Fig. 27.13: Osteochondroma in long bone. It is composed of cartilaginous cap undergoing enchondral ossification with orderly arrangement of chondrocytes with minimal atypia towards epiphyseal growth plate. Chondrocytes contain single small nucleus with fine chromatin in benign osteochondroma. Chondrocytes may contain two nuclei during active bone growth. Cancellous bone is present beneath the cartilaginous cap. Intertrabecular spaces are filled with hematopoietic tissue and fat (100X).

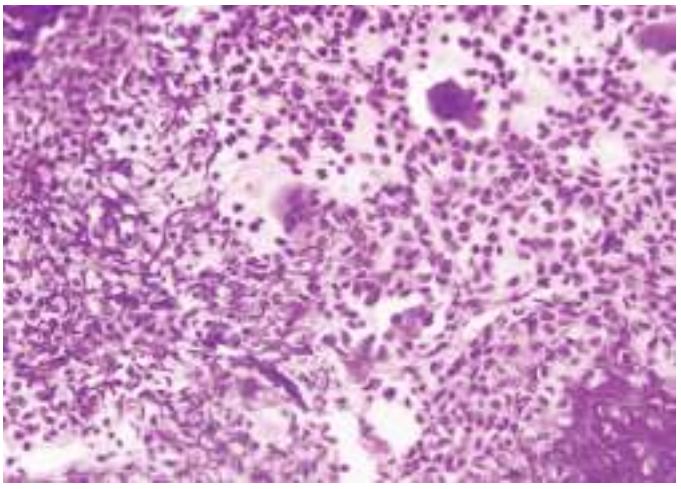

Fig. 27.14: Chondroblastoma. Tumor is a cellular tumor composed of round or polyhedral chondroblasts with well-defined outlines. These cells contain grooved round nuclei and pale cytoplasm. Mitoses and atypia are absent. The tumor cells merge with areas of hyaline cartilage. There is presence of chicken wire mesh-like areas of calcification among tumor cells. Scattered multinucleated giant cells are present among tumor cells (400X).

bones before the closure of epiphysis. Tumor features primitive chondroblasts and cartilaginous amphophilic or eosinophilic matrix.

Incidence and Locations

Chondroblastoma accounts for <1% of bone tumors, which originates in the epiphysis of long bones. Rare sites of chondroblastoma are flat bones of cranium, pelvis, ribs, vertebrae and small bone of feet.

Age and Sex Predilection

Chondroblastoma most often occurs in the first two decade of life with peak incidence in the second decade of life. Males are more affected than females.

Clinical Features

Patient presents with history of pain in the affected bone over months to years associated with limp.

Radiologic Findings

Conventional radiograph shows a well circumscribed osteolytic lesion with multiple areas of calcification.

Surgical Pathology: Chondroblastoma

Gross Morphology

- Curettage fragments of tumor demonstrate granular texture, tan-pink firm tissue with calcifications without typical pale blue hyaline cartilage.
- Focal blue gray areas resemble chondroid cartilage.

Light Microscopy

- Chondroblastoma is a cellular tumor composed of round or polyhedral chondroblasts with well-defined outlines. Chondroblasts contain grooved round nuclei and pale cytoplasm. Mitoses and atypia are absent. The tumor cells merge with areas of hyaline cartilage.
- There is presence of chicken wire mesh-like areas of calcification among tumor cells. Scattered multinucleated giant cells are present among tumor cells.
- In some cases, typical areas of chondroblasts show alternate arrangement of large vascular blood-filled spaces. Such tumors are referred as cystic chondroblastomas (Fig. 27.14).

Differential Diagnosis

Chondroblastoma should be differentiated from giant cell tumor of bone, aneurysmal bone cyst and chondromyxoid fibroma.

Prognosis and Treatment

Curettage of chondroblastoma and bone graft is curative. Recurrence of tumor may occur in <15% of cases.

CHONDROMYXOID FIBROMA

Chondromyxoid fibroma is a benign cartilaginous tumor with aggressive behavior. Tumor is composed of nodules with myxoid matrix and spindle to stellate cells, which rarely exceeds >5 cm in size. Chromosomal abnormalities are frequently observed in the tumor.

Incidence and Locations

Chondromyxoid fibroma accounts for <1% of bone tumors. Most common site of chondromyxoid fibroma

is proximal end of tibia, and other sites are distal femur, small bones of the feet and jaw.

Age Group

Chondromyxoid fibroma occurs in adolescents and young adults during second and third decades.

Clinical Features

Patient presents with pain in distal femur and mass in small bones of feet. Tumor may extend into the soft tissue.

Surgical Pathology: Chondromyxoid Fibroma
Gross Morphology
▪ Tumor is solid, lobulated and pale blue. Presence of translucency suggests cartilaginous origin of tumor. Matrix is softer in consistency than hyaline cartilage. ▪ Margin of the tumor shows sclerotic rim.
Light Microscopy
▪ Tumor exhibits lobular growth pattern separated by bands of fibrous tissue. Tumor is composed of spindled to stellate cells with long cytoplasmic processes. ▪ Tumor contains immature cartilage showing prominent myxoid tissue, among which are scattered chondroblasts alternate with stellate myxoid cells and scattered large pleomorphic cells. ▪ Peripheral portion of lobules shows increased tumor cells and multinucleated cells. Occasional cells show hyperchromatic nuclei but maintaining normal nuclear to cytoplasmic ratio. ▪ Rarely, tumors representing hybrids contain chondromyxoid fibroma and chondroblastoma components (Fig. 27.15).
Immunohistochemistry Technique
Tumor cells show positivity for SOX2.
Differential Diagnosis
Chondromyxoid fibroma should be differentiated from chondroblastoma, enchondroma and chondroblastic osteosarcoma.

Prognosis and Treatment

Chondromyxoid fibroma is treated with curettage and bone grafting. Recurrence occurs in 25% of cases after surgery.

CONVENTIONAL CHONDROSARCOMA (GRADES 1, 2, 3)

Conventional chondrosarcoma is a malignant cartilaginous matrix forming tumor with diverse morphologic features and clinical course. It accounts for 15–20% of all primary malignant bone tumors during fourth to seventh decades. Chondrosarcoma is classified into four categories:

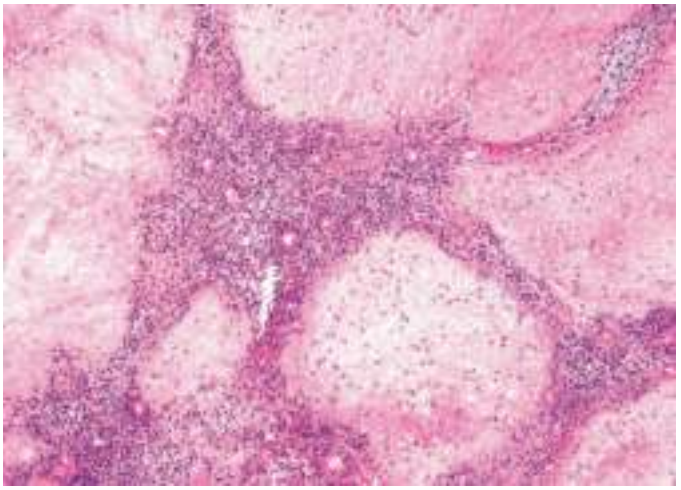

Fig. 27.15: Chondromyxoid fibroma. Tumor is composed of lobules separated by bands of fibrous tissue. The lobules are composed of contain multinucleated giant cells, immature cartilage, myxoid tissue (100X).

- **Primary central chondrosarcoma:** Primary central chondrosarcoma originates in any bone derived from enchondral ossification without a precursor bone lesion (*de novo*). It accounts for 85% of conventional chondrosarcomas. Most common sites of tumor are pelvic girdle (ilium), shoulder girdle (scapula), proximal and distal femur, proximal humerus, ribs and base of skull. Short bones of hands and feet, spine and base of the skull are rarely affected.
- **Secondary central chondrosarcoma:** Secondary central chondrosarcoma originates in a previously existing enchondroma and familial nonhereditary enchondromatosis disorders, e.g. Ollier disease and Maffucci syndrome. It most often affects young persons. Continued progression of known enchondroma should raise the suspicion of malignant transformation.
- **Secondary peripheral chondrosarcoma:** Secondary peripheral chondrosarcoma is a low-grade tumor, which occurs after second decade of life. It is juxtaposed to the cartilaginous cap on osteochondroma. Clinical features combined cartilaginous cap of osteochondroma >1.5–2 cm establishes the diagnosis after taking into consideration of histologic features.
- **Periosteal chondrosarcoma:** Periosteal chondrosarcoma originates from periosteum of distal femur and humerus in the metaphyseal region. It occurs during second to fourth decades of life.

Clinical Features

Patient presents with pain and tenderness in the affected bone. Tumor arising from base of the skull can cause neurological symptoms. Pain may be referred due to involvement of the vertebral or sacral nerve roots by the tumor.

Table 27.22 Radiologic findings in chondrosarcoma variants

Conventional Chondrosarcoma Variants	Comments
Primary central chondrosarcoma	
Conventional radiograph	▪ Fusiform expansion in long bones with cortical thickening and erosion; and scant or absence of periosteal reaction ▪ Radiolucent areas with variable ring-like opacities due to mineralization
Computed tomography scan	Matrix calcification in tumor
Magnetic resonance imaging	Helpful in delineating the extent of tumor, presence of extension into the soft tissues and diagnosing progression towards high-grade chondrosarcoma
Secondary central chondrosarcoma	
Conventional radiograph	Cortical destruction by the tumor and extension into soft tissues
Secondary peripheral chondrosarcoma	
Conventional radiograph	Irregular mineralization
Magnetic resonance imaging	▪ Demonstrates size of the cartilaginous cap ▪ Presence of cartilaginous cap >1.5–2 cm raises the suspicion of malignant transformation of osteochondroma
Parosteal chondrosarcoma	
Conventional radiograph	▪ Demonstrates a large lobular mass >5 cm located on the surface of the long bone delineated towards the soft tissue ▪ Presence of cartilaginous calcification and calcified shell ▪ Bone marrow involvement rare

Radiologic Findings

Radiologic findings in chondrosarcoma variants are given in Table 27.22.

Surgical Pathology: Conventional Chondrosarcoma

Gross Morphology

- Tumor appears as nodular, expansile and pale blue firm cartilage with glistening translucent appearance. Myxoid and viscous liquid change in the matrix is seen. Periosteal chondrosarcoma is attached to the surface of the bone. Gritty calcifications may be seen.
- Resected specimens show permeation through medulla or cortex into the soft tissues (Fig. 27.16).

Light Microscopy

- Tumor is composed of atypical pleomorphic chondrocytes.
- Lacunae of the chondrocytes contain >2 hyperchromatic nuclei. Atypical mitosis is best demonstrated at the edge of the tumor.
- Permeation through viable lamellar bone or haversian canal of bone is the most important diagnostic criteria of chondrosarcoma.
- Myxoid change or chondroid matrix liquefaction is a common feature of chondrosarcoma. Necrosis and mitoses can be demonstrated (Fig. 27.17).

Histologic Grading

Histologic grading of chondrosarcoma is the most important predictor of local recurrence and metastasis. Conventional chondrosarcomas are graded on a scale of I, II and III based on nuclear size, hyperchromasia of the nuclei, mitoses and cellularity of the tumor.

- **Grade 1 chondrosarcoma:** It is a locally aggressive tumor. Metastasis can occur in an occasional case. On histologic examination, grade 1 chondrosarcoma is moderately cellular and well differentiated tumor. Tumor is composed of uniform chondrocytes. Cartilaginous lacunae contain >2 cells with hyperchromatic nuclei. Tumor in long bone is treated by curettage. Five-year survival rate is seen in >80% of cases.
- **Grade 2 chondrosarcoma:** On histologic examination, grade 2 chondrosarcoma is more cellular. Tumor is composed of chondrocytes. Cartilaginous lacunae contain >2 cells with hyperchromatic nuclei and atypical mitoses. It is treated by *en bloc* resection. Patients have poor prognosis.
- **Grade 3 chondrosarcoma:** On histologic examination, grade 3 chondrosarcoma is highly cellular and composed of chondrocytes containing hyperchromatic nuclei and atypical mitoses. It is treated by *en bloc* resection. Patients have very poor prognosis. Histologic grading of conventional chondrosarcoma variants is given in Table 27.23.

Molecular Genetic Alterations: Conventional Chondrosarcoma

- **IDH1 and IDH2 gene mutations:** IDH1 and IDH2 gene mutations are demonstrated in primary central chondrosarcoma (35–70%), secondary central chondrosarcoma (85%) and periosteal chondrosarcoma (100%). IDH1 and IDH2 gene mutations are also demonstrated in Ollier disease and Maffucci syndrome. IDH1 gene mutation is demonstrated by using IDH1 R82H antibody.

