoring method of HER2/neu expression in breast carcinoma by immunohistochemistry based on the cell membrane staining pattern

Criteria of Cell Membrane Staining Pattern	Score	Interpretation
<30% of neoplastic cells showing membranous immunostaining	0	Negative
>30% of neoplastic cells showing partial membranous immunostaining	1	Negative
>30% of neoplastic cells showing moderate to complete membranous immunostaining	2	Weakly positive
>30% of neoplastic cells showing moderate to strong complete membranous immunostaining	3	Strongly positive

Breast carcinomas showing weakly positive HER2/neu expression or equivocal cases should be further analyzed by FISH or CISH.

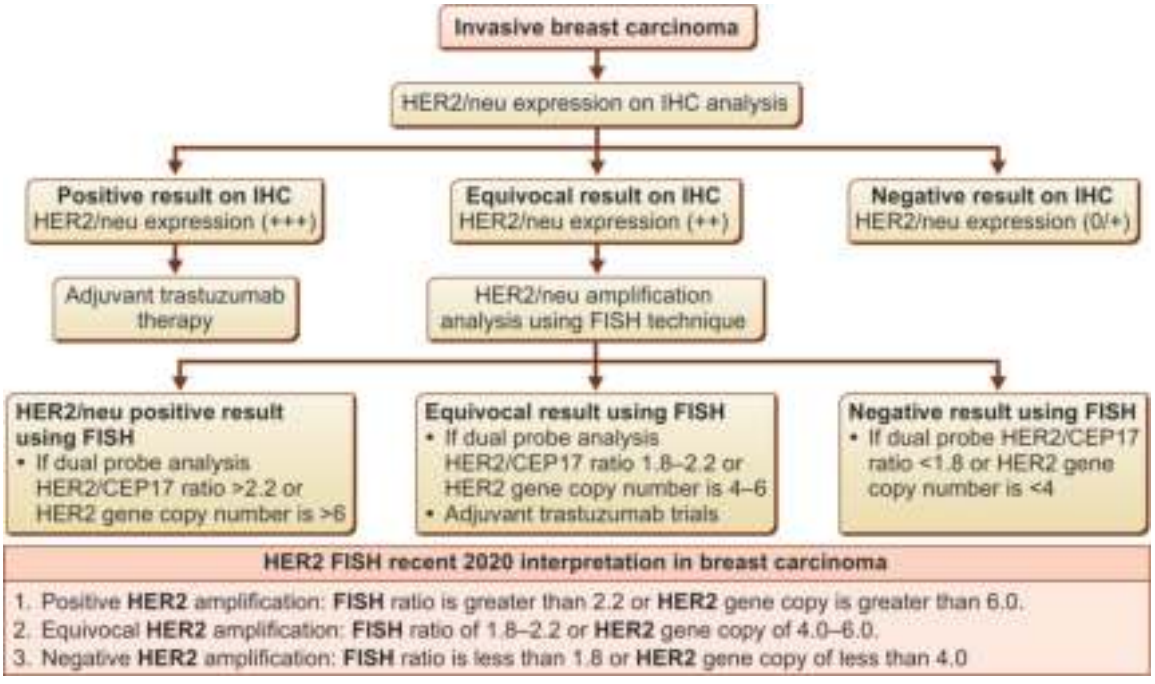

Fig. 25.61: Algorithm of oncotype DX in diagnosis of breast carcinoma.

Table 25.33 Application of E-cadherin in normal breast and breast carcinoma

Breast Epithelial Cells	E-cadherin Expression
Epithelial cells lining ducts and ductules	Positive
Breast *in situ* ductal carcinoma/invasive ductal carcinoma, atypical ductal hyperplasia	Positive
Breast *in situ* lobular carcinoma and invasive lobular carcinoma	Negative

immunomarker is analyzed to demonstrate breast carcinoma metastases. ICDFP-15 immunostaining pattern is patchy in the cytoplasm of neoplastic cells in ≤50% of breast carcinoma cases.

- GCDFP-15 is also expressed in lung carcinoma, salivary duct carcinoma and some skin adnexal tumors.
- Therefore, GCDFP-15 is always analyzed in conjunction with ER and PR. Breast lobular carcinoma showing apocrine differentiation shows positivity for GCDFP-15.

Mammaglobin Analysis

Mammaglobin gene encodes a 10 kilodalton glycoprotein, which is expressed in adult female mammary glands. Like gross cystic disease fluid protein 15 (GCDFP-15), mammaglobin recognizes apocrine differentiation of breast and sweat glands. Mammaglobin is a cytoplasmic immunostaining marker. Mammaglobin expression is increased in breast carcinoma, and carcinomas of ovary, endometrium and cervix. It is less specific but more sensitive immunomarker than GCDFP-15.

Myoepithelial Cell Immunomarkers

Myoepithelial cells are smooth muscle-like cells present in the glandular epithelium as a thin layer above the basement membrane and beneath the luminal cells of breast. Myoepithelial cell layer is intact in benign and *in situ* breast lesions; but absent in invasive ductal carcinoma. Microglandular adenosis also lacks myoepithelial cells.

Pathology Pearls: Myoepithelial Cell Markers

Panel of markers is used on paraffin-embedded tissue section of breast lesions to demonstrate myoepithelial cells in breast. Smooth muscle actin (α-actin), calponin, smooth muscle myosin heavy chain (SMMHC) and p63 are usual immunomarkers for myoepithelial cells. Other immunomarkers are CK14 (HMWCK), S-100 protein, glial fibrillary acidic protein (GFAP) and CD10.

Myoepithelial Cell Immunomarkers	Expression
▪ Smooth muscle actin (α-actin)	▪ Positive
▪ Calponin	▪ Positive
▪ Smooth muscle myosin heavy chain (SMMHC)	▪ Positive
▪ p53	▪ Positive
▪ CK14 (HMWCK)	▪ Positive
▪ S-100 protein	▪ Positive
▪ Glial fibrillary acidic protein (GFAP)	▪ Positive
▪ CD10	▪ Positive

Other Immunomarkers

Other immunomarkers include p53, galectin 3, NY-BR1, cathepsin D, stress response protein 27 (Srp27), milk fat globulin membrane antigen and lactalbumin.

RECENT ADVANCES: MOLECULAR GENETIC TECHNIQUES IN BREAST CANCER

Oncotype DX Assay

Oncotype DX is a RT-PCR based assay of 16 cancer-related genes and 5 normal comparator genes.

- Oncotype DX has been designed to use in estrogen positive breast carcinoma. The test is run on formalin-fixed paraffin-embedded tissue.
- The assay computes a recurrence score (RS) from 0 to 100. Oncotype DX results are reported as a recurrence score
  - Recurrence rate <18 is considered low risk for breast carcinoma recurrence.
  - Recurrence rate 18–30 is considered intermediate risk for breast carcinoma recurrence.
  - Recurrence rate >30 is considered high risk of breast carcinoma recurrence. It is associated with poor prognosis referring to the likelihood of recurrence without treatment. Higher recurrence rate for breast carcinoma is also associated with a higher probability of response to chemotherapy, which is termed a positive predictive factor.

Algorithm of oncotype DX in diagnosis of breast carcinoma is shown in Fig. 25.62.

MammaPrint Gene Expression Profile Test

MammaPrint gene expression profile test analyzes 70 genes from an early-stage breast carcinoma tissue sample to figure out if the breast carcinoma has a low or high risk of recurrence within 10 years after diagnosis.

- MammaPrint is the first FDA approved gene microarray based prognostic score performed on fresh frozen tissue of breast carcinoma.

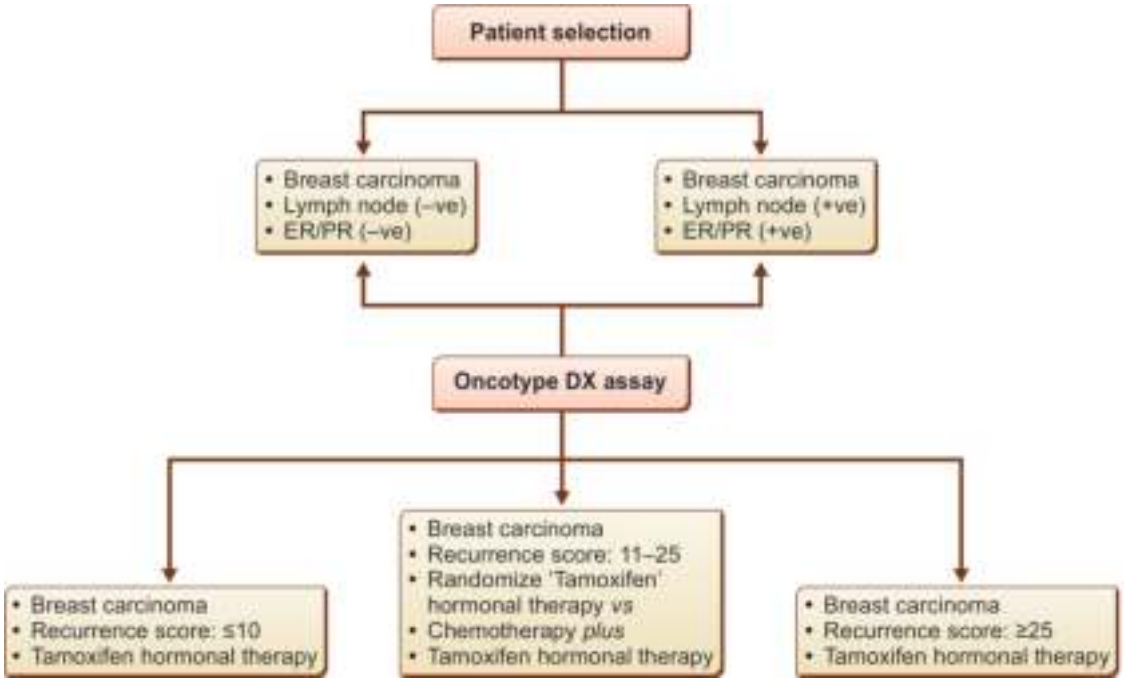

Fig. 25.62: Algorithm of oncotype DX in diagnosis of breast carcinoma.

- Top 70 genes that regulate cell cycle, invasion and metastasis and angiogenesis are evaluated in cases of breast carcinoma. A tumor has been categorized as low or high risk for breast carcinoma.
- MammaPrint can determine whether or not patient with breast carcinoma will be benefited from chemotherapy.
- MammaPrint can be used to analyze breast carcinomas that are in stage I or stage II of invasive ductal carcinoma of breast measuring <5 cm and involvement of three or more lymph nodes.

Algorithm of MammaPrint in diagnosis of breast carcinoma is shown in Fig. 25.63.

Prosigna Kit Test (PAM50) Risk of Recurrence Score

Prosigna kit utilizes formalin-fixed paraffin-embedded tissue from breast carcinoma to quantify mRNA expression of 50 genes used in the PAM50 molecular classification algorithm and 50 housekeeping genes.

Prosigna kit is indicated for *in vitro* diagnostic use in postmenopausal women with hormone receptor positive, lymph node negative (stage I or II), or lymph node positive (stage II) of breast carcinoma to be treated with adjuvant endocrine therapy for assessment of risk of distant recurrence of disease.

Breast Carcinoma Index Test

The breast carcinoma index (BCI) test analyzes the activity of seven genes, that predict the risk for lymph node negative, hormone receptor positive breast carcinoma in patients, who visit hospital after 5–10 years after diagnosis of breast carcinoma.

- BCI test can help the patient or attending oncologist to decide whether extending hormonal therapy 5 more years (for a total of 10 years of hormonal

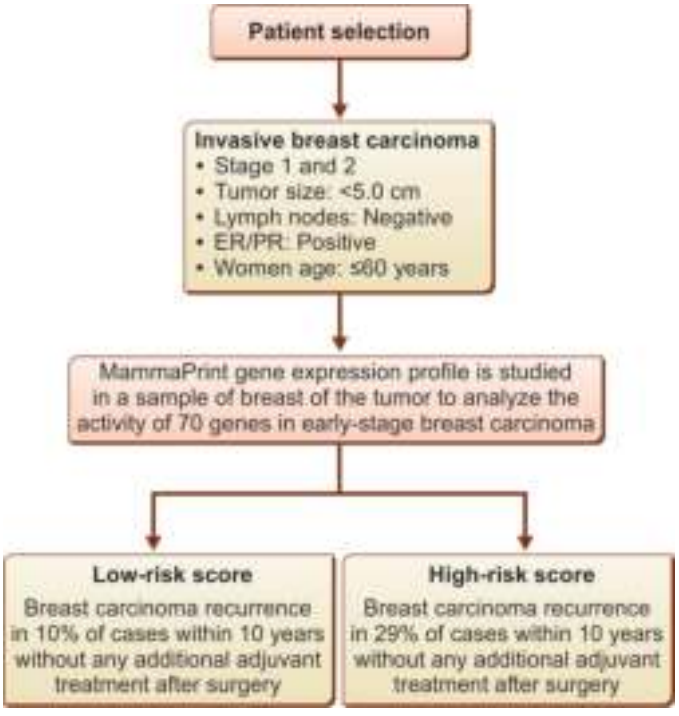

Fig. 25.63: Algorithm of MammaPrint in diagnosis of breast carcinoma.

therapy) would be beneficial to the breast carcinoma patient.
- BCI test is performed on formalin-fixed paraffin-embedded (FFPE) tissue from breast carcinoma that was removed after surgery.

EndoPredict Breast Cancer Prognostic Test

The EndoPredict test is a genomic test for patients newly diagnosed with early stage, estrogen-receptor positive and ERBB2/HER2/neu negative breast carcinoma.
- EndoPredict test is an RT-PCR-based assay using formalin-fixed paraffin-embedded tissue, which measures the expression of 8 breast carcinoma-related genes and 3 housekeeping genes.
- The EndoPredict test provides a score that is either low risk or high risk for breast carcinoma recurring as distant metastases. Test helps the patient and doctor to decide whether chemotherapy or other treatment required to reduce risk for breast carcinoma after surgery.

Next-Generation Sequencing in Breast Cancer

Molecular biomarkers indicating disease diagnosis, prognosis and treatment decisions in patients with breast carcinoma are being covered by next-generation sequencing (NSG) technologies. Over the past many years, various molecular profiling technologies such as immunohistochemistry (IHC), gene expression microarrays and germline DNA sequencing have had considerable impact on the clinical care of patients with breast carcinoma. Although the molecular subtyping of breast carcinoma has been extensively studied and incorporated into clinical care guidelines. Next-generation sequencing has improved our understanding of breast cancer with the genomic landscapes of early- and advanced-stage disease being well documented.
- Next-generation sequencing (NGS) is applied in a variety of ways such as whole genome sequencing, target sequencing, gene expression profiling, chromatin immunoprecipitation sequencing and small RNA sequencing to accelerate biomedical and biological research.
- Next-generation sequencing is applied to analyze genomic alterations such as insertion, deletions and copy number changes in breast carcinomas.
- Next-generation sequencing with breast carcinoma successfully reveals actionable genetic alterations in BRCA1, BRCA2, PIK3CA, HER2/neu, CCND1, ESR1, CDK6, FGFR1, EGFR, K-RAS, PDGFRA and AKT. Gene mutations are more frequently detected by plasma-based tests, whereas gene amplifications are analyzed by tissue-based tests. Plasma-based testing has utility in monitoring for resistance mutation status in patients with breast carcinoma.
- It is expected to provide insights on personalized treatment of breast carcinoma patients. With its increasing use, novel therapeutic target therapy is expected to be identified.

Microarray Studies in Breast Cancer

Microarray studies on prognostic gene expression profiles in breast carcinoma are done by using multiple microarray platforms that use varying parameters.
- These parameters include distinct sets of genes either cDNA of variable lengths or small oligonucleotide sequences.
- Different methods to determine gene include fluorescently labeled cDNA from breast carcinoma neoplastic cells to the microarray or hybridization of both a test and reference set of differently labeled cDNA to single microarray and measure the ratio.

cDNA Microarray in Breast Cancer

cDNA microarray study is performed to analyze 456 intrinsic genes in breast carcinoma.
- Luminal 'A' breast carcinoma has better prognosis than luminal 'B' breast carcinoma.
- Worst prognosis is for basal-like and ERBB2 (HER2/neu) positive breast carcinomas.

Oligonucleotide Microarray in Breast Cancer

Oligonucleotide microarray study is done to analyze 70 genes, 76 genes and 442 genes by different methods.
- Good signature genes are related to low metastasis risk for breast carcinoma.
- Poor signature genes are associated with a high metastasis risk for breast carcinoma.

BREAST CARCINOMA: MANAGEMENT

Treatment of breast carcinoma depends on the stage of the disease. Several options for treatment are most often used in combination for best results. These are described as under.

Surgical procedures include lumpectomy, mastectomy (partial, total, or radical).

Clinical Pearls: Levels of Intervention in Breast Carcinoma

Levels of intervention in breast carcinoma important in management are mentioned below.

- Identification of risk factors and risk reduction therapy
- Screening of cases
- Staging and management
- Hormonal therapy
- Chemotherapy
- Radiotherapy
- Follow-up

BREAST LUMPECTOMY

Lumpectomy is a segmental mastectomy with microscopically free margins, plus sentinel lymph node and low level I and II axillary node resection (breast conservative therapy) that is followed by radiation therapy of breast carcinoma.

MODIFIED RADICAL MASTECTOMY

Modified radical mastectomy in patient with breast carcinoma is removal of all ipsilateral breast tissue, the pectoralis minor muscle, the nipple–areola complex, and levels I, II and III axillary lymph nodes below axillary vein.

Lymph nodes are examined for signs of further metastases. A winged scapula may occur due to damage of the long thoracic nerve. There is also a danger for developing lymphedema in patients with breast carcinoma, who have undergone modified radical mastectomy.

Clinical Pearls: Adjuvant Therapy in Breast Carcinoma

- After surgical excision, adjuvant therapy for breast carcinoma is based on tumor size, modified Bloom-Richardson (MBR) grade, lymphovascular invasion and ERBB2/HER2/neu.
- Adjuvant therapy includes cytotoxic chemotherapeutic and/or endocrine therapy or radiotherapy of the primary tumor.
- Adjuvant therapy is used to ensure that all microscopic disseminated carcinoma cells are destroyed.

RADIATION THERAPY

Radiation therapy can be directed at the breast carcinoma tumor in the breast, the chest wall, or other tissues known or suspected to have remaining breast carcinoma neoplastic cells. Radiation therapy is aimed to slow or shrink breast carcinoma tumor to make surgery easier.

CHEMOTHERAPY

Chemotherapy is used to reduce the size of breast carcinoma growth for making surgery easier. It is used to help eliminate breast carcinoma neoplastic cells that may still remain in the breast or that may have already spread to other parts of the body.

HORMONAL THERAPY

Hormone therapy with **tamoxifen** is used to block the effects of estrogen that may otherwise help breast carcinoma neoplastic cells to survive and grow.

Most women with breast carcinoma neoplastic cells expressing estrogen or progesterone benefit from treatment with tamoxifen.

AROMATASE INHIBITORS THERAPY

A new class of medicines called *aromatase inhibitors*, such as **aromasin** has been shown to be as good as or possibly even better than tamoxifen in women with stage IV breast carcinoma.

BIOLOGICAL THERAPY

Monoclonal antibodies may be administered to attack potential breast carcinoma neoplastic cells and reduce the risk for recurrence. **Herceptin** monoclonal antibody binds HER2/neu on breast carcinoma neoplastic cell surface and induces receptor internalization. Investigation of a breast lump is shown in Fig. 25.64.

MISCELLANEOUS DISORDERS OF THE FEMALE BREASTS

CONGENITAL HYPOPLASIA OF BREAST

Absence of the underlying pectoralis muscles is often associated with congenital hypoplasia of female breast.

GIANT JUVENILE HYPERTROPHY OF BREAST

The redness of breast in patient with juvenile hypertrophy of breast occurs due to cellulitis from ulceration caused by wearing a bra that is too tight. This benign lesion is removed followed by reconstruction of breast.

ACCESSORY NIPPLE

Accessory nipple occurs in both sexes and may be found anywhere on the 'milk line' from the axilla to the groin.

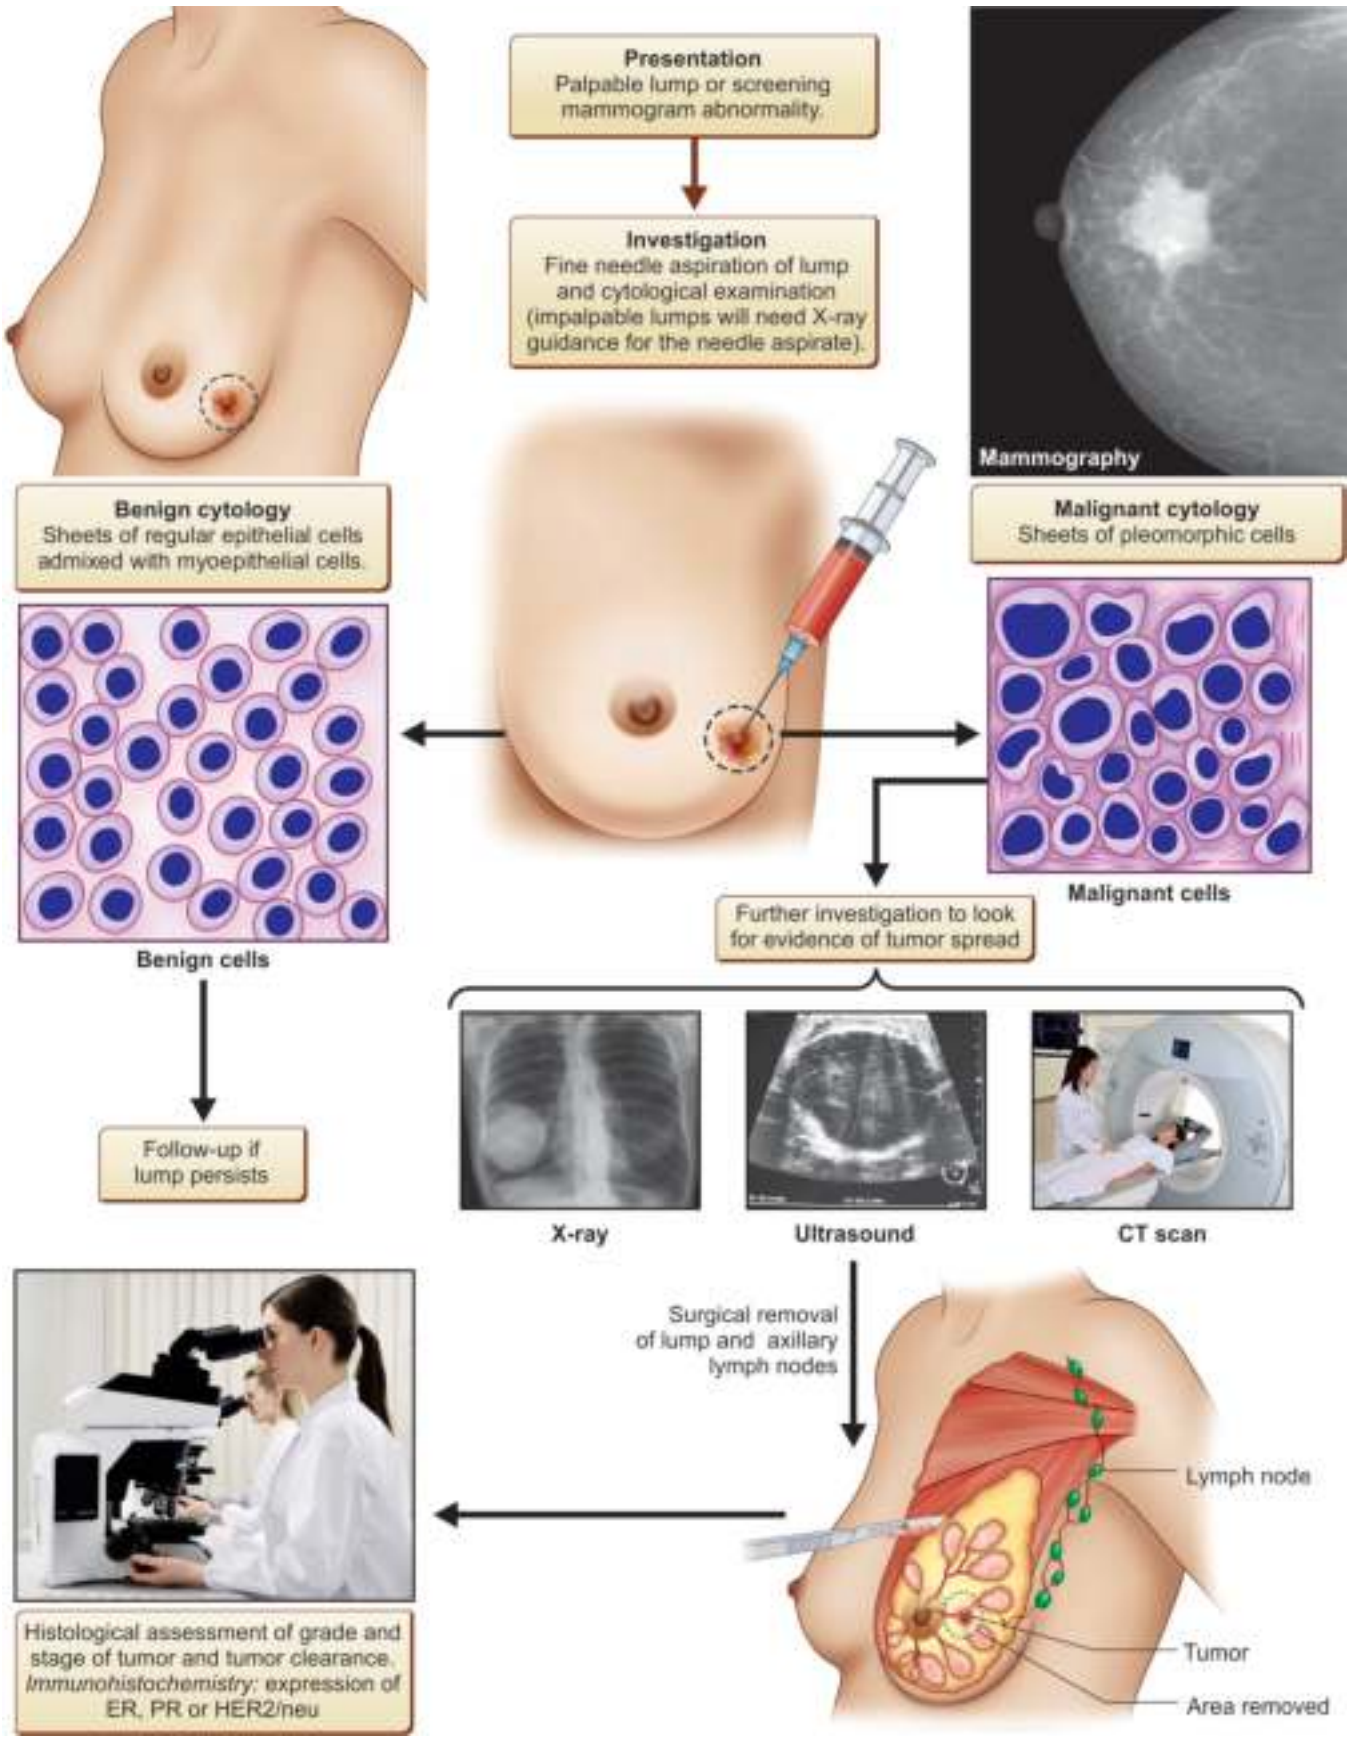

Fig. 25.64: Investigation of a breast lump.

MALE BREASTS

NON-NEOPLASTIC DISORDERS OF MALE BREASTS

GYNECOMASTIA

Gynecomastia is enlargement of the male breast analogous to giant juvenile hypertrophy of the female breast, which occurs most commonly at about puberty, presumably resulting from mild hormonal imbalance. Gynecomastia may occur also during adult life. The patient presents with unilateral or bilateral breast enlargement initially in the subareolar region.

Etiopathogenesis

Unilateral gynecomastia is most often idiopathic. Only very occasional case of gynecomastia is caused by an endocrine tumor. Gynecomastia is most often bilateral due to secondary causes, which occurs due to excess of circulating estrogens or a relative increase in the estrogen and androgen ratio. Estrogen excess relative to androgens results in proliferation of both ducts and stroma of male breasts.

- Gynecomastia is associated with: (a) hormone-secreting adrenal or testicular neoplasms (estrogenic), (b) paraneoplastic production of gonadotropins by carcinomas, (c) Klinefelter's syndrome, and (d) liver cirrhosis resulting in increased conversion of androstenedione into estrogens.
- Liver normally inactivates estrogen in men. Male patients with cirrhosis no longer inactivate estrogen. Hyperestrinism in men manifests gynecomastia, loss of chest and pubic hair, impotence, testicular atrophy and palmar erythema (liver palms); spider nevi (capillary telangiectasia) of the face, upper arms, and chest.

Surgical Pathology: Gynecomastia

Gross Morphology

- Gynecomastia is soft rubbery to firm gray-white subareolar mass.
- Gynecomastia can be ill-defined subareolar induration

Light Microscopy

- Histologic examination of gynecomastia specimen shows active epithelium within a proliferation of mammary ducts with piling of nuclei in the ducts, periductal fibrosis with numerous fibroblast nuclei.
- No lobules are found in the male breast.

Immunohistochemistry Technique

- Luminal epithelium of ducts expresses CK5/CK6 and KC14.
- Intermediate cuboidal to columnar cells express ER, PR and AR (androgen receptor).
- Outer myoepithelial cells express CK5/CK6 and CK14.

NEOPLASTIC DISORDERS OF MALE BREASTS

INVASIVE DUCTAL CARCINOMA

Invasive ductal carcinoma occurs in elderly men of 60–70 years of age when compared to women. Most invasive ductal carcinoma of male breast is ER positive. Clinical presentation, imaging findings and ultimately image-guided biopsies of the lesion provide tissue for accurate histologic diagnosis.

Risk Factors

BRCA1 is the strongest familial risk factor for invasive ductal carcinoma of male breast in 17% of cases. Prognosis is very poor to that of female breast carcinoma. Klinefelter's syndrome and BRCA1 mutation increase risk for breast carcinoma in men. Other risk factors linked to invasive ductal carcinoma of male breast include hereditary BRCA2 mutation, PTEN mutation (Cowden syndrome) and CHEK2 mutation carriers; radiation, antiandrogen therapy, testicular atrophy, occupational exposure to high temperatures, pituitary gland dysfunction, and therapeutic drugs such as digitalis, tricyclic antidepressants. Annual screening of invasive ductal carcinoma of male breast is recommended in men with BRCA mutations.

Clinical Features

Patient with invasive ductal carcinoma of male breast presents with nipple retraction, painless, firm subareolar mass or a mass in the outer quadrant of the breast, and serous nipple discharge. Lymph node metastases are more common in men than women due to paucity of breast tissue in men. Axillary lymph nodal staging is done by sentinel lymph node biopsy. The tumor invades the chest wall muscles.

Surgical Pathology: Invasive Ductal Carcinoma of Male Breast

Gross Morphology

Male breast invasive ductal carcinoma is grossly identical to female breast carcinoma. Cystic papillary carcinoma can be striking.

Light Microscopy

- About 85% of breast carcinomas of male breast are of invasive ductal type. Tumor is poorly differentiated invasive ductal carcinoma followed by papillary carcinoma and other subtypes similar to female breast carcinoma.
- Tumor is composed of pleomorphic atypical cells with hyperchromatic nuclei and prominent nucleoli. Cells are arranged in sheets and clusters with presence of mitotic figures.

Immunohistochemistry Technique

- Older patients over 65 years are most likely to have ER positive, PR positive and AR positive tumors. ER positive invasive ductal carcinoma has better prognosis than ER negative.

Markers	Expression
ER	Positive (85–90%)
PR	Positive (85%)
AR	Positive (90–95%)
BCL-2	Positive (84% mostly luminal A and luminal B)
HER2/neu	Positive (younger patients)

Prognostic Factors

Poor prognostic factors for invasive ductal carcinoma of male breast include lymphovascular invasion, tumor size over 2 cm, poor histologic differentiation, HER2/neu overexpression, TP53 inactivation/biallelic loss, and amplification of CCND1 (11q13), contralateral breast involvement, androgen receptor (AR) positive luminal type A male breast carcinoma (ER positive, HER2/neu negative, high tumor grade) has better survival rate.

Management

Modified radical mastectomy followed by external radiation therapy is the standard treatment for breast invasive ductal carcinoma of male breast. Hormonal therapy, as an adjuvant treatment, is the first-line approach in a majority of patients, and chemotherapy is reserved for patients with poor prognostic factors.

Endocrine System: Pancreas, Thyroid, Parathyroid, Adrenal and Pituitary Glands

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

DISORDERS OF ENDOCRINE PANCREAS

- Endocrine pancreas: embryology, anatomy and physiology
  - Embryology of pancreas
  - Anatomy of pancreas
  - Physiology of pancreas
- Insulin hormone
  - Insulin synthesis
  - Insulin release
  - Insulin actions
  - Insulin signaling pathways
- Diabetes mellitus
  - Diabetes mellitus: classification
  - Acute diabetic complications
  - Diabetes mellitus and complications: cellular metabolic signaling pathways
  - Long-term complications of diabetes mellitus
  - Laboratory diagnosis of diabetes mellitus

DISORDERS OF THYROID GLAND

- Anatomy of thyroid gland
- Physiology of thyroid gland
  - Regulation of thyroid hormones
  - Synthesis of thyroid hormones
- Thyroiditis
  - Hashimoto's thyroiditis
  - Subacute painless lymphocytic thyroiditis
  - Subacute granulomatous thyroiditis
  - Riedel's thyroiditis
  - Acute bacterial thyroiditis
- Hypothyroidism
  - Congenital hypothyroidism
  - Cretinism (thyroid dwarf)
  - Myxedema (hypothyroidism) in adults
- Hyperthyroidism
  - Toxic nodular goiter
  - Graves' disease
  - Hyperthyroidism: other causes
- Goiter
  - Simple nontoxic goiter
  - Multinodular goiter
- Neoplastic disorders of thyroid gland
  - General considerations
  - Follicular thyroid adenoma
  - Hyalinizing trabecular tumor
  - Papillary thyroid carcinoma
  - Follicular thyroid carcinoma
  - Oncocytic thyroid neoplasms
  - Medullary thyroid carcinoma
  - Poorly differentiated thyroid carcinoma
  - Anaplastic thyroid carcinoma
  - Secondary thyroid tumors
- Thyroid gland anomalies
  - Thyroglossal duct cyst
  - Ectopic thyroid tissue
  - Lingual thyroid
- Thyroid disorders: diagnostic approach
  - Thyroid function tests
  - Imaging techniques
  - Fine needle aspiration cytology
  - Histopathologic examination
  - Molecular genetic testing
  - Serum tumor markers
  - 24 hours urinary catecholamines assay

DISORDERS OF PARATHYROID GLANDS

- Anatomy of parathyroid glands
- Physiology of parathyroid glands
  - Calcium metabolism: regulation
  - Vitamin D metabolism: regulation
- Hyperparathyroidism
  - Primary hyperparathyroidism
  - Secondary hyperparathyroidism
  - Tertiary hyperparathyroidism
  - α-Hydroxylase deficiency (vitamin D-resistant rickets)
- Hypoparathyroidism
  - Tetany (tetanic seizure)
  - Pseudohypoparathyroidism
- Neoplastic disorders of parathyroid glands
  - Parathyroid adenoma
  - Parathyroid carcinoma

DISORDERS OF ADRENAL GLANDS

- Anatomy and physiology
  - Adrenal cortex
  - Adrenal medulla
- Adrenal cortex hyperfunctioning
  - Cushing's syndrome
  - Hyperaldosteronism
- Adrenocortical insufficiency
  - Addison's disease
  - Waterhouse-Friderichsen syndrome
  - Adrenogenital syndrome
- Neoplastic disorders of adrenal medulla
  - Pheochromocytoma
  - Neuroblastoma
- Neoplastic disorders of adrenal cortex
  - Adrenocortical adenoma
  - Adrenocortical carcinoma

DISORDERS OF PITUITARY GLAND

- Anatomy and physiology
- Anterior pituitary gland: hypofunctioning
  - Primary hypopituitarism
  - Other causes of hypopituitarism
- Posterior pituitary gland: hypofunctioning
  - ADH deficiency
    - Central diabetes insipidus
    - Nephrogenic diabetes insipidus
- Syndrome of inappropriate ADH secretion (SIADH)
- Neoplastic disorders of pituitary gland
  - Pituitary adenomas
  - Lactotroph adenoma (prolactinoma)
  - Somatotroph adenoma
  - Corticotroph adenoma
  - Mixed somatotroph–lactotroph adenoma
  - Craniopharyngioma

DISORDERS OF ENDOCRINE PANCREAS

ENDOCRINE PANCREAS: EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

EMBRYOLOGY OF PANCREAS

The pancreas is formed during embryonic development from two pancreatic buds that originate from the duodenal part of the foregut of endodermal origin.

- The pancreas development results from rotation of the ventral bud and the fusion of the two buds.
  - Ventral pancreatic bud gives rise to main pancreatic duct, uncinate process, and head of the pancreas.
  - Dorsal pancreatic bud ultimately gives rise to accessory pancreatic duct, the body, isthmus and tail of the pancreas.
- Annular pancreas is a congenital condition in which the head of the pancreas surrounds the second portion of the duodenum, which may be associated with duodenal atresia. Infants present with feeding disorders and growth retardation.

ANATOMY OF PANCREAS

Pancreas is a compound gland with exocrine and endocrine functions. Pancreas consists of the head, neck, body and tail. The widest part is the head, which is attached to the first part of small intestine, known as the duodenum through which pancreatic duct of Wirsung.

- Pancreas has a rich blood supply, with blood vessels originating as branches of both celiac artery and superior mesenteric artery.
- Pancreas receives parasympathetic innervation from the vagus nerve and sympathetic innervation from the greater and lesser splanchnic nerves (T5–T12).

PHYSIOLOGY OF PANCREAS

Pancreas has two main functions: (a) **exocrine function** helps in digestion by releasing peptidases, lipases and amylase into the duodenum; and (b) **endocrine function** regulates blood sugar by releasing hormones such as insulin (β cells 60%), glucagon (α cells 25%) and somatostatin (δ cells 10%) of islets of Langerhans. Islets of Langerhans constitute 1–2% of pancreatic tissue (Fig. 26.1). Flowchart demonstrates actions of insulin and glucagon on glucose, lipid and protein metabolism (Fig. 26.2).

Pancreatic Islets of Langerhans

The pancreatic islets of Langerhans contain endocrine hormone producing cells. These cells constitute 1–2% of the pancreas volume. Islets of Langerhans cells secrete glucagon (α cells), insulin (β cells) and somatostatin (δ cells), which regulate glucose, lipid and protein metabolism.

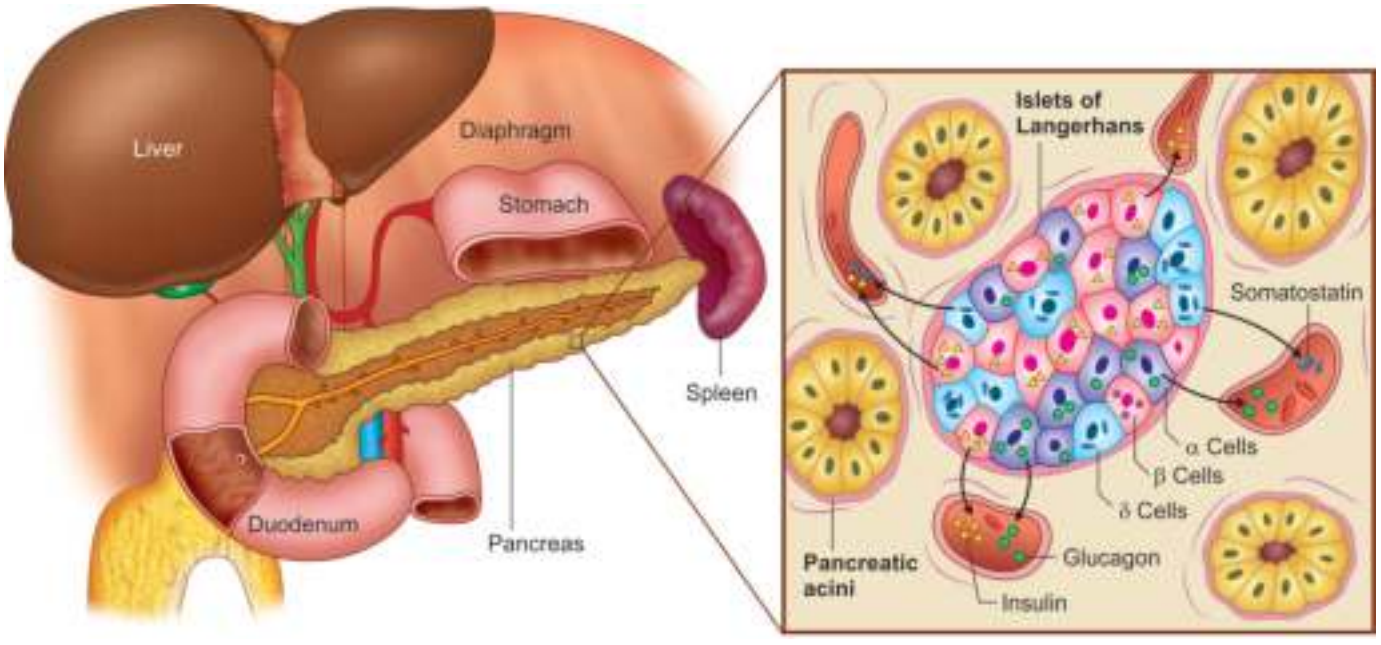

Fig. 26.1: Pancreas demonstrates arrangement of α, β and δ cells of islets of Langerhans. These cells secrete glucagon (α cells), insulin (β cells) and somatostatin (δ cells).

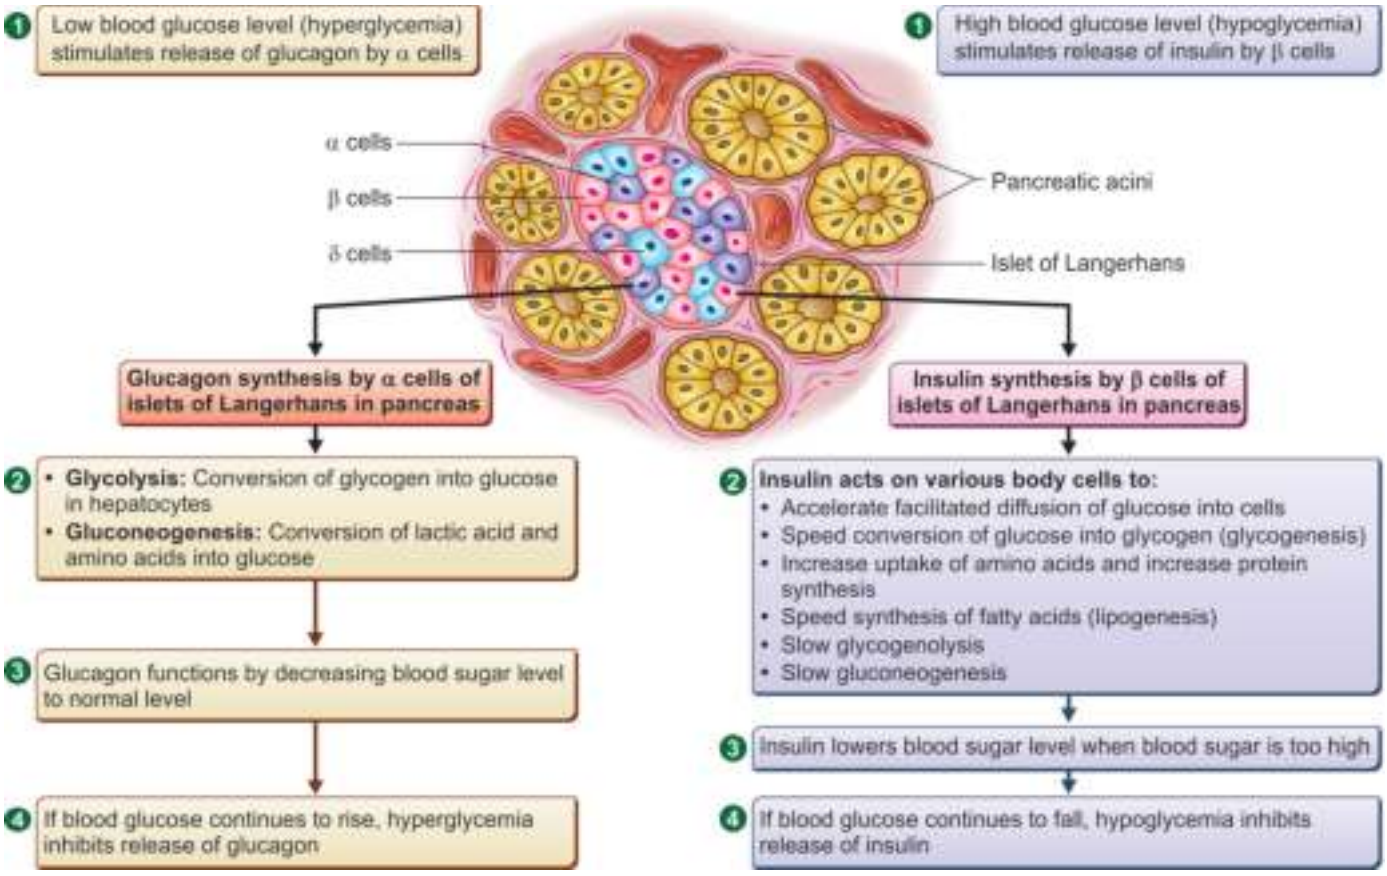

Fig. 26.2: Flowchart demonstrates actions of insulin and glucagon on glucose, lipid and protein metabolism.

α Cells of Islets of Langerhans

Under hypoglycemic state, α cells secrete glucagon that increases blood glucose levels. Hyperglycemia inhibits release of glucagon. Glucagon acts on liver and adipose and causes hyperglycemia by breaking down of glycogen into glucose (glycogenolysis) and making glucose derived from lipids or proteins in the liver (gluconeogenesis). Functional effects of glucagon on blood glucose in tissues are given in Table 26.1.

β Cells of Islets of Langerhans

β Cells of islets of Langerhans are situated around capillaries within pancreatic lobules, which synthesize insulin. Hyperglycemia stimulates synthesis of insulin that acts on liver, adipose tissue and skeletal muscles. Insulin synthesis and its actions are given in Table 26.2.

- **Glucose metabolism:** Insulin facilitates diffusion of glucose into the cells and coverts glucose into glycogen (glycogenesis) by glucose synthase enzyme in liver and thus decreases blood sugar levels. Insulin inactivates liver phosphorylase enzyme that causes liver glycogen to split into glucose and this step prevents breakdown of the glycogen that has been stored in the hepatocytes. Insulin increases the activity of the glucokinase enzyme that causes initial phosphorylation of glucose after it diffuses into the

Table 26.1 Functional effects of glucagon on blood glucose in tissues

Metabolic Effects	Target Organ	Target Enzyme
↑Glycogen breakdown (Glycogen → Glucose)	Liver	↑Glycogen phosphorylase
↓Glycogen synthesis	Liver	↓Glycogen synthase
↓Glycolysis	Liver	↓Phosphofructose 1
↑Gluconeogenesis	Liver (amino acids, glycerol and oxaloacetate → glucose synthesis)	▪ ↑Fructose-1,6-bisphosphatase ▪ ↓Pyruvate kinase
↑Fatty acid mobilization	Adipose tissue (less glucose used as fuel by liver and striated muscle)	↑Triacylglycerol lipase

Table 26.2 Insulin synthesis and its actions

Parameters	Comments
Site of synthesis	β Cells in pancreas
Chemical nature	51-amino acids peptide (A chain and B chain)
Biosynthesis	Peptide hormone
Transport in the blood circulation	Insulin dissolved in the plasma
Half-life of insulin	5–9 minutes
Insulin degradation	Maximum insulin is degraded by insulinase enzyme in liver and least in vascular endothelium
Insulin release inducing conditions	▪ ↑Blood glucose level (>100 mg) ▪ ↑Blood amino acids ▪ ↑Gastrointestinal tract hormones ▪ ↑Parasympathetic activity ▪ ↓Sympathetic activity
Target cells/tissues	▪ Liver ▪ Skeletal muscle ▪ Adipose tissue ▪ Brain ▪ Kidney
Target insulin receptor on cells/tissues	Cell membrane receptor with tyrosine kinase activity; insulin signaling pathways by binding insulin to its insulin-receptor substrate (IRS)
Insulin action on cells/tissues	▪ Carbohydrate metabolism • ↑Glucose uptake by cells/tissues via GLUT4 • ↑Glycogen synthesis (glucokinase, glycogen synthase, phosphorylase) • ↓Glycogenolysis • ↓Gluconeogenesis ▪ Lipid metabolism • ↑Lipogenesis (↑triglyceride, fatty acids and cholesterol synthesis) • ↓Lipolysis, ↓ketogenesis by HMG-CoA synthetase • ↑Utilization of acetyl-CoA in Krebs's cycle ▪ Protein metabolism • ↑Transcription of proteins • ↑Amino acids uptake

hepatocytes and the phosphorylated glucose cannot diffuse back through the cell membrane.

- **Lipid metabolism:** Insulin promotes the uptake of fatty acids and synthesis of fatty acids (lipogenesis), whilst inhibiting metabolic breakdown of lipids (lipolysis). Recent studies indicate that lipid synthesis requires an increase in the transcription factor steroid regulatory element-binding protein-1c (SREBP-1c) due to unknown mechanism. Insulin inhibits lipid metabolism through downregulating cellular concentrations of cAMP by a cAMP specific phosphodiesterase in adipocytes.
- **Protein metabolism:** Insulin increases uptake of amino acids and promotes protein synthesis by liver. Insulin inhibits breakdown of proteins.

δ Cells of Islets of Langerhans

δ Cells secrete somatostatin hormone, that inhibits the release of insulin from β cells of islets of Langerhans. Somatostatin also inhibits the release of growth hormone from anterior pituitary gland. Somatostatin decreases secretion, motility and absorption in the digestive tract.

INSULIN HORMONE

Insulin is synthesized by β cells in the pancreas via transcription and translation of DNA into mRNA and amino acid chains (polypeptide chains). Thereafter, the protein undergoes structural changes to achieve its final form. Insulin synthesis is regulated by several mechanisms: glucose stimulates nuclear translocation of PDX-1 → PDX1-1+RIPE3b1/MAFA binding → transcription regulation (insulin gene) → mRNA formation → mRNA stability → translation regulation of mRNA to polypeptide chains → regulation of post-translational modifications and formation of quaternary structure.

INSULIN SYNTHESIS

Insulin is synthesized by β cells of islets of Langerhans in pancreas. Insulin messenger RNA is translated as a single chain precursor in inactive form called preproinsulin. Thereafter the removal of its signal peptide during insertion into the endoplasmic reticulum

generates proinsulin. Synthesis of human insulin is shown in Fig. 26.3.

- **Proinsulin:** Proinsulin has 82 amino acids consists of three domains: (a) a carboxy-terminal A chain (21 amino acids), (b) an amino-terminal B chain (30 amino acids), and (c) a connecting peptide in the middle known as the C peptide. Chain A and chain B are linked by two disulfide bridges (Cys7A–

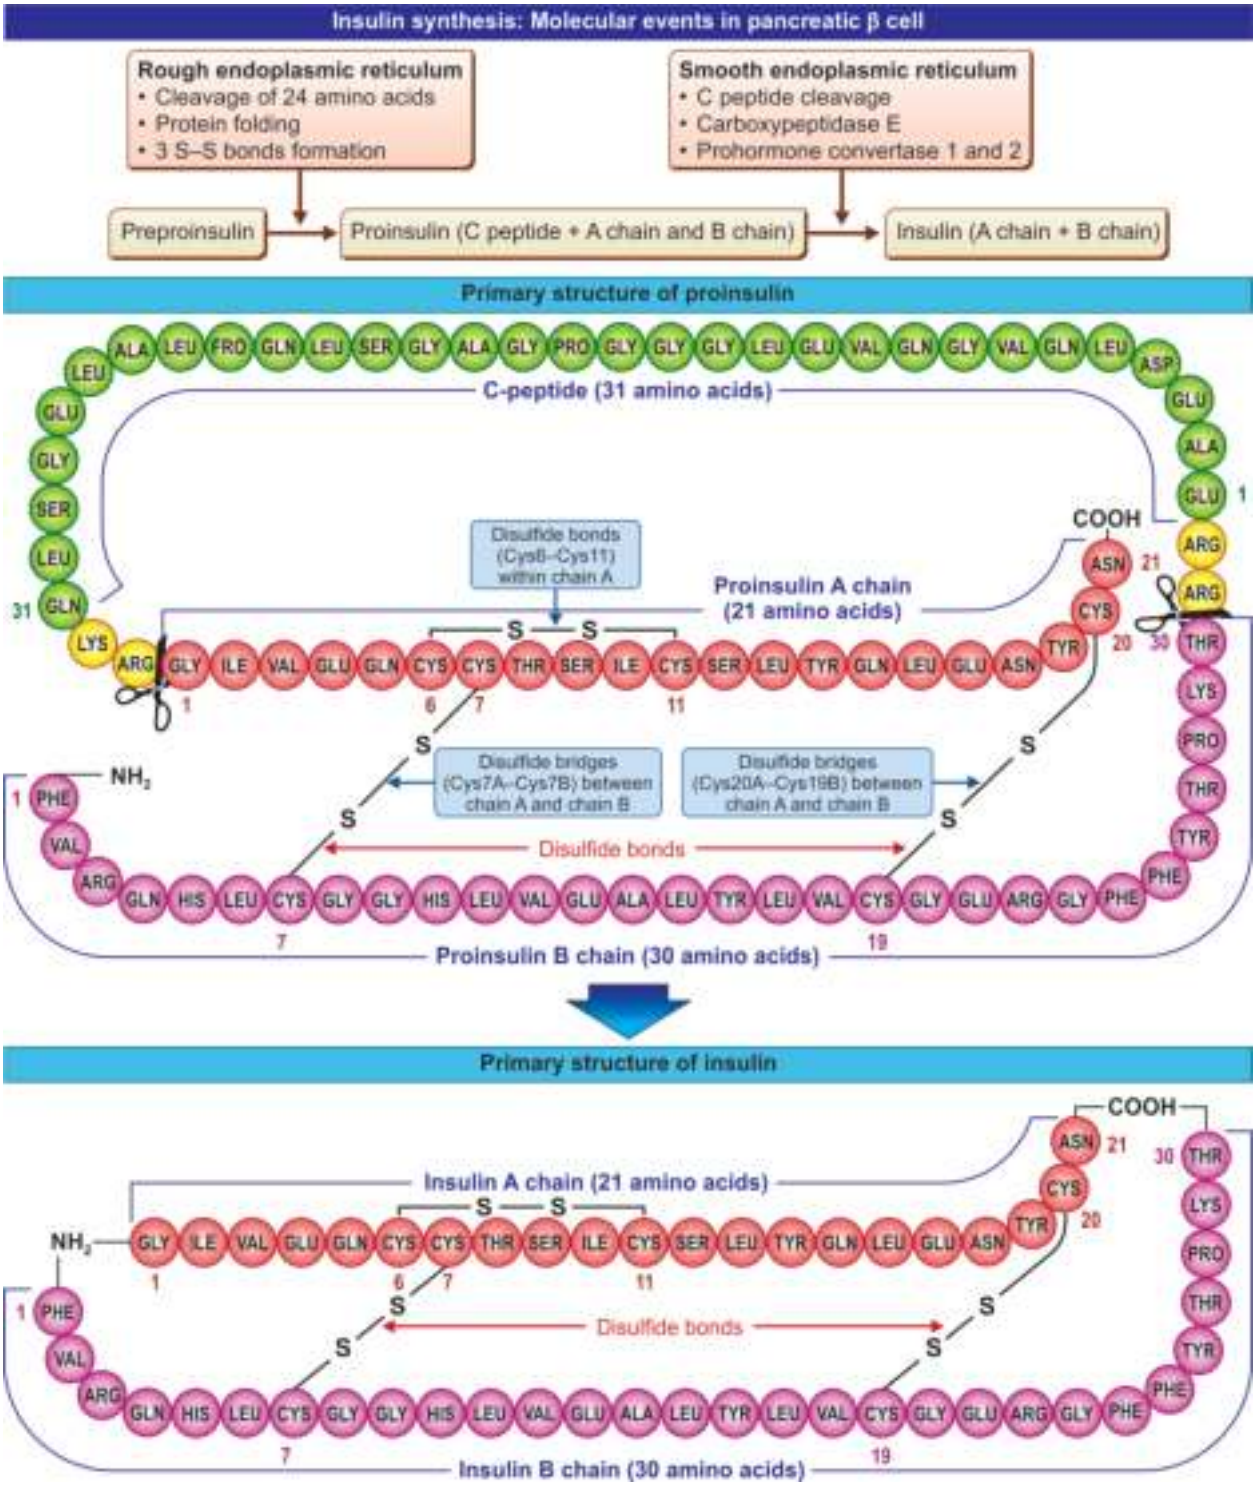

Fig. 26.3: Synthesis of human insulin. Proinsulin is an 82-polypeptide hormone consisting of C peptide (31 amino acids), chain A (21 amino acids) and chain B (30 amino acids) linked by two disulfide bonds (Cys7A–Cys7B/Cys20A–Cys19B). One more intrachain disulfide bond is located between Cys20A and Cys19B between chain A and chain B. Proinsulin is exposed to several specific endopeptidases which excise the C peptide, thereby generating mature form of insulin distributed only in extracellular compartment. Human insulin consists of chain A (21 amino acids) and chain B (30 amino acids) linked by disulfide bonds.

Cys7B/Cys20A–Cys19B). One or more intrachain disulfide bonds is located between Cys6 and Cys11 within the A chain.

- **Proinsulin conversion to mature insulin:** Within the endoplasmic reticulum, proinsulin is exposed to several specific endopeptidases, which excise the C peptide, thereby generating mature form of insulin distributed only in extracellular compartment of islets of Langerhans. Insulin and free C peptide are packaged in the Golgi apparatus into secretory granules, which accumulate in the cytoplasm of the β cells in the pancreas.
- **Mature insulin:** Mature insulin is a protein composed of two chains: (a) A chain with 21 amino acids and (b) B chain with 30 amino acids, which are linked together by sulfur atoms.

INSULIN RELEASE

When the β cell in pancreas is appropriately stimulated in response elevated blood glucose levels, insulin is secreted and released from the cell by the process of exocytosis. The insulin then diffuses into blood vessels of the pancreas. The 'C peptide' is also secreted into the blood circulation, but has no known biological activity. Insulin release from the pancreatic β cell in response to hyperglycemia is shown in Fig. 26.4.

- **Insulin release:** Glucose is transported into the pancreatic β cells via glucose transporter 'GLUT2' in an insulin-independent mechanism of concentration gradient. Then glucose is phosphorylated by glucokinase to glucose-6-phosphate, that takes part in the metabolic process to generate ATP. Elevated ATP level triggers accumulation of K^+ ions along with membrane depolarization. Membrane depolarization then activates Ca^{++} channels resulting in increased intracellular concentration of Ca^{++} ions inside the β cell and consequent release of insulin along with C peptide from the vesicles by the process of exocytosis and diffuses into capillary blood around islets of Langerhans. C peptide molecule is also secreted into the blood, but has no known biological activity.
- **Insulin degradation:** Maximum insulin entering portal vein from pancreas is degraded in the liver

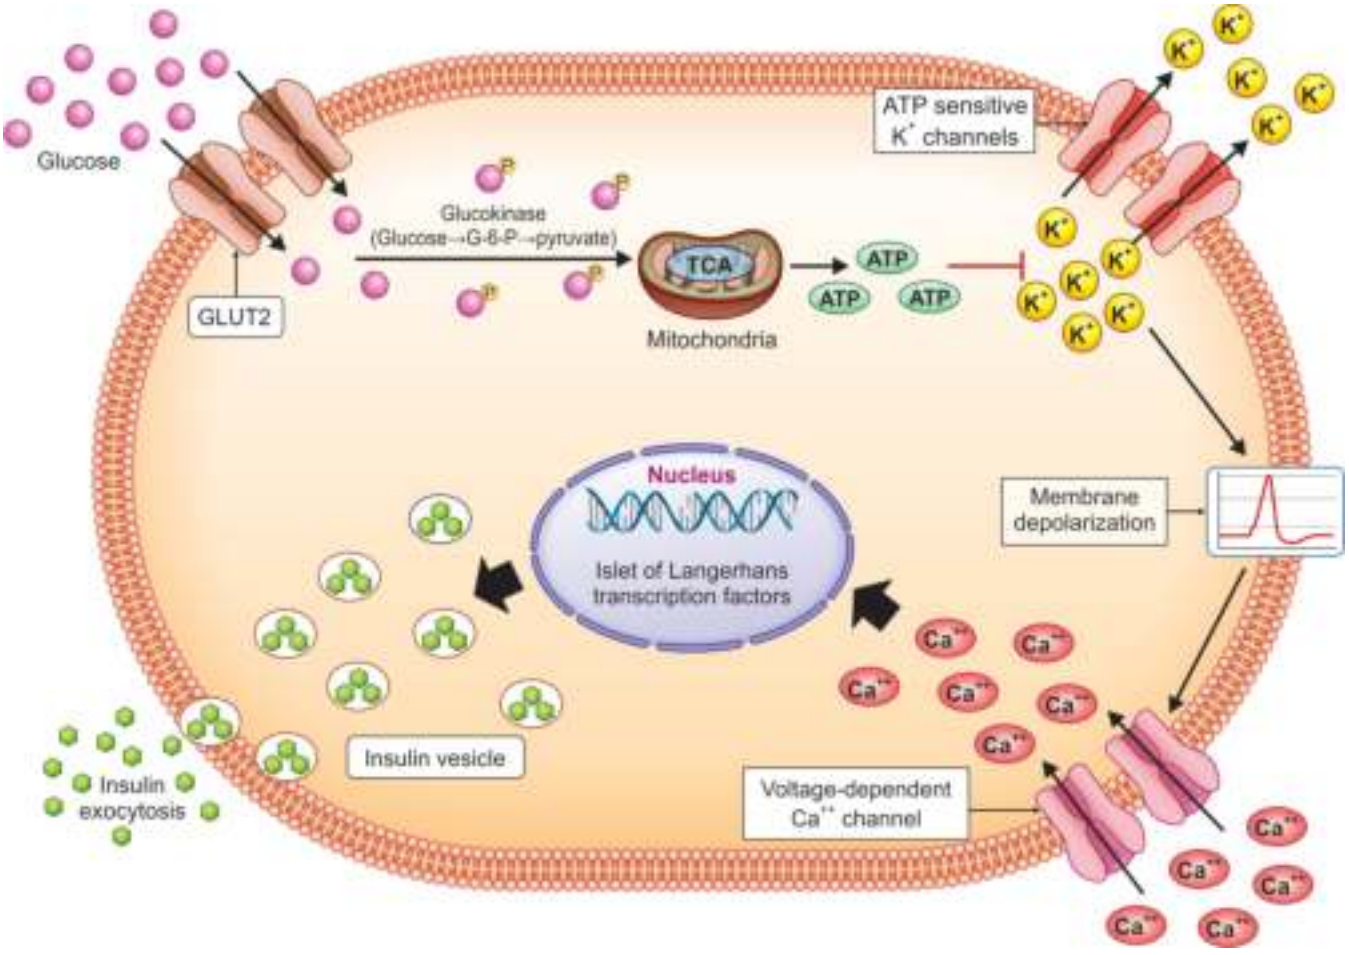

Fig. 26.4: Insulin release from the pancreatic β cell in response to hyperglycemia. Pancreatic β cell releases insulin in response to hyperglycemia in the extracellular fluid bathing the β cells. Insulin release is stimulated by growth hormone, cortisol, prolactin and the gonadal steroids.

and least in the vascular endothelium. During biotransformation, the sulfide bonds are reduced. A and B chains of insulin are separated and further broken down to the constituent amino acids. Half-life of the mature insulin is 5–9 minutes.

- **C peptide analysis:** 'C peptide' analysis in blood is used to analyze endogenous insulin synthesis and to differentiate type 1 diabetes mellitus from type 2 diabetes mellitus. Type I diabetes mellitus is characterized by the body's inability to produce insulin due to the autoimmune destruction of the β cells of islets of Langerhans in the pancreas. Type 2 diabetes mellitus is characterized by lack of functional response to insulin in tissues and/or insulin deficiency. Blood concentration of C peptide in type 1 and type 2 diabetes mellitus is given in Table 26.3.

INSULIN ACTIONS

Insulin is a peptide hormone that predominantly functions to reduce blood glucose concentration. It is synthesized by pancreatic β cells of islets of Langerhans in response to elevated nutrients in the blood. Insulin triggers the uptake of glucose, amino acids and lipids into liver, striated muscle and adipose tissue, and promotes the storage of nutrients in the form of glycogen, proteins and lipids respectively. Insulin is essential for cell proliferation, metabolism and survival.

- **Insulin receptor substrate (IRS):** The insulin receptor substrate (IRS) is a tyrosine kinase, that functions as an enzyme that transfers phosphate groups from ATP to tyrosine residues on intracellular target proteins, which in turn phosphorylation of target intracellular proteins alters its activity, thereby generating a biologic response in maintaining basic cellular functions such as growth, survival and normal homeostasis of glucose, fat and protein metabolism. At least four mammalian insulin receptor substrate molecules are well studied (IRS1, IRS2, IRS3, IRS4).
- **Binding of insulin-to-insulin receptor substrate (IRS):** When insulin binds to its receptors on target cells (e.g. skeletal muscle cells and adipocytes, a signaling cascade is initiated by phosphorylation of target intracellular proteins, which culminates in the translocation of the glucose transporter type 4 (GLUT4) from intracellular vesicles to the cell membrane. Once GLUT4 is incorporated into the plasma membrane, it functions to promote the uptake of extracellular glucose and glycogen synthesis, which is then stored as glycogen in the skeletal muscles and adipocytes, thereby regulating blood glucose. Most common GLUT family of glucose transporters is given in Table 26.4.
- **Insulin actions:** Insulin regulates blood sugar concentration through gluconeogenesis (*de novo* glucose production) and glycogenolysis (glycogen breakdown) in the liver. Besides regulating blood sugar concentration, insulin also plays essential role in facilitating synthesis of proteins and lipids; and preventing conversion of protein and lipids to glucose (gluconeogenesis). Metabolic functions of insulin in tissues/organs are shown in Fig. 26.5 and Table 26.5.
- **Insulin deficiency or insulin resistance:** Diabetes mellitus is a metabolic disorder in which the body does not produce enough insulin or body becomes resistant to its effects and causing abnormally high blood glucose levels. Type 1 diabetes mellitus is characterized by the inability to synthesize insulin, whereas in type 2 diabetes mellitus, the body becomes resistant to the effects of insulin, presumably because of defects in the insulin signaling pathway.

Pathology Pearls: Family of Insulin Receptor Substrates

- **Insulin receptor substrate 1 (IRS1):** IRS1 is predominantly found in the cytoplasm. Tyrosine phosphorylated IRS1 is an intracellular signaling adaptor protein that binds to signaling effectors, activates signaling cascades, integrates and coordinates numerous biologically key extracellular signals within the cell. IRS1 regulates several biological processes including cell proliferation and survival.
- **Insulin receptor substrate 2 (IRS2):** IRS2 belongs to the insulin receptor substrate protein family that is an alternative route for signaling mediated by the insulin receptor. IRS2 mediates mitogenic and antiapoptotic signaling from important cellular receptors. IRS2 regulates important biological processes involved in cell proliferation, metabolism and survival.
- **Insulin receptor substrates 3 and 4 (IRS3 and IRS4):** IRS-3 and IRS-4 play central role in insulin signaling by impairing IRS1 and IRS2.

Table 26.3 Blood concentration of C peptide in type 1 and type 2 diabetes mellitus

Parameters	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
β Cell mass	β Cell mass reduced/ depleted	β Cell mass normal
Endogenous insulin synthesis	Absent or reduced	Normal synthesis of insulin, but peripheral tissue resistance to insulin
Blood C-peptide concentration	Absent/low concentration	Increased concentration

Table 26.4 Most common GLUT family of glucose transporters in human tissues

Glucose Transporter (GLUT) Name	Insulin Sensitivity	GLUT in Tissues	Function(s)
GLUT1	Insulin-independent	RBC membrane, brain barrier, recently identified in human β cells	Basal glucose uptake isoform for cellular metabolism and glucose transport
GLUT2	Insulin-independent	▪ Liver ▪ Pancreatic β cells ▪ Renal proximal tubule ▪ Intestinal cells	▪ GLUT2 removes excess glucose from the blood ▪ GLUT2 regulates insulin in pancreatic β cells ▪ GLUT2 regulates transmembrane glucose transport
GLUT3	Insulin-independent	All tissues	Basal glucose uptake
GLUT4	Insulin-dependent	Skeletal muscles, adipose tissue	Insulin stimulates translocation of GLUT4 to plasma membrane
GLUT5	Insulin-dependent	Small intestine, brain	Primarily fructose transporter

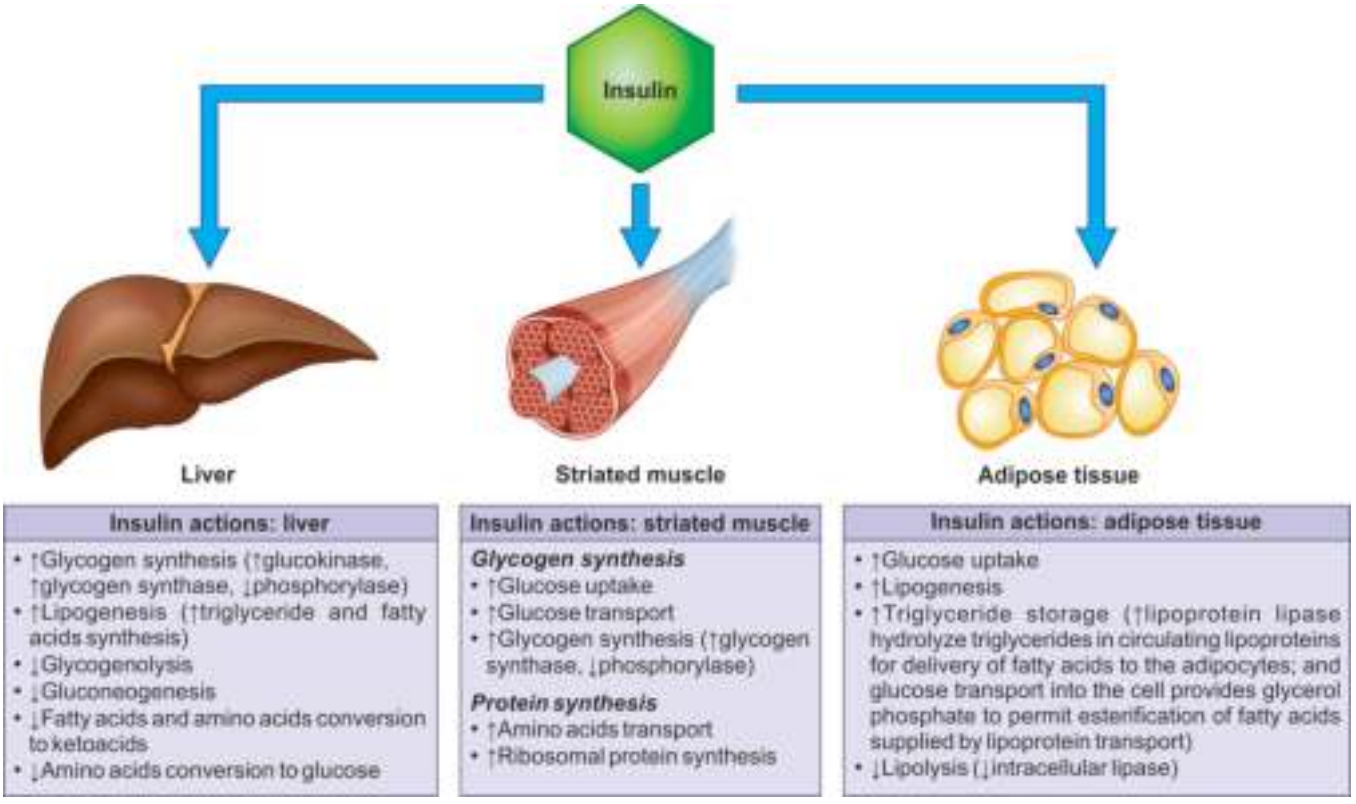

Fig. 26.5: Metabolic functions of insulin in various tissues/organs (liver, striated muscle and adipose tissue).

Table 26.5 Metabolic functions of insulin in tissues/organs

Tissues/Organs	Insulin Actions
Liver	▪ ↑Glycogen synthesis (↑glucokinase, ↑glycogen synthase, ↓phosphorylase) ▪ ↑Lipogenesis (↑triglyceride and fatty acids synthesis) ▪ ↓Glycogenolysis (glycogen → glucose) ▪ ↓Gluconeogenesis ▪ ↓Fatty acids and amino acids conversion to ketoacids ▪ ↓Amino acids conversion to glucose

Contd...