- **EXT1 and EXT2 gene mutations:** EXT1 and EXT2 gene mutations play an important role in the pathogenesis of osteochondroma. But their role in the pathogenesis of chondrosarcoma is not known.
- **Single numerical or structural chromosomal aberrations to heavily rearranged karyotype:** These chromosomal alterations are demonstrated in chondrosarcoma.
- **RB1 signaling pathway:** RB1 signaling pathway is affected in high-grade chondrosarcoma in 85% of cases.
- **CDKN2A loss:** CDKN2A loss is demonstrated in conventional chondrosarcoma.
- **CDK4 gene amplification:** CDK4 gene amplification is demonstrated in conventional chondrosarcoma.
- **IHH/PTHLH signal pathway:** IHH/PTHLH signal pathway is active in primary central chondrosarcoma, secondary central chondrosarcoma and secondary peripheral chondrosarcoma. But activity of this signal pathway is decreased in high-grade chondrosarcoma.

Prognosis

Histologic grade of chondrosarcoma is the most important predictor of local recurrence and metastasis. Depending on surgical treatment of periosteal chondrosarcoma, local recurrence occurs in 15–30% of cases. Metastasis is rare in periosteal chondrosarcoma. In primary central chondrosarcoma and secondary central chondrosarcoma, prognosis depends on grade of the tumor and treatment.

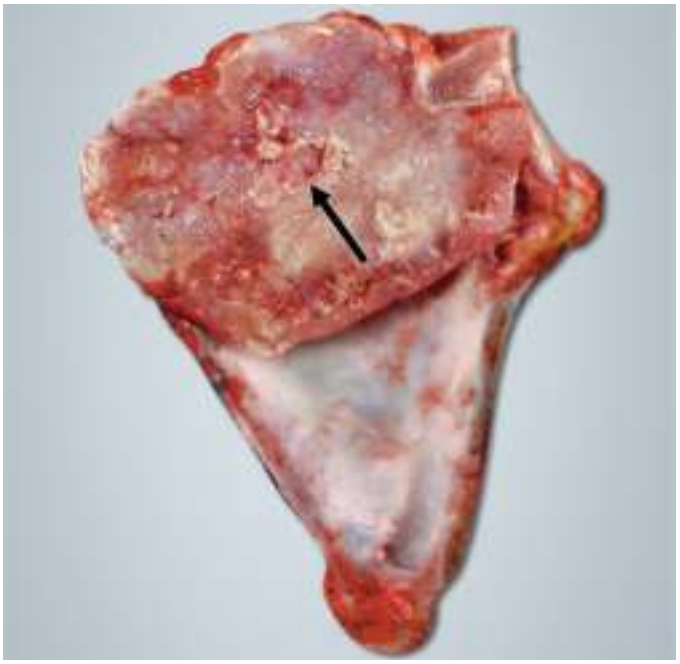

Fig. 27.16: Chondrosarcoma. Tumor is arising in the scapula. It appears as nodular, expansile and pale blue firm cartilage with glistening translucent appearance. Myxoid and viscous liquid change in the matrix is seen (arrow). Periosteal chondrosarcoma is attached to the surface of the bone. Gritty calcifications may be seen.

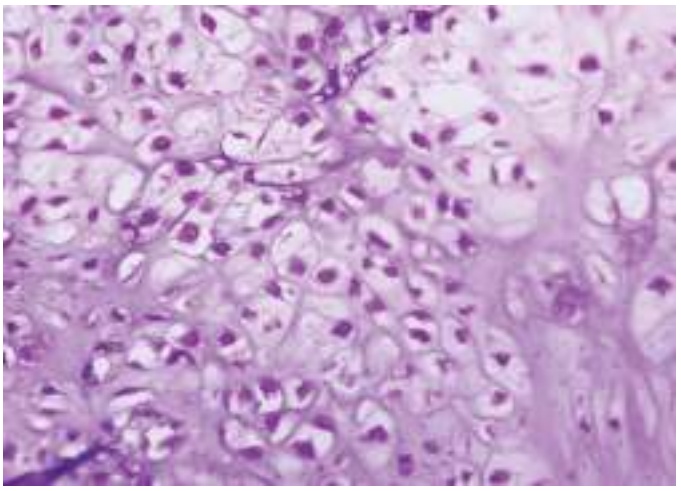

Fig. 27.17: Chondrosarcoma. Tumor is moderately cellular and well differentiated tumor. It is composed of atypical chondrocytes. Cartilaginous lacunae contain >2 cells with hyperchromatic nuclei.

- **Grade 1 chondrosarcoma:** It is locally aggressive tumor. Metastasis may occur in an exceptional case. Five-year survival rate is seen in >80% of cases treated by curettage.
- **Grades 2 and 3 chondrosarcoma:** Five-year survival rate is seen in these cases treated by *en bloc* resection.

DEDIFFERENTIATED CHONDROSARCOMA

Dedifferentiated chondrosarcoma is defined by the presence of a biphasic tumor composed of a conventional chondrosarcoma (most often grade 1) and a high-grade noncartilaginous sarcoma.

Incidence and Locations

Dedifferentiated chondrosarcoma accounts for 10–15% of all chondrosarcomas. Most common sites are pelvic girdle (ilium) and proximal femur in the epiphyseal region, distal femur, proximal humerus and ribs.

Age and Sex Predilection

Dedifferentiated chondrosarcoma has bimodal age distribution. Patient with exostosis may develop chondrosarcoma earlier in life. It occurs during fourth to seventh decades of life. Males and females are equally affected.

Clinical Features

Patient presents with pain, paresthesia and hard mass in the affected bone over 6–10 months.

Radiologic Findings

Radiograph shows a biphasic tumor. Presence of intramedullary component (central zone) with ring or stippled calcification is suggestive of cartilaginous component of tumor. Second component (peripheral

Table 27.23 Histologic grading of conventional chondrosarcoma variants

Parameters	Grade 1 Conventional Chondrosarcoma	Grade 2 Conventional Chondrosarcoma	Grade 3 Conventional Chondrosarcoma
Matrix	Abundant and well developed	Abundant along with myxoid areas	Sparse often chondroid with myxoid areas
Cellularity of tumor	Relatively low cellular tumor	Moderately cellular tumor especially at the periphery of tumor lobules	Highly cellular tumor
Nuclear morphology in atypical chondrocytes	Small and dark nuclei with large nucleoli	Large nuclei with irregular hyperchromatic nuclei and large nucleoli	Pleomorphic hyperchromatic nuclei and large nucleoli
Mitoses	Absent or rare	Scattered mitoses <2/10 high power field	Scattered mitoses >2/10 high power field
Necrosis in tumor	Necrosis absent	Necrosis focal to abundant	Necrosis abundant

zone) of tumor is aggressive with cortical permeation and a large soft tissue mass lacking calcification.

Surgical Pathology: Dedifferentiated Chondrosarcoma

Gross Morphology

- Dedifferentiated chondrosarcoma consists of two components, i.e. central zone and peripheral zone.
- Central zone of tumor is composed of pale blue hyaline cartilage with rubbery to myxoid tissue and soft in consistency.
- Peripheral zone of tumor is composed of fleshy soft tissue component. Areas of hemorrhage and necrosis.

Light Microscopy

- Dedifferentiated chondrosarcoma consists of two components, i.e. central zone and peripheral zone. Both zones are sharply demarcated.
- Central zone of tumor is composed of uniform chondrocytes containing hyperchromatic nuclei (grade 1 conventional chondrosarcoma).
- Peripheral zone of tumor is high-grade component of osteosarcoma, chondrosarcoma or malignant fibrous histiocytoma with features of pleomorphic nuclei, abundant atypical mitoses and necrosis.

Differential Diagnosis

Dedifferentiated chondrosarcoma should be differentiated from chondroblastic osteosarcoma, conventional chondrosarcoma and malignant fibrous histiocytoma.

Prognosis and Treatment

Patient with dedifferentiated chondrosarcoma is treated with wide surgical excision usually with wide amputation and adjuvant chemotherapy. Long-term survival is seen in <10% of cases.

MESENCHYMAL CHONDROSARCOMA

Mesenchymal chondrosarcoma is high-grade bone tumor with biphasic pattern. It is characterized by primitive (undifferentiated) stromal or mesenchymal cells in which islands of well differentiated cartilage is interspersed.

Incidence and Locations

Mesenchymal chondrosarcoma accounts for 1–3% of all cartilaginous bone tumors. Most common sites are pelvis, ribs and jaw. Extraskeletal (extraosseous) chondrosarcoma occurs in 30% of cases.

Age and Sex Predilection

Mesenchymal chondrosarcoma most often affects young persons with peak incidence during second and third decades of life with sex predilection.

Clinical Features

Patient with mesenchymal chondrosarcoma presents with pain and tender mass in the affected bone.

Radiologic Findings

Radiograph shows permeative osteolytic lesion with cortical and soft tissue destruction.

Surgical Pathology: Mesenchymal Chondrosarcoma

Gross Morphology

Tumor is an admixture of firm blue cartilage and soft fleshy pink tissue. Gritty calcifications may be demonstrated.

Light Microscopy

- Tumor is composed of two components, i.e. well differentiated hyaline cartilage and small round blue cells component. Both components of the tumor are haphazardly arranged. Interface may be abrupt or gradual.
- Small round blue cells component shows spindled areas, necrosis, hemorrhage and hemangiopericytoma-like vascular spaces.

Differential Diagnosis

Mesenchymal chondrosarcoma should be differentiated from chondroblastic osteosarcoma, Ewing sarcoma and dedifferentiated sarcoma.

Prognosis and Treatment

Patient with mesenchymal chondrosarcoma is treated with wide local excision and adjuvant chemotherapy in most cases. Recurrence and metastasis may be observed decades after initial diagnosis and treatment.

CLEAR CELL CHONDROSARCOMA

Clear cell chondrosarcoma is a low-grade malignant tumor with low metastatic potential. Tumor is composed of cartilage with characteristic large clear cells.

Incidence and Locations

Clear cell chondrosarcoma accounts for 1–2% of all cartilage forming tumors. Most common site is proximal femur in epiphyseal region. Less common sites of tumor are proximal humerus and distal femur.

Age and Sex Predilection

Clear cell chondrosarcoma most often affects young persons with peak incidence during third decade of life with male predilection.

Clinical Features

Patient with clear cell chondrosarcoma presents with pain and tender mass in the affected bone over years.

Radiologic Findings

Radiograph shows a well-circumscribed radiolucent lesion in the epiphysis of long bone especially proximal femur with sclerotic border and absence of periosteal reaction and soft tissue mass. Stippled calcifications in tumor are demonstrated in 25% of cases.

Surgical Pathology: Clear Cell Chondrosarcoma

Gross Morphology

- Curettage of clear cell chondrosarcoma has gritty calcifications and pale blue cartilage.
- Consistency is softer than normal hyaline cartilage. Cystic areas are demonstrated.

Light Microscopy

- Tumor is composed of large clear tumor cells with prominent clear-to-pale eosinophilic cytoplasmic borders, round-to-oval nuclei and prominent nucleoli. Mitotic activity is low.
- The growth pattern is at least permeative. Variable amount of woven bone is present.
- Multinucleated osteoclast-like giant cells may be present.

Immunohistochemistry Technique

Clear cells of tumor are strongly positive for S-100 protein.

Differential Diagnosis

Clear cell chondrosarcoma should be differentiated from chondroblastic osteosarcoma and osteoblastoma.

Prognosis and Treatment

En bloc resection of clear cell chondrosarcoma tumor is curable. Incomplete curettage of tumor may result in metastasis and mortality in 15% of cases.

OSTEOGENIC TUMORS

Osteogenic tumors according to revised 2020 WHO classification of bone tumors are given in Table 27.24. Osteoid osteoma and osteoblastoma constitute 13% bone forming tumors. Facial bones are the most common site for osteoma. Osteoid osteoma originates in cortex of long bone; and is characterized by nidus of immature bone surrounded by sclerotic bone. Vertebrae and cortex of long bones are most common site for osteoblastoma. Osteosarcoma is a malignant osseous neoplasm and the most common primary cancer of childhood. Selected osteosarcoma variants, their age and salient pathologic features are given in Table 27.25.

OSTEOMA

Osteoma is a benign bone forming tumor and composed of cortical bone and less frequently cancellous bone. It is usually a solitary tumor except in Gardner's syndrome. Gardner's syndrome occurs due to APC gene mutation, and is characterized by formation of multiple osteomas, colonic polyps and soft tissue tumors.

Incidence and Locations

True incidence of osteoma is not known. Most common site is craniofacial skeleton around paranasal sinuses. Rare sites of tumor are spine and long bones.

Age and Sex Predilection

Osteoma is diagnosed in the middle-aged persons, which has slight male predilection.