Table 26.5 Metabolic functions of insulin in tissues/organs (*Contd...*)

Tissues/Organs	Insulin Actions
Striated muscle	▪ Glycogen synthesis • ↑Glucose uptake • ↑Glucose transport • ↑Glycogen synthesis (↑glycogen synthase, ↓phosphorylase) ▪ Protein synthesis • ↑Amino acids transport • ↑Ribosomal protein synthesis
Adipose tissue	▪ ↑Glucose uptake ▪ ↑Lipogenesis ▪ ↑Triglyceride storage (↑lipoprotein lipase hydrolyze triglycerides in circulating lipoproteins for delivery of fatty acids to the adipocytes; and glucose transport into the cell provides glycerol phosphate to permit esterification of fatty acids supplied by lipoprotein transport) ▪ ↓Lipolysis (↓intracellular lipase)
Other insulin actions	▪ ↑Gene expression ▪ ↑DNA synthesis ▪ ↑Na^+ and K^+ pump ▪ ↓Apoptosis ▪ ↓Autophagy

Glycolysis is a process of breaking down a glucose molecule in pyruvate, ATP and NADH. Glycogenolysis is the process of breakdown glycogen into glucose.

Pathology Pearls: GLUT Family of Glucose Transporters in Human Tissues

- SLC2 gene codes for a family of GLUT transport proteins thereby cooperatively function to provide a supply of glucose in the direction needed for cell metabolic processes. There are 14 known glucose transporters present in different concentrations in tissues.
- Glucose transporters are stored within cell in membrane GLUT vesicle. When insulin interacts with its receptor, membrane GLUT vesicle moves to surface and fuses with the plasma membrane. GLUT transports glucose inside the cell.
- When insulin level drops, glucose transporter is removed from the plasma membrane by endocytosis forming small GLUT vesicle.
- The small GLUT vesicle fuses with larger endosome. Then patches of endosome enriched with GLUT buds off to become small GLUT vesicle, ready to return to the surface when insulin level rises again.
- Pathophysiologic abnormalities in GLUT transport proteins are associated with type 2 diabetes mellitus, other tissue disorders and cancer.

INSULIN SIGNALING PATHWAYS

Insulin is the major hormone regulating critical energy functions such as glucose, lipid and protein metabolism. The insulin receptor is composed of two extracellular α-subunits and two transmembrane β-subunits linked together by disulfide bonds.

- **Insulin binding to its receptor:** Binding of insulin to the α-subunit of insulin receptor induces a conformational change resulting in the autophosphorylation of a number of tyrosine kinase residues present in the β-subunit. These molecular changes form the binding sites for insulin receptor substrate family adaptor proteins and initiate multiple intracellular signaling pathways leading to diverse metabolic events in almost every tissue.
- **Major insulin signaling pathways:** There are two major routes of intracellular signaling pathways resulting from the insulin-insulin receptor substrate interaction: (a) PI3K (phosphoinositol 3-kinase)/AKT signaling pathway (also known as protein kinase or PKB); and (b) RAS/MAPK signaling pathway (also known as extracellular signal regulated kinase or ERK). Insulin intracellular signaling pathways resulting from the insulin-insulin receptor substrate interaction are shown in Fig. 26.6.
- **Actions of insulin signaling pathways:** PI3K/AKT signaling pathway is linked exclusively through insulin receptor substrate (IRS) and produce insulin's effects in the cells such as synthesis of glycogen, lipids and proteins. RAS/MAPK signaling pathway is involved in regulation of gene expression and in cooperation with PI3K/AKT pathway, also regulates cell proliferation, growth differentiation and survival.

PI3K/AKT Signaling Pathway

Glucose uptake is regulated by several mechanisms, where insulin hormone plays most important role. Insulin regulates the transport of glucose into the cells through translocation of glucose transporter, 'GLUT4' from an intracellular pool in the plasma membrane mainly in metabolically active tissues like liver, skeletal muscle and adipose tissue. GLUT4 translocation occurs through multiple steps of PI3K/AKT signaling pathway.

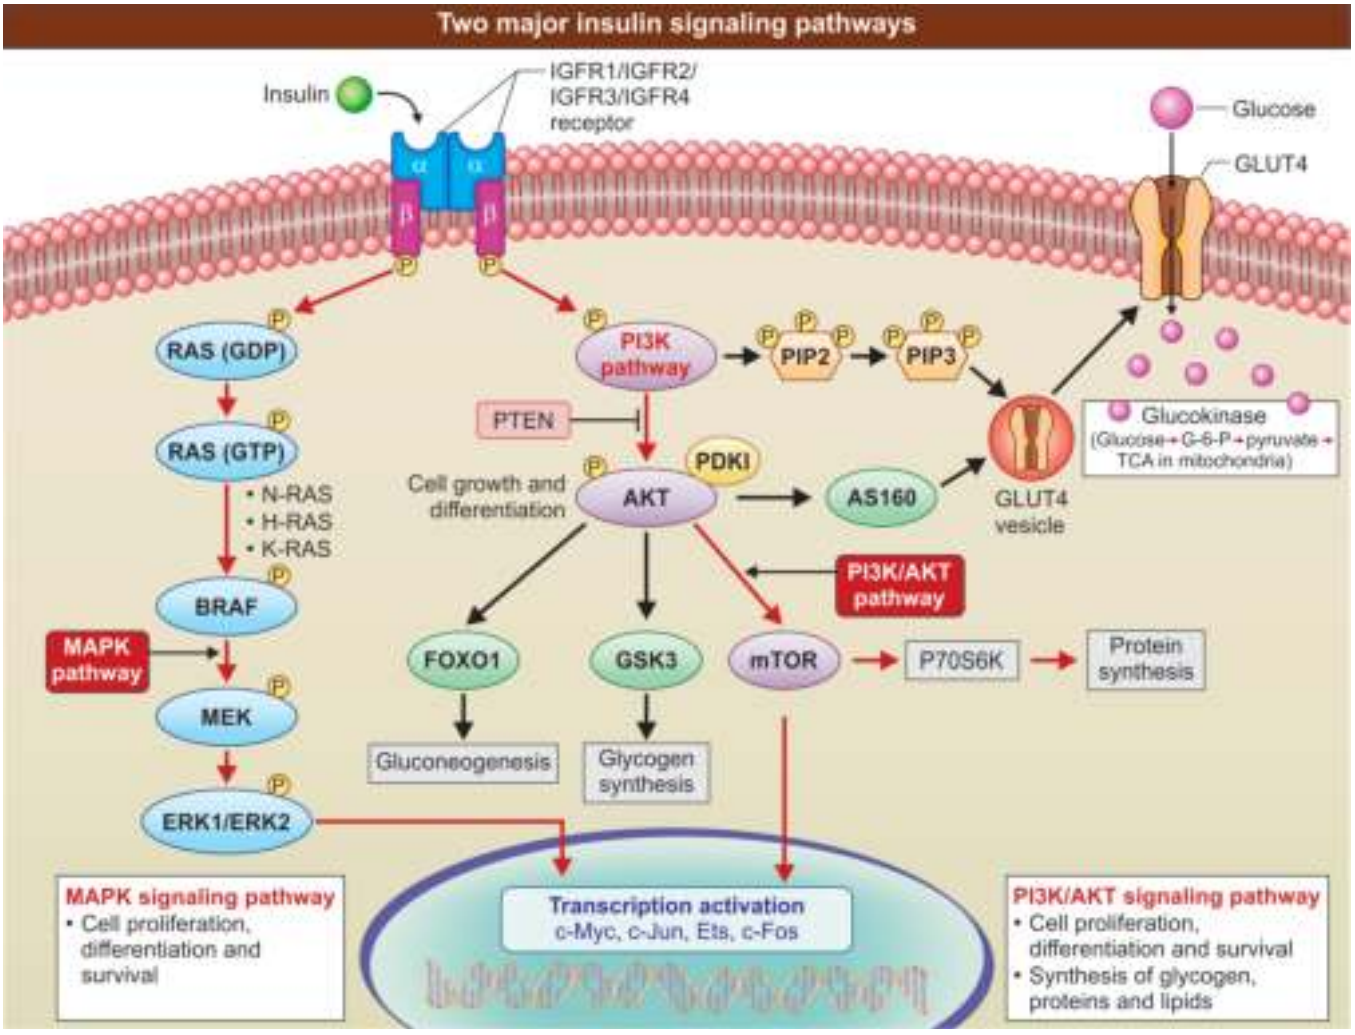

Fig. 26.6: Insulin intracellular signaling pathways resulting from the insulin-insulin receptor substrate (IRS) interaction: (a) PI3K (phosphoinositol 3-kinase)/AKT signaling pathway (also known as protein kinase or PKB) and (b) RAS/MAPK signaling pathway (also known as extracellular signal regulated kinase or ERK) involved in cell proliferation, growth differentiation and survival.

- Insulin binds to insulin receptors via SH2 domains to PI3K (phosphoinositol 3-kinase) regulatory subunits, and triggers dimerization and intracellular autophosphorylation.
- P13 kinase catalyzes the production of PIP3 (phosphatidylinositol 3,4,5-triphosphate) by phosphorylating PIP2 (phosphatidylinositol 4,5-bisphosphate).
- PIP3 is bound to the inner lipid layer of the plasma membrane that recruits and AKT and **PDK1** (phosphoinositide-dependent kinase 1) to the plasma membrane, where phosphorylation of PDK1 occurs. PDK1 then activates serine/threonine residues of AKT, subsequently eliciting phosphorylation of AS-160 substrate protein that stimulates translocation of glucose transporter 4 (GLUT4) vesicles from intracellular pool to the cell membrane surface, thereby increases the insulin-dependent transport of glucose into the cell.
- Activated AKT usually inhibits activity of **GSK-3** (glycogen synthase kinase 3) through phosphorylation of serine 21 in GSK-3 α and serine 9 in GSK-3. AKT promotes MAPK (mitogen activated protein kinase) phosphorylation.
- AKT and GSK-3 (glycogen synthase 3) are serine threonine kinases that cooperatively modulate signaling pathways in the regulation of glycogen synthesis in response to insulin receptor stimulation. Most recent studies indicate that GSK-3 phosphorylates a broad range of substrates, including several transcription factors such as c-Myc, c-Jun and c-Myb and the translator factor elF2B.
- Glycogen synthase (UDP-glucose-glycogen glucosyltransferase) is a key enzyme in glycogenesis, conversion of glucose into glycogen in tissues. Glycogen synthase enzyme is activated by glucose-6-phosphate dehydrogenase (**G6PD**) and inhibited by glycogen

synthase kinase 3 (GSK-3). These two mechanisms play an important role in glycogen metabolism.

- In addition to glycogenesis, insulin downregulates the expression of genes encoding hepatic enzymes, which inhibit gluconeogenesis and glycogenolysis.
- PI3K/AKT signaling pathway regulates synthesis of glycogen, lipids and proteins involved in cell proliferation, growth, differentiation and survival.
- Activated AKT stimulates the activity of translation of initiation factors and upregulates ribosome biogenesis. Insulin stimulates amino acid uptake into cells, inhibits protein degradation and promotes protein synthesis. Upon receipt of insulin signal, inactivation of GSK3 by AKT leads to the dephosphorylation of a guanine nucleotide exchange factor elF2B (a regulator of protein translation), thereby promoting protein synthesis and the storage of amino acids. AKT also activates mammalian target of rapamycin (mTOR), which promotes protein synthesis through p70S6K (p70 ribosomal protein S6-kinase) and inhibition of elf-4EBP1 (eukaryotic translation initiation factor 4E-binding protein 1).
- Aberrant activation of the PI3K/AKT signaling pathway is linked to diabetes mellitus and human cancers.

Pathology Pearls: Insulin-mediated GLUT4 (Glucose Transporter 4)

- Insulin stimulates glucose transport across cell membrane by ATP-dependent translocation of glucose transporter 4 (GLUT4) to the plasma membrane.
- The second messenger PIP3 (phosphatidylinositol 3, 4, 5-trisphosphate) is bound to the inner lipid layer of the plasma membrane and phosphorylated PDK1 (phosphoinositide-dependent kinase 1).
- AKT plays key role in the insulin sensitive translocation of GLUT4 from cytosol to the plasma membrane, especially in skeletal muscles and adipose tissue, thereby increases the insulin-dependent transport of glucose into the cell.
- Over the period of time, insulin also promotes expression of genes directing synthesis of GLUT4.
- Genes encoding large number of enzymes are regulated by insulin through RAS/RAF/MEK/ERK/MAPK and PI3K/AKT signaling pathways.

RAS/RAF/MEK/ERK (MAPK) Signaling Pathway

RAS/RAF/MEK/ERK (MAPK—mitogen-activated protein kinase) signaling pathway is another insulin signaling pathway, which regulates cellular proliferation, differentiation and survival.

- MAPK signaling pathway is activated independently of the PI3K/AKT pathway either through binding of a **Grb2** (growth factor receptor-bound protein 2) to tyrosine-phosphorylated Shc adaptor protein, or through Sh2 adaptor protein binding to insulin receptor. It leads to recruitment of guanine nucleotide exchange factor protein SOS, which promotes the active GTP-bound RAS and subsequent activation of the MAPK signaling pathways.
- Activated RAS-GTP stimulates downstream RAF serine/threonine kinase, the latter proceeds to phosphorylate and activate MEK. Then MEK phosphorylates and activates extracellular signal-regulated kinases (ERK-1 and ERK-2).
  - Activated ERK-1 and ERK-2 are involved multiple cellular processes such as cellular proliferation, differentiation and survival.
  - ERK1/ERK2 act by regulating gene expression as well as extranuclear events such as cytoskeleton reorganization, through the phosphorylation of kinases in the cytoplasm and activation of target proteins in both cytosol and nucleus.
- RAS/RAF/MEK/ERK (MAPK) signaling pathway mediates stimulation of glucose uptake during exercise by elevating the expression levels of glucose transporter 'GLUT4' and increasing PGC1-α activity that entails mitochondrial biogenesis and oxidative metabolism. MAPK signaling pathway regulates cell proliferation, growth, differentiation and survival.

NEGATIVE REGULATORS: TERMINATION OF INSULIN-SIGNALING PATHWAYS

After the insulin acts on its receptor, insulin may be released back into the extracellular environment and then degraded by the cell. Insulin degradation involves endocytosis of the insulin-receptor complex followed by the action of insulin degrading enzymes. Insulin degradation mainly takes place in the liver within one hour after its initial release into blood circulation.

- The enzymes that are important in the attenuation of PIP3 (phosphatidylinositol 3,4,5-trisphosphate) signaling are protein tyrosine phosphatase and family of Src homology 2 containing inositol 5-phosphatase (**SHIP 5-phosphatase**) proteins, which include two gene products, SHIP1 and SHIP2 phosphatases, which degrade PIP3 (phosphatidylinositol 3,4, 5-trisphosphate) and PIP2 (phosphatidylinositol 4, 5-bisphosphate).
- Termination of the insulin-signaling event also occurs when the insulin-insulin receptor substrate (IRS) complex is internalized into endosomes and dephosphorylated leading to its degradation by IDE (insulin-degrading enzyme).

DIABETES MELLITUS

Diabetes mellitus is a metabolic disease characterized by elevated levels of blood glucose, brought about by impaired pancreatic β cell, which leads over time to serious damage to cardiovascular system (heart, brain, blood vessels), kidneys, eyes and nerves. Uncontrolled diabetes mellitus is linked to long-term complications such as atherosclerosis, coronary artery disease (myocardial infarction), cerebral stroke, peripheral vascular disease, nephropathy, retinopathy, and neuropathy.

- Diabetes mellitus is classified as primary or secondary diabetes mellitus. Based on pathogenesis, primary diabetes mellitus can be immune-mediated or nonimmune-mediated mechanism. Secondary diabetes mellitus, there is excess activity of hormones antagonistic to insulin.
- Type 1 diabetes mellitus, once known as juvenile diabetes mellitus or insulin-dependent diabetes mellitus, in which the pancreas produces little or no insulin by itself. Type 2 diabetes mellitus is more common in persons older than 40 years, which occurs when the body becomes resistant to insulin. Diagnostic criteria of diabetes mellitus adapted from the American Diabetes Association are given in Table 26.6.

DIABETES MELLITUS: CLASSIFICATION

Symptoms in diabetes mellitus vary depending on elevation of blood glucose level. Symptoms tend to appear in type 1 diabetes mellitus than type 2 diabetes mellitus. Type 1 diabetes mellitus is an autoimmune disorder that attacks β cells in pancreas leading to little or no insulin production. Type 2 diabetes mellitus happens when body becomes resistant to insulin. Potentially reversible diabetes mellitus conditions include prediabetes and gestational diabetes mellitus (GDM). Classification of diabetes mellitus is given in Table 26.7. Differences between type 1 and type 2 diabetes mellitus are given in Table 26.8.

Prediabetes Stage

Diabetes mellitus evolves through prediabetes stage and is defined as impaired fasting blood sugar and/or impaired glucose tolerance test.

- Person has prediabetes stage if fasting blood glucose is between 100 mg/dl (5.6 mmol/L) and 125 mg/dl (6.9 mmol/L) or if blood glucose level, 2 hours after a oral glucose tolerance test is between 140 mg/dl (7.8 mmol/L) and 199 mg/dl (11.0 mmol/L).
- Prediabetes stage carries high risk for type 2 diabetes mellitus and its long-term complications later in life.
- Reducing body weight by 5–10% through diet and exercise can significantly decrease the risk for diabetes mellitus and its complications later in life.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (formerly called insulin-dependent or juvenile-onset diabetes mellitus) is a chronic metabolic disorder characterized by the body's inability to produce very little or no insulin due to the autoimmune destruction of the >90% of β cells of islets of Langerhans in the pancreas.

- Four autoantibodies are markers of β cell autoimmune destruction in type 1 diabetes mellitus: islet cell antibodies (ICA), against cytoplasmic proteins in the β cell, insulin autoantibodies (IAA), autoantibodies to glutamic acid decarboxylase (GAD-65)

Table 26.6 Diagnostic criteria of diabetes mellitus adapted from the American Diabetes Association (any one of these diagnostic criteria)

Test	Abnormal Blood Glucose Level in Diabetes Mellitus	Comments
Fasting blood glucose	≥126 mg/dl (7 mmol/L)	▪ Fasting is defined as no caloric intake for at least 8 hours ▪ Euglycemic fasting blood sugar is <100 mg/dl (5.6 mmol/L)
Blood glucose OGTT (two-hour oral glucose tolerance test with maximum dose of 75 g)	≥200 mg/dl (11.1 mmol/L)	▪ Euglycemic blood glucose is <140 mg/dl (7.8 mmol/L) ▪ Prediabetic state blood glucose is 140–200 mg/dl
HbA1c (glycated hemoglobin) additional diagnostic criteria	≥6.5%	▪ Glycated HbA1c is formed by nonenzymatic combination of glucose with globin of hemoglobin ▪ Euglycemic HbA1c level is <5.6% ▪ Prediabetes HbA1c level is 5.7–6.4% ▪ Diabetes mellitus (HbA1c level is ≥6.5%)
Random blood glucose	≥200 mg/dl (11.1 mmol/L)	Patient has classical signs and symptoms of diabetes mellitus due to hyperglycemia

- *One of the preceding first diagnostic criteria must be present on a subsequent day to confirm the diagnosis of diabetes mellitus.*
- *In the absence of unequivocal hyperglycemia, fasting blood glucose and HbA1c (glycated hemoglobin) should be confirmed by repeat testing.*

Table 26.7 Classification of diabetes mellitus

Diabetes mellitus due to lack of insulin and/or insulin resistance in tissues
▪ Type 1 diabetes mellitus (juvenile onset insulin-dependent DM): It occurs due to β cell destruction (immune-mediated or idiopathic), usually resulting in absolute insulin deficiency associated with ketoacidosis prone, islet cell autoantibodies, glutamic acid decarboxylase autoantibodies and decreased C peptide. ▪ Type 2 diabetes mellitus (adult-onset non-insulin-dependent DM): It occurs as a result of combination of insulin resistance in peripheral tissues and β cell dysfunction associated with high glycosylated hemoglobin, increased C peptide and increased risk for diabetic retinopathy and absence of glutamic acid decarboxylase autoantibodies ▪ Gestational diabetes mellitus (GSD): It occurs due to insulin resistance in peripheral tissues during pregnancy.
Diabetes mellitus due to genetic defects in β cell function
▪ Maturity onset diabetes mellitus of the young (MODY): It occurs due to mutations in MODY genes include: hepatocyte nuclear factor 4α: (HNF4A, MODY1 in 30–60%), glucokinase (GCK: MODY2 in 30–60%), hepatocyte nuclear factor 1 alpha (HNF1A, MODY3 in 30–60%), pancreatic and duodenal homeobox (PDX1, MODY4), hepatocyte nuclear factor 1 β (HNF1B, MODY5 in 50%) and neurogenic differentiation factor (NEUROD1, MODY6). Other gene mutations such as INS, PAX4, ABCC8, KCNJ11, KLF11, CEL, BLK and APPL1 may also be demonstrated in these patients. ▪ Neonatal diabetes mellitus (NDM): It occurs due to activating mutations in KCNJ11 and ABCC8, encoding Kir6.2 and SUR1 respectively ▪ Maternal inherited diabetes mellitus and deafness (MIDD): It is due to mitochondrial DNA mutations (m.3243A–G) ▪ Diabetes mellitus due to defects in proinsulin conversion to insulin ▪ Diabetes mellitus due to mutations in insulin gene
Diabetes mellitus due to genetic defects in insulin action
▪ Type A insulin resistance diabetes mellitus ▪ Lipoatrophic diabetes mellitus
Diabetes mellitus due to exocrine pancreatic defects
▪ Hereditary hemochromatosis ▪ Chronic pancreatitis ▪ Cystic fibrosis ▪ Pancreatic amyloidosis ▪ Fibrocalculous pancreatopathy ▪ Pancreatectomy/trauma
Diabetes mellitus due to endocrinopathies
▪ Pituitary gland (acromegaly) ▪ Adrenal gland diseases (Cushing syndrome, pheochromocytoma) ▪ Thyroid gland disorders (hyperthyroidism) ▪ Pancreatic carcinoma of α cells (glucagonoma)
Diabetes mellitus due to infections
▪ Mumps ▪ Cytomegalovirus ▪ HIV infections ▪ Coxsackie B virus ▪ Congenital rubella
Diabetes mellitus due to drugs and chemical agents
▪ Glucocorticoids ▪ Thyroid hormones ▪ Thiazide drugs ▪ Cyclosporine ▪ Protease inhibitors ▪ Phenytoin (dilantin) ▪ γ-Interferon ▪ β-Adrenergic agonists ▪ Pentamidine ▪ Vacor

and autoantibodies to protein tyrosine phosphatase in susceptible genotype.

- Genetic and environmental factors are thought to play a role in the onset of the disease, which usually occurs in childhood and young adulthood.

Pathogenesis of type 1 diabetes mellitus is shown in Fig. 26.7.

Predisposing Factors

Although the exact cause of type 1 diabetes mellitus is unknown. However, predisposing factors may signal an increased risk for disease discussed here.

- **Geography:** Certain countries, such as Sweden and Finland, have higher rates of type 1 diabetes mellitus.
- **Environmental factors:** Exposure to environmental pathogens in early life is important for the development of immunity. The lack of early priming of the immune system results in deficient of immunoregulation. If pathogens are encountered at a later stage, autoimmune diseases can be triggered. Several viruses (e.g. mumps, Coxsackievirus and rubella) and the dietary factors (e.g. early exposure to gluten or cow's milk) trigger autoimmune destruction of β cells in pancreas leading to deficient insulin

Table 26.8 Differences between type 1 and type 2 diabetes mellitus

Parameters	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
Prevalence	5–10%	90–95%
Age of onset	Children and adolescents <20 years	Adults >30 years
Type of onset	Rapid (abrupt), symptomatic polyuria, polydipsia, polyphagia often with severe ketoacidosis (fruity odor to breath)	Gradual often symptomatic
Body habitus	Normal, recent loss of weight (usually thin)	Usually obese (80%)
Family history	Uncommon (<20%)	Common (>60%)
Monozygotic twins	50% concordant	90% concordant
HLA association	Present	Absent
Insulin gene VNTR (variable number of tandem repeats)	Present	Absent
Diabetogenic and obesity related candidate genes	Present	Absent
Islet lesions	Early inflammation, late fibrosis and atrophy	Late fibrosis and atrophy
Islet cell autoantibodies	Present	Absent
β Cells mass	Markedly reduced	Normal to slightly reduced
Circulating insulin status	Lack of insulin	Peripheral resistance to insulin
Insulin in blood	Decreased	Normal or increased
C-peptide level in blood	Decreased	Increased
Hyperglycemia	Common	Uncommon
Pathogenesis	T cell cytokines and autoantibodies are formed against pancreatic β cells in resulting to destruction	▪ Decreased insulin receptors on adipose tissue ▪ Post-receptor defects due to abnormalities of tyrosine kinase and glucose transport unit (GLUT4) ▪ Fibrosis of pancreatic β cells occurs due to amyloid deposition
Pathology	▪ Insulitis (T cells and macrophages infiltration) ▪ β Cells depletion ▪ Islet cells atrophy present	▪ No insulitis ▪ β Cells normal in number ▪ Islets cells atrophy absent
Ketoacidosis (fruity odor to breath)	Common	Ketoacidosis rare
Hyperosmolar nonketotic coma	Absent	Present
Laboratory findings	Urine analysis shows presence of ketone bodies	Reactive hypoglycemia occurs due to much insulin is released for a glucose load (early finding)
Management	Insulin absolutely required	Insulin usually not required initially. Insulin may be needed at later stage

production. These patients require insulin therapy for their survival.

- **Genetic predisposition:** Type 1 diabetes mellitus is usually present in persons without a family history. Only 10–15% of the patients have a first- or second-degree relative with the disease. HLA complex polymorphic alleles are responsible for 40–50% of the genetic predisposition to development of diabetes mellitus. The human leukocyte antigen locus on chromosome 6 contributes to type 1 diabetes mellitus in 50% of familial cases. The point mutation in the HLA genes DR3-DQ2 and DR4-DQ8 are present in 80% of children with type 1 diabetes mellitus. The HLA gene DR15-DQ6 is thought to have a protective role in <1% of children. The variable number tandem repeats (VNTR) polymorphism is located in the insulin promoter (INS-VNTR) on the short arm of chromosome 11 and is close to the gene encoding proinsulin. VNTR polymorphism upstream is strongly associated with type 1 diabetes mellitus. Short class 1 alleles are predisposing to diabetes mellitus and the long alleles are protective. CTLA-4 gene

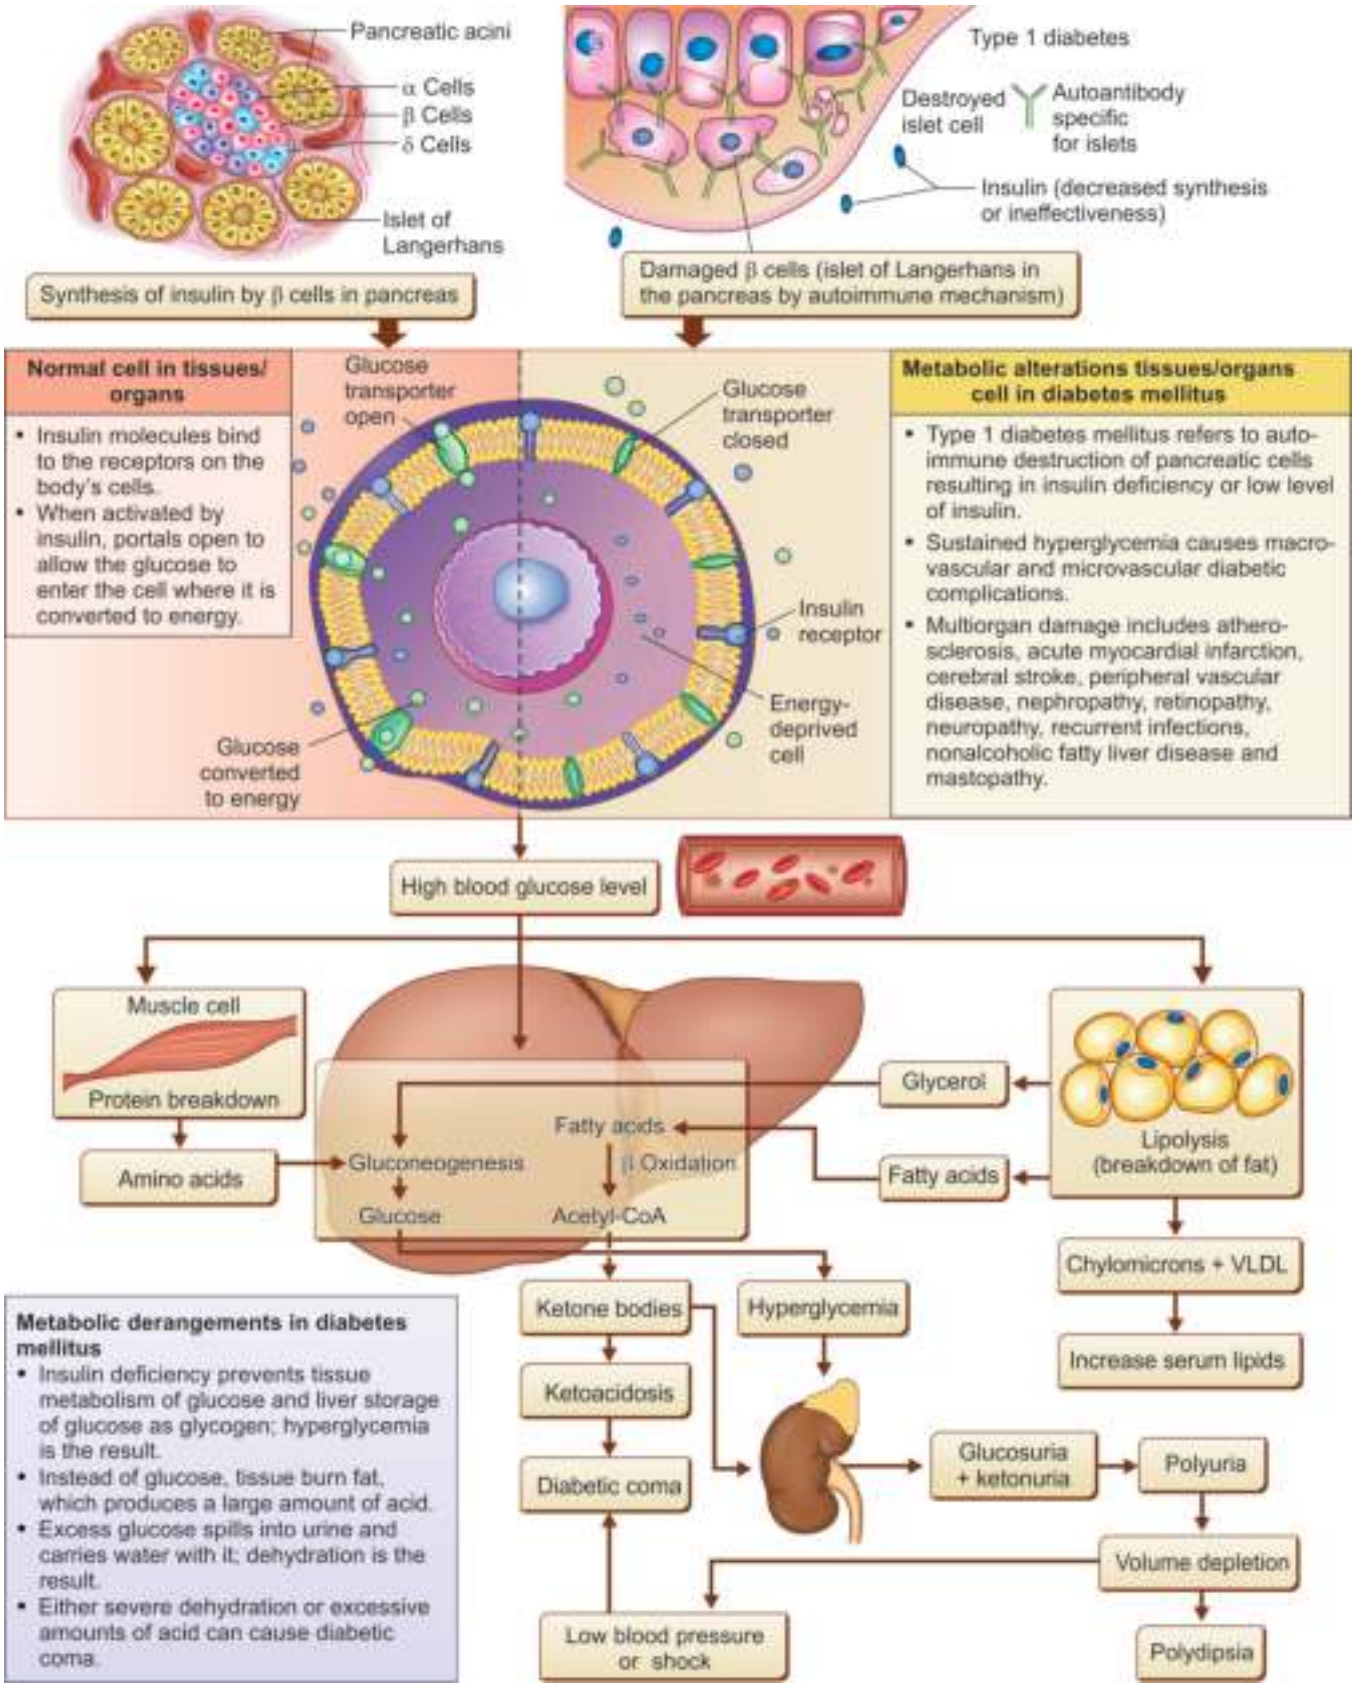

Fig. 26.7: Pathogenesis of type 1 diabetes mellitus. Type 1 diabetes mellitus is thought to be caused by an autoimmune reaction that destroys the insulin making β cells in the pancreas leading to deficient insulin or no insulin production.

(cytotoxic T lymphocyte-antigen-4) polymorphism located on the long arm of chromosome 2 (2q33) may directly influence type 1 diabetes mellitus.

Pathophysiology

Type 1 diabetes mellitus results from the autoimmune destruction of β cells of Langerhans in the endocrine pancreas leading to deficient insulin production. As the β cell mass decline, insulin secretion decreases until the available insulin no longer is adequate to maintain normal blood glucose levels. After 80–90% of the pancreatic β cells are destroyed, before overt type 1 diabetes mellitus becomes evident. On histologic examination, the islets of Langerhans are small with decrease in number or complete absence of β cells. Heavy lymphocytic infiltrate is present within and around islets of Langerhans.

Clinical Features

Unless insulin is replaced in a new case of type 1 diabetes mellitus, patient develops marked carbohydrate intolerance associated with hyperglycemia, resulting to polyuria, polydipsia, dehydration, weight loss, acetone smell and unconsciousness.

- Weight loss occurs due to breakdown of proteins and lipids, despite polyphagia. Osmotic diuresis due to glucose excretion results in dehydration.
- Acetone formed from acetoacetate is exhaled giving acetone smell. Both diabetic ketoacidosis and blood hyperosmolarity impair nervous system function resulting in diabetic coma with fatal outcome.
- Patient may develop flu-like disease, possibly myocarditis due to coxsackievirus infection.

Type 2 Diabetes Mellitus

In type 2 diabetes mellitus (formerly called non-insulin-dependent or adult-onset diabetes mellitus), the pancreatic β cells often continue to produce insulin, however body develops resistance to insulin due to decreased peripheral cell membrane insulin receptors or post-receptor dysfunction.

- As disease progresses, the insulin producing ability of pancreatic β cells decreases. Diabetic ketoacidosis is unusual, but does occur due to unusual stress such as infection and surgical procedure.
- Type 2 diabetes mellitus usually begins in persons older than 30 years and becomes more common in advancing age.

Predisposing Factors

Obesity and sedentary lifestyle accelerate the onset of type 2 diabetes mellitus. Central or visceral obesity (abdominal fat) is strongly linked to insulin resistance. Other predisposing factors for development of type 2 diabetes mellitus include corticosteroid drugs, Cushing syndrome, pregnancy (gestational diabetes mellitus), acromegaly and chronic pancreatitis discussed below.

- **Central or visceral obesity:** Obese persons require very large quantity of insulin to maintain blood sugar levels in type 2 diabetes mellius.
- **Physical inactivity:** Physical inactivity increases risk for type 2 diabetes mellitus. Physical activity helps in weight loss and makes cells more sensitive to insulin.
- **Genetic susceptibility:** Risk increases if a parent or sibling has type 2 diabetes mellitus. Disease incidence is more in monozygotic twins.
- **Race or ethnicity:** Type 2 diabetes mellitus is more prevalent in Blacks, Asian Americans. Indians, Spanish or Latin ancestry compared with White population. Disease can run in families.
- **Advancing age:** Risk for type 2 diabetes mellitus increases as one gets older, because people tend to have less physical activity hence gain weight. However, type 2 diabetes mellitus is also increasing among children, adolescents and young children.
- **Gestational diabetes mellitus:** Pregnant women with gestational diabetes mellitus are at higher risk to develop prediabetes mellitus and type 2 diabetes mellitus. If such pregnant woman gives birth to a baby weighing more than 4 kg, there is increased risk to develop type 2 diabetes mellitus.
- **Polycystic ovary syndrome:** Women suffering from polycystic ovary syndrome present with irregular menstrual cycle, excess hair growth, acne, obesity, greater risk for type 2 diabetes mellitus.
- **Hypertension:** Persons having blood pressure over 140/90 mm Hg is linked to an increased risk for type 2 diabetes mellitus.
- **Abnormal plasma cholesterol and triglyceride levels:** Persons having abnormal plasma cholesterol and triglyceride levels are linked to higher risk for type 2 diabetes mellitus.

Pathophysiology

The β cells of islets of Langerhans in pancreas continue to produce insulin; however, body develops resistance to insulin-mediated by decreased peripheral cell membrane insulin receptors or post-receptor dysfunction. Type 2 diabetes mellitus may be associated with impaired processing of proinsulin to insulin by pancreatic β cells, decreased sensing of glucose by β cells, or impaired function of intracellular carrier proteins. The plasma insulin concentration is normal or increased. On histologic examination, the islets of Langerhans show focal fibrosis and hyalinization due to deposition of amylin, also known as islet amyloid polypeptide (**IAPP**).

- **Peripheral tissue resistance to insulin by NEFAs:** Nonesterified fatty acids (NEFAs) are increased

in liver and striated muscle in obese persons and correlated with peripheral tissue resistance to insulin in type 2 diabetes mellitus. NEFAs intermediate toxic products such as ceramide and diacylglycerol decrease signaling response and thus adversely affect insulin receptors on tissues. Excess of visceral fat accumulation results in altered release of adipokines (i.e. adiponectin, leptin, chemerin, omentin, retinol binding protein 4, resistin, vaspin, and visfatin/PBEF/Nampt), which result in central nervous system-mediated skeletal muscle and hepatic insulin resistance. Leptin stimulates pro-inflammatory cytokines such as IL-6 and TNF-α, that may also reduce insulin sensitivity.

- **β cells dysfunction:** TCF7L2 and other gene alterations cause dysfunctional pancreatic β cells leading to synthesis of more insulin to maintain blood glucose in type 2 diabetes mellitus due to increased resistance to insulin in tissues/organs. Amyloid deposition may be directly toxic to β cells of pancreas.

Treatment

Patient with type 2 diabetes mellitus is managed by diet and oral antidiabetic agents, who does not require insulin therapy. These patients may do reasonably well on diet, exercise and oral hypoglycemic agents for years before they need insulin therapy.

Maturity-onset Diabetes Mellitus of the Young

Maturity-onset diabetes mellitus of the young (MODY) is a monogenic autosomal disorder caused by a single gene mutation that leads to a defect in development of pancreatic islets of Langerhans and impaired insulin secretion in response to glucose stimulation.

- Penetration can vary among family members and the phenotype of MODY is dependent on the gene involved. MODY typically begins before 30 years of persons. Maturity-onset diabetes mellitus of the young is classified on the basis of MODY gene involved. MODY gene mutations affect insulin secretion via impairment of insulin sensing, glucose metabolism in pancreatic β cells, or activation of adenosine triphosphate (ATP)-dependent potassium channels.
- There are about 14 different known MODY mutations which include: hepatocyte nuclear factor 4 α (HNF4A) in MODY1 (30–60%), glucokinase (GCK) in MODY2 (30–60%), hepatocyte nuclear factor 1α (HNF1A) in MODY3 (30–60%), pancreatic and duodenal homeobox (PDX1) in MODY4, hepatocyte nuclear factor 1β (HNF1B) in MODY5 (50%) and neurogenic differentiation factor 1 (NEUROD1) in MODY6. Other mutations in INS, PAX4, ABCC8, KCNJ11, KLF11, CEL, BLK and APPL1 genes may also be demonstrated in these patients. Mutations of several genes adversely affect synthesis of insulin receptors on tissues, insulin binding and intracellular signaling.
- Both HNF1A and HNF4A genes regulate the expression of numerous genes encoding serum proteins such as coagulation factors and apolipoproteins. HNF1A is found in the liver, kidney, intestine and pancreas, which acts by inhibiting the key steps of glucose transport and metabolism as well as mitochondrial metabolism in pancreatic β cells. Glucokinase enzyme enables the β cells and hepatocytes to respond to blood glucose levels. PDX1 is a homeobox-containing transcription factor that affects development of pancreas and insulin gene expression.
- MODY genes associated with various syndromes include: (a) Wolfram syndrome (diabetes mellitus, diabetes insipidus, optic atrophy and deafness), (b) thiamine-responsive megaloblastic anemia, and (c) maternally-inherited diabetes mellitus with sensorineural deafness (MIDD) due to mitochondrial DNA mutations in 3243A–G that results in decreased ATP production leading to diminished insulin release.
- The different MODY gene mutations vary with respect to age of onset, response to treatment and the presence of extra-pancreatic manifestations. Genetic testing for MODY should be performed in cases, where there is a high index of suspicion that the patient does not have type 1 diabetes mellitus or type 2 diabetes mellitus. Genetic defects of maturity-onset diabetes mellitus of the young (MODY) is given in Table 26.9.

Neonatal Diabetes Mellitus (NDM)

Neonatal diabetes mellitus (also known as congenital diabetes mellitus of infancy) occurs due to an underlying monogenic (single gene) defect during first six months of life. Infants do not produce enough insulin leading to an increased glucose accumulation in the tissues.

- **Gene mutations:** NDM occurs due to mutations in KCNJ11 and ABCC8 (affecting the pancreatic β cells K^+ ATP channel). Other gene mutations are also demonstrated in neonatal diabetes that include INS, GATA6, EIF2AK3, GCK, PTF1, FOXP3, ZEP57, GLIS3, PDX1, SLC2A2, SLC19A2, GATA4, NEUROD1, NEUROG3, NKX2-2. RFX6, IER3IP1, MNX1 and HNF1B.
- **Clinical features:** Neonatal diabetes mellitus associated with mutations in KCNJ11 and ABCC8 genes presents with low-birth weight, developmental delay and neonatal diabetes syndrome (DEND syndrome). Monitoring of fetal growth during pregnancy and blood glucose levels in neonates are essential.

Table 26.9 Genetic defects of maturity-onset diabetes mellitus of the young (MODY)

MODY	Genetic Defects	Comments
MODY1	HNF4A (30–60%)	▪ HNF4A (hepatocyte nuclear factor 4 α) regulates expression of genes encoding coagulation factors and apolipoproteins ▪ MODY1 accounts for 30–60% of cases ▪ MODY1 with transient neonatal hypoglycemia, high birth weight and macrosomia
MODY2	GCK (30–60%) (chromosome 7)	▪ GCK (glucokinase) enzyme enables the pancreatic β cells and hepatocytes to respond to blood glucose levels ▪ MODY2 accounts for 30–60% of cases ▪ MODY2 presents with mild and nonprogressive hypoglycemia ▪ Increased risk for macrovascular and macrovascular complications in 10% of cases
MODY3	HNF1A (chromosome 12)	▪ HNF1A (hepatocyte nuclear factor 1 α) is found in the liver, kidney, intestine and pancreas ▪ HNF1A acts by inhibiting the key steps of glucose transport and metabolism as well as mitochondrial metabolism in pancreatic β cells. ▪ MODY3 accounts for 60% cases between 21–26 years of age and responds to oral sulfonylureas and meglitinide drugs
MODY4	PDX1 also known as insulin promoter factor 1 (chromosome 13)	PDX1 (pancreatic and duodenal homeobox 1) is a homeobox-containing transcription factor that affects pancreatic development and insulin gene expression
MODY5	HNF1B (chromosome 17)	▪ HNF1B (hepatocyte nuclear factor 1 β) is found in the liver, kidney, intestine, lungs and ovaries ▪ MODY5 accounts for less than 5% of cases ▪ MODY5 can present with renal cysts. Dysplasia, renal tract malformations or hypoplastic glomerulocystic renal disease. It is sometimes referred to a RCAD (renal cysts and diabetes mellitus) ▪ There can be a progressive loss of renal function independent of diabetic nephropathy ▪ MODY5 patients do not respond to oral hypoglycemic drugs, hence these require insulin therapy
MODY6	NEUROD1 (chromosome 17)	▪ NEUROD1 (neurogenic differentiation factor) is a gene mutation in a basic-loop-helix transcription factor that affects development of pancreas and neurons ▪ MODY6 requires insulin therapy

1. *HNF4A (hepatocyte nuclear factor 4α), HNF1A (hepatocyte nuclear factor 1α), GCK (glucokinase). PDX-1 (pancreatic and duodenal homeobox 1),*
2. *Lipoatrophic diabetes mellitus is accompanied by loss of subcutaneous adipose due to mutation of OPAR-γ.*

Gestational Diabetes Mellitus

Pregnancy associated transient diabetes mellitus is known as gestational diabetes mellitus (GDM) that is usually identified in the 24–28 weeks of gestation. Woman, with GDM, has high-risk for developing type 2 diabetes mellitus later in life.

- During pregnancy, anti-insulin hormones are synthesized by placenta such as estrogen, prolactin, human chorionic somatomammotropin, cortisol, and progesterone.
- Human chorionic somatomammotropin regulates carbohydrate and protein metabolism of the mother to ensure delivery of glucose and protein to fetus for fetal growth. Human chorionic somatomammotropin is also known as chorionic growth hormone-prolactin, and placental lactogen.

Predisposing Factors

Pregnant women can develop gestational diabetes mellitus. Some women are at higher risk than other women.

- **Pregnant women age:** Women older than age 25 are at higher risk for gestational diabetes mellitus.
- **Family and personal history:** Risk for gestational diabetes mellitus increases if women have prediabetes a precursor of type 2 diabetes mellitus or if a close family member such as a parent or sibling has type 2 diabetes mellitus. Women, who had gestational diabetes mellitus during a previous pregnancy or delivered overweight newborn baby are at higher risk for developing gestational diabetes mellitus.
- **Weight:** Overweight women before pregnancy increase risk for gestational diabetes mellitus.
- **Race and ethnicity:** Black pregnant women in Asia or Europe are more likely to develop gestational diabetes mellitus.

Gestational Diabetes Mellitus: Maternal Complications

- **Cesarean delivery:** Due to increased fetal birth weight, there is increased indication of cesarean section in women with gestational diabetes mellitus.

- **Pre-eclampsia and eclampsia of pregnancy and their complications:** Pregnant women can develop pre-eclampsia, eclampsia and its life-threatening complications for both mother and baby.
- **Subsequent gestational diabetes mellitus:** Once the mother has gestational diabetes mellitus, she is more likely develop subsequent gestational diabetes mellitus with next pregnancy.

Gestational Diabetes Mellitus: Complications in Neonates

- **Macrosomia (large baby):** In pregnant women with gestational diabetes mellitus, extra glucose can cross the placenta, which triggers baby's β cells of islets of Langerhans in pancreas to produce more insulin, that can cause baby to grow too large (macrosomia). Such large babies are more likely to require cesarean birth.
- **Low-blood glucose level:** Sometimes babies born in mother with gestational diabetes mellitus develop hypoglycemia shortly after birth because their insulin production is high as a result of pancreatic β cells hyperplasia in response to hyperglycemia and increased demand of insulin during early gestation. Prompt breastfeeding and sometimes an intravenous glucose solution administration can return the baby's blood glucose level within normal range.
- **Higher-risk for type 2 diabetes mellitus:** Babies of mothers who have gestational diabetes mellitus have higher risk for gaining weight and developing type 2 diabetes mellitus. Untreated gestational diabetes mellitus can result in a baby's death either during intrauterine life or shortly after birth.
- **Other newborn complications:** There is increased risk for fetal birth weight, brachial plexus injuries, and neonatal respiratory distress syndrome (hyaline membrane disease).

Diagnostic Approach of Gestational Diabetes Mellitus

Gestational diabetes mellitus is diagnosed with a glucose tolerance test, in which the woman drinks 75 g glucose. Blood glucose level after an hour more than 140 mg/dl is considered positive. The confirmatory test is a 3-hour, 100 g glucose tolerance test in which the blood glucose values are set at highest sensitivity. Urine analysis is done for sugar.

ACUTE DIABETIC COMPLICATIONS

Diabetes ketoacidosis (DKA) and hyperosmolar hyperglycemic state (HHS), also known as hyperosmotic hyperglycemic nonketotic state (HHNK), are the two most serious acute complications of diabetes mellitus. Each represents an extreme in the spectrum of hyperglycemia. Differences between diabetic ketoacidosis and hyperosmolar hyperglycemic state are given in Table 26.10.

Diabetic Ketoacidosis

Diabetic ketoacidosis is mainly a complication of type 1 diabetes mellitus. It produces severe volume depletion due to loss of sodium and water associated with osmotic diuresis and the patient becomes unconscious. Pathophysiology of diabetic ketoacidosis is shown in Fig. 26.8.

Pathophysiology

In the absence of insulin, glucose cannot be used by the body and blood glucose levels rise. The liver responds by increasing hepatic glucose output via gluconeogenesis and glycolysis worsening hyperglycemia.

- Insulin also suppresses lipolysis. In the absence of insulin, fat is consequently broken down to free fatty acids by lipase enzyme. β-Oxidation of fatty acids results into increased production of acetyl-CoA.

Table 26.10 Differences between diabetic ketoacidosis and hyperosmolar hyperglycemic state

Parameters	Diabetic Ketoacidosis	Hyperosmolar Hyperglycemic State (HHS)
Prevalence	Type 1 diabetes mellitus	Type 2 diabetes mellitus
Age	Younger age group	Older age group
Prodromal symptoms appear	Less than 24 hours	Several days
Abdominal pain and Kussmaul respiration symptoms	Present	Absent
Acidosis	Moderate/severe	Absent
Blood glucose	More than 250 mg/dl	High (more than 600 mg/dl)
Serum bicarbonate	Less than 15 mEq/L	More than 15 mEq/L
Blood/urine ketones	++++	+/–
β-Hydroxybutyrate	High	Normal or raised
Arterial blood pH	Low (less than 7.3)	Normal (more than 7.3)
Effective serum osmolarity	Variable	Increased (more than 320)
Anionic gap	More than 12	Variable

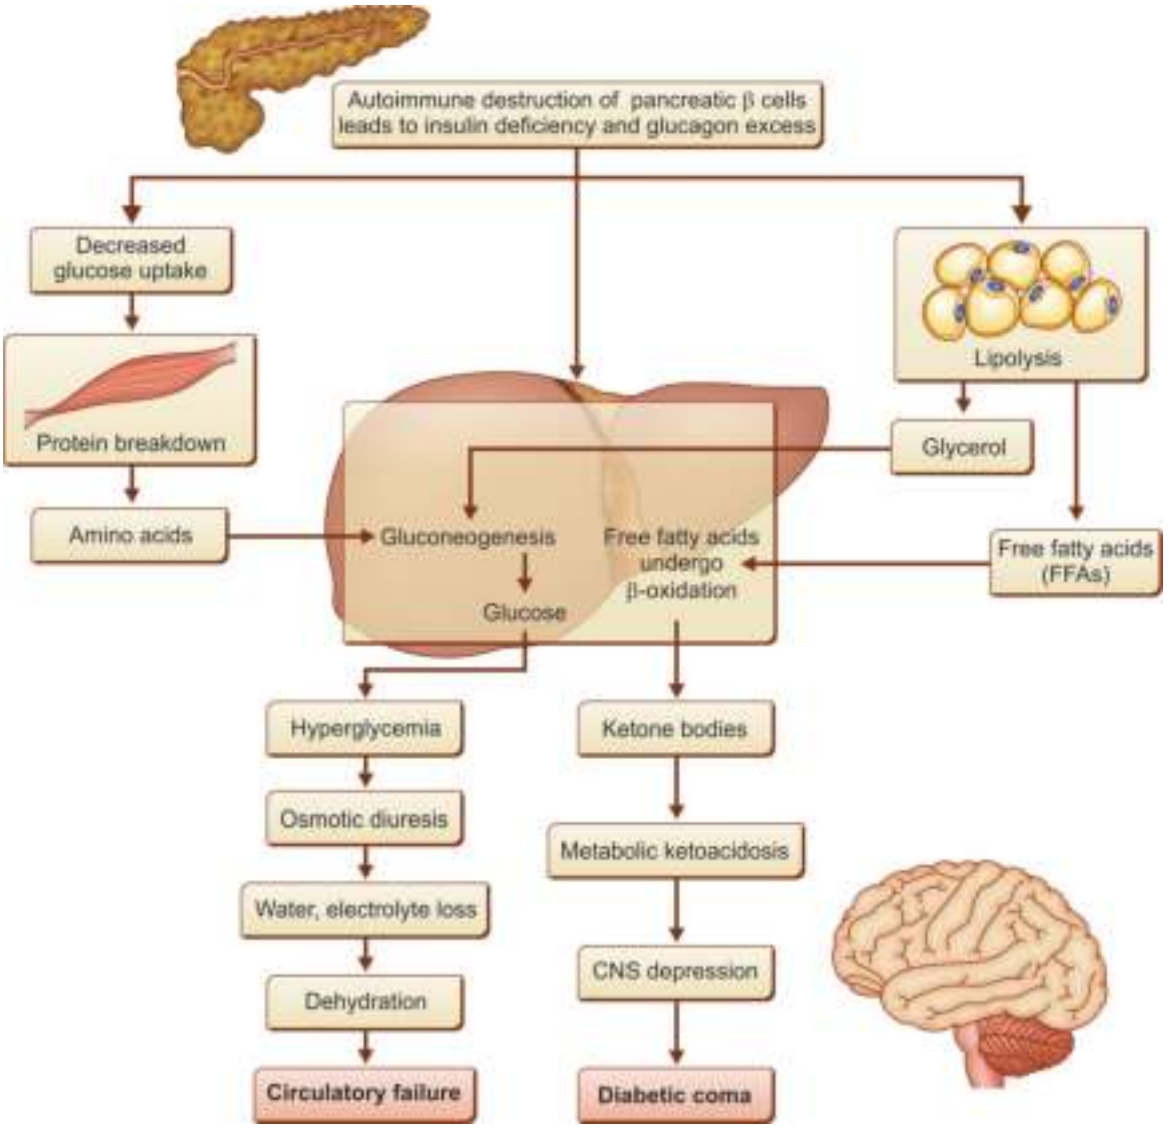

Fig. 26.8: Pathophysiology of diabetic ketoacidosis (DKA). DKA is associated with very low insulin levels and extremely high levels of glucagon, catecholamines, and other counter-regulatory hormones. Increased levels of glucagon and catecholamines lead to mobilization of substrates for gluconeogenesis and ketogenesis by the liver. Gluconeogenesis in excess of that is needed to supply glucose for the brain and other glucose-dependent tissues produces a rise in blood glucose levels. Mobilization of free fatty acids (FFAs) from triglyceride stores in adipose tissue leads to accelerated ketone production and diabetic ketoacidosis.

- Conversion of acetyl-CoA into ketone bodies results into increased production of ketone bodies with acetone-fruity odor (principally β-hydroxybutyric acid, acetoacetic acid along with small quantities of acetone) in liver, giving a fruity odor to the breath. Ketones are acidic and their accumulation results in the life-threatening systemic acidosis. The triad of hyperglycemia, ketosis and acidosis is known as diabetic ketoacidosis.

Clinical Features

Patient with diabetic ketoacidosis develops nausea, vomiting, fatigue, abdominal pain, drowsiness and coma in extreme cases.

- Patient is often profoundly dehydrated at presentation. Breathing tends to become deep and rapid as the body attempts to correct the acidosis. Breath smells fruity odor and nail polish remover.
- Without treatment, patient may progress to coma and death. It is worth mentioning that diabetic ketoacidosis is not limited to type 1 diabetes mellitus, but milder form of ketoacidosis is also seen in prolonged starvation.

Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS) is characterized by severe dehydration and severe hyperglycemia without diabetic ketoacidosis. It is one of the two

most serious metabolic derangements that occurs in diabetic patients. Life-threatening complications are associated with high mortality, if not adequately treated. Predisposing factors include acute infections, glucocorticoids, diuretics and nonadherence to diabetes mellitus treatment.

- **Pathophysiology:** Hyperosmolar hyperglycemic state (HHS) occurs when blood glucose of a person with diabetes mellitus becomes >600 mg/dl for long time. The extra glucose is excreted into the urine, which causes the person to urinate frequently. As a result, patient loses a lot of fluid, which can lead to severe dehydration.
- **Clinical features:** Patient presents with signs of severe dehydration, extreme thirst, dry mouth, frequency of micturition, weakness, leg cramps, blurred vision and an altered level of unconsciousness. Onset of HHS is typically over days to weeks. Complications of HHS include coma, seizures and death.
- **Management:** HHS is diagnosed by blood glucose analysis and serum osmolarity. Patient is treated by intravenous fluids, electrolytes and insulin to control blood sugar levels.

DIABETES MELLITUS AND COMPLICATIONS: CELLULAR METABOLIC SIGNALING PATHWAYS

Diabetes mellitus (DM) is a metabolic disorder that is characterized by hyperglycemia and glucose intolerance. It is associated with impaired insulin secretion and peripheral sensitivity, as well as eventual β cell dysfunction.

- **Diabetes mellitus classification:** Diabetes mellitus is classified into type 1 diabetes mellitus (defects in insulin synthesis), type 2 diabetes mellitus (peripheral resistance to insulin), gestational diabetes mellitus during pregnancy and monogenic diabetes mellitus.
- **Hyperglycemic state:** Hyperglycemia promotes cellular glucose uptake and oxidative metabolism, generation of reactive oxygen species (ROS) and subsequent inhibition of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) enzyme. Additionally, hyperglycemia activates metabolic pathways that eventually promote the release of cytokines such as TGF-β, ICAM-1, VCAM-1, TNF-α, connective tissue growth factor (CTGF) and plasminogen activator inhibitor 1, involved in various diabetic complications.
- **Diabetic complications:** Hyperglycemia activates certain metabolic processes including enzymes and their intermediates that induce diabetic complications such as cardiovascular diseases (coronary artery disease, cerebral stroke, peripheral vascular disease), diabetic nephropathy, diabetic neuropathy, diabetic ocular complications, infectious diseases, skin diseases and nonalcoholic fatty liver disease.

Cellular Metabolic Signaling Pathways

Metabolic pathways are facilitated by enzyme activities of protein kinase C due to diacylglycerol (DAG) synthesis, polyol pathway (sorbitol-aldose reductase pathway), hexosamine biosynthetic pathway (HBP), glucose autooxidation and degradation, as well as being associated with advanced glycated end products (AGEs) synthesis, hexokinase II driven glycolytic overload and enhanced activities of cyclooxygenase (COX) enzyme, lipoxygenase (LOX) enzyme. The inhibition of the enzymes involved in these metabolic pathways and potentially more effective antidiabetic drugs could serve to mitigate and inhibit diabetic complications. Interaction between metabolic pathways leading to diabetic complications is shown in Fig. 26.9.

Protein Kinase C Activation Signaling Pathway

Out of more than eleven isoforms of serine threonine kinases of protein kinase C (PKC) family, PKC activation causes upregulation of extracellular matrix synthesis, cytokines synthesis, contractility, vascular permeability, vascular cell proliferation and cytosolic phospholipase A2; and downregulation of Na^+/K^+ ATPase in diabetic patients. Alterations of metabolic protein kinase C pathway activation cause abnormal retinal hemodynamics resulting disruption in blood retinal barrier (BRB).

- Hyperglycemia is accompanied by PKC activation in heart, retina and renal glomeruli, which eventually escalates complications in diabetic patients.
- Additionally, continuous PKC activation stimulates various growth factors including VEGF (vascular endothelial growth factor), IGF-1 (insulin growth factor 1), PDGF (platelet-derived growth factor), TGF-β (transforming growth factor-β), and HGF (hepatocyte growth factor).

Polyol Pathway Activation (Sorbitol/Aldose Reductase Activation Pathway)

Under physiologic state, glucose is converted to glucose-6-phosphate by hexokinase III. In hyperglycemic milieu the hexokinase II pathway becomes saturated, and rising intracellular glucose level activates aldose reductase (AR) enzyme that eventually converts glucose to sorbitol (alcohol) followed by oxidation of sorbitol to fructose by sorbitol dehydrogenase (SD) enzyme.

- Both aldose reductase and sorbitol dehydrogenase-catalyzed steps involve using nicotinic acid adenine dinucleotide phosphate (NADPH). Once sorbitol is produced, it does not diffuse easily across the cell membrane. Sorbitol permeates the cell membranes

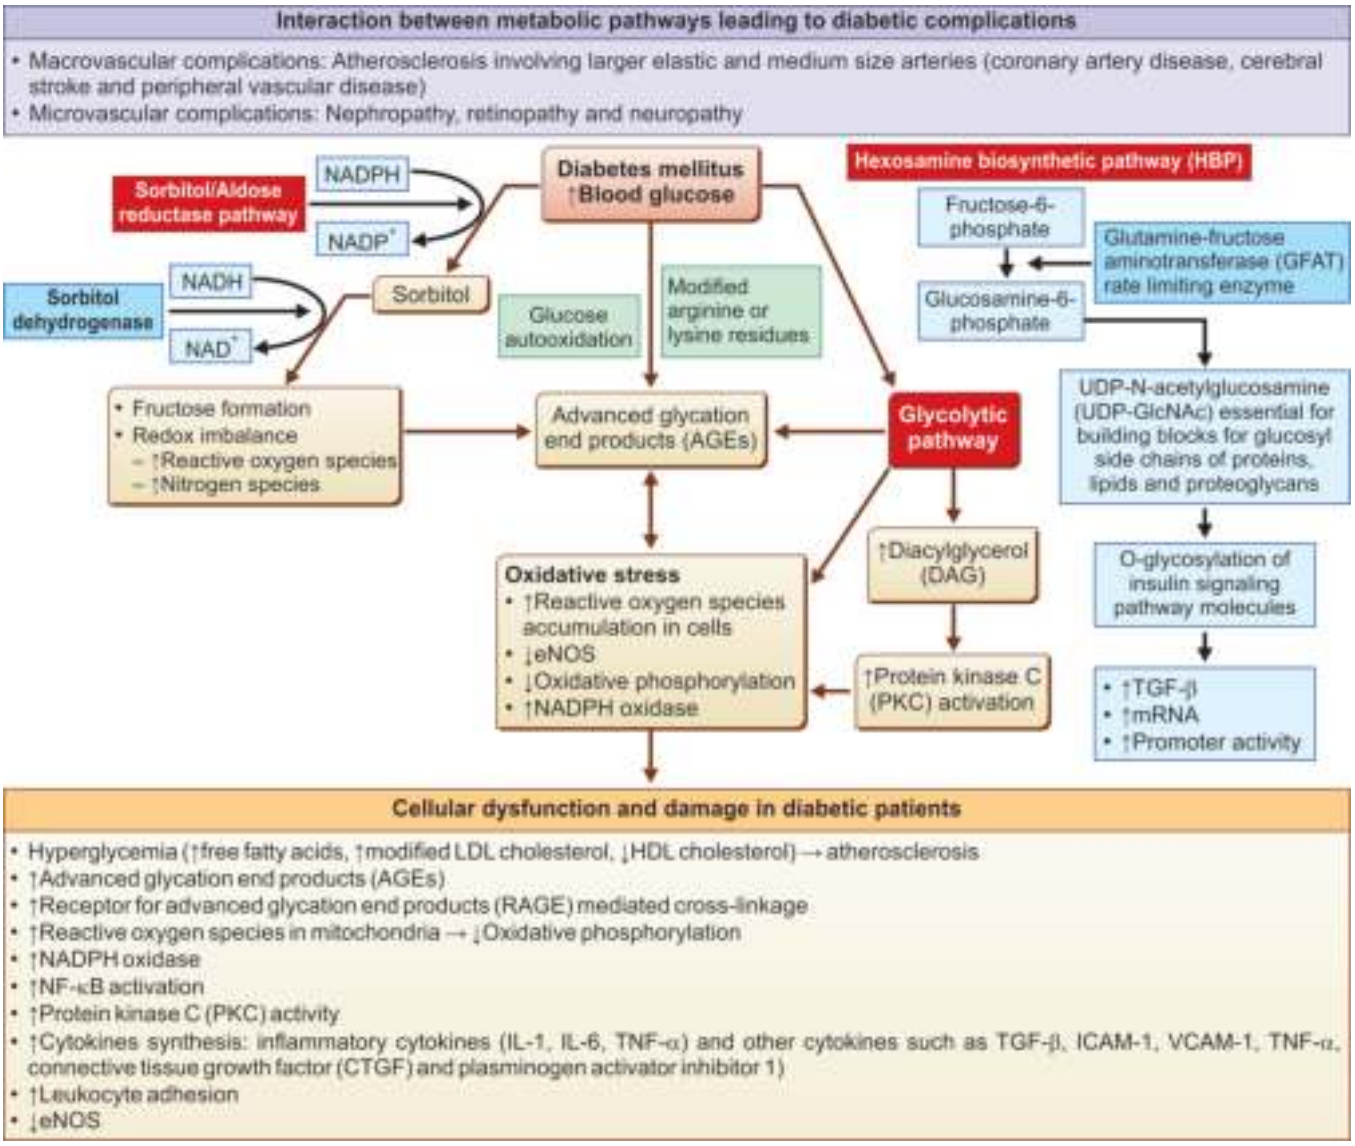

Fig. 26.9: Interaction between metabolic pathways leading to diabetic complications.

leading to disruption of cellular structure and osmotic cell swelling and reduction in ATPase function.

- Sorbitol in hyperglycemic state gives rise to increased intracellular osmolarity, decreases the availability of enzyme cofactor nicotinamide adenine dinucleotide phosphate leading to altered vascular endothelial cell functions that changes the course of leukocyte–endothelial interaction.
- Rising intracellular glucose in hyperglycemic state also directly activates the polyol pathway leading to decreased availability of NADPH (cofactor of GSH), which depletes GSH. It has been reported that NADH produced in the polyol pathway translocates into mitochondria and is oxidized by the respiratory chain, thus generating superoxide oxygen-derived free radicals responsible for diabetic complications.
- Sorbitol also activates pyruvate kinase C (PKC) that plays key role in inducing diabetic complications. Thus, polyol pathway is associated with a vast variety of diabetic complications.

Hexosamine Biosynthetic Signaling Pathway

The hexosamine biosynthetic pathway (HBP) is involved in the development of insulin resistance as well as diabetic vascular complications. It has been demonstrated that transforming growth factor-β (TGF-β) mediated by the hexosamine pathway is involved in the development of diabetic nephropathy.

- Upon cellular uptake of glucose, relatively large glucose concentrations are catabolized and channelized towards glycogenolysis, glycolysis and pentose phosphate metabolism.

- Moreover, a small fraction (2–3%) of glucose molecules is channelized into the hexosamine biosynthetic pathway. Glucose enters insulin-sensitive tissues either by using the insulin-independent glucose transporter (GLUT), and glucose phosphorylating enzyme hexokinase I (HK-I) or with the help of the glucose transporter GLUT4 and hexokinase II (HK-II) is metabolized to hexosamine products in the presence of glutamine (GluN): fructose-6-phosphate amidotransferase (the first and rate-limiting step of hexosamine biosynthetic pathway).
- The end product of hexosamine biosynthetic pathway is uridine diphosphate (UDP)-N-acetylglucosamine (UDP-GlcNAc), which can be covalently linked to serine and threonine residues of specific proteins (O-linked glycosylation) such as insulin signaling molecules and GLUT4. The uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc) is the precursor for the biosynthesis of the essential amino sugars required for the generation of glycoproteins, proteoglycans, glycosaminoglycans and glycolipids.
- The O-linked glycosylation seems to decrease insulin action and GLUT4 translocation leading to insulin resistance diabetes mellitus. O-linked glycosylation can modify the functions of many proteins, including transcription factors.
- With hyperglycemia, some of the excess glucose is shunted into the hexosamine biosynthetic pathway. In addition, increased generation of UDP-GlcNAc could alter gene expression and cellular function through the excess glycosylation of proteins contributing to the pathogenesis of microvascular disease.
- Sustained hyperglycemia induces metabolic pathway through elevation of fructose-6-phosphate concentration, which flows into the hexosamine biosynthetic pathway, that eventually promotes the release of cytokines such as TGF-β, ICAM-1, VCAM-1, TNF-α, connective tissue growth factor (CTGF) and plasminogen activator inhibitor 1 involved in inducing diabetic complications.

Glycolytic/Glucose Auto-oxidation Pathway and Formation of Advanced Glycation End Products (AGEs)

Glycolytic/glucose auto-oxidation regulated by phosphofructokinase 1 (PFK-1) and pyruvate dehydrogenase (PDH) is the primary stimulus for insulin secretion, which plays central role in maintenance of glucose homeostasis. The mutation in mitochondrial DNA that disrupts glycolytic/glucose auto-oxidation signaling pathway has been linked to type 2 diabetes mellitus.

- In hyperglycemic state, glycolytic/glucose auto-oxidation of glucose induces functional damage to proteins via modifications of critical arginine residues. Nonenzymatic modification of proteins, termed advanced glycation end products (AGEs) are derived from dicarbonyl species (i.e. 3-deoxyglucosone, methylglyoxal and glyoxal), which perturb protein function, thus contributing to diabetic vascular complications.
- Reactive dicarbonyl species (i.e. 3-deoxyglucosone, methylglyoxal and glyoxal) bind with arginine and lysine residues, the N-terminal of proteins to produce a Schiff base, subsequent rearrangement of Amadori intermediate α-amino groups products and then production of advanced glycation end products (AGEs) at high rate; and thereby provoke pathogenesis of diabetes mellitus. Unlike glucose modifies lysine residues, reactive dicarbonyl species react preferentially with arginine as well as lysine residues with high reaction rates.
- Advanced glycation end products (AGEs) and their receptors (RAGEs) modulate generation of oxidative stress, enhance release of growth factors and cytokines via NF-κB (nuclear factor kappa-light-chain-enhancer of activated B cells) signaling and stimulate cell adhesion molecules, all of which eventually result in inflammatory response and escalate arteriosclerosis progression. Increased level of advanced glycation end products (AGEs) is linked with unstable angina and myocardial infarction and other diabetic complications.

Clinical Pearls: Drug Inhibitors of Advanced Glycation End Products (AGEs)

Various drugs are administered (e.g. atorvastatin, pravastatin, telmisartan, ramipril, rosiglitazone, exendin 4 and aminoguanidine) to prevent diabetic complications by inhibiting generation of harmful advanced glycation end products.

- **Atorvastatin** is an antioxidant, that acts by blocking the production of AGEs.
- **Pravastatin** acts by reducing destruction of renal tubular cells in diabetic nephropathy, and mitigates cell apoptosis induced by the AGEs.
- **Telmisartan** acts by inhibiting expression of AGEs on renal mesangial cells, endothelial cells and hepatocytes.
- **Telmisartan** and **ramipril** also ameliorate the induction of oxidative stress, inflammation and arteriosclerosis associated with AGEs expression.
- **Rosiglitazone** mitigates the expression of AGEs receptors on tissues.
- **Exendin 4** acts by blocking the interaction between AGEs and their receptors (RAGEs) on tubular cells, thus inhibiting development of diabetic nephropathy.

Hyperglycemia and Cyclooxygenase (COX) Enzyme Activation

The cyclooxygenase enzyme exists in COX-1 and COX-2 isoforms. COX-1 isoform is present in almost all tissues,

whereas COX-2 exists in trace amounts in brain and kidney. Cyclooxygenase 2 (COX-2) enzyme has been implicated in the pathogenesis of several inflammatory diseases.

- Activation of protein kinase C (PKC), oxidative stress, growth factors, inflammatory cytokines and tumor promoters induce synthesis of COX-2. The cyclooxygenase enzyme synthesizes thromboxane A_2 (TXA_2), and prostaglandins (PGI_2, PGD_2, PGE_2).
- Thromboxane A_2 causes vasoconstriction and promotes platelet aggregation. Prostaglandins induce inflammation: (a) prostacyclin (PGI_2) causes vasodilation and inhibits platelet aggregation, and (b) PGD_2 and PGE_2 cause vasodilation and increase vascular permeability.
- Glucose auto-oxidation and aldose reductase (AR) activation pathway leads to increased COX-1, that has been linked to hyperglycemia and onset of diabetes mellitus resulting in diabetic complications. AR activation pathway is accompanied by secondary reduction of nicotinamide adenine dinucleotide phosphate (NADPH) and nicotinamide adenine dinucleotide (NAD), activation of protein kinase C, increased expression of receptor for advanced glycation end products (RAGEs), as well as increased generation of reactive oxygen species (ROS).
- Many studies revealed abundant COX-2 in the coronary arterioles and renal podocytes in diabetic patients. The inhibitory effect of nonsteroidal anti-inflammatory drugs (NSAIDs) on COX-2 has been extensively reported.

Lipoxygenase 12 Enzyme Activation Signaling Pathway

Lipoxygenase enzyme has two isoforms: 12-LOX (ALOX12 gene product) and 5-LOX. The 12-lipoxygenase (LOX) enzyme activated by hyperglycemia inserts molecular oxygen into polyunsaturated fatty acids (arachidonic acid and linoleic acid) to generate 12-hydroperoxyl-eicosatetraenoic acid (12-HPETE) and 12-hydroxyeicosatetraenoic acid (12-HETE). The 12-HPETE plays a critical role in the pathogenesis of diabetic retinopathy, a severe microvascular complication in diabetes mellitus is the main cause of vision loss.

- Emerging evidence has demonstrated that 12-LOX and its main product 12-hydroperoxyl-eicosatetraenoic acid (HPETE) activate retinal vascular endothelial cells through activation of nicotinamide adenine dinucleotide phosphate with hydrogen atom (NADPH) and subsequent generation of reactive oxygen species (ROS), mediating multiple pathologic changes in retinal cells and show their potential as future targets for diabetic retinopathy. Further studies are needed on the specific mechanism including 12-LOX pathway related 12-HETE receptors and downstream signaling pathways.
- Eventually, proinflammatory cytokines induce an elevation of reactive oxygen species (ROS), oxidative stress, and endoplasmic reticulum (ER) stress, which act in an autocrine, paracrine and endocrine manner and cause impairment and apoptosis of β cells of islets of Langerhans leading to development of diabetes mellitus.

Hexokinase II (HK-II) Activation Signaling Pathway Driven Glycolytic Metabolic Products Overload

Hexokinase is the rate-limiting first step of glycolysis that catalyzes the first step of glycolysis involving the phosphorylation of glucose to glucose-6-phosphate.

- Under physiologic state, hexokinase II (HK-II) regulates glucose metabolism and also functions as a protective signaling molecule. Glucose transported through glucose transporters (GLUTs) on the plasma membrane is phosphorylated by hexokinase II isoform to produce glucose-6-phosphate (G6P) in insulin-sensitive tissues such as heart, skeletal muscle, and adipose tissue.
  - Glucose-6-phosphate (G6P) serves as a precursor for glycolysis (ATP) as well as the pentose phosphate pathway (NADPH and ribose-5-P), glycogenesis (glycogen) and hexosamine biosynthetic pathway (UDP-GlcNAc). HK-II therefore plays key role in the regulation of anabolic and catabolic processes.
  - HK-II expression is phosphorylated by AKT/mTOR signaling pathway. HK-II binds to voltage-dependent anion channel 1 (VDAC1), the outer mitochondrial membrane protein and provide mitochondrial protection by facilitating coupling between glycolysis and oxidative phosphorylation.
  - The mTOR is a protein kinase that signals via two complexes: TORC1 and TORC2. Hexokinase II also binds and inhibits TORC1 to facilitate autophagy in response to glucose deprivation.
- Under pathologic (hyperglycemic) state, HK-II initiates an abnormal elevation in glycolytic metabolic flux with increase in the level of glycolytic intermediate metabolic products without concurrent transcriptional and functional regulation.
  - This process is known as glycolytic overload and is accompanied by several diabetic complications.
  - Steps in the pathogenic mechanism of diabetes mellitus associated with glycolytic overload include: (a) glucose-6-phosphate (G6P) induces mitochondrial dysfunction, (b) fructose-6-phosphate (F6P) is channelized to the hexamine pathway, and (c) dihydroxyacetone phosphate (DHAP) activates pyruvate kinase C (PKC) through glyceraldehyde 3 phosphate and dihydroxyacetone phosphate (DHAP) intermediate products.

LONG-TERM COMPLICATIONS OF DIABETES MELLITUS

Long-term diabetic complications develop gradually depending on elevation of blood glucose level. Duration and severity of disease are key factors underlying the clinical presentation of diabetes mellitus. Symptoms tend to appear in type 1 diabetes mellitus than type 2 diabetes mellitus. Long-term complications of uncontrolled diabetes mellitus are given in Table 26.11 and Fig. 26.10.

- Long-term diabetic complications result from elevated blood glucose levels due to impairment of metabolic pathways of glucose, lipids and proteins. Hyperglycemia adversely affects blood vessels such as abdominal aorta, coronary arteries, carotid arteries, cerebral arteries, anterior tibial, posterior tibial and popliteal vessels causing them to narrow and therefore restricting blood flow to the tissues/organs.

Table 26.11 Long-term complications of uncontrolled diabetes mellitus

Macrovascular Complications (Large Elastic and Medium-sized Arteries)
▪ Coronary artery disease (atheromatous plaque) ▪ Cerebral vessel disease (atheromatous plaque) ▪ Peripheral vascular disease (atheromatous plaque)
Microvascular Complications (Small Blood Vessels)
▪ Diabetic nephropathy • Diffuse glomerulosclerosis • Nodular glomerulosclerosis • Renal papillary necrosis • Fibrin cap • Capsular drop • Tubulointerstitial disease
▪ Diabetic neuropathy • Polyneuropathies • Amyotrophy (diabetic radiculopathy) • Autonomic nervous system neuropathy • Cranial nerve neuropathy
▪ Diabetic oculopathy • Diabetic retinopathy (nonproliferative and proliferative) • Cataract • Glaucoma • Retinal ganglion cells (RGCs) neuropathy • Ischemic optic neuropathy • Diabetic keratopathy
▪ Diabetic mellitus related infections • Skin infections • Urinary tract infections • Rhinocerebral mucormycosis
▪ Diabetic dermatopathy • Xanthomas • Necrobiosis lipoidica diabeticorum
▪ Nonalcoholic fatty liver disease (NAFLD) in diabetic patients
▪ Diabetic mastopathy

Internal mammary arteries and arteries of the upper limb are always spared of atheromatous plaques.

- Diabetic patients are prone to develop life-threatening complications such as myocardial infarction, cerebral stroke and atherosclerosis, retinopathy, nephropathy and neuropathy. Hyperglycemia also causes disturbances in the body's immune system, so these patients are more susceptible to bacterial and fungal infections.
- Tight control of blood glucose level, hypertension and serum lipids reduces the onset of severity of diabetic complications such as cerebral stroke, myocardial infarction, retinopathy, nephropathy and neuropathy.

Diabetic Macrovascular Complications

Diabetes mellitus is a prime risk factor for cardiovascular diseases. Atherosclerosis is the major threat to the macrovasculature for patients with or without diabetes mellitus. Healthy vascular endothelium is vasodilatory, antithrombogenesis and anti-inflammatory properties. Vascular endothelial dysfunction and dyslipidemia play important role in the pathogenesis of atherosclerosis.

- **Dyslipidemia in diabetes mellitus:** Clinically, dyslipidemia is highly correlated with atherosclerosis. It has been observed that 97% of patients with diabetes mellitus have dyslipidemia (i.e. high triglycerides and low-density lipoproteins and low-HDL cholesterol). Dyslipidemia is the only mechanism by which diabetes mellitus promotes atherosclerosis. Hyperglyceridemia can also lead to increased production of the low-density lipoproteins and decreased HDL transport of cholesterol back to the liver.
- **Low-density lipoproteins:** Low-density lipoproteins are atherogenic, because these can more easily penetrate and form stronger attachments to the large elastic and medium-sized arterial wall, and LDLs are more susceptible to oxidation. Oxidized low-density lipoproteins acquire new properties, which produce several biological responses: (a) chemotaxis of leukocytes to the intima of the arterial wall, (b) necrosis of vascular endothelial and smooth muscle cells, (c) leukocytes ingest lipids and differentiate into foam cells, and (d) proliferation and migration of smooth muscle cells also lead to ingestion of oxidized low-density lipoproteins. All these steps lead to formation of atheromatous plaque. LDL molecules can also become glycated that increases the ability of the LDL to accelerate atherogenesis.

Diabetic Cardiovascular Disease

Hyperglycemia accelerates atherosclerosis in coronary arteries and may cause angina pectoris, acute myocardial infarction and cardiac failure. Clinically, dyslipidemia is highly correlated with atherosclerosis in diabetic

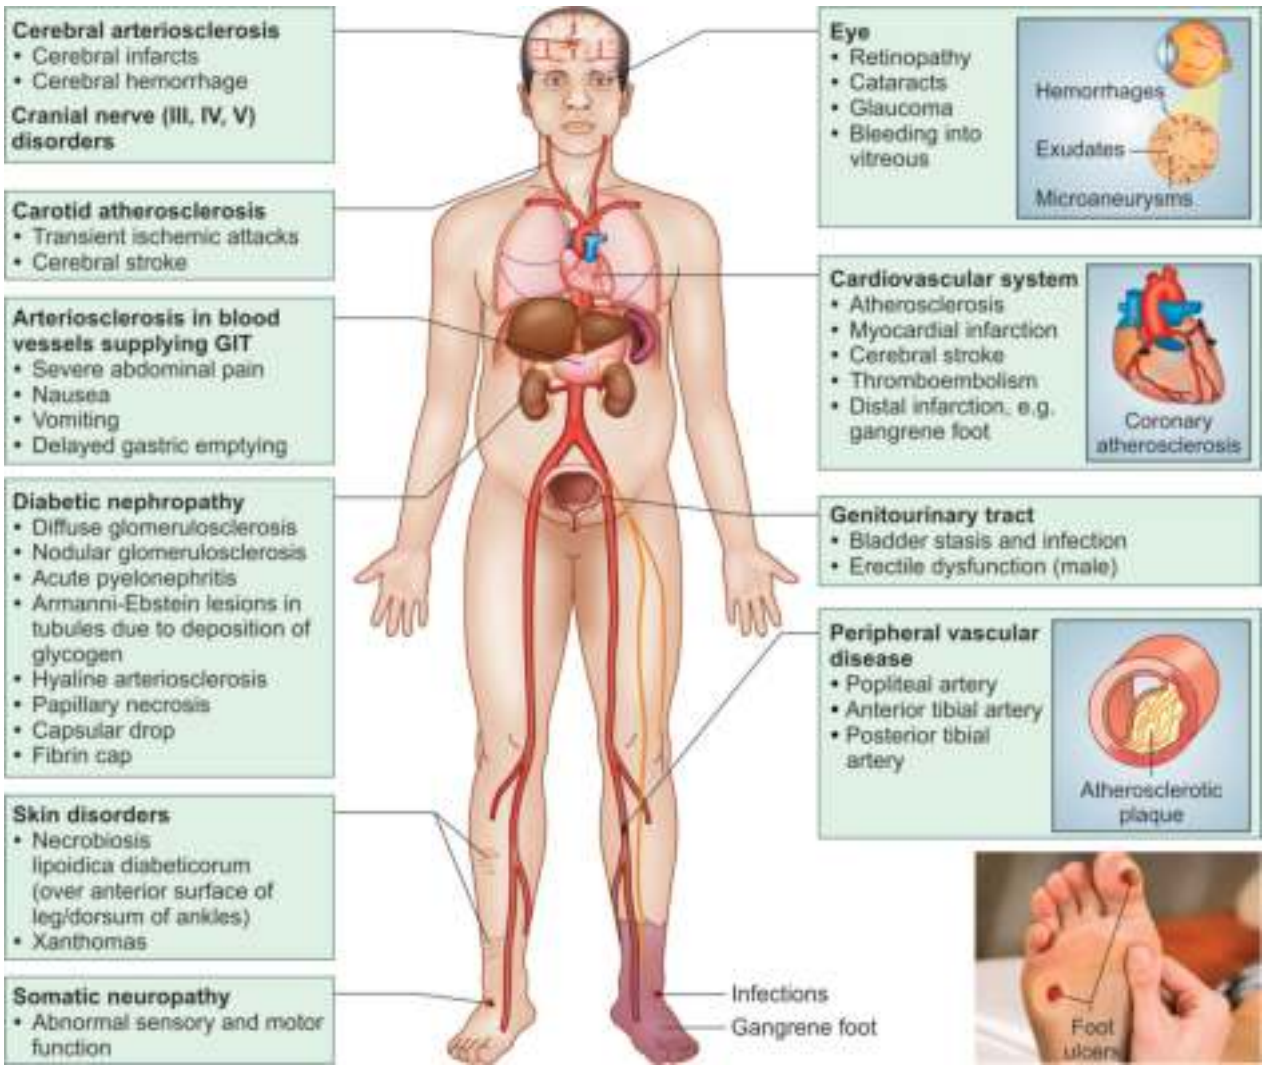

Fig. 26.10: Long-term complications of uncontrolled diabetes mellitus. Macrovascular diabetic complications such as coronary artery disease, cerebral stroke and peripheral vascular disease reflect the combined effects of unregulated blood glucose levels, elevated blood pressure and hyperlipidemia. The most common cause of death with diabetes mellitus is myocardial infarction. Microvascular complications include nephropathy, neuropathy, retinopathy and dermatopathy.

patients. Patient becomes symptomatic if coronary arteries consist of atherosclerotic plaque involving >75% of lumen.

- **Clinical features:** Patient with acute myocardial infarction presents with tightness in the chest, severe pain in the chest, back, jaw and other regions of the upper body that persists for several minutes, shortness of breath, sweating, nausea, vomiting and anxiety.
- **Treatment modalities:** Treatment modalities of acute myocardial infarction include angioplasty, stents and coronary artery bypass graft surgery. Kindly refer acute myocardial infarction discussed in Chapter 16.

Diabetic Cerebral Stroke

Brain tissue needs a constant supply of oxygen and nutrients to keep nerve cells and supporting tissues alive and functioning. Occlusion of the arteries supplying brain results in cerebral stroke. Diabetes mellitus is a well-established risk factor for cerebral stroke.

- **Pathophysiology:** Several possible mechanisms wherein diabetes mellitus leads to cerebral stroke, which include vascular endothelial dysfunction, increased arterial stiffness, at an early age, thickened capillary basement membrane, and systemic inflammation. The C-reactive protein, cytokines (e.g. IL-1, IL-6, TNF-α) and adiponectin are the main serum markers of inflammation. Adiponectin appears to be a modular of lipid metabolism and systemic inflammation. Vascular endothelial function is critical in maintenance of structural and functional integrity of the arterial walls as well as vasomotor control. Nitric oxide (NO) mediates vasodilation, but decreased availability of nitric oxide can cause

vascular endothelial dysfunction and trigger a cascade of atherosclerosis.

- **Cerebral stroke patterns:** There is higher occurrence of atherothrombotic and lacunar cerebral infarctions in diabetic patients.
  - Partial blockage in cerebral arterial may result in temporary reduction of blood supply to a part of the brain (transient ischemic attacks).
  - A complete loss of blood supply to an area of the brain due to clogging or breaking of a cerebral artery results in cerebral stroke.
- **Clinical features:** Cerebral stroke is a medical emergency. Patient presents with sudden numbness or weakness in the face, arm of leg on one side of the body, difficulty in speaking, blurred vision, difficulty in swallowing, dizziness, lack of coordination, paralysis and explained intense headache.

Diabetic Peripheral Vascular Disease

Hyperglycemia accelerates atherosclerosis in popliteal arteries, anterior and posterior tibial arteries resulting to peripheral vascular disease.

- **Pathophysiology:** Endothelial dysfunction, vascular smooth muscle dysfunction, inflammation, hypercoagulability, and decrease in a vasodilator nitric oxide production by dysfunctional endothelium, are the key factors in diabetic arteriopathy in lower legs. All these mechanisms lead to reduction in vascular blood flow, which in turn results in development of skeletal muscle ischemia and peripheral vascular disease. Dysfunctional endothelium induces defective synthesis of bioactive molecules such as potent vasodilator (i.e. nitric oxide), reactive oxygen species (ROS), endothelin, prostaglandins and angiotensin II.
- **Clinical features:** Partial or complete arterial blockage adversely affects the circulation to lower extremities. Patient with partial arterial blockage presents with intermittent claudication (cramps, pain in calf, thigh, hip and buttocks when walking and relieved by taking rest) and ischemic ulcers. Complete arterial blockage causes gangrene foot. Patient condition becomes worse through the development of diabetic neuropathy, leading to propensity for injury. Physical signs in the legs in peripheral vascular disease comprise skeletal muscle atrophy, hair loss, smooth shiny skin, decreased or absent pulses in the feet, non-healing ulcers or wounds in the lower extremities and numbness in the toes. The **six Ps** of acute limb ischemia include: **P**ain, **P**allor, **P**aresthesia, **P**ulselessness, **P**aralysis and **P**erishing cold (poikilothermia).

Diabetic Nephropathy

Morphological changes due to diabetes mellitus are similar in type 1 and type 2 diabetes mellitus and can be observed in all the four structural compartments of the kidney: glomeruli, tubules, interstitial tissue and blood vessels. Renal lesions include diffuse glomerulosclerosis, nodular glomerulosclerosis (also known as Kimmelstiel-Wilson disease), papillary necrosis, hyaline arteriolosclerosis, tubulointerstitial disease, capsular drop and fibrin cap. Renal lesions in diabetic nephropathy are given in Table 26.12.

- **Pathogenesis:** Diabetic nephropathy is caused by the metabolic and hemodynamic changes. Pathogenesis is complex, involving glycosylation of proteins in glomerular basement membrane, hormonally influenced transforming growth factor-β cytokine release, deposition in mesangial matrix and alteration of glomerular hemodynamics. Advanced glycated end (AGE) products bind to collagen fibers in glomerular basement membrane (GBM) and impair the interaction of laminin with GBM resulting in increased capillary permeability and albuminuria. Increased width of GBM is the earliest and most common renal manifestation. In diffuse glomerulosclerosis and nodular glomerulosclerosis, there is increased synthesis of type IV collagen in glomerular basement membrane and deposition in mesangial matrix.
- **Clinical features:** Diabetic nephropathy manifests as slowly progressive albuminuria with worsening hypertension and renal inefficiency.
- **Laboratory diagnosis:** Diagnosis is based on clinical history, physical examination, blood biochemistry, urine analysis and urine albumin/creatinine ration.
- **Treatment:** Patients are treated by strict blood glucose control, angiotensin-converting enzyme (ACE) inhibitors administration, controlling blood pressure and serum lipids.

Diabetic Glomerulopathy

Diffuse thickening of the glomerular basement membrane is the earliest morphologic change. Diffuse increase in mesangial matrix is demonstrated in the early phase which progresses to nodular mesangial sclerosis (Kimmelstiel-Wilson disease) in the later stage of the renal disease. These morphologic changes in glomeruli take a decade or longer to develop and gradually worsen.

- **Diffuse glomerulosclerosis:** Accumulation of basement-like stroma in the mesangium parallels the diffuse thickening of the glomerular basement membrane. These morphologic changes gradually advance until the entire glomerulus is sclerotic. Focal

Table 26.12 Renal lesions in diabetic nephropathy

Renal Lesions	Comments
Glomerular lesions	
Diabetic glomerulosclerosis	Widening of mesangial areas occurs due to accumulation of basement like stroma in the mesangial region, increased number of mesangial cells in 2–5 years after the onset of diabetes mellitus
Nodular glomerulosclerosis (also known as Kimmelstiel-Wilson disease)	Sclerotic nodules are formed in the peripheral region of intercapillary region of glomeruli demonstrated by PAS staining
Bowman capsule lesion	
Capsular drop	Accumulation of plasma proteins inside Bowman's capsule is known as capsular drop
Glomerular subendothelial region lesion	
Fibrin cap	Fibrin cap is formed by plasma proteins deposition in subendothelial region
Papillary necrosis	Diabetic glomerulosclerosis leads to ischemia of papillae (papillary necrosis). Necrotic papillae may detach and pass in the urine as tissue fragments. Undetached papillae may resolve by fibrosis
Renal arterioles lesion	
Hyaline arteriolosclerosis of renal arterioles	Hyaline arteriolosclerosis of renal arterioles is the main cause of renal microangiopathy
Tubulointerstitial tissue lesions	
Armanni-Ebstein lesions	Deposition of glycogen in renal tubules is known as Armanni-Ebstein lesions in uncontrolled diabetes mellitus patients
Acute pyelonephritis	▪ Acute pyelonephritis occurs most frequently secondary to infection by bacteria or fungi and characterized by pus in the tubule and multiple grayish white areas of small microabscesses ▪ Microscopic urine analysis is the presence of white blood cell (WBC) casts

effacement of foot processes is common. Diffuse glomerulosclerosis associated with long-standing diabetes mellitus can be demonstrated by periodic acid–Schiff (PAS) stain. Diffuse glomerulosclerosis in diabetic nephropathy is shown in Fig. 26.11.

- **Nodular glomerulosclerosis:** Nodular glomerulosclerosis is also known as 'Kimmelstiel-Wilson disease'. Sclerotic nodules are formed in the mesangial region as a result of nonenzymatic glycation of proteins and increased synthesis of type IX collagen between capillary loops. The nodules have a hypocellular matrix core which may be homogenous or exhibit lamellations with peripherally arranged mesangial nuclei. The nodules vary in size that can be demonstrated by periodic acid–Schiff and silver methenamine stains. The periphery of the nodules may demonstrate mesangiolysis resulting in the formation of capillary microaneurysms due to the detachment of anchoring points of the glomerular basement membrane to the mesangium. Intercapillary glomerulosclerosis leads to renal ischemia, tubular atrophy, marked interstitial fibrosis, increased mesangial region, arteriolosclerosis and ultimately small contracted kidney. Nodular glomerulosclerosis (Kimmelstiel-Wilson disease) in diabetic nephropathy is shown in Fig. 26.12. Microaneurysm in glomerulus in diabetic nephropathy is shown in Fig. 26.13.

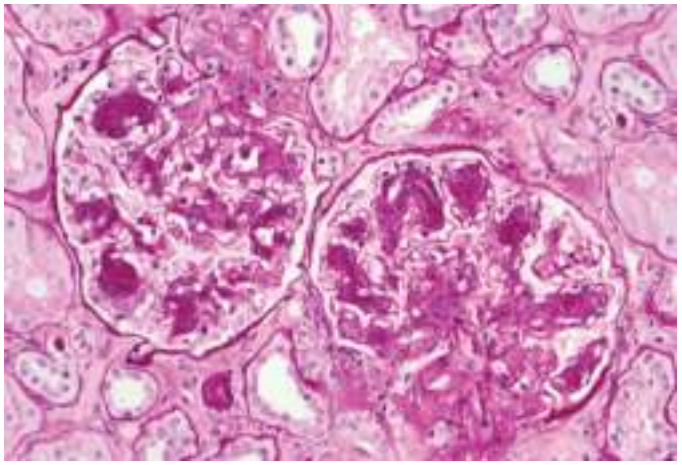

Fig. 26.11: Diffuse glomerulosclerosis in diabetic nephropathy. It shows widening of mesangial areas due to accumulation of basement like stroma in the mesangial region. Electron microscopy is required in the early stages to detect the glomerular basement membrane thickening but it becomes appreciable by light microscopy when the thickness is increased more than four times (X40).

Diabetic Renal Papillary Necrosis

Renal papillary necrosis is caused by diabetes mellitus and urinary tract infection. Renal papillae are considered to be anatomically vulnerable to ischemic changes (papillary necrosis). Renal papillary necrosis is shown in Fig. 26.14.

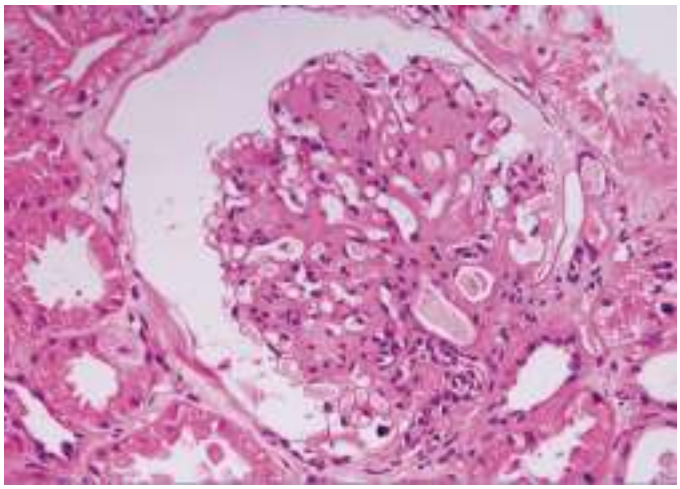

Fig. 26.12: Nodular glomerulosclerosis (also known as Kimmelstiel-Wilson disease) in diabetic nephropathy. Histologic examination shows sclerotic nodules in the peripheral region of intercapillary region of glomeruli. The nodules are formed due to accumulation of trapped proteins and synthesis of type IV collagen in mesangial matrix. The nodules can be demonstrated by periodic acid–Schiff and silver methenamine stains (X40).

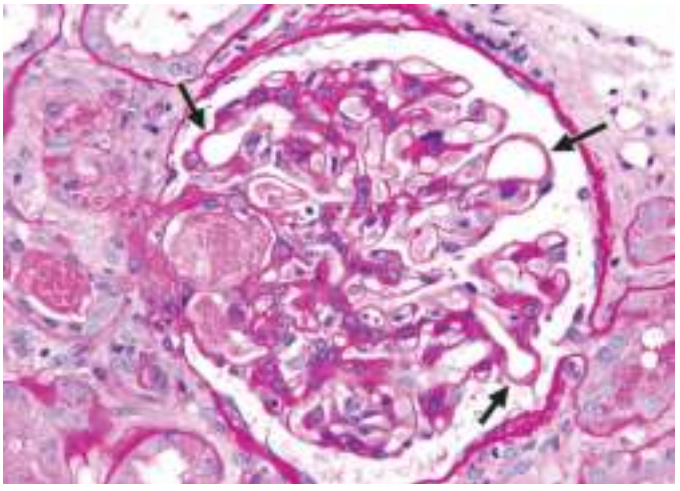

Fig. 26.13: Microaneurysm in glomerulus in diabetic glomerulopathy. Microaneurysm is demonstrated in glomerulus (arrows).

- Necrotic renal papillae may detach and pass in the urine as tissue fragments. Undetached renal papillae may resolve by fibrosis.
- Renal papillary necrosis can be seen in the setting of diabetic nephropathy, chronic analgesic abuse, infectious pyelonephritis and sickle cell anemia.

Diabetic Renal Hyaline Arteriolosclerosis

Hyaline arteriolosclerosis typically involves both the afferent and efferent arterioles. Some authors consider this finding to be most specific for diabetic nephropathy. Renal arterioles exhibit varying degrees of mild intimal fibrosis.

- Hyalinosis lesions result from insudation or exudation of plasma proteins from the blood vessels. It is the main cause of renal microangiopathy in diabetic patients. Blood vessels exhibit homogenous eosinophilic appearance and also show two characteristic patterns: fibrin cap and capsular drop.
- As the disease advances, segmental and global glomerular sclerosis develops. Hyaline arteriolosclerosis in diabetic nephropathy is shown in Fig. 26.15.

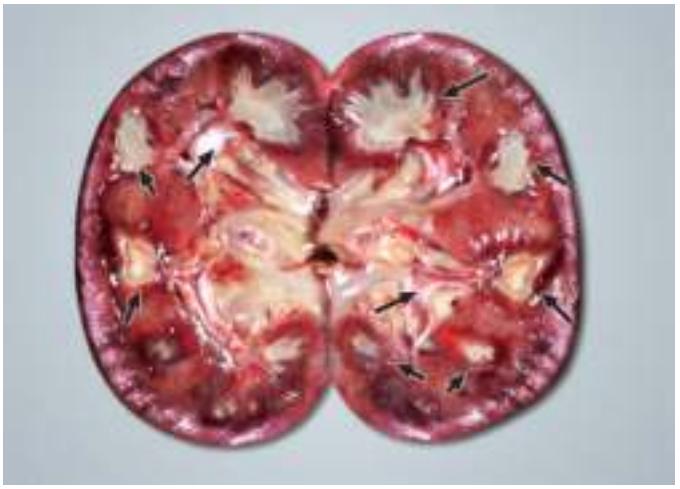

Fig. 26.14: Renal papillary necrosis. Renal papillary necrosis is typically thought to be caused by diabetes mellitus and urinary tract infection (arrows).

Diabetic Capsular Drop in Bowman's Capsule

Capsular drop is produced by accumulation of plasma proteins between parietal cells and Bowman's capsule. The capsular drop lesion is characteristic but not specific for diabetic nephropathy and also has been described in other nondiabetic diseases. Capsular drop in diabetic nephropathy is shown in Fig. 26.16.

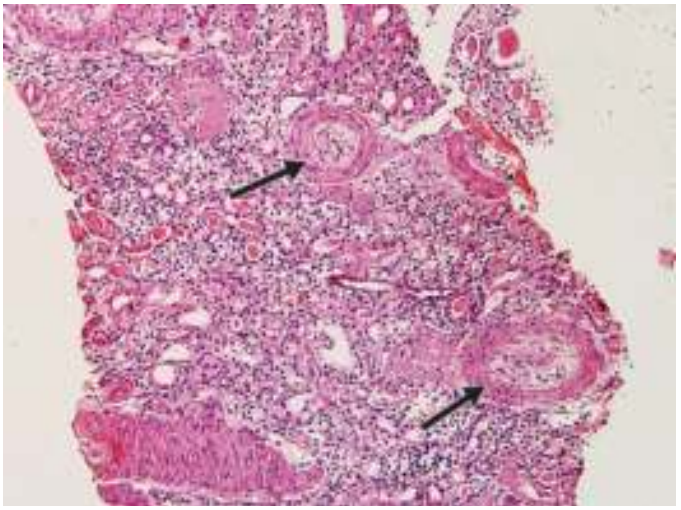

Fig. 26.15: Hyaline arteriolosclerosis in diabetic nephropathy. Histologic examination shows hyalinization of arterioles in diabetic nephropathy (arrows) (X10).

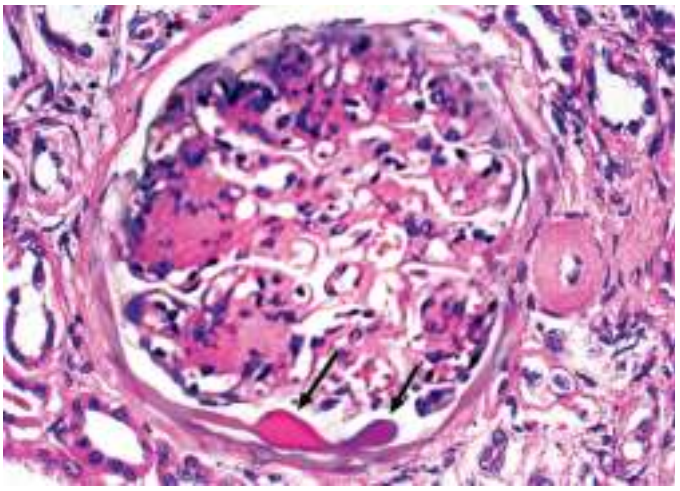

Fig. 26.16: Capsular drop in glomerulus. Accumulation of plasma proteins inside Bowman's capsule is known as capsular drop (arrows).

Diabetic Fibrin Cap in Glomerular Subendothelial Region

Accumulation of plasma proteins in the subendothelial region of glomeruli is known as fibrin cap. Fibrin cap essentially represents segmental sclerosis and is a misnomer as the lesion consists of primarily hyaline and not fibrin.

Diabetic Tubulointerstitial Disease

The earliest change in diabetic nephropathy involving the tubules is thickening of the tubular basement membrane. Tubular basement thickening can be demonstrated by periodic acid–Schiff (PAS) stain. As the disease advances, there is increase in the degrees of intestinal fibrosis and tubular atrophy. Nonspecific chronic inflammation may be demonstrated with the areas of fibrosis.

- **Armanni-Ebstein lesions:** Armanni-Ebstein lesions occur due to increased permeability of renal tubules and deposition of glycogen in renal tubules and are seen in uncontrolled hyperglycemia, which can occur in either type of diabetes mellitus.
- **Acute pyelonephritis:** It is most frequently secondary to infection by bacteria or fungi and characterized by pus in the tubule and by abscess formation. Microscopic urine analysis reveals presence of white blood cell casts. Acute pyelonephritis may progress to chronic pyelonephritis. The kidneys show multiple grayish white areas of small microabscesses in the renal parenchyma. Renal gross morphologic changes in acute pyelonephritis are shown in Fig. 26.17. Renal parenchyma is infiltrated by polymorphonuclear cells. Histologic changes in acute pyelonephritis are shown in Fig. 26.18.

Fig. 26.17: Renal gross morphologic changes in acute pyelonephritis. Acute pyelonephritis is often a focal disease, and much of the kidney often appears normal. The kidney shows multiple grayish white areas of small microabscesses in the renal parenchyma.

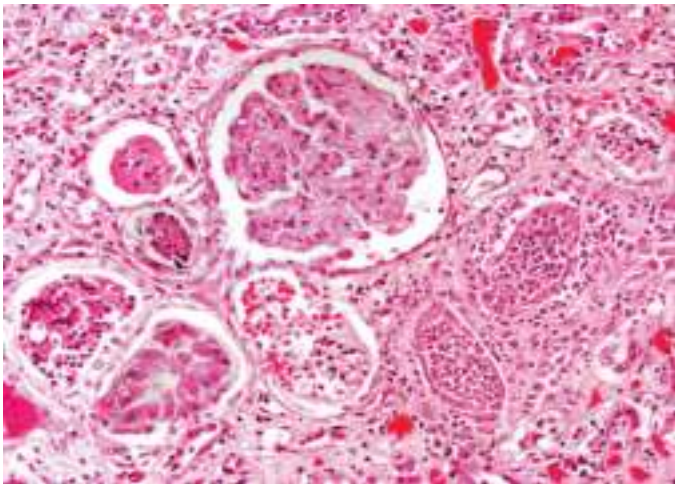

Fig. 26.18: Histologic changes in acute pyelonephritis. Renal parenchyma is infiltrated by polymorphonuclear cells (100X).

Diabetic Ocular Complications

Diabetes mellitus is a metabolic disease defined by elevated blood glucose. Ocular complications can occur in uncontrolled diabetes mellitus that can be reversed by using biodegradable polymers and implantable ocular devices.

- Diabetic ocular complications include: retinopathy, macular edema, retinal ganglion cells neuropathy, ischemic optic neuropathy, glaucoma, keratopathy, corneal edema, corneal nerve alterations, and cataract.
- Proliferative diabetic retinopathy is characterized by retinal exudates, edema, hemorrhages, and microaneurysms of small vessels leading to blindness. Diabetic ocular complications are given in Table 26.13.

Table 26.13 Diabetic ocular complications

Diabetic nonproliferative and proliferative retinopathy
Macular edema
Glaucoma
Cataract
Retinal ganglion cells (RGCs) neuropathy
Ischemic optic neuropathy
Diabetic keratopathy (corneal edema, corneal nerve alterations)

Diabetic Retinopathy

Diabetic retinopathy is a progressive disease that can cause blindness as a result of retinal detachment. It is related to the duration of the disease, occurring in most patients with diabetes mellitus after 10 years. Vascular changes in the inner retina in diabetic patients are given in Table 26.14. Pathologic changes in diabetic retinopathy are given in Table 26.15.

- **Diabetic retinopathy types:** Diabetic retinopathy can be divided into two types: nonproliferative diabetic retinopathy (NPDR) and proliferative diabetic retinopathy (PDR). NPDR can be further divided into three stages (e.g. early prediabetes stage, mid-point diabetes mellitus stage and late stage of diabetes mellitus) before progressing to PDR. NPDR usually progresses to PDR leading to vision impairment. Annual ophthalmic examination is mandatory in diabetic patients.
- **Diabetic retinopathy pathogenesis:** Retina has dual blood supply: retinal arteriole supplies inner two-thirds of inner retina and choroid arteriole nourishes pigmented epithelial cells and the outer one-third of the retina.
  - Initially, reduction in retinal perfusion triggers a series of adverse metabolic reactions such as increased expression of angiogenic factors and tissue modelling factors such as VEGF, IL-6, IL-1 and tumor necrosis factor-α, polyol accumulation, oxidative stress and activation of protein kinase C.
  - Moreover, hyperglycemia directly impairs retinal mitochondria leading to increased reactive oxygen species (ROS), inflammation and DNA damage.
  - Together with microvascular changes, reduced retinal perfusion, thickening of the basement membrane, retinal pericyte loss ultimately resulting in neovascularization.
  - Pericyte death, breakdown of vascular endothelial tight junctions, and basement membrane thickening damages blood retinal barrier (BRB) and cause

Table 26.14 Vascular changes in the inner retina in diabetic patients

Biochemical Changes (Metabolic Stress)	
↑Glucose transport	↑Hexosamine biosynthetic pathway (HBP)
↑Redox imbalance	↑Glucose autooxidation and degradation
↑Oxidative stress (mitochondrial reactive oxygen species)	↑Advanced glycated end products (AGEs) synthesis (AGEs/RAGEs interaction)
↑Na^+/K^+ ATPase activity	↑Hexokinase II driven glycolytic overload
↑PKC (protein kinase C)	↑Cyclooxygenase (COX) and lipoxygenase (LOX) enzyme activities
↑Polyol pathway (sorbitol-aldose reductase pathway)	
Growth Factors Synthesis	
↑VEGF (vascular endothelial growth factor)	↑FGF-β (fibroblastic growth factor-β)
↑IGF-1 (insulin growth factor 1)	↑TGF-β (transforming growth factor-β)
↑PDGF (platelet-derived growth factor)	↑EGF (epidermal growth factor)
↑HGF (hepatocyte growth factor)	↑NGF (nerve growth factor)
↑ET-1 (endothelin 1)	↓Antiangiogenic factors
Functional Changes	
Blood flow alteration	Vascular permeability changes
Intercellular junctions' disruption	
Structural Changes	
Reduced oxygen transport	Local swelling of retina
Pericyte loss	Occlusion of precapillary arterioles
Endothelial dropout	Acellular capillaries
Basement membrane thickening	Focal saccular venous bulges due to significant retinal ischemia
Diabetic Retinopathy Consequences	
Extracellular matrix synthesis (ECM)	Severe hemorrhage in retina and vitreous
Endothelial cell migration and proliferation	Retinal tear/detachment and bleeding into vitreous cause visual loss
Angiogenesis	

Table 26.15 Pathologic changes in diabetic retinopathy (DR)

Diabetic Retinopathy	Retinal Findings on Fundus Examination	Pathology
Nonproliferative diabetic retinopathy (NPDR)		
Mild nonproliferative DR	Microaneurysms	Outpouchings of the weakened capillary walls or endothelial buds attempt to revascularize the ischemic retina
Moderate nonproliferative DR	▪ Dot/blot hemorrhages ▪ Hard exudate ▪ Cotton-wool spots	▪ Weakened blood retinal barrier (BRB) results in rupture into deeper retinal layers ▪ Disrupted blood–brain barrier (BRB) results in leakage of lipoproteins and other proteins leading to formation of yellow lipid deposits with sharp margins ▪ Occlusion of the precapillary arterioles results in nerve fiber infarcts
Severe nonproliferative DR	▪ Flame hemorrhages ▪ Venous beading	▪ Retinal hemorrhages occur in the more superficial nerve layer ▪ Focal areas of saccular venous bulges due to significant retinal ischemia
Proliferative diabetic retinopathy (PDR)		
Proliferative retinopathy	Neovascularization	Localized retinal ischemia causes upregulation of VEGF causing fine, irregular, and easily friable neovascularization in the disc, macula, and/or retina leading to traction retinal detachment and vitreous hemorrhage.

Pathophysiology of diabetic retinopathy: Pericyte death, breakdown of endothelial tight junctions, and basement membrane thickening damages blood retinal barrier cause leakage of fluid into the retinal tissues resulting in macular edema in patients with moderate-to-severe nonproliferative retinopathy and proliferative retinopathy.

leakage of fluid into the retinal tissues resulting in macular edema in patients with moderate-to-severe nonproliferative retinopathy and proliferative retinopathy.

- **Clinical features:** Diabetic retinopathy affects both eyes. Patient presents with increase in number of floaters, blurring vision, black and dark areas in fields of vision, poor night vision and blindness.

Pathology Pearls: Nonproliferative and Proliferative Diabetic Retinopathy

Nonproliferative Diabetic Retinopathy (NPDR)

- Nonproliferative diabetic retinopathy (NPDR) is an early mild stage, in which microvascular changes manifest as microaneurysms on the retina.
- Microaneurysms may rupture and forming soft cotton wool exudates (microinfarcts) and later hard exudates as a result of deposits of protein that have leaked from damaged capillaries.
- In moderate NPDR, two or less quadrants of retina demonstrate intraretinal hemorrhages, hard exudates, 'cotton wool spots' and venous beading without hampering vision.
- The microvascular changes are reversible within two to three weeks without hampering vision. In severe NPDR, all four quadrants demonstrate intraretinal hemorrhages; and venous beading is visible in more than two quadrants.

Proliferative Diabetic Retinopathy (PDR)

- The microvascular changes lead to reduction in retinal perfusion. In response to the retinal perfusion reduction and retinal hemorrhages, new blood vessels are formed (neovascularization) in the retina. The neovascularization marks a critical distinction between NPDR and PDR.
- Newly formed blood vessels contain red blood cells hence hamper absorption of light and thus obscure the vision. Newly formed blood vessels can grow into the vitreous and if left untreated can result in retinal tearing and detachment.
- Additionally, newly formed blood vessels are fragile and susceptible to breakage resulting in vitreous hemorrhage. Vitreous hemorrhage can be surgically removed. Bleeding into the vitreous hampers vision.
- Retinal blood vessels possess a blood retinal barrier that prevents plasma, growth factors and other inflammatory mediators from entering the immunologically quiescent eye.
- Therefore, vitreous hemorrhage triggers additional neovascularization and inflammation that perpetuates proliferative diabetic retinopathy. Proliferative retinopathy is treated with laser surgery (photocoagulation).

Diabetic Macular Edema

Macula is located in part of the retina that contains the highest number of cones, which provides the ability to observe color details. Diabetes mellitus-related macular edema happens when fluid builds up under the macula, the center of retina. Macular edema results in central vision loss. When the newly formed blood vessels rupture, the fluid accumulates in macular region causing thickening of the retina resulting in blurry vision. These retinal findings can be viewed with the ophthalmoscope.

Diabetic Glaucoma

In severe diabetic retinopathy, neovascularization can cause adhesions (synechiae) between iris and cornea or iris and lens resulting in improper drainage of aqueous humor through the trabecular meshwork and Schlemm's canal and increased intraocular pressure known as glaucoma. Glaucoma can damage nerves and

blood vessels, producing changes in vision and leading to glaucoma (open-angle and closed-angle).

- **Open-angle glaucoma:** Open-angle glaucoma is usually painless and asymptomatic, which becomes painful on significant progression of glaucoma. These patients are treated with medications.
- **Closed-angle glaucoma:** Closed-angle glaucoma presents with sudden ocular pain, redness, nausea, and intraocular pressure spikes. These patients generally require medical emergency care.

Diabetic Cataract

Cataract is one of the main causes of vision impairment in diabetic patients. It is 15–20 times more common in diabetic patients than nondiabetic counterparts.

- Aqueous humor is produced by the ciliary processes and present in the posterior and anterior chambers of the eye. Since the lens and cornea have no blood supply, the aqueous humor carries nutrients and oxygen to these structures. Aqueous humor also maintains intraocular pressure.
- Hyperglycemia in the aqueous humor results in cataract due to accumulation of sorbitol that induces osmotic damage to the crystalline lens.
- Posterior capsular opacification (PCO) is a common finding following cataract surgery in diabetic patients. In some cases, diabetic retinopathy progresses following extracapsular cataract extraction. As with diabetic retinopathy, there are concerns that cataract surgery in diabetic patients may exacerbate the progression of macular edema.

Diabetic Retinal Ganglion Cells Neuropathy

Retinal ganglion cells (RGCs) are present near the inner surface of the retina. RGCs receive visual information from photoreceptors via two intermediate neuron types: bipolar cells and amacrine cells.

- RGCs together form the optic nerve, optic chiasma, and optic nerve that transmits visual information to the brain.
- Hyperglycemia causes stress to the retina that triggers apoptosis of RGCs in diabetic patients. The stress to retina occurs due to ischemia, oxidative stress, reduction of trophic factors, increased intraocular pressure, neuroinflammation and aldose reductase inhibition. RGCs neuropathy can also occur even during the early stages of diabetes mellitus.

Ischemic Optic Neuropathy

The reduced retinal perfusion and microaneurysms can reduce the oxygen supply to optic nerve in diabetic patients. Prolonged interruption of oxygen supply to optic nerve triggers optic nerve apoptosis resulting in permanent vision loss. The ischemia and optic neuropathy trigger release of additional apoptotic factors that can adversely affect the other areas of retina. Ischemia also triggers release of hypoxia-inducible factors that promote angiogenesis and inflammation.

Diabetic Keratopathy

Diabetic keratopathy results in impaired vision as a result of decreased wound healing, corneal edema and an altered epithelial basement membrane. Corneal repair is most often difficult in diabetic patients. As the diabetic keratopathy progresses, central region of cornea thickens followed by reduced corneal sub-basal nerve density, increased corneal sensitivity and corneal erosion syndrome and later reduced tear meniscus parameters, and less nerve fiber and branch length.

- Cornea suffers from dysfunctional wound healing/repair mechanisms. Some authors observed that presence of diminished corneal peripheral sensation suggests some kind of neuropathy.
- Other studies revealed that abnormal adhesions of the corneal epithelium to the underlying basement membrane can lead to prolonged and recurrent defects in cornea.
- Weakening of the epithelial barrier in diabetic patients increases risk for corneal infections and stromal fibrosis resulting in vision loss.

Diabetic Neuropathy

Diabetic neuropathy is a serious diabetic complication that may affect about 50% of diabetic patients. Development of diabetic neuropathy can be prevented by regulating blood glucose levels. Hyperglycemia can cause neuropathy throughout the body. Depending on the affected nerves, diabetic neuropathy can range from numbness and pain in the legs and feet to symptoms related to gastrointestinal tract, urogenital system and cranial nerves. Classification of diabetic neuropathies is given in Table 26.16.

Diabetic Peripheral Neuropathy

Peripheral neuropathy is also called distal symmetric peripheral neuropathy. It is most common type of diabetic neuropathy that affects feet and legs followed by hands and arms. Signs and symptoms of peripheral neuropathy are often worse at night.

- **Pathophysiology:** The pathophysiology of diabetic peripheral neuropathy results from hyperglycemia induced vascular disease occluding tiny blood vessels that nourish peripheral nerves (vasa nervorum) in lower limbs, vascular endothelial dysfunction, deficiency of myoinositol-altering myelin synthesis and diminished sodium-potassium

Table 26.16 Classification of diabetic neuropathies

Nerves Involved	Comments
Somatic nerves	
Polyneuropathies (bilateral sensory nerves)	▪ Paresthesis including tingling, numbness ▪ Decreased pain, light touch, temperature, two-point discrimination and vibratory sensations ▪ Impaired ankle and knee jerk reflexes
Mononeuropathies (involvement of a mixed nerve trunk)	▪ Impaired sensory nerves associated with pain ▪ Impaired motor nerve associated with skeletal muscle weakness
Amyotrophy	Skeletal muscle weakness, wasting and severe pain in the pelvic girdles and thigh
Autonomic nervous system	
Impaired vasomotor function	Postural hypertension
Impaired vasomotor function	Postural hypertension
Impaired gastro-intestinal tract functions	▪ Gastroparesis ▪ Diarrhea (postprandial and nocturnal)
Impaired genito-urinary tract functions	▪ Paralytic urinary bladder ▪ Incomplete voiding ▪ Erectile ejaculation ▪ Retrograde ejaculation
Cranial nerves	
Cranial nerves (III, IV, and V)	▪ Extraocular muscles affected ▪ Impaired pupillary response

adenine triphosphatase (ATPase) activity, and chronic hyperosmolarity causing edema of nerve trunks and adverse effects of sorbitol and fructose. Osmotic damage to Schwann cells affects both motor (skeletal muscle weakness) and sensory (paresthesia) nerves of peripheral nerves in type 1 and type 2 diabetes mellitus (70%).

- **Clinical features:** Loss of sensation can cause tingling, numbness, burning pain that usually begins at the tips of the toes or fingers and gradually spreads upwards in hands and arms. Patient presents with numbness, tingling, sharp burning pain and neuropathic ulcers at pressure points on the plantar surfaces of both feet.

Diabetic Autonomic Nervous System Neuropathy

Autonomous nervous system controls heart, gastrointestinal tract, genitourinary system, heart and eyes. Diabetes mellitus can affect nerves in any of these regions. Signs and symptoms are related to the involvement of autonomic nervous system.

- **Clinical features:** Patient can present with gastroparesis (delayed gastric emptying), impotence, urinary bladder dysfunction, cardiac arrhythmias and inability of eyes to adjust from light to dark.
- **Urinary tract infection:** Urine remains in the dysfunctional urinary bladder after incomplete voiding that leads to bacterial growth in stagnant urine. The bacteria travel up to the kidney and cause acute pyelonephritis.

Diabetic Proximal Neuropathy (Diabetic Radiculopathy)

Proximal neuropathy is also called diabetic radiculopathy that affects nerves in the thighs, hips, buttocks or legs. Disease can also affect abdominal and chest regions. Signs and symptoms are most often unilateral, but may spread to other side. Patient presents with severe pain in hip, thigh, buttock, and legs, weakness and shrinkage of thigh muscles and difficulty in rising from a sitting posture.

Diabetic Mononeuropathy (Focal Neuropathy)

Mononeuropathy refers to damage to a specific nerve. There are two types of mononeuropathy: involving cranial nerves and peripheral nerves. Cranial nerves (III, IV, and V) are most commonly affected. Patient presents with difficulty in focusing (i.e. double vision), aching behind one eye, unilateral facial palsy (bell's palsy), tingling or numbness in hands or fingers except little finger and weakness of hand.

Recurrent Infections in Diabetic Patients

Diabetes mellitus increases the susceptibility to various types of infections. Hyperglycemia in tissues and body fluids provides favorable growth conditions for bacteria and fungi. Diabetes mellitus impairs the function of neutrophils. Angiopathy caused by hyperglycemia leads to tissue ischemia, and such ischemic tissues are more prone to infections.

- The most common sites of infection in diabetic patients are the skin (*Staphylococcus aureus*), vulvovaginal region (*Candida albicans*) and urinary tract.
- Diabetic patient presents with well-demarcated yellow plaques over anterior surface of the leg/dorsum of ankles, known as necrobiosis lipoidica diabeticorum due to increased synthesis of fat at insulin injection site. Patient may develop xanthomas (collections of lipid-laden macrophages in the dermis).
- Chronic otitis externa (*Pseudomonas aeruginosa*) and rhinocerebral mucormycosis are two head and neck infections seen almost exclusively in patients with diabetes mellitus. Rhinocerebral mucormycosis spreads to face, orbit, skull, and frontal lobe of brain. Mucormycosis has pauciseptate, broad ribbon-like hyphae observed on histologic evaluation.

Diabetes Mellitus-related Nonalcoholic Fatty Liver Disease

Diabetes mellitus increases the risk for nonalcoholic fatty liver disease (NAFLD), a condition in which excess of triglycerides build up in the hepatocytes. In some cases, NAFLD may progress from steatosis to steatohepatitis with evidence of inflammation and hepatocyte injury, cirrhosis (hepatic fibrosis) and ultimately hepatocellular failure. Most patients of NAFLD remain asymptomatic, however the liver functions are impaired. Maintenance of body weight can prevent and treat NAFLD. It is essential to regulate blood glucose in type 2 diabetes mellitus.

Pathology Pearls: Diabetes Mellitus-related Nonalcoholic Fatty Liver Disease (NAFLD)

Gross Morphology

- Mild fatty change in liver may not affect the gross appearance. Severe fatty change results in enlargement of liver.
- Liver becomes progressively yellow on cut surface until it may weigh 3–6 kg. This uniform change is consistent with fatty metamorphosis (fatty change).

Frozen Section Technique

In paraffin-embedded sections, fat is dissolved during processing of tissue in histokinette. Fat can be demonstrated by frozen section technique with the fat stains such as Sudan III, Sudan IV, Sudan black, Oil red O and osmic acid.

Light Microscopy

- Initially, hepatocytes show small fat vacuoles around nucleus (mild fatty change or microvesicular) in hematoxylin and eosin-stained sections.
- Progressive accumulation of fat vacuoles in the cytoplasm coalesces to create spaces that displace the nucleus toward periphery (severe fatty change).
- Occasionally contiguous cells rupture, and the enclosed fat globules unite to produce so-called fatty cysts. Distribution of lipid vacuoles may be diffuse, focal or zonal, midzonal or peripheral depending on severity and etiology.

Diabetic Mastopathy/Lymphocytic Mastitis

Diabetic mastopathy is a fibrous painless breast mass with a prominent lymphocytic infiltrate most often occurring in patients with long-standing diabetes mellitus. Diagnostic criteria of diabetic mastopathy include: (a) prominent keloidal fibrosis, (b) prominent circumscribed lymphocytic infiltrate (B cells) around perivascular, periductal, perilobular regions that may infiltrate lobular epithelium forming lymphoepithelial lesions, and (c) epithelioid stromal cells.

- **Pathophysiology:** Diabetic mastopathy can occur as a result of hyperglycemia that leads to stromal matrix expansion and accumulation of advanced glycosylation end products (AGEs) and B cell inflammatory response. It can also occur as a result of immunologic response to exogenous insulin.
- **Clinical features:** Diabetic mastopathy is associated with insulin-dependent diabetes mellitus and autoimmune disorders. Patient presents with firm, palpable, nontender, mobile lumps or diffuse nodularity at presentation common.
- **Laboratory diagnosis:** Ultrasonographic study shows irregular shaped breast lump(s), indistinct margins, parallel orientation to chest wall, hypoechogenicity with posterior shadowing. Diagnosis is confirmed by needle core biopsy or surgical excision with histologic examination.

LABORATORY DIAGNOSIS OF DIABETES MELLITUS

Diabetes mellitus (DM) refers to a group of metabolic disorders characterized by hyperglycemia resulting from defects in insulin secretion, insulin actions in peripheral tissues or both.

- Type 1 diabetes mellitus (DM) occurs due to autoimmune destruction of β cells of islets of Langerhans of pancreas leading to absolute insulin deficiency. Type 2 diabetes mellitus (DM) may range from predominantly insulin resistance with relative insulin deficiency to a predominantly defect with insulin resistance in peripheral tissues. Other types of DM include gestational pregnancy-associated diabetes mellitus and monogenic diabetes mellitus.
- Diabetes mellitus may be diagnosed based on blood glucose criteria, either fasting blood glucose or two-hour blood glucose values during 100 g oral glucose tolerance test (OGTT) or glycosylated hemoglobin (HbA1c) criteria. Diagnostic criteria of diabetes mellitus are given in Table 26.17.

Table 26.17 Diagnostic criteria of diabetes mellitus

Laboratory Test	Diagnostic Criteria
1. Fasting blood glucose (8 hours) on two separate tests	≥126 mg/dl (7 mmol/L)*
2. Two-hour blood glucose during oral glucose tolerance test (OGTT)	≥200 mg/dl (11.1 mmol/L)
3. Glycated hemoglobin A1c (HbA1c)	≥6.5
4. Random blood glucose associated with classic symptoms of diabetes mellitus	≥200 mg/dl (11.1 mmol/L)

**Fasting blood glucose value in normal persons (less than 100 mg/dl), prediabetes (100–125 mg/dl) and diabetes mellitus (≥126 mg/dl).*

Pathology Pearls: Metabolic Alterations in Diabetes Mellitus

- **Hyperlipidemia:** Lack of insulin decreases capillary lipoprotein lipase activity in peripheral blood. It leads to accumulation of chylomicrons and VLDL in blood, which may precipitate acute pancreatitis and eruptive xanthoma in the skin (called the hyperchylomicronemia syndrome). Hyperlipidemia accelerates atherosclerosis at an early age. The risk of cerebrovascular disease is high and frequency to develop foot gangrene is about 100 times increased.
- **Skeletal muscle wasting:** In diabetes mellitus, increased protein degradation results in skeletal muscle wasting.
- **Dilutional hyponatremia:** Serum sodium is decreased in diabetes mellitus. Glucose overrides sodium in controlling the osmotic gradient. Hence, water shifts out of the intracellular fluid compartment into the extracellular compartment resulting in dilution hyponatremia.
- **Hyperkalemia:** Serum K^+ is increased in diabetes mellitus, which occurs due to transcellular shift as excess H^+ ions enter cells in exchange of potassium.
- **Metabolic acidosis:** Metabolic acidosis in diabetes mellitus occurs due to diabetic ketoacidosis and lactic acidosis.
- **Severe volume depletion:** Diabetes mellitus produces severe volume depletion and coma due to loss of sodium and water with osmosis diuresis.
- **Prerenal azotemia:** Prerenal azotemia in diabetes mellitus occurs due to volume depletion resulting in accumulation of waste products in body.

Fasting Blood Glucose

Fasting blood glucose measures the amount of glucose in the blood without food intake, which is a good indicator of glucose metabolism. Fasting blood glucose is defined as no caloric intake for at least 8 hours. Normal fasting blood glucose value is less than 100 mg/dl (<5.6 mmol). Fasting blood glucose value in prediabetes ranges between 100 and 125 mg/dl (5.6–6.9 mmol/L). Fasting blood glucose value in diabetes mellitus is 126 mg/dl or higher (7 mmol/L or higher) on two separate tests.

Random Blood Glucose

A random blood glucose analysis is done to measure the amount of glucose circulating in a person's blood. It is useful for persons who need a speedy diagnosis such as those with type 1 diabetes mellitus who require supplement insulin as a matter of emergency. Patients with type 1 diabetes mellitus present with classic symptoms of hyperglycemia or has hyperglycemic crisis (postprandial random blood sugar 200 mg/dl).

Oral Glucose Tolerance Test

Persons with diabetes mellitus can sometimes demonstrate normal results of fasting or random blood glucose levels yet still have diabetes mellitus.

- If clinicians still suspect that a person has diabetes mellitus, they may recommend an oral glucose tolerance test (OGTT).
- OGTT also requires a person not to eat or drink for eight hours. After giving the first blood sample, person drinks a liquid containing 75 g of glucose. The clinician then takes additional blood samples hourly over the next two hours.
- For an oral glucose tolerance test, blood glucose <140 mg/dl is considered normal.
- Blood glucose values between 140 and 199 mg/dl indicates prediabetes. Prediabetes stage means that a person's blood glucose levels are higher than usual, but clinicians do not consider that they have diabetes mellitus. Clinicians sometimes call this impaired glucose tolerance (IGT) or impaired fasting blood glucose. Persons with prediabetes stage are at higher risk of developing diabetes mellitus. Lifestyle modifications, such as exercise, weight loss and other medications can help to reduce this risk.
- Blood glucose value of ≥200 mg/dl indicates diabetes mellitus. Oral glucose tolerance test in diagnosing diabetes mellitus (samples are drawn after 100 g glucose drink) is given in Table 26.18.

Clinical Pearls: Procedural Alert of Glucose Tolerance Test

- Glucose tolerance test (GTT) is contraindicated in patients with a recent history of surgery, myocardial infarction or labor and delivery. Because these conditions can produce invalid values.
- Glucose tolerance test should be postponed in common illness, i.e. flu or severe cold.
- Reactions during glucose tolerance test should be recorded and reported. Patient may develop weakness, unconsciousness and sweating during the second and third hours of the test. In these cases, GTT should be aborted.
- GTT is declared invalid in case the patient vomits out glucose. Therefore, test can be repeated in three days.

Glycosylated Hemoglobin (HbA1c) for Routine Glycemic Control

The glycosylated hemoglobin (HbA1c) has strong predictive value for diabetic complications and HbA1c analysis should be performed routinely in all diabetic patients. Clinicians should interpret when using HbA1c to monitor patients with hemoglobin variants or conditions that affect red blood cells (RBCs).

- HbA1c analysis is the primary assessment diagnostic tool for glycemic control at every three months including self-monitoring of blood glucose to determine whether glycemic targets have been reached and maintained.
- Hemoglobin is a protein in red blood cells that carries oxygen to organs/tissues and transports carbon

Table 26.18 Two-hour oral glucose tolerance test in diagnosing diabetes mellitus except during pregnancy

Oral Glucose Tolerance Test (OGTT)	Fasting Blood Glucose Level	Two-hour Blood Glucose Level
Normal glucose tolerance	<100 mg/dl (5.5. mmol/L)	<140 mg/dl (7.8. mmol/L)
Impaired glucose tolerance (prediabetes)	100–125 mg/dl (5.6 to 6.9 mmol/L)	140 mg/L (7.8 mmol/dl) to 199 mg/L (11.1 mmol/L)
Diabetes mellitus	>126 mg/dl (7.0 mmol/L)	≥200 mg/dl (11.1 mmol/L)

Blood glucose levels are applicable except during pregnancy. Blood samples are drawn fasting and two hours after a glucose drink.

dioxide from organs/tissues. Glucose molecule in the blood is normally bound to hemoglobin molecule. This means the hemoglobin has become glycosylated, and is also referred to as HbA1c.

- As a person's blood glucose becomes higher, more of hemoglobin becomes glycosylated. The glucose molecule remains bound to the hemoglobin for the life span of the red blood cell or about two to three months.
- Glycosylated hemoglobin (HbA1c) is analyzed to monitor the long-term control of diabetes mellitus. The level of glycosylated hemoglobin is increased in the red blood cells of persons with poorly controlled diabetes mellitus including type 2 diabetes mellitus in pediatric patients.
- Normal range for glycosylated hemoglobin (HbA1c) level is between 4% and 5.6%. Glycosylated hemoglobin level in prediabetes stage ranges between 5.7% and 6.4%. The percentage of glycosylated hemoglobin is increased depending upon the degree of hyperglycemia. Glycosylated hemoglobin level >6.5 is diagnostic of diabetes mellitus, which is directly related to the average concentration of glucose in the blood.
- HbA1c analysis is not recommended in postpartum period due to increased red blood cells count related to pregnancy and/or blood loss at delivery, that can affect HbA1c results. Oral glucose tolerance test (OGTT) is more sensitive test than HbA1c analysis during postpartum period.

Monitoring Long-term Diabetic Complications

Monitoring Diabetic Cardiovascular Diseases

Persons with diabetes mellitus usually have cardiovascular diseases related to risk factors including dyslipidemia as a result of accumulation of chylomicrons and VLDL in blood. Lipid profile should be performed to treat and monitor dyslipidemia.

Monitoring Diabetic Nephropathy

Screening for diabetic nephropathy using urinary albumin analysis and estimated glomerular filtration rate (GFR) testing at least once in a year in patients who have had type 1 diabetes mellitus for more than five years and those with type 2 diabetes mellitus.

- **Urine analysis:** Diabetic nephropathy patient may show proteins, glucose, ketone bodies, pus cells, hyaline casts, fatty casts and oval fat bodies (lipid-containing renal tubular epithelial cells). Free fat droplets, fatty casts, and oval fat bodies; when examined by polarized light, the lipids in casts are seen as being doubly refractile or birefringent and they display a symmetric "Maltese-cross" pattern.
- **Serum proteins:** Total serum proteins are decreased, with reversal of albumin/globulin ratio (normal 2:1) in diabetic nephropathy.
- **Blood urea (20–40 mg/dl):** Blood urea is increased in diabetic nephropathy. Never use anticoagulant containing NH_4^+ salt as it increases urea concentration.
- **Serum creatinine (normal 0.6–1.5 mg%):** Serum creatinine is increased in diabetic nephropathy.
- **Renal biopsy:** Renal biopsy should consist of at least five glomeruli to comment. Formalin-fixed paraffin-embedded sections stained with hematoxylin and eosin, and periodic acid–Schiff stain should be examined under light microscope.

Monitoring Autoimmune Disorders in Diabetic Patients

Consider screening patients with type 1 diabetes mellitus for autoimmune disorders such as autoimmune thyroiditis and celiac disease soon after the diagnosis, as autoimmune disorders occur more frequently in patients with type 1 diabetes mellitus.

Diabetes Mellitus-related Autoantibodies Analysis

Classic differentiation between type 1 and type 2 diabetes mellitus may not always be appropriate on overlapping clinical features.

- Diabetes-related autoantibodies analysis such as islet cell antibodies (ICAs), insulin antibodies (IAs) and glutamic acid decarboxylase antibodies (GADAs, i.e. GAD 65) can be helpful in establishing an autoimmune etiology in persons with previously diagnosed type 1 diabetes mellitus and to exclude the diagnosis of type 2 diabetes mellitus.
- Routine screening for type 1 diabetes mellitus risk with autoantibody testing is recommended only

in the setting of a research trial or in first-degree family members of a proband with type 1 diabetes mellitus.

Molecular Genetic Analysis

Molecular genetic testing is recommended in patients suspected of having monogenic diabetes syndromes, such as maturity-onset diabetes mellitus of the young (MODY) and neonatal diabetes mellitus (NDM) to verify genetic etiology, establish treatment and identify affected family members.

Pathology Pearls: Molecular Genetic Defects of Pancreatic β Cell Functions

- Chromosome 12: HNF-1α (MODY 3)
- Chromosome 7: Glucokinase (MODY 2)
- Chromosome 20: HNF-4α (MODY 1)
- Chromosome 13: Insulin promoter factor 1 (IPF-1, also known as PDX1 (pancreatic and duodenal homeobox 1 [MODY 4])
- Chromosome 17: HNF-1β (MODY 5)
- Chromosome 2: Neuro-D1 (MODY 6)
- Mitochondrial DNA defect: Mitochondrial diabetes mellitus

DISORDERS OF THYROID GLAND

ANATOMY OF THYROID GLAND

The thyroid gland is one of the largest endocrine glands. It consists of two lateral lobes connected in the middle by broad isthmus just below the larynx. It weighs 20–25 g in adults. It is composed of two types of secretory element: the follicular and parafollicular cells. Fibrovascular stroma is present in between the thyroid follicles. The follicular cells are responsible for the synthesis of thyroid hormones, and the parafollicular cells elaborate calcitonin.

- The genes responsible for the development of thyroid follicular cells include TTF-1, TTF-2 (thyroid transcription factor 1 and 2), PAX8, TSH and TSHR.
- Homeobox expressed embryonic stem cells 1 (HESX1) is transcriptional repressor essential in the early development of thyroid gland. The factors that control thyroid embryogenesis, agenesis or dysgenesis are poorly understood.
- Although the thyroid gland is capable of performing independent function, the thyroid hormone synthesis is regulated by the hypothalamic-pituitary-thyroid axis. Hypothalamic tripeptide TSH-releasing hormone (TRH) stimulates pituitary gland to synthesize TSH. TSH in turn stimulates the thyroid follicular cells to synthesize prohormone (T_4) and its active form triiodothyronine (T_3). Because thyroid hormones have a profound influence on cellular metabolic process, which play a key role in the normal growth and development.

Structure ot Thyroid Gland

Thyroid gland is composed of thyroid follicles lined by cuboidal epithelium and containing colloid. Fibrovascular stroma is present in between the thyroid follicles.

- **Thyroid follicular cells:** These cells synthesize thyroxine (T_4) and triiodothyronine (T_3), which are needed to keep the body functioning at its normal rate. The thyroid gland needs a regular supply of iodine (which is added to table salt and found in fish and milk) in order to produce thyroid hormones.
- **Parafollicular cells or C cells of thyroid gland:** These cells synthesize thyrocalcitonin (TC), which lowers the blood level of calcium ions by transporting calcium in the bones. Calcitonin secretion is controlled by calcium ion level in the blood.

PHYSIOLOGY OF THYROID GLAND

Thyroid gland responds to many stimuli as in a constant state of adaptation. Thyroid follicular epithelium proliferates and becomes more active during puberty, pregnancy and physiologic stress. When the stress abates, involution occurs and the thyroid follicular cells resume their normal size and architecture.

REGULATION OF THYROID HORMONES

- Low blood levels of T_3 and T_4 or low basal metabolic rate stimulate release of TRH by hypothalamus.
- TRH, carried by hypophyseal portal veins to anterior pituitary gland, stimulates release of TSH by thyrotrophs.
- TSH released into blood stimulates the thyroid follicular cells.
- Thyroid hormones (T_4 and T_3) are synthesized from iodine and tyrosine within thyroglobulin (TBG) and transported in the blood bound to plasma proteins, mostly thyroid-binding protein (TBG).
- Elevated T_3 and T_4 inhibit release of TRH and TSH by negative feedback mechanism, i.e. inhibiting synthesis of TRH by hypothalamus and TSH synthesis by anterior pituitary gland.

SYNTHESIS OF THYROID HORMONES

Synthesis of thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) depend on sufficient quantities

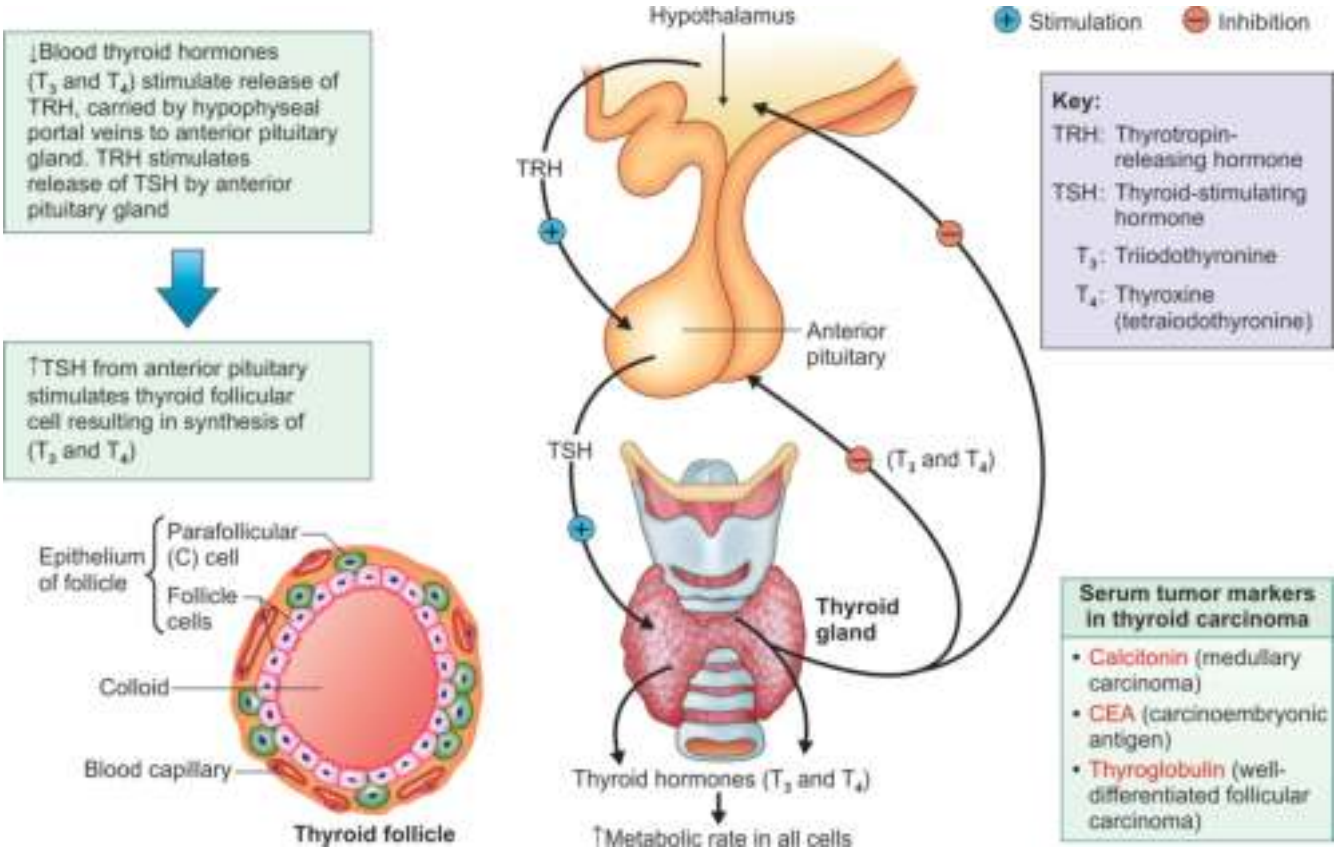

Fig. 26.19: Regulation of thyroid hormones synthesis.

of iodine from dietary sources. Thyroid stimulating hormone (TSH) regulates the rate of extraction of iodine from the bloodstream, synthesis of T_4 and T_3, release from storage as thyroglobulin and secreted into the bloodstream.

Feedback mechanisms regulate TSH synthesis by pituitary gland. Serum T_4 and T_3 are bound to thyroid-binding globulin (TBG). Regulation of thyroid hormones synthesis is shown in Fig. 26.19.