Table 27.24 Osteogenic tumors according to revised 2020 WHO classification of bone tumors

Osteogenic Tumors	
Benign tumors	
▪ Osteoma ▪ Osteoid osteoma	
Intermediate tumors (locally aggressive)	
Osteoblastoma	
Malignant tumors	
▪ Low-grade osteosarcoma ▪ Conventional osteosarcoma (chondroblastic osteosarcoma, fibroblastic osteosarcoma) ▪ Telangiectatic osteosarcoma	▪ Small cell osteosarcoma ▪ Secondary osteosarcoma ▪ Parosteal osteosarcoma ▪ Periosteal osteosarcoma ▪ High-grade surface osteosarcoma

Table 27.25 Selected osteosarcoma variants, their age and salient pathologic features

Histologic Variant	Location	Age Group	Pathologic Features
Conventional osteoblastic osteosarcoma	Metaphysis of long bones around knee joint (distal end of femur or proximal end of tibia) are commonly affected in 65% of cases	10–20 years	Formation of lace-like pattern bone formed by the neoplastic cells is a diagnostic feature of conventional osteoblastic osteosarcoma
Low-grade osteosarcoma	Metaphysis of long bones (distal femur, proximal tibia) within medullary cavity	Third decade	Tumor is composed of spindle-shaped neoplastic cells forming variable amounts of osteoid formation. Neoplastic cells are arranged in interlacing bundles showing minimal atypia and a few mitoses
Telangiectatic osteosarcoma	Metaphysis (distal femur, proximal tibia) within medullary cavity	10–20 years	Blood filled spaces with highly malignant osteoid element
Parosteal osteosarcoma	Cortex outside periosteum (distal femur)	10–20 years	Abundant cartilage matrix with variable amount of malignant osteoid element
Periosteal osteosarcoma	Cortex inside periosteum (distal femur and upper tibia)	10–20 years	Osteoid bone formed by neoplastic cells composed of abundant cartilaginous matrix formed by neoplastic cells. Tumor cells show cytologic atypia

Clinical Features

Patient develops a sessile periosteal or endosteal growth in the skull and facial bones. Patient is usually asymptomatic and detected as incidental finding. Symptoms depend on location of tumor.

Radiologic Findings

Radiograph shows surface based, homogenous and well demarcated radiodense tumor.

Surgical Pathology: Osteoma

Gross Morphology

Osteoma tumor is hard, tan-white and mimicking normal bone.

Light Microscopy

- Osteoma tumor is composed of admixture of lamellar and woven bone mimicking compact cortical or trabecular bone. Bony trabeculae are broad, mature and irregular.
- Intertrabecular space is filled with fibrous tissue, which sometimes become vascularized. These intertrabecular spaces may contain foci of hematopoietic tissue (Fig. 27.18).

Prognosis and Treatment

Patient does not require any treatment unless becomes symptomatic. Excision of symptomatic tumor is curative. Large size osteoma in long bone may require biopsy to exclude a low-grade osteosarcoma.

OSTEOID OSTEOMA

Osteoid osteoma is a benign bone forming painful tumor and is characterized by a central osseous tissue; nidus measuring <2 cm surrounded by reactive sclerotic bone. It accounts for 11% of benign bone tumors.

Osteoid osteoma originates from the cortex of diaphysis of femur, humerus, radius and fibula. Proximal end of tibia is the most common sites. Other sites are phalanges, talus and calcaneum.

Age and Sex Predilection

Children and young adults during 5–25 years of age are affected with male predominance.

Clinical Features

Patient presents with osteoid osteoma tumor mass <2 cm size and severe localized nocturnal pain due to synthesis of prostaglandins by the tumor. Pain is relieved by administration of nonsteroidal anti-inflammatory

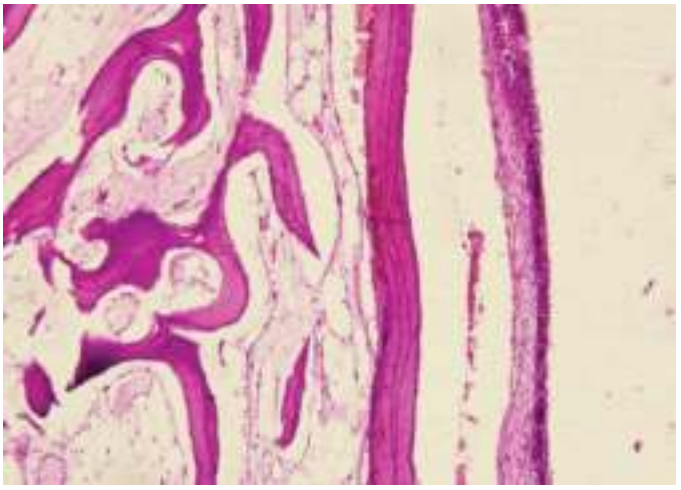

Fig. 27.18: Osteoma. Tumor is composed of admixture of lamellar and woven bone mimicking compact cortical or trabecular bone. Bony trabeculae are broad, mature and irregular. Intertrabecular space is filled with fibrous tissue, which sometimes become vascularized. These intertrabecular spaces may contain foci of hematopoietic tissue (400X).

aspirin drug. Tumor located close to joints may cause symptoms mimicking arthritis. Involvement of the vertebrae by the tumor can result in painful scoliosis.

Radiologic Findings

Radiograph shows well-demarcated radiolucent tumor with central mineralization surrounded by dense sclerosis.

Surgical Pathology: Osteoid Osteoma

Gross Morphology

- Osteoid osteoma is solitary tumor measuring <2 cm in diameter.
- The nidus of tumor is well demarcated, dark red, gritty and surrounded by dense sclerotic tissue (Fig. 27.19).

Light Microscopy

- In early stage, the nidus of osteoid osteoma is composed of inter-anastomosing woven bone with prominent osteoblastic rimming with intervening fibrovascular stroma.
- In later stage, there is presence of tangled islands and trabeculae of partially mineralized osteoid within the fibrous stroma; and densely packed irregular bony trabeculae.

Differential Diagnosis

Osteoid osteoma should be differentiated from osteoblastoma.

Immunohistochemistry Technique

Immunohistochemical stains demonstrate immunomarkers for nerve fibers within the tumor and surrounding reactive zone.

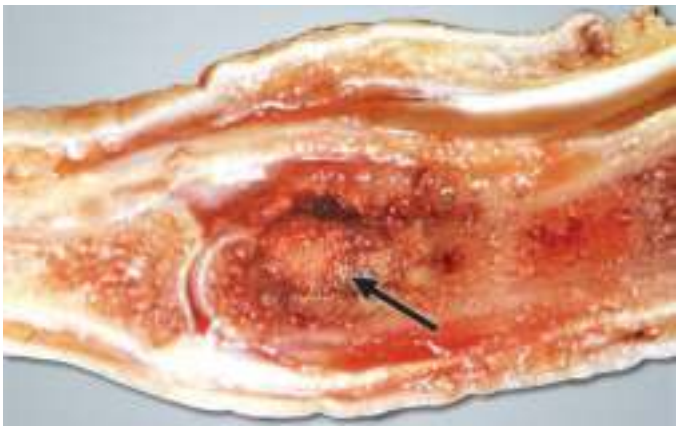

Fig. 27.19: Osteoid osteoma in the proximal phalanx of finger. The nidus of tumor is well demarcated, dark red, gritty and surrounded by dense sclerotic tissue (arrow). The treatment of choice is bone curettage. Proximal end of tibia is the most common sites.

Prognosis and Treatment

Patient is treated with aspirin and related analgesic drugs, surgical resection and percutaneous ablation. Local recurrence is seen in 5% of cases.

OSTEOBLASTOMA

Osteoblastoma is a benign bone forming tumor. Histologic features of osteoblastoma and osteoid osteoma are similar. Osteoblastoma measures >2 cm and osteoid osteoma <2 cm in diameter. Osteoblastoma lacks surrounding sclerotic bone, but osteoid osteoma has surrounding sclerotic bone. Comparison of osteoid osteoma and osteoblastoma is given in Table 27.26.

Table 27.26 Comparison of osteoid osteoma and osteoblastoma

Features	Osteoid Osteoma	Osteoblastoma
Age group	Children and young adults <25 years	Second to fourth decades of life
Sex distribution ratio	2:1	1:1
Size of tumor	<2 cm	>2 cm
Locations	Cortex of diaphysis of femur, humerus, radius and fibula. Proximal end of tibia is the most common site. Other sites are phalanges, talus and calcaneum	Metaphysis or diaphysis of femur, tibia, vertebrae, small bones of foot and ankle; and iliac bones
Pain in tumor	Severe nocturnal pain due to synthesis of prostaglandins and relieved by nonsteroidal anti-inflammatory aspirin and related analgesic drugs	Dull pain with minimal response to nonsteroidal anti-inflammatory aspirin and related analgesic drugs
Conventional radiograph	Well-demarcated radiolucent tumor with central mineralization surrounded by dense sclerosis	Well defined, predominantly osteolytic lesion surrounded by rim of sclerotic lesion
Gross morphology	Solitary round to oval tumor <2 cm with nidus dark red, gritty and surrounded by dense sclerotic tissue	Solitary round to oval tumor >2 cm with nidus dark red, gritty and surrounded by dense sclerotic tissue
Light microscopy (histological features similar)	Randomly interconnecting trabeculae of woven bone rimmed by osteoblasts with intervening fibrovascular stroma	Randomly interconnecting trabeculae of woven bone rimmed by osteoblasts with intervening fibrovascular stroma
Treatment and prognosis	Treated with aspirin, resection and percutaneous ablation; and local recurrence in 5% of cases	Treated by curettage or *en bloc* resection and local recurrence in 10–20% of cases

Incidence and Locations

Osteoblastoma accounts for 1% of primary bone tumors, which originates from metaphysis or diaphysis of femur and tibia. Other sites of tumor are vertebrae, small bones of hands and feet; and iliac bones.

Age and Sex Predilection

Osteoblastoma tumor occurs during second to fourth decades of life with male predominance.

Clinical Features

Patient with osteoblastoma presents with mass and dull pain in the femur or tibia of other bones. There is minimal response to nonsteroidal anti-inflammatory aspirin or related analgesic drugs to relieve pain.

Radiologic Findings

Radiograph shows well defined, predominantly osteolytic lesion surrounded by rim of sclerotic lesion of >2 cm in diameter.

Surgical Pathology: Osteoblastoma

Gross Morphology

Osteoblastoma is solitary round to oval tumor >2 cm with nidus dark red, gritty and surrounded by dense sclerotic tissue.

Light Microscopy

- Osteoblastoma is identical to giant osteoid osteoma. The nidus of tumor is composed of irregular reactive trabeculae of woven bone, lined by prominent osteoblastic rimming and osteoclasts separated by richly vascularized fibrovascular stroma.
- Tumor lacks mitosis and atypical cells (Fig. 27.20).

Differential Diagnosis

Osteoblastoma should be differentiated from osteoid osteoma, aneurysmal bone cysts, osteosarcoma and fibro-osseous lesions.

Prognosis and Treatment

Patient with osteoblastoma is treated by curettage and *en bloc* resection of tumor. Local recurrence after curettage of tumor occurs in 10–20% of cases.

CONVENTIONAL INTRAMEDULLARY OSTEOSARCOMA

Conventional intramedullary osteosarcoma is the most common malignant bone forming tumor; in which neoplastic cells form variable amount of osteoid, collagen and mineralized bone matrix. Histologic variants of osteosarcoma and their descriptive terms used in their diagnosis are given in Table 27.27.

Incidence and Locations

Conventional intramedullary osteosarcoma accounts for 20% of primary nonhematopoietic malignant bone tumors.

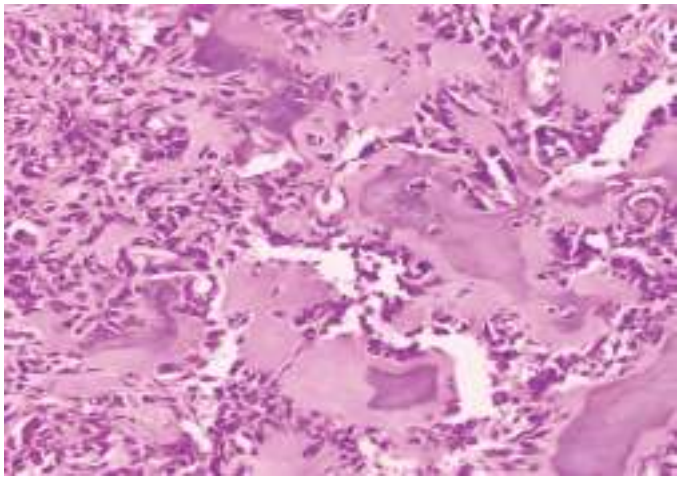

Fig. 27.20: Osteoblastoma. It is identical to giant osteoid osteoma. The nidus of tumor is composed of irregular reactive trabeculae of woven bone, lined by prominent osteoblastic rimming and osteoclasts separated by richly vascularized fibrovascular stroma. Tumor lacks mitosis and atypical cells (400X).