Pathology Pearls: Thyroid Hormones Synthesis and Regulation

- Thyroid transcription factors (TTF-1, TTF-2) and PAX8 participate in thyroid gland development and functioning.
- TTF-1 is a multifunctional nuclear protein that mediates DNA replication fork arrest and regulates RNA polymerase 1 transcription on chromatin. Its biological functions include activation, silencing of transcription, and transcription termination.
- TTF-2 regulates transcription of thyroglobulin (TG) and thyroid peroxidase (TPO). Thyroid hormone receptor inhibits cAMP-response element binding protein (CREB) transcriptional activity.
- Thyroid gland is regulated by hypothalamus and anterior pituitary gland located in the brain. The hypothalamus releases thyrotropin-releasing hormone (TRH), which stimulates the anterior pituitary gland to release thyroid-stimulating hormone (TSH).
- Iodine and tyrosine are essential for synthesis of thyroid hormones. Iodine requirement is 1 mg per week. Iodine consumed through diet is converted into iodide and absorbed by gastrointestinal tract. Sodium iodide is added to common salt to prevent iodine deficiency.

THYROID HORMONES SYNTHESIS: STEPS

- **Thyroglobulin synthesis by thyroid follicular cells:** Endoplasmic reticulum and Golgi appratus in the thyroid follicular cells synthesize and secrete thyroglobulin continuously and stored in the thyroid follicle. Thyroglobulin molecule contains 140 molecules of amino acid tyrosine.
- **Iodide trapping:** TSH participates in trapping of iodide in thyroid follicular cells. Iodide is actively transported from blood into thyroid follicular cells against electrochemical gradient along with sodium by sodium/iodide symporter. Normally, concentration of iodide is 30 times in thyroid gland than in the blood. Concentration of iodide increases 200 times more in thyroid follicular cells during hyperactivity of thyroid gland.
- **Oxidation of iodide:** Peroxidase enzyme converts iodide to organically bound iodine in thyroid

follicular cells. The iodide ions lose electrons to form iodine molecules.

- **Transport of iodide into thyroid follicular cavity:** Iodide is transported from the thyroid follicular cells into the follicular cavity by an iodide-chloride pump called pendrin.
- **Organification of thyroglobulin:** Iodide transported from the thyroid follicular cells into the follicular cavity and binds with thyroglobulin. This process is called the organification of thyroglobulin.
- **Iodination of tyrosine:** Thyroid stimulating hormone (TSH) participates in incorporation of iodide into tyrosine resulting in formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). Combination of iodide with tyrosine already present in thyroglobulin is known as iodination, which takes place in thyroglobulin. Iodination process is accelerated by the enzyme iodinase, which is synthesized by thyroid follicular cells. Iodination occurs in several stages: (a) tyrosine is oxidized first into MIT and later into DIT, and (b) MIT and DIT are called the iodotyrosine residues.
- **Coupling reactions:** Iodotyrosine residues (MIT and DIT) get coupled with one another and give rise to different thyroid hormones T_3 and T_4. One molecule of MIT and one molecule of DIT combine to form triiodothyronine (T_3). Two molecules of DIT combine to form tetraiodothyronine (T_4). Thyroid hormones (T_4, T_3) are stored as colloid in thyroid follicles.
- **Endocytosis of thyroglobulin colloid into thyroid follicular cells:** Thyroglobulin colloid containing T4 and T_3 is endocytosed and combine with lysosomes leading to formation of phagolysosome.
- **Proteolysis of thyroglobulin colloid in lysosome:** Proteolysis of thyroglobulin colloid containing T_4 and T_3 occurs by lysosomal enzyme and leading to release of T_4 and T_3 in thyroid follicular cells. This step is TSH-mediated process. Thyroid hormones T_4 and T_3 are exocytosed into the blood circulation.

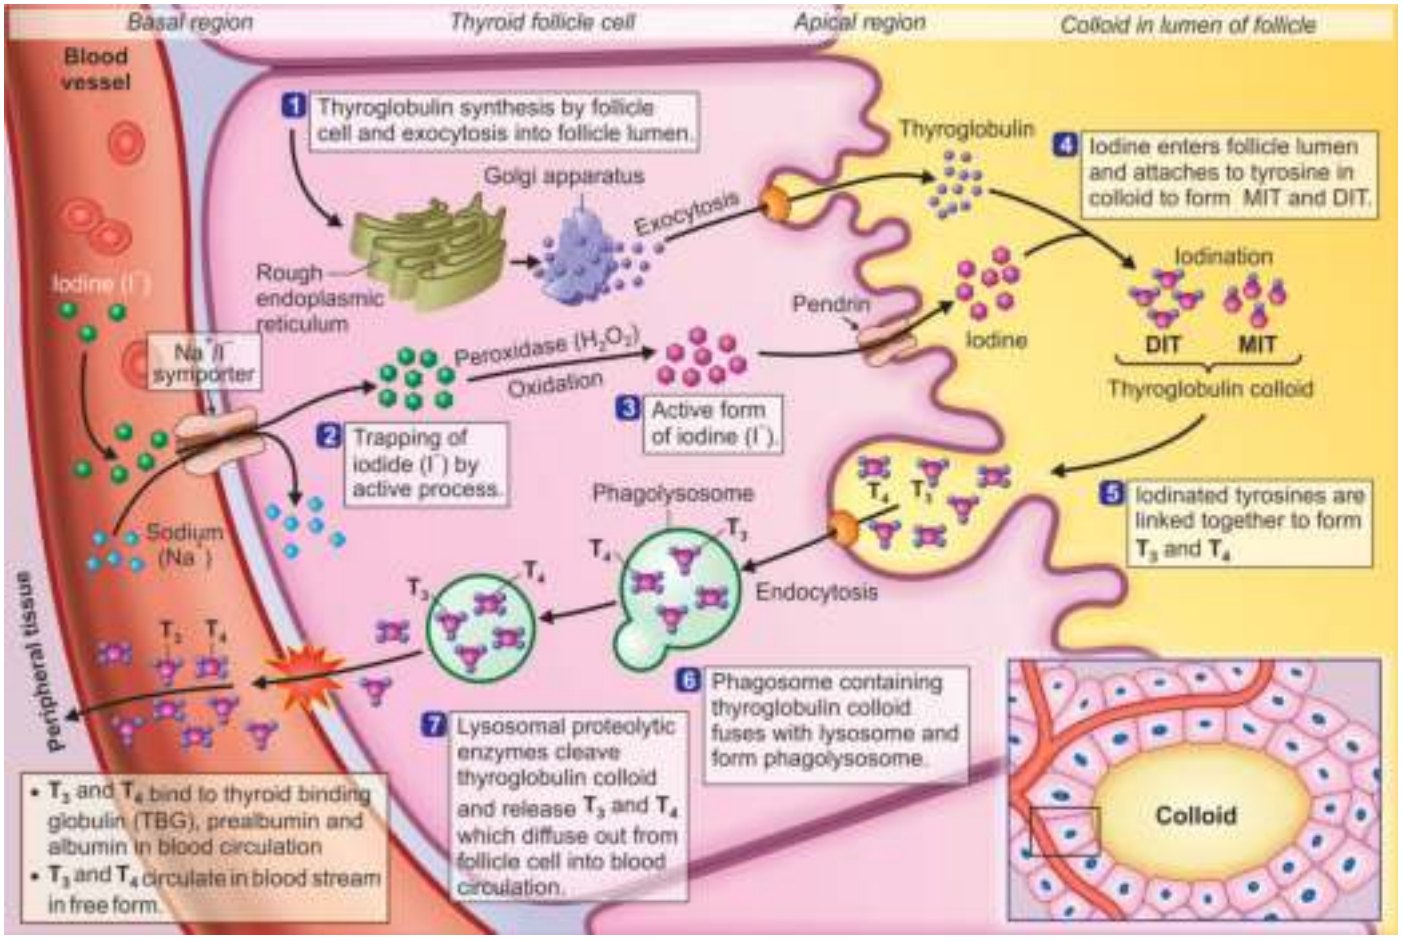

Fig. 26.20: Mechanism of synthesis of thyroid hormones. Steps in synthesis of thyroid hormones include thyroglobulin synthesis, iodide trapping, oxidation of iodide, transport of iodine into follicular cavity, organification of thyroglobulin, iodination of tyrosine, coupling reactions (iodotyrosine residues get coupled with one another and give rise to different thyroid hormones T_3 and T_4, endocytosis of thyroglobulin colloid into thyroid follicular cell, proteolysis of thyroglobulin colloid in lysosome, and exocytosis of T_4 and T_3 and binding to TBG in blood and also circulate in free forms. Note: Thyroid transcription factors 1 and 2 (TTF-1, TTF-2) and PAX8 participate in thyroid gland development and functioning.

- **Exocytosis of T_4 and T_3 and binding to TBG in blood stream:** Thyroid hormones (T_4, T_3) bind to thyroid binding globulin (TBG), prealbumin and albumin. One-third of TBG binding sites are normally occupied. Thyroid hormones (T_4, T_3) circulate and act on peripheral tissues. Mechanism of synthesis of thyroid hormones is shown in Fig. 26.20.

THYROID HORMONES IN CIRCULATION AND TISSUES

- **Synthesis of thyroid hormones in circulation:** Thyroid gland synthesizes T_4 (80 μg) and triiodothyronine T_3 (6 μg) daily.
- **Conversion of T_4 to T_3 in various tissues:** Only a small fraction of thyroid hormones circulates in free form. Outer ring of 5-deiodinase enzyme converts T_4 to T_3 mainly in liver, kidneys (80%) and dendritic cells of nervous system (some conversion).
- **Mechanism of actions of T_3 on various tissues:** T_3 is metabolically active hormone. It acts on nuclear receptors thus increases messenger RNA and protein synthesis.

THYROID HORMONES: ACTIONS

- **Central nervous system:** Thyroid hormones are essential for axonal, dendritic development and myelinization of CNS especially in early first year of postnatal life.

  Deficiency of thyroid hormones during intrauterine life results in mental retardation due to nonmyelinization of central nervous system and causes cretinism (thyroid dwarf) in children.
- **Maturation of growing epiphyseal region and skull:** Thyroid hormones enhance synthesis of growth hormones and insulin-like growth factor; which is necessary for maturation of growing epiphyseal region (linear growth), skull; tooth eruption and dentition.
- **Peripheral vasodilatation:** Thyroid hormones enhance synthesis of β-adrenergic receptors and cause vasodilatation.
- **Basal metabolic rate:** Thyroid hormones increase basal metabolic rate resulting in increased oxygen consumption.
- **Regulation of metabolism:** Thyroid hormones regulate carbohydrate, fat and protein metabolism.
- **Maintenance of water and electrolyte balance:** Thyroid hormones maintain water and electrolyte balance.
- **Hematopoiesis:** Thyroid hormones play an important role in hematopoiesis.

THYROIDITIS

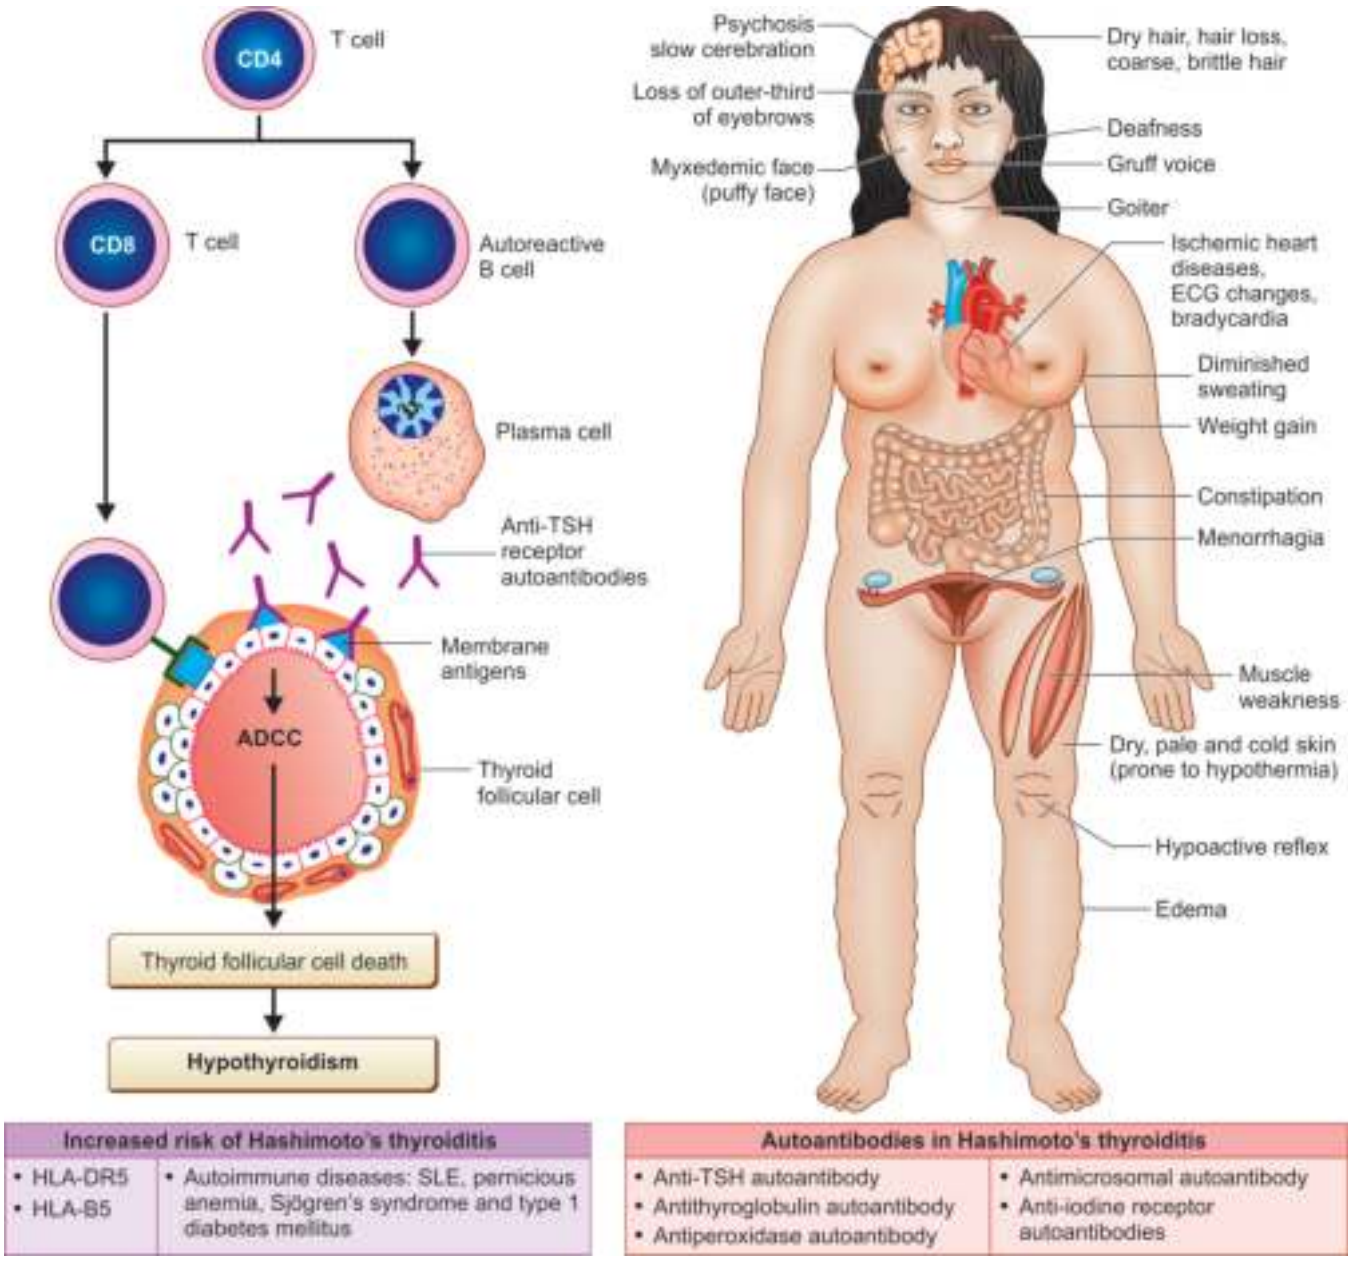
HASHIMOTO'S THYROIDITIS

Hashimoto's thyroiditis is an autoimmune disease. It is the most common cause of hypothyroidism. Autoantibodies such as antithyroid peroxidase antibody, antithyroglobulin antibody and anti-TSH antibody are implicated in its pathogenesis. Infiltrates of lymphocytes with germinal center formation are seen in Hashimoto's thyroiditis (Figs 26.21 to 26.23).

Age Group and Incidence

Hashimoto's thyroiditis occurs more often in women (30–50 years) than men. Its incidence is increased in HLA-DR5, HLA-B5 and autoimmune disorders, i.e. systemic lupus erythematosus, rheumatoid arthritis, pernicious anemia, Sjögren's syndrome, adult-onset type 1 diabetes mellitus, chronic active hepatitis and adrenalitis.

Pathogenesis of Hashimoto's Thyroiditis



Type II Hypersensitivity Reaction-mediated Disorder

Loss of activity of T-suppressor cells in Hashimoto's thyroiditis results in formation of autoantibodies (IgG or IgM) such as anti-TSH receptor autoantibody, antithyroglobulin autoantibody, antiperoxidase autoantibody (peroxidase enzyme located in the apical region of follicular cells), anti-microsomal autoantibody and anti-iodine receptor autoantibody.

- Anti-TSH receptor autoantibody inhibits intracellular iodine transport resulting in decreased synthesis of thyroid hormones.
- Fc portion of IgG or IgM binds to Fc receptors of cytotoxic leukocytes, i.e. natural killer cells (most important), macrophages, neutrophils and eosinophils which destroy sensitized cells. The cytotoxic leukocytes release hydrolytic enzymes and oxygen-derived free radicals resulting in tissue damage.

Type IV Hypersensitivity Reaction-mediated Disorder

Type IV hypersensitivity reaction plays key role in pathogenesis of Hashimoto's thyroiditis. (a) CD8+ cytotoxic T cells destroy thyroid follicular cells and induce apoptosis through the Fas–FasL system. (b) CD4+ helper T cells synthesize cytokines that cause chemotaxis of macrophages. These macrophages cause destruction of thyroid gland. Initially, patient develops hyperthyroidism due to release of thyroid hormones, and eventually hypothyroidism as a result of depleted thyroid hormones.

Increased risk of Hashimoto's thyroiditis	
• HLA-DR5 • HLA-B5	• Autoimmune diseases: SLE, pernicious anemia, Sjögren's syndrome and type 1 diabetes mellitus

Autoantibodies in Hashimoto's thyroiditis	
• Anti-TSH autoantibody • Antithyroglobulin autoantibody • Antiperoxidase autoantibody	• Antimicrosomal autoantibody • Anti-iodine receptor autoantibodies

Fig. 26.21: Pathogenesis of Hashimoto's thyroiditis.

Surgical Pathology: Hashimoto's Thyroiditis

Gross Morphology

Thyroid gland is diffusely enlarged and firm, weighing 60–200 g. Cut surface is fleshy, pale tan, exhibiting a vaguely nodular pattern.

Light Microscopy

Thyroid gland displays following histologic features in Hashimoto's thyroiditis:

- **Mononuclear inflammatory infiltrate:** It comprises lymphocytes, plasma cells and macrophages. The inflammatory infiltrates are focally arranged in the form of lymphoid follicles, often with germinal centers.
- **Destruction of thyroid follicles:** Extensive destruction and atrophy of the thyroid follicles occur due to heavy inflammatory infiltrate of CD8+ cytotoxic T cells, CD4+ helper T cells, recruited macrophages and cell-mediated cytotoxicity by antithyroid antibodies. The remaining thyroid follicles vary in size and shape.
- **Oxyphil metaplasia:** The persistent thyroid follicular epithelium is transformed into so-called Hürthle cells or oncocytes or Askanazy cells (oxyphilic metaplasia). Hürthle cells have an abundant brightly eosinophilic granular cytoplasm packed with mitochondria and lysosomes. Hürthle cells produce a little or absence of T_3, T_4 and thyroglobulin.
- **Interlobular fibrosis:** Variable interlobular fibrosis in the thyroid is seen in long-standing cases of Hashimoto's thyroiditis.

- Fibrosing variant of Hashimoto's thyroiditis shows extensive dense fibrosis within the capsule of thyroid gland with atrophy of thyroid follicles. It should be differentiated from Riedel's thyroiditis.
- It is worth mentioning that Riedel's thyroiditis invades the surrounding structures with extensive fibrosis and scant thyroid tissue.

Clinical Features

Early in the course of Hashimoto's thyroiditis, there may be transient hyperthyroidism due to excessive release of thyroid hormones from damaged thyroid follicles, but later hypothyroidism occurs due to depletion of thyroid hormones in 40–50% of cases.

- Patient presents with painless diffuse enlargement of thyroid gland, sometimes appear lobulated mass mimicking a tumor.
- Due to destruction of the thyroid follicles over the years, thyroid gland undergoes marked atrophy, which is often not palpable.

Fig. 26.22A and B: Hashimoto's thyroiditis. Cut surface is fleshy, pale tan, exhibiting a vaguely nodular pattern. (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru.)

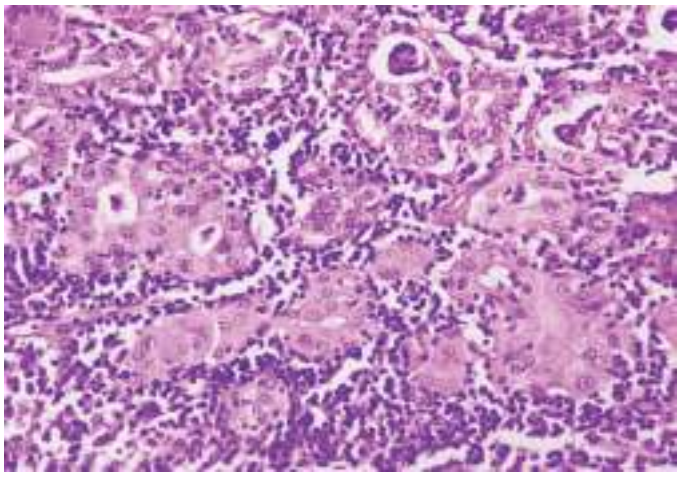


Fig. 26.23: Hashimoto's thyroiditis. Thyroid follicles show destruction due to infiltration by chronic inflammatory cells. Hürthle cell change in follicular cells is seen (400X).

Risk for Development of Malignancy

There is increased risk for subsequent development of primary B cell non-Hodgkin's lymphoma, papillary thyroid carcinoma and Hürthle cell neoplasms.

Laboratory Diagnosis

Diagnostic tests include detection of circulating auto-antibodies against the tissues involved anti-microsomal in 90% of cases, anti-thyroglobulin in 50% of cases, and antiperoxidase are analyzed in Hashimoto's thyroiditis.

Presence of antibody in the lesion (biopsy) is demonstrated by immunofluorescence microscopy. TSH is markedly increased in these patients.

SUBACUTE PAINLESS LYMPHOCYTIC THYROIDITIS

Subacute painless lymphocytic thyroiditis is an autoimmune disorder developing during postpartum period. Thyroid gland lacks germinal follicles.

Clinical Features

Patient presents with abrupt onset of thyrotoxicosis due to gland destruction, painless enlarged thyroid gland. It progresses to primary hypothyroidism in 40–50% of cases. It lacks immunological markers as demonstrated in Hashimoto's thyroiditis.

SUBACUTE GRANULOMATOUS THYROIDITIS

Subacute granulomatous thyroiditis most often affects women of 40–50 years age group. It is also known as de Quervain granulomatous thyroiditis, or giant cell thyroiditis. It is associated with HLA-B35. It has self-limited course of several weeks' duration. Subacute granulomatous thyroiditis is characterized by granulomatous inflammation with multinucleated giant cells resulting in focal destruction of thyroid gland (Fig. 26.24).

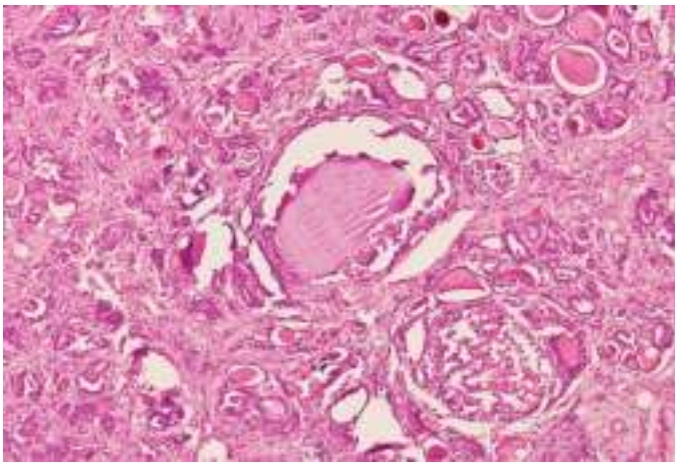

Fig. 26.24: Subacute granulomatous thyroiditis. Histologic examination shows destruction of thyroid follicular cells with colloid depletion by inflammatory cells, mumerous noncaseating granulomas and multinucleated giant cells surrounding thyroid follicles (400X).

Pathogenesis

Subacute granulomatous thyroiditis typically occurs after upper respiratory tract infections caused by influenza virus, adenovirus, echovirus, and coxsackievirus. Thyroid gland destruction initially results in hyperthyroidism, i.e. increased serum T_4 and decreased TSH. Permanent hypothyroidism is uncommon.

Surgical Pathology: Subacute Granulomatous Thyroiditis
Gross Morphology
The thyroid gland is enlarged to 40 g and weighing 60 g, and the cut surface is firm and pale.
Light Microscopy
▪ Initially, thyroid gland shows acute inflammation with microabscesses. It is followed by infiltration by lymphocytes, plasma cells, and macrophages throughout the thyroid gland. ▪ Destruction of thyroid follicles allows the release of colloid, which elicits a conspicuous granulomatous reaction.

Clinical Features

Initially, the patient may develop transient hyperthyroidism with decreased uptake of ^{123}I followed by hypothyroidism in late stage. Patient presents with painful, tender and enlarged thyroid gland often preceded by an upper respiratory tract infection.

RIEDEL'S THYROIDITIS

In Riedel's thyroiditis, the thyroid gland is replaced by fibrous tissue and can clinically mimic carcinoma, which may cause tracheal obstruction. Extension of fibrous tissue occurs in soft tissues of the neck, progressing in retroperitoneum, mediastinum and orbit. Surgical treatment of Riedel's thyroiditis is required to relieve tracheal or esophageal obstruction.

Surgical Pathology: Riedel's Thyroiditis
Gross Morphology
▪ Part or the entire thyroid is hard and is described as woody thyroid. ▪ Cut surface shows tan-gray woody and a vascular areas.
Light Microscopy
▪ Thyroid gland lacks normal lobular pattern. ▪ Thyroid follicles are obliterated or compressed by extensive fibrosis, which also invades surround tissue. ▪ Lymphocytes, plasma cells, and eosinophils are also trapped.

Clinical Features

Riedel's thyroiditis most often affects only one lobe of thyroid gland. Patient presents with inspiratory stridor due to tracheal obstruction, dysphagia (esophagus compression) and hoarseness due to involvement of recurrent laryngeal nerves. Patient may develop hypothyroidism.

ACUTE BACTERIAL THYROIDITIS

Acute thyroiditis is caused by *Staphylococcus aureus*. Thyroid gland destruction initially results in hyperthyroidism due to increased serum T_4 and decreased TSH. Permanent hypothyroidism is uncommon. ^{123}I uptake is decreased.

Clinical Features

Patient presents with fever and tender thyroid gland with cervical lymphadenopathy. Patient is treated by course of antibiotics.

HYPOTHYROIDISM

Impaired activity of any component of the hypothalamic-pituitary-thyroid axis can result in decreased thyroid function. The most common causes of hypothyroidism include faulty embryogenesis, Hashimoto's thyroiditis or reduction in functioning thyroid tissue due to prior surgery, radiation damage, and thyroid malignancy. Hypothyroidism manifests as cretinism in children and myxedema in adults. Hypothyroidism in adults most often affects middle-aged persons. Females are affected eight times more than males.

CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism is the most common congenital endocrine disorder with an incidence of about 1 in 3500 births. About 85% of cases occur due to faulty embryogenesis. A small number of cases presenting with goiter occur as a result of enzyme defects in thyroid hormone biosynthesis (dyshormonogenesis). Clinically, congenital hypothyroidism often manifests in the first few days of life.

- The genes responsible for the development of thyroid follicular cells include TTF-1, TTF-2 (thyroid transcription factors 1 and 2), PAX8, TSH and TSHR. Mutations of these genes are responsible for 5% of hypothyroidism patients. TTF-1, TTF-2 and PAX8 mutations give rise to nonsyndromic congenital hypothyroidism. On the other hand, mutations of TSH and TSHR are responsible for syndromic congenital hypothyroidism.
- Mutations in sodium iodide symporter (NIS), pendrin (PDS also known as SLC264A), thyroid peroxidase (TPO), thyroid oxidase 2 (THOX2, also known as DUOX2, LNOX2) and thyroglobulin (TG) affect organification of iodide and have been linked to congenital hypothyroidism.
- Depending on the etiology, three types of congenital hypothyroidism can be distinguished: (a) central congenital hypothyroidism due to defect at hypothalamus or pituitary gland, (b) primary hypothyroidism due to impairment of thyroid gland itself, and (c) peripheral hypothyroidism as a result of resistance to thyroid hormones. Gene mutations responsible for hypothyroidism in children and adults are given in Table 26.19.

CRETINISM (THYROID DWARF)

Cretinism results from deficiency of thyroid hormones during fetal development and during postnatal life. Cretinism denotes physical and mental insufficiency secondary to congenital hypothyroidism in children. Cretinism may be endemic, sporadic, or familial, which affects both girls and boys.

- **Physiologic state:** Thyroid hormones are essential for brain development, i.e. axonal and dendrite development especially myelination of central nervous system (formation of myelin sheath around a nerve) in postnatal period in the first two years of life. Thyroid hormones are also necessary for

Table 26.19 Gene mutations responsible for hypothyroidism in children and adults

Characteristics	Gene Locus on Chromosome	Protein Function	Gene Mutation and its Defective Protein	Comments
Central congenital hypothyroidism due to defect at hypothalamus and pituitary gland				
Thyroid-stimulating hormone (TSH)	▪ TSHα-chain on 6p14.3 ▪ TSHβ-chain on 1p22	Synthesis of biologically active TSH	Synthesis of biologically inactive TSH	Homozygous or compound heterozygous patients
Thyroid-stimulating hormone receptor (TSHR)	14q31	Normal synthesis of protein with normal structure and function associated with normal cyclic AMP response to TSH	Abnormal synthesis of protein with normal structure and function associated with defective cyclic AMP response to TSH	Homozygous or compound heterozygous patients
Thyroid dyshormonogenesis				
Sodium/iodide symporter (NIS)	19p12-13.2 with 15 exons	Normal uptake of iodide by thyroid gland	Abnormal uptake of iodide by thyroid gland	Homozygous or compound heterozygous patients
Pendrin (expressed in thyroid, inner ear and kidney)	7q22-31	Normal iodide transport and hence iodide organification	Abnormal iodide transport and hence iodide organification	Pendred syndrome has triad of deafness, goiter (euthyroid or subclinical hypothyroid influenced by dietary iodide uptake) and a partial organification defect
Thyroid peroxidase (TPO)	2p25 with 17 exons	Normal synthesis of iodination of thyroglobulin (TG)	Defects in the synthesis of iodination of thyroglobulin (TG)	Autosomal recessive patients develop goitrous congenital hypothyroidism
Thyroid oxidase 2 (THOX2) expressed in airway epithelium and skin	15q15.3	Generates H_2O_2 that is used by thyroid peroxidase (TPO) in the oxidation of iodine prior to iodination of the tyrosyl residue of thyroglobulin	H_2O_2 not synthesized so not available by thyroid peroxidase (TPO) in the oxidation of iodine prior to iodination of the tyrosyl residue of thyroglobulin	Homozygotes and compound heterozygous patients develop severe and permanent congenital hypothyroidism

Contd...

Table 26.19 Gene mutations responsible for hypothyroidism in children and adults (*Contd...*)

Characteristics	Gene Locus on Chromosome	Protein Function	Gene Mutation and its Defective Protein	Comments
Resistance to thyroid hormone receptor				
Thyroid hormone receptor (TR) genes	▪ TRα-chain on 17 ▪ TRβ-chain on 3	TR protein has a central DNA binding-domain	Defective TR protein without DNA binding-domain	*TRβ gene mutation is associated with thyroid hormone resistant congenital hypothyroidism
Thyroid hormone cell transporter	**MCT8 gene on Xq13.2	Protein encoded by MCT8 gene transports thyroid hormone from extracellular compartments across the cell membrane	Defective protein produced by MCT8 unable to transport thyroid hormone from extracellular compartments across the cell membrane	Milder phenotype with elevated level of serum T_3

**TRβ gene mutation is also demonstrated in pituitary adenomas, **MCT8—monocarboxylate transporter gene.*

linear growth, i.e. maturation of growing epiphyseal region of bones, closure of fontanelle skull and tooth eruption elicitation (Fig. 26.25).

- **Pathologic state:** Deficiency of thyroid hormones causes defective development of brain due to nonmyelination of nervous system and maturation of the growing fetus leading to stunted growth called cretinism (thyroid dwarf).

Predisposing Factors

Most important cause of cretinism is maternal hypothyroidism before development of fetal thyroid gland.

- Transplacental transfer of antithyroid antibodies from a mother suffering from autoimmune thyroid disease may produce cretinism.
- Cretinism may also be caused due to deficiency of iodine and enzymes required for the synthesis of thyroid hormones.
- Other causes of cretinism include maldevelopment of the thyroid gland and failure of the fetal thyroid to descend from its origin at the base of the tongue.

Clinical Features

Initial clinical manifestations of congenital hypothyroidism appear in the early weeks of life such as sluggishness, slow reflexes due to severe mental retardation, large protuberant abdomen often with umbilical herniation flattened broad nose, thick protuberant tongue, hoarse husky voice, coarse dry skin, periorbital edema, eyes seem widely spaced and low body temperature.

- Later on, impairment of physical growth with retarded bone development results in dwarfism. There is delay in closure of fontanelle, eruption of deciduous teeth and refractory anemia.

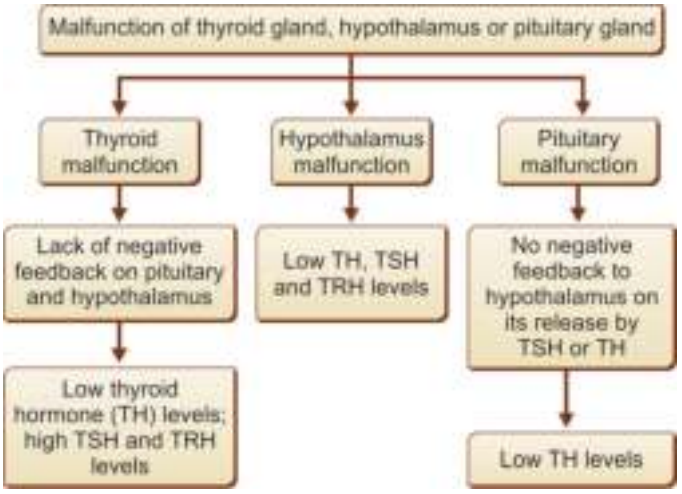

Fig. 26.25: Pathogenesis of hypothyroidism.

- Mental retardation, stunted growth, and characteristic facies become evident. If thyroid hormone replacement therapy is not promptly provided, congenital hypothyroidism results in mentally retarded thyroid dwarf.

Laboratory Diagnosis

The diagnosis of congenital hypothyroidism in infants is confirmed by decreased serum free T_4 and increased TSH. If maternal antibody transfer is suspected, then tests for antithyroid antibody testing can be performed in both the mother and child.

Pathology Pearls: Thyroid Profile in Hypothyroidism

- ↑ TSH
- ↓ T_4
- ↓ T_3
- Possible antibodies to thyroglobulin or thyroid peroxidases

Therapeutic Correlation

Hypothyroid newborns attain normal development, if early hormonal therapy is started. If hormonal therapy is delayed by 6–12 months, then mental retardation becomes permanent due to brain damage.

MYXEDEMA (HYPOTHYROIDISM) IN ADULTS

Hypothyroidism manifests as myxedema in adults primarily after age of 40 years, which is more common in women than men. Decreased synthesis of thyroid hormones, triiodothyronine (T_3) and/or thyroxine (T_4) slows down cellular metabolic processes leads to hypothyroidism. Hypothyroidism in adults is classified as primary or secondary.

Predisposing Factors

Congenital causes of myxedema include congenital absence of thyroid gland or inborn errors of metabolism.

Acquired causes of myxedema include iodine deficiency (endemic goiter), autoimmune thyroiditis, i.e. Hashimoto's thyroiditis, post-radiotherapy to hyperthyroidism, post-surgical thyroidectomy, antithyroid drugs (carbimazole), and primary tumors of thyroid.

Classification

- **Primary hypothyroidism (myxedema):** Primary hypothyroidism most often occurs due to autoimmune mechanism. Approximately 75% of these patients have circulating autoantibodies to thyroid antigens, suggesting that these cases represent the end stage of autoimmune thyroiditis. Nongoitrous hypothyroidism may also result from antibodies that block TSH itself or the TSH receptor, without activating the thyroid gland. Some cases are associated with Hashimoto's disease, amyloidosis, sarcoidosis and irradiation.
- **Secondary hypothyroidism (myxedema):** Secondary hypothyroidism normal thyroid functions are impaired in these patients due to: (a) hypothalamus fails to release thyrotropin-releasing hormone (TRH); (b) anterior pituitary gland fails to secrete thyroid stimulating hormone (TSH); (c) thyroid gland is not able to synthesize thyroid hormones due to iodine deficiency (usually dietary); and (d) patient receiving antithyroid drugs for the treatment of hyperthyroidism (Table 26.20).

Clinical Features

Early Clinical Manifestations in Myxedema

Patient presents with insidious onset symptoms due to decreased metabolic rate such as fatigue, cold intolerance, unexplained weight gain, low pitch voice, progressive constipation (decreased GIT motility), anorexia, and skeletal muscle cramps.

Late Clinical Manifestations in Myxedema

With progression of disease, the patient develops systemic manifestations:

- **Periorbital puffiness and non-pitting edema:** Patient develops periorbital puffiness and non-pitting edema legs due to subcutaneous accumulation of mucopolysaccharides and hyaluronic acid.
- **Tongue:** Tongue becomes dry and thick causing hoarseness, slow and slurred speech.
- **Hair loss:** There is hair loss in axillary region, pubic region and lateral aspect (outer-third) of the eyebrows.
- **Skin manifestations:** Skin becomes dry, inelastic, coarse and yellow due to less conversion of carotene into retinoic acid.
- **Congestive heart failure:** Patient develops flabby congestive heart, bradycardia, and poor peripheral circulation, pleural and pericardial effusions.
- **Serum lipid level:** Serum cholesterol concentration is increased due to decreased synthesis of low-density lipoprotein (LDL) receptors.
- **CNS manifestations:** Patient develops nervous system manifestations such as ataxia (loss of coordination), delayed recovery of 'Achilles reflex'

Table 26.20 Differences between primary and secondary hypothyroidism

Parameters	Primary Hypothyroidism	Secondary Hypothyroidism
Etiology	Hashimoto's thyroiditis	Pituitary gland disorder
Serum TSH	Increased	Increased
Free T_4	Decreased	Decreased
Thyrotropin-releasing hormone stimulation test	Increased response	No response
Autoantibodies	▪ Anti-TSH receptor autoantibody ▪ Anti-thyroglobulin autoantibody ▪ Anti-peroxidase autoantibody ▪ Anti-microsomal autoantibody ▪ Anti-iodine receptor autoantibody	▪ Absent ▪ Absent ▪ Absent ▪ Absent ▪ Absent

(increase in relaxation phase of deep tendon reflexes), behavioral changes ranging from slight mental slowness to severe impairment (dementia).

- **Infertility:** There is impaired fertility in these patients. Women with hypothyroidism suffer from ovulatory failure, progesterone deficiency, decreased libido and irregular and excessive menstrual bleeding (menorrhagia). Erectile dysfunction and oligospermia are common symptoms of hypothyroidism in men.

Laboratory Diagnosis

Increased TSH level and T4 level establish hypothyroidism. Hypercholesterolemia occurs due to decreased synthesis of low-density lipoprotein (LDL) receptors on tissues in patients with hypothyroidism.

Treatment

Patient is administered levothyroxine in small increments every 6–8 weeks to bring serum TSH to the normal range (euthyroid state).

HYPERTHYROIDISM

Hyperthyroidism is a clinical syndrome characterized by hypermetabolic state due to elevation of free serum thyroxine (T4) and/or free triiodothyronine (T3). It can be caused by inherited or acquired factors. It can result from follicular epithelial hyperplasia, hyperpituitarism, various forms of thyroiditis, metastatic tumors and various drugs.

TOXIC NODULAR GOITER (PLUMMER'S DISEASE)

Increased synthesis of thyroid hormone creates a metabolic imbalance, i.e. increased metabolic rate called hyperthyroidism or thyrotoxicosis. Thyrotoxicosis describes excess of thyroid hormones regardless of etiology. Excess thyroid hormones can be due to various thyroid disorders, i.e. Graves' disease (most common) and toxic nodular goiter (Table 26.21 and Fig. 26.26).

Clinical Features

Patient presents with weight loss, increased appetite, recent onset of heat intolerance, warm, moist, flushed skin especially hot sweaty palms, nervousness, fine tremors, bounding peripheral pulses, cardiac arrhythmias (atrial fibrillation), dyspnea on exertion, and menstrual abnormalities, e.g. amenorrhea or oligomenorrhea. Males develop impaired fertility, decreased libido and gynecomastia.

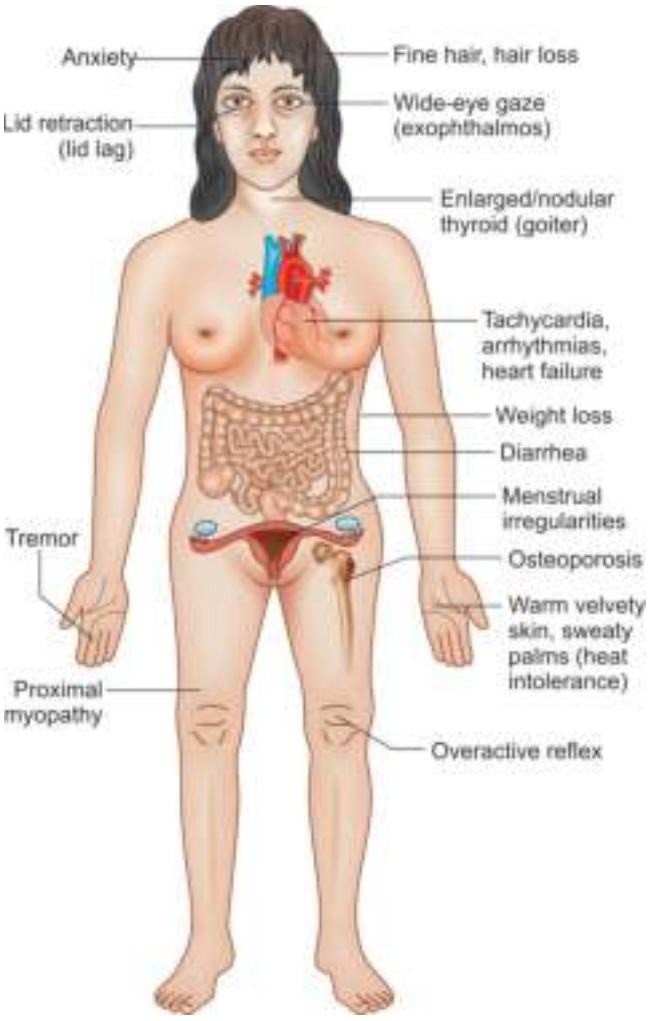

Fig. 26.26: Clinical features of thyrotoxicosis.

GRAVES' DISEASE

Graves' disease is an autoimmune disease associated with decreased TSH activity. TSH receptors are stimulated by thyroid-stimulating immunoglobulin, an IgG autoantibody, not by TSH. Thyroid stimulating immunoglobulin (TSI) mimics the action of TSH, but is not regulated by natural negative feedback controls. Thyroid growth immunoglobulin (TGI) autoantibody stimulates thyroid follicular glandular

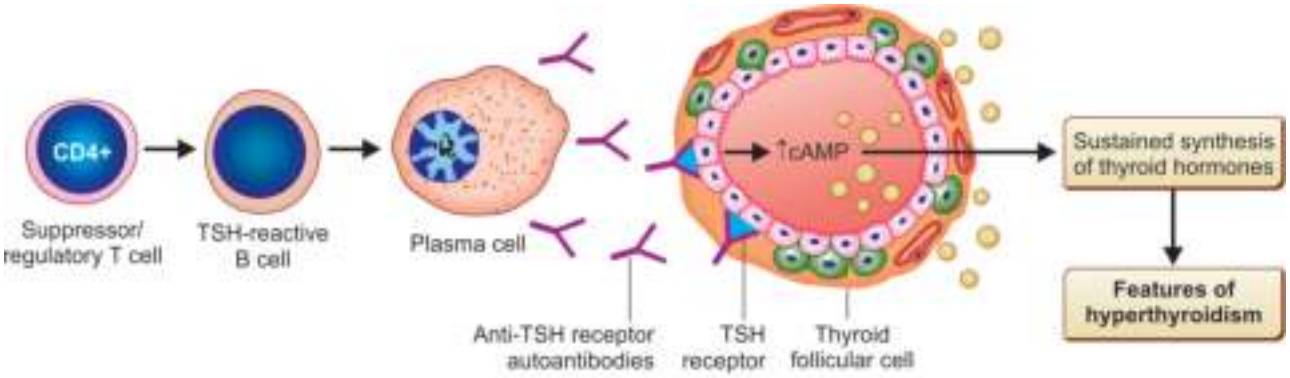
Table 26.21 Comparison of Graves' disease and toxic nodular goiter

Parameters	Graves' Disease	Toxic Nodular Goiter
Sex predilection	Women > Men	Women = Men (equally affected)
Eye signs	Exophthalmos most severe common finding	Exophthalmos less severe
Heart	Tachycardia and fibrillation	Angina
Weight	May lose weight	Often profound

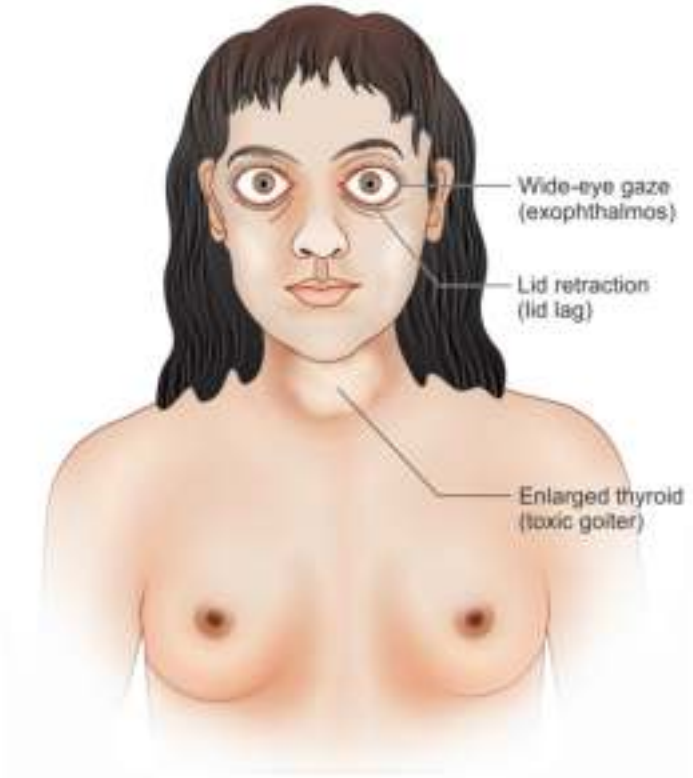
hyperplasia resulting in thyroid enlargement. Patient develops diffuse toxic goiter, hyperthyroidism, and exophthalmos. Onset is initiated by infection, iodide excess and postpartum state.

Epidemiology

Graves' disease occurs more often in women than men of young age group. The incidence is increased in HLA-DR3 and HLA-B8 positive individuals. CTL4 and PTPN22 gene mutations increase the risk for Graves' disease. Thyroid acropatchy is associated with swelling of digits and clubbing in patient with Graves' disease.



Pathogenesis



Type 2 hypersensitivity reaction plays an important role in its pathogenesis. CD4+ suppressor/regulatory T cells induce B cells resulting in synthesis of thyroid-stimulating immunoglobulin (TSI), an IgG antibody that reacts with TSH receptors and activates adenyl cyclase resulting in increased production of thyroid hormones.

- Synthesis of thyroid growth immunoglobulin (TGI) stimulates thyroid follicular glandular hyperplasia and thyroid enlargement.
- In addition to TSI and TGI, anti-microsomal and anti-thyroglobulin autoantibodies are also present (Figs 26.27 and 26.28).

Clinical Features

Patient presents with nontender diffuse symmetric thyroid gland enlargement with features of thyrotoxicosis. Graves' disease is associated with exophthalmos in 60–90%, dermatopathy and constitutional symptoms.

Risk factors for Graves' disease

- Young women
- HLA-DR3 and HLA-B8
- CTL4 or PTPN22 gene mutation

Clinical manifestations of Graves' disease

- Exophthalmos (lid lag, upper lid retraction, weakness of extraocular muscles).
- Dermatopathy
- Constitutional symptoms (weight loss, warm skin, fine tremors, increased heart rate).

Demonstration of autoantibodies in blood in Graves' disease

- TGI (thyroid growth immunoglobulin) stimulates glandular hyperplasia and enlargement.
- TSI (thyroid-stimulating immunoglobulin) mimics TSH and reacts with TSH receptors resulting in sustained synthesis of thyroid hormones.
- Anti-microsomal autoantibodies.
- Anti-thyroglobulin autoantibodies.

Fig. 26.27: Pathogenesis of Graves' disease.

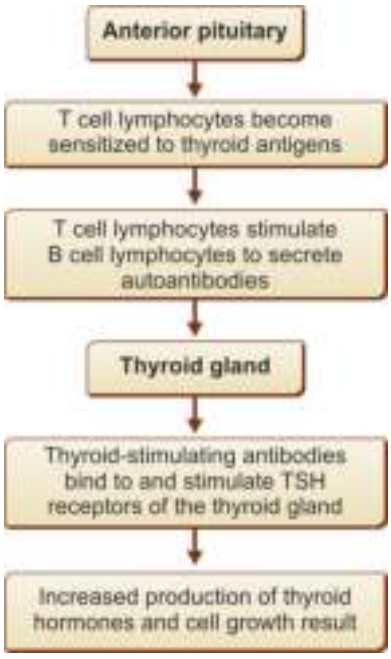


Fig. 26.28: Pathogenesis of Graves' disease.

Thyroid gland and retrobulbar ocular muscles are infiltrated with B cells.

- **Exophthalmos:** Extraocular muscles and retro-orbital tissues are infiltrated by chronic inflammatory cells.
  - There is deposition of hydrophilic mucopolysaccharides, fibrosis and contractures of extraocular muscles resulting in incoordination of eye movements.
  - Patient presents with proptosis, lid lag, upper lid retraction, weakness of eye muscles, diplopia, and periorbital edema.
- **Dermatopathy:** Skin over dorsum of legs or feet becomes edematous and thick orange peeling. Skin may also show discrete plaque-like lesions in 10–15% of cases. Pretibial dermal swelling occurs due to excessive deposition of glycosaminoglycans in 1–2% of cases.
- **Constitutional symptoms:** Constitutional symptoms due to Graves' disease include weight loss, warm skin, fine tremors particularly when hands are stretched, heat intolerance, diarrhea, anxiety, lid stare due to increased sympathetic stimulation of eyelid muscles; cardiac symptoms (e.g. sinus tachycardia, increased risk for atrial fibrillation, systolic hypertension, high-output heart failure due to increased synthesis of α-adrenergic receptors in the heart).

Surgical Pathology: Graves' Disease

Gross Morphology

- The thyroid gland is diffusely enlarged weighing 80–90 g.
- Cut surface reveals soft, red brown, meaty appearance closely resembling cross-section of normal muscle.
- Preoperative administration of iodine causes accumulation of colloid and alters the gross appearance.

Light Microscopy

- Marked thyroid follicular glandular hyperplasia with micropapillary infoldings, thin colloid with peripheral scalloping of the colloid and lymphocytic infiltration in stroma between thyroid follicles are prominent features.
- Peripheral scalloping occurs due to increased proteolysis of colloid and rapid uptake of thyroglobulin by the hyperfunctioning thyroid follicular cells (Figs 26.29 and 26.30).

Laboratory Diagnosis

The best screening test for Graves' disease is free T_4 elevated in Graves' disease and TSH greatly decreased in Graves' disease. Blood sugar is raised

Fig. 26.29: Graves' disease. Cut surface shows a hyperemic, meaty, shiny appearance. Graves' disease is an autoimmune disorder that leads to hyperthyroidism due to circulating autoantibodies, fine fremors of hands, bulging of eyes and dermatopathy.

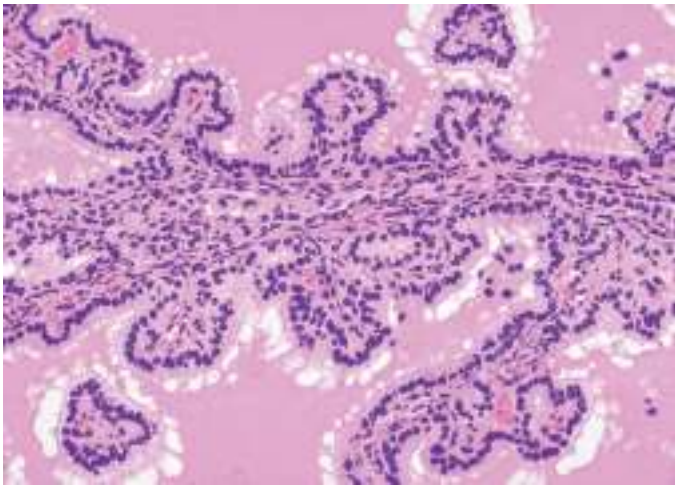

Fig. 26.30: Graves' disease. Histologic examination shows resorption induced scalloping of the margins of the colloid. Antibody-mediated hyperplastic papillary epithelial infoldings result from the lining cells becoming columnar in shape and increased in number (400X).

due to glycogenolysis. Peripheral blood smear examination shows absolute lymphocytosis. Autoantibodies such as thyroid growth immunoglobulin (TGI), thyroid-stimulating immunoglobulin (TSI), antimicrosomal antibody and anti-thyroglobulin antibody should be analyzed in Graves' disease.

Pathology Pearls: Thyroid Profile in Hyperthyroidism

- ↓ TSH
- ↑ T_4
- ↑ T_3
- ↑ ^{131}I uptake

Treatment

Administration of β-blockers decreases adrenergic effects. Thionamides decrease synthesis of thyroid hormones.

HYPERTHYROIDISM: OTHER CAUSES

- **Plummer's disease:** This order is a combination of hyperthyroidism, nodular goiter, and absence of exophthalmos. The 'hot' nodules can be adenomas or non-neoplastic areas of nodular hyperplasia.
- **Pituitary hyperfunction:** It can cause excessive synthesis of TSH resulting in secondary hyperthyroidism.
- **Struma ovarii:** It is variant of ovarian teratoma composed of thyroid tissue. It can be hyperfunctional. Surgical excision of tumor brings thyroid hormones level to normal range.

Differences between primary and secondary hyperthyroidism are given in Table 26.22 and clinical manifestations of hypothyroid and hyperthyroid states are given in Table 26.23.

Table 26.22 Differences between primary and secondary hyperthyroidism

Parameters	Primary Hyperthyroidism	Secondary Hyperthyroidism
Etiology	Graves' disease, toxic adenoma, toxic multinodular goiter	Pituitary gland
Serum TSH	Low	Normal
Free T_4	Increased	Increased
Autoantibodies	▪ TGI (thyroid growth immunoglobulin) ▪ TSI (thyroid-stimulating immunoglobulin) ▪ Anti-microsomal autoantibody ▪ Anti-thyroglobulin autoantibody	▪ Absent ▪ Absent ▪ Absent ▪ Absent

Table 26.23 Clinical manifestations of hypothyroid and hyperthyroid states

Level of Organization	Hypothyroidism	Hyperthyroidism
Basal metabolic rate	Decreased	Increased
Sensitivity to catecholamines	Decreased	Increased
Clinical features	▪ Myxedema features ▪ Deep voice ▪ Impaired growth in children	▪ Exophthalmos in Graves' disease ▪ Lid lag ▪ Accelerated growth in children
General behavior	▪ Mental retardation (infant) ▪ Physical and mental sluggishness ▪ Somnolence	▪ Restlessness ▪ Hyperkinesis ▪ Wakefulness
Cardiovascular system	▪ Decreased cardiac output ▪ Bradycardia	▪ Increased cardiac output ▪ Tachycardia and palpitation
Gastrointestinal tract	▪ Constipation ▪ Loss of appetite	▪ Diarrhea ▪ Increased appetite
Respiratory system	Hypoventilation	Breathlessness
Muscle tone and reflexes	Decreased	Increased with tremor and twitching
Temperature tolerance	Cold intolerance	Heat intolerance
Skin and hair	▪ Decreased sweating ▪ Coarse and dry skin and hair	▪ Increased sweating ▪ Thin silky skin and hair
Weight	Gain	Loss
Blood cholesterol	Increased	Decreased

GOITER

Persistent thyroid gland enlargement from excess colloid is known as goiter. Physiologic enlargement is not uncommon in puberty and pregnancy. Other causes of goiter include iodine deficiency either endemic or sporadic, Hashimoto's thyroiditis, goitrogenic drugs, food and dyshormonogenesis, i.e. enzyme deficiencies. Classification of goiter, morphology and functional activity due to iodine deficiency are given in Table 26.24.

SIMPLE NONTOXIC GOITER

Simple nontoxic goiter occurs due to increased thyroglobulin levels resulting in decreased synthesis of T_3 and T_4. Patient presents with diffuse symmetric enlargement of thyroid. Females are more affected than males.

Predisposing Factors

- **Dietary factors:** Diet deficient in iodine and water rich in Ca^{++} and fluoride play an important role in the pathogenesis of nontoxic goiter. Goitrogens are present in vegetables such as cabbage, turnips, cassava (e.g. containing thiocyanate inhibiting iodine transport), brussels, sprouts, i.e. young shoot of a plant, turnips, Brassica plants, Cruciferae plants and soya beans.
- **Goitrogenic drugs:** Most commonly used goitrogenic drug is lithium being prescribed in the management of manic-depressive states.Therapeutic administration of drugs (e.g. salicylates, cyanates, thiocyanates, resorcinol, lithium chloride and cobalt chloride) may result into nontoxic goiter.
- **Peroxidase enzyme deficiency:** Deficiency of peroxidase enzyme inhibits conversion of iodide to organically bound iodine process and patient develops goiter. Dehalogenase deficiency inhibits the conversion of MIT and DIT to form T_3 and T_4, and results in goiter.

Table 26.24 Classification of goiter, morphology, and functional activity due to iodine deficiency

Parameters	Goiters
Based on morphology	▪ Diffuse goiter is also known as simple or colloid goiter without thyroid hormone dysfunction ▪ Nodular goiter occurs in the late stage of simple goiter and results to irregular thyroid enlargement either consisting of single nodule or multiple nodules. Most nodular goiters become hyperplastic and do not take up radioactive iodine ('*cold nodules*')
Based on functional activity	▪ Nontoxic goiter is also termed simple, colloid, or multinodular goiter. It refers to an enlargement of the thyroid that is not associated with functional, inflammatory, or neoplastic alterations. It occurs due to increased thyroglobulin levels resulting in decreased synthesis of T_3 and T_4. Patient presents with diffuse symmetric enlargement of thyroid. Females are more affected than males ▪ Toxic goiter is associated with hyperthyroidism as seen in Graves' disease
Based on iodine deficiency	▪ Endemic goiter occurs in iodine deficient geographical areas. Without sufficient iodine, thyroid hormones are not produced and the pituitary continuously secretes thyroid stimulating hormone (TSH) ▪ Sporadic goiter occurs in non-iodine-deficient geographical areas. It is caused by enzyme deficiency, goitrogens, puberty, and pregnancy. Females are more affected than males

Pathogenesis

Goiter is caused by absolute or relative deficiency of thyroid hormones. There are two stages, i.e. (a) hyperplasia/hypertrophy of thyroid follicles and (b) involution stage. Enlarged thyroid gland weighs 100–150 g. Initial diffuse thyroid enlargement is followed by multinodular goiter.

- **Hyperplastic stage:** Absolute or relative deficiency of thyroid hormones increase synthesis of TSH by anterior pituitary gland. TSH acts on thyroid follicles, which may undergo hyperplasia/hypertrophy with formation of new thyroid follicles, which attempt to increase thyroid hormones synthesis. Hyperplastic stage is followed by involution stage.
- **Involution stage:** Accumulation of abundant colloid leads to flattening of the epithelium of thyroid follicles. Thyroid gland fails to sustain synthesis of thyroid hormones.

Clinical Features

Patient presents with thyroid enlargement, respiratory distress and dysphagia (Fig. 26.31).

Surgical Pathology: Simple Nontoxic Goiter

Gross Morphology

- During involution stage, cut surface of goiter specimen shows numerous cystic nodules filled with gelatinous glistening excess of colloid.
- Areas of hemorrhages are seen into many of these cystic nodules (Fig. 26.32).

Light Microscopy

- During hyperplastic stage, thyroid follicular cells show hyperplasia and hypertrophy of thyroid follicular cells, with regeneration of new thyroid follicles.
- During involution stage, abundant colloid accumulation in the thyroid follicles results in flattening of epithelium of thyroid follicles (Fig. 26.33).

Fig. 26.31: Diffuse goiter. Diffuse enlargement of thyroid gland in male. (*Courtesy*: Dr. Prasad S Dange.)

Fig. 26.32: Thyroid nodular goiter with cystic degeneration. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

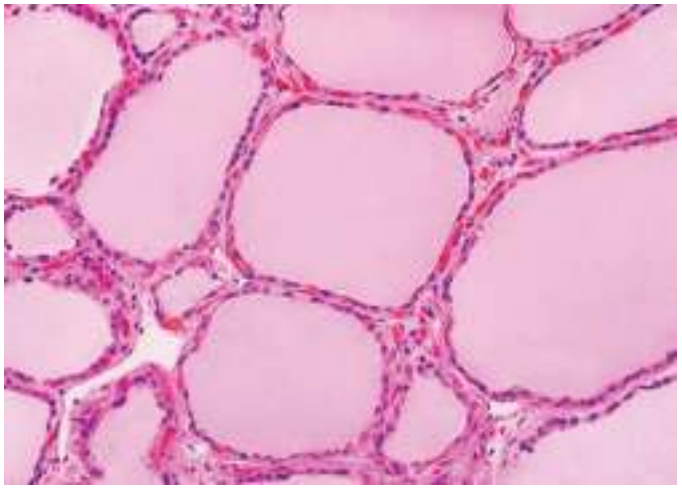

Fig. 26.33: Simple colloid goiter. It is also called euthyroid goiter. The thyroid follicles are filled with an abundant amount of colloid in their lumens and lined by flattened squamous follicular cells (400X).

MULTINODULAR GOITER

Multinodular goiter (MNG) is most often caused by dietary iodine deficiency. Nodules are both monoclonal and polyclonal. Serum T_3 and T_4 are usually within normal limits. Histologic examination shows cystic inactive thyroid follicles and areas of follicular hyperplasia with focal areas of hemorrhage, calcification, macrophages and foreign body giant cells.

- Nearly all cases of long-standing simple nontoxic goiter result in multinodular goiter. It commonly affects older age group. Women are more affected than men (8:1). Dominant nodule in multinodular goiter has risk for malignancy in 2–5% of cases.
- There is uneven proliferation of thyroid follicles, nodules, scar formation, cysts, degeneration and calcification. Enlarged thyroid gland weighs up to 500–1000 g.
- Patient presents with neck mass, compression of esophagus, i.e. dysphagia, compression of trachea, i.e. dyspnea, and compression of great blood vessels of neck (Fig. 26.34).

Pathogenesis

Absolute or relative deficiency of thyroid hormones stimulates increased synthesis of TSH. It results in hyperplasia and hypertrophy of thyroid follicles, with formation of new follicles and colloid accumulation.

- Uneven accumulation of colloid throughout thyroid follicles leads to tension and stress within thyroid gland resulting in rupture of thyroid follicles and blood vessels.
- Fibrosis further adds to tension within thyroid gland. Sometimes areas of dystrophic calcification are seen in multinodular goiter.

Fig. 26.34: Multinodular goiter obstructing superior vena cava. Dilated veins are seen due to superior vena cava (SVC) syndrome. (*Courtesy*: Dr. Prasad S Dange.)

Clinical Features

- Patient presents with inspiratory stridor (compression of trachea), dysphagia (compression of esophagus). Hoarseness of voice may result from compression of recurrent laryngeal nerve. Compression of jugular vein leads to dizziness or syncope known as 'Pemberton's sign', when the patient raises arms above head.
- Hemorrhage into colloid nodule causes sudden painful enlargement of thyroid. Features of hypothyroidism or toxic nodular goiter (TSH-independent 'hot' nodule) may be present. Dominant nodule in multinodular goiter has 2–5% risk for malignancy.

Surgical Pathology: Multinodular Goiter

Gross Morphology

- Most goiters weigh >40 g (some <25 g).
- Cut surface is heterogenous with areas of scarring and calcification.
- Condensation about themselves creates appearance of complete encapsulation so-called adenomatous goiter and multiple colloid adenomatous goiters (Fig. 26.35).

Light Microscopy

Histologic examination reveals variable sized thyroid follicles, random irregular scarring with focal areas of hemorrhage, calcification, microcysts formation; macrophages and foreign body giant cells (Fig. 26.36).

NEOPLASTIC DISORDERS OF THYROID GLAND

GENERAL CONSIDERATIONS

Classification of Thyroid Neoplasms

Thyroid neoplasms are classified into primary (benign or malignant) and secondary. Thyroid adenoma is a benign neoplasm. Primary malignant neoplasms of thyroid are papillary carcinoma, follicular carcinoma, medullary carcinoma and undifferentiated carcinoma. Papillary thyroid carcinoma accounts for 50% of all thyroid cancers. Malignant tumors of thyroid gland are more common in women than men over 40 years of age.

Fig. 26.35: Multinodular goiter in thyroid gland. Cut surface shows multiple nodules filled with colloid material.

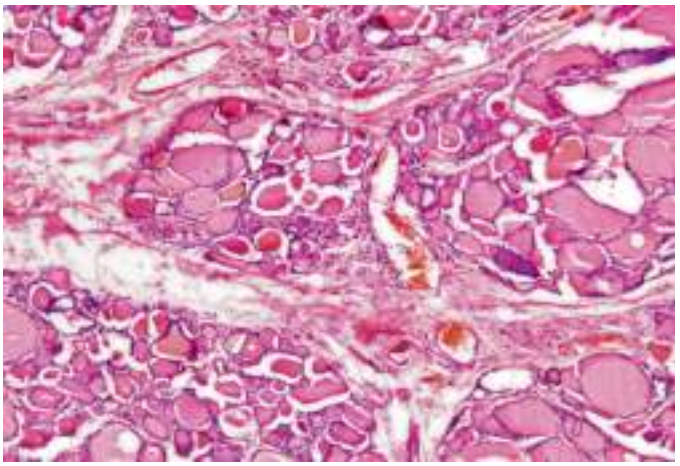

Fig. 26.36: Multinodular goiter. Histologic examination shows variable sized thyroid follicles, random irregular scarring with focal areas of hemorrhage and calcification (400X). (*Courtesy:* Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

- Fixation of growth or cervical lymphadenopathy and distant metastases indicates thyroid malignancy.
- Thyroid nodule is well circumscribed grey white solitary nodule delineated from surrounding normal thyroid tissue. Majority of thyroid nodules are neoplastic in nature. Toxic, i.e. hyperfunctioning nodule concentrates iodine. Such thyroid nodules may be benign or malignant tumors.
- Recent WHO classification of thyroid neoplasms has divided the thyroid neoplasms into several new categories that allow for better understanding of the cell of origin, pathologic features (cytopathology and histopathology), molecular classification and biologic behavior.
- Follicular cell-derived neoplasms constitute majority of thyroid neoplasms, which can be benign, low-risk and malignant neoplasms. Benign follicular cell-derived neoplasms include thyroid follicular nodular disease (TFND) in the clinical settings of multinodular goiter showing multifocal hyperplastic/neoplastic lesions, follicular thyroid adenoma, follicular thyroid adenoma with papillary architecture, and oncocytic thyroid adenoma. Low-risk follicular cell-derived neoplasms include non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP), follicular tumor of uncertain malignant potential (FTUMP), well differentiated thyroid tumor of uncertain malignant potential (WDUMP) and hyalinizing trabecular tumor (HTT). Malignant thyroid follicular cell-derived neoplasms are stratified based on molecular profiles and aggressive biologic behavior.

- Papillary thyroid carcinoma (PTC) can be categorized into minimally invasive, encapsulated angioinvasive and widely invasive subtypes. Papillary thyroid carcinomas with many morphologic subtypes represent the BRAF-like malignancies, whereas encapsulated follicular variant of papillary carcinoma and follicular thyroid carcinoma represent RAS-like malignancies.
- Anaplastic thyroid carcinoma remains the most undifferentiated form. Squamous cell carcinoma of thyroid is considered subtype of anaplastic carcinoma.
- Medullary thyroid carcinoma (MTC) is derived from parafollicular cells (C cells residing in upper lobes of thyroid). Tumor is composed of both parafollicular cells and any follicular cell-derived malignancy. A grading system for medullary thyroid carcinoma is based on mitotic count, tumor necrosis and Ki-67 labeling proliferative index.
- Mucoepidermoid carcinoma and secretory carcinoma of the salivary gland type are now included in revised 2024 WHO classification of thyroid neoplasms (Table 26.25) as salivary gland carcinomas of thyroid.

Table 26.25 Revised 2024 WHO classification of thyroid neoplasms

Epithelial Thyroid Neoplasms

- **Follicular cell-derived neoplasms**
  - Benign thyroid follicular neoplasms include thyroid follicular disease (TFD), follicular thyroid adenoma, follicular thyroid adenoma with papillary architecture (often hyperfunctional), oncocytic adenoma.
  - Low-risk thyroid follicular neoplasms include non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP), follicular thyroid tumor of uncertain malignant potential (FT-UMP), well differentiated thyroid tumor of uncertain malignant potential (WD-UMP), hyalinizing trabecular thyroid tumor (HTT).
  - Malignant thyroid follicular neoplasms include follicular thyroid carcinoma (minimal invasive, encapsulated, angioinvasive, widely invasive histologic subtypes).
- **Papillary thyroid carcinoma (PTC)**
  - Histologic subtypes of papillary thyroid carcinoma (infiltrative, follicular, tall cell, columnar cell, hobnail, solid, diffuse sclerosing, Warthin-like, oncocytic histologic subtypes)
  - Invasive encapsulated follicular variant of papillary thyroid carcinoma (minimal invasive, encapsulated angioinvasive, widely invasive histologic subtypes)
- **Oncocytic thyroid carcinoma**
  - Oncocytic thyroid carcinoma includes minimal invasive, encapsulated angioinvasive and widely invasive
  - Oncocytic follicular cell-derived carcinoma of thyroid is composed of >75% oncocytic cells, that lack characteristic nuclear features of papillary thyroid carcinoma and high-grade features (necrosis and mitotes ≥5/cu mm)
- **Differentiated high grade-thyroid carcinoma (DHGTC)**
  - Histologic subtypes of differentiated high-grade thyroid carcinoma (papillary, follicular or solid, invasive, any nuclear cytology with any one of features such as necrosis or mitotic count ≥5/cu mm)
- **Poorly differentiated thyroid carcinoma (PDTC)**
  - Poorly differentiated thyroid carcinoma (solid, trabecular or insular growth patterns)
  - Poorly differentiated thyroid carcinoma (invasive pattern)
  - Poorly differentiated thyroid carcinoma with at least one of features (necrosis or mitotic count ≥3/cu mm or convoluted nuclei)

Contd...

- **Anaplastic thyroid carcinoma**
  - Anaplastic thyroid carcinoma with anaplastic features
  - Anaplastic thyroid carcinoma undifferentiated phenotype
- **Other thyroid epithelial neoplasms**
  - Salivary gland type carcinoma
  - Mucoepidermoid carcinoma
  - Sclerosing mucoepidermoid carcinoma with eosinophilia
  - Mucinous carcinoma
  - Thymic neoplasm
  - Ectopic thymoma
  - Intrathyroid epithelial thymoma/CASTLE (carcinoma showing thymus like differentiation)
  - Spindle epithelial tumor with thymoma-like differentiation

Neural Crest Origin Parafollicular Cell-derived Thyroid Neoplasms

- Medullary thyroid carcinoma (MTC): MTC low grade, MTC high grade (necrosis, mitoses ≥5/cu mm or Ki-67 proliferative index ≥5%)
- Note: Grading system for medullary thyroid carcinomas is based on mitotic count, tumor necrosis and Ki-67 labeling index

Non-epithelial Thyroid Neoplasms

- Peripheral nerve sheath neoplasms include schwannoma, malignant peripheral nerve sheath tumor (MPNST)
- Vascular neoplasms include hemangioma, lymphangioma, angiosarcoma
- Smooth muscle neoplasms include leiomyoma, leiomyosarcoma
- Solitary fibrous neoplasm
- Histiocytic neoplasms include Langerhans cell histiocytosis, Rosai-Dorfman disease, follicular dendritic cell sarcoma
- Hematolymphoid neoplasms include primary thyroid lymphoma, follicular dendritic cell lymphoma
- Germ cell neoplasms include benign teratoma, immature teratoma, malignant teratoma

Secondary Thydoid Neoplasms

Metastatic neoplasms to thyroid gland include squamous cell carcinoma of larynx, renal cell carcinoma, lung carcinoma, breast carcinoma, colon carcinoma, malignant melanoma, and lymphoma

Risk Factors

Risk factors for thyroid carcinomas are iodine deficiency, radiation exposure, high doses of X-rays and hereditary.

Gene mutations associated with thyroid carcinoma are given in Table 26.26. Molecular pathogenesis of thyroid carcinomas is shown in Fig. 26.37.

Table 26.26 Gene mutations associated with thyroid carcinoma

Category	Proto-oncogene	Mechanism	Associated Cancers
Growth factors			
Hepatocyte growth factor (HGF)	HGF	Overexpression	▪ Thyroid carcinoma ▪ Hepatocellular carcinoma
Growth factor receptors			
Receptors for neurotrophic factors	RET	Point mutation	*Multiple endocrine neoplasia:* MEN IIa, MEN IIb familial thyroid medullary carcinoma
Mitogenic signaling pathway inhibitors (tumor suppressor genes)			
APC gene	Adenomatous polyposis protein (locus 5p21). Mutation by deletion or nonsense	APC inhibits Wnt signaling activator pathway, thus prevents nuclear transcription. It also degrades catenin	*Sporadic cancers:* Thyroid carcinoma, colon carcinoma, gastric carcinoma, pancreas carcinoma and melanoma

Low doses of ionization radiation (radiotherapy) in head and neck region can cause or enhance DNA mutations and chromosomal abnormalities.

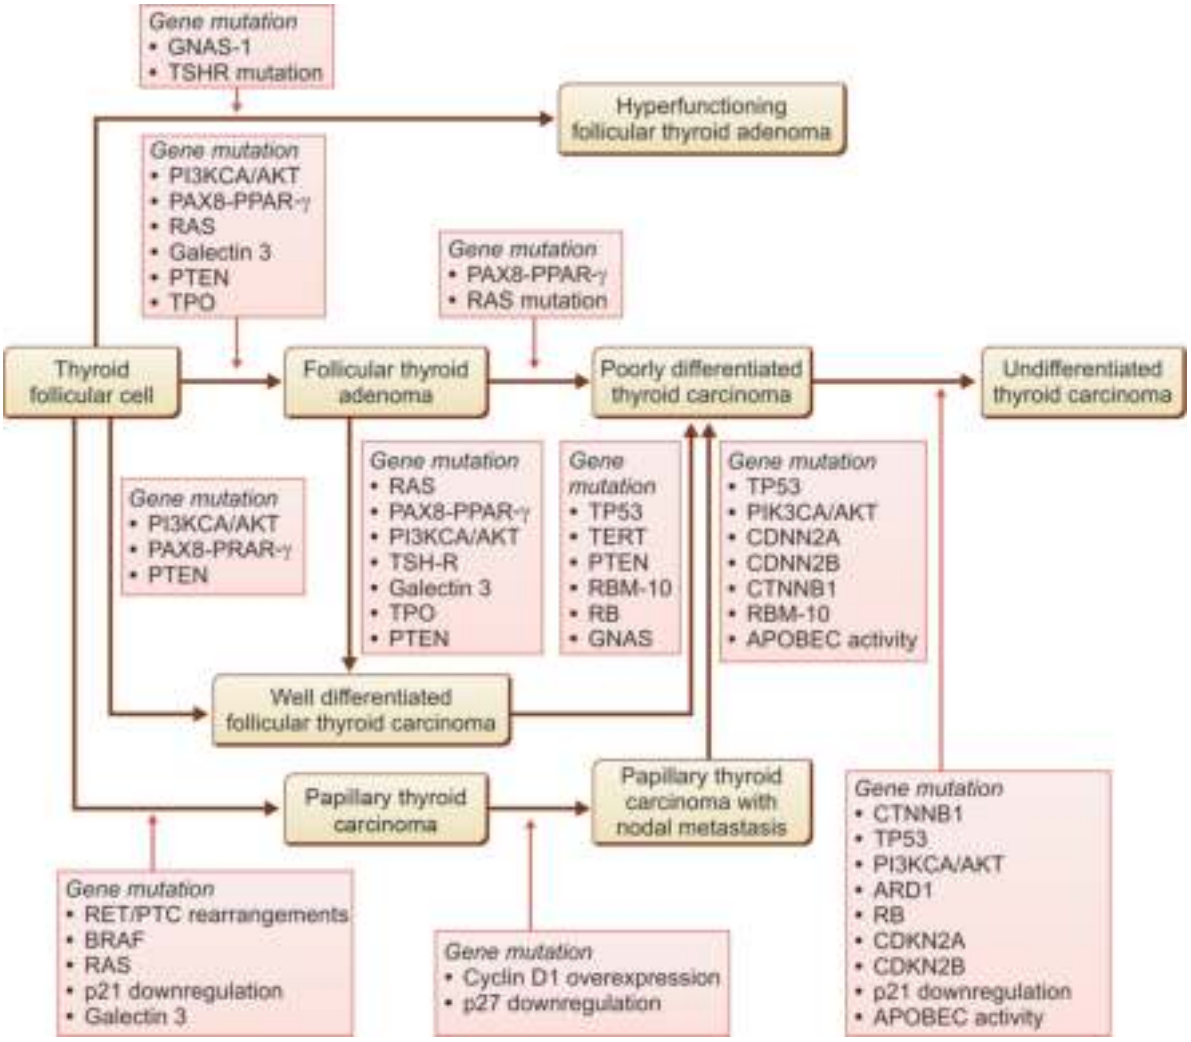

Fig. 26.37: Molecular pathogenesis of thyroid carcinomas.

Clinical Course

Papillary thyroid carcinoma is least aggressive neoplasm with slow metastases. Follicular thyroid carcinoma is less common but spreading early to lymph nodes and distant organs. Medullary thyroid carcinoma synthesizes thyrocalcitonin, histaminase, prostaglandins and ACTH.

Prognosis

Prognosis of thyroid carcinomas is good in children in >70% of cases with 10 years survival. Rapid growth suggests malignancy.

FOLLICULAR THYROID ADENOMA

Follicular thyroid adenoma is the most common benign encapsulated tumor of thyroid gland, which shows follicular cell differentiation that consists of thyroid follicles lined by cuboidal epithelial cells.

- Tumor lacks evidence of capsular and vascular invasion, and also lacks of papillary thyroid carcinoma nuclear features. Tumor is firm or rubbery, homogenous, round or oval and surrounded by a thin fibrous capsule. Most patients with follicular thyroid adenoma are clinically and biochemically euthyroid.
- About 1% of follicular thyroid adenomas attaining 3 cm size can become functional as a result of a monoclonal expansion of thyroid follicular cells and mutation in TSH receptor gene that result in increased thyroid hormone secretion independent of TSH and patients develop hyperthyroidism.
- On radioiodine thyroid scintigraphy, functioning follicular thyroid adenomas avidly concentrate radioiodine and may suppress iodine uptake in the rest of thyroid gland. About 20% of nonfunctioning follicular thyroid adenomas possess proto-oncogene N-RAS, H-RAS and K-RAS mutations that may predispose them to progression to follicular thyroid carcinoma.

Laboratory Diagnosis

The diagnostic evaluation of a patient with a thyroid solitary nodule consists of fine needle aspiration cytology (FNAC), an ultrasound imaging of the neck and a screening serum TSH.

- Fine needle aspiration cytology of thyroid nodule reveals abundant follicular epithelial cells in sheets with crowding and overlapping of cells, microfollicles and scant/no colloid.
- Limitation of fine needle aspiration cytology is the inability to distinguish a follicular thyroid adenoma from follicular thyroid carcinoma. Histologic examination is essential to establish diagnosis of follicular thyroid adenoma.

Clinical Features

Most patents with a follicular thyroid adenoma present with a solitary palpable nodule in normal thyroid gland identified on clinical examination and on ultrasound imaging study. However, tumor may occur in association with thyroiditis and/or nodular hyperplasia.

- Most patients are euthyroid and asymptomatic. Patients with large tumors may present with breathlessness, hoarseness of voice and dysphagia related to compression of structures such as trachea, recurrent laryngeal nerve and esophagus respectively. Patients with functional follicular thyroid adenoma may manifest with hyperthyroidism.
- Secondary changes may occur in large follicular thyroid adenoma, i.e. intratumoral hemorrhage, edema, cystic degeneration, fibrosis, dystrophic calcification and bone formation. Patients may complain of multiple nodules in thyroid and neck pain as a result of sudden tumor enlargement from intratumoral hemorrhage or cystic degeneration.

Treatment

Thyroid lobectomy or isthmusectomy is a definitive treatment for patients with follicular thyroid adenoma. Functional follicular thyroid adenoma with low serum TSH and high T3 and T4 levels analyzed by iodine-123 thyroid scan should be treated by levothyroxine drug for three to six months to reduce size of thyroid nodule before surgery.

Surgical Pathology: Follicular Thyroid Adenoma

Gross Morphology

- Follicular thyroid adenoma is solitary, encapsulated and of variable size (1–10 cm). Tumor resembles multinodular goiter due to secondary changes of intratumoral hemorrhage and cystic degeneration.
- Cut surface reveals solid, fleshy, tam to brown tumor that bulges when fresh tumor compresses adjacent thyroid (Fig. 26.38).

Light Microscopy

The diagnostic histologic criteria of follicular thyroid adenoma include: (a) follicular thyroid adenoma is surrounded by a complete thin capsule without evidence of capsular and vascular invasion, (b) tumor exhibits distinct architecture of thyroid follicles inside and outside capsule, (c) tumor shows uniform histologic features inside capsule, (d) tumor causes compression of surrounding tissue, and there is lack of multinodularity in the remaining thyroid gland, (e) tumor is composed of closely packed thyroid follicles lined by cuboidal to low columnar cells arranged in trabeculae or solid sheets with histologic patterns such as normofollicular (simple), macrofollicular, microfollicular, and trabecular/

solid. Commonly secondary changes in follicular thyroid adenoma include hemorrhage, hemosiderin deposition, edema, necrosis and cystic changes (Fig. 26.39).

- **Normofollicular (simple) thyroid adenoma:** Tumor is composed of uniform normal looking thyroid follicles, which resemble normal thyroid follicles.
- **Macrofollicular (colloid) thyroid adenoma:** Tumor is composed of large thyroid follicles containing colloid.
- **Microfollicular (fetal) thyroid adenoma:** Tumor is composed of closely packed small thyroid follicles with scant colloid arranged in edematous fibrovascular stroma. It is most common histologic pattern of follicular thyroid adenoma.
- **Trabecular/solid (embryonal) thyroid adenoma:** Tumor is composed of thyroid follicles lined by epithelium arranged in solid/trabecular pattern or branching cords.

Fig. 26.38: Gross morphology of thyroid follicular adenoma. Tumor is well circumscribed. Cut surface of tumor is gray-white. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

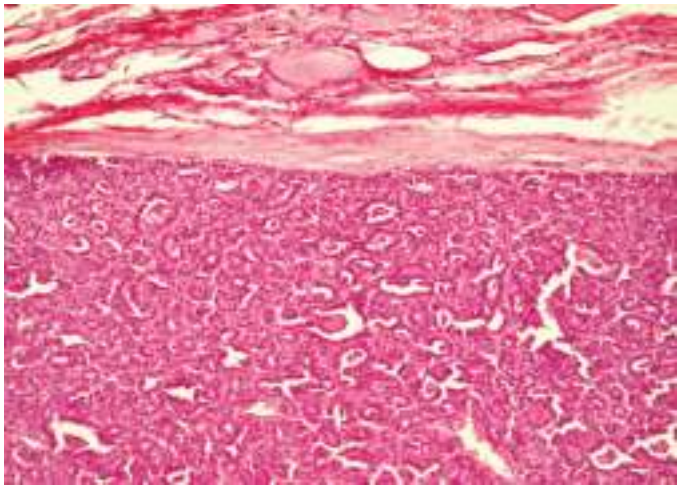

Fig. 26.39: Thyroid follicular adenoma. Tumor is completely surrounded by capsule. Uniform histopathological pattern of thyroid adenoma cells is seen. Tumor has compressed surrounding parenchyma.

HYALINIZING TRABECULAR TUMOR

Hyalinizing trabecular tumor (HTT) is an uncommon neoplasm of the thyroid follicular derivation, with morphology that is similar with papillary thyroid carcinoma. The tumor contains hyaline material that often confuses it for medullary carcinoma of thyroid, because hyaline mimics amyloid material.

- Therefore, the tumor is misdiagnosed as solid variant of papillary thyroid carcinoma, hyalinizing papillary thyroid carcinoma and hyalinizing trabecular adenoma like variant of medullary thyroid carcinoma, because its cytological features resemble papillary thyroid carcinoma and hyaline material resembles amyloid material.
- Both hyalinizing trabecular tumor and papillary carcinoma share significantly RET/PTC fusion gene. BRAF or NRAS mutations present in papillary thyroid carcinoma, but absent in hyalinizing trabecular tumor of thyroid gland.

Clinical Features

Hyalinizing trabecular tumor most often occurs in the females than males between fourth to seventh decades of age. Patients have no obvious symptoms. Clinical examination reveals mass in the neck region.

Surgical Pathology: Hyalinizing Trabecular Tumor
Light Microscopy
▪ Tumor is composed of follicular cells without atypia arranged in trabecular pattern with marked hyalinized vascular stroma. ▪ These features along with invasion of capsule and blood vessels are termed hyalinizing trabecular neoplasm.
Immunohistochemistry Technique
▪ Tumor cells show positivity for MiB1. ▪ MiB1 stains membrane and cytoplasm of tumor cells.

PAPILLARY THYROID CARCINOMA

Papillary thyroid carcinoma (PTC) is the commonest thyroid carcinoma. It accounts for 70–80% of all thyroid carcinomas.

- It most often affects young women 20–30 years of age group. Tumor is usually multifocal in origin within the gland and least aggressive thyroid cancer.
- Papillary thyroid carcinomas with many morphological subtypes (infiltrative, follicular, tall columnar cells, hobnail, solid, diffuse sclerosing, oncocytic and warthin-like) with minimally invasive, encapsulated angioinvasive and widely invasive; represent BRAF mutation malignancies, whereas invasive encapsulated follicular thyroid carcinoma represent the RAS mutation malignancies.

- Tumor most often remains localized to the thyroid and adjacent tissues for many years. It has a slow tendency to metastasize to regional lymph nodes, but distant metastases are rare. Prognosis is excellent even when adjacent lymph nodes are involved.

Diagnostic Features

Histologic features of papillary thyroid carcinoma are presence of true papillae, psammoma bodies, dark red colloid, crowded nuclei, optically clear chromatin exhibiting 'Orphan Annie appearance', irregular nuclear contours, nuclear groove and intranuclear cytoplasmic inclusions.

Radionuclide Scan

Papillary thyroid carcinoma is almost always nonfunctional. It invariably produces a cold nodule on radionuclide scanning.

Risk Factors

Hashimoto's thyroiditis and radiation exposure to the neck increase risk for papillary thyroid carcinoma in 5–10% of cases. Ionizing radiations pose a potential worldwide threat in this nuclear age. Low doses of ionizing radiation can cause DNA mutations and chromosomal abnormalities resulting in thyroid carcinoma. Large doses of radiation can inhibit cell division. Ionizing radiation also can enhance the effects of genetic abnormalities.

Molecular Genetic Alterations

Possible molecular genetic alterations associated with papillary thyroid carcinoma are rearrangement of RET/PTC, BRAF mutation and RAS mutation. Molecular pathogenesis of papillary thyroid carcinoma is shown in Figs 26.40 and 26.41.

- **RET-PTC fusion oncogene:** In some instances, papillary thyroid carcinoma may be associated with changes in chromosome 10. Either there is paracentric inversion of chromosome 10, or a reciprocal translocation between chromosomes 10 and 17.
  - These chromosomal changes activate the tyrosine kinase domain of RET. These novel fusion genes are referred to as RET-PTC oncogene.
  - Mutations in B-type RAS kinase (BRAF) are also common and predictive of tumor behavior and progression.
- **Hepatocyte growth factor (HGF):** Many cancer stem cells acquire the ability to synthesize the same growth factors to which they are responsive, generating an autocrine loop. Increased baseline activity of HGF oncogene product is associated with hepatocellular carcinoma and thyroid carcinoma.

Clinical Features

- The patient presents with slow growing painless occult (<1.5 cm in diameter) to palpable solitary or multifocal thyroid nodule. In some cases, papillary thyroid carcinoma is not palpable, i.e. occult, presenting with lymphadenopathy nearby thyroid gland called Delphian node containing metastases in 50–70% of cases. Distant metastases are uncommon, i.e. lungs and bone in 10% of cases.

Surgical Pathology: Papillary Thyroid Carcinoma

Gross Morphology

- Tumor may be small microscopic occult lesion <1 cm to large 10 cm nodule. Multifocal areas are observed in 20–75% of cases.
- On cut surface, tumor is usually solid grey white and sometimes cystic mass.
- Tumor is clearly invading the capsule.
- Approximately in <10% of cases, tumor is surrounded by a complete capsule (Fig. 26.42).

Light Microscopy

- Tumor is composed of fibrovascular stroma lined by tumor cells exhibiting branching tree-like pattern.
- Tumor cells contain optically clear ground glass nuclei giving (Orphan Annie) appearance. The nuclei show longitudinal nuclear groove and intranuclear pseudoinclusions due to cytoplasmic invagination into the nuclei.
- Fibrovascular stroma is edematous and infiltrated by lymphocytes, foamy histiocytes and hemosiderin.
- Fibrovascular stroma shows laminated calcific spherules called 'psamomma bodies' formed due to necrosis of cells with dystrophic calcification in 50% of cases. Their presence is strong indicator of papillary thyroid carcinoma (Figs 26.43 to 26.45).

Papillary Thyroid Carcinoma: Histologic Variants

- **Follicular variant of papillary thyroid carcinoma:** It consists of neoplastic follicular component and psammoma bodies. Prognosis is similar to conventional papillary carcinoma of thyroid.
- **Encapsulated variant of papillary thyroid carcinoma:** It is well encapsulated tumor associated with lymph node metastases but no distant metastases. Prognosis of this variant of papillary thyroid carcinoma is excellent.
- **Diffuse sclerosing variant of papillary thyroid carcinoma:** It is characterized by diffuse dense fibrous stroma, numerous psammoma bodies, squamous metaplasia and inflammation. It is associated with lymph node and distant lung metastases. Prognosis is poor than conventional papillary thyroid carcinoma.
- **Tall cell variant of papillary thyroid carcinoma:** It consists of tumor cells with abundant eosinophilic cytoplasm and lymphocytic infiltrate. It has worse prognosis than conventional papillary thyroid carcinoma.

- **Columnar variant of papillary thyroid carcinoma:** Tumor is composed of tall columnar cells with nuclear stratification arranged in papillary pseudoglandular formation with CDX2 immunoreactivity in 50% of tumors.

Immunohistochemistry Technique

A panel of immunomarkers for thyroid follicular cells in papillary thyroid carcinoma includes CK AE1/AE3, CK7, TTF-1, thyroglobulin and PAX8. A proportion of cases demonstrates BRAF V600E (VE antibody) and RET–PTC.

Markers	Expression
▪ CK AE1/AE3	▪ Positive
▪ CK7	▪ Positive
▪ TTF-1	▪ Positive
▪ Thyroglobulin	▪ Positive
▪ PAX8	▪ Positive
▪ BRAF V600E	▪ Positive
▪ RET–PTC	▪ Positive

Clinical Course

Patient with papillary thyroid carcinoma without evidence of metastasis has an excellent prognosis especially in persons younger than 45 years of age. Prognosis is good with 10-year survival rate in 80–90% of cases. Cure rate is nearly 100% in young patient

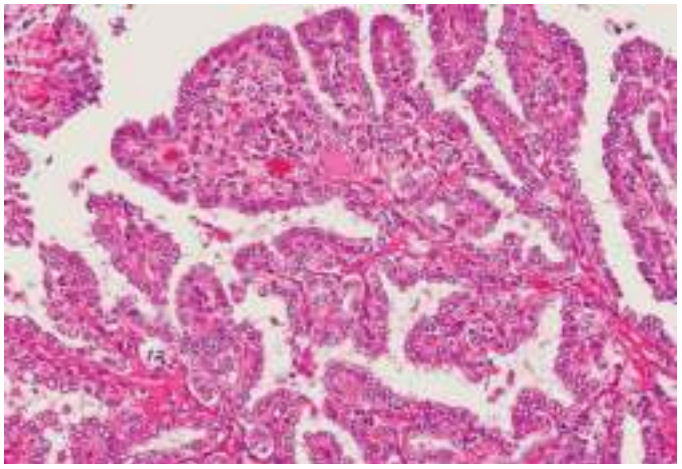

Fig. 26.43: Papillary thyroid carcinoma. Histologic examination shows fibrovascular stroma lined by neoplastic cells exhibiting branching tree-like pattern (100X).

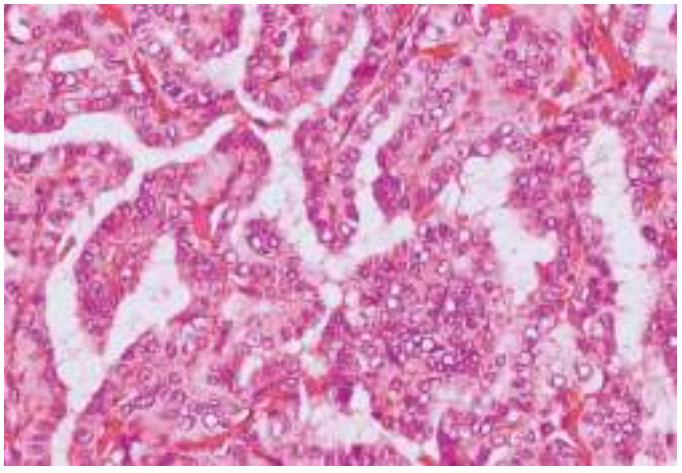

Fig. 26.44: Papillary thyroid carcinoma. Tumor is composed of fibrovascular core lined by neoplastic cells with optically clear nuclei exhibiting overcrowding. Fibrovascular stroma shows psammoma bodies and inflammatory cells (200X).

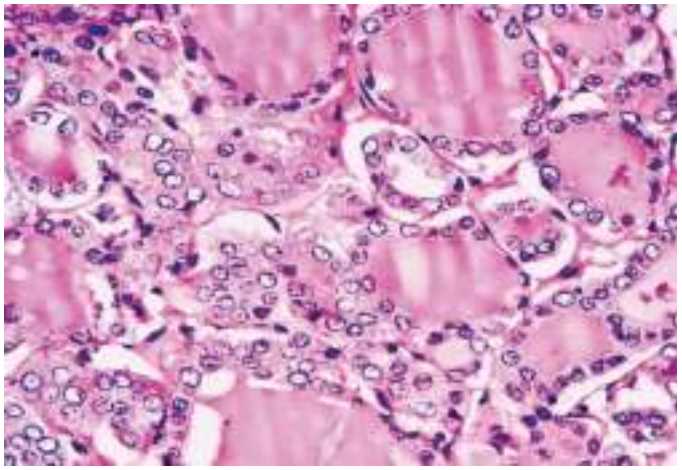

Fig. 26.45: Papillary thyroid carcinoma (follicular variant). Tumor is composed of neoplastic cells with optically clear nuclei exhibiting nuclear grooves (400X).

Table 26.27 Prognostic factors of papillary thyroid carcinoma

Parameters	Good Prognosis	Poor Prognosis
Sex predilection	Female patients	Male patients
Age group	<40 years of age especially children	>40 years of age
Location	Unicentric (unifocal) tumor	Multicentric (multifocal) tumor
Tumor differentiation	Well differentiated carcinoma	Poorly differentiated carcinoma
Extension of tumor	Tumor is confined within thyroid gland	Tumor is extending outside thyroid gland
Aneuploidy	Absent	Present

Table 26.28 Histologic variants of papillary thyroid carcinoma and biologic behavior, when compared with conventional/classic variant

Biologic Behavior	Histologic Variants of Papillary Carcinoma of Thyroid Gland	
Excellent prognosis (less aggressive histologic variants)	▪ Conventional/classic variant ▪ Follicular variant ▪ Warthin-like variant	▪ Papillary microcarcinoma ▪ Encapsulated variant
Poor prognosis (highly aggressive histologic variants)	▪ Solid trabecular variant ▪ Diffuse sclerosing variant	▪ Tall cell variant ▪ Hobnail variant
Variable (less highly aggressive histologic variants)	▪ Columnar cell variant	
Unknown biological behavior	▪ Unknown biological behavior ▪ Cribriform-morular variant ▪ Papillary carcinoma with fibromatosis/ fasciitis like stroma	▪ Oncogenic variant ▪ Spindle cell variant ▪ Clear cell variant

with small focus of cancer. Relapses occur 20–35 years after treatment. Prognostic factors of papillary thyroid carcinoma are given in Table 26.27. Histologic variants of papillary thyroid carcinoma and biologic behavior, when compared with conventional/classic variant are given in Table 26.28.

FOLLICULAR THYROID CARCINOMA

Follicular thyroid carcinoma (FTC) accounts for 6–10% of thyroid carcinomas and occurs in women over 40–60 years, who have dietary iodine deficiency and irradiation exposure. Tumor has hematogenous dissemination but usually lacks lymphatic spread. Three types of FTC include: (a) minimally invasive with capsular invasion only, (b) encapsulated angioinvasive with limited capsular invasion (<4 vessels) has better prognosis, and (c) widely angioinvasive (>4 vessels) with extensive invasion of thyroid and extrathyroid tissue. Extensive sampling of tumor capsule is recommended. Radionuclide scan reveals solitary 'cold' nodule.

Diagnostic Criteria

Follicular thyroid carcinoma is distinguished from a follicular thyroid adenoma on the basis of thick irregular capsule, capsular invasion and lymphovascular invasion, extrathyroidal tumor extension, lymph node metastases or system metastases (lungs, bones, liver, brain and skin).

- Diagnosis of follicular thyroid carcinoma relies on capsular and/or lymphovascular invasion by atypical cells of the tumor. Capsular invasion is defined as follicular thyroid carcinoma extension through the entire capsule. A follicular neoplasm with tumor invasion into but not through entire capsule is considered a follicular thyroid adenoma. Vascular invasion is defined as follicular thyroid carcinoma penetration into a wall of large caliber blood vessel with identifiable vascular endothelial lining within or outside the capsule. Vascular invasion is the most reliable sign of follicular thyroid carcinoma.
- Follicular thyroid carcinoma can be minimally invasive (less aggressive tumor with a disease-free survival in young persons), and invasive (most aggressive tumor metastasizing to lungs, bones, liver, brain and skin) histologic variants based on morphologic criteria. Minimally invasive follicular thyroid carcinoma is an encapsulated tumor with microscopic invasion of tumor capsule without vascular invasion. Invasive follicular thyroid carcinoma is defined by capsular invasion and vascular invasion and/or extension

beyond the thick tumor capsule into the adjacent thyroid parenchyma. It has been suggested that minimally invasive follicular thyroid carcinoma may be precursor to its invasive counterpart.

Pathogenesis

Pathogenesis of follicular thyroid carcinoma may be linked to iodine deficiency, radiation exposure and various oncogenic activation and/or microRNA (miR-192, miR-197 and miR-346) activation.

- About 80% of follicular thyroid carcinomas contain RAS gene mutations or a paired box 8/peroxisome proliferator-activated receptor gamma (PAX8-PPAR-γ) gene rearrangement.
- The RAS genes code for multiple G proteins that are involved in intracellular signaling through the RAF-MEK-MAPK kinase signaling pathway. Point mutations in RAS (N-RAS, H-RAS and K-RAS) may be implicated in the evolution of follicular thyroid adenoma to follicular thyroid carcinoma, producing continuously activated signaling proteins leading to uncontrolled growth. Other gene mutations can be linked to follicular thyroid carcinoma, which include TP53, c-Myc, c-Fos and the thyrotropin (TSH) receptor.
- PAX8-PPAR-γ gene rearrangement has been implicated in many cases of follicular thyroid adenoma and follicular thyroid carcinoma. PAX8 gene codes for nuclear protein product of thyroid specific transcription factor that is involved in differentiation of follicular cell. Mutation in PAX8 leads to its fusion with PPAR-γ, which causes to impaired function of PPAR-γ resulting in loss of growth inhibitory regulation.
- Advances in molecular genetic testing for gene mutations help in the evolution of a follicular thyroid adenoma to follicular thyroid carcinoma. Molecular pathogenesis of follicular thyroid carcinoma is shown in Fig. 26.46.

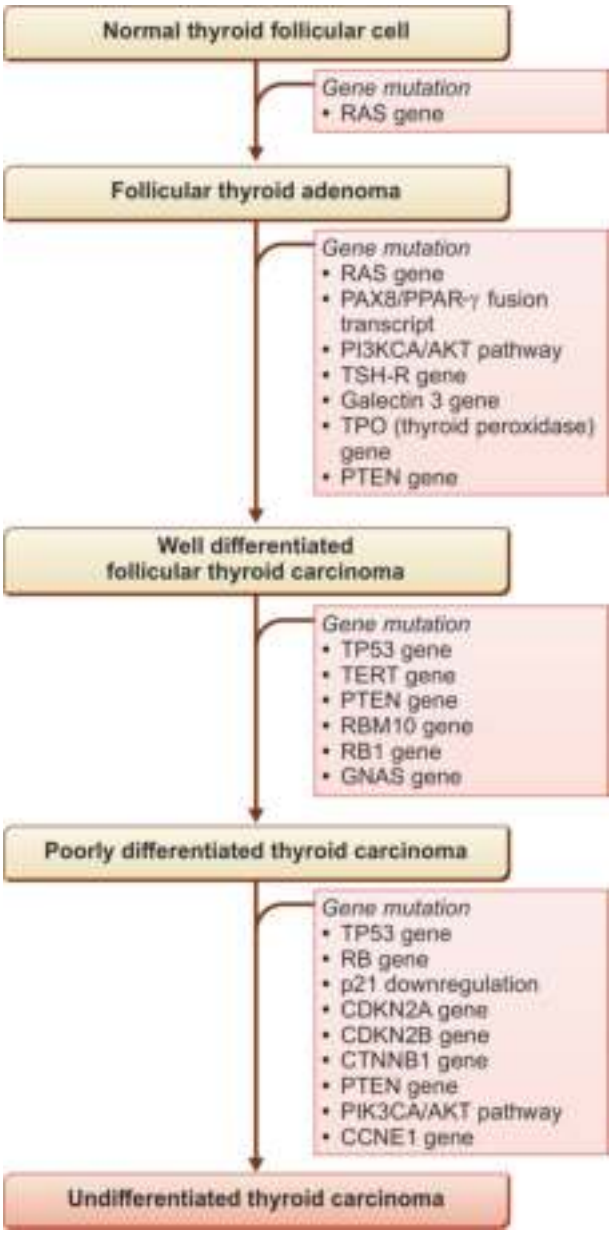

Fig. 26.46: Molecular pathogenesis of follicular thyroid carcinoma.

Clinical Features

Most patients with a follicular thyroid carcinoma present with a solitary palpable nodule in thyroid gland identified on clinical examination and on ultrasound imaging study. However, tumor may occur in association with thyroiditis and/or nodular hyperplasia and radiation exposure.

- Most patients are euthyroid and asymptomatic. Patients with large tumors may present with breathlessness (compression of trachea), hoarseness of voice (compression of recurrent laryngeal nerve) or dysphagia (compression of esophagus). Patients with functional follicular thyroid adenoma may manifest with hyperthyroidism.
- Follicular thyroid carcinoma is usually unifocal and <10% of patients have lymph node metastases via lymphatic route. Tumor has a propensity for distant metastasis via hematogenous route to lungs, bones liver, brain and skin.
- Secondary changes may occur in large follicular thyroid adenoma, i.e. intratumoral hemorrhage, edema, cystic degeneration, fibrosis, dystrophic calcification and bone formation. Patients may complain of multiple nodules in thyroid and neck pain as a result of sudden tumor enlargement from intratumoral hemorrhage or cystic degeneration.

Laboratory Diagnosis

Fine needle aspiration cytology (FNAC) of follicular thyroid neoplasm reveals abundant follicular epithelial cells in sheets with crowding and overlapping of cells, microfollicles and scant/no colloid. Limitation of fine needle aspiration cytology is the inability to distinguish follicular thyroid adenoma from follicular thyroid carcinoma.

- Ultrasonographic features alone cannot distinguish a follicular thyroid adenoma from a follicular thyroid carcinoma. In a patient with a follicular thyroid neoplasm, ultrasound demonstration of thyroid nodular disease in the contralateral thyroid lobe has important implications for operative management.
- Patient with follicular thyroid neoplasm should undergo diagnostic thyroid lobectomy and isthmusectomy for histologic examination, which is essential to distinguish follicular thyroid carcinoma from follicular thyroid adenoma. The assessment of capsular invasion and vascular invasion is essential for diagnosis of follicular thyroid carcinoma. The use of immunohistochemical techniques to identify PAX8-PPAR-γ gene rearrangement is helpful in diagnosing follicular thyroid carcinoma.
- Molecular genetic testing of RAS gene mutations justifies a recommendation for surgery in all patients with RAS gene mutations. Detection of circulating tumor cells in the blood using reverse transcriptase polymerase chain reaction (RT-PCR) for TSH receptor and thyroglobulin messenger RNA may help in distinguishing follicular thyroid carcinoma from follicular thyroid adenoma. TSH receptor and thyroglobulin mRNA transcripts found in the peripheral blood is sensitive and specific diagnostic test for follicular thyroid carcinoma. Detection of carcinoembryonic antigen (CEA) in the peripheral blood is useful in differentiating follicular thyroid carcinoma from follicular thyroid adenoma.

Treatment

Patients with invasive follicular thyroid carcinoma are treated by complete thyroidectomy with tumor-free margins, postoperative radioactive iodine ablation, whole body scanning, and thyrotropin suppressive doses of thyroid hormones. Less than 10% of patients with follicular thyroid carcinoma develop lymph node metastases and hence compartment-oriented neck dissection is reserved for patients with macroscopic disease.

- Regular follow-up of patients is essential which includes clinical history, physical examination, cervical ultrasonography and analysis of serum TSH, thyroglobulin and antithyroglobulin antibody levels.
- Computed tomography (CT) and magnetic resonance imaging (MRI) studies are reserved for patients with an elevated serum thyroglobulin level, negative ultrasonography, and distant metastases to lung and bone (osteolytic lesions in vertebral bodies followed by the pelvis, femur, skull and ribs), and less commonly to liver, brain and skin.
- Microscopic metastases are treated with high doses of radioactive iodine. Isolated macroscopic metastasis should be treated by surgical excision. The overall 10-year survival for patients with minimally invasive follicular thyroid carcinoma is 98% compared with 80% in patients with invasive follicular thyroid carcinoma.
- Comparison of papillary carcinoma and follicular carcinoma of thyroid gland is given in Table 26.29. Histologic features differentiating solitary follicular thyroid adenoma and follicular thyroid carcinoma are given in Table 26.30.

Table 26.29 Comparison of papillary thyroid carcinoma and follicular thyroid carcinoma

Parameters	Papillary Thyroid Carcinoma	Follicular Thyroid Carcinoma
Role of radiation	Present	Absent
Encapsulation	Rare	Common
Invasion	Strongly invasive, invades in small islands	Variably invasive in large islands with pushing borders
Multiple tumor foci	Common	Rare
Blood vessel invasion	Rare	Common
Cellular pattern	Papillae, follicles, solid cell group	Follicles, trabeculae, no papillae, pseudopapillary infoldings may occur
Psammoma bodies	Present in 50% in fibrovascular stroma	Absent, but calcified colloid may occur
Nuclear features	Ground glass (**Orphan Annie**) appearance, grooves, pseudoinclusions, often overlapping	Normochromatic or hyperchromatic, no grooves, no overlap

Table 26.30 Histologic features differentiating follicular thyroid adenoma from follicular thyroid carcinoma

Follicular Thyroid Adenoma	Follicular Thyroid Carcinoma
Complete but delicate capsule	Dense circumferential fibrosis of capsule
Entrapped or sequestered thyroid in near capsule	Transcapsular '**mushrooming**' invasion
Juxtaposed or prolapsed thyroid tissue near vessels, but with intact endothelium	Adherence of thyroid tissue to vascular endothelium with associated fibrosis

Surgical Pathology: Follicular Thyroid Carcinoma

Gross Morphology

- It is difficult to differentiate between well circumscribed follicular thyroid carcinoma and follicular thyroid adenoma. Some follicular thyroid carcinomas bulge from the confines of its capsule. Neoplastic cells show invasion of capsule and blood vessels, thus distinguished from follicular thyroid adenoma.
- Minimally invasive follicular thyroid carcinoma is seen grossly as a well-defined, unifocal encapsulated soft tumor.
- Cut surface of tumor is grey white soft with areas of hemorrhage, necrosis and cyst formation (Fig. 26.47).

Light Microscopy

- Tumor is composed of variable sized thyroid follicles lined by tumor cells with normochromatic/hyperchromatic nuclei with oxyphil/clear cytoplasm arranged in cords and invading capsule.
- Minimally invasive follicular thyroid carcinoma, which shows only capsular invasion without vascular invasion has better prognosis (Fig. 26.48).

Follicular Thyroid Carcinoma: Histologic Variants

- **Encapsulated variant of follicular thyroid carcinoma:** It is well encapsulated with minimal capsular invasion or invasion of blood vessels and distant metastases in 15% of cases.
- **Langhans' struma variant of follicular thyroid carcinoma:** It is sluggish tumor compressing respiratory airway.
- **Insular type of follicular thyroid carcinoma:** It is rare poorly differentiated variant of follicular carcinoma. Its phenotype is similar to the pancreatic insulinoma. It is more aggressive tumor, which shows positivity for thyroglobulin, but negativity for calcitonin.
  - Tumor is composed of broad trabeculae of small primitive cells with evenly distributed chromatin with inconspicuous nucleoli and scant cytoplasm.
  - Tumor cells are arranged around the blood vessels with numerous mitosis and extrathyroid involvement of lymph nodes (Fig. 26.49).

Immunohistochemistry Technique

- Thyroglobulin (Tg) and TTF-1 can be used as a tumor marker for well differentiated follicular thyroid carcinoma.
- Follicular thyroid carcinoma with or without metastases shows significant overexpression of *Ki-67* proliferative marker.

Fig. 26.47: Follicular thyroid carcinoma. Cut surface of tumor is grey white with areas of hemorrhage and necrosis and cyst formation. (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

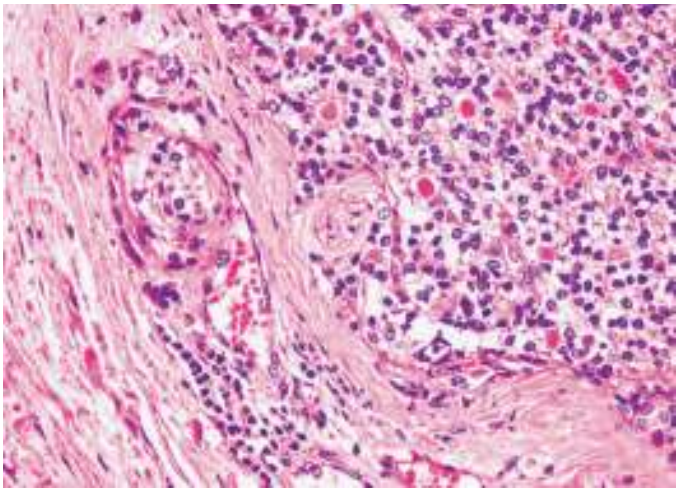

Fig. 26.48: Follicular thyroid carcinoma: Tumor is composed of variable sized thyroid follicles lined by tumor cells with normochromatic/hyperchromatic nuclei with oxyphil/clear cytoplasm. These are arranged in cords and invading capsule (400X).

Markers	Expression
▪ Thyroglobulin	▪ Positive
▪ TTF-1	▪ Positive
▪ Ki-67 proliferation index	▪ Positive

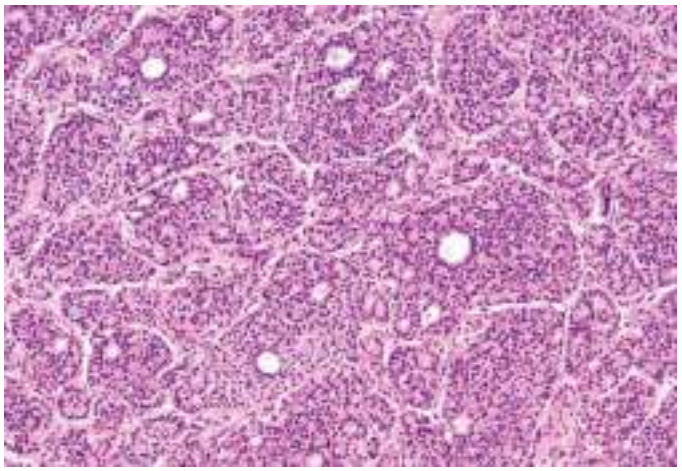

Fig. 26.49: Follicular thyroid carcinoma (insular variant). Tumor shows broad trabeculae of small cells with evenly distributed chromatin with inconspicuous nucleoli and scanty cytoplasm. Tumor cells are arranged around blood vessels with numerous mitosis (200X).

Routes of Metastasis

Tumor mainly spreads by hematogenous route to liver, lungs and bones. Lymphatic spread to regional lymph nodes may also occur.

ONCOCYTIC THYROID NEOPLASMS

Oncocytic thyroid neoplasms are derived from follicular cell composed of >75% of oncocytic tumor cells. Oncocytes (also known as Ashkenazy cells and oxyphil cells) are large polygonal cells found in thyroid and parathyroid glands, which have an abundance of eosinophilic cytoplasm secondary to increased dysfunctional mitochondria content. It is worth mentioning that oncocytic metaplasia occurs due to various cellular stress responses in benign adenomatous nodules, Hashimoto's thyroiditis, papillary thyroid carcinoma (PTC) and poorly differentiated thyroid carcinoma.

- Oncocytic thyroid neoplasms are categorized into benign and malignant. Oncocytic thyroid adenoma is a benign tumor without recurrence after surgical excision. Oncocytic thyroid carcinoma previously known as 'Hurthle cell carcinoma' accounts for 1–2% of all thyroid carcinomas, and is more common in older men with median age of 55 years, which is associated with worse prognosis in older persons, tumor size >4 cm and extensive lymphovascular invasion and metastasis to lymph nodes and distant organs.
- According to the recent 2022 World Health Organization (WHO) classification of thyroid neoplasms, oncocytic thyroid carcinoma is a distinct entity, which indicates oncocytic follicular cell-derived neoplasm composed of >75% of oncocytic tumor cells, which lacks the characteristic nuclear features of papillary thyroid carcinoma (PTC). High-grade follicular cell-derived oncocytic thyroid carcinomas comprise both differentiated oncocytic carcinoma (necrosis and ≥5 mitoses/cu mm) and poorly differentiated oncocytic thyroid carcinoma.

Clinical Features

Patient with oncocytic thyroid adenoma presents with solitary palpable nodule in normal thyroid gland. Patient with large size oncocytic thyroid carcinoma presents with breathlessness (compression of trachea), hoarseness of voice (compression of recurrent laryngeal nerve), dysphagia (compression of esophagus) and metastatic manifestations.

Laboratory Diagnosis

A definite diagnosis of oncocytic thyroid adenoma and oncocytic thyroid carcinoma is confirmed after complete surgical excision and histologic examination. Fine needle aspiration cytology (FNAC), ultrasonography, and occasional computed tomography (CT) do not always provide a definite diagnosis. On histologic examination, oncocytic thyroid adenoma is benign tumor if there is no evidence of capsular or vascular invasion.

- Oncocytic thyroid carcinoma is an aggressive neoplasm than conventional follicular thyroid carcinoma, with extrathyroidal extension, capsular invasion, lymphovascular invasion, and high risk of metastasis, local recurrence after surgical excision, and associated with poor prognosis.
- Typical mutations of thyroid cancer genes including RAS, TSHR, TP53, PTEN, BRAF, PAX8-PPAR-γ, and MEN1 are uncommon in oncocytic thyroid carcinoma. Molecular pathogenesis of oncocytic thyroid carcinoma is shown in Fig. 26.50.

Treatment

Oncocytic thyroid adenoma is treated by thyroid lobectomy. Oncocytic thyroid carcinoma tends to be aggressive with a high risk of metastasis and low survival and is treated by total thyroidectomy or radiation ablation. Oncocytic thyroid carcinoma is likely to be radioiodine-resistant compared to conventional follicular thyroid carcinoma. Prognosis depends on the size of the tumor, extent of extrathyroidal invasion, vascular invasion, cancer stage at diagnosis and degree of dissemination to distant organs.

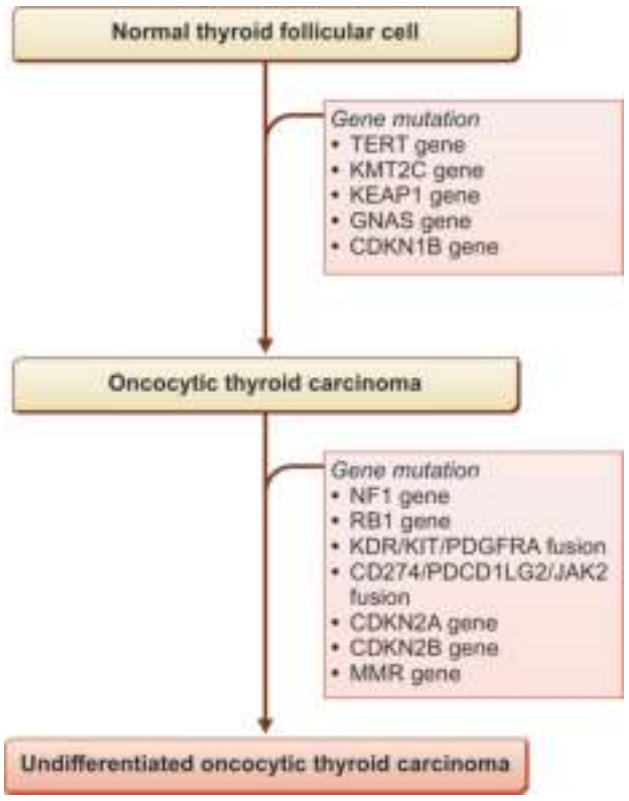

Fig. 26.50: Molecular pathogenesis of oncocytic thyroid carcinoma.

Surgical Pathology: Oncocytic Thyroid Neoplasms

Gross Morphology

- Most oncocytic thyroid neoplasms are >2 cm in dimeter. Tumor is prone to hemorrhage and infarction especially after fine needle aspiration or core biopsy.
- Oncocytic thyroid adenoma is encapsulated solitary, solid, and brown to mahogany color. Tumor may be lobulated with central scarring.
- Invasive oncocytic thyroid carcinoma has irregular borders, may have satellite nodule/multinodular appearance.

Light Microscopy

- **Oncocytic thyroid adenoma:** Histologically, oncocytic thyroid adenoma is benign tumor if there is no evidence of capsular or vascular invasion.
  - Tumor is composed of >75% of oncocytic large tumor cells with distinct cell borders, deeply eosinophilic and granular cytoplasm, large nucleus with prominent nucleus and complete loss of cell polarity.
  - Oncocytic tumor cells are arranged in follicular, trabeculae, solid or papillary growth patterns. Presence random nuclear cytologic atypia is common but not evidence of malignancy.
- **Oncocytic thyroid carcinoma:** Histologically, oncocytic thyroid carcinoma is malignant if there is evidence of capsular or vascular invasion.
  - Tumor tends to have thick capsule than that of oncocytic thyroid adenoma. Tumor is composed of large polygonal tumor cells with abundant eosinophilic granular cytoplasm, large round nuclei, vascular chromatin and prominent nucleoli and mitoses, arranged in solid and trabecular architecture rather than follicular pattern of growth and separated by delicate vasculatures.
  - High-grade differentiated oncocytic thyroid carcinoma shows necrosis and ≥5 mitoses/cu mm. Poorly differentiated oncocytic thyroid carcinoma measures >4 cm in size and is composed of small oncocytic tumor cells, numerous mitoses and tumor necrosis.

MEDULLARY THYROID CARCINOMA

Medullary thyroid carcinoma (MTC) is derived from the parafollicular cells (C cells residing in upper lateral lobes of thyroid gland), i.e. neural crest origin. Parafollicular cells synthesize calcitonin, which is tumor marker for screening medullary thyroid carcinoma. Altered calcitonin contributes to amyloid deposition within the tumor in majority of patients and demonstrated by Congo red stain. Paraneoplastic syndrome and carcinoid syndrome can occur in medullary thyroid carcinoma, which can synthesize hormones such as corticotropin, histamine, serotonin, prostaglandins, somatostatin, gastrin-releasing peptides (bombesin) and melanin.

Sporadic and Familial Medullary Thyroid Carcinoma

About 75–80% of medullary thyroid carcinomas are sporadic tumors (usually unilateral), and the remainder is familial tumors (multicentric and bilateral) as a part of multiple endocrine neoplasia, MEN IIa (pheochromocytoma and parathyroid adenoma), MEN IIb (i.e. pheochromocytoma and multiple mucosal neuromas) and familial medullary thyroid carcinoma (FMTC). RET mutations in neural crest tissue in the thyroid gland can lead to development of medullary thyroid carcinoma. Prophylactic thyroidectomy is recommended for patients with germline RET mutations that run family members at high risk to develop medullary thyroid carcinoma.

Molecular Genetic Alterations

Germline mutations of RET proto-oncogene located on chromosome 11 codes for transmembrane receptor tyrosine kinase are associated with MEN IIa, MEN IIb and FMTC.

- About 40–50% of sporadic thyroid carcinomas have acquired RET mutations located on chromosome 11, involving sequencing of exons 10, 11 and 13 through 16.

- Sporadic medullary thyroid carcinoma has a peak incidence in the fifth to sixth decade of life, whereas those medullary thyroid carcinomas associated with MEN IIa, MEN IIb and FMTC peak around the second or third decade of life. Molecular pathogenesis of medullary thyroid carcinoma (sporadic and hereditary types) is given in Fig. 26.51.

Clinical Features

About 70% of patients can manifest with cervical lymphadenopathy and a few of patients have compression symptoms like dysphagia, hoarseness of voice or respiratory difficulty. Liver, bone, lung and brain are common sites for metastases in a minority of patients.

Laboratory Diagnosis

Fine needle aspiration cytology (FNAC) of medullary thyroid carcinoma is potentially helpful in establishing the diagnosis. Diagnosis is confirmed on histologic examination of thyroid lobectomy specimen. Histologic examination reveals tumor is composed nests of round or ovoid cells and fibrovascular core stroma.

- Once the diagnosis of medullary thyroid carcinoma is made on histologic examination, serum calcitonin and carcinoembryonic antigen (CEA) should be analyzed to assess secretory activity of tumor and preoperative levels can be compared to postoperative levels to confirm the biologic response after surgical removal of tumor. The postoperative serum calcitonin and CEA doubling time provoke a sensitive tumor marker for progression of disease.
- Ultrasonography and computed tomography (CT) are performed to evaluate the involvement of cervical lymph nodes and liver by medullary thyroid carcinoma. Magnetic resonance imaging (MRI) is indicated in patients suspected of having metastatic disease. This can include patients with lymph node metastatic disease and serum calcitonin levels >400 ng/ml.
- Molecular genetic testing for mutation in RET gene mapped on chromosome 11, involving sequencing of exons 10, 11 and 13 through 16 is essential for all patients with parafollicular cell hyperplasia or sporadic medullary thyroid carcinoma. Screening for pheochromocytoma and hyperparathyroidism by using plasma metanephrines and serum calcium respectively is recommended for a patient with unknown RET gene mutational status and confirmed germline RET gene mutational status.

Treatment

Total thyroidectomy is indicated for all patients with medullary thyroid carcinoma (MTC). Bilateral neck dissection is indicated for MTC with more than one cm in diameter as well as for bilateral disease. Total prophylactic thyroidectomy is performed by the age of five years or when RET mutation codon 609, 611, 618, 630, 634. In MEN IIb with RET mutation codon 883, 918 or compound heterozygotes, total prophylactic thyroidectomy is performed by age of one year. Various receptor tyrosine kinase (RTK) inhibitors are administered to treat patients with medullary thyroid carcinoma such as cabozantinib an oral multikinase inhibitor, which inhibits RET, EGFR and VEGFR.

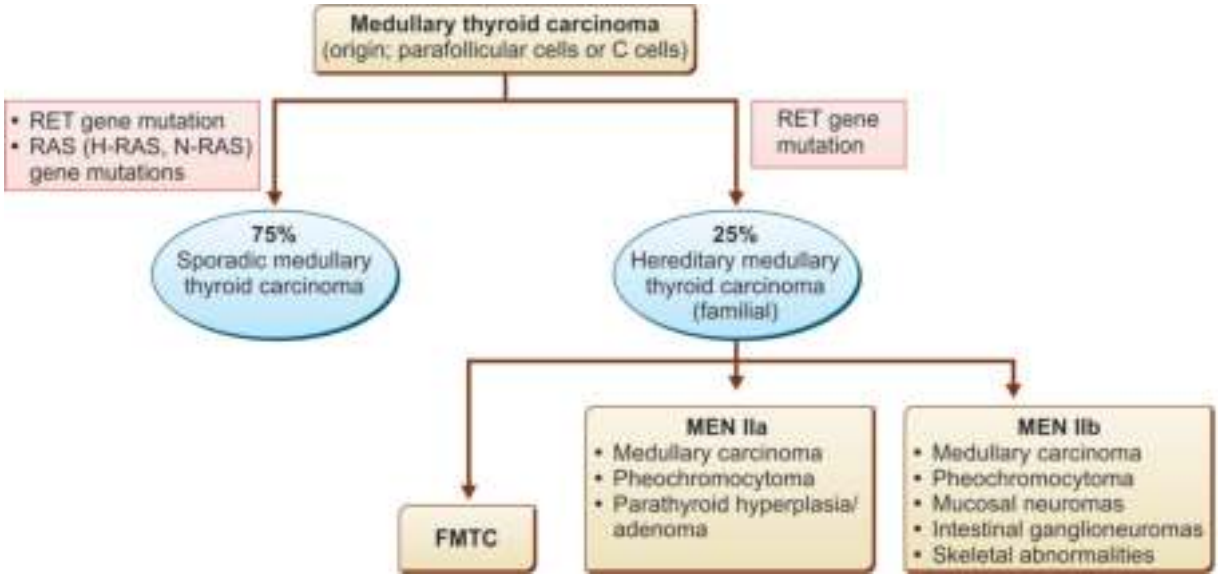

Fig. 26.51: Molecular pathogenesis of medullary thyroid carcinoma (sporadic and hereditary types).

Pathology Pearls: Sporadic and Familial/Hereditary Medullary Thyroid Carcinoma

Sporadic Medullary Thyroid Carcinoma (75%)

Patient presents with solitary tumor located in mid-portion or upper half of thyroid gland corresponding to a greater concentration of parafollicular 'C' cells in this region. Hormones, e.g. calcitonin, prostaglandins, serotonin, or vasoactive intestinal peptide (VIP) synthesized by the tumor increase gastrointestinal secretion and motility responsible for diarrhea in 33% of cases.

Familial Medullary Thyroid Carcinoma (25%)

Familial medullary thyroid carcinoma has a better prognosis than sporadic type. It is associated with pheochromocytoma, and completely curable when detected before it causes symptoms. It is associated with autosomal dominant MEN IIa (Sipple syndrome), MEN IIb and inherited medullary thyroid carcinoma without associated endocrinopathies. Patient with multiple endocrine neoplasia syndromes has gene mutations that make them susceptible to neoplasia or hyperplasia in multiple organs.

- **MEN IIa syndrome (Sipple syndrome):** It is also known as Sipple syndrome. It comprises medullary thyroid carcinoma, parathyroid adenoma or hyperplasia (hyperparathyroidism (33%) and bilateral pheochromocytomas. Hirschsprung's disease (congenital megacolon) and a variety of neural crest tumors (e.g. glioma). Patients with MEN IIb have mutations in RET oncogene, a transmembrane receptor of the tyrosine kinase family. When a diagnosis of pheochromocytoma is made, demonstration of mutation in RET oncogene would justify prophylactic thyroidectomy keeping in view of fatal outcome of medullary thyroid carcinoma.
- **MEN IIb syndrome (Gorlin syndrome):** It is associated with medullary thyroid carcinoma, bilateral pheochromocytomas, and multiple mucosal ganglioneuromas in lips/tongue. In contrast to MEN IIa, it does not induce hyperparathyroidism. It is linked to different mutations in the RET oncogene compared with MEN IIa. Poor prognostic factors in these patients include age >50, male, and distant metastases. Inherited medullary thyroid carcinoma without associated endocrinopathies is the least aggressive with peak incidence in the ages of 40 and 50.

Clinical Features

Patient presents with symptoms related to paraneoplastic syndrome and carcinoid syndrome due to secretory products of medullary thyroid carcinoma such as corticotropin, histamine, serotonin, prostaglandins. Somatostatin, gastrin-releasing peptides and melanin. Patient develops atypical Cushing's syndrome (ACTH) and watery diarrhea due to secretion of vasoactive intestinal peptide in 33% of cases.

Surgical Pathology: Medullary Thyroid Carcinoma

Gross Morphology

- Tumor is well circumscribed, solid, firm with grey white to yellow brown. Foci of hemorrhage necrosis are seen in large tumors.
- Tumor diameter 1 cm or less is referred to as medullary microcarcinoma (Fig. 26.52).

Light Microscopy

- Tumor is composed of round to polyhedral granular cells arranged in trabecular, glandular, carcinoid-like patterns.
- The tumor cells are separated by a distinctly fibrovascular stroma containing amyloid material representing deposition of procalcitonin.
- Amyloid material may elicit a florid foreign body type of giant cell reaction. This material is eosinophilic with the hematoxylin and eosin stain and takes up the Congo red stain.
- The stroma may be scanty, hemorrhagic or ossified or edematous (Fig. 26.53).

Immunohistochemistry Technique

- Tumor cells show positivity for calcitonin, creatine kinase, neuron-specific enolase, chromogranin, synaptophysin, TTF-1 and carcinoembryonic antigen.
- Carcinoembryonic antigen (CEA) is an oncofetal glycoprotein presents in large quantities in medullary carcinoma of thyroid. Monoclonal antibodies offer a greater degree of tumor specificity.

Markers	Expression
Calcitonin	Positive
Neuron-specific enolase (NSE)	Positive
Chromogranin	Positive
Synaptophysin	Positive
Thyroid transcription factor 1 (TTF-1)	Positive
Creatine kinase	Positive
Carcinoembryonic antigen (CEA)	Positive

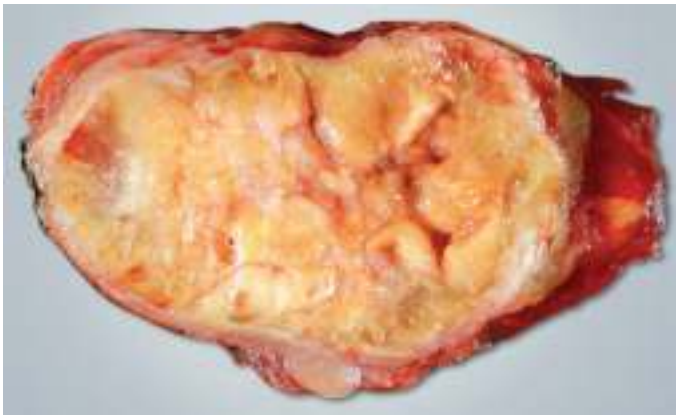

Fig. 26.52: Gross morphology of medullary thyroid carcinoma. Tumor is well circumscribed, fleshy, solid, grey white to yellow brown, firm inconsistency, foci of hemorrhage necrosis are seen. (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

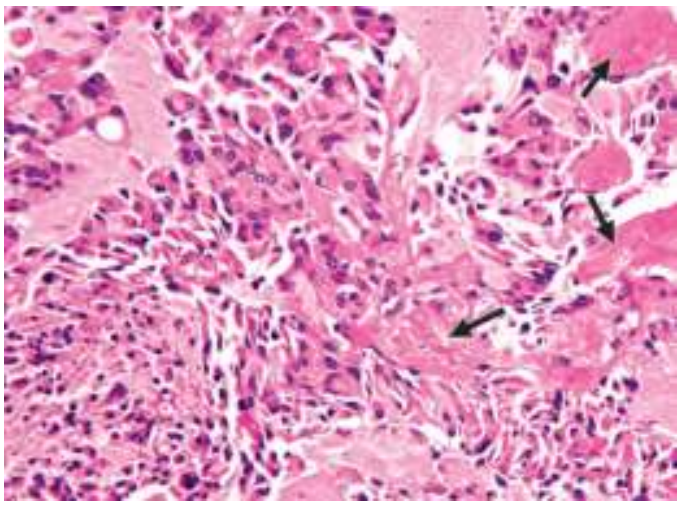

Fig. 26.53: Medullary thyroid carcinoma. The tumor is composed of round to polyhedral granular cells arranged in trabecular, glandular, carcinoid-like patterns. The tumor cells are separated by a distinct fibrovascular stroma containing amyloid material (arrows) representing deposition of procalcitonin (400X).

Mode of Spread

Medullary thyroid carcinoma extends by direct invasion into soft tissues and metastasizes via lymphatic route to the regional lymph nodes, e.g. cervical and mediastinal regions, and distant organs such as lungs, liver, bone, brain, and adrenal medulla by hematogenous route.

Surgical Correlation

Prior to thyroid surgery in MEN IIa and MEN IIb, 24-hour urinary catecholamine estimations are done to confirm pheochromocytomas. Prior to thyroidectomy, pheochromocytoma must be surgically excised first to prevent the risk for severe hypertensive episodes.

Residual Disease Following Surgery or Recurrence

Residual disease of medullary thyroid carcinoma can be detected by measuring calcitonin. Comparison of papillary, follicular and medullary thyroid carcinomas is given in Table 26.31.

Table 26.31 Comparison of papillary, follicular and medullary thyroid carcinomas

Parameters	Papillary Thyroid Carcinoma	Follicular Thyroid Carcinoma	Medullary Thyroid Carcinoma
Incidence	70–80%	17%	6%
Age group	20–30 years	50–60 years	Middle age
Etiology	Irradiation	Endemic goiter	Sporadic or familial
Encapsulation	Rare	Common	Circumscribed
Gross morphology	On cut surface, tumor is usually solid grey white and sometimes cystic mass	Cut surface is grey white soft with areas of hemorrhage (tan), necrosis and cyst formation	Circumscribed, solid, firm with grey white to yellow brown
Cellular pattern	Papillae, follicles, solid cell group	Follicles, trabeculae, no papillae, pseudopapillary in foldings may occur	Round to polyhedral granular cells arranged in trabecular, glandular with carcinoid-like patterns and separated by fibrovascular stroma containing amyloid material representing deposition of procalcitonin
Psammoma bodies	Psammoma bodies are present in fibrovascular stroma (50%)	Psammoma bodies are absent, but calcified colloid may occur	Psammoma bodies are absent
Nuclear features	Ground glass (**Orphan Annie**) appearance, grooves, pseudo-inclusions, often overlapping	Normochromatic or hyperchromatic, no grooves, no overlap	Normochromatic or hyperchromatic, no grooves, no overlap
Amyloid material in tumor	Absent	Absent	Present
Invasion	Strongly invasive, invades in small islands	Variably invasive in large islands with pushing borders	Invades locally
Multiple tumor foci	Common	Rare	Rare
Blood vessel invasion	Rare	Common	Common
Metastases	Lymph nodes	Lungs, liver, bones	Lungs, liver, bones, brain, and adrenal medulla
Prognosis	Excellent	Good	Poor

POORLY DIFFERENTIATED THYROID CARCINOMA

Poorly differentiated thyroid carcinoma is a follicular cell-derived neoplasm, which occupies an intermediate position between well differentiated follicular thyroid carcinoma or papillary thyroid carcinoma and anaplastic thyroid carcinoma in respect of morphology and clinical behavior. Response to radioiodine treatment is poor in poorly differentiated thyroid carcinoma.

Molecular Genetic Alterations

Poorly differentiated thyroid carcinoma has multiple gene mutations load intermediate between papillary thyroid carcinoma and anaplastic thyroid carcinoma. Micro-RNA profile is also different from well differentiated and anaplastic thyroid carcinomas.

Surgical Pathology: Poorly Differentiated Thyroid Carcinoma

Gross Morphology

Tumor size is large with pushing margins and may be partially encapsulated. Cut surface is grayish white and pale areas of necrosis.

Light Microscopy

- Poorly differentiated thyroid carcinoma originates from follicular epithelial cells, which lies between well-differentiated follicular and undifferentiated thyroid carcinomas.
- Diagnostic criteria for poorly differentiated thyroid carcinoma include: (a) presence of at least one of the three growth patterns (i.e. solid, trabecular, insular), (b) absence of the conventional nuclear features of papillary thyroid carcinoma, (c) presence of at least one of the following features: convoluted nuclei, mitotic activity ≥3 per 10 high power fields, and (d) tumor necrosis.
- Tumor with insular growth pattern is composed of uniform small cells with round or convoluted hyperchromatic arranged in solid nests, atypical mitoses, and necrosis. Tumor may contain microfollicles.

ANAPLASTIC THYROID CARCINOMA

Anaplastic thyroid carcinoma is the least common malignancy. It mostly occurs in older patients associated with very poor prognosis. Invasion beyond capsule, blood vessel involvement and foci of infarct necrosis highlight the aggressive rapid growth of anaplastic thyroid carcinoma.

Etiopathogenesis

Anaplastic thyroid carcinoma occurs as a result of anaplastic transformation of a pre-existing well differentiated papillary thyroid carcinoma, and follicular thyroid carcinoma, i.e. insular variant of oncocytic carcinoma. Approximately 50% of cases with multinodular goiter develop anaplastic thyroid carcinoma.

Clinical Features

Rapidly growing tumor in neck region invades esophagus (dysphagia symptom) or trachea (dysphonia symptom) and vocal cord paralysis. Extrathyroid extension is encountered at the time of initial presentation in most cases. Presence of cervical lymph node metastases is responsible for high recurrence.

Molecular Genetic Alterations

TP53 tumor suppressor gene is often demonstrated anaplastic thyroid carcinoma, which may also harbor activating mutation of β-catenin.

Surgical Pathology: Anaplastic Thyroid Carcinoma

Gross Morphology

The tumor is solid with areas of hemorrhage and necrosis.

Light Microscopy

- The tumor does not make thyroid follicles, papillae, or even trabeculae, but it still retains epithelial (squamoid) appearance on morphologic and immunohistochemical grounds.
- Presence of admixture of follicular and papillary element may represent residual of previously existing low-grade thyroid carcinoma (Fig. 26.54).

Histologic Variants: Anaplastic Carcinoma

- **Small cell carcinoma:** Tumor is composed of compact, closely packed cuboidal to polygonal cells growing in cords or clusters and numerous mitoses; separated by a fibrous stroma. It should be differentiated from malignant lymphoma.
- **Carcinosarcoma:** Tumor is composed of malignant epithelial and mesenchymal component.
- **Giant cell carcinoma:** Tumor is composed of highly anaplastic cells having multiple or multilobate nuclei. Other cells may assume spindle shape or elongated with numerous mitoses. Bizarre mitoses and giant cells are characteristic.

Immunohistochemistry Technique

Anaplastic thyroid carcinoma shows positivity with cytokeratins and PAX8 (50%). It is usually negative for TTF-1. PAX8 is useful marker to establish the thyroid origin of tumor.

Markers	Expression
▪ Cytokeratins	▪ Positive
▪ PAX8	▪ Positive (50%)
▪ TTF-1	▪ Negative

SECONDARY THYROID TUMORS

Thyroid gland is a vascular organ, which harbors metastases at a higher frequency than many other organs. The tumors metastasize to thyroid gland either by direct extension from adjacent structures or via hematogenous route.

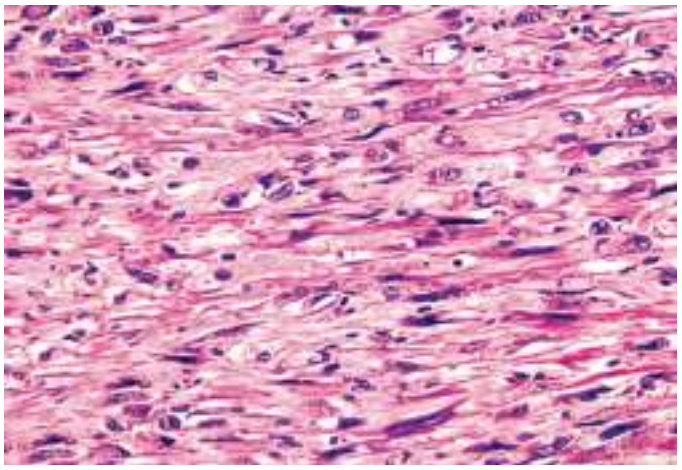

Fig. 26.54: Anaplastic thyroid carcinoma. Tumor is composed of compact closely packed tumor cells arranged in clusters and separated by fibrous stroma. Numerous mitoses are present (400X).

- Squamous cell carcinoma of larynx metastasizes to thyroid gland by direct invasion.
- Most common tumors metastasizing to thyroid gland via hematogenous route are renal cell carcinoma, lung carcinoma, breast carcinoma, colon carcinoma and malignant melanoma.
- Fine needle aspiration cytology (FNAC), histologic examination and immunohistochemistry are useful for planning adjuvant therapy for primary tumor.

THYROID GLAND ANOMALIES

THYROGLOSSAL DUCT CYST

During its normal development, the thyroid gland descends from the base of the tongue to its final position in the neck.

- Thyroglossal duct cyst, a remnant of the thyroglossal duct is the most common thyroid anomaly, which may occur anywhere along the path of descent. It is midline cystic swelling close to or within the hyoid bone.
- Patient presents with dysphonia, sore throat and midline swelling evident during adolescence and pregnancy.
- Patient does not develop endocrine complications. Surgical excision of the proximal duct along with hyoid bone cures it. Thyroglossal duct cyst versus branchial cleft cyst is given in Table 26.32.

ECTOPIC THYROID TISSUE

Ectopic thyroid tissue may be found anywhere along the course of thyroglossal duct.

LINGUAL THYROID

Lingual thyroid occurs due to failure of descent of thyroid gland from the base of the tongue. Patient presents with

Table 26.32 Thyroglossal duct cyst versus branchial cleft cyst

Parameters	Thyroglossal Duct Cyst	Branchial Cleft Cyst
Origin	Thyroglossal duct	Usually second branchial cleft or pouch
Location	▪ Midline location ▪ Usually near hyoid bone with connection through fibrous remnant of thyroglossal duct	▪ Lateral location ▪ Usually along anterior border of sternocleidomastoid muscle near angle of mandible ▪ May be associated with cutaneous or mucosal sinus or fistula
Cyst contents	▪ Mucoid or gelatinous material ▪ Purulent exudate if infected	▪ Serous, mucoid, or pasty ▪ Purulent exudate if infected
Microscopic features	▪ Variable lining • Ciliated respiratory epithelium • Stratified squamous epithelium • Cuboidal epithelium • Granulation tissue secondary to inflammation ▪ Variable acute or chronic inflammation in wall ▪ About half contain thyroid follicles in wall	▪ Usually stratified squamous epithelium • Ciliated respiratory epithelium may be seen • Granulation tissue secondary to inflammation ▪ Lymphoid tissue in wall ▪ Variable acute or chronic inflammation in wall
Age	Usually children to young adults	Usually children to young adults
Gender ratio	Even (males and females equally affected)	Even (males and females equally affected)
Neoplasia	▪ Occurs in 1% or less ▪ Usually papillary carcinoma	▪ Extremely rare ▪ Putative cases usually metastatic squamous cell carcinoma from primary in head or neck

dysphagia for solids and swelling in the base of tongue. ^{123}I is a diagnostic tool to locate the lesion. Lingual thyroid is usually hypofunctional. Lingual thyroid is ablated with thyroxine. Surgical excision is indicated, if lesion causing obstructive symptoms. Forms of thyroid dysgenesis are given in Table 26.33. Differential diagnosis of thyroid tissue with abnormal location in neck is given in Table 26.34.

THYROID DISORDERS: DIAGNOSTIC APPROACH

THYROID FUNCTION TESTS

In many patients with thyroid disease, thyroid gland produces excessive amounts of thyroid T_3 and T_4 hormones (hyperthyroidism) or insufficient amounts of thyroid hormone (hypothyroidism).