Table 27.27 Histologic variants of osteosarcoma and their descriptive terms used in their diagnosis

Intramedullary Osteosarcoma

- Conventional osteosarcoma
  - Osteoblastic osteosarcoma
  - Chondroblastic osteosarcoma
  - Fibroblastic osteosarcoma
  - Malignant fibrous histiocytoma-like osteosarcoma
  - Giant cell-rich osteosarcoma
  - Osteoblastoma-like osteosarcoma
  - Small cell osteosarcoma
  - Epithelioid osteosarcoma
- Telangiectatic osteosarcoma
- Well differentiated (low-grade intraosseous) osteosarcoma

Surface Osteosarcoma

- Parosteal (juxtacortical) osteosarcoma
- Periosteal osteosarcoma
- High-grade (*de novo* and dedifferentiated) osteosarcoma

Intracortical Osteosarcoma

Osteosarcoma arising within cortex

Extraskeletal Osteosarcoma

Osteosarcoma arising in extraskeletal region

Secondary Osteosarcoma

- Paget's disease of bone
- Post-radiation
- Bone infarct
- Fibrous dysplasia
- Metallic implant
- Chronic osteomyelitis

Osteosarcoma Associated with Specific Clinical Syndromes

- Hereditary retinoblastoma
- Li-Fraumeni syndrome
- Rothmund-Thomson syndrome
- Bloom syndrome (also known as Bloom-Torre-Machacek syndrome)
- Werner syndrome
- Diamond-Blackfan anemia
- Neurofibromatosis type 1
- Familial Paget's disease of bone
- Mazabraud syndrome
- McCune-Albright syndrome

- Long bones around knee joint (distal end of femur or proximal end of tibia) are commonly affected conventional intramedullary osteosarcoma in 65% of cases.
- However, it may originate from any bone, e.g. hip bone (15%), proximal humerus (10%) and mandible (8%). Rarely, it may occur in the upper end of femur.
- Tumor may extend into epiphysis, joint space and soft tissue. Unusual sites are bones distal to the wrists and joints. Locations of conventional intramedullary osteosarcoma and frequency are shown in Fig. 27.21 and Table 27.28.

Age and Sex Predilection

Conventional intramedullary osteosarcoma has bimodal age distribution, which affects below the age of 25 years (60%) and older than 40 years of age (10–30%). Peak incidence of tumor is seen during 10–20 years of age. Males and females are equally affected.

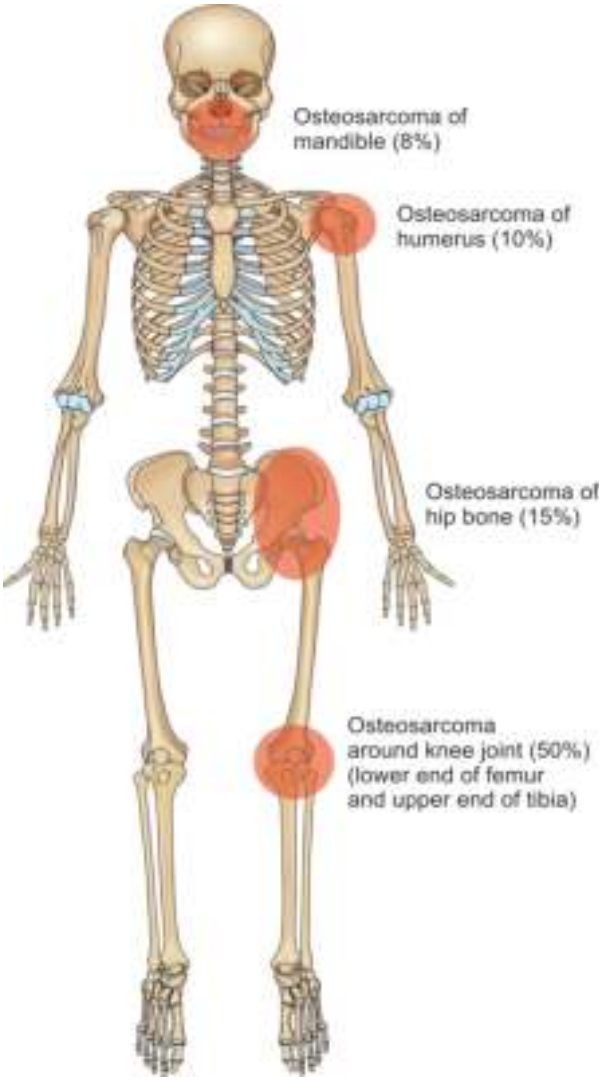

Fig. 27.21: Locations of conventional intramedullary osteosarcoma and frequency.

Table 27.28 Locations of conventional intramedullary osteosarcoma and frequency

Location of Conventional Osteosarcoma	Frequency
Around knee joint (distal end of femur or proximal end of tibia)	65%
Hip bones	15%
Proximal humerus	10%
Mandible	8%
Upper end of femur	Occasional case

Risk Factors

Risk factors for conventional intramedullary osteosarcoma are categorized in high risk, moderate risk and low risk precursor lesions (Table 27.29). Genetic or inherited disorders associated with increased risk for osteosarcoma are given in Table 27.30. Molecular genetic alterations in various histologic subtypes of conventional intramedullary osteosarcoma are given in Table 27.31.

Clinical Features

Initially patient with conventional intramedullary osteosarcoma presents with localized intermittent pain in deep-seated region with or without a mass.

Table 27.29 Risk factors for development of osteosarcoma

Categories of Risk Factors of Osteosarcoma	Examples of Precursor Lesions
High risk precursor lesions	▪ Familial retinoblastoma (RB gene mutation) ▪ Ollier disease (enchondromatosis) ▪ Maffucci syndrome (enchondromatosis associated with hemangiomas) ▪ Rothmund-Thomson syndrome ▪ Occupational exposure to radium used in watch-dial
Moderate risk precursor lesions	▪ Multiple osteochondromas ▪ Paget's disease of bone (polyostotic) results in parosteal osteosarcoma ▪ Previous exposure to radioisotope (phosphorus)
Low risk precursor lesions	▪ Fibrous dysplasia of bone ▪ Chronic osteomyelitis ▪ Bone infarct ▪ Giant cell tumor of bone ▪ Li-Fraumeni syndrome (germline TP53 gene mutation) ▪ Diamond-Blackfan anemia ▪ Werner syndrome ▪ Osteoblastoma ▪ Chondroblastoma ▪ Metallic and polyethylene implants ▪ Osteogenesis imperfecta

Table 27.30 Genetic or inherited disorders associated with increased risk for osteosarcoma

Genetic or Inherited Disorder	Inheritance Pattern	Gene Involved, Chromosomal Site and Molecule Malfunction	Other Associated Tumors
Hereditary retinoblastoma	Autosomal dominant	RB-1 cell cycle regulator gene on chromosome 13q14	Retinoblastoma, soft tissue sarcoma
Li-Fraumeni syndrome	Autosomal dominant	p53 (DNA repair protein) on chromosome 17q13.1	Breast carcinoma, adrenocortical carcinoma, bronchoalveolar carcinoma, soft tissue sarcoma including rhabdomyosarcoma, nervous system tumors, leukemia, lymphoma and myelodysplastic syndrome
Diamond-Blackfan anemia	Autosomal dominant	Ribosomal protein genes such as RPS19, RPL5 and others on multiple chromosomes	Leukemia, lymphoma, myelodysplastic syndrome
Rothmund-Thomson syndrome	Autosomal recessive	DNA helicase and REQL4 on chromosome 8q24.3	Leukemia, lymphoma, myelodysplastic syndrome, carcinoma
Bloom syndrome (also known as Bloom-Torre-Machacek syndrome)	Autosomal recessive	DNA helicase on chromosome 15q25.1	No other associated tumors
Werner syndrome	Autosomal recessive	DNA helicase on chromosome 8p12	Soft tissue sarcoma
Neurofibromatosis type 1	Autosomal dominant (50%) and sporadic (50%)	NF1 (neurofibromatosis 1) on chromosome 17q11	Neurofibromas, gastrointestinal stromal tumors, CNS tumors, leukemia, lymphoma, myelodysplastic syndrome, carcinoma
Familial Paget's disease of bone	Autosomal dominant	Multiple genes on multiple chromosomes 18q21, 5q31, 5q35 and others	Chondrosarcoma
Mazabraud syndrome	Unknown (sporadic)	GNAS1 (guanine nucleotide-binding protein; stimulating polypeptide 1) on chromosome 20q13	Polyostotic fibrous dysplasia, intramuscular myxomas
McCune-Albright syndrome	Unknown (sporadic)	GNAS1 (guanine nucleotide-binding protein; stimulating polypeptide 1) on chromosome 20q13	Polyostotic fibrous dysplasia

Table 27.31 Molecular genetic alterations in various histologic subtypes of conventional intramedullary osteosarcoma

Chromosomal Alterations	Chromosomal Aberrations	Comments
Numerical and structural chromosomal aberrations	1p36, 1q21.22, 6p12.21, 8q21.24, 12q11.14, 7p11.13 and 10q12.13	Recurrent amplification and DNA copy number gains at various chromosomal regions
Deletion and heterozygosity	3q13 involving LSAMP gene	Appears to correlate with progression and poor survival
Amplification of genes	▪ Amplification of RUNX2 gene mapping on 6p12.21 and other potential E2F3 and CDC5 genes ▪ VEGFA gene also maps on 6p12.21	▪ Promote terminal osteoblastic differentiation in conventional osteosarcoma associated with poor response to therapy ▪ Amplification of VEGFA gene promotes angiogenesis
Amplification and gain-of-function	Myc oncogene maps on 8q21.24	Amplification of Myc oncogene is demonstrated in 45–55% of cases of conventional osteosarcoma
Increased baseline activity of gene encoding protein synthesizing growth factor	PDGFB overexpression	Increases risk for osteosarcoma
Increased baseline activity of gene encoding protein synthesizing growth factor	FGF3 and HST1	Increases risk for osteosarcoma

Contd...

Table 27.31 Molecular genetic alterations in various histologic subtypes of conventional intramedullary osteosarcoma (*Contd...*)

Chromosomal Alterations	Chromosomal Aberrations	Comments
Chromothripsis	Small group of chromosomes	Chromothripsis has been proposed to involve shattering of small groups chromosome and their random assembly by non-homozygous end joining as a single event involved in *de novo* osteosarcoma
RB and TP53 gene mutations	RB gene (13q14), TP53 gene (Li-Fraumeni syndrome)	RB gene and TP53 gene increase risk for osteosarcoma
Amplification of cyclin-dependent kinase (CDK) gene	CDK4 (12q13.14), CCNE1 and CDKN2A	Loss of CDKN2A is associated with reduced survival in these cases
Exposure to occupational radiation (radium used in watch dial) induced osteosarcoma	Loss of 1p	Radiation-induced osteosarcoma in patient with bilateral retinoblastoma increases risk for osteosarcoma
Normal INK4a gene encoding $p14^{ARF}$, $p16^{NK4\alpha}$ function to arrest cell cycle	Inactivating of INK4α gene encoding $p14^{ARF}$, $p16^{NK4\alpha}$	INK4a gene mutations demonstrated in osteosarcoma

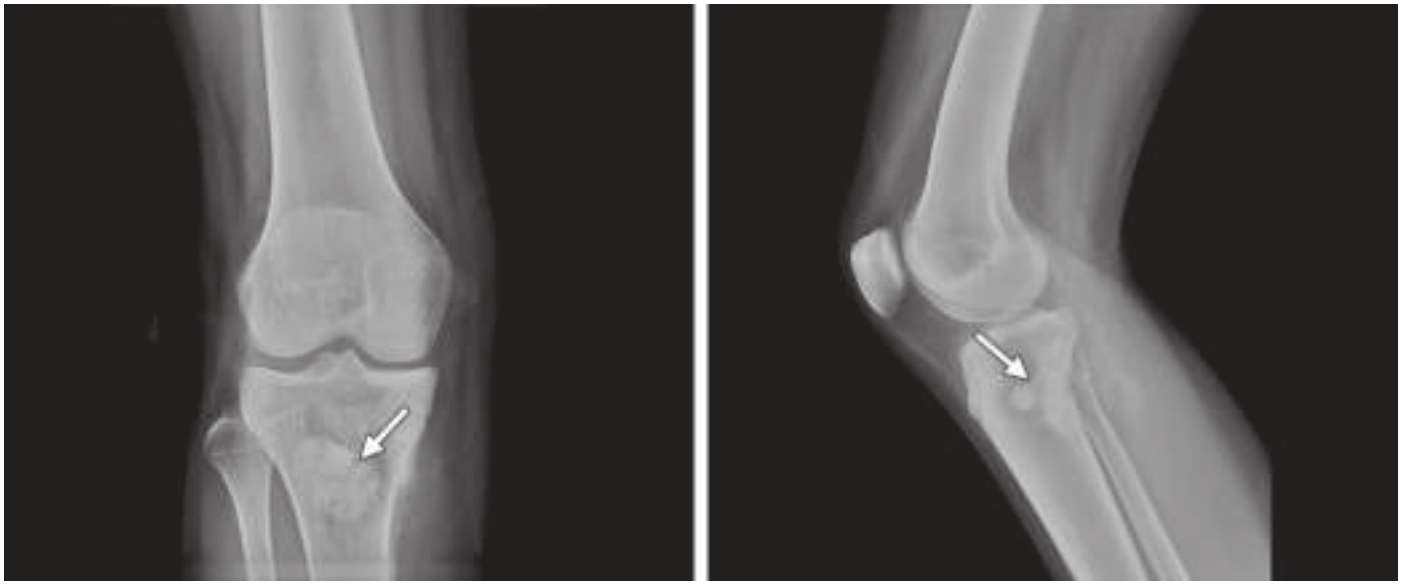

Fig. 27.22: Osteosarcoma of upper tibia in 16 years patient. Radiograph demonstrates a large irregularly marginated solid lesion in upper tibia involving epiphysis, upper growth plate, metaphysis and adjoining upper diaphysis. Tumor is extending up to subarticular region of upper tibia with erosion of articular surface in intercondylar eminence. Periosteal reaction is noted along posterior cortex with erosion and destruction of posterior cortex with associated soft tissue component posterior to upper tibia. Findings are suggestive of neoplastic etiology-osteosarcoma shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

Progressive enlargement of tumor may restrict range of movements, joint effusions and pathologic fracture. Pulmonary metastasis is associated with loss of weight and cachexia in advanced stage.

Radiologic Findings

- Radiologic appearance of conventional intramedullary osteosarcoma is extremely variable, i.e. large destructive poorly defined tumor or mixed osteoblastic and osteolytic mass that breaks the cortex and invades the soft tissue resulting in formation of mass in the soft tissue compartment.
- '**Codman triangle**' is a triangular shadow between the cortex and raised ends of periosteum demonstrated on radiograph. It is formed due to lifting of the periosteum away from the bone by the tumor. Bony spicules formed by the tumor cells give '**sunburst (sun ray) appearance**' (Fig. 27.22).
- Carcinomas of prostate and breast metastasizing to bones may show osteoblastic reaction. These tumors should be taken into consideration in differential diagnosis on radiological examination. Immunohistochemistry plays significant role in establishing metastatic bone disease.

Surgical Pathology: Conventional Intramedullary Osteosarcoma

Gross Morphology

- Gross morphology of conventional intramedullary osteosarcoma is variable depending on the presence of bone and other components.
- Cut surface of tumor shows variable appearance due to presence of osteoid, mineralized bone matrix, blood vessels in variable proportion; and presence of hemorrhage and necrosis. Gross morphology of conventional intramedullary osteoblastic osteosarcoma is shown in Fig. 27.23A and B.

Light Microscopy

Conventional intramedullary osteosarcoma is classified according to specific clinical features. However, there is no relationship between histologic variants (subtypes), treatment and prognosis.

- **Conventional intramedullary osteoblastic osteosarcoma:** Tumor is composed of malignant pleomorphic polyhedral and spindle-shaped neoplastic cells with hyperchromatic nuclei, numerous mitoses; and formation of 'lace-like' bone formation by neoplastic cells.
  - Formation of lace-like pattern of bone formed by the neoplastic cells is a diagnostic feature of conventional osteoblastic osteosarcoma.
  - The neoplastic cells also form island of reactive new woven bone (pinkish lace-like osteoid and calcified bone spicules) in response to the infiltration and destruction of the normal bone by the neoplastic cells.
  - Approximately in 60% of cases, there may be considerable histologic variation within a single tumor at primary site.
  - Metastasis may not exactly resemble the primary site tumor on histologic examination. Histologic features of conventional osteoblastic osteosarcoma are shown in Fig. 27.24.
- **Conventional intramedullary chondroblastic osteosarcoma:** Tumor is composed of pleomorphic polyhedral to spindle-shaped cells with hyperchromatic nuclei and numerous mitosis. Formation of hyaline chondroid islands by neoplastic cells is diagnostic feature. The lacunae contain neoplastic cells with severe cytological atypia (Fig. 27.25).
- **Conventional intramedullary fibroblastic osteosarcoma:** Tumor is composed of spindled neoplastic cells associated with extracellular collagen fibers arranged in 'storiform pattern'.
- **Conventional intramedullary giant cell-rich osteosarcoma:** Tumor is composed of neoplastic cells admixed with osteoclast type of giant cells.
- **Conventional intramedullary small cell-rich osteosarcoma:** Tumor is composed of small round cells that produce variable amount of osteoid.
- **Conventional intramedullary clear cell osteosarcoma:** Tumor is composed of neoplastic cells with sharply defined cell borders and clear or ground glass appearance cytoplasm containing vacuoles and central nuclei. There is presence of small trabeculae of reactive bone.
- **Conventional intramedullary chondroblastoma-like osteosarcoma:** Tumor is composed of neoplastic cells growing in an infiltrative pattern.
- **Conventional intramedullary malignant fibrohistiocytoma-like osteosarcoma:** Tumor is composed of lace-like osteoid deposits, hemangiopericytoma like blood vessels, formation of rosette-like structures and epithelioid neoplastic cells.

Electron Microscopy

Presence of mesenchymal neoplastic cells containing dilated rough endoplasmic reticulum, prominent Golgi apparatus, calcium hydroxyapatite crystals admixed with matrix collagen fibers in conventional osteoblastic osteosarcoma differentiate Ewing sarcoma/primitive neuroectodermal tumor (PNET), lymphoma and melanoma.

Immunohistochemistry Technique

Conventional intramedullary osteosarcoma, whether primary or secondary, has broad immunoprofile, but lacks specificity shown as below:

Markers	Expression
Osteocalcin	Positive
Osteonectin	Positive (neoplastic cells and neoplastic matrix)
S-100 protein	Positive
Actin	Positive
Smooth muscle actin	Positive
NSE (neuron-specific enolase)	Positive
Factor VIII	Positive
CD31	Positive
CD45	Positive
CK (cytokeratin)	Positive (diagnostic pitfall)
EMA (epithelial membrane antigen)	Positive (diagnostic pitfall)

Differential Diagnosis

Conventional intramedullary osteosarcoma should be differentiated from variety of benign and malignant tumors. In young patients, malignant bone tumors show prominent cartilaginous differentiation is almost conventional intramedullary chondroblastic osteosarcoma rather than conventional chondrosarcoma, which occurs in elderly patients. Conventional osteoblastoma like osteosarcoma can be confused with osteoblastoma and fibrous dysplasia. Aneurysmal bone cyst needs to be differentiated from telangiectatic osteosarcoma. Small cell osteosarcoma can mimic Ewing sarcoma and other round cell tumors. Stress fracture with callus formation and myositis ossificans should be differentiated from osteosarcoma.

Mode of Spread

Conventional intramedullary osteosarcoma invades surrounding soft tissue and metastasizes via

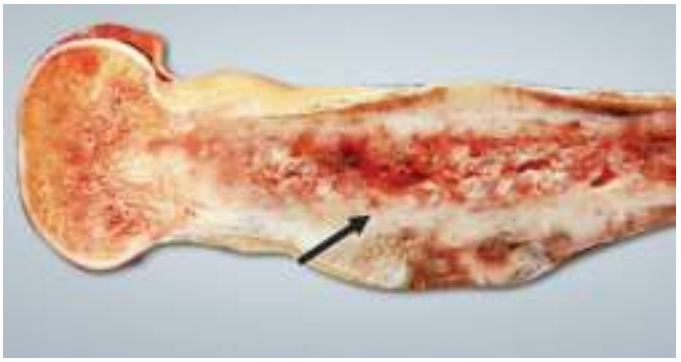

Fig. 27.23A: Osteosarcoma. Tumor has involved the medullary cavity of lower end of femur and broken through the cortical bone and caused elevation of the periosteum shown by arrow.

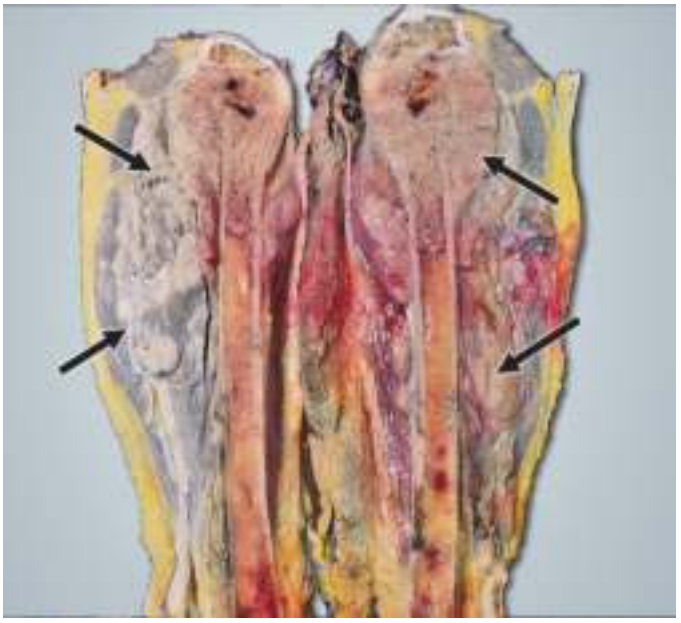

Fig. 27.23B: Conventional intramedullary osteosarcoma. Cut section of the specimen shows intramedullary mass arising from the metaphyseal region of tibia, which is permeating with in medullary region and surrounding soft tissues shown by arrows. (*Courtesy*: Dr. Tushar Kalonia.)

hematogenous route to the lungs (most common), liver, brain and other sites.

- **Local invasion:** Tumor spreads extensively within the medullary cavity bone marrow, evidentially eroding through the cortical plate and invading the surrounding tissue. Tumor usually does not cross the epiphyseal plate and thus spares involvement of joint cavity. Involvement of joint may occur due to either extension of tumor cells along the tendinoligamentous structures or through the attachment site within the joint capsule.
- **Hematogenous route:** Initially, the tumor metastasizes via hematogenous route to lungs in 20% of cases. Later, it may spread to liver, brain, other sites including involvement of other bones.

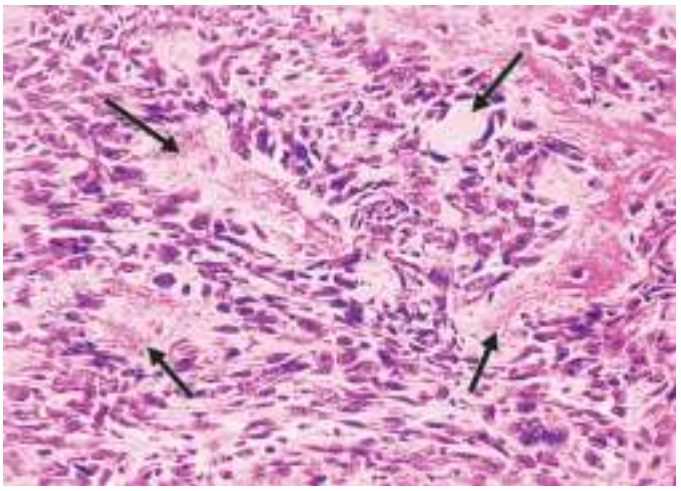

Fig. 27.24: Conventional intramedullary osteoblastic osteosarcoma. Tumor is composed of malignant pleomorphic neoplastic cells with hyperchromatic nuclei, numerous mitoses; and formation of 'lace-like' bone formation by neoplastic cells. Formation of lace-like pattern bone formed by the neoplastic cells is a diagnostic feature of conventional osteoblastic osteosarcoma. The neoplastic cells also form island of reactive new woven bone (pinkish lace-like osteoid and calcified bone spicules shown by arrows) in response to the infiltration and destruction of the normal bone by the neoplastic cells (400X).

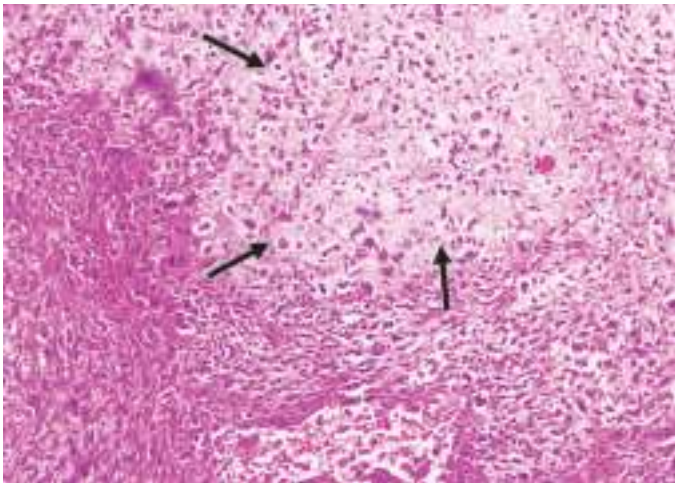

Fig. 27.25: Conventional intramedullary chondroblastic osteosarcoma. Tumor is composed of pleomorphic polyhedral to spindle-shaped cells with hyperchromatic nuclei and numerous mitosis. Formation of hyaline chondroid islands by neoplastic cells is diagnostic feature. The lacunae of neoplastic cells with severe cytological atypia (400X).