Table 26.33 Forms of thyroid dysgenesis

Type of Dysgenesis	Features	Thyroid Function Tests
Ectopic thyroid	Abnormal location of thyroid follicular tissue due to defective descent	Hypothyroidism
Thyroid agenesis	Absence of thyroid follicular tissue in ectopic or orthotropic location	Hypothyroidism
Thyroid hemigenesis	Absence of one of the lateral lobes of thyroid gland	Euthyroid state
Thyroid hypoplasia	Hypoplastic thyroid gland in orthotropic location	Hypothyroidism

Table 26.34 Differential diagnosis of thyroid tissue with abnormal location in neck

Specific Entity	Clinical Examination	Light Microscopic Features
Ectopic non-neoplastic thyroid tissue		
Ectopic thyroid tissue due to abnormal descent of median anlage	▪ Most commonly located in the base of tongue (lingual thyroid) ▪ Present along midline descent tract with well or ill-defined borders and presence of thyroid tissue	▪ Thyroid follicles varying from normofollicular and/or microfollicular patterns lacking features of papillary carcinoma ▪ Thyroid follicles may be admixed with skeletal muscle or other soft tissue
Thyroglossal duct cyst	▪ Thyroglossal duct cyst ranges 1–5 cm with smooth outer surface ▪ Thyroglossal cyst contains gelatinous or mucoid content without thyroid tissue	▪ Cyst lining variable ranging ciliated columnar, and/or cuboidal epithelium or granulation tissue ▪ Foci of thyroid follicles may be present in wall in 50% of cases ▪ Variable admixture of acute and chronic inflammatory cells
Benign lymph node inclusions	Inclusions in lymph node median to jugular vein not grossly visible	Histology lacks features of papillary carcinoma
Parasitic thyroid nodule	Swelling separate from thyroid gland; may be attached by a thin fibrous strand with thyroid nodular hyperplasia	Thyroid nodular hyperplasia seen without evidence of lymph node
Thyroid neoplasms		
Papillary thyroid carcinoma metastasizing to other areas	Present within one or more lymph nodes revealing cystic change	▪ Papillary and/or follicular architecture ▪ Psammoma bodies may be demonstrated ▪ Neoplastic cells are optically clear with **Orphan Annie** appearance
Thyroid neoplasm arising in ectopic non-neoplastic tissue	▪ Usually occurs in the thyroglossal duct cyst ▪ Rarely occurs in lingual thyroid	▪ Papillary carcinoma most common followed by squamous cell carcinoma ▪ Follicular carcinoma and anaplastic carcinoma very rare ▪ Medullary carcinoma unusual
Teratoma	Pediatric cervical teratoma may involve thyroid gland, adult cervical teratoma rarely involves thyroid gland	Teratomas occurring in the cervical region rarely contain thyroid tissue as a component

- The pituitary TSH stimulates the thyroid gland to synthesize and release thyroid hormones. When thyroid hormone levels decrease, the TSH rises and *vice versa*.
- Basically, a normal TSH excludes primary thyroid disease. TSH assay is able to differentiate hypothyroid and hyperthyroid patients from normal individuals. Thyroid carcinoma rarely occurs in a hyperfunctioning nodule.

Serum TSH, T_4 and T_3 Levels

The pituitary TSH stimulates the thyroid gland to make and release the thyroid hormone. When thyroid hormone levels (T_4 and T_3) decrease, the TSH rises and *vice versa*.

Increased serum TSH level is suggestive of hypothyroidism. Decreased serum TSH level suggests hyperthyroidism. Thyroid profile in normal persons and thyroid function tests are given in Tables 26.35 and 26.36.

Thyroid Hormone Binding Protein (TBP)

Antithyroglobulin and antimicrosomal proteins are thyroid hormone binding proteins. Free portion of TBP is active at tissue level. Increased serum level of TBP occurs due to pregnancy, contraceptive pills and increased estrogen level. Increased serum TBP results in increased synthesis of T_4 and T_3 in the body.

Table 26.35 Thyroid profile in normal persons

Parameters	Reference Range
Total serum T_4	5.0–12 µg/dl
Free serum T_4	0.7–1.9 ng/dl
Total serum T_3	80–180 ng/dl
Free serum T_3	2.3–4.2 pg/ml
Radioactive iodine uptake	10–30%

IMAGING TECHNIQUES

Ultrasonography

Ultrasonography detects 2–3 mm thyroid lesion. Cystic nodules in thyroid are seldom malignant. Approximately 80% of patients with thyroid carcinoma do not show cystic change.

Table 26.36 Thyroid function tests in various disorders

Parameters	Total T_4 (µg/dl)	Total T_3 (µg/dl)	TSH [Total T_4 (µl/ml)]	% Radioactive Iodine Uptake by Thyroid Gland in 24 Hours (µg/dl)	Comments
Normal range	5–12	95–190	0.3–5	10–30	
Thyrotoxicosis					
Primary hyperthyroidism (untreated cases)	↑	↑	↓	↑	Thyroid stimulating immunoglobulin increased in Graves' disease
Secondary hyperthyroidism	↑	↑	↑	↑	
Thyrotoxicosis due to treated cases with overdose of T_4	↑	↓	↓	↓	
Thyrotoxicosis due to treated cases with overdose of T_3	↓	↑	↓	Normal or ↑	
Hypothyroidism					
Primary hypothyroidism untreated cases	↓	↓	↑	↓	
Secondary hypothyroidism untreated cases due to pituitary failure	↓	↓	↓	↓	
Euthyroid					
Euthyroid patient treated with T_4	Normal	Varies	Normal or ↓	↓	
Patient on iodine therapy	Normal	Normal	Normal	↓	Correct dosage determined by clinical effects
Euthyroid sick syndrome	Normal or ↓	Normal	Varies	↓	No clinical evidence of hypothyroidism

Solitary thyroid nodules in adult women occur as a cyst in goiter in 60% or a follicular thyroid adenoma in 25% of cases. Approximately 85–90% of cases are euthyroid. Presence of irregular poorly defined margins and microcalcifications are suggestive of thyroid carcinomas.

Computed Tomography (CT) Scan

CT scan defines extent of thyroid lesion, metastases, tracheal and retrosternal involvement.

Radioactive Iodine Uptake and Thyroid Imaging

^{131}I, ^{123}I or ^{99}Tc scanning play major role in evaluation of metastatic disease and in treatment of well-differentiated thyroid carcinoma. Patient is advised to stop levothyroxine drug prior to radionuclide scan.

Although its sensitivity is variable, its specificity in follow-up of thyroid cancer is very high, i.e. 96–100%. Most solitary thyroid nodules are cold, i.e. 95%. Most thyroid carcinomas arise in cold nodules. Risk for thyroid carcinoma in a cold nodule is 10–15%; while negligible in a hot nodule.

Scintigraphy

Scintigraphy is of minimal use in evaluation of solitary thyroid nodules; but useful in diagnosis of recurrent thyroid swellings, retrosternal goiters and thyroid carcinomas.

FINE NEEDLE ASPIRATION CYTOLOGY

Fine needle aspiration cytology (FNAC) plays an important role in diagnosing colloid goiter, Hashimoto's thyroiditis (Fig. 26.55), papillary thyroid carcinoma (Fig. 26.56) and medullary thyroid carcinoma (Fig. 26.57).

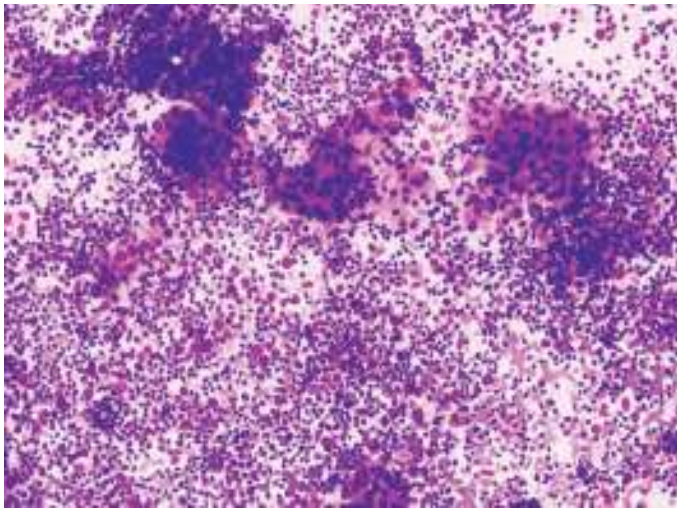

Fig. 26.55: Hashimoto's thyroiditis. FNAC smear shows lymphocytes and plasma cells infiltrating thyroid follicles, Hurhle cell change, multinucleated giant cells and epithelioid cells cluster (400X).

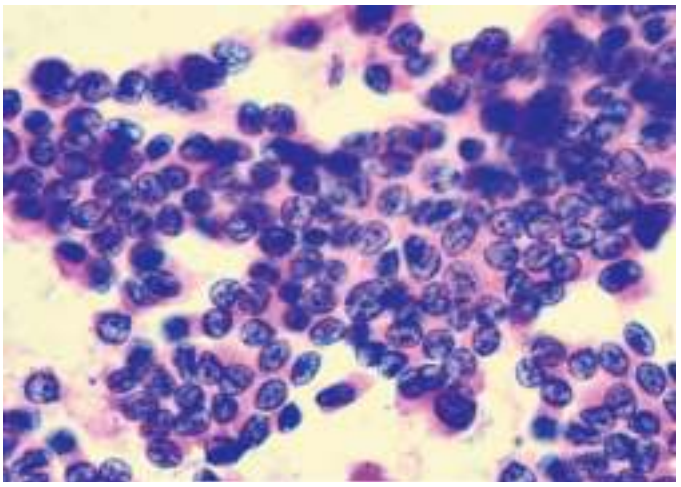

Fig. 26.56: Papillary thyroid carcinoma. FNAC obtained smear shows tumor cells arranged in sheets and forming syncytial aggregates with distinct cell borders, dense cytoplasm, nuclear crowding and overlapping, intranuclear cytoplasmic inclusions and nuclear grooves (400X).

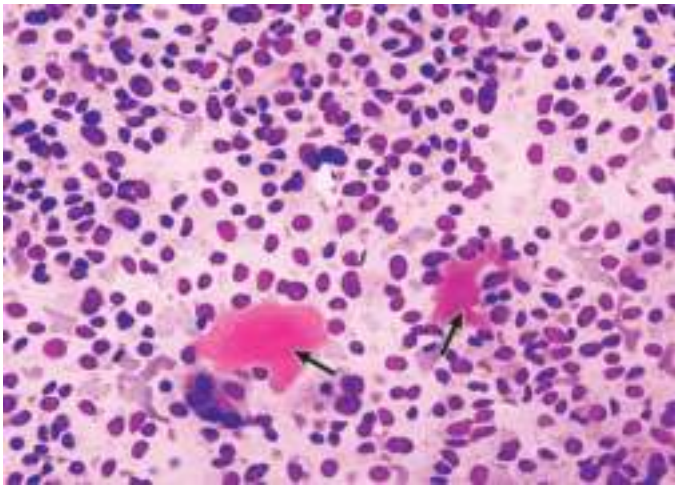

Fig. 26.57: Medullary thyroid carcinoma. Fine needle aspiration cytology obtained smear shows many neoplastic cells and amyloid material deposits. Amyloid material deposits are shown by arrows (400X).

HISTOPATHOLOGIC EXAMINATION

Thyroid biopsy and histologic examination are confirmatory. The specimens are processed, stained by hematoxylin and eosin and examined under microscope. Monoclonal antibodies used in diagnosis of thyroid carcinomas are given in Table 26.37.

MOLECULAR GENETIC TESTING

Mutation of the RET proto-oncogene is also responsible for familial medullary thyroid carcinoma and MEN IIb. Prophylactic thyroidectomy is performed in these cases. Genetic alterations in histologic variants of thyroid carcinoma is given in Table 26.38.

Table 26.37 Monoclonal antibodies used in diagnosis of thyroid carcinomas

Antibody	Specificity	Immunoreactivity	Interpretation
Thyroglobulin	Thyroid follicular differentiation	Follicular adenoma/follicular carcinoma, papillary carcinoma, poorly differentiated carcinoma of thyroid	Anaplastic carcinoma is negative for thyroglobulin. This marker is invaluable for confirming thyroid origin of metastatic tumor
Calcitonin	Parafollicular cells (C cells)	Medullary thyroid carcinoma	Calcitonin immunoreactivity in metastatic medullary carcinoma of thyroid
Chromogranin	Pan-neuroendocrine tumor marker	Medullary thyroid carcinoma, paraganglioma. Intrathyroid–parathyroid tumor, metastatic neuroendocrine tumor	Chromogranin supports a diagnosis of medullary carcinoma of thyroid
Synaptophysin	Pan-neuroendocrine most sensitive and specific marker	Similar to chromogranin (medullary carcinoma, paraganglioma. Intrathyroid–parathyroid tumor, metastatic neuroendocrine tumor)	Similar to chromogranin supports a diagnosis of medullary carcinoma of thyroid
Thyroid transcription factor 1 (TTF-1)	TTF-1 is a transcriptional factor	Follicular carcinoma (100%), papillary carcinoma (100%), medullary carcinoma (100%), anaplastic carcinoma (0–50%) of thyroid	TTF-1 is also positive in lung cancers (adenocarcinoma, small cell carcinoma and carcinoid tumor)
Cytokeratin	Epithelial marker	Follicular epithelial tumors, intrathyroid–parathyroid tumors	Neuroendocrine tumors positive
Leukocyte common antigen (LCA)	Leukocyte-specific marker	Lymphoma, leukemia	Useful in work up of undifferentiated thyroid tumors
S-100 protein	Expressed in normal thyroid follicular cells and especially Hürthle cells	Many thyroid tumors are positive for S-100 protein	Not used in diagnosis of thyroid carcinoma
Parathormone	Specific for parathyroid cells	Intrathyroid–parathyroid tumors	Most useful in diagnosis of parathyroid origin tumors

SERUM TUMOR MARKERS

Serum Calcitonin

Plasma calcitonin, the product of the parafollicular cells, is the most sensitive marker for diagnosis and monitoring of medullary thyroid carcinoma. It should be measured when medullary thyroid carcinoma is suspected in a patient with a positive family history.

Serum Thyroglobulin

Thyroglobulin is a reliable marker of diagnosing papillary thyroid carcinoma. It shows positivity for tumor cells in primary site including recurrent disease or secondary sites such as lymph nodes and distant metastases.

Serum Carcinoembryonic Antigen

Medullary thyroid carcinoma (MTC) originates from parafollicular cell and synthesizes excess of calcitonin (neuroendocrine peptide) and carcinoembryonic antigen. CEA is an excellent marker for residual MTC disease.

Table 26.38 Genetic alterations in histologic variants of thyroid carcinoma

Histologic Variants
Papillary thyroid carcinoma
▪ RET tyrosine kinase receptor (10q) arrangement ▪ BRAF V600E mutation
Follicular thyroid carcinoma
▪ RAS family of oncogene mutation ▪ t(2,3) fusion of PAX8 and PPAR-γ
Medullary thyroid carcinoma
RET proto-oncogene mutation (MEN II)
Anaplastic thyroid carcinoma
▪ TP53 mutation ▪ BRAF V600E mutation

24 HOURS URINARY CATECHOLAMINES ASSAY

In patients with neuroblastoma (most common) and pheochromocytoma, adrenal gland synthesizes excess of catecholamines (dopamine, norepinephrine, and epinephrine), which are degraded to inactive metabolic products in brain and liver, excreted in the urine. In MEN II syndrome (medullary thyroid carcinoma and pheochromocytoma), 24 hour-urine catecholamines assay is done to exclude pheochromocytoma prior to medullary thyroid carcinoma surgery.

DISORDERS OF PARATHYROID GLANDS

ANATOMY OF PARATHYROID GLANDS

There are two each superior and inferior parathyroid glands embedded on the posterior surfaces of the lateral lobes of the thyroid gland. Parathyroid glands are derived from fourth pharyngeal and third pharyngeal pouches, respectively.

Parathyroid glands consist of principal/chief and oxyphil cells arranged in cords; supported by a network of reticulin fibers. Numerous sinusoids lie in close relationship to the cells.

PHYSIOLOGY OF PARATHYROID GLANDS

Principal/chief cells synthesize parathormone, which regulates the homeostasis of calcium and phosphate ions by increasing blood calcium level and decreasing phosphate level. Secretion of parathormone (PTH) is regulated by calcium level in the blood. Secretion of parathormone is not under control of pituitary gland.

CALCIUM METABOLISM: REGULATION

Calcium metabolism is regulated by parathormone and clacitonin.

- **Parathormone (PTH):** Decreased plasma concentration of ionized calcium stimulates principal cells to synthesize parathormone. Parathormone maintains ionized calcium level in blood by release of calcium due to bone resorption, and retarding renal excretion of calcium in the urine. Thus, serum calcium level is increased. Parathormone decreases phosphorus reabsorption in the proximal renal tubule and increases the synthesis of 1α-hydroxylase in proximal renal tubules.

  The 1α-hyroxylase enzyme converts 25-hydroxycholecalciferol (vitamin D_2) to 1, 25-dihydroxycholecalciferol (vitamin D_3). Decreased serum calcium and increased phosphate levels stimulate the synthesis of parathormone (Fig. 26.58).
- **Calcitonin:** Increased plasma calcium concentration stimulates thyroid parafollicular cells (C cells) to synthesize calcitonin.
  - Calcitonin promotes deposition of calcium into bone matrix. With respect to regulation of blood Ca^{++}, calcitonin and parathormone are antagonists.
  - Total body calcium in adults is approximately 1.0 kg. It is present in cellular compartment of bones, i.e. 995 g and skeletal muscles, i.e. 4–5 g. Calcium is circulating in blood in three forms.

Calcium in Blood

- **Albumin bound calcium (45%):** It is physiologically inactive form.
- **Calcium complexed with citrates and phosphates (5%):** It is diffusible, non-ionized, but physiologically inactive.
- **Free ionized calcium (50%):** It is diffusible metabolically active form. Normal free ionized calcium maintains normal parathormone levels.

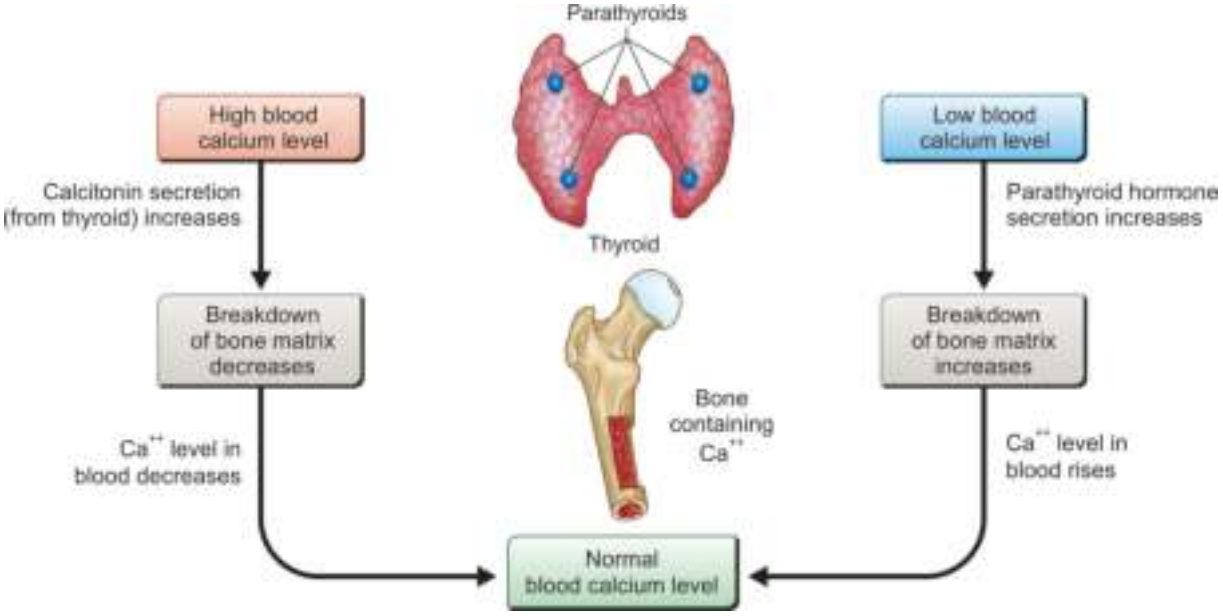

Fig. 26.58: Regulation of calcium by parathormone and calcitonin.

Calcium Absorption

Gastric hydrochloric acid makes calcium in ionic form and hence gets easily absorbed by whole length of small intestine.

- Calcium absorption is increased in younger and normal secretion of bile.
- While absorption is decreased due to aging process, phosphates in diet and decreased bile secretion, which results in increased fatty acids in the gut which form calcium salts.

Calcium Functions

Calcium participates in bone calcification, excitation/contraction of muscles, stabilization of cell membranes, release of neurotransmitters, secretion of material from glands, synthesis of nucleic acids and proteins, promotion of mitosis in thymus, bone marrow, activation, regulation of enzymes and blood coagulation.

VITAMIN D METABOLISM: REGULATION

Vitamin D is normal requisite for normal mineralization of bone and cartilage. It maintains normal blood levels of calcium and phosphates.

Vitamin D collaborates with parathormone in mobilizing calcium from bone and stimulates parathormone-dependent reabsorption of calcium in distal renal tubules. It stimulates intestinal absorption of calcium independent phosphorus.

Vitamin D Sources

Preformed vitamin D in the diet (20%) consists of cholecalciferol derived from sea fish and ergocalciferol, i.e. vitamin D_2 in plants, and grains. Endogenous synthesis of vitamin D in the skin occurs by photoconversion of 7-dehydrocholesterol via sunlight to vitamin D_3, i.e. cholecalciferol. Dietary source of vitamin D is reabsorbed by small intestine.

Vitamin D Transport

Vitamin D binds with vitamin D binding proteins to form complex is carried to liver.

Vitamin D Metabolism in Organs

- **Liver:** In liver, first hydroxylation of vitamin D conversion to 25-hydroxyvitamin D occurs in the liver cytochrome 450 enzyme system. This conversion is augmented by calcium. 25-hydroxyvitamin D and 5–10 times more active than parent vitamin D.
- **Kidney:** In kidneys, second hydroxylation of vitamin D occurs by 1α-hydroxylase enzyme synthesized in proximal renal tubule cells. The enzyme converts 25-hydroxycholecalciferol (vitamin D_2) to calcitriol (vitamin D_3).

Vitamin D Storage Sites

Vitamin D is stored in adipose tissue and liver.

Vitamin D_3 (Calcitriol): Functions

Vitamin D attaches to nuclear receptors in target tissues. It increases reabsorption of calcium in the duodenum, and phosphorus in jejunum and ileum.

- Vitamin D increases bone mineralization by alkaline phosphatase derived from osteoclasts. Alkaline phosphatase participates in bone mineralization by hydrolysis of inhibitors (pyrophosphate), which prevent calcium phosphate mineralization.
- Vitamin D increases the production of osteoclasts from macrophage stem cells. Parathormone and vitamin D_3 act on distal convoluted tubules, hence Ca^{++} absorption occurs.

Vitamin D Deficiency: Causes

- Causes of vitamin D include low dietary intake, decreased synthesis of vitamin D, malabsorption of fats, and deranged metabolism of vitamin D in chronic renal failure.
- Depending on severity, duration, stresses on bones and age of the patients, vitamin D deficiency causes failure of bone mineralization resulting in excessive formation of mineralized matrix and abnormally wide osteoid seams.

HYPERPARATHYROIDISM

Hyperparathyroidism can be primary as a result of autonomous proliferation of chief cells or may be secondary, in which case it is a compensatory mechanism. Disorders of calcium homeostasis are given in Table 26.39.

PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is most common cause of hypercalcemia. It occurs in postmenopausal women. More than 50% of patients are asymptomatic. It is diagnosed when an asymptomatic patient has increased serum calcium levels in routine laboratory tests. Women are more affected than men over 40 years of age. Pathophysiology of hyperparathyroidism is shown in Fig. 26.59.

Etiopathogenesis

Primary hyperparathyroidism occurs due to parathyroid adenoma in 80% of cases, hyperplasia in 20% or carcinoma (rarely). Primary hyperparathyroidism can occur as a part of MEN I and MEN IIa. Parathormone like hormone may be synthesized by bronchogenic squamous cell carcinoma or renal cell carcinoma.

Table 26.39 Disorders of calcium homeostasis

Disorder	Parathormone (PTH)	Calcium	Phosphate
Primary hyperparathyroidism due to parathyroid adenoma and hyperplasia	Increased	Increased	Decreased
Secondary hyperparathyroidism due to chronic renal failure or vitamin D deficiency	Increased	Decreased	Increased
Tertiary hyperparathyroidism due to autonomous transformation of secondary hyperparathyroidism	Increased	Increased	Increased
Primary hypoparathyroidism	Decreased	Decreased	Increased
Pseudohypoparathyroidism	Increased	Decreased	Increased
Vitamin D deficiency	Increased	Decreased	Decreased

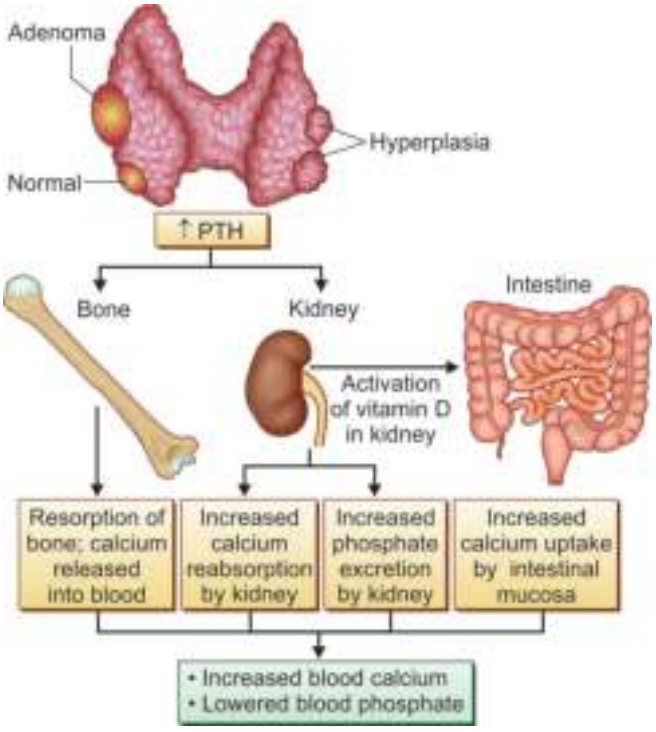

Fig. 26.59: Pathophysiology of hyperparathyroidism.

Clinical Features

Patient develops symptoms due to increased bone resorption, i.e. osteitis fibrosa cystica by osteoclasts resulting in increased serum calcium levels. Skeletal manifestations are less common. Patient presents with bone pains and pathologic fractures due to generalized demineralization of skeleton. Clinical manifestations of hyperparathyroidism is shown in Fig. 26.60.

Primary Hyperparathyroidism: Bone Lesions

- Osteoclastic bone resorption results in osteitis fibrosa cystica also known as brown tumor in jaw and long bones.
- When osteitis fibrosa cystica is generalized, it is called von Recklinghausen disease of bone. The lesion is expansile and multilocular with solid and cystic areas. Cystic areas have a brown color due to presence of abundant hemosiderin.
- Radiologic examination reveals decrease in bone densities, i.e. osteoporosis, bone deformities, chondrocalcinosis, i.e. pseudogout, and fractures. Subperiosteal bone resorption occurs along margins of middle phalanges on radial aspect of fingers and tooth sockets. X-ray skull shows salt and pepper appearance.
- Histologic examination of tissue section reveals loss of osseous tissue, poorly calcified immature bone formation, numerous osteoclasts associated with cystic areas and hemosiderin-laden macrophages.

Metastatic Calcification

Metastatic calcification occurs in various tissues such as kidney, lungs, cornea, blood vessels, fundal glands of stomach and heart. Blood vessels show metastatic calcification in media and internal elastic lamina.

- **Renal changes:** Calcium stones are most common presentation. Metastatic calcification occurs in tubular epithelial cells and basement membranes in acute cases, while in chronic cases, calcification occurs in whole nephron including collecting ducts known as nephrocalcinosis with formation of calcific casts, foci of fibrosis, nephron atrophy and chronic inflammatory cells infiltration, thereby formation of calcium oxalate calculi which may cause hydronephrosis and chronic pyelonephritis.
- **Peptic ulcer disease:** Hypercalcemia predisposes to duodenal peptic ulcer. Calcium stimulates gastrin, which increases gastric acid secretion.
- **Acute pancreatitis:** Calcium activates phospholipase that causes acute pancreatitis. Patient may develop constipation. Serum amylase is analyzed in these patients.
- **Diastolic hypertension:** Diastolic hypertension occurs due to hypercalcemia. Electrocardiogram shows shortening of QT interval.
- **Ocular changes:** Patient develops band keratopathy in the limbus of the eye due to metastatic calcification.
- **Central nervous system changes:** Patient may develop psychosis, confusion, anxiety and coma.

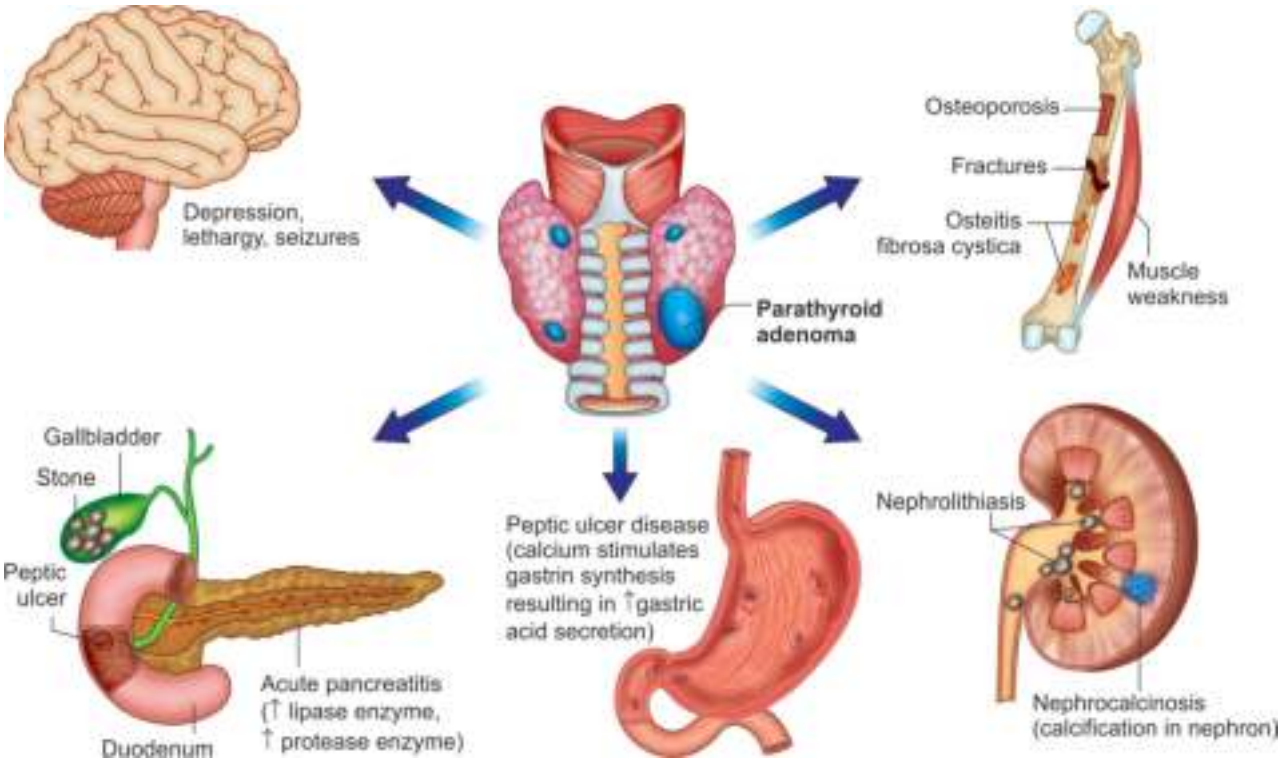

Fig. 26.60: Clinical manifestations of hyperparathyroidism.

Laboratory Diagnosis

Serum parathormone (PTH) analysis is the best initial screening test. Patient with bone metastases has increased serum calcium level with normal PTH.

- Technetium 99m sestamibi radionuclide scan is done to localize parathyroid adenoma. Serum calcium, phosphorus and alkaline phosphatase are increased.
- Urine analysis shows increased excretion of calcium. Decreased tubular reabsorption of phosphorus and increased excretion of phosphorus result in decreased serum phosphorus levels.

SECONDARY HYPERPARATHYROIDISM

Decreased concentration of serum ionized calcium due to renal retention of phosphate causes compensatory hyperplasia of parathyroid glands resulting in secondary hyperparathyroidism.

Etiopathogenesis

Chronic kidney disease and intestinal malabsorption are important causes of secondary hyperparathyroidism. Diabetic glomerulosclerosis is a major cause of renal insufficiency. Uncommon causes of secondary hyperparathyroidism are Fanconi syndrome, and renal tubular acidosis. Advanced renal disease contributes to reduction in serum calcium. Other causes are rickets and vitamin D deficiency.

- **Physiologic state:** Normally, 1α-hydroxylase enzyme synthesized in the proximal renal tubule cells converts 25-hydroxycholecalciferol (vitamin D_2) to 1, 25-dihydroxycholecalciferol (vitamin D_3) also called calcitriol.
- **Pathologic state:** In chronic kidney disease, kidneys fail to convert 25-hydroxycholecalciferol (D_2) to 1, 25-dihydroxycholecalciferol (D_3). Deficiency of vitamin D_3 impairs reabsorption of calcium in the duodenum, and phosphorus in jejunum and ileum. Chronic kidney disease also impairs reabsorption of calcium by distal tubules. Decreased serum calcium level stimulates parathormone.
  - Bone changes in chronic kidney disease are known as renal osteodystrophy. Bone changes such as diffuse osteoclastic bone disease and metastatic calcification are similar to those seen in primary hyperparathyroidism. Patient may develop tertiary hyperparathyroidism. Parathyroid glands become autonomous regardless of calcium level. It may bring serum calcium into normal or increased range.
  - Blood vessels show metastatic calcification in media and internal elastic lamina, which is more severe in secondary hyperparathyroidism. Some patients develop ischemic skeletal muscle pains in extremities and even gangrene. Stomach, heart, lungs and eyes also show ischemic changes.

Laboratory Diagnosis

Radioimmunoassay determination of circulating parathormone is roughly proportionate to the severity of kidney disease. Serum calcium is decreased. There is increased serum levels of phosphorus, alkaline phosphatase and parathormone.

TERTIARY HYPERPARATHYROIDISM

Persistent parathyroid hyperfunction occurs in spite of correction of hypocalcemia and pre-existing secondary hyperparathyroidism. Most often, the cause is development of an adenoma in a previously hyperplastic parathyroid gland.

α-HYDROXYLASE DEFICIENCY (VITAMIN D-RESISTANT RICKETS)

Patient with vitamin D-resistant rickets has increased secretion of parathormone. But congenital deficiency of 1α-hydroxylase in renal tubular cells impairs hydroxylation of 25-hydroxycholecalciferol. Kidneys are not able to reabsorb calcium, in spite of increased plasma parathormone levels.

HYPOPARATHYROIDISM

Hypoparathyroidism occurs due to deficiency of parathormone resulting in decreased plasma calcium level.

- Most common cause of hypoparathyroidism is accidental surgical excision of parathyroid glands during thyroidectomy. Autoimmune hypothyroidism is common cause of hypoparathyroidism.
- DiGeorge syndrome is characterized by congenital thymic hypoplasia as a result of failure of descent of third and fourth pharyngeal pouches between 2nd and 10th week of embryogenesis. When this midline development does not occur properly, the parathyroid glands are not formed.
- Hypomagnesemia occurs due to diarrhea, aminoglycosides, diuretics and alcoholism. Magnesium is a cofactor for adenyl cyclase. Cyclic adenosine monophosphate (cAMP) is required for parathormone activation.
- Patient with hypoparathyroidism may develop tetany, cataracts, loss of hair, abnormal nail growth, increased bone density, convulsions, papilledema, gastrointestinal disturbances, and calcification of blood vessels of basal ganglia of nervous system. Increased phosphorus level drives calcium into the brain tissue.

TETANY (TETANIC SEIZURE)

Tetany is a classical sign and symptom of low serum-free ionized calcium levels in blood (hypocalcemia) that involves involuntary contraction of skeletal muscles that leads to painful muscle cramps, spasms of larynx and sensory disturbances. Hypocalcemia can result from a decreased level of parathormone (PTH) in the settings of hypoparathyroidism, surgical removal of parathyroid gland and DiGeorge syndrome.

- Maintaining stable normal ionized calcium level in blood plays an important role in stabilizing the resting membrane potential of neurons, thereby preventing their spontaneous activation. Blood calcium level is regulated by parathormone, which is released into the blood circulation, when serum levels are too low.
- Low serum-free ionized calcium in blood causes increased neuromuscular hyperexcitability of nerves and skeletal muscles by decreasing the threshold needed for the activation of neurons. As a result, neurons become unstable and fine spontaneous action potentials that trigger the involuntary contraction of the skeletal muscles, which eventually leads to tetany.
- The main goal of treatment of tetany is to normalize calcium levels in blood using calcium supplements and, if appropriate, vitamin D and magnesium supplementation.

Clinical Features

Patient presents with quick ipsilateral facial muscle contraction on tapping the facial nerve at the external auditory meatus (Chvostek's sign) or carpopedal spasm—interphalangeal joint extension, metaphalangeal joint flexion, and thumb adduction elicited by occluding the brachial artery of arm with a blood pressure cuff (Trousseau's sign).

Laboratory Diagnosis

Tetany is most often suspected in persons with muscle spasms, paresthesias affecting the hands and feet and numbness around mouth. In some cases, Trousseau's sign and Chvostek's sign can be indicative of hypocalcemia-related tetany. A tetany diagnosis is most often confirmed by evidence of low calcium levels in blood. In addition, blood levels of parathormone (PTH), vitamin D (1,25-hydroxyvitamin D_3), magnesium and phosphorus may help in identifying underlying cause of tetany in an individual.

Table 26.40 Revised 2024 WHO classification of parathyroid tumors

Histologic Diagnostic Criteria	Immunohistochemistry Technique
Parathyroid adenoma	
▪ Parathyroid adenoma encapsuled ▪ Capsule lacks tumor cells infiltration ▪ No atypical features of tumor cells	▪ Parafibromin is encoded by CDC73 gene ▪ Parafibromin positive/negative: no risk of recurrence of tumor ▪ Parafibromin negative: need for CDC73 gene sequencing ▪ FGP9.5 positive ▪ APC positive ▪ Galectin 3 negative ▪ Ki-67 labeling index (<1%)
Atypical parathyroid adenoma	
▪ Cellular nests in a thickened connective tissue ▪ Capsule shows tumor cells infiltration ▪ Adherence to adjacent structures without frank invasion ▪ Band-like fibrosis ▪ Trabecular growth ▪ Increased mitotic activity (>5 per 10 mm^2) ▪ Atypical mitotic figures ▪ Coagulative necrosis ▪ Ki-67 labeling index (>5%) ▪ Other immunohistochemical aberrancies ▪ Low-risk of tumor recurrence	▪ Parafibromin is encoded by CDC73 gene ▪ Parafibromin positive: very low-risk of tumor recurrence, and no need for CDC73 gene sequencing ▪ Parafibromin negative: low-risk of tumor recurrence and need for CDC73 gene sequencing ▪ FGP9.5 positive/negative ▪ APC positive/negative ▪ Galectin 3 positive/negative ▪ Ki-67 upregulation/downregulation
Parathyroid carcinoma	
▪ Angioinvasion ▪ Lymphatic invasion ▪ Perineural invasion ▪ Unequivocal invasion into adjacent structures ▪ Histologically confirmed metastasis ▪ Parafibromin (PFIB) positive/negative on immunohistochemistry ▪ High-risk of tumor recurrence	▪ Parafibromin is encoded by CDC73 gene ▪ Parafibromin positive/negative: high-risk of recurrence and need for CDC73 gene sequencing ▪ FGP9.5 positive ▪ APC negative ▪ Galectin 3 positive ▪ Ki-67 upregulation

Breast carcinoma, renal cell carcinoma, lung carcinoma and melanoma can metastasize to parathyroid glands.

PSEUDOHYPOPARATHYROIDISM

Pseudohypoparathyroidism is characterized by end-organ unresponsiveness to parathormone.

Molecular Genetic Alterations

Pseudohypoparathyroidism is related to gene mutation, whose product couples hormone receptors to the stimulation of adenylyl cyclase. Gene mutation impairs the synthesis of cAMP by renal tubular epithelium resulting in inadequate resorption of calcium from the glomerular filtrate.

Clinical Features

Patient develops **Albright hereditary osteodystrophy**, characterized by short stature, obesity, mental retardation, subcutaneous calcification, and a number of congenital anomalies of bone.

NEOPLASTIC DISORDERS OF PARATHYROID GLANDS

Tumors of parathyroid glands include parathyroid adenoma, parathyroid carcinoma and secondary tumors. Revised 2024 WHO classification of parathyroid tumors is given in Table 26.40.

PARATHYROID ADENOMA

Parathyroid adenoma usually involves right inferior parathyroid gland. It is the cause of primary hyperparathyroidism in 85% of cases. Tumor arises sporadically or as a part of multiple endocrine neoplasia (MEN I and MEN IIa, 20% of cases).

In a small number of cases of sporadic adenoma, molecular genetic analysis has identified rearrangement and overexpression of the cyclin D proto-oncogene.

Surgical Pathology: Parathyroid Adenoma

Gross Morphology

Tumor appears as well circumscribed, encapsulated, reddish brown, solitary mass, measuring 1–3 cm in diameter.

Light Microscopy

- Tumor is composed of sheets of chief cells in a rich capillary network with no intervening adipose tissue.
- A rim of normal parathyroid tissue is usually evident outside the tumor capsule and distinguishes adenoma from parathyroid hyperplasia.

PARATHYROID CARCINOMA

Parathyroid carcinoma is a rare malignant neoplasm. Most patients present with hyperparathyroidism and hypercalcemia (blood calcium >16 mg/dl with secondary nephrolithiasis, renal insufficiency, osteopenia and/or brown tumor of bone, weakness, fatigue and depression. A palpable neck mass may be present.

Surgical Pathology: Parathyroid Carcinoma

Gross Morphology

- Tumor is usually large, poorly circumscribed and adherent to surrounding structures especially thyroid gland. It ranges from 1.5 to 6 cm or larger with average weight 6.7 kg.
- Cut section is usually firm, pinkish tan with lobular appearance.

Light Microscopy

- Tumor exhibits nodular and solid patterns. Tumor is composed of uniform chief cells with mild to moderate nuclear atypia; and increased mitoses. Broad fibrous bands can be present.
- One of the following features is essential for definitive diagnosis, which include vascular invasion, lymphatic invasion, perineural invasion, invasion of adjacent structures, organs and distant metastasis.

Management

The tumor is difficult to separate from the surrounding structure during surgery. En bloc surgical resection with ipsilateral thyroid lobe is the recommended treatment.

DISORDERS OF ADRENAL GLANDS

ANATOMY AND PHYSIOLOGY

Each adrenal gland consists of cortex and medulla.

ADRENAL CORTEX

Adrenal cortex consists of zona glomerulosa, zona fasciculata and zona reticularis. Adrenal cortex participates in synthesis of glucocorticoids, mineralocorticoids and sex hormones. Critical enzymes in the biosynthetic pathways of adrenal cortex include 11β-hydroxylase and 21-hydroxylase.

Zona Glomerulosa

Zona glomerulosa secretes mineralocorticoids mainly aldosterone and deoxycorticosterone. Aldosterone acts on distal convoluted tubules, which results in absorption of Na^+, Cl^- and water; and hence controls electrolyte and water balance. In exchange K^+ enters the tubules.

Zona Fasciculata

Zona fasciculata synthesizes cortisol, corticosterone and cortisone, which participate in gluconeogenesis in the liver resulting in increased blood glucose level. These hormones cause breakdown of fat, i.e. lipolysis and proteins, i.e. proteolysis and inhibit cellular uptake and utilization of amino acids. These hormones are anti-inflammatory and immunosuppressants.

Zona Reticularis

Zona reticularis synthesizes sex hormones, i.e. androgens and estrogens and glucocorticoids. Their main actions on gonads result in development of secondary sexual characteristics, particularly those of the male, i.e. growth of axillary hairs, pubic hairs and facial hairs during puberty. Concentrations of these hormones in adults are so low that their effects are usually insignificant (Figs 26.61 to 26.63).

ADRENAL MEDULLA

Adrenal medulla synthesizes catecholamines, i.e. adrenaline and noradrenaline, also called **emergency hormones** or hormones of fight or flight in response to stress.

Adrenaline (Epinephrine)

Adrenaline mainly acts on skeletal muscles, cardiac muscles, smooth muscles, blood vessels and fat cells. Adrenaline converts liver glycogen into glucose, thus blood glucose is increased. It raises blood pressure; accelerates heart rate and force of heartbeat. Adrenaline causes constriction of capillaries of skin and visceral smooth muscle; dilation of arterioles of heart and skeletal muscles; increase in oxygen consumption; erection of hairs, i.e. piloerection; dilation of pupils and initiation of stress responses.

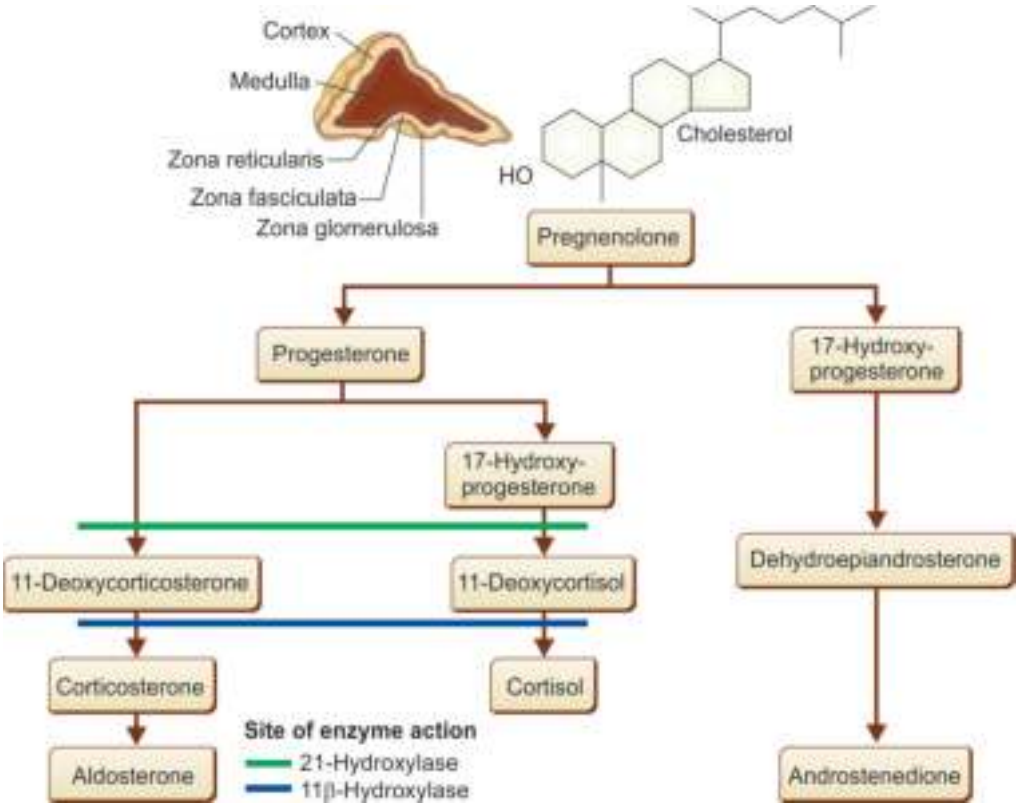

Fig. 26.61: The adrenal gland shows the medulla and the three layers of the cortex. Outer layer of the cortex (zona glomerulosa) is primarily responsible for mineralocorticoid production, and the middle layer (zona fasciculata) and the inner layer (zona reticularis) produce the glucocorticoids and the adrenal androgens.

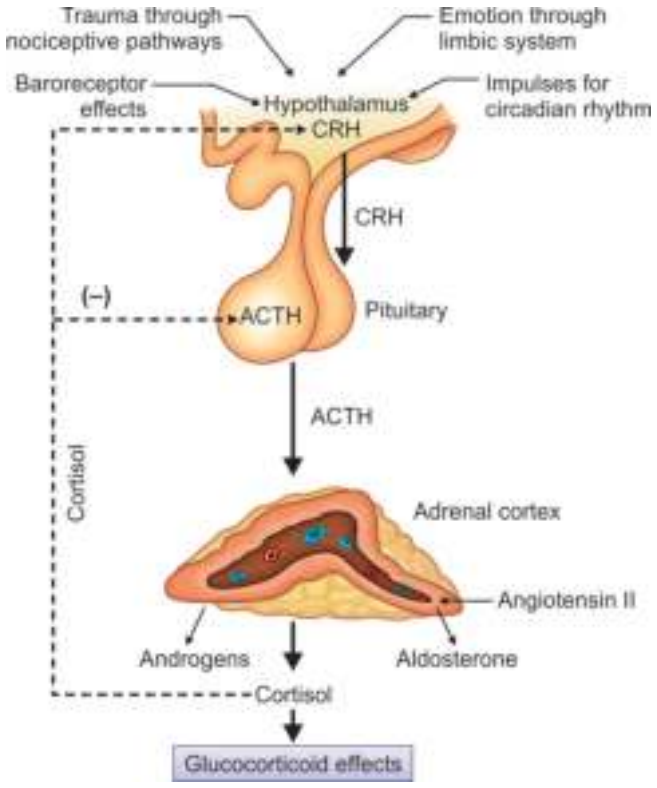

Fig. 26.62: Regulation of glucocorticoids synthesis.

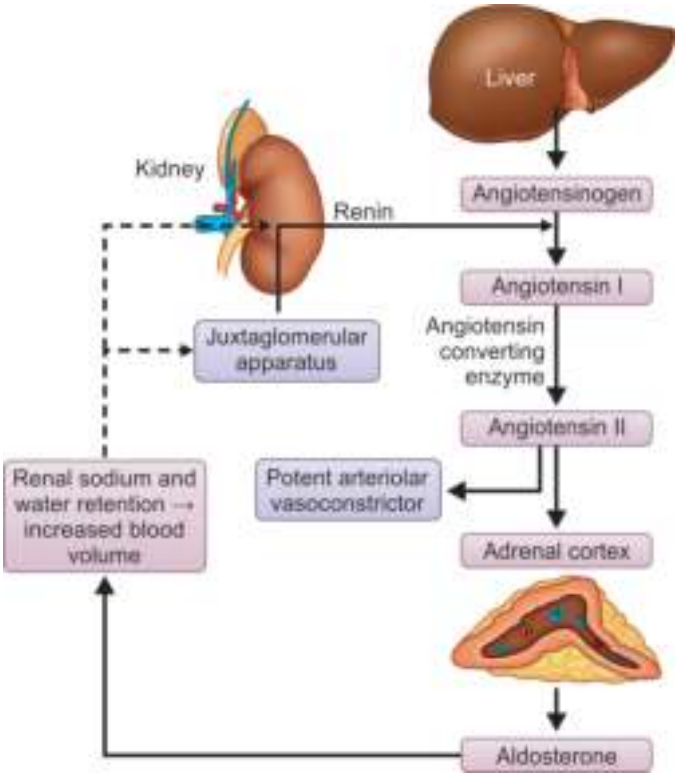

Fig. 26.63: Renin-angiotensin-aldosterone system.

Noradrenaline (Norepinephrine)

Noradrenaline also mainly acts on skeletal muscles, cardiac muscles, smooth muscles, blood vessels and fat cells. It converts liver glycogen into glucose, resulting in increased blood glucose. The functions of noradrenaline are similar to adrenaline.

ADRENAL CORTEX HYPERFUNCTIONING

Excessive synthesis of corticosteroids occurs due to adrenal cortical adenoma and carcinoma. Cushing's syndrome and Conn's syndrome are disorders of adrenal cortex due to excess of corticosteroids and aldosterone respectively.

Cushing's disease is reserved for excess synthesis of ACTH by pituitary corticotroph tumors.

CUSHING'S SYNDROME

Cushing's syndrome results from excess of circulating glucocorticoids especially cortisol.

- Cushing disease is reserved for excess of adrenocorticotropic hormone by pituitary corticotroph tumors. Cushing's disease due to pituitary disorders is five times more common than Cushing's syndrome.
- Cushing's syndrome most often occurs in women between 20 and 45 years of age than men. Causes of Cushing's syndrome are given in Table 26.41.

Etiopathogenesis

- **Therapeutic administration of corticosteroids:** Most common cause of Cushing's syndrome is the prolonged administration of corticosteroids in the treatment of immunological and inflammatory diseases. Long-term administration of corticosteroids causes increased bone resorption and decreased bone formation, thereby resulting in osteoporosis. Approximately 20% of patients with Cushing's syndrome suffer from compression fractures of the vertebrae.
- **Adrenal gland disorders:** Adrenal cortical adenoma, carcinoma and hyperplasia synthesize excess of corticosteroids resulting in Cushing's syndrome.
- **Pituitary disorders:** Pituitary corticotroph microadenoma, adenoma and hyperplasia synthesize excess of corticosteroids resulting in Cushing's disease. Cushing's disease is reserved for excess synthesis of ACTH by pituitary corticotroph tumors.
- **Respiratory system:** Small cell lung carcinoma and bronchial carcinoid tumor synthesize ectopic corticosteroids resulting in atypical Cushing's syndrome.

Clinical Features

Clinical manifestations of Cushing's syndrome depend on the degree and duration of excessive corticosteroid levels, as well as on the levels of adrenal androgens and mineralocorticoids.

Patient presents with redistribution of subcutaneous fat with round moon face, dorsal buffalo hump and diabetes mellitus (Fig. 26.64).

Physical Examination

Physical examination reveals relatively thin extremities caused by muscle wasting (muscle weakness); skin atrophy with easy bruising and purplish striae, especially over the abdomen, and hirsutism.

Other clinical manifestations include osteoporosis, amenorrhea, hypertension and psychiatric dysfunction.

Diagnostic Approach

In addition to dexamethasone suppression test, ACTH determinations are useful diagnostic measures in determining the cause of hypercorticism.

ACTH is increased in pituitary hypercorticism and ectopic ACTH production. ACTH is low in hypercorticism of adrenal origin. Half of patients exhibit absolute lymphopenia. Dexamethasone suppression test in Cushing's syndrome is shown in Fig. 26.65.

HYPERALDOSTERONISM

Hyperaldosteronism is a disorder in which the adrenal gland releases too much aldosterone hormone into the blood. Urine aldosterone is elevated in both primary and secondary aldosteronism. There is decreased

Table 26.41 Causes of Cushing's syndrome

Etiology	Disorders	ACTH Dependent or Independent
Therapeutic administration of corticosteroids	Corticosteroid administration in immunological and inflammatory disorders	–
Adrenal causes	Adrenal hyperplasia, adrenal cortical adenoma, adrenal cortical carcinoma	ACTH independent
Pituitary gland causes	Corticotrope microadenoma, corticotrope adenoma, corticotrope hyperplasia	ACTH dependent
Respiratory system	Small cell lung carcinoma, bronchial carcinoid tumor	ACTH dependent

Cushing's disease is reserved for excess synthesis of ACTH by pituitary corticotroph tumors.

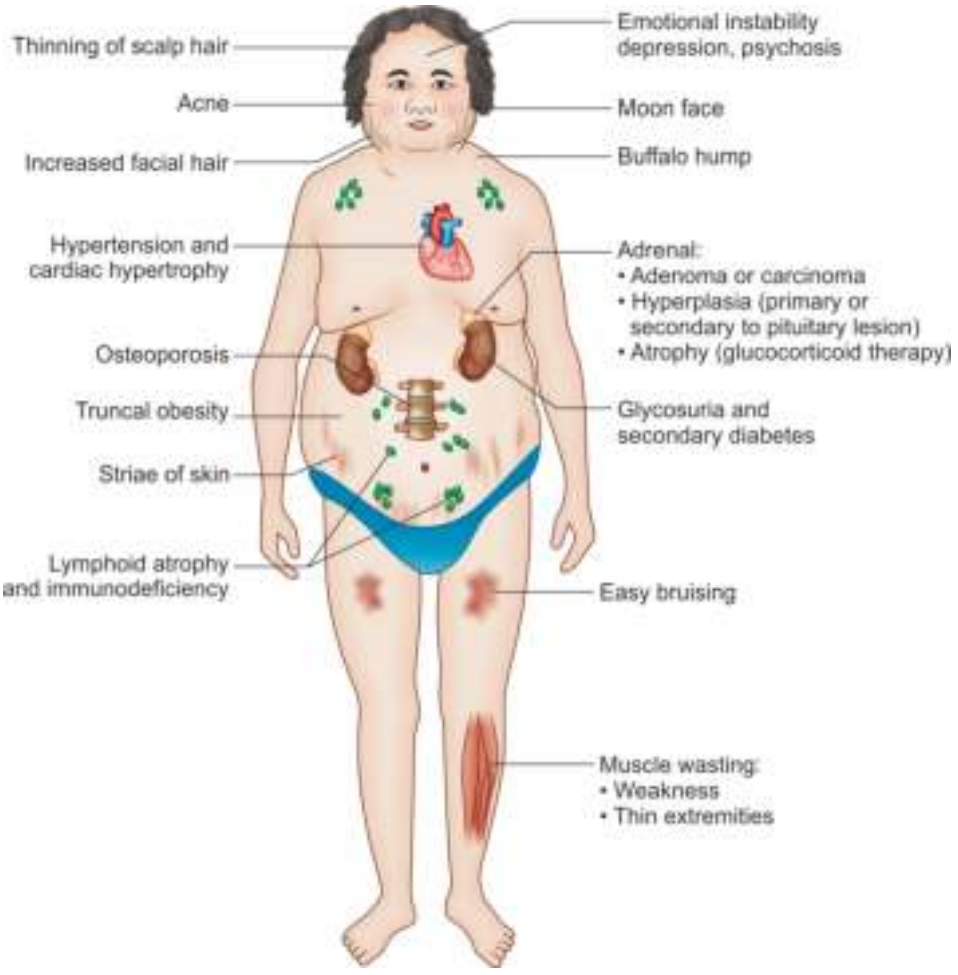

Fig. 26.64: Clinical manifestations of Cushing's syndrome.

plasma renin level in primary aldosteronism. Secondary aldosteronism has increased blood renin level.

Primary Aldosteronism

Primary aldosteronism is also known as Conn's syndrome, which reflects inappropriate secretion of aldosterone by an adrenal adenoma in 75% of cases or hyperplastic adrenal glands. Rarely, it may be caused by adrenocortical carcinoma.

- Patient presents with asymptomatic diastolic hypertension, persistent hypokalemia with alkalosis and slightly elevated serum sodium. Skeletal muscle weakness and fatigue are produced by the effects of potassium depletion in skeletal muscle. Decreased serum renin level occurs due to negative feedback of increased blood pressure.
- The diagnosis of primary aldosteronism can be confirmed by demonstration of increased aldosterone, lack of response of aldosterone to sodium loading, and decreased serum renin.

Secondary Aldosteronism

Secondary aldosteronism occurs due to renal ischemia, renal tumors, and edema. The cause of secondary aldosteronism is stimulation of the renin-angiotensin-aldosterone system. Serum renin is increased in contrast to primary aldosteronism.

Renin synthesized in the juxtaglomerular apparatus of the kidney promotes the conversion of angiotensinogen to angiotensin I, which is converted catalytically by angiotensin-converting enzyme (mainly in the lungs) to angiotensin II. The release of aldosterone is facilitated by angiotensin II.

Glucocorticoid-remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA) is an autosomal dominant disorder characterized by ectopic production of aldosterone by zona fasciculata of adrenal cortex.

- **Physiologic state:** Aldosterone-synthase gene and 11β-hydroxylase gene are present on chromosome 8.

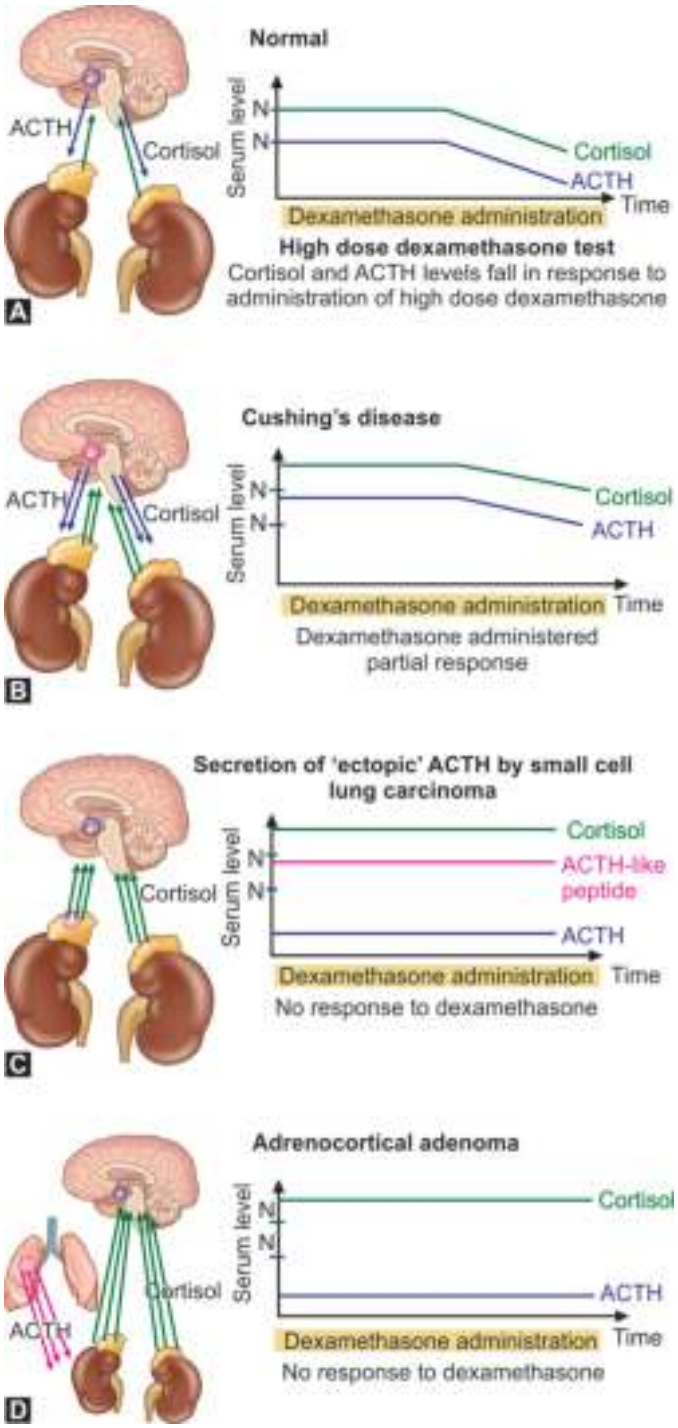

Fig. 26.65A to D: Dexamethasone suppression test in Cushing's syndrome has many causes. Cushing's disease is caused by a pituitary adenoma. The dexamethasone suppression test can help to identify the underlying problem. The principles of the test are shown here.

Aldosterone-synthase acts on zona glomerulosa to synthesize aldosterone hormones. 11β-Hydroxylase gene controls the synthesis of cortisol by zona fasciculata of adrenal glands.

- **Pathologic state:** Mutations of aldosterone-synthase gene and 11β-hydroxylase gene present on chromosome 8 form hybrid genes resulting in ectopic production of aldosterone by zona fasciculata of adrenal cortex, which leads to expansion of blood volume resulting in hypertension.

ADRENOCORTICAL INSUFFICIENCY

Hypocorticism (adrenocortical insufficiency) can be due to primary adrenal cause or secondary to hypothalamic or pituitary dysfunction. Deficiency of glucocorticoids, primarily cortisol, is often associated with mineralocorticoid deficiency.

Examples of hypocorticism are Addison's disease and Waterhouse-Friderichsen syndrome.

ADDISON'S DISEASE

Primary chronic adrenal insufficiency also known as Addison's disease most often reflects autoimmune destruction of the adrenal gland in 70% of cases. Until recently the most frequent cause of Addison's disease was tuberculosis.

Addison's disease may be caused due to metastatic tumor, and various infections. Atrophic adrenal gland fails to produce glucocorticoids, mineralocorticoids, and androgens.

Clinical Features

More than 90% of the adrenal gland must be destroyed before the symptoms of chronic adrenal insufficiency appear.

Patient with Addison's disease presents with weakness, weight loss, gastrointestinal symptoms, hypotension, electrolyte disturbances such as decreased serum sodium, bicarbonate, chloride and increased serum potassium, and hyperpigmentation due to compensatory hypothalamic production of proopiomelanocortin, the precursor peptide of both corticotropin and melanocyte-stimulating factor. Clinical manifestations of Addison's disease are shown in Fig. 26.66.

WATERHOUSE-FRIDERICHSEN SYNDROME

Waterhouse-Friderichsen syndrome is life-threatening disorder associated with bilateral adrenal hemorrhage. Sometimes it occurs due to dissemination of meningococcal infection, most often in association with meningococcal meningitis.

Clinical Features

Patient presents with vascular collapse due to hemorrhagic necrosis of the adrenal cortex. It is often associated with disseminated intravascular coagulation (DIC).

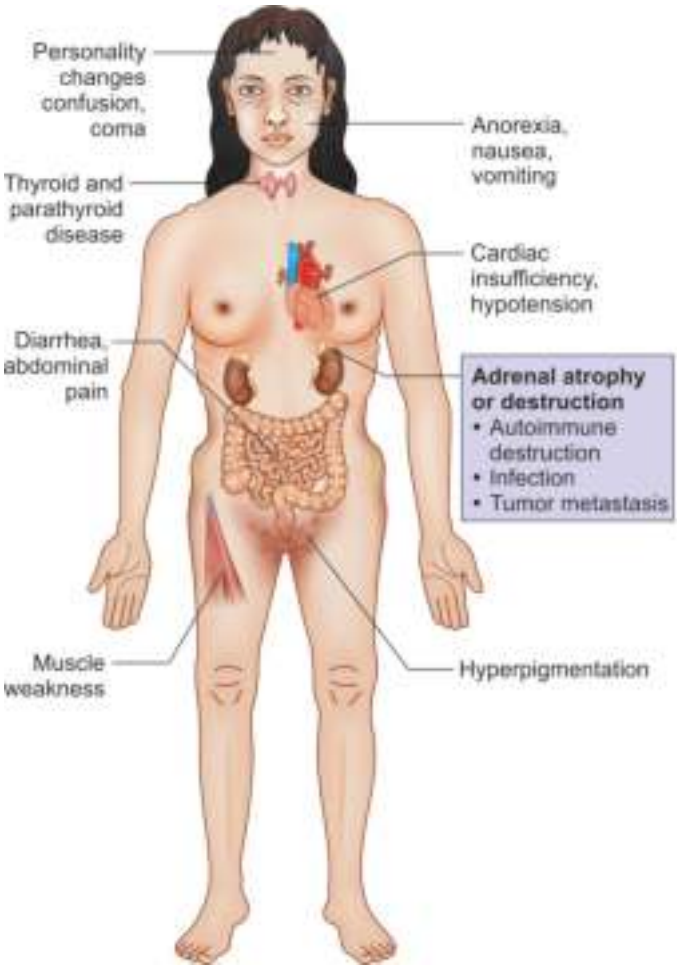

Fig. 26.66: Clinical manifestations of Addison's disease.

ADRENOGENITAL SYNDROME

Congenital deficiency of 21-hydroxylase is most common cause of adrenogenital syndrome. It is characterized by decreased synthesis of cortisol, and mineralocorticoids, and an increase in androgenic steroid sex hormones resulting in salt-losing hypotension and virilization, i.e. masculinization. Compensatory increased ACTH leads to resultant adrenal hyperplasia.

- Adrenogenital syndrome may also be caused by functional adrenocortical hormone producing adenomas, common component of MEN I, Carney complex, and McCune-Albright syndrome.
- Adrenogenital syndrome can occur in the settings of sporadic adrenocortical carcinoma, Li-Fraumeni and Beckwith-Wiedemann syndromes.

Clinical Features

Patient with adrenogenital syndrome presents with virilization, ambiguous genitalia such as hypertrophic clitoris and partial fusion of labioscrotal folds in female infants.

Male infants show normal external genitalia, but develop precocious puberty. Eventually, high levels of adrenal androgens lead to premature closure of the epiphyses and stunted growth. Clinical manifestations in adrenogenital syndrome in male and female are given in Table 26.42.

NEOPLASTIC DISORDERS OF ADRENAL MEDULLA

PHEOCHROMOCYTOMA

Pheochromocytoma is a rare tumor derived from chromaffin cells of the adrenal medulla, which releases excess of epinephrine and norepinephrine. There is increased levels of their metabolites such as vanilylmandelic acid (VMA) and metanephrin. Tumor arising from extra-adrenal chromaffin cells is called paraganglioma.

- Pheochromocytoma has most often benign course in 90% of cases. The 10% rule of pheochromocytoma includes 10% malignant, 10% familial, 10% bilateral, 10% children involvement and 10% extra-adrenal.
- Classic triad of pheochromocytoma includes episodic headaches, sweating and tachycardia is present in 30% of cases. Other common clinical features include paroxysmal hypertension, palpitations, anxiety and postural hypotension. Additional features may be present in hereditary syndromes associated with pheochromocytoma.

Association of Pheochromocytoma in Various Syndromes

Pheochromocytoma can be part of MEN IIa (Sipple syndrome) or MEN IIb. It can also be associated with neurofibromatosis or with von Hippel-Lindau disease.

Table 26.42 Clinical manifestations in adrenogenital syndrome in male and female

Patient	Findings
Pre-pubertal male	Premature puberty
Post-pubertal male	Asymptomatic or paradoxical oligospermia
Pre-pubertal female	Virilization of external genitalia, which may appear ambiguous
Post-pubertal female	Clitoris—megaly, male-type hirsutism, deepening of the voice, menstrual irregularities

- **MEN IIa syndrome (Sipple syndrome):** It is associated with familial medullary thyroid carcinoma, bilateral pheochromocytomas and primary hyperparathyroidism as a result of parathyroid adenoma or hyperplasia.
- **MEN IIb syndrome:** It is associated with medullary thyroid carcinoma, bilateral pheochromocytomas, and multiple mucosal ganglioneuromas in lips/tongue. In contrast to MEN IIa, it does not induce hyperparathyroidism. MEN IIa is linked to different mutations in the RET oncogene compared with MEN IIa. Poor prognostic factors in these patients include age >50, male, and distant metastases.

Surgical Pathology: Pheochromocytoma

Gross Morphology

- Pheochromocytoma fixed in dichromate solution gives brown discoloration (Fig. 26.67).
- Tumor is well circumscribed and unencapsulated.
- Cut surface reveals solid white to red brown with areas of hemorrhage (Fig. 26.67).

Light Microscopy

- Tumor is composed of large polygonal cells with abundant granular cytoplasm with eccentric nuclei arranged in alveolar, nests, trabecular or solid patterns.
- Nests of tumor cells are separated by thin vascular septa. The tumor cells contain intranuclear inclusions.
- Cytoplasm of tumor cells may show pink hyaline diastase resistant PAS positive globules (Fig. 26.68).

Immunohistochemistry Technique

Tumor cells show positivity for synaptophysin, chromogranin A, neuron-specific enolase (NSE), S-100 and N-CAM (CD56).

Markers	Expression
Synaptophysin	Positive
Chromogranin A	Positive
Neuron-specific enolase (NSE)	Positive
S-100 (calcium binding protein)	Positive
N-CAM (CD56)	Positive

- **Composite pheochromocytoma:** Pheochromocytoma admixed with ganglioneuroma or neuroblastoma or ganglioneuroblastoma or malignant nerve sheath tumor is known as composite pheochromocytoma.

Clinical Features

Approximately 66% of patients are asymptomatic. One-third cases show fluctuating (paroxysmal or episodic) hypertension and tachycardia due to excessive secretion of catecholamines (epinephrine and norepinephrine) by the tumor. Patient is resistant to antihypertensive therapy.

Patient may also develop hyperglycemia, malignant hypertension (e.g. encephalopathy, papilledema, and proteinuria), myocardial infarction, aortic dissection, and convulsions.

Fig. 26.67: Pheochromocytoma—adrenal gland. Tumor is solid white to red brown and hemorrhagic on cut surface and mean diameter of benign tumor is 4–6.5 cm. Classic triad of pheochromocytoma includes paroxysmal hypertension, episodic headaches, sweating and tachycardia in about 30% of patients.