Prognosis and Treatment

Conventional intramedullary osteosarcoma is treated by combination of surgery and chemotherapy. Prognosis depends on histologic variants, grade of tumor, localized tumor and metastasis. Survival rate for localized tumor is higher than in tumor metastasizing to distant organs.

- Preoperative chemotherapy is administered in patient with conventional intramedullary high-grade osteosarcoma. Chemotherapy has improved five-year

survival rate in these patients. Accurate assessment of the chemotherapeutic response is critical. A good prognostic response is defined by the presence of >90% necrosis of neoplastic cells within the tumor.

- Combined chemotherapy and surgery are curable in children and adolescents in 80% of cases. Osteosarcoma affecting elderly person has less favorable response to chemotherapy. Prognosis in histologic variants of osteosarcoma are given in Table 27.32.

LOW-GRADE CENTRAL OSTEOSARCOMA

Low-grade central osteosarcoma is a malignant bone forming tumor, which arises within the medullary cavity of bone. It is also known as low-grade intramedullary osteosarcoma, which accounts for 1–2% of osteosarcomas. Most common sites are distal femur and proximal tibia in 80% of cases. However, any bone may be affected. Other sites are flat bones and small bone of hands and feet.

Age and Sex Predilection

Peak of low-grade central osteosarcoma incidence is in the third decade of life with slight male predominance.

Clinical Features

Patient presents with localized pain with or without swelling over months to years. Low-grade central osteosarcoma has indolent course when compared with conventional intramedullary osteosarcoma.

Radiologic Findings

Radiograph shows a large intramedullary poorly demarcated osteolytic mass, coarsely trabeculated with aggressive features in the metaphyseal or metadiaphyseal regions most often extending to the end of affected bone. CT scan and MRI are helpful in delineating the extent of tumor and identification of cortical abnormalities, that may not be evident on conventional radiograph.

Surgical Pathology: Low-grade Central Osteosarcoma

Gross Morphology

- Tumor shows a gritty gray medullary mass that may contain fleshy and fibrous areas. Cortical destruction may be demonstrated in some cases.
- Tumor may extend along the length of long bone with poor demarcation between the tumor and uninvolved bone.

Light Microscopy

- Tumor is composed of spindle-shaped neoplastic cells forming variable amounts of osteoid formation. Neoplastic cells are arranged in interlacing bundles showing minimal cytologic atypia and a few atypical mitoses.
- Some tumors contain irregular anastomosing branching and curved trabeculae mimicking woven bone in fibrous dysplasia. Tumor permeates the bone and extends into soft tissue. These histologic features are absent in fibrous dysplasia.

Immunohistochemistry Technique

- Tumor demonstrates one or more ring chromosomes showing amplification in the chromosomal 12q13.15 region.
- Potential target genes in this region include MDM2 and CDK4 showing amplification in majority of cases. Immunohistochemical analysis of MDM2 and CDK4 provides a useful diagnostic tool in low-grade central osteosarcoma.

Markers	Expression
MDM2	Positive
CDK4	Positive

Table 27.32 Prognosis in histologic variants of osteosarcoma

Features	Clinical Prognostic Significance
Osteosarcoma of jaw	Good prognosis (five-year survival in 80%)
Low-grade central osteosarcoma	Good prognosis
Osteosarcoma below knee joint	Better prognosis than located in proximal extremity
Parosteal osteosarcoma	Better prognosis than conventional osteosarcoma
Periosteal osteosarcoma	Better prognosis than conventional osteosarcoma
Osteosarcoma of vertebrae and skull	Poor prognosis
Multifocal osteosarcoma	Poor prognosis
Telangiectatic osteosarcoma	Poor prognosis
Osteosarcoma arising in Paget's disease of bone	Poor prognosis
High-grade surface osteosarcoma	Poor prognosis
Small cell osteosarcoma	Poor prognosis

Prognosis and Treatment

Patient with low-grade central osteosarcoma is treated with wide surgical excision of tumor. Prognosis is excellent in 90% of cases with five-year survival. Tumor may transform into high-grade osteosarcoma in 10–35% of cases. Such patients are treated with administration of chemotherapy.

TELANGIECTATIC OSTEOSARCOMA

Telangiectatic osteosarcoma is a high-grade malignant tumor and variant of central intramedullary osteosarcoma. It accounts for <4% of all osteosarcomas. Tumor is characterized by formation of large cystic spaces filled with blood. Cystic spaces show septations. Most common sites of tumor are metaphysis of distal femur (40%), proximal tibia (15%), proximal humerus (10%) and proximal femur (8%). Telangiectatic osteosarcoma is more prone to pathologic fracture.

Age and Sex Predilection

Telangiectatic osteosarcoma occurs in the second decade of life with male predominance.

Clinical Features

Patient with telangiectatic osteosarcoma presents with localized pain and enlarging. Massive bone destruction by the tumor may result in fracture in 25% of cases.

Radiologic Findings

- Radiograph shows osteolytic lesion with evidence of extensive destruction of bone and extension into the soft tissues. Most tumors are located in the metaphysis and extending into the soft tissue.
- Tumor most often expands the cortex and/or disrupts the cortex. Periosteal reaction forming 'Codman triangle' and 'onion-skin appearance' are frequent in these tumors.

Surgical Pathology: Telangiectatic Osteosarcoma

Gross Morphology

- Tumor shows a hemorrhagic multicystic lesion filled with blood clot, described a 'bag of blood'. Fleshy or sclerotic areas are not demonstrated.
- Extensive cortical erosion or destruction associated with involvement of soft tissue may be demonstrated in these cases.

Light Microscopy

- Tumor is composed of blood-filled or empty spaces simulating aneurysmal bone cyst. Cystic spaces are separated by septa of variable thickness. These cystic spaces are populated with pleomorphic neoplastic cells containing hyperchromatic nuclei. Some neoplastic cells float in the hemorrhagic areas. Atypical mitoses are demonstrated.
- Osteoclastic type of giant cells is demonstrated in the septa and edges of tumor.
- Osteoid formation by neoplastic cells is most often focal and confluent. Neoplastic cells permeating in pre-existing bone trabeculae are most often demonstrated.

Molecular Genetic Alterations

Telangiectatic osteosarcomas are genetically less complex than conventional intramedullary osteosarcoma. Trisomy and chromosomal aberrations and regional gains at 1q21–23.2, 1q25.2–31.1 and 7q21.13–21.2 are demonstrated by metaphase CGH and array CGS.

Prognosis and Treatment

Telangiectatic osteosarcoma is an aggressive tumor, but has sensitivity to chemotherapy and radiotherapy. The overall survival rate is similar to other histologic subtypes of osteosarcoma.

SMALL CELL OSTEOSARCOMA

Small cell osteosarcoma is high-grade bone forming tumor with variable degrees of osteoid element formed by neoplastic cells. It accounts for 2% of all osteosarcomas. Most common sites are **metaphysis of long bones**. It may affect 5–80 years of age group. Peak incidence of small cell osteosarcoma is during second decade of life with slight female predominance.

Clinical Features

Patient presents with localized pain with or without a mass. Patient may develop pathologic fracture.

Radiologic Findings

Radiograph shows destruction of cortex with osteolytic and radiodense components. Mineralized tissue in the tumor invading soft tissue strongly suggests small cell osteosarcoma.

Surgical Pathology: Small Cell Osteosarcoma

Gross Morphology

- Morphologic features of small cell osteosarcoma are similar to conventional intramedullary osteosarcoma.
- Tumor is firm gritty white, but not homogenous due to presence of neoplastic cells admixed with osteoid element, blood vessels and necrosis.

Light Microscopy

- Tumor is composed of small blue cells with scanty cytoplasm, round to oval nuclei with fine to chromatin and mitoses in the range of 3–5/high power fields.
- Lace-like osteoid production by neoplastic cells is always present and should be differentiated from fibrin deposits present in Ewing sarcoma.

Immunohistochemistry Technique

- Small cell osteosarcoma shows membrane positivity for **CD99** and osteoid element. Therefore, some authors consider this tumor as a variant of Ewing sarcoma with diverse differentiation showing positivity for CD99 and lacking osteoid element.
- Non-Hodgkin's lymphoma shows positivity for leukocyte common antigen (LCA), but lacks osteoid element.

Prognosis and Treatment

Small cell osteosarcoma has relatively poor prognosis than conventional intramedullary osteosarcoma. Patient is treated by surgery and chemotherapy.

PAROSTEAL OSTEOSARCOMA

Parosteal osteosarcoma is a low-grade malignant bone forming tumor arising from the **surface of long bones**. Osteoid element is formed by the neoplastic cells.

Incidence and Locations

Parosteal osteosarcoma accounts for 4% of all osteosarcomas. Most common site is the **surface of distal femur** in 70% of cases. Other important sites are proximal ends of tibia and humerus. The tumor wraps around the involved long bone. Flat bones are not involved.

Age and Sex Predilection

Parosteal osteosarcoma occurs in young adults during third decade of life with slight female predominance.

Clinical Features

Patient presents with painless swelling around knee joint or humerus, and inability to flex the joint. Sometimes, patient presents with painful swelling.

Radiologic Findings

Radiograph shows presence of heavily mineralized mass attached to the cortex with broad base. The tumor has a tendency to wrap around the involved bone. CT scan and MRI are useful in analyzing the extent of medullary involvement. Outer portion of tumor is less vascularized.

Surgical Pathology: Parosteal Osteosarcoma

Gross Morphology

- Tumor is hard lobulated mass affixed to the involved bone. In occasional case, presence of nodular cartilage with incomplete cap wrapping the tumor may simulate osteochondroma.
- Periphery of the tumor may be soft in consistency due to invasion of the tumor into surrounding soft tissue.
- Presence of fleshy areas in tumor suggests progression of the tumor to high-grade osteosarcoma. Focal invasion of the cortex and medullary cavity may be present.

Light Microscopy

- Tumor is composed of spindle cells with minimal cytologic atypia arranged in parallel pattern. Neoplastic cells form bony trabeculae. Hypercellular tumor composed of spindle cells show moderate cytologic atypia. Tumor may be hypocellular in <20% of cases.
- Cartilaginous differentiation in the tumor is demonstrated in 50% of cases. Tumor composed of high-grade spindle cells indicates progression of parosteal osteosarcoma to high-grade osteosarcoma.

Immunohistochemistry Technique

Immunohistochemical analysis of MDM2 (chromosome 12q region) and CDK4 provides a useful diagnostic tool in parosteal osteosarcoma.

Markers	Expression
▪ MDM2	▪ Positive
▪ CDK4	▪ Positive

Molecular Genetic Alterations

Parosteal osteosarcoma demonstrates one or more ring chromosomes showing amplification of genes in the chromosomal 12q13.15 region. Potential target genes in this region include MDM2 and CDK4 showing amplification in >85% of cases.

Prognosis and Treatment

Parosteal osteosarcoma is treated by wide local resection of tumor and prosthetic replacement. Prognosis is excellent with five-year survival in 90% of cases. Recurrence occurs in incompletely excised tumor and tumor undergoing dedifferentiation and progressing to high-grade osteosarcoma.

PERIOSTEAL OSTEOSARCOMA

Periosteal osteosarcoma is an intermediate grade malignant tumor, in which neoplastic cells form both cartilage and osteoid element. Tumor originates from the region between cortex and overlying periosteum on the surface of long bones, i.e. lower femur, upper tibia, fibula, humerus, ulna, and ilium.

Incidence and Locations

Tumor accounts for <2% of all osteosarcomas, which originates from diaphyseal or meta-diaphyseal region of distal femur and upper tibia in 80% of cases. Other sites are humerus, fibula, ulna and pelvis. Tumor may completely wrap around circumference of the long bones. Uncommon sites are clavicle, ribs, jaw and cranium.

Age and Sex Predilection

Periosteal osteosarcoma most often occurs during second to third decades of life with male predominance. Tumor may also affect persons >50 years of age.

Clinical Features

Patient presents with lump and/or associated pain over <6 moths to one-year duration.

Radiologic Findings

- Radiograph shows a soft tissue mass extending from cortex. Cortical thickening and extrinsic cortical scalloping are demonstrated in >80% of cases. Periosteal reaction caused by tumor perpendicular to the long axis of bone gives 'sun-burst' appearance or 'hair-on-end' pattern in 95% of cases.
- Both CT scan and MRI are useful to analyze tumor margins, medullary extension and relation of tumor to major blood vessels and peripheral nerves.

Surgical Pathology: Periosteal Osteosarcoma

Gross Morphology

- Tumor shows glistening gray cartilaginous lobulated mass over bony surface. Base of the tumor may be heavily ossified.
- Spiculed calcification perpendicular to the long axis of bone is demonstrated. Tumor may erode the cortex but not extend into the medullary cavity.

Light Microscopy

- Tumor is composed of abundant cartilaginous matrix formed by neoplastic cells. Tumor cells show cytologic atypia.
- Osteoid element or myxoid matrix or fibroblastic element may be demonstrated in the tumor.

Molecular Genetic Alterations

Point mutation of TP53 gene is demonstrated in 40% of cases. Chromosomal alterations are constant in periosteal osteosarcoma, i.e. gain of 8q, loss of 6q and amplification of 8q11.24 and 12q11.15.

Prognosis and Treatment

Patient with periosteal osteosarcoma is treated by surgical excision of tumor or limb salvage. Patient is not benefited by chemotherapy. Patient has good prognosis with five-year survival in >80% of cases. Metastasis may be demonstrated in >80% of cases.

HIGH-GRADE SURFACE OSTEOSARCOMA

High-grade surface osteosarcoma originates from cortical surface of long bones. Lace-like bone is formed by neoplastic cells. It accounts for <1% of all osteosarcomas. Most common sites of tumor are femur (50%), tibia (20%) and humerus (10%). It most often occurs in the second decade of life with male predominance.

Clinical Features

Patient presents with lump and pain in involved long bone over short duration.

Radiologic Findings

Radiologic findings of high-grade surface osteosarcoma and periosteal osteosarcoma are similar except the presence of mineralization of tumor. Radiograph shows a surface radiolucent tumor with spiculed calcification perpendicular to the long axis of bone. New bone formation is common in the peripheral portion of tumor.

Surgical Pathology: High-grade Surface Osteosarcoma

Gross Morphology

- Tumor is situated on the cortical surface of bone, and often eroding the cortex.
- Tumor is large lobulated and soft to firm in consistency depending on the presence of predominant osteoblastic, chondroblastic or fibroblastic component.
- Tumor extends into the surrounding soft tissue and forms a well circumscribed lobulated mass. Rarely, it may extend into medullary cavity.

Light Microscopy

- High-grade surface osteosarcoma and conventional central osteosarcoma have identical histologic features.
- Tumor is composed of polyhedral to spindle-shaped neoplastic cells containing hyperchromatic nuclei and numerous atypical mitoses.
- Formation of lace-like bone formation by neoplastic cells is diagnostic feature.
- Degree of cytologic atypia is greater in high-grade surface osteosarcoma than conventional central osteosarcoma.

Molecular Genetic Alterations

Amplification of the TSPAN31 (formerly known as SAS) gene located on 12q13.14 has been demonstrated in a case with high-grade surface osteosarcoma.

Mode of Spread

High-grade surface osteosarcoma spreads by local invasion into soft tissue compartment and via hematogenous route to lungs and other sites.

Prognosis and Treatment

- Prognosis is identical in high-grade surface osteosarcoma and conventional central osteosarcoma. Patient with unresectable tumor is treated by radiotherapy.
- Multi-agent chemotherapy has a dramatic impact on outcome of the disease. Five-year survival is demonstrated in >80% of cases.

EWING SARCOMA/PRIMITIVE NEUROECTODERMAL TUMOR

EWING SARCOMA

Ewing sarcoma and primitive neuroectodermal tumor (PNET) are related entities. Ewing sarcoma/PNET is composed of small cells with uniform round hyperchromatic nuclei.

- Distinguishing feature of Ewing sarcoma/PNET is degree of neural differentiation demonstrated by light microscopy (Homer-Wright rosettes), electron microscopy and immunohistochemistry. Approximately 20% cases of Ewing sarcoma show features of neural differentiation.
- Ewing sarcoma is currently used to describe a tumor composed of small, round cells lacking extracellular matrix, containing variable amounts of glycogen, and scant evidence of neuroectodermal derivation histologically, ultrastructurally and immunohistochemically.
- Ewing sarcoma tends to originate in skeletal sites populated by hematopoietic marrow of long bones in meta-diaphyseal regions.
- Ewing sarcoma is characterized by recurrent balanced chromosomal translocations in almost all cases. Reciprocal chromosomal translocation between chromosomes 11 and 22 results in fusion of the amino terminus of EWSR1 gene to the FLT1 gene (EWSR-FLT1 fusion gene), which encodes a nuclear transcription factor resulting in cellular proliferation.

Diagnostic Features

Generally, two or more major features of neural differentiation are essential for diagnosis of primitive neuroectodermal tumor (PNET). Approximately 20% cases of Ewing sarcoma show features of neural differentiation. Diagnostic criteria of Ewing sarcoma/primitive neuroectodermal tumor (PNET) are given in Table 27.33.

Incidence and Locations

Ewing sarcoma accounts 6–8% of primary most malignant tumors. It is the second most common bone sarcoma in children after osteosarcoma. Tumor originates from primitive bone marrow elements or immature mesenchymal cells of bones. Most common sites are meta-diaphyseal regions of femur, humerus; pelvis and ribs. Rare sites skull, scapula and short tubular bones of hands and feet.

Age and Sex Predilection

Ewing sarcoma most often occurs during second decade of life. Nearly 80% of patients are below the age of 20 years. Only 20% of patients are below the age of 8 years or older than 20 years.

Clinical Features

Patient presents with severe pain may be associated with a swelling in the bone. Systemic systems are intermittent low-grade fever, weight loss and early fatigued. Pathologic fracture of bone may be demonstrated in 10% of cases. Physical examination reveals localized tenderness associated with fullness or even mass in the bone. Clinically Ewing sarcoma simulates osteomyelitis. Laboratory findings are nonspecific, which include leukocytosis, increased erythrocyte sedimentation rate and anemia.

Ancillary Laboratory Tests

Ancillary laboratory tests performed in Ewing sarcoma are conventional cytogenetic analysis, FISH (fluorescence *in situ* hybridization) and PCR (polymerase chain reaction) are given in Table 27.34.

Radiologic Findings

- **Conventional radiograph:** Ewing sarcoma has no definite radiologic appearance. Tumor is most often radiolucent and ill-defined in the metaphysis or diaphysis of long bones giving 'moth-eaten' appearance. Degree of periosteal reaction may be disproportionate to the amount of bone destruction giving 'onion skin' appearance on radiograph. The outer cortex of bone may be identified from outside, even when the mass originates from soft tissue.
- **CT scan:** It may demonstrate cortical destruction by Ewing sarcoma.

Table 27.33 Diagnostic criteria of Ewing sarcoma/primitive neuroectodermal tumor (PNET)

Diagnostic Criteria (≥2 Major Features of Neural Differentiation)	Comments
Light microscopy	Neural differentiation (Homer-Wright rosettes)
Electron microscopy	Neural differentiation
Immunohistochemistry	Expression of neural differentiation markers, i.e. NSE (neuron-specific enolase), synaptophysin and chromogranin
MIC2 expression	Present
Vimentin expression	Present

Table 27.34 Ancillary laboratory tests performed in Ewing sarcoma

Ewing Sarcoma/PNET: Ancillary Laboratory Tests
Conventional cytogenetic analysis: It is performed to demonstrate reciprocal chromosomal translocation between chromosomes 11 and 22 (85%), chromosomes 21 and 22 (10–15%), chromosomes 7 and 22, chromosomes 17 and 22, chromosomes 2 and 22.
FISH (fluorescence *in situ* hybridization): FISH is performed to diagnose Ewing sarcoma.
PCR (polymerase chain reaction): PCR is performed to analyze **EWSR1/FLT1** and **EWSR1/ERG fusion genes**.

- **MRI scan:** It demonstrates extraosseous soft mass (Fig. 27.26).
- **Radionuclide scanning:** It demonstrates intramedullary spread better than on conventional radiograph.

Surgical Pathology: Ewing Sarcoma

Gross Morphology

- Ewing sarcoma is grayish yellow with soft consistency. Necrotic yellowish and semi-fluid material obtained from intramedullary or subperiosteal lesion on open biopsy erroneously interpreted as pus by the surgeons.
- Gross morphology demonstrates permeative destruction prior to chemotherapy.
- In majority of cases, overlying soft tissue tumor mass is connected to the intraosseous tumor on light microscopy; even though its gross continuity is not always obvious. Gross morphology of Ewing sarcoma is shown in Fig. 27.27.

Light Microscopy

- On histologic examination, Ewing sarcoma gives monotonous appearance on low magnification.
- Tumor is composed of uniform monotonous small round neoplastic cells with poorly defined cell borders. Neoplastic cells contain round dark nuclei, fine chromatin and nucleoli; and surrounded by scant clear to amphophilic cytoplasm.
- A few tumors are composed of large neoplastic cells containing prominent nuclei and increased mitotic activity. Scant mitotic activity is demonstrated. There is no extracellular matrix in the tumor (Fig. 27.28A).
- Aggregates of neoplastic cells may be arranged along delicate fibrous septae or around blood vessels forming 'Homer-Wright rosettes'.
- 'Necrosis' is a regular feature of Ewing sarcoma even in the absence of prior chemotherapy administered to the patient.

Histochemistry

'Neoplastic' cells of Ewing sarcoma contain glycogen in the cytoplasm demonstrated by PAS/diastase sensitive stain.

Differential Diagnosis

Ewing sarcoma has morphologic resemblance to various lesions. It should be differentiated from non-Hodgkin lymphoma, leukemia, osteomyelitis, metastatic neuroblastoma, small cell osteosarcoma, mesenchymal chondrosarcoma and embryonal sarcoma; by histologic examination, histochemistry, immunohistochemistry, conventional cytogenetic analysis, fluorescence *in situ* hybridization (FISH) and polymerase chain reaction (PCR) techniques for analysis of fusion protein.

Immunohistochemistry Technique

Ewing sarcoma shows positivity for panel of markers, which include MIC2, CD99, FLT1, vimentin, cytokeratins and neural differentiation markers, e.g. NSE (neuron-specific enolase), synaptophysin and neuron triplet filament protein. Ewing sarcoma shows positivity for CD99 and FLI-1 immunohistochemical markers (Fig. 27.28B and C).

Markers	Expression
MIC2 (specific marker)	Positive
CD99 (O-13, HBA-74)	Positive (membranous staining)
FLI-1 (sensitive but not specific)	Positive
Vimentin	Positive
CK (cytokeratins low molecular weight)	Positive
NSE (neuron-specific enolase), neural differentiation marker	Positive
Synaptophysin (neural differentiation marker)	Positive
Neuron triplet filament protein (neural differentiation marker)	Positive

Molecular Genetic Alterations

Specific molecular genetic aberrations in Ewing sarcoma/PNET and Ewing sarcoma-like tumors without ETS involvement are given in Table 27.35.

- About 85% of Ewing sarcomas harbor a somatic reciprocal chromosomal translocation between chromosomes 11 and 22 resulting in fusion of another amino terminus of the EWRS1 gene with FLT1 gene, leads to generation of EWRS1-FLT1 fusion protein that functions as an aberrant transcription factor required for cellular proliferation.
- In 10–15% of Ewing sarcomas harbor a somatic reciprocal chromosomal translocation between chromosomes 21 and 22. It leads to fusion of EWRS1 with members of ETS family resulting in generation of oncoprotein that function as an aberrant transcription factor required for unrestricted cellular proliferation.
- The remaining Ewing sarcomas show harbor a somatic reciprocal chromosomal translocation between chromosomes 7 and 22, chromosomes 17 and 22, chromosomes 2 and 22 and inversion of chromosome 22. The resulting chimeric proteins function as abnormal transcription factors required for unrestricted cellular proliferation.