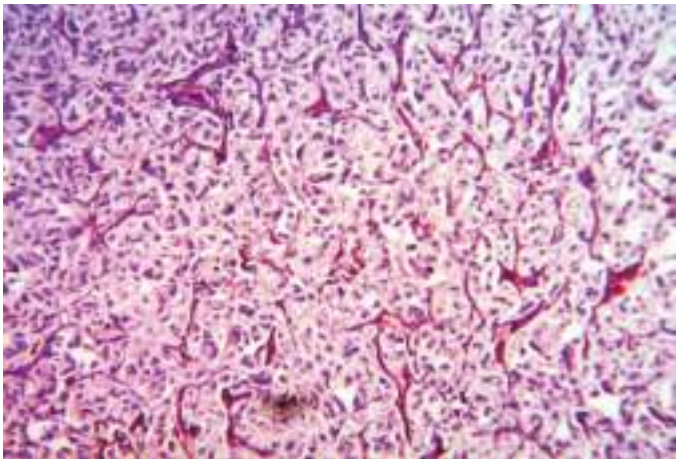

Fig. 26.68: Pheochromocytoma. Tumor is composed of large polygonal cells with abundant granular cytoplasm with eccentric nuclei arranged in alveolar, nests, trabecular or solid patterns. These nests of tumor cells are separated by thin vascular septa (400X).

Molecular Genetic Testing

Pheochromocytoma is linked to mutations in the RET oncogene, a transmembrane receptor of the tyrosine kinase family in sporadic cases in 25–70%.

When a diagnosis of pheochromocytoma is made, demonstration of RET oncogene would justify prophylactic thyroidectomy keeping in view of fatal outcome of medullary thyroid carcinoma.

Urine Analysis

Urinary vanillylmandelic acid (VMA), a norepinephrine metabolite, is markedly elevated in pheochromocytoma.

NEUROBLASTOMA

Neuroblastoma is a highly malignant catecholamine-producing tumor of neural crest origin from adrenal medulla or precursor cells of autonomic nervous system closely related to sympathetic ganglia. Tumor is composed of neoplastic neuroblasts. *In situ* neuroblastoma reported in infancy, has higher frequency of apparent spontaneous regression. Occasionally, tumor converts into a more differentiated form termed ganglioneuroma.

Association of Neuroblastoma in Various Syndromes

Neuroblastoma may be seen in patients with Beck-with-Wiedemann syndrome, neurofibromatosis, Hirschsprung's disease and fetal hydantoin syndrome.

Neuroblastoma Sites

Adrenal medulla is the most common site of neuroblastoma in 50–80% of cases. Posterior mediastinum in paravertebral regions is next common site. Rare sites of tumor include pelvis, lower cervical sympathetic chain, and posterior cranial fossa. In some cases, having heredofamilial basis, both adrenal glands and multiple extra-adrenal sites are involved.

Age Group

Neuroblastoma most often affects children under 5 years with peak incidence is in the first 3 years of life. Adults are rarely affected.

Molecular Genetic Testing in Neuroblastoma

Tumor reveals amplification of the N-Myc oncogene. Multiple copies of the N-Myc oncogene are demonstrated as homogeneously staining regions or as extrachromosomal double minute chromatin bodies. A greater degree of amplification correlates with worse prognosis.

N-Myc Oncogene Amplification

- **Physiologic state:** The 'myc' protein acts as a transcription factor and controls the expression of several genes. It is activated by gene rearrangement (breaking and sealing of chromosomes) or amplification.
- **Pathologic state:** Neuroblastoma reveals amplification of the N-Myc oncogene forming thousands of N-Myc oncogene copies per cell in neuroblastoma (30% cases).
  - Multiple copies of the N-Myc proto-oncogene are demonstrated as homogeneously staining regions (HSRs) or as extrachromosomal double minute chromatin bodies. A greater degree of N-Myc proto-oncogene amplification correlates with worse prognosis.
  - The malignant cells of neuroblastoma sometimes differentiate into benign cells, and this change is reflected by a marked reduction in gene amplification.

NPM-ALK Fusion Oncogene

- **Physiologic state:** ALK (anaplastic lymphoma kinase) gene is located on chromosome 2. ALK gene provides instructions for making a protein is called ALK receptor tyrosine kinase (RTK).
- **Pathologic state:** As a result of the t(2:5) chromosomal translocation ALK gene is fused with the NPM (nucleophosmin) gene, leading to production of a hybrid NPM–ALK protein. Mutant ALK receptors deliver continuous mitogenic signals to the cell, even in the absence of growth factor in the environment. It is associated with anaplastic large cell lymphoma, i.e. most important, rare cases of lung adenocarcinoma, and neuroblastoma. These cancers synthesize excessive ALK receptors.

Surgical Pathology: Neuroblastoma

Gross Morphology

Neuroblastoma grows rapidly to become well-circumscribed to multilobular mass. Cut surface reveals variable amounts of hemorrhage, necrosis and calcification. Calcification is demonstrated on radiological examination (Fig. 26.69).

Light Microscopy

Neoplasms of neuroectodermal origin are comprised of neuroblasts or ganglion cells. These neoplasms can be least differentiated to well differentiated: neuroblastoma → ganglioneuroblastoma → ganglioneuroma.

- **Neuroblastoma** is composed of small round blue immature tumor cells (neuroblasts) forming Homer-Wright pseudorosettes around blood vessels.
  - Tumor cells contain round to ovoid nuclei with stippled 'salt and pepper chromatin', inconspicuous nucleoli, and minimal cytoplasm.
  - Homer-Wright pseudorosettes are circular, ovoid, angular zones of pale staining neuritic cell processes surrounded by tumor cell nuclei (Fig. 26.70).
- **Ganglioneuroblastoma** is composed of mixture of immature neuroblasts and ganglion cells (Schwannian stroma-rich).
- **Ganglioneuroma** is composed only of ganglion cells (Schwannian stroma-dominant).

Immunohistochemistry Technique

Tumor cells of neuroblastoma show positivity for neuron-specific enolase (NSE), neurofilament, chromogranin A, and synaptophysin.

Markers	Expression
Neuron-specific enolase (NSE)	Positive
Neurofilament	Positive
Chromogranin A	Positive
Synaptophysin	Positive

Clinical Features

Patient with neuroblastoma often presents with a large abdominal mass, malaise, fever, pallor and loss of weight. Tumor synthesizes catecholamines (norepinephrine) in 90% of cases, but it rarely causes hypertension.

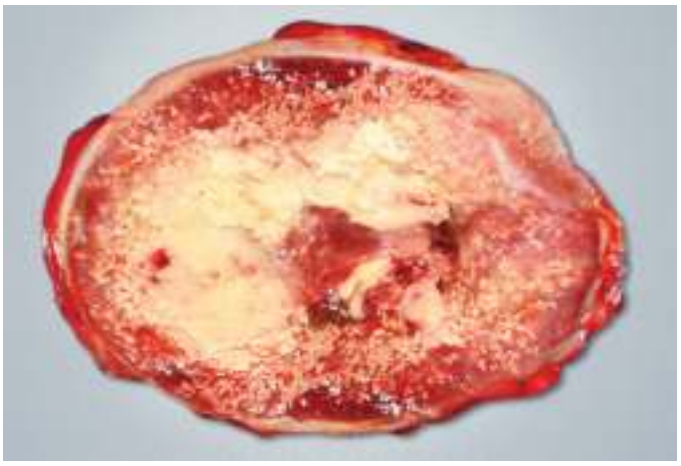

Fig. 26.69: Gross morphology of neuroblastoma of adrenal gland. Tumor is well circumscribed and multilobular. Cut surface reveals variable amounts of hemorrhage, necrosis and calcification in background of solid areas. (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

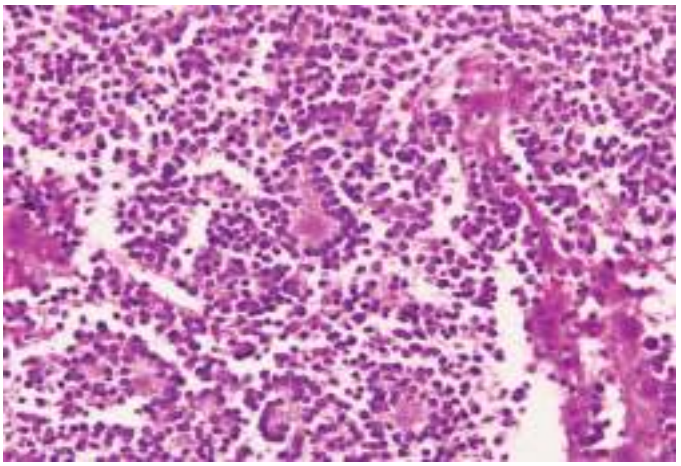

Fig. 26.70: Histology of neuroblastoma of adrenal gland. Tumor is composed of small round blue cells (neuroblasts) and Homer-Wright pseudorosettes. Tumor cells contain round to oval nuclei with stippled salt and pepper chromatic and scanty cytoplasm (400X).

On clinical examination, neuroblastoma has knobby contour in contrast to smooth contour of Wilms' tumor. As the tumor enlarges, it crosses midline.

Metastasis

Neuroblastoma spreads to the liver, bones (skull, orbit), scalp, lymph nodes, subcutaneous tissue, intraspinal extension or kidney. Bone metastases are multiple and sometimes symmetric.

- **Pepper type of neuroblastoma:** It is characterized by primary neuroblastoma and its secondaries especially liver metastases on right side of body.
- **Hutchinson's type of neuroblastoma:** It is characterized by left side primary neuroblastoma and metastases in the orbit and skull.

Urine Analysis

More mature descendants of tumor cells in the adrenal medulla may secrete catecholamines. These catecholamines are metabolized and excreted as urinary vanillylmandelic acid (VMA) in the urine. Urinary catecholamines and catecholamine metabolites are the same as in pheochromocytoma.

Prognostic Factors

Amplification of N-Myc proto-oncogene, gain of 17q, deletion of 1p, and high expression of neuron-specific enolase are associated with poor prognosis. Prognostic factors of neuroblastoma are given in Table 26.43.

Table 26.43 Prognostic factors of neuroblastoma

Features	Good Prognosis	Bad Prognosis
Age group	Less than 2 years	More than 2 years
Site of tumor	Extra-adrenal tumor	Adrenal gland
Stage	Tumor confined to organ	Tumor extending outside organ
DNA ploidy	Hyperdiploid or near triploid	Diploid near diploid or near tetraploid
N-Myc proto-oncogene amplification	Absent	Present
Gain of chromosome 17q	Absent	Present
Loss of chromosome 11q	Absent	Present
Telomerase overexpression	Absent	Present
MRP expression	Absent	Present
TrkB expression	Absent	Present
TrkB expression-A (Trk family of neutropin receptors)	Present (respond to TrkA inhibitor drug with spontaneous regression)	Absent
CD44 expression	Present	Absent

Contd...

Table 26.43 Prognostic factors of neuroblastoma (*Contd...*)

Features	Good Prognosis	Bad Prognosis
Lymphocytes around tumor	Present	Absent
S-100 protein expression in tumor cells	Present	Absent
Ratio of vanillylmandelic acid to homovanillic acid	Ratio >1	Ratio <1
Serum ferritin level	Low level	High level
Serum LDH	<1500 U/ml	>1500 U/ml
Neuron-specific enolase levels (cut of value is 15 ng/ml)	Low	High
Creatine kinase BB (normal cut of less than 1 ng/dl)*	Increased	Highest in stage IV

**Creatine kinase level is highest in stage IV of neuroblastoma.*

NEOPLASTIC DISORDERS OF ADRENAL CORTEX

ADRENOCORTICAL ADENOMA

Adrenocortical adenoma is a benign tumor in adults during 5th–7th decades. Tumor can be functional (a few cases) and nonfunctional (most cases). The patient shows signs and symptoms of Cushing's syndrome is characterized by upper truncal obesity and hypercortisolism.

Surgical Pathology: Adrenocortical Adenoma

Gross Morphology

The surgical specimen reveals a circumscribed tumor of the adrenal cortex.

Light Microscopy

Tumor is composed of nests of clear, lipid-laden epithelial cells.

Immunohistochemistry Technique

Tumor cells show positivity for Ki-67, p53, phosphohistone H3 and steroidogenic factor 1.

Markers	Expression
▪ Ki-67	▪ Positive
▪ p53	▪ Positive
▪ Phosphohistone H3	▪ Positive
▪ Steroidogenic factor 1	▪ Positive

ADRENOCORTICAL CARCINOMA

Adrenocortical carcinoma is a rare neoplasm affecting any age group. It is most often functional tumor associated with clinical manifestations in contrast to nonfunctional adrenocortical adenoma. Tumor has strong tendency to invade adrenal vein, inferior vena cava and lymphatic channels.

- Tumor is associated with Li-Fraumeni syndrome, Beckwith-Wiedemann syndrome and congenital adrenal hyperplasia.
- Lung adenocarcinoma frequently metastasizes to adrenal glands. It is difficult to differentiate from primary adrenocortical carcinoma.

Mode of Spread

- **Lymphatic route:** Tumor metastasizes to para-aortic lymph nodes.
- **Hematogenous route:** Tumor invades blood vessels and spread to lungs and liver. Bone metastases are unusual.

Surgical Pathology: Adrenocortical Carcinoma

Gross Morphology

- Adrenocortical carcinoma is unencapsulated large tumor weighing 200 g and measuring 20 cm.
- Cut surface shows variegated appearance due to hemorrhage, necrosis and cysts.
- Tumor is often soft, friable intratumoral necrosis; often invading major veins (Fig. 26.71).

Light Microscopy

- Adrenocortical carcinoma has various growth patterns of well-differentiated to anaplastic cells.
- Tumor shows capsular invasion marked mitotic activity, tumor giant cells, neutrophils and eosinophils.
- Only definitive criteria of malignancy are distant metastasis and local invasion (Fig. 26.72).

Modified Weiss Diagnostic Criteria of Adrenocortical Carcinoma

- Mitotic figures >5 per 50 high power fields
- Abnormal mitosis
- Cytoplasm (clear cells comprising about 25% of the tumor)
- Necrosis
- Capsular invasion
- Calculate diagnostic criteria:
  - 2 × mitotic rate criteria +
  - 2 × clear cytoplasm criteria + abnormal mitoses + necrosis + capsular invasion (score of ≥ suggests malignancy).

Each criterion is scored 1 when present in the tumor and zero when absent.

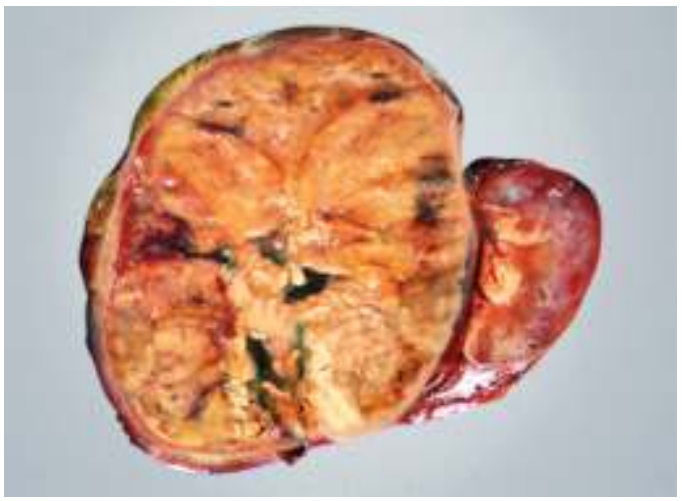

Fig. 26.71: Gross morphology of adrenocortical carcinoma. Tumor is large, fleshy partially necrotic tumor that has completely replaced adrenal gland. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

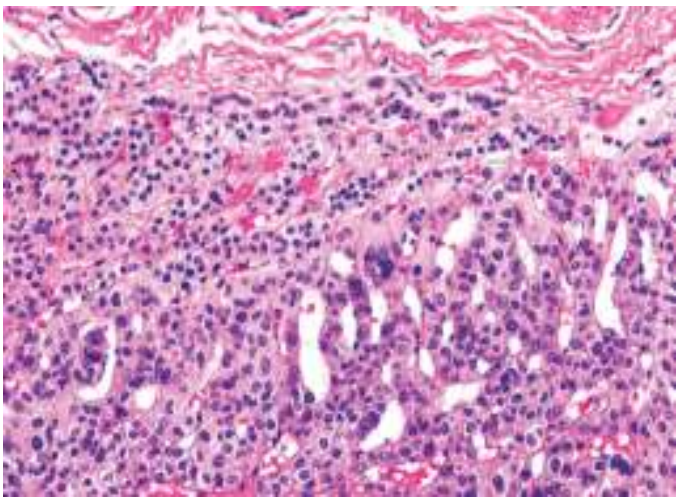

Fig. 26.72: Histology of adrenocortical carcinoma. Histologic examination shows tumor cells containing clear to eosinophilic cytoplasm and hyperchromatic nuclei. There is presence of capsular invasion, marked mitotic activity, tumor giant cells, neutrophils and eosinophils (400X).

DISORDERS OF PITUITARY GLAND

ANATOMY AND PHYSIOLOGY

Pituitary gland consists of adenohypophysis, i.e. anterior pituitary or pars distalis, pars intermedia and neurohypophysis, i.e. posterior pituitary or pars nervosa.

- **Anterior pituitary gland:** Hormones synthesized by anterior pituitary are growth hormone, prolactin, thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), follicle stimulating hormone (FSH) and luteinizing hormone (LH).
- **Pars intermedia:** It is merged with anterior pituitary gland. It synthesizes melanocyte-stimulating hormone (MSH).
- **Posterior pituitary gland:** Hypothalamic neurons synthesize oxytocin and antidiuretic hormone (ADH), i.e. vasopressin, which pass through axons and released at nerve endings and hormones reach the posterior pituitary gland through portal circulatory system and regulate the functions of the posterior pituitary gland. Posterior pituitary gland is under the direct neural regulation of the hypothalamus.

Hormones synthesized by anterior pituitary gland and their actions are given in Table 26.44. Pituitary gland consists of anterior and posterior divisions (Fig. 26.73).

Table 26.44 Hormones synthesized by anterior pituitary gland and their actions

Cells in Pituitary Gland	Hormone Synthesis by Anterior Pituitary Gland	Target Organs	Actions on Target Cells	Net Result
Somatotropes (basophilic cells)	Growth hormone (acidophilic cells)	Skeletal system	Growth promoting and anti-insulin actions	Linear bone growth in children
Corticotropes (basophilic cells)	ACTH	Adrenal glands	Synthesis of aldosterone and corticosteroids	Regulate carbohydrate, fat and proteins
Thyrotropes (basophilic cells)	TSH (basophilic cells)	Thyroid gland	T_3, T_4	Regulation of metabolism of carbohydrate, fat and proteins
Lactotropes (acidophilic cells)	Prolactin (PRL)	Female breasts	Synthesis and ejection of milk	Controls reproduction, osmoregulation, growth and metabolism

Contd...

Table 26.44 Hormones synthesized by anterior pituitary gland and their actions (*Contd...*)

Cells in Pituitary Gland	Hormone Synthesis by Anterior Pituitary Gland	Target Organs	Actions on Target Cells	Net Result
Gonadotropes (basophilic cells)	FSH, LH	▪ Testes ▪ Ovaries	▪ FSH: Spermatogenesis ▪ LH: Acts on Leydig cells to synthesize testosterone ▪ FSH ▪ LH	▪ Increased sperms count ▪ Growth, development, maturation of spermatozoa and development of secondary characters ▪ Stimulates formation of graafian follicles ▪ Triggers ovulation, and formation of corpus luteum
Melanophores	Melanocyte-stimulating hormone (MSH)	Skin	Synthesis of cutaneous pigmentation	Subcutaneous dispersion of melanin granules

Somatostatin inhibits synthesis of growth hormone by anterior pituitary gland.

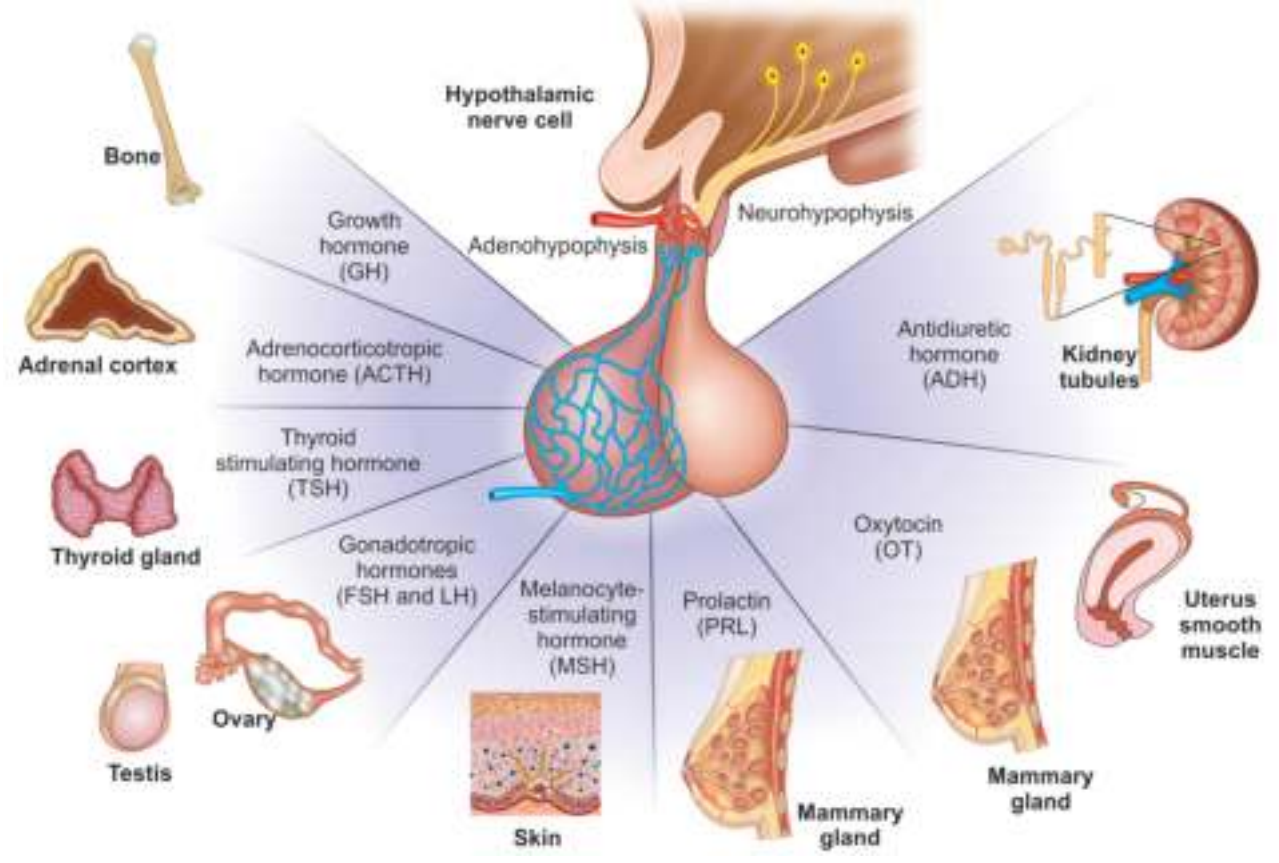

Fig. 26.73: Pituitary gland consists of anterior and posterior divisions.

ANTERIOR PITUITARY GLAND: HYPOFUNCTIONING

Partial or complete forms of hypopituitarism of anterior pituitary gland most often affects children and adults, which may cause dwarfism and delayed puberty. Initially, there is decreased FSH and LH levels resulting in hypogonadism, impotence in men and menstrual disturbances in women.

Growth hormone deficiency leads to short stature, delayed growth and delayed puberty in children. There is subsequent decrease in TSH and ACTH.

PRIMARY HYPOPITUITARISM

Primary hypopituitarism of anterior pituitary gland is caused by nonsecretory adenoma, Sheehan's syndrome (postpartum pituitary necrosis), empty sella syndrome, partial or total hypophysectomy;

TB meningitis, irradiation, hemochromatosis and Hand-Schüller-Christian disease.

Etiopathogenesis

- **Simond's disease:** Patient presents with cachexia (marked wasting) due to destruction of pituitary gland by pituitary tumors usually adenomas in >50% of cases.
- **Sheehan's syndrome:** Sheehan's syndrome refers to infarction of anterior pituitary gland due to postpartum hemorrhage and shock during childbirth.
  - During pregnancy, pituitary gland becomes enlarged, that renders it vulnerable to a reduction in blood flow.
  - Patient presents with adrenal cortical insufficiency, and ovarian failure (gonadotropin deficiency with decreased FSH and LH), pallor, (MSH deficiency), secondary hypothyroidism (decreased TSH), and failure of lactation (decreased prolactin). Clinical manifestations of Sheehan's syndrome are shown in Fig. 26.74.
- **Iatrogenic hypopituitarism:** Pituitary gland may be damaged due to radiation therapy in the head or neck region and intracranial neurosurgical procedures.
- **Traumatic injury to skull:** Basal skull fractures and trauma to the sella turcica may cause damage to the pituitary gland.
- **Infiltrative diseases:** Pituitary gland may be damaged by bacterial or viral infections. Hemochromatosis of pituitary may cause panhypopituitarism. Hand-Schüller-Christian disease most often causes diabetes insipidus, but may also cause hypopituitarism.

Molecular Genetic Alterations

Mutation of Pit1 gene (3p11), PROP1 gene (5q) or HSEX1 gene (3p21) causes hypopituitarism (Table 26.45).

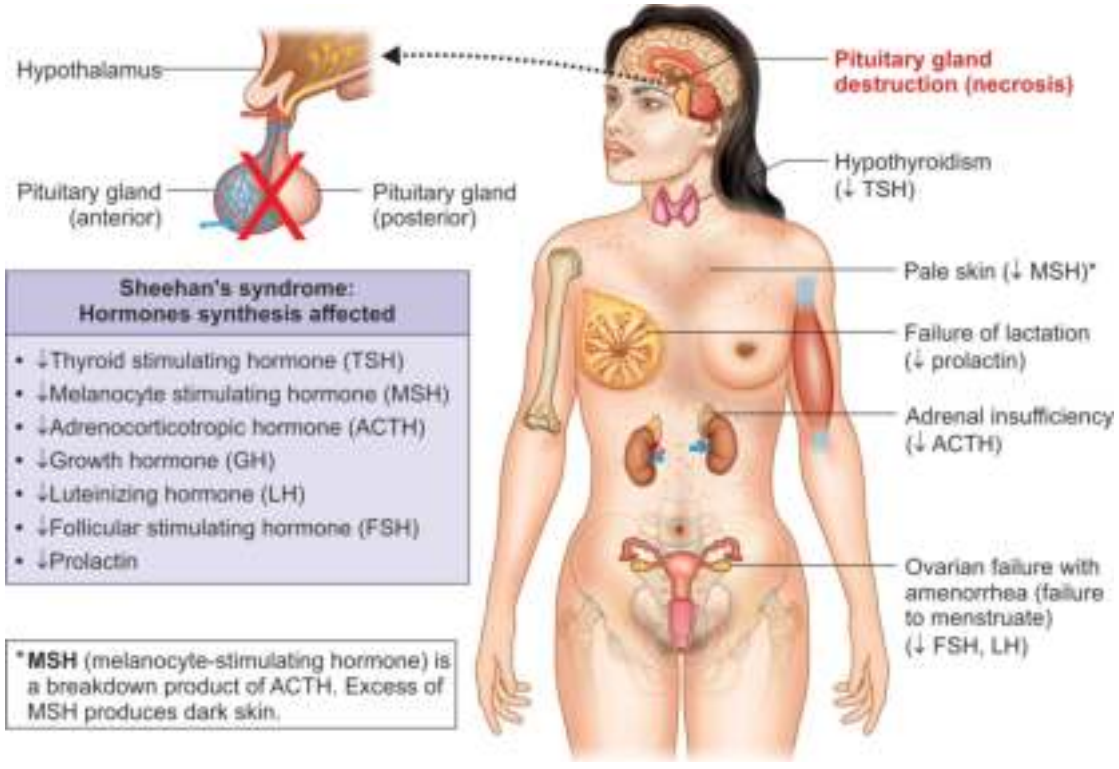

Fig. 26.74: Sheehan's syndrome. Clinical manifestations of Sheehan's syndrome is caused by hemorrhagic destruction of the pituitary gland during pregnancy or postpartum period.

Table 26.45 Molecular genetic alterations in hypopituitarism

Gene Mutations	Deficiency of Hormones
Pit1 gene (3p11)	Growth hormone, prolactin and thyroid stimulating hormone
PROP1 gene (5q) transcription factor	Inactivation of FSH, LH, prolactin and thyroid stimulating hormone
HSEX1 gene (3p21) participates in development of optic nerves and pituitary gland	Growth hormone and ADH

Clinical Manifestations

- **Growth hormone deficiency:** Deficiency of growth hormone in children results in growth retardation, i.e. pituitary dwarfism. In adults, patient develops increased insulin sensitivity associated with hypoglycemia, decreased muscle strength, and anemia.
- **Gonadotropin deficiency:** In preadolescent children, gonadotropin deficiency results in retarded sexual maturation. Adult men present with loss of libido, impotence, inhibition of spermatogenesis, loss of muscular mass, and decreased facial hair. Women develop amenorrhea and vaginal atrophy.
- **TSH deficiency:** Deficiency of TSH results in secondary hypothyroidism. Patient presents with weight gain, constipation, cold intolerance, fatigue and coarse hair.
- **Prolactin deficiency:** Patient presents with lactation dysfunction in women or gynecomastia in men. Serum ACTH, FSH, LH, and TSH levels are analyzed. CT scan and MRI of pituitary gland and target glands are essential diagnostic tools.
- **ACTH deficiency:** Deficiency of ACTH results in secondary adrenal failure. It does not result in hyperpigmentation of the skin, probably because of the lack of both ACTH and β-melanocyte-stimulating hormone; this is in contrast to primary adrenal failure, i.e. Addison's disease, in which ACTH is increased and hyperpigmentation is the rule.

  Patient presents with weakness, fatigue, hypoglycemia, loss of hair in axillae and pubic regions, hypotension, and decreased sodium level.

OTHER CAUSES OF HYPOPITUITARISM

- **Empty sella syndrome:** It is caused by conditions that destroy all or part of the pituitary gland.
- **Nelson syndrome:** Nelson syndrome involves the development of large pituitary adenomas following bilateral adrenalectomy. This is thought to be due to loss of feedback inhibition on growth of pre-existing pituitary microadenoma.
- **Growth hormone insensitivity (Laron syndrome):** It is an autosomal recessive disorder characterized by extreme resistance to growth hormone resulting in short stature and obesity. Biochemical analysis shows high level of serum growth hormone and low level of insulin-like growth factor 1 (IGF-1).
- **Isolated gonadotropin deficiency (Kallmann syndrome):** It occurs due to mutation of KAL1 gene resulting to failure of migration of gonadotropin releasing hormone (GnRH) from its origin in olfactory anlage to their normal location in hypothalamus.

POSTERIOR PITUITARY GLAND: HYPOFUNCTIONING

Hormones are synthesized in the hypothalamus and transported via axons to the posterior pituitary.

- Oxytocin induces uterine contraction during labor and ejection of milk from mammary alveoli.
- Antidiuretic hormone (ADH, vasopressin) promotes water retention through action on the renal collecting ducts. Mutations in genes causing combined pituitary hormone deficiency (CPHD) are given in Table 26.46.

ADH DEFICIENCY

Antidiuretic hormone (ADH) participates in determining the concentration of urine by affecting water reabsorption in the distal renal tubules.

- Low ADH activity results in dilute urine and free water excretion. Decreased synthesis of ADH by posterior pituitary gland results in central diabetes insipidus.
- Kidneys unresponsive to ADH results in nephrogenic diabetes insipidus.

Central Diabetes Insipidus

Central diabetes insipidus may be caused by trauma that damages the posterior lobe of pituitary gland (neurohypophysis) and interrupts the secretion of ADH.

- Approximately 25% cases of central diabetes insipidus occur due to brain tumors such as craniopharyngioma and germ cell tumor. Other causes include inflammatory processes, lipid storage disorders resulting in damage to the neurohypophysis or hypothalamus.
- Patient presents with polyuria, with consequent dehydration and insatiable thirst. Patient drinks water constantly to avoid feeling dehydrated. On clinical examination, patient appears dehydrated.

Nephrogenic Diabetes Insipidus

Kidneys unresponsive to ADH results in nephrogenic diabetes insipidus. Demeclocycline and lithium are potential causes of nephrogenic diabetes insipidus.

SYNDROME OF INAPPROPRIATE ADH SECRETION

Syndrome of inappropriate ADH (SIADH) secretion most often occurs due to ectopic production of ADH by small cell lung carcinoma (most common). It is also reported in patient with carcinomas of the prostate, gastrointestinal tract, and pancreas, thymomas, NHL, Hodgkin's disease, trauma, and infections.

Table 26.46 Mutations in genes causing combined pituitary hormone deficiency (CPHD)

Gene	Chromosome Locus	Normal Functions	Gene Mutations
HESX1 (homeobox expressed in embryonic stem cells)	3p14.3	Transcriptional repressor essential for early determination and differentiation of the pituitary gland, PROP1 gene has opposite action	Missense, insertion and deletion (homozygotes/heterozygotes)
LHX3	▪ 9p34.3 (LHX3) ▪ 1q25.2 (LHX4)	Transcriptional factors essential for early development and maintenance of mature anterior pituitary cells	Missense, nonsense mutations, with frameshift, partial or complete gene deletion
PROP1 gene	5p25.3	Transcriptional factor developing anterior pituitary gland (somatotrophs, lactotrophs and thyrotrophs)	Autosomal recessive disorder
POU1F1	3p11	Transcriptional factor essential for terminal differentiation and expansion of somatotrophs, lactotrophs and thyrotrophs resulting in deficiency growth hormone, prolactin and TSH deficiency	Autosomal dominant, autosomal recessive (missense, nonsense, frameshift, and splicing mutation)
Zinc finger protein GLI2 (GLI2)	2q14	Transcription factor mediates Sonic hedgehog signals	Forebrain defect holoprosencephaly, malformed anterior pituitary and panhypopituitarism

A number of genes have been demonstrated to cause CPHD. Among these are the homeobox expressed in embryonic stem cells 1 (HESX1), LIM homeobox protein 3 (LHX3), LIM homeobox protein 4 (LHX4), prophet of pit-1 (PROP1), POU domain class 1, transcription factor 1 (POU1F1), and zinc finger protein GLI2 (GLI2). Homeobox expressed in embryonic stem cells 1 (HESX1) is transcriptional repressor essential to the early development.

Clinical Features

Syndrome of inappropriate ADH (SIADH) secretion results in retention of water with consequent dilutional hyponatremia, reduced serum osmolality, and inability to dilute the urine. Water intoxication with hyponatremia results in altered mental status, seizures, coma, and sometimes death.

NEOPLASTIC DISORDERS OF PITUITARY GLAND

PITUITARY ADENOMAS

Pituitary adenomas occur in the regions of sella turcica (most common) and extracellular region (rare site) of anterior pituitary gland during 4th to 7th decades. These tumors are classified according to pituitary cell lineage, i.e. lactotroph, somatotroph, corticotroph, gonadotroph and pleurihormonal adenomas. Pituitary adenomas be functional (secretory) or nonfunctional. Secretory adenomas may secrete hormones. Clinical manifestations depend on synthesis of hormones by pituitary adenomas. Frequency of pituitary adenomas is described in Table 26.47.

- **Molecular genetic alterations:** Guanine nucleotide binding protein, α-stimulating (GNAS) is a cytoplasmic signal-transducing protein. Alteration of GNAS is associated with pituitary adenoma and other endocrinal tumors.

Table 26.47 Frequency of adenomas of anterior pituitary gland

Cell Type	Hormone	Frequency (%)
Lactotrope	Prolactin	32
Somatotrope	Growth hormone	21
Corticotrope	ACTH (adrenocorticotropic hormone)	13
Lactotrope/ somatotrope	Mixed PRL/GH	6
Gonadotropes	▪ FSH (follicle-stimulating hormone) ▪ LH (luteinizing hormone)	<4
Thyrotrope	TSH (thyroid-stimulating hormone)	
Nonfunctional tumors	–	25

- **Pathogenesis:** Pituitary adenomas may be part of multiple endocrine neoplasia type 1 (MEN1). Acquired adenomas may occur due to mutation of cyclin D1, CREB, RAS, and pituitary tumor transforming gene (PTTG).
- **Histologic classification:** Pituitary adenomas of anterior lobe have been classified according to the functional properties of cells.
  - **Chromophil adenomas:** Acidophil adenoma synthesizes excess of growth hormone and prolactin. Basophil adenomas synthesize excess of ACTH, TSH, FSH and LH.
  - **Chromophobe adenomas:** These are nonfunctional tumors without synthesis of hormones.

Table 26.48 Revised 2024 WHO classification of pituitary neuroendocrine tumors (PitNETs)

PitNETs Type and Hormones Synthesis	Subtype	Transcription Factors	Low Molecular Weight Cytokeratin
Somatotroph tumors (GH)	▪ Somatotroph tumors with densely distributed granules ▪ Somatotroph tumors with sparsely distributed granules	▪ PIT1 ▪ PIT1	▪ Perinuclear staining ▪ Fibrous bodies (>70%)
Lactotroph tumors (prolactin)	▪ Lactotroph tumors with sparsely distributed granules ▪ Lactotroph tumors with densely distributed granules	▪ PIT1, ER-α ▪ PIT1, ER-α	▪ Weak or negative staining ▪ Weak or negative staining
Mammosomatotroph tumors (GH)	No subtype	PIT1, ER-α	Perinuclear staining
Thyrotroph tumors (TSH-α and TSH-β subunits)	No subtype	PIT1, GATA3	Weak or negative staining
Mature plurihormonal IPT1-lineage tumor (GH++ and variable prolactin, α-TSH or β-TSH)	No subtype	PIT1, ER-α, GATA3	Perinuclear staining
Immature PIT1-lineage tumor	No subtype	PIT1 (ER-α, GATA3)	Focal/variable staining
Acidophil stem cell tumor (deficient hormones synthesis)	No subtype	PIT1, ER-α	Scattered fibrous bodies
Mixed somatotroph and lactotroph tumors	No subtype	PIT1, ER-α	Tumor subtype characteristics
Corticotroph tumors (ACTH and POMC derivatives)	▪ Corticotroph tumors with densely distributed granules ▪ Corticotroph tumors with sparsely distributed granules ▪ Crook cell tumor	▪ TPIT ▪ TPIT ▪ TPIT	▪ Strong diffuse staining ▪ Variable diffuse staining ▪ Perinuclear ring-like cytoplasmic staining
Gonadotroph tumor	No subtype	SF1, ER-α, GATA3	Variable or negative staining
Plurihormonal tumor	No subtype	Multiple combinations	Variable staining
Null cell tumor	No subtype	None	Variable staining

- **Revised 2024 WHO classification:** Revised 2024 WHO classification of pituitary neuroendocrine tumors (PitNETs) is given in Table 26.48.
- **Consequences:** Microadenoma is small <1 cm in diameter. It does not produce symptoms unless it secretes hormones. Macroadenoma is space occupying lesion with clinical effects such as visual disturbances and increased intracranial pressure. Functional adenoma, which synthesizes growth hormone leads to gigantism, acromegaly, Cushing's syndrome, Nelson's syndrome and increased prolactin.
  - **Visual disturbances:** Tumor erodes the sella turcica and impinges on adjacent cranial structures such as the optic chiasm resulting in bitemporal hemianopia and loss of central vision.
  - **Cranial nerve palsy:** Tumor invading the cavernous sinuses leads to oculomotor nerve palsies and headache.
  - **Hyperphagia and loss of temperature regulation:** Tumor invading hypothalamus results in loss of temperature regulation, hyperphagia, and hormonal syndromes because it interferes with the normal hypothalamic input to the pituitary.

Surgical Pathology: Adenomas of Anterior Pituitary Gland

Gross Morphology

Tumors measuring <1 cm are microadenomas, and >1 cm are macroadenomas. Giant adenomas are rare tumors of >5 cm in diameter.

Light Microscopy

- Tumors are composed of large cells with moderately abundant cytoplasm, uniform nuclear morphology and delicate stippled (salt and pepper) chromatin and inconspicuous nucleoli. Tumor cells may appear without definite pattern, i.e. pseudorosettes-rich, papillary or organized fashion.

- Tumor cells may be classified as chromophilic (acidophilic, basophilic) or chromophobic based on tinctorial differences. Cytoplasmic appearance of tumor cells usually correlates with content of hormone containing secretory cells (dense versus sparse granules).
- Crooke's hyaline change occurs due to accumulation of cytokeratin filaments in eosinophilic or chromophobic cells, if prominent, called Crooke's hyaline adenoma as per WHO terminology of neoplasms of the pituitary gland.
- Null cell adenoma is composed of adenohypophyseal cells that does not exhibit any cell type specific differentiation.

LACTOTROPH ADENOMA (PROLACTINOMA)

Lactotroph adenoma (prolactinoma) is most common prolactin-secreting benign tumor of the pituitary gland, which constitutes 30% of pituitary adenomas. Staining is usually chromophobic. Tumor is generally of small size in 90% of cases. Large tumor impinges on adjacent structures, and bitemporal hemianopia from pressure on the optic chiasm is common (Fig. 26.75).

Age and Sex Predilection

Lactotroph adenoma occurs more common in men than women (20–50 years). Increased synthesis of prolactin can be caused by hypothalamic lesions or by medication of methyldopa, or reserpine that interfere with dopamine (prolactin-inhibitory factor) secretion. Lactotroph adenoma can also be associated with estrogen therapy.

Clinical Features

Young women present with amenorrhea, galactorrhea and infertility. There is increased concentration of serum prolactin level. Increased prolactin level inhibits LH, which is essential for ovulation. Men present with decreased libido and erectile dysfunction.

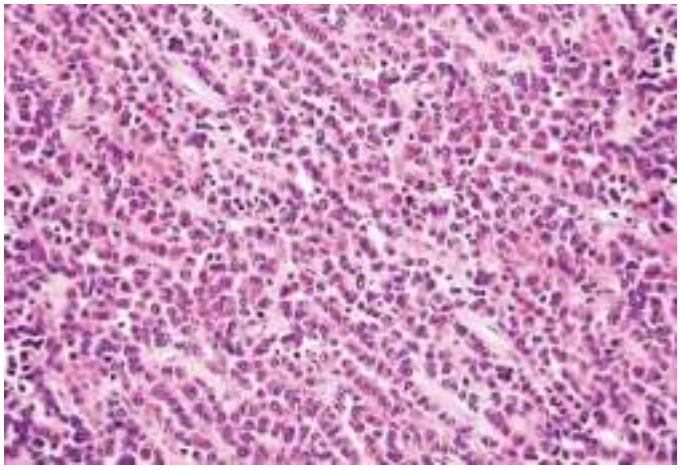

Fig. 26.75: Lactotroph adenoma (prolactinoma). Tumor consists of acidophilic or chromophobe cells (100X).

Management

Functional lactotroph adenoma is treated with dopamine agonists to inhibit prolactin synthesis. Macroadenoma may require surgery or irradiation.

Tumor resected post-therapy usually shows interstitial fibrosis and reduction in size. Tumor cells show low proliferative index and focally positive for prolactin.

SOMATOTROPH ADENOMA

Somatotroph adenoma is the second most common pituitary tumor, which secretes growth hormone, causing acromegaly or gigantism.

- Most cases of acromegaly are diagnosed in the fourth and fifth decades. Gigantism most often affects infants and children.
- Somatotroph adenoma arising before epiphyseal closure in children or adolescents cause gigantism. However, adenoma originating after the fusion of epiphyses of the long bones leads to acromegaly in adults. Expansion of the tumor within the sella turcica may cause local compression effects.
- Patient develops acromegaly due to combined effects of growth hormone, somatomedin C and insulin-like growth factor 1, headache, and symptoms due to compression of optic chiasma. Patient also develops generalized enlargement of viscera.

Growth Hormone

- Growth hormone is synthesized by somatotropes in the anterior pituitary gland, which has growth promoting and anti-insulin actions. Growth hormone is essential for linear bone growth in children.
- Growth hormone increases rate of transport amino acids across cell membranes and utilization of fatty acids. Growth hormone decreases the utilization of carbohydrates. Mechanism of action of growth hormone is given in Table 26.49. Growth promoting and anti-insulin effects of growth hormone are shown in Fig. 26.76.

Clinical Features

Clinical manifestations of acromegaly are shown in Fig. 26.77.

- **Head and neck:** Patient has prominent frontal and orbital ridges, coarsened features, recurrent serous otitis media, macroglossia, prominent jaw and thyroid enlargement.
- **Axilla:** There is increased perspiration in axillae.
- **Cardiovascular system:** Patient presents with hypertension, heart failure, cardiomegaly, edema and breathlessness.
- **Skeletal system:** Patient presents with barrel chest, enlarged hands, paresthesia in hands, broad feet, joint

Table 26.49 Mechanism of action of growth hormone

Actions	Effects
Growth promoting actions	
Growth hormone stimulates liver to synthesize IGF-1 (insulin-like growth factor 1)	▪ IGF-1 increases linear growth of bone and cartilage ▪ IGF-1 participates in increase in size of organs and their functions ▪ IGF-1 increases lean muscle mass ▪ IGF-1 participates in protein synthesis
Anti-insulin actions	
Growth hormone has anti-insulin actions	▪ Growth hormone promotes lipolysis, utilization of fatty acids leading to decrease in adiposity ▪ Growth hormone decreases utilization of glucose leading to increased blood sugar level

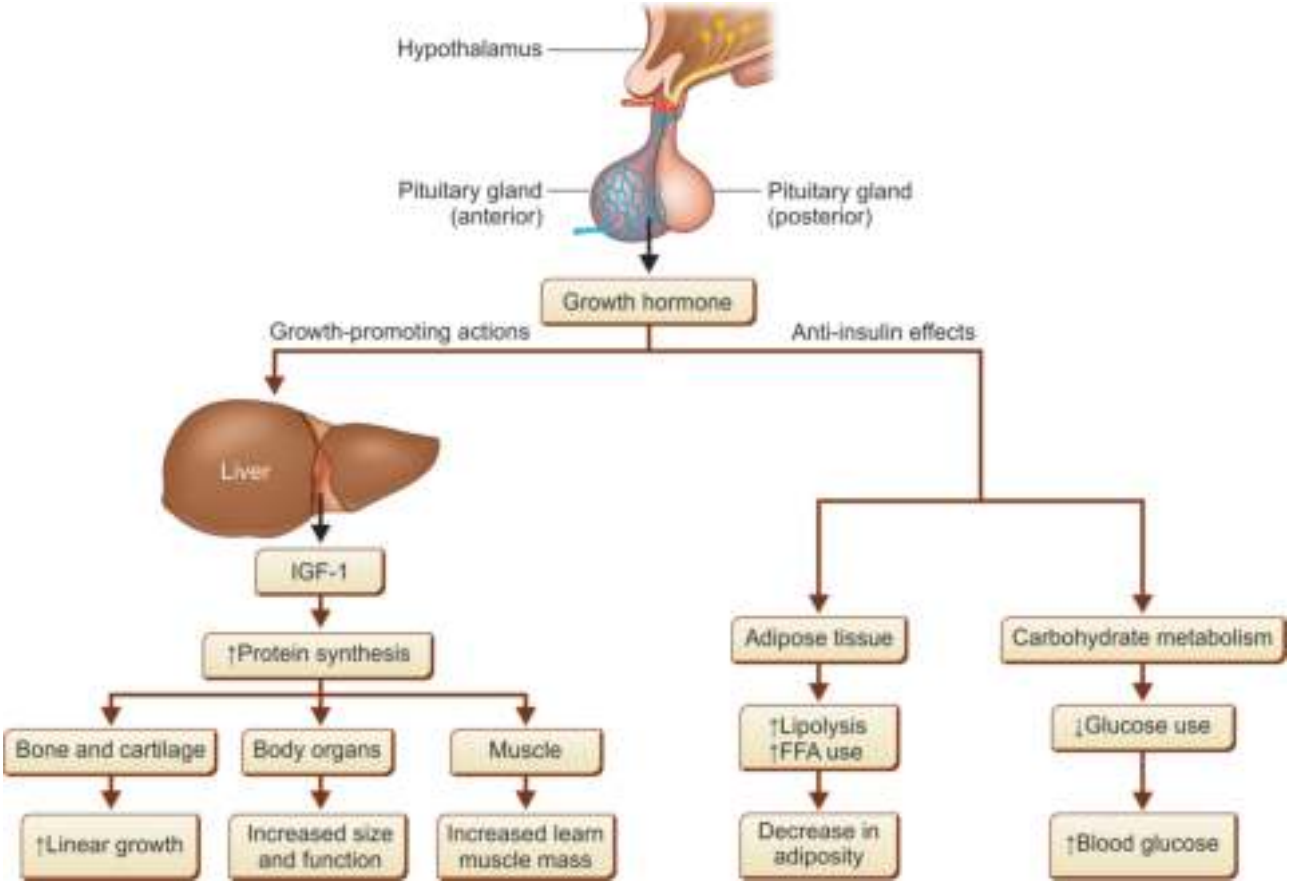

Fig. 26.76: Growth promoting and anti-insulin effects of growth hormone (FFA, free fatty acids; IGF-1, insulin-like growth factor 1).

pain, degenerative arthritis, peripheral neuropathy, and myopathy.

- **Skin:** Patient develops pigmentation and thickened skin.
- **Sexual problems:** Male develops sexual dysfunction. Female presents with menstrual disturbances.

Diagnostic Serum Marker

Growth hormone excess causes elevation in serum concentration of insulin-like growth factor 1 (somatomedin C) by the liver, measurement of which is a reliable indicator of disease activity.

CORTICOTROPH ADENOMA

Corticotroph adenoma secretes excess of ACTH, resulting in Cushing's syndrome of pituitary origin (Cushing's disease). It is five times more frequent than adrenal tumor associated with Cushing's syndrome.

Clinical Features

Patient develops hypercorticism most often of pituitary gland origin and less often of adrenal origin. It is worth mentioning that ectopic ACTH production occurs in small cell lung carcinoma.

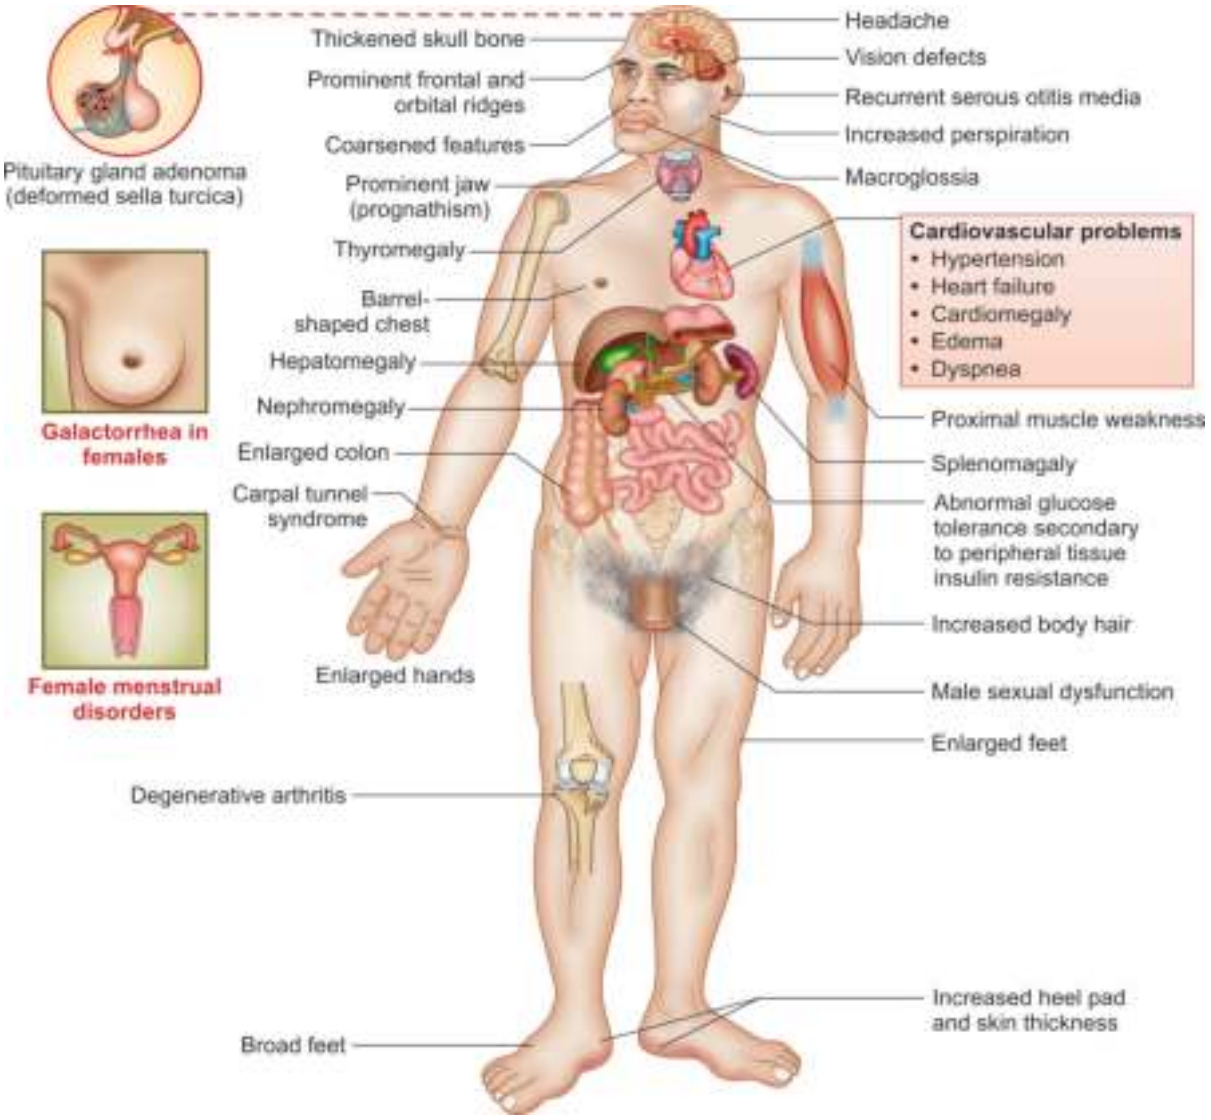

Fig. 26.77: Clinical manifestations of acromegaly. Growth hormone excess leads to enlargement of hands, feet and skull.

Dexamethasone Suppression Test

Dexamethasone suppression test distinguishes between ACTH-dependent and ACTH-independent forms of Cushing's syndrome.

Dexamethasone suppresses pituitary secretion of corticotropin, whereas it has no effect in cases of adrenal hyperplasia or functional adrenal tumors.

MIXED SOMATOTROPH–LACTOTROPH ADENOMA

Tumor consists of two types of cells: somatotropic cells synthesize growth hormone and lactotropic cells secrete prolactin.

Clinical Features

Approximately 50% of tumors with acromegaly, excess synthesis of prolactin causes loss of libido and erectile dysfunction in men.

Management

Patients are treated with dopamine agonists, which inhibit prolactin secretion.

CRANIOPHARYNGIOMA

Craniopharyngioma is an infiltrative epithelial tumor located in the region of the pituitary fossa above the sella turcica. It does not secrete hormones.

Tumor Origin

Tumor is derived from remnants of Rathke's pouch located above the sella turcica, the embryological source of the anterior pituitary gland. It is similar to ameloblastoma of the jaw.

Pathology

Clinical manifestations vary depending on destruction or pressure caused by tumor. Destruction of either/or

both lobes of pituitary gland result in hypopituitarism. It causes local destruction displacing the midline structures in the region of the hypothalamus.

Clinical Features

Tumor compresses the pituitary gland and damages the overlying hypothalamus and optic chiasma, presenting with either hypopituitarism or visual disturbances with bilateral hemianopia (loss of peripheral visual fields) or hydrocephalus and headaches in children between 10 and 20 years. Cranial nerve damage by tumor causes palsies.

- Patient often presents with diabetes insipidus due to ADH deficiency, which is characterized by an inability to concentrate the urine, with consequent chronic water diuresis, thirst, and polydipsia.
- Approximately 25% of cases of central diabetes insipidus are associated with brain tumors, particularly craniopharyngioma.

Surgical Pathology: Craniopharyngioma

Gross Morphology

- Tumor shows solid and cystic areas. It also shows areas of calcification.
- The cyst is filled with thick fluid containing lipid derived from breakdown of the lining epithelium.

Light Microscopy

- Tumor is composed of solid and cystic areas. Cystic areas are lined by nests and cords of squamous or columnar cells in a loose stroma, closely resembling the appearance of the embryonic tooth bud enamel organ.
- It is most often lined by flat or columnar cells resulting in papillary projections (Fig. 26.78).

Immunohistochemistry Technique

β-Catenin gene mutation study is useful in the diagnosis of colorectal adenocarcinoma versus adenocarcinomas of other sites, craniopharyngioma, solid and pseudopapillary tumor of the pancreas, and other neoplasms.

Radiological Analysis

Calcification in craniopharyngioma apparent on radiograph is often prominent; facilitating diagnosis.

Recurrence of Tumor after Surgical Excision

Although craniopharyngioma is benign, local recurrence is often a problem because of inability to completely excision of infiltrative tumors.

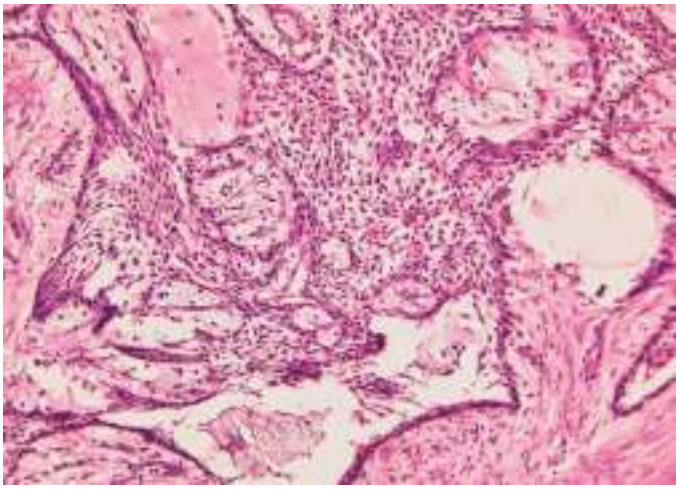

Fig. 26.78: Craniopharyngioma—tumor is composed of solid and cystic areas. Solid areas exhibit solid sheets of well-differentiated nonkeratinizing squamous epithelium (400X).

LEARNING OBJECTIVES

DISORDERS OF BONES

- Bones: overview
  - Cells in normal bone
  - Histology
  - Bone diseases

OSTEOMYELITIS (BONE INFECTION)

- Pyogenic osteomyelitis
- Tubercular osteomyelitis

METABOLIC BONE DISEASES

- Metabolic bone disease: overview
  - Rickets
  - Osteomalacia
  - Renal osteodystrophy
  - Calcification in tissues
  - Osteitis fibrosa cystica
  - Osteoporosis
  - Paget's disease of bone (osteitis deformans)
  - Scurvy

BONE TUMORS

- Bone tumors: diagnostic approach
  - Clinical features
  - Physical examination
  - Imaging studies
  - Histologic examination
  - Immunohistochemistry Technique
  - Staging system
  - Grading system
- Chondrogenic tumors
  - Chondromas (enchondroma and periosteal chondroma)
  - Enchondromatosis (Ollier disease)
  - Osteochondroma
  - Chondroblastoma
  - Chondromyxoid fibroma
  - Conventional chondrosarcoma (grades 1, 2, 3)
  - Dedifferentiated chondrosarcoma
  - Mesenchymal chondrosarcoma
  - Clear cell chondrosarcoma
- Osteogenic tumors
  - Osteoma
  - Osteoid osteoma
  - Osteoblastoma
  - Conventional intramedullary osteosarcoma
  - Low-grade central osteosarcoma
  - Telangiectatic osteosarcoma
  - Small cell osteosarcoma
  - Parosteal osteosarcoma
  - Periosteal osteosarcoma
  - High-grade surface osteosarcoma
- Ewing sarcoma/primitive neuroectodermal tumor
  - Ewing sarcoma
- Adamantinoma
- Osteoclastic giant cell-rich bone tumors and cystic lesion
  - Giant cell tumor of bone (osteoclastoma)
  - Aneurysmal bone cyst
- Notochordal tumors
  - Conventional chordoma
- Fibrogenic bone tumors
  - Desmoplastic fibroma of bone
  - Fibrosarcoma of bone
- Fibrohistiocytic tumors of bone
  - Benign fibrous histiocytoma nonossifying fibroma (metaphyseal fibrous defect)
  - Malignant fibrous histiocytoma of bone
- Hematopoietic neoplasms of bone
  - Multiple myeloma
  - Primary bone marrow lymphoma (PBML)
- Bone tumors of undefined neoplastic nature
  - Simple bone cyst
  - Fibrous dysplasia of bone
  - Osteofibrous dysplasia (ossifying fibroma)
  - Langerhans cell histiocytosis
  - Erdheim-Chester disease
  - Chondromesenchymal hamartoma
  - Rosai-Dorfman disease
  - Achondroplasia
  - Osteogenesis imperfecta
  - Osteopetrosis
  - Osteonecrosis (avascular necrosis)
- Secondary bone tumors (metastatic bone disease)

DISORDERS OF JOINTS

- Classification of joints
- Arthritis of probable autoimmune origin
  - Rheumatoid arthritis
  - Ankylosing spondylitis
- Degenerative disease of joints
  - Osteoarthritis
- Arthritis of metabolic origin
  - Gouty arthritis
  - Chondrocalcinosis (pseudogout)
  - Ochronosis of joints
- Infective arthritis
  - Gonococcal arthritis
  - Lyme arthritis
  - Tubercular arthritis
- Miscellaneous disorders of joints
  - Hypertrophic osteoarthropathy
  - Ganglion cyst
  - Tibial pseudoarthrosis

DISORDERS OF BONES

BONES: OVERVIEW

Bone comprises osteocytes, osteoblasts and osteoclasts, which are related to bone formation, bone maintenance, and resorption of the bone matrix.

- Bone also contains fibroblasts, and blood vessels. The joint space of the mature bone and growth plate of the growing long bones contain cartilage cells.
- The bone marrow contains hematopoietic cells and adipocytes. Osteoblast derived proteins of bone matrix are given in Table 27.1. Most common type of collagen found in the bone is type 1 collagen.

CELLS IN NORMAL BONE

- **Osteocytes:** Osteocytes are mature resting cells involved in the maintenance of the basic functional and anatomic units of bone, called osteons. Osteocytes participate in the maintenance of the blood concentration of calcium and phosphate.
- **Osteoblasts:** Osteoblasts are bone forming cells, which synthesize osteoid and participate in its calcification, which can be stimulated by parathormone (PTH), vitamin D, and estrogens.

Table 27.1 Osteoblast derived proteins of bone matrix

Categories	Examples
Collagen fibers	Collagen fibers type 1
Cell adhesion proteins	Osteopontin, thrombopontin and fibronectin
Proteins participating in mineralization	Osteocalcin
Calcium binding proteins	Osteonectin, bone sialoprotein
Enzymes	Alkaline phosphatase, collagenase
Growth factors	Insulin-like growth factor (IGF), TGF-β, platelet-derived growth factor (PDGF)
Cytokines	IL-1, IL-6

- **Osteoclasts:** Osteoclasts participate in resorption of bone, which are closely related to macrophages. Thus, they are derived from the same bone marrow precursors responding to granulocyte macrophage colony stimulating factor (GM-CSF). In contrast to mononuclear macrophages, osteoclasts are multinucleated.

HISTOLOGY

- **Woven bone:** Woven bone is newly formed bone in growing children and composed of haphazardly arranged strands of collagen, appearing like woven cloth when examined microscopically under polarized light.
- **Lamellar bone:** Woven bone gradually transforms into lamellar bone and is composed of parallel arrays of mineralized osteoid, which is stronger and more resistant to stress. Lamellar bone is a typical component of adult bones.

BONE DISEASES

Bones are affected by numerous developmental, metabolic, infectious and neoplastic diseases. Bones are also prone to mechanical trauma. Most common site of infection and tumors is the fastest growing end of the long bones. Genetic disorders may result in the formation of short, deformed, or structurally abnormal bones.

- Patient presents with focal pain in fracture/trauma, osteomyelitis, or osteoid osteoma. Diffuse pain occurs due to bone metastases, osteoporosis, and osteomalacia. Focal or diffuse pain is observed in bone metastases and Paget's disease of bone. Salient features of non-neoplastic bone disorders are given in Table 27.2.
- Avascular necrosis of bone occurs in femoral head, proximal scaphoid, posterior talus, tibia, lunate and navicular bone due to absence of collateral arterial supply.

Table 27.2 Salient features of non-neoplastic bone disorders

Tumor/Lesion	Location	Age	Radiologic Findings	Pathologic Findings	Differential Diagnosis
Congenital/ developmental disorders	Diffuse, sometimes localized; usually symmetrical	<10	Modeling abnormality	Disease-dependent	Very broad
Traumatic disorders	Any part of bone	Any	Fracture lines; dislocation	Hemorrhage; organization; woven bone and chondroid matrix	Osteosarcoma and chondrosarcoma
Circulatory disorders					
Avascular necrosis	Convex ends of long bones	5–40	Wedge-shaped radiodensity: crescent sign; collapse of articular cartilage	Necrotic marrow and bone; subarticular plate fracture	None

Contd...

Table 27.2 Salient features of non-neoplastic bone disorders (*Contd...*)

Tumor/Lesion	Location	Age	Radiologic Findings	Pathologic Findings	Differential Diagnosis
Idiopathic infarction	Medulla of long bones	>20	Serpiginous radio-opacities	Necrotic marrow and bone; calcification and ossification of marrow fat	Enchondroma
Metabolic disorders					
Paget's disease of bone (osteitis deformans)	Any portion of any bone; almost always extending to articular end	>50	▪ *Early:* Bone resorption in wedge-shaped edge ▪ *Later:* Coarse trabeculation: loss of corticomedullary differentiation	Osteoclastic resorption + increased vascularity and marrow fibrosis: *Mosaic* cement lines in middle to late stages	Hyperparathyroidism; myelodysplasia and myelofibrosis; metastatic carcinoma
Infectious disorders					
Hematogenous	Cortex of long bones	2–15	▪ *Early:* ↑Uptake on bone scan; change of marrow signal on MRI ▪ *Later:* Mixed sclerosis and radiolucency	Marrow fibrosis with osteonecrosis and exudate/mixed inflammatory cell infiltrate	Round cell tumors and Langerhans cell histiocytosis
Direct	Any; open trauma or deep ulcer	Varies	Mixed sclerosis and radiolucency	Marrow fibrosis with osteonecrosis and exudate/mixed inflammatory cell infiltrate	Round cell tumors and Langerhans cell histiocytosis

OSTEOMYELITIS (BONE INFECTION)

Osteomyelitis is inflammation of bone marrow caused by bacteria. Infectious organisms may reach the bone through the bloodstream.

- Osteomyelitis primarily affects the metaphyseal region of the long bones of extremities around knee, ankle, and hip joints because of the unique vascular supply in these regions.
- Normally, arterioles entering calcified portion of the growth plate form a loop, and then drain into the medullary cavity without establishing a capillary bed.
- Slow blood flow into vascular loop allows more time for the bacteria to invade the walls of the blood vessels and establish an infective focus within bone marrow.

PYOGENIC OSTEOMYELITIS

Pyogenic osteomyelitis may affect neonates, children, adolescents and adults described as under.

AGE GROUP

Pyogenic Osteomyelitis in Children and Adolescents

- *Staphylococcus aureus* is the most common cause of pyogenic osteomyelitis in children >14 years of age due to penetrating injuries and post-surgical wounds.
- In growing bones of the children, most bone infection begins predominantly in the highly vascularized growth plate (metaphyseal region) of long bones, with greatest blood flow in the nutrient artery.
- Pyogenic osteomyelitis most often involves femur (distal end), tibia (proximal end) and humerus (proximal end). Salmonella infection causing osteomyelitis is frequent in association with sickle cell anemia.

Pyogenic Osteomyelitis in Adults

Pyogenic osteomyelitis occurs usually as a complication of compound fracture or sequelae of surgery. Osteomyelitis is an uncommon complication of closed fracture. Osteomyelitis in adults most often begins in epiphyseal and subchondral locations due to hematogenous dissemination of *Staphylococcus aureus*.

- Hematogenous dissemination of *Escherichia coli*, *Pseudomonas* and *Klebsiella* species occurs in urinary tract infection and intravenous drug addicts.
- *Pseudomonas aeruginosa* infection also occurs through nail puncture in persons wearing rubber footwear.
- Patient may develop osteomyelitis due to extension of infection from contiguous sites (e.g. periodontal abscess).

Pyogenic Osteomyelitis in Neonates

Haemophilus influenzae, *Escherichia coli* and Streptococci group B (β-hemolyticus) are responsible for pyogenic osteomyelitis in neonates.

ANATOMICAL ASPECT

Metaphyseal arteries give terminal branches and forming irregular loops of afferent venous sinusoids at growth plate. Blood flow becomes slow and turbulent in the regions of growth plate in metaphyseal region of bone, predisposing to bacterial seeding.

In addition, bone lining cells (BLCs) in metaphyseal region have little or no phagocytic activity. This region becomes a catch basin for bacteria and forms an abscess.

PATHOGENESIS

Focus of infection in the metaphysis of long bones attracts polymorphonuclear cells. Entire bone marrow cavity space becomes edematous due to exudates. In the acute stage, pyogenic osteomyelitis may resolve with antibiotic therapy.

Chronic pyogenic osteomyelitis results from persistent suppurative acute infection of bone. Sequence of events in the pathogenesis of pyogenic osteomyelitis is shown in Fig. 27.1.

Sequestrum (Necrotic Bone) Formation

Due to rigid structure and limited bone space, inflammatory exudates in bone marrow cavity compress endosteal blood vessels and impair the inflow of blood.

- Pyogenic abscess, limited by growth plate, spreads transversely along 'Volkmann haversian canals' and elevates the periosteum. It will further compress the perforating blood vessels of periosteum in subperiosteal region. Then it extends subperiosteally and may invade shaft of bone in infants of less than one year of age.
- Some metaphyseal arterial branches pass through growth plate, and infection may invade epiphysis and joints.
- Osteolytic enzymes detach dead bone from main bone that floats inside the abscess cavity. The necrotic bone is called a sequestrum (Fig. 27.2).

Involucrum (Reactive Viable Bone Formation)

Involucrum is the formation of reactive viable bone in the periosteum that surrounds necrotic bone (sequestrum) in pyogenic 'osteomyelitis' (Fig. 27.3A).

Brodie Abscess (Chronic Bone Pyogenic Abscess)

Brodie abscess is a chronic bone pyogenic abscess, which consists of dense reactive bone from the periosteum and endosteum that surrounds and contains infective focus (Fig. 27.3B and C).

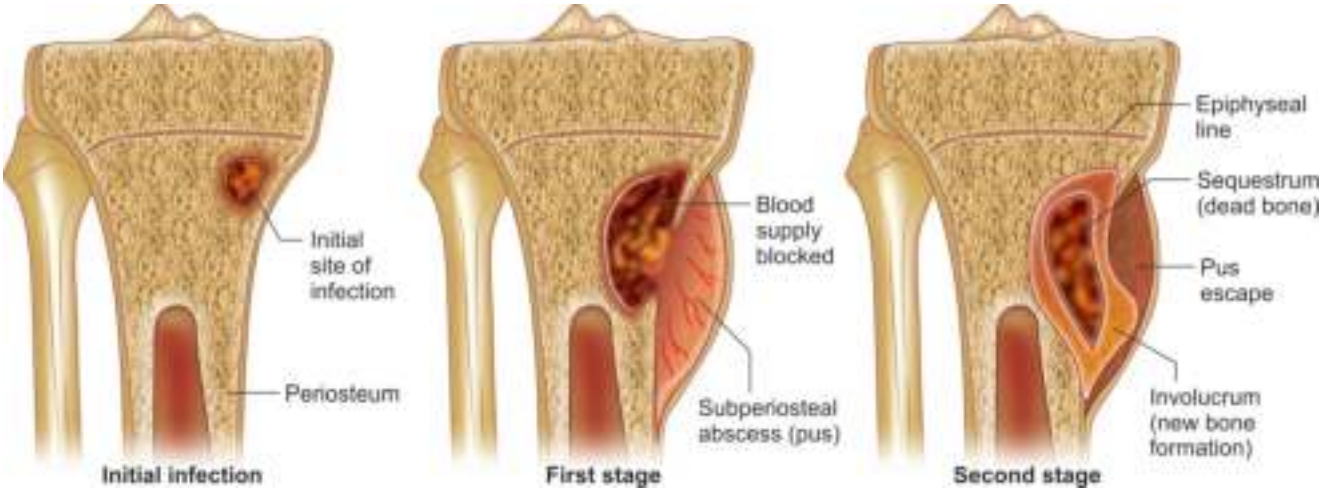

Fig. 27.1: Osteomyelitis shows stages of abscess formation, sequestrum and involucrum.

Fig. 27.2: Acute osteomyelitis. There is a large collection of pus in the medullary cavity of the shaft of the femur (arrows).

Cloacae Cortical Defect in Pyogenic Osteomyelitis

Cloaca is the hole found in the bone during formation of a draining sinus. Pyogenic osteomyelitis may erode periosteum and form discharging sinuses onto the skin surface of the body through holes in bones. Process of cloaca in the bone is influenced by virulence of organism, development of host resistance to administration of antibiotics and fibrotic and sclerotic responses.

RADIOGRAPHIC FINDINGS

Initially, bony lesion is osteolytic in pyogenic osteomyelitis. Sclerosis appears only after the disease has progressed and persisted for >2 months. Early diagnosis of pyogenic osteomyelitis is made by **Indium-labeled leukocytic scintigram**, which shows focal signal increase in the site of infection.

Fig. 27.3A: Chronic osteomyelitis. This specimen shows death of shaft of the tibia. This has separated completely as a sequestrum. New bone—an involucrum has formed around the dead bone. Lacunae open through the involucrum and result in discharging sinuses on the skin surface (arrow).

CLINICAL FEATURES

Patient with pyogenic osteomyelitis of long bone presents with fever, pain and tenderness (most common), swelling in acute cases; later followed by discharging sinuses onto the skin surface, effusions in adjacent joints and limitation of joint movement.

- In acute pyogenic osteomyelitis, peripheral blood shows leukocytosis and blood culture may be positive.
- Systemic manifestations in vertebral involvement are usually milder. Pain may be principal manifestation especially in adults.

COMPLICATIONS

- Pyogenic osteomyelitis fails to resolve in 5–25% of patients, which progresses to chronic osteomyelitis. The weakened bone is prone to fracture complicated by pyogenic osteomyelitis, which fails to heal and resulting in development of pseudoarthrosis.
- Pyogenic osteomyelitis may be complicated by secondary (reactive systemic) amyloidosis and cutaneous squamous cell carcinoma within sinus tract.

Fig. 27.3B: Brodie's abscess in diaphysis of tibia. Radiograph demonstrates a well-defined, vertically oval, intramedullary osteolytic lesion with narrow zone of transition in distal metaphysis of tibia. The lesion does not show any new bone formation. No periosteal cortical break is seen. No periosteal reaction or swelling or calcification seen. These findings are suggestive of infective etiology: Brodie's abscess in diaphysis of left tibia shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

Fig. 27.3C: Osteomyelitis of skull in 45-year-old patient with history of road traffic accident. Skull radiograph demonstrates diffuse lytic bone destruction with moth-eaten appearance and soft tissue component involving the frontal bone and maxilla. Few punctate shaped bony fragments are noted involving superficial soft tissues in frontal region. Findings are suggestive of osteomyelitis shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

TUBERCULAR OSTEOMYELITIS

Tubercular osteomyelitis occurs most commonly secondary to hematogenous extension from a primary tubercular focus in the lung, which principally targets the vertebral column, called *Pott's disease* in 1–3% of people. Vertebral body destruction may result in impingement on the spinal cord (Fig. 27.4). Tubercular oseomyelitis also targets hip bone, long tubular bones (femur, tibia) and small bones (hands, feet).

However, any bone may be affected in tubercular osteomyelitis. In the long tubular bones, tuberculosis originates in the epiphysis and disseminates to the adjacent joint. This feature differentiates tubercular osteomyelitis from pyogenic osteomyelitis, which starts in the metaphysis but cannot extend to the epiphysis in children. Tubercular dactylitis occurs frequently in young children.

CLINICAL FEATURES

Patient presents with fever, fatigue, bone pain, soft tissue swelling decreased range of motion, difficult ambulation and discharging sinuses (Fig. 27.5).

Surgical Pathology: Tubercular Osteomyelitis

Light Microscopy

- In tubercular osteomyelitis marrow shows fibrosis infiltrated by chronic inflammatory infiltrate composed of lymphocytes, macrophages and plasma cells.
- Caseous necrosis and epithelioid cell granulomas are present.

COMPLICATIONS

Patient may develop many complications such as deformities of bones, pathologic fractures, secondary amyloidosis or squamous cell carcinoma. The skin at the edges of sinus tracts draining the pus from the infected bone may undergo malignant transformation.

LABORATORY DIAGNOSIS

In tubercular osteomyelitis, radiograph demonstrates cortical destruction, juxtacortical abscess formation, and medullary infarction.

- Pus culture and sensitivity performed in patients with tubercular osteomyelitis may demonstrate pyogenic bacteria due to superadded infection.
- Patients with tubercular osteomyelitis do not respond to antibiotic therapy. Biopsy may not demonstrate epithelioid cell granulomas.

Fig. 27.4: Tuberculosis in the spine of a young boy (Pott's fracture of the vertebrae). In spinal tuberculosis, there is destruction of the intervertebral disk space and the adjacent vertebral bodies, collapse of the spinal elements, and anterior wedging leading to the characteristic angulation and gibbus (palpable deformity due to involvement of multiple vertebrae) formation shown by arrow.

Fig. 27.5: Tuberculous psoas abscess. Two lumbar vertebrae involved by tuberculosis with extension of the caseation into the psoas muscle. When such infection spreads along the psoas, the abscess may point in the groin (arrow).

- Therefore, in every case of osteomyelitis with discharging sinuses, blood culture on Lowenstein-Jensen medium should be done. Imaging techniques are employed as diagnostic tools.

METABOLIC BONE DISEASES

Metabolic bone disease refers to osteopenia (diffuse radiolucency of bone). It occurs due to abnormalities in vitamin D metabolism, phosphate deficiency and defects in the mineralization process. Vitamin D deficiency causes rickets in children and osteomalacia in adults. Intramembranous ossification occurs in multiple skeletal healing scenarios. Mesenchymal cells form osteoblasts, resulting in formation of collagenous osteoid matrix. Endochondral ossification occurs in the development of long tubular bones. Growing cartilage at epiphyseal plate gets mineralized, and then resorbed and is replaced by osteoid matrix and then mineralized to form bone.

METABOLIC BONE DISEASE: OVERVIEW

RICKETS

Rickets is the softening and weakening of bones in children usually due to an extreme and prolonged vitamin D deficiency.

Rickets is caused by failure of action of calcitriol (1,25-dihydroxycholecalciferol), the active form of vitamin D in children and due to diet deficient in vitamin D, lack of exposure to sunlight, intestinal malabsorption, renal and liver disease. The bony abnormalities in rickets occur due to decreased bone mineralization (calcification), which results in excessive accumulation of unmineralized matrix (osteoid), wide osteoid seams, increased thickness of the epiphyseal growth plates and other skeletal deformities. During infancy, head and neck are under greatest stress; hence changes are marked in these regions. Clinical features are given in Table 27.3 and Fig. 27.6.

Pathology Pearls: Key Features of Vitamin D

Vitamin D occurs in two forms, i.e. vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol).

- **Sources:** Vitamin D may be derived from endogenous (80%) or exogenous (20%) sources. Endogenous source exists in the form of dehydrocholesterol in the skin. When skin is under exposure to ultraviolet rays, dehydrocholesterol is converted into vitamin D_3 (cholecalciferol).
- **Metabolism:** After absorption, vitamin D combines with α-globulin, and 2-hydroxyvitamin D (vitamin D_2) is formed in the liver. Vitamin D_2 to vitamin D_3 (active form of vitamin D) conversion takes place in kidneys. Low level of serum calcium augments the conversion of vitamin D_2 to vitamin D_3. Vitamin D is stored in adipose tissue.
- **Functions:** Vitamin D maintains normal plasma levels of calcium and phosphorus. Vitamin D enhances calcium absorption by small intestine. It collaborates with parathormone in mobilization of calcium from bone. It stimulates parathormone-dependent absorption of calcium in distal tubular cells parathormone. It is requisite for normal mineralization of epiphyseal cartilage and osteoid.

OSTEOMALACIA

Osteomalacia is softening of bones in adults and characterized by inadequate mineralization, i.e. calcification

Table 27.3 Clinical features of rickets

Terms	Clinical Findings
Craniotabes	There is thinning and softening of occipital and parietal bones. There is late closure of fontanelles
Frontal bossing	Frontal bone is squared due to increased formation of osteoid
Rachitic rosary	Thickening of costochondral junction occurs due to overgrowth of cartilage and osteoid tissue results in a string of beads-like appearance
Harrison's groove	A depression occurs along the line of insertion of the diaphragm into the rib cage due to inward pull of diaphragm
Pigeon-shaped chest	Anterior protrusion of sternum occurs due to inward pull of metaphyseal areas of ribs by respiratory muscles
Pelvis bones	Pelvis bones are deformed
Spine deformity	Lumbar lordosis occurs, when child is ambulatory

Fig. 27.6: Rickets in a two-year-old male child. Radiograph demonstrates irregular fraying and cupping of metacarpals with growth-plate widening. Findings are suggestive of rickets shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

of newly formed bone matrix. The bones are susceptible to fracture, but few with bone deformities.

Etiopathogenesis

Vitamin D deficiency in adults occurs due to malabsorption syndrome (commonest cause), chronic kidney disease (renal osteodystrophy) and paraneoplastic syndrome due to PTH-like protein synthesized by squamous cell lung carcinoma, breast carcinoma, ovarian carcinoma and Fanconi's syndrome. Osteomalacia in Fanconi's syndrome occurs due to renal wastage of phosphate, amino acids and glucose in urine.

Clinical Features

Patient presents with bone pain and tenderness, and weakness of proximal limb muscles.

Radiologic Findings

- Spontaneous incomplete fractures (looser's zones) often occur in the long bones or pelvis. Vertebral bodies become biconcave due to central compression of softened vertebrae by intervertebral discs.
- These bone changes can be reversed by supplementing the diet with adequate amounts of vitamin D and normalization of calcium metabolism.

Surgical Pathology: Osteomalacia

Light Microscopy

- In osteomalacia, the bony trabeculae are normal in thickness and rimmed by broad bony spicules of osteoid (incompletely calcified) lined by osteoclasts.
- Central portion of bony spicules are normally calcified, but their peripheral portion uncalcified.
- On the other hand, the bone spicules in osteoporosis are thin but normally mineralized.

Blood Biochemistry

Blood calcium is decreased. Serum alkaline phosphatase is increased due to increased activity of osteoblasts. These biochemical changes are absent in osteoporosis.

RENAL OSTEODYSTROPHY

Bone changes in chronic renal failure are known as renal osteodystrophy. Patient develops clinical, radiologic or pathologic evidence of bone diseases, i.e. osteoporosis, osteomalacia, bone necrosis, and soft tissue calcification.

Pathogenesis

- **Physiologic state:** Normally, $25(OH)_2D_3$ (inactive form) is converted to the systematically $1,25(OH)_2D_3$ by the renal enzyme 1α-hydroxylase. Vitamin D_3 participates in absorption of calcium by intestine.
- **Pathologic state:** In chronic renal disease, kidneys fail to convert vitamin D_2 to vitamin D_3 (active form).
  - Prolonged hemodialysis inhibits calcification of osteoid leading to osteomalacia. High level of serum phosphates inhibits renal enzymes catalyzing formation of $1,25(OH)_2D_3$. Therapeutic administration of steroid in patients with chronic glomerulonephritis causes osteoporosis and avascular necrosis of bone.
  - Nonavailability of vitamin D_3 results in decreased ionized calcium in serum, which stimulates parathyroid glands to synthesize parathormone.
  - Parathormone causes resorption of bone resulting in osteomalacia. Disordered remodeling of such bones leads to alternating areas of thickened bone (osteosclerosis) and osteoporosis. In renal osteodystrophy, spine shows '**rugger jersey appearance**'.

CALCIFICATION IN TISSUES

Deposition of calcium in tissues is demonstrated by imaging technique and light microscopy.

- Nephrocalcinosis can cause interstitial nephritis further aggravating kidney disease.
- Calcium deposition occurs in joint cartilage (chondrocalcinosis), periarticular region at the junction of metacarpals and proximal phalanges, and intra-articular and periarticular regions of shoulders.
- Calcium deposits in cornea are demonstrated by slit-lamp examination revealing band keratitis.
- Medial calcification occurs in tunica media of small size arteries, aorta and major branches.

OSTEITIS FIBROSA CYSTICA

Osteitis fibrosa cystica is a skeletal disorder caused by an increased synthesis of parathormone in late manifestation of primary hyperparathyroidism as a result of bone resorption by parathormone.

Pathogenesis

- Osteoclasts lining subperiosteum and endosteum invade the cortex. As the disease progresses, trabecular bone resorption occurs resulting in replacement of bone marrow by loose fibrosis and cystic degeneration.
- These areas contain reactive woven bone, and hemosiderin-laden macrophages and often display many giant cells, which are actually osteoclasts.
- The bone lesion has been termed a 'brown tumor of hyperparathyroidism'. This is not a true tumor, but rather a bone repair reaction.

Clinical Features

Patient presents with nephrolithiasis, nephrocalcinosis, calcification in blood vessels, epulis (mouth),

Table 27.4 Clinical manifestations of osteitis fibrosa cystica

Organs	Clinical Manifestations
Kidneys	Nephrolithiasis, nephrocalcinosis
Skull (X-ray)	Salt and pepper appearance
Bone	Cyst formation and fractures
Mouth	Epulis
Vertebrae	Codfishing of vertebrae
Blood vessels	Calcium deposition
Eye	Limbus keratopathy
GIT	Peptic ulcer disease
Pancreas	Pancreatitis
Miscellaneous	Multiple adenomas in endocrines

cod fishing of vertebrae, limbus keratopathy, peptic ulcer, pancreatitis and multiple adenomas in pituitary, thyroid gland, pancreas and adrenal glands. Clinical manifestations of osteitis fibrosa cystica are given in Table 27.4.

Laboratory Diagnosis

Blood tests on patients with osteitis fibrosa cystica generally show high levels of calcium, parathormone and alkaline phosphatase. Laboratory findings in metabolic bone disorders are given in Table 27.5.

OSTEOPOROSIS

Osteoporosis is characterized by decreased bone mass but otherwise normally mineralized bone, which occurs either due to impaired synthesis of bone matrix or increased resorption of bone matrix proteins. Bone loss and eventually fractures (hip, wrist, and vertebrae) are the hallmarks of osteoporosis. Serum calcium and phosphate levels are within normal range.

Types of Osteoporosis

Primary Osteoporosis

- Type 1 primary osteoporosis is more common in women with postmenopausal state due to estrogen deficiency. It occurs due to absolute increase in osteoclast activity.
- Type 2 primary osteoporosis occurs in elderly persons of both sexes, which reflects decreased osteoblastic activity.

Secondary Osteoporosis

Secondary osteoporosis results from a variety of identifiable conditions that may include: hyperparathyroidism, multiple myeloma or metastatic carcinoma, malnutrition, drug therapy (corticosteroids), prolonged immobilization and weightlessness with space travel.

Clinical Features

The affected bones in osteoporosis are unable to bear weight. Patient commonly develops compression fractures of the vertebrae resulting in spinal deformity (kyphosis most common) and shortened stature.

- **Axial osteoporosis:** Patient develops vertebral compression fractures in mid-thoracic or mid-lumbar region progression to thoracic kyphosis. Patient presents with continuous pain in acute phase and intermittent pain in chronic phase.
- **Appendicular osteoporosis:** Patient develops fractures caused by minimal trauma. Common sites of fracture in osteoporosis are head or neck of femur (intertrochanteric or intracapsular), vertebrae of thoracic or lumbar region, Colles fracture in distal radius and fracture of proximal end of humerus.

Laboratory Diagnosis

Radiographic measurement of bone density is the best diagnostic tool. Approximately 40% of bone mass must be lost before a routine radiograph will show signs of osteopenia.

- Radiograph shows diffuse radiolucency of bone. Increased risk for fracture correlates with decreasing bone density.
- Various imaging diagnostic techniques to measure bone density include single-photon absorptiometry, dual-photon absorptiometry, quantitative computed tomography, and dual X-ray absorptiometry.

PAGET'S DISEASE OF BONE (OSTEITIS DEFORMANS)

Paget's disease of bone is an increased thickness of abnormal bone architecture due to increased osteoclastic and osteoblastic activity.

- Paget's disease of bone results from disordered remodeling, in which excessive bone resorption initially results in osteolytic lesions, followed by disorganized and excessive bone formation.

Table 27.5 Laboratory findings in metabolic bone disorders

Disorders	Serum Calcium	Serum Phosphate	Alkaline Phosphatase	Parathormone (PTH)	Vitamin D
Osteoporosis	Normal	Normal	Normal	Normal	Normal
Osteomalacia	Low	High/low	High	Normal	Low/normal
Hyperparathyroidism	High	Low	Normal/high	High	Normal
Renal osteodystrophy	Normal/high	High	High	High	Normal

- There is marked increase in serum alkaline phosphatase (a manifestation of osteoblastic activity) and normal serum calcium and phosphorus levels.

Diagnostic Hallmark in Late Disease

Paget's disease of bone is characterized by abnormal arrangement of lamellar bone containing islands of irregular bone formation, which resembles pieces of a **jig-saw puzzle**, which are separated by prominent cement lines known as **mosaic pattern**.

Pathology Pearls: Morphologic Phases of Paget's Disease of Bone

There are three phases of Paget's disease of bone: osteolytic, mixed and late phases described as under:

- **Osteolytic phase:** Osteolytic phase causes resorption of bone.
- **Mixed phase:** Osteoblastic and osteoclastic phase's lead to new bone formation resulting in mosaic pattern.
- **Osteosclerotic phase:** Osteosclerotic phase is characterized by increased bone density, thickened trabeculae with prominent 'mosaic pattern'.

Age Group

Paget's disease of bone begins after the age of 40 years and mainly affects elderly males.

Predisposing Factors

Paget's disease of bone is of unknown etiology. Viral etiology has been suggested by presence of intranuclear inclusions in osteoclasts demonstrated by electron microscopy. The studies suggest the possible role of a slow virus infection by a paramyxovirus.

Pathogenesis

The majority of patients are first recognized by the presence of an unexpectedly high serum alkaline phosphatase level on biochemical analysis. There are three phases in the development of Paget's disease of bone described as under:

- **Osteoclastic phase:** In this phase, there is excessive resorption of bones.
- **Osteoclastic and osteoblastic phases:** Resorption of bones is followed by bone formation with raised alkaline phosphatase activity.
- **Osteosclerotic phase:** Osteosclerotic phase is followed by production of thick bone without a normal lamellar bone. The bones are weak in osteosclerotic stage.

Bones Involvement

Paget's disease of bone usually involves multiple bones (polyostotic) in 85% of cases or single bone (monostotic) in 15% of cases.

- **Polyostotic lesions:** Polyostotic lesions occur in spine (70%), pelvis (65%), skull (frontal and occipital regions), sacrum, femur, tibia or humerus.
- **Monostotic lesions:** In decreasing order of frequency, bones involved in monostotic lesions include tibia, pelvis, skull (frontal and occipital regions), femur, vertebrae and humerus. Bone changes begin in subchondral ends of tibia, femur and humerus.

Complications

- **Microfractures:** Although the affected bone is thick but it lacks strength, which becomes painful due to microfractures.
- **Anterior bowing of leg bones:** Anterior bowing of tibia and femur is common deformity.
- **Hearing loss:** It occurs due to narrowing of the auditory foramen and compression of the eighth cranial nerve or direct involvement of middle ear bones (malleus, incus, and stapes).
- **Frontal bossing:** It occurs due to head enlargement.
- **Narrowing of foramen magnum:** It occurs due to flattening of base of skull (platybasia) resulting in compression of spinal cord.
- **Osteosarcoma:** Approximately 1% of cases may develop osteosarcoma in a focus of Paget's disease of bone, usually in the femur, humerus, or pelvis.
- **Cardiovascular manifestations:** High output cardiac failure may result from multiple functional arteriovenous shunts within highly vascular early lesions.

SCURVY

Scurvy occurs due to deficiency of vitamin C and is characterized by defective formation of mesenchymal tissue and osteoid matrix; defective wound healing and hemorrhagic phenomena.

Vitamin C is required for hydroxylation of proline and lysine essential for synthesis of reticulin and collagen fibrils from mucopolysaccharide ground substance in wound healing.

Source of Vitamin C

Vitamin C is derived from fruits, vegetables, milk, liver and fish. It is not synthesized endogenously. Vitamin C is stored in the body (normal range 1.5–4.0 g).

Causes of Vitamin C Deficiency

Deficiency may be observed in elderly individuals and alcoholics. Peritoneal and hemodialysis patients and infants on processed milk may develop scurvy.

Clinical Features

Hemorrhages and wound healing defects occur in both children and adults.

Bleeding (Hemorrhages)

- Defective connective tissue also leads to fragile capillaries, resulting in abnormal bleeding.
- Infants and children present with hemorrhages in mucocutaneous and skeletal muscles along fascial planes at mechanical stress points due to loosened endothelial cells from capillaries especially in nail beds, subperiosteal hematomas, bleeding into spaces: joints, retrobulbar, subarachnoid, and intracerebral regions. In adults, ulceration and hemorrhage in gums occur due to loosening of teeth.

Skeletal Changes

- Bone changes in scurvy are secondary to defective osteoid matrix formation. Insufficient production of osteoid matrix results in cartilaginous overgrowth, widening of epiphysis, bowing of the long bones and chest deformity.
- Osteoporosis is seen especially at the metaphyseal ends of bone.

Other Changes

Patient presents with gingival swelling and periodontal infection, impaired wound healing, and anemia.

BONE TUMORS

Conventional approach to the classification of bone tumors is divided into various categories: chondrogenic, osteogenic, myogenic, fibrogenic, fibrohistiocytic, hematopoietic tissue, osteoclast-rich tumors, notochordal tissue, vascular tissue, and miscellaneous tissue of origin, tumors of undefined neoplastic nature and metastatic tumors.

- Primary benign bone tumors such as osteochondroma and osteoid osteoma are seven times more common than malignant tumors.
- Most common primary malignant bone tumors in decreasing frequency are multiple myeloma, osteosarcoma, chondrosarcoma, Ewing sarcoma and giant cell tumor of bone.
- Metastatic bone disease is more common than primary malignant tumors. Bone forming and fibrogenic tumors are more common. Recent 2020 WHO classification of bone tumors is given in Table 27.6. Most common metastatic tumors to bone are given in Table 27.7.

Table 27.6 Recent 2020 WHO classification of bone tumors

Chondrogenic Tumors

- Benign tumors
  - Osteochondroma
  - Chondroma (enchondroma, periosteal chondroma)
  - Osteochondromyxoma
  - Subungual exostosis
  - Bizarre parosteal osteochondromatosis proliferation
  - Synovial chondromatosis
- Intermediate tumors (locally aggressive)
  - Chondromyxoid fibroma
  - Atypical cartilaginous tumor/chondrosarcoma grade 1
- Malignant tumors
  - Chondrosarcoma grade 2
  - Chondrosarcoma grade 3
  - Dedifferentiated chondrosarcoma
  - Mesenchymal chondrosarcoma
  - Clear cell chondrosarcoma

Osteogenic Tumors

- Benign tumors
  - Osteoma
  - Osteoid osteoma
- Intermediate tumors (locally aggressive)
  - Osteoblastoma
- Malignant tumors
  - Low-grade osteosarcoma
  - Conventional osteosarcoma (chondroblastic osteosarcoma, fibroblastic osteosarcoma)
  - Telangiectatic osteosarcoma
  - Small cell osteosarcoma
  - Secondary osteosarcoma
  - Parosteal osteosarcoma
  - Periosteal osteosarcoma
  - High-grade surface osteosarcoma

Fibrogenic Tumors

- Intermediate tumor (locally aggressive)
  - Desmoplastic fibroma of bone
- Malignant tumors
  - Fibrosarcoma of bone

Fibrohistiocytic Tumors

- Benign tumors
  - Benign fibrous histiocytoma/nonossifying fibroma
- Malignant tumors
  - Malignant fibrous histiocytoma

Hematopoietic Neoplasms

- Malignant tumors
  - Plasma cell myeloma
  - Solitary plasmacytoma of bone
  - Primary non-Hodgkin's lymphoma of bone

Contd...

Contd...

Table 27.6 Recent 2020 WHO classification of bone tumors (*Contd...*)

Osteoclastic Giant Cell-rich Tumors

- Benign tumors
  - Giant cell lesion of the small bones
- Intermediate tumors (locally aggressive, rarely metastasizing)
  - Giant cell tumor of bone
  - Aneurysmal bone cyst
- Malignant tumor
  - Giant cell tumor of bone, malignant

Notochordal Tumors

- Low malignant tumor
  - Conventional chordoma
- Malignant tumors
  - Chondroid chordoma (conventional chordoma with chondroid component)
  - Poorly differentiated chordoma
  - Dedifferentiated chordoma

Vascular Tumors

- Benign tumors
  - Hemangioma
- Intermediate tumors (locally aggressive, rarely metastasizing)
  - Epithelioid hemangioma
- Malignant tumors
  - Epithelioid hemangioendothelioma
  - Angiosarcoma

Myogenic Tumors

- Malignant tumors
  - Leiomyosarcoma of bone

Contd...

Lipogenic Tumors

- Malignant tumor
  - Liposarcoma of bone

Tumors of Undefined Neoplastic Nature

- Benign tumors
  - Simple bone cyst
  - Fibrous dysplasia
  - Osteofibrous dysplasia
  - Chondromesenchymal hamartoma
  - Rosai-Dorfman disease
- Intermediate tumors (locally aggressive)
  - Langerhans cell histiocytosis (monostotic, polyostotic) (Letterer-Siwe disease, Hand-Schüller-Christian disease and eosinophilic granuloma)
  - Erdheim-Chester disease

Miscellaneous Tumors

- Ewing sarcoma
- Adamantinoma
- Undifferentiated high-grade pleomorphic osteosarcoma

Secondary Tumors (Metastatic Bone Disease)

- Adult males
  - Prostatic carcinoma
  - Lung carcinoma
- Adult females
  - Breast carcinoma
  - Thyroid carcinoma
  - Renal cell carcinoma
  - Endometrial carcinoma
  - Cervical carcinoma
- Children (males and females)
  - Rhabdomyosarcoma
  - Neuroblastoma
  - Clear cell sarcoma of kidney

Table 27.7 Most common metastatic tumors to bone

Age Group and Gender	Most Common Metastatic Tumors to Bone	Most Common Bone Sites
Adult males	▪ Prostatic carcinoma ▪ Lung carcinoma	▪ Axial skeleton ▪ Proximal femur ▪ Proximal humerus
Adult females	▪ Breast carcinoma ▪ Thyroid carcinoma ▪ Renal cell carcinoma ▪ Endometrial carcinoma ▪ Cervical carcinoma	Appendicular skeleton
Children (males and females)	▪ Rhabdomyosarcoma ▪ Neuroblastoma ▪ Clear cell sarcoma of kidney	Appendicular skeleton

- Clinical behavior of bone tumors under each category is different.
  - Benign bone tumors behave in a nonaggressive fashion with little tendency to recur locally after surgical excision without distant metastasis.
  - Intermediate bone tumors are locally aggressive with metastatic potential.
  - Malignant bone tumors such as osteosarcoma are capable of invasive locally destructive growth with recurrence tendency after surgical excision as well as metastatic potential to distant sites.

Table 27.8 Salient features of common primary malignant tumors of bone

Bone Tumor	Frequency	Age Group and Male to Female Ratio	Location of Tumor	Clinical Behavior	Treatment and Cure Rate
Osteosarcoma	30%	10–20 years (3:2)	Knee joint (distal femur, upper tibia) and jaw	Rapid growth, pain, swelling and distant metastases	Surgery, chemo-therapy (40%)
Chondrosarcoma	15%	40–60 years (2:1)	Pelvis, vertebrae, long bones	Slow growth, vascular invasion	Surgery (75%)
Ewing sarcoma	7%	5–20 years (1:1)	Long bones in diaphyseal region	Fever, pain, widespread metastases	Surgery, chemo-therapy (50%)
Fibrosarcoma and malignant fibrous histiocytoma	20%	30–40 years (3:2)	Long bones in diaphyseal regions (femur, tibia, humerus and pelvis)	Local growth, vascular invasion	Surgery (40%)

BONE TUMORS: DIAGNOSTIC APPROACH

Analytic approach to establish diagnosis of bone tumors includes clinical features, radiologic findings, laboratory findings, gross morphologic study of bone tumors, histologic examination and molecular genetic alteration studies.

CLINICAL FEATURES

Generally small-sized benign bone tumors tend to be asymptomatic and represent incidental finding. Most patients present with pain, swelling, or pathologic fracture.

- Osteoid osteoma presents nocturnal pain in tibia or femur due to synthesis of prostaglandins by the tumor.
- Symptoms may be misleading in Ewing sarcoma and osteomyelitis; as both may present with fever. Patient may develop pathologic fracture in benign and malignant tumors.
- Laboratory investigations such as radiologic studies, serum and urinary findings are important in diagnosis of multiple myeloma.
- Certain bone tumors are relatively specific to particular age.
- The duration of symptoms, rate of growth of tumor, pain associated with the bone mass, history of trauma, personal history, family history of carcinoma and systemic manifestations can help to elucidate the diagnosis. The small size bone lesions tend to be symptomatic and represent as incidental findings.

Age-related Predilection

Certain bone tumors are specific to particular age group. Most common bone tumors according to patient age are described as under. Salient features of common primary malignant tumors of bone are given in Table 27.8.

- **First and second decades:** Bone tumors occurring during this period include nonossifying fibroma, unicameral bone cyst, aneurysmal bone cyst, osteoma, osteochondroma, chondroblastoma, chondromyxoid fibroma, Langerhans cell histiocytosis, conventional intramedullary osteosarcoma (10–20 years) and Ewing sarcoma (5–20 years).
- **Third to fifth decades:** Bone tumors occurring during this period include giant cell tumor, lymphoma, Erdheim-Chester disease and hemangioma.
- **Fourth decade and above:** Bone tumors occurring during this period include metastatic bone disease, multiple myeloma, mesenchymal chondrosarcoma, dedifferentiated chondrosarcoma (40–60 years), chordoma, lymphoma and malignant fibrous histiocytoma. Primary malignant bone tumors and their site of occurrence are shown in Fig. 27.7.

Benign Entities with Multiple Presentations

Certain benign entities that may be multiple at clinical presentations, e.g. brown tumor of hyperparathyroidism, enchondromatosis, fibrous dysplasia, hemangiomatosis, Langerhans cell histiocytosis, nonossifying fibromas (Jaffe-Campanacci syndrome), osteochondromatosis, SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis and osteitis) and Paget's disease of bone (Table 27.9).

Neoplastic and Non-neoplastic Precursor Lesions of Malignancy in Bone

Neoplastic and non-neoplastic precursor lesions of malignancy in bone are given in Table 27.10.

Duration of Complaint-related to Bone Lesions

Benign bone lesions are observed for an extended period over years. On the other hand, malignant bone tumors are noticed within weeks to months.

Rate of Bone Tumor Growth

A rapidly growing bony mass within weeks to months is most likely to be malignant. However, deep-seated bone tumor is noticed late by the patient.

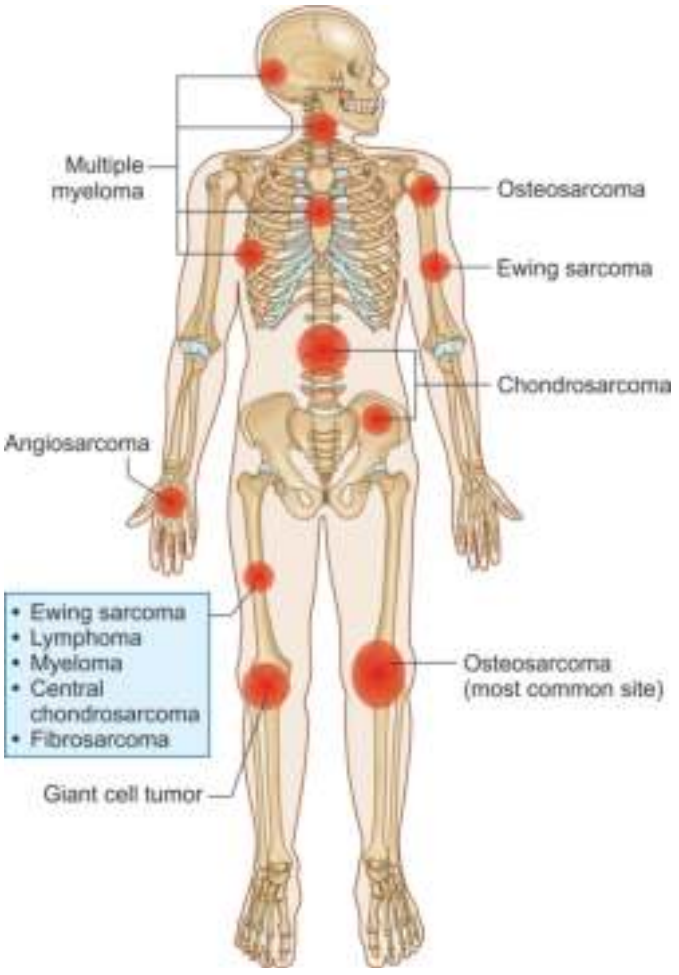

Fig. 27.7: Primary malignant bone tumors and their site of occurrence.

Pain Associated with Bony Mass

Benign bone lesions are usually asymptomatic except osteoid osteoma that is associated with nocturnal pain in tibia or femur due to synthesis of prostaglandins by the tumor. Osteochondroma may produce secondary symptoms because of its encroachment on the surrounding structures. Pain may be noticed due to locally aggressive osteoblastoma, giant cell tumor of bone and malignant bone tumors.

History of Penetrating/Blunt Trauma

Clinician must rule out pyogenic osteomyelitis in a patient with history of penetrating trauma. With a history of blunt trauma, healing of bone fracture must be entertained.

Pathologic Bone Fracture

Many malignant bone tumors may metastasize and weaken the bone resulting in pathologic fracture. Patient may also sustain pathologic fracture complicating primary benign and malignant bone tumors.

Table 27.9 Select benign entities with multiple presentations

Brown tumor of hyperparathyroidism
Enchondromatosis, fibrous dysplasia
Hemangiomatosis
Langerhans cell histiocytosis
Nonossifying fibromas (Jaffe-Campanacci syndrome)
Osteochondromatosis
SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis and osteitis)
Paget's disease of bone

Table 27.10 Neoplastic and non-neoplastic lesions are precursors of malignancy in bone

Non-neoplastic Conditions	Benign Bone Tumors
▪ Paget's disease of bone ▪ Chronic osteomyelitis ▪ Bone infarct ▪ Metallic implant ▪ Radiation osteitis ▪ Osteogenesis imperfecta ▪ Fibrous dysplasia ▪ Bone cyst ▪ Synovial chondromatosis	▪ Osteochondroma ▪ Enchondroma ▪ Chondromyxoid fibroma ▪ Giant cell tumor of bone ▪ Osteoblastoma ▪ Ollier's disease ▪ Maffucci syndrome ▪ Metaphyseal fibrous defect ▪ Osteofibrous dysplasia ▪ Adamantinoma of long bones

Clinical History

Adults with a history of carcinomas of prostatic, breast, lung, renal and thyroid are at risk for development of metastatic bone disease.

- Children with neuroblastoma are prone to bony metastasis in skull. Patient with retinoblastoma is at greater risk for development of osteosarcoma.
- Secondary osteosarcoma and other carcinomas can result from treatment of childhood carcinomas with radiotherapy and/or chemotherapy.
- Patient with history of Li-Fraumeni syndrome may develop osteosarcoma and soft tissue sarcoma. Multiple hereditary exostosis can run in families.

Clinical Features

Patient presents with fever, chills, malaise, night sweats, change in appetite and other symptoms should alert the clinician that an infectious or neoplastic process may be involved.

PHYSICAL EXAMINATION

A thorough physical examination is also important to evaluate bone lesion. The clinician must assess the location and size of tumor mass, quality of overlying skin and warmth over bony lesion, tenderness and firmness of the bony lesion.

- Bone tumor mass >5 cm should raise the suspicion of malignancy.
- Tenderness may reflect a more rapidly growing bone tumor.
- Malignant bone tumors tend to be firmer on clinical examination than benign bone lesions.
- Involvement of lymph node and examination for enlarged liver or spleen should be carried out in these patients. Lymph node involvement is most often demonstrated in rhabdomyosarcoma, epithelioid sarcoma and clear cell sarcoma.

IMAGING STUDIES

Imaging studies are done to evaluate bony lesions by conventional radiography, ultrasonography, isotope scanning, computed tomography and magnetic resonance imaging.

Conventional Radiograph

Initial evaluation of bone or soft tissue lesion is done by conventional plain radiograph. While analyzing bone lesions, one must evaluate whether a mass arising from soft tissue is involving and possibly eroding the bone cortex. Primary bone tumors and their locations according to age group predilection are shown in Fig. 27.8. Conventional plain radiograph demonstrates location of the bone lesion in epiphysis, metaphysis or diaphysis (Table 27.11). Origin of selected bone tumors in long bones, age group and location is given in Table 27.12.

Bone Lesions: Location

- **Epiphyseal bone lesions:** Epiphyseal bone lesions include chondroblastoma (open epiphysis), giant cell tumor of bone (closed epiphysis, subarticular), osteomyelitis and clear cell chondrosarcoma.
- **Metaphyseal bone lesions:** Metaphyseal bone lesions include non-ossifying fibroma (eccentric), unicameral bone cyst (central), enchondroma, osteochondroma, aneurysmal bone cyst, solitary bone cyst, osteoid osteoma, osteoblastoma, osteosarcoma,

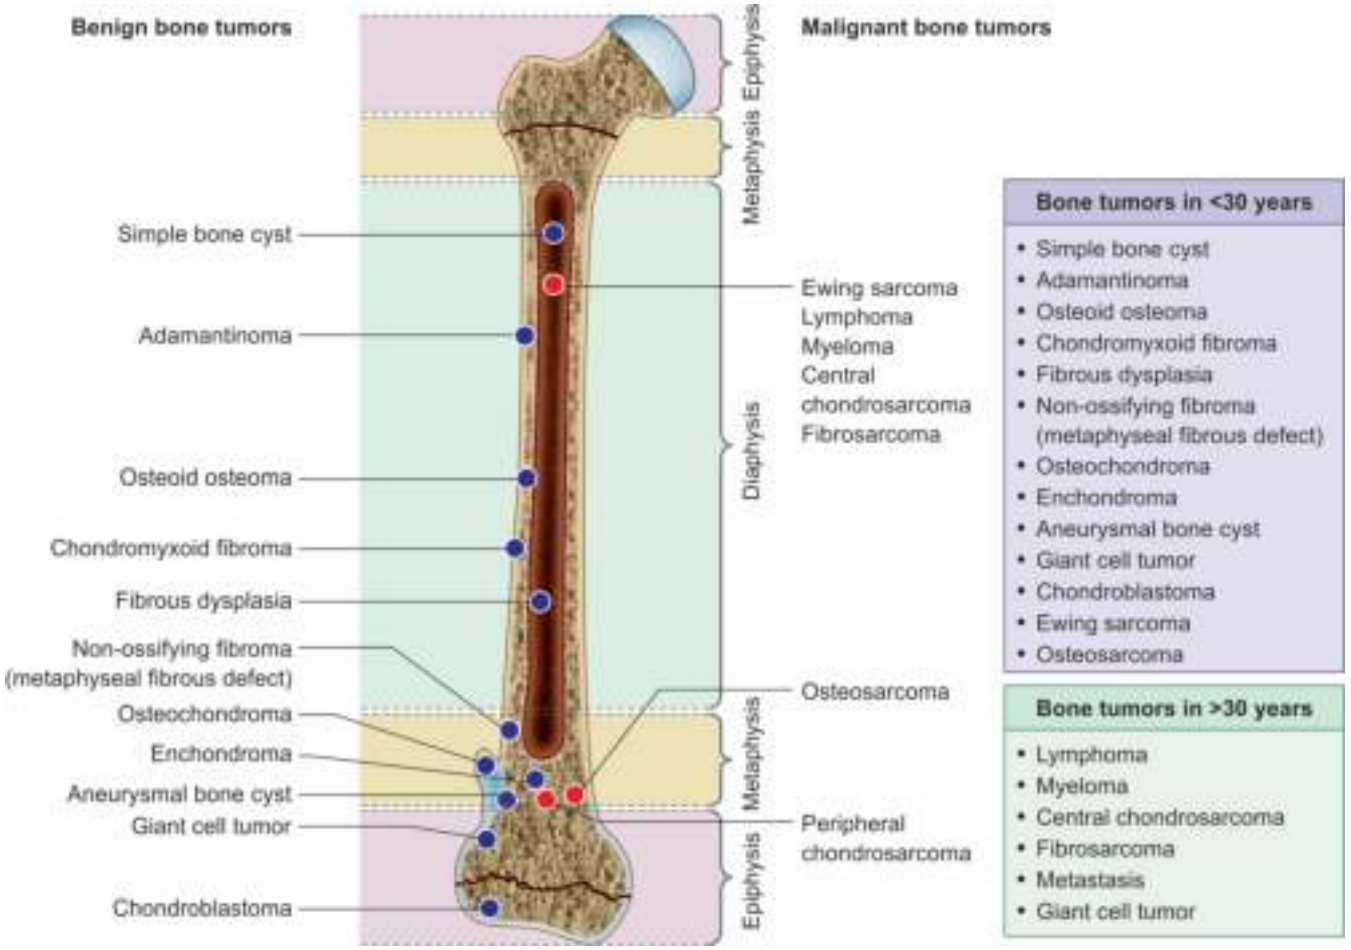

Fig. 27.8: Primary bone tumors and their locations according to age group predilection.

Table 27.11 Location of common tumors and tumor-like lesions within bone

Epiphysis of Bone
▪ Chondroblastoma (open epiphysis) ▪ Giant cell tumor of bone (closed epiphysis, subarticular) ▪ Osteomyelitis ▪ Clear cell chondrosarcoma
Metaphysis of Bone
▪ Nonossifying fibroma (eccentric) ▪ Unicameral bone cyst (central) ▪ Enchondroma ▪ Osteochondroma ▪ Aneurysmal bone cyst ▪ Solitary bone cyst ▪ Osteoid osteoma ▪ Osteoblastoma ▪ Osteosarcoma ▪ Chondrosarcoma ▪ Malignant fibrous histiocytoma ▪ Lymphoma (within medullary cavity)
Diaphysis of Bone
▪ Fibrous dysplasia ▪ Enchondroma ▪ Osteofibrous dysplasia ▪ Adamantinoma ▪ Ewing sarcoma ▪ Periosteal osteosarcoma ▪ Lymphoma, round cell tumor (within medullary cavity) ▪ Multiple myeloma, round cell tumor (within medullary cavity) ▪ Langerhans cell histiocytosis

chondrosarcoma, malignant fibrous histiocytoma, and lymphoma (within medullary cavity).

- **Diaphyseal bone lesions:** Round cell tumors such as Ewing sarcoma, multiple myeloma, and lymphoma arise within medullary cavity in diaphyseal region; however, these may also be demonstrated in the metaphyseal regions. Other tumors arising in diaphyseal region include fibrous dysplasia, enchondroma, osteofibrous dysplasia, adamantinoma, periosteal osteosarcoma and Langerhans cell histiocytosis. It is worth mentioning that osteochondroma and parosteal osteosarcoma arise from the surface region of bone.

Radiographic Features of Bone Tumors

Radiographic appearance of bone tumors has been classified into geographic, moth-eaten and infiltrative appearance on conventional radiograph (Table 27.13). Pyogenic osteomyelitis can present with any of three appearances on radiograph and suggest a neoplastic lesion. Radiographic appearances in bone lesions are given in Table 27.14.

- **Geographic appearance:** The term 'geographic appearance' refers to a lytic area of bone destruction. Presence of lytic area surrounded by a rim of sclerosis indicates a benign bone lesion. Presence of sharp line of demarcation from normal bone also indicates a benign bone lesion. Loss of sharp line of demarcation from normal bone indicates an aggressive process.

Table 27.12 Origin of selected bone tumors in long bones, age group and location

Bone Tumor	Age Group	Location
Epiphyseal region		
Giant cell tumor of bone	20–40 years	Knee joint and distal radius (65%). It is practically never demonstrated in children or person older than 60 years
Chondroblastoma	10–20 years	Epiphysis of long bones around knee joint (most common), skull, ribs, vertebrae, small bones of feet
Chondrosarcoma	40–60 years	Axial skeleton (bones of pelvic girdle, shoulder girdle, trunk, vertebrae), pelvic bones affected in 25–30%
Metaphyseal region		
Osteosarcoma	10–20 years	Long bones of extremities around knee joint in 60% (lower end of femur and upper end of tibia most common sites)
Osteosarcoma arising in Paget's disease of bone	>40 years	Upper end of tibia (most common site), humerus and upper end of femur (occasional site)
Nonossifying fibroma (metaphyseal fibrous defect)	Children during skeletal growth	Distal femur or proximal tibia in 80%
Diaphyseal fibrous defect		
▪ Ewing sarcoma ▪ Malignant lymphoma ▪ Multiple myeloma	▪ 5–15 years ▪ Elderly persons ▪ Elderly persons	Hematopoietic marrow in axial skeleton
Adamantinoma/ameloblastoma	Young adults	Long bone, jaw

Table 27.13 Radiographic features associated with benign and malignant tumors

Bone Tumor	Type of Lesion	Radiographic Appearance
Benign tumor	Well circumscribed lesion	Geographic appearance (lytic area indicative of bone destruction)
Malignant tumor	Ill-defined infiltrative process with loss of cortical integrity	▪ **Moth-eaten appearance** (presence of multiple tiny lucencies admixed with normal appearing bone seen in lymphoma) ▪ **Permeative appearance** (presence of multiple tiny lucencies coursing through bone seen in Ewing sarcoma)

Periostitis appearance (soft tissue mass invading periosteum)

Table 27.14 Radiographic appearances in bone lesions

Bone Lesion	Radiographic Appearance
Osteoid osteoma	Geographic appearance (lytic area of bone destruction surrounded by rim of sclerosis)
Lymphoma	Moth-eaten appearance (presence of multiple tiny lucencies admixed with normal appearing bone)
Ewing sarcoma	Permeative appearance (presence of multiple tiny lucencies coursing through bone; lesion deceptively looks like normal bone; and onion skin appearance)
Multiple myeloma	Multiple punched out lesions
Giant cell tumor of bone	Soap bubble appearance
Conventional osteosarcoma involving periosteum	Sun-ray (sun-burst) appearance forming Codman triangle
Fibrosarcoma	Bear bite lesions
Chondrosarcoma	Ring and arc chondroid matrix mineralization within tumor
Eosinophilic granuloma	Solitary punched out area
Fibrous dysplasia	Ground glass appearance
Aneurysmal bone cyst	Expansile osteolytic lesion with fluid-fluid levels on MRI
Enchondroma	Popcorn calcification with ring and arc appearance
Congenital syphilis involving bone	Rat-bite appearance
Rickets/osteomalacia	Looser's line
Bone medullary infarct	Central lucency with sclerosis having serpiginous border
Neurofibromatosis	Scallops the bone
Osteogenesis imperfecta	Gracile bones

- **Moth-eaten appearance:** The term 'moth-eaten appearance' refers to the presence of multiple tiny lucencies admixed with normal appearing bone. Moth-eaten appearance of bone suggests an aggressive neoplasm such as lymphoma. Moth-eaten appearance is a poorly defined infiltrative process and sometimes characterized by periosteal reaction. An exception to the rule is multiple myeloma, which frequently demonstrates punched out lesions on multiple sites on conventional radiographs.
- **Permeative appearance:** The term 'permeative appearance' refers to the presence of multiple tiny lucencies coursing through the bone, which may deceptively appear a normal bone. Permeative appearance is most often demonstrated in Ewing sarcoma.

Computed Tomography Scan

Computed tomography scan provides the best evaluation of cortical integrity, osseous remodeling and bone matrix mineralization. Thin-section computed tomography (CT) imaging provides fine bone details, which demonstrates the nidus in osteoid osteoma. CT imaging is particularly useful to evaluate to bone lesions that may not be seen on conventional radiograph especially in the pelvis, spine, ribs, scapula and chest wall. CT imaging-guided biopsy is taken to evaluate the lungs for metastasis. It is worth mentioning that lungs are the most common site of metastases via hematogenous route from primary high-grade bone sarcomas.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the examination of choice for the staging of bone tumors and planning limb salvage and tissue sparing surgical procedures.

- MRI is the best technique to evaluate bone marrow involvement and soft tissue extent of the bone tumor.
- MRI is best technique to demonstrate fluid, necrosis and hemorrhage. It is the best diagnostic tool for accurate delineating the extent of the bone tumor.
- Measurements of the bone tumor are taken before induction of chemotherapy in order to dissect the involved segment of bone after chemotherapy.

Bone Scintigraphy

Bone scintigraphy uses Tc ^{99}m-labeled diphosphonates that bind to hydroxyapatite at the sites of osteoclastic activity resulting in increased uptake of radionuclide at areas of bone turnover. Uptake of radionuclide can occur in both benign and malignant bone tumors, osteomyelitis and fractures. It is most consistently performed to determine the distribution of metastases in the whole skeleton. It does not evaluate the extent of lesion in intraosseous region or soft tissue.

- Increased uptake of radionuclide is demonstrated in fibrous dysplasia, giant cell tumor and Paget's disease of bone.
- Radionuclide uptake is most often absent in multiple myeloma, lymphoma and highly anaplastic tumors.
- Langerhans cell histiocytosis and chondrosarcoma may not show increased radionuclide uptake. Therefore, bone scintigraphy alone cannot be used and hence, it should be correlated with clinical history and conventional radiographs.

Positron Emission Tomography-Computed Tomography (PET-CT) Scan

Positron emission tomography-computed tomography (PET-CT) scan plays most valuable role in evaluation of systemic disease staging, skeletal survey, lung metastasis and response to neoadjuvant therapy.

- PET-CT technique uses fluorodeoxyglucose (FDG), a glucose analog labeled with fluorine 18 that is administered by intravenous route to detect lesions with increased metabolic activity.
- PET-CT is most accurate and sensitive technique to detect bone metastasis. It is commonly performed in staging of Ewing sarcoma. False positive results are obtained in enchondroma, fibrous dysplasia, fracture and osteomyelitis.
- Chondrosarcoma may be mistaken for a benign bone lesion based on the low to moderate radionuclide uptake depending on the grade of the bone lesion.

HISTOLOGIC EXAMINATION

Fundamental to the diagnosis of bone tumors is the histologic examination of formalin-fixed (calcified or decalcified) paraffin-embedded tissue and stained with hematoxylin and eosin in conjunction with clinical and radiologic data.

- Histologic grade is the most important prognostic feature of bone sarcomas.
- Periodic acid–Schiff (PAS) stain is used to demonstrate intracellular glycogen in Ewing sarcoma and clear cell chondrosarcoma. It also demonstrates neutral mucin to outline the basement membrane and stains fungi and parasites.
- Salient features of most common benign bone tumors and tumor-like lesions are given in Table 27.15. Salient features of most common malignant bone tumors are given in Table 27.16.

IMMUNOHISTOCHEMISTRY TECHNIQUE

Immunohistochemistry technique plays a diagnostic role for most mesenchymal tumors. It is based on the binding of a specific cellular or extracellular substance by the antibody, with subsequent visualization of the bound antibody by a color-based detection system. Visualization

Table 27.15 Salient features of most common benign bone tumors and tumor-like lesions

Tumor/Lesion	Locations	Age Predilection	Salient Pathologic Features
Chondrogenic tumors or tumor-like lesions			
Osteochondroma	Metaphysis of long bones	10–30 years	Cartilage-capped bony protrusion
Chondroma	Hands/feet; medulla of long bones	Any group	Variably cellular hyaline cartilage
Chondroblastoma	Epiphysis/apophysis of long bones	10–20 years	Chondroid-like matrix; S-100 positive cells with grooved nuclei
Chondromyxoid fibroma	Metaphysis of long bones	10–30 years	Hypocellular chondromyxoid lobules surrounded by more cellular spindle cell areas

Contd....

Table 27.15 Salient features of most common benign bone tumors and tumor-like lesions (*Contd...*)

Tumor/Lesion	Locations	Age Predilection	Salient Pathologic Features
Osteogenic tumors			
Osteoma	Facial bones	Adults	Mineralized compact bone
Osteoid osteoma	Cortex of long bones	10–30 years	Nidus of immature bone surrounded by sclerotic bone
Osteoblastoma	Vertebrae; cortex of long bones	10–30 years	Identical to osteoid osteoma but larger; often no sclerosis
Fibrous tissue-derived lesions			
Fibrous dysplasia	Ribs, jaw, long bones—medullary	10–30 years	Irregular woven bone within fibroblastic stroma
Osteofibrous dysplasia	Tibial cortex	<20 years	Similar to fibrous dysplasia but with appositional osteoblasts
Desmoplastic fibroma	Long bones, jaw, pelvis	20–30 years	Fibromatosis-like proliferation
Nonossifying fibroma	Long bones	5–15 years	Bland spindle cells in storiform pattern + histiocytes + giant cells
Histiocytic tumors			
Benign fibrous histiocytoma	Long bones, pelvis	>20 years	Identical to nonossifying fibroma but variable
Langerhans cell histiocytosis	Skull, jaw, metaphysis and diaphysis of long bones	5–15 years	Mixed inflammatory cells and eosinophils and S-100/CD1a-positive cells with grooved/multi-lobated nuclei
Erdheim-Chester disease	Long bones	>40 years	Foamy histiocytes and fibrosis
Giant cell tumor of bone	Epiphysis/metaphysis of long bones	20–45 years	Evenly placed giant cells among mononuclear cells with identical nuclei and normal serum calcium/phosphate/blood urea nitrogen/creatinine
Miscellaneous lesions			
Aneurysmal bone cyst	Vertebrae, flat and long bones	10–20 years	Blood-filled spaces separated by fibrous septae and giant cells
Simple bone cyst	Metaphysis of long bones	10–20 years	Fluid-filled cysts lined by connective tissue
Hemangioma	Vertebrae, flat and long bones	20–50 years	Capillary and/or cavernous-sized vessels

Table 27.16 Salient features of most common primary malignant bone tumors

Tumor/Lesion	Locations	Age Predilection	Salient Pathologic Features
Chondrogenic malignant tumors			
Chondrosarcoma	Flat bones, metaphysis and epiphysis of long bones	20–80 years	Variably cellular hyaline cartilage permeating bone
Conventional (not otherwise specified)	Metaphysis	20–80 years	Variably cellular hyaline cartilage permeating bone
Dedifferentiated chondrosarcoma	Metaphysis	>30 years	Conventional chondrosarcoma + high-grade spindle cell sarcoma
Mesenchymal chondrosarcoma	Metaphysis	20–50 years	Undifferentiated small cell tumor + hyaline cartilage
Clear cell chondrosarcoma	Epiphysis	20–70 years	Conventional tumor with abundant large clear tumor cells
Osteogenic malignant tumors			
Osteosarcoma	Metaphysis of long bones, jaw	10–20 years, >40 bimodal	Osteoid formed directly by malignant cells
Conventional osteosarcoma	Medullary region	10–20 years, >40 bimodal	Osteoid formed directly by malignant cells

Contd...

Table 27.16 Salient features of most common primary malignant bone tumors (*Contd...*)

Tumor/Lesion	Locations	Age Predilection	Salient Pathologic Features
Low-grade central osteosarcoma	Medullary region	10–20 years, >40 bimodal	Mildly atypical fibroblastic + thick bone trabeculae
Telangiectatic osteosarcoma	Medullary region	10–20 years, >40 bimodal	Blood-filled spaces + fibrous septae + highly malignant osteoid
Parosteal osteosarcoma	Cortex outside periosteum	10–20 years, >40 bimodal	Mildly atypical fibroblastic proliferation + thick bone trabeculae
Periosteal osteosarcoma	Cortex inside periosteum	10–20 years, >40 bimodal	Abundant cartilage matrix with variable malignant osteoid
Ewing sarcoma (primitive neuroectodermal tumors)			
Ewing sarcoma	Diaphysis of long bones	5–20 years	Small round blue cells ± rosettes, characteristic IHC, translocation
Fibrous/fibrohistiocytic malignant tumors			
Fibrosarcoma	Metaphysis of long bones, may extend to end of bone	20–60 years	Malignant spindle cells in a fascicular pattern
Malignant fibrous histiocytoma	Metaphysis of long bones, may extend to end of bone	20–80 years	Malignant spindle cells in storiform pattern + histiocytic cells (other patterns may be seen)
Hematolymphoid malignant tumors			
Myeloma	Skull, vertebrae, pelvis, long bones	>40 years	Variably atypical (monoclonal) plasma cells
Lymphoma	Any bone	Any age group	Lymphoid proliferations similar to non-bony lesions
Notochord derived tumors			
Chordoma	Base of skull, sacrum	>30 years	Lobules of vacuolated cells embedded in myxoid matrix
Blood vessels derived malignant tumors			
Angiosarcoma and hemangioendothelioma		20–60 years	Anastomosing vascular channels lined by highly atypical cells or vacuolated cells in myxoid background; characteristic immunochemistry staining
Miscellaneous tumors			
Adamantinoma	Cortex of tibia and/or fibula	20–35 years	Epithelial cells + fibroblasts + woven or lamellar bone
Metastatic carcinomas	Any bone	>40 years	IHC confirmatory

of bound antibodies with different reactions include: (a) direct and indirect staining methods using primary and secondary antibody, (b) avidin–biotin method, in which preformed complex reactions with the secondary antibody, (c) labeled streptavidin–biotin method, in which there is a linkage between primary antibody with a streptavidin-peroxidase conjugate, and (d) two-step polymer method.

STAGING SYSTEM

Staging system refers to an assessment of the grade of the malignant bone tumor and the extent to which the disease has spread. It helps the clinician to plan a logical treatment and establish prognosis for the patient. Staging of malignant bone tumors is done by imaging techniques and categorized into local and systemic disease. Local staging is achieved with MRI to determine the intra-compartmental disease and its relation to nerves and blood vessels. Systemic staging is done with CT of thorax and bone scintigraphy; but it is gradually replaced by positron emission tomography-computed tomography (PET-CT). The two major staging systems are discussed here, i.e. American Joint Committee on Cancer Staging System and Enneking Staging System.

American Joint Committee on Cancer Staging System

According to this staging system, malignant bone tumors are classified on the basis of their histologic appearance as grades 1, 2, 3 or 4. Grade 1 or 2 tumor in

this equivalent to stage 1 tumor in the Enneking system; grade 3 or 4 is equivalent to Enneking stage II.

Enneking Staging System

According to Enneking staging system, bone tumors are classified based on their histologic and biologic appearance and their metastatic potential to regional lymph nodes and distant sites, i.e. lung. Enneking staging system of malignant bone tumors is given in Table 27.17. Enneking staging system further classifies tumors based on location of tumor as intra-compartmental (type A) or extra-compartmental (type B).

- **Intra-compartmental (type A) tumors:** These malignant bone tumors are confined to muscle facial planes with better prognosis.
- **Extra-compartmental (type B) tumors:** These malignant bone tumors are located in popliteal space, axilla, pelvis or mid-portion of hands and feet. Tumor measuring >5 cm has a poor prognosis.

Table 27.17 Enneking staging system of malignant bone tumors

Stage	Comments
Stage I	It refers to low-grade bone sarcomas with <25% chance of metastatic potential
Stage II	It refers to high-grade bone sarcomas with >25% chance of metastatic potential
Stage III	It refers to either low- or high-grade bone sarcomas with metastasis to regional lymph nodes and or distant sites

Table 27.18 French Federation of Comprehensive Carcinoma Center Grading System of bone tumors

Criterion	Score
Tumor differentiation according to Table 27.6	
▪ Well differentiated tumor closely resembling normal adult mesenchymal tissue sarcoma closely resembling normal adult mesenchymal tissue	▪ Score 1
▪ Moderately differentiated tumor of well-defined certain histogenetic types	▪ Score 2
▪ Poorly differentiated (undifferentiated) tumors and undefined histogenetic type	▪ Score 3
Mitotic count	
▪ 0–9/10 per high power fields	▪ Score 1
▪ 10–19/10 per high power fields	▪ Score 2
▪ 20/10 per high power fields	▪ Score 3
Tumor necrosis on histologic examination	
▪ No necrosis	▪ Score 0
▪ ≤50% tumor necrosis	▪ Score 1
▪ >50% tumor necrosis	▪ Score 2
Grade on histologic examination	**Sum of the above scores**
▪ Grade 1	▪ Total score 2 or 3
▪ Grade 2	▪ Total score 4 or 5
▪ Grade 3	▪ Total score 6, 7 or 8

Table 27.19 French Federation of Comprehensive Carcinoma Center Grading System of bone sarcomas

Grade	Bone Sarcoma: Histologic Type
Grade 1	▪ Parosteal osteosarcoma ▪ Low-grade intramedullary osteosarcoma ▪ Chondrosarcoma grade 1 ▪ Clear cell chondrosarcoma ▪ Adamantinoma classic type
Grade 2	▪ Periosteal osteosarcoma ▪ Chondrosarcoma grade 2 ▪ Chordoma
Grade 3	▪ Conventional osteosarcoma ▪ Osteosarcoma telangiectatic variant ▪ Osteosarcoma small cell variant ▪ Osteosarcoma secondary ▪ Osteosarcoma high-grade surface variant ▪ Undifferentiated high-grade pleomorphic sarcoma ▪ Ewing sarcoma ▪ Chondrosarcoma grade 3 ▪ Chondrosarcoma dedifferentiated type ▪ Chondrosarcoma mesenchymal type ▪ Chordoma dedifferentiated type ▪ Malignant change in giant cell tumor

GRADING SYSTEM

French Federation of Comprehensive Carcinoma Center Grading System is based on tumor differentiation, mitotic count, tumor necrosis and histologic grade of bone tumors (Tables 27.18 and 27.19). Grade 1 bone tumors have better prognosis than grade 3. Grade 2 bone tumors have intermediate prognosis. French Federation of Comprehensive Carcinoma Center Grading System is based on multivariable analysis of tumor differentiation, mitotic count, tumor necrosis and grade on histologic examination.

CHONDROGENIC TUMORS

Chondrogenic tumors according to revised 2020 WHO classification of bone tumors are given in Table 27.20. Salient features of commonest chondrogenic tumors and tumor-like lesions are given in Table 27.21.

CHONDROMAS (ENCHONDROMA AND PERIOSTEAL CHONDROMA)

Chondromas (enchondroma and periosteal chondroma) are derived from hyaline cartilage, which share many histologic features. However, chondromas differ in the location and clinical features.

Table 27.20 Chondrogenic tumors according to revised 2020 WHO classification of bone tumors

Chondrogenic Tumors
Benign tumors
▪ Osteochondroma ▪ Chondroma (enchondroma, periosteal chondroma) ▪ Osteochondromyxoma ▪ Subungual exostosis ▪ Bizarre parosteal osteochondromatosis proliferation ▪ Synovial chondromatosis
Intermediate tumors (locally aggressive)
▪ Chondromyxoid fibroma ▪ Atypical cartilaginous tumor/chondrosarcoma grade 1
Malignant tumors
▪ Chondrosarcoma grade 2 ▪ Chondrosarcoma grade 3 ▪ Dedifferentiated chondrosarcoma ▪ Mesenchymal chondrosarcoma ▪ Clear cell chondrosarcoma

Origin of Chondroma

Enchondroma arises within the medullary cavity. Parosteal chondroma arises beneath the periosteum; and it is also known as juxtacortical chondroma. Both chondragenic tumors are sporadic and most often solitary lesion.

Incidence, Location and Clinical Features

- **Enchondromas:** Enchondromas constitute 10–25% of benign bone tumors. Most common sites are short tubular bones in 40% of cases. Proximal end of humerus and both ends of femur are next common sites. Patient presents with palpable swelling and pathologic fracture. Enchondroma is tumor of long bones and asymptomatic.
- **Parosteal chondromas:** Parosteal chondromas most often occur in the metaphyseal and diaphyseal regions of long bones especially femur and humerus. Patient presents with painless mass for years. Tumor may be detected as incidental finding on radiologic examination done for unrelated complaints.

Table 27.21 Salient features of commonest chondrogenic tumors and tumor-like lesions

Tumor/Lesion	Locations	Age Group	Salient Pathologic Features
Osteochondroma	Metaphysis of long bones	10–30 years	Cartilaginous capped bony protrusion
Chondroma	Hands and feet bones and medulla of long bones	Any age group	Variably cellular hyaline cartilage
Chondroblastoma	Metaphysis/epiphysis of long bones	10–20 years	Chondroid-like matrix with S-100 protein positive cells with grooved nuclei
Chondromyxoid fibroma	Metaphysis of long bones	10–30 years	Hypocellular chondromyxoid lobules surrounded by more cellular spindle cell areas
Conventional chondrosarcoma (not otherwise specified)	Flat bones, metaphysis of long bones	30–80 years	Tumor is composed of atypical pleomorphic chondrocytes. Lacunae of the chondrocytes contain >2 hyperchromatic nuclei
Dedifferentiated chondro-sarcoma	Flat bones, metaphysis of long bones	30–80 years	Dedifferentiated chondrosarcoma consists of two components. Central zone of tumor is composed of uniform chondrocytes containing hyperchromatic nuclei
Mesenchymal chondrosarcoma	Flat bones, metaphysis of long bones	20–50 years	Tumor is composed of two components: Well differentiated hyaline cartilage and small round blue cells component. Both components of the tumor are haphazardly arranged. Small round blue cells component shows spindled areas, necrosis, hemorrhage and hemangiopericytoma-like vascular spaces
Clear cell chondrosarcoma	Flat bones, metaphysis of long bones	20–70 years	Tumor is composed of large clear cells with prominent clear-to-pale eosinophilic cytoplasmic borders, round-to-oval nuclei and prominent nucleoli. Mitotic activity is low. The growth pattern is at least permeative. Variable amount of woven bone is present. Multinucleated osteoclast-like giant cells may be present

Radiologic Findings

Conventional radiograph shows radiolucent nodule of cartilage with thin central calcification and intact cortex.

Surgical Pathology: Chondromas
Gross Morphology
▪ Most enchondromas measure 3 cm in size. These tumors are pale blue firm cartilage attached to cortical surface. ▪ Parosteal chondromas form well marginated bone surface tumors. Cortex underlying the parosteal enchondroma is indented (Figs 27.9 and 27.10).
Light Microscopy
▪ Histologic features are similar in both enchondroma and parosteal chondroma. Both are avascular tumors with moderate cellularity. ▪ These tumors are composed of well differentiated hyaline cartilage. Chondrocytes contain small round nuclei with condensed chromatin. These are situated within sharp-edged lacunar spaces.
Differential Diagnosis
Chondromas should be differentiated from synovial chondromatosis and periosteal osteosarcoma.
Molecular Genetic Alterations: Ancillary Studies
▪ Both enchondroma and parosteal chondroma frequently harbor heterozygous IHD gene mutation (IHD1 and IHD2). ▪ Clonal chromosomal abnormality such as loss of chromosome 6 material has been demonstrated in parosteal chondroma.

Prognosis and Treatment

Enchondromas are treated by curettage. Local recurrences are uncommon. Parosteal chondroma is treated with intralesional, marginal and en bloc excision. Recurrence rate is low after surgical intervention.

Fig. 27.9: Chondroma. The small cartilaginous tumor resected from the tibia measuring 3 cm in diameter. Cut surface shows gray-blue discoloration.

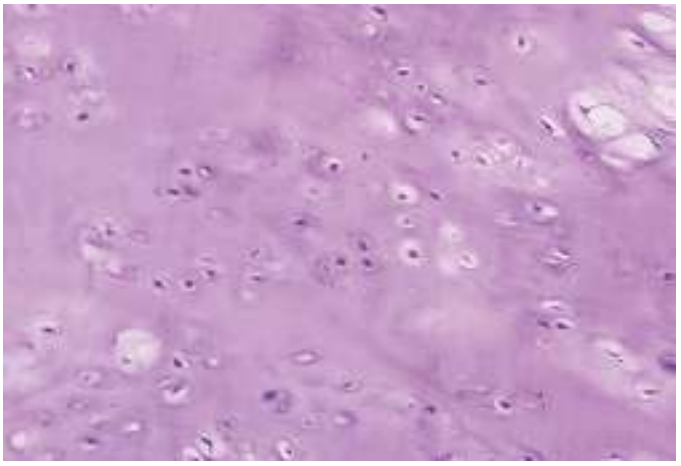

Fig. 27.10: Chondroma. Tumors are composed of well differentiated hyaline cartilage. Chondrocytes contain small round nuclei with condensed chromatin. These are situated within sharp-edged lacunar spaces (100X).

ENCHONDROMATOSIS (OLLIER DISEASE)

Ollier disease is a rare nonhereditary sporadic disorder, where intraosseous benign cartilaginous tumors (enchondroma) develop close to the growth plate cartilage.

- Ollier disease is characterized by multiple enchondromas, which usually develop during childhood. The growth of enchondromas stops after skeletal maturation. The affected extremity becomes shortened and sometimes undergoes bowing due to epiphyseal fusion abnormalities.
- Patient presents with swollen arching extremities resulting in fracture.
- Patients with Ollier disease carry high risk for skeletal, visceral and brain malignancy in 25% of cases. The deformities are managed surgically to preserve the function of the limbs. Gross morphology of multiple enchondromatosis (Ollier disease) is shown in Fig. 27.11.

Radiologic Findings

Conventional radiograph shows streaks of low density presenting through the diaphysis into the epiphyses of the long bones due to ectopic cartilage deposits.

OSTEOCHONDROMA

Osteochondroma is a benign mushroom-shaped exophytic tumor. Tumor is composed of bone capped with cartilage near the growth plate. It is also known as exostosis. Benign osteochondroma has <2 cm thick cartilaginous cap. But presence of irregular cartilaginous cap >2 cm in thickness may indicate tumor with metastatic potential. EXT1 and EXT2 gene mutations play important role in the pathogenesis of osteochondroma.

Fig. 27.11: Multiple enchondromatosis (Ollier disease). The head of the humerus is greatly expanded by the intramedullary chondromas resulting in bony deformities. The residual hyaline cartilage from the growth plate does not undergo enchondral ossification and remains confined within the bones resulting in formation of multiple tumor-like masses of abnormally arranged hyaline cartilage. It has strong tendency to undergo malignant change, i.e. chondrosarcoma.

Incidence and Locations

Multiple osteochondromas occur in various syndromes. Sporadic osteochondroma is solitary and six times more common than those seen in the setting of multiple osteochondromas. Most common sites of osteochondroma are metaphysis of long bones, e.g. femur, proximal tibia and proximal humerus. Pelvic bones and scapula are uncommon sites.

Age and Sex Predilection

Peak incidence of osteochondroma is seen in second decades of life (<25 years) with male predilection.

Clinical Features

Initially, patient is asymptomatic because the osteochondroma starts growing in childhood and becomes clinically painless mass over long duration. It may be an incidental finding on radiograph done for unrelated complaints. Osteochondroma may become painful due to nerve compression or fracture of affected bone.

Surgical Pathology: Osteochondroma

Gross Morphology

- Osteochondroma may be pedunculated with a stalk or sessile/flat or cauliflower shaped. Thin <2 cm thick pale blue cartilaginous cap overlies a stalk composed of hard cancellous bone.
- Cut surface of tumor shows medullary and cortical contiguous with underlying native bone (Fig. 27.12).

Light Microscopy

- Osteochondroma is composed of cartilaginous cap undergoing enchondral ossification with orderly arrangement of chondrocytes with minimal atypia towards epiphyseal growth plate.
  - Chondrocytes contain single small nucleus with fine chromatin in benign osteochondroma.
  - Chondrocytes may contain two nuclei during active bone growth.
- Cancellous bone is present beneath the cartilaginous cap. Intertrabecular spaces are filled with hematopoietic tissue and fat. Occasionally, degenerative changes are demonstrated in the cartilaginous cap (Fig. 27.13).

Electron Microscopy

Chondrocytes show accumulation of glycogen, lipid droplets and dilatation of rough endoplasmic reticulum.

Differential Diagnosis

Osteochondroma should be differentiated from chondrosarcoma arising in osteochondroma, parosteal osteosarcoma and bizarre periosteal osteochondromatosis proliferation (Nora's lesion).

Prognosis and Treatment

Asymptomatic patients with osteochondroma should be followed up. Symptomatic osteochondroma is treated by surgical excision. Malignant transformation in osteochondroma occurs in <1% of sporadic cases; and multiple osteochondroma syndrome in 5–20% of cases.

CHONDROBLASTOMA

Chondroblastoma is a rare benign matrix forming tumor arising from the epiphyseal cartilage of long

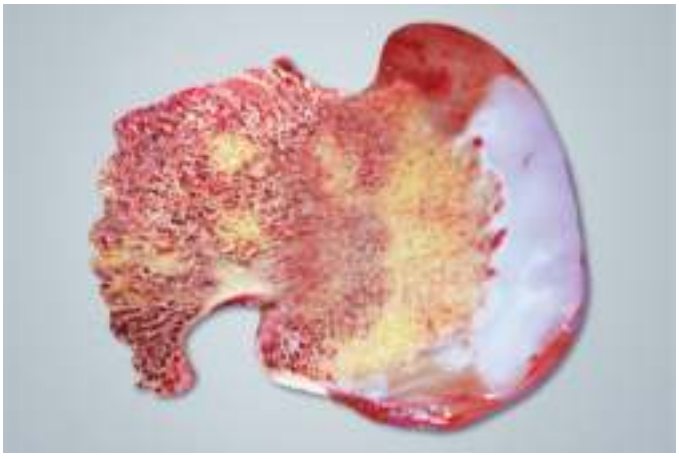

Fig. 27.12: Osteochondroma in long bone. Osteochondroma is pedunculated and cauliflower shaped with a stalk. Thin <2 cm thick pale blue cartilaginous cap overlies a stalk composed of hard cancellous bone. Cut surface of tumor shows medullary and cortical contiguous with underlying native bone.