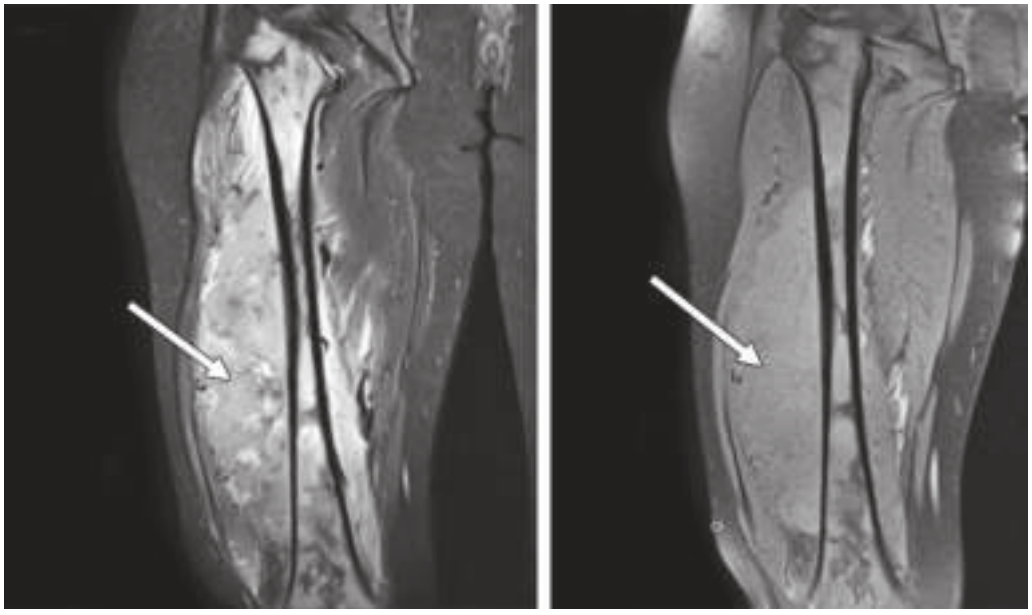

Fig. 27.26: Ewing sarcoma in the diaphysis of femur in a child. Post-contrast enhancement on magnetic resonance imaging demonstrates a heterogenous large mass lesion around the femoral diaphysis with few areas of calcification. The tumor is predominantly involving anterior and anterolateral compartment of thigh and smoothly elevating the vastus muscles. Possibility of round cell tumor likely Ewing sarcoma needs consideration. Other differential diagnosis includes lymphoproliferative disorder shown by arrows. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

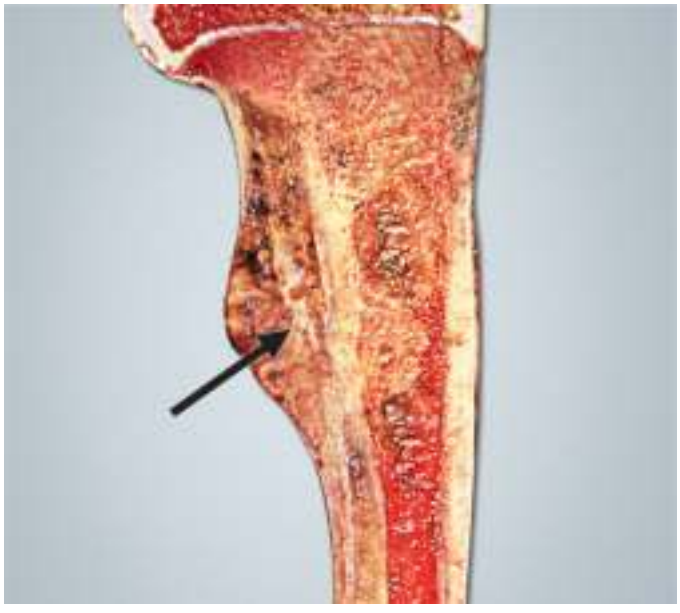

Fig. 27.27: Ewing sarcoma. A large tumor in the upper diaphysis of tibia has eroded the cortical bone and extended and duplicated beneath the periosteum having an onion-skin configuration. Tumor is grayish yellow necrotic with soft consistency (arrow).

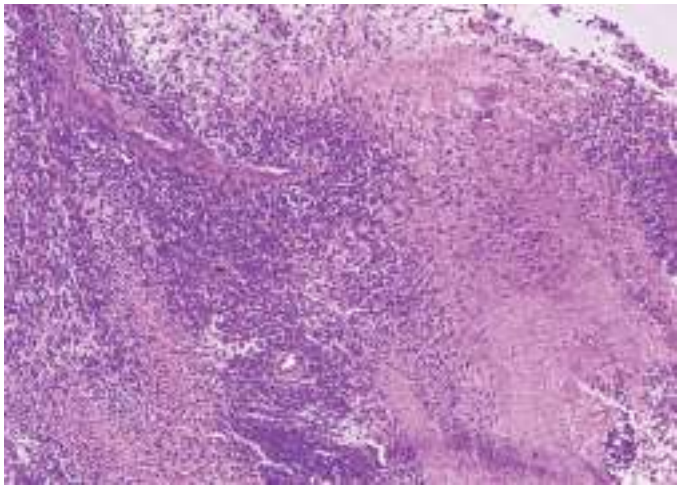

Fig. 27.28A: Ewing sarcoma. Tumor is composed of uniform monotonous small round neoplastic cells with poorly defined cell borders. Neoplastic cells contain round dark nuclei, fine chromatin and nucleoli; and surrounded by scant clear to amphophilic cytoplasm. Scant mitotic activity is demonstrated. There is no extracellular matrix in the tumor. Tumor cells forming Homer-Wright rosettes are also demonstrated in some cases. Cytoplasm of tumor cells is rich in glycogen demonstrated by PAS staining (100X).

Prognosis and Treatment

- Patients who present with metastatic disease have survival rates of about 20%. Ewing sarcoma follows an extremely adverse clinical course with early metastasis to lungs, liver, brain and other bones (multifocal lesions). Overall survival rate depends on anatomic location, size of tumor, and stage. Large size tumor arising in pelvis and spine, pathologic fracture and distant metastasis are poor prognostic factors and associated with poor prognosis.
- It has been reported that patients with Ewing sarcoma have most common type of fusion transcript (EWS/

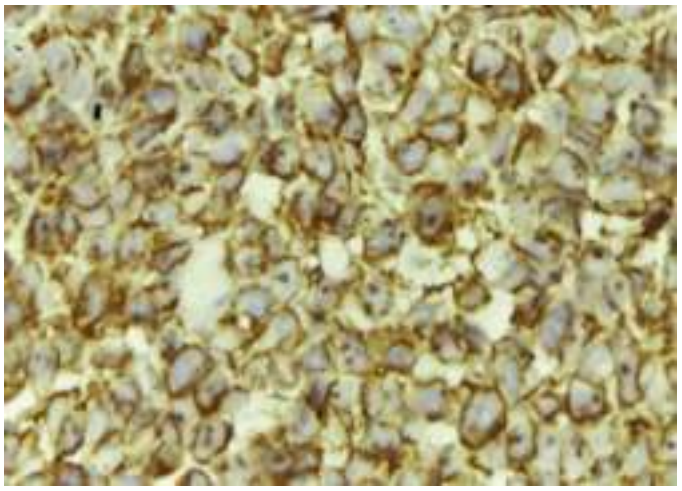

Fig. 27.28B: CD99 positivity in Ewing sarcoma. Certain types of soft tissue tumor are positive for CD99. CD99 is a membranous protein that is expressed in most cases of Ewing sarcoma (EWS), synovial sarcoma (SS) and low-grade fibromyxoid sarcoma.

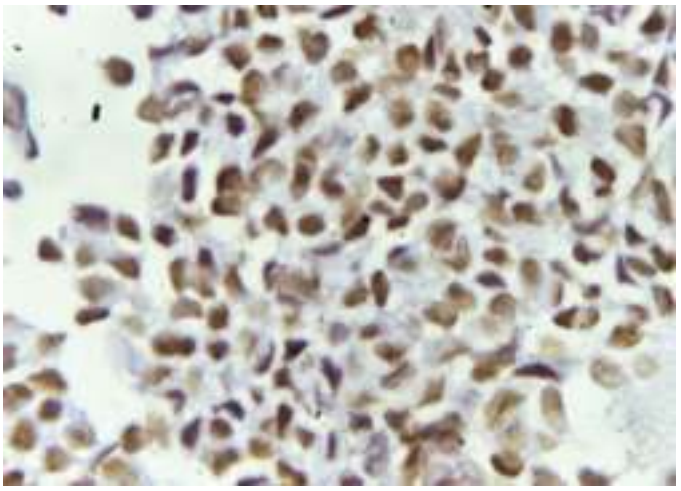

Fig. 27.28C: FLI-1 positivity in Ewing sarcoma. About 90% of Ewing sarcoma/primitive neuroectodermal tumors (PNET) have t(11;22) (q24;q12), which results in fusion of EWS to FLI-1.

Table 27.35 Specific genetic aberrations in Ewing sarcoma/PNET and Ewing sarcoma-like tumors without ETS involvement

Neoplasms	Chromosomal Translocation	Involved Genes and Fusion Protein	Frequency
Ewing sarcoma/ PNET	▪ t(11;22) (q24;q12) ▪ t(21;22) (q22;q12) ▪ t(7;22) (q22;q12) ▪ t(17;22) (q12;q12) ▪ t(2;22) (q33;q12) ▪ t(16;21) (p11;q22) ▪ t(2;16) (q35;p11)	▪ EWSR1-FLT1 ▪ EWSR1-ERG ▪ EWSR1-ETV1 ▪ EWSR1-ETV4 ▪ EWSR1-FEV ▪ FUS-ERG ▪ FUS-FEV	▪ 85–90% ▪ 10–15% ▪ <1% ▪ <1% ▪ <1% ▪ Rare ▪ Rare
Ewing sarcoma-like tumors without ETS involvement	▪ t(6;22) (p21;q12) ▪ Inv(22) (p12) ▪ t(4;22) (q31;q12) ▪ t(2;22) (q31;12) ▪ t(1;22) (q36.1;q12) ▪ Complex ring chromosome with amplification of the translocated segments ▪ t(4;19) (q35;q13) ▪ Inversion involving Xp11.4;Xp11.22	▪ EWSR1-POU5F1 ▪ EWSR1-ZSG (ZNF278) ▪ EWSR1-SMARCCA ▪ EWSR1-SP3 ▪ EWSR1-ZNF278 ▪ EWSR1-NFATc2 ▪ CIC-DUX4 ▪ BCOR-CCNB3	▪ Rare ▪ Rare ▪ Rare ▪ Rare ▪ Rare ▪ Rare ▪ Rare ▪ Rare

Ewing sarcoma/PNET and Ewing sarcoma-like tumors without ETS involvement are treated in a similar fashion.

FLI1) associated with better prognosis than those with EWS/ERG and other less common fusion transcripts. Recent studies revealed a strong positive correlation between telomerase activity and negative outcome in patients with nonmetastatic Ewing sarcoma tumors.

- Patient responds well to surgical excision of tumor, chemotherapy and radiotherapy. Five-year survival rate is demonstrated in 65–75% of cases. Patient receiving chemotherapy and local radiation has increased risk for osteosarcoma.

ADAMANTINOMA

Adamantinoma is a low-grade epithelial neoplasm involving predominantly tibia with or without involvement of fibula. Characteristics of classic and differentiated types of adamantinoma are given in Table 27.36.

- **Incidence and Locations:** Adamantinoma accounts for <0.5% of all primary malignant bone tumors. Most common sites are tibia (85%), and both tibia and fibula (10%). Less common sites are ulna, femur,

Table 27.36 Characteristics of classic and differentiated types of adamantinoma

Feature	Classic Adamantinoma	Differentiated Adamantinoma
Age distribution	Most often after 20 years	Most often below 20 years
Location	▪ Tibia ▪ Fibula	▪ Tibia ▪ Fibula
Radiologic findings	Lesion expands beyond periosteum	Intracortical lesion
Histology	Neoplastic cells are forming basaloid, spindled, tubular, or squamous pattern	Predominance of osteofibrous dysplasia pattern
Immunohistochemistry	Neoplastic cells show positivity for cytokeratin	Scattered neoplastic cells show positivity for cytokeratin

Local recurrence occurs 90% of cases in adamantinoma and lung metastasis in some cases.

humerus, radius, ribs, ischium, tarsal, metatarsal, and capitate.

- **Age and sex predilection:** Tumor most often occurs during 20–35 years of age with slight male predominance.
- **Clinical features:** Patient presents with slow-growing swelling with or without pain in the involved bone. Pathologic fracture occurs in some cases.
- **Radiologic findings:** Imaging techniques play important role in diagnosis, assessment of extent and invasiveness of adamantinoma.
  - Radiograph shows osteolytic, eccentric and expansile lesion in the medullary region of bone giving 'soap bubble appearance'. Sclerotic margin of lesion is indicative of slow growth of tumor. Longitudinal oriented average length of tumor is 11 cm. The expansile element of tumor tends to involve the anterior tibial surface, and the tumor may produce a bowing deformity of the tibia.
  - CT scan and MRI are useful in assessing extent and invasiveness of tumor. Extracortical extension of adamantinoma into the soft tissue is demonstrated in 15% of cases.

Surgical Pathology: Adamantinoma of Bone

Gross Morphology

Tumor is well-demarcated with peripheral lobulated contours. Eccentric tumor involves both cortex and medulla.

Light Microscopy

- **Squamous cell variant of adamantinoma:** Tumor resembles a well-differentiated squamous cell carcinoma and may exhibit keratinization or cell separation may result in formation of the stellate reticulum pattern. Tumor is composed of nests of epithelial cells within fibrous or fibro-osseous (woven or lamellar bone) stroma.
  - The epithelial cells are arranged in tubular, basaloid, squamous with stellate reticulum or spindle cell patterns.
  - Epithelial cells consist of peripheral tall columnar basal cells showing cytoplasmic vacuolation with reverse polarization of nuclei. Squamous metaplasia may be demonstrated.
- **Tubular variant of adamantinoma:** The most frequent is the tubular variant of adamantinoma in which narrow cords of epithelial cells form branching and anastomosing tubular structures. A central gland-like space produces tubular appearance due to cellular cohesion rather than true gland formation.
- **Basaloid variant of adamantinoma:** Tumor resembles basal cell carcinoma with palisading of its peripheral layer.
- **Spindle cell variant of adamantinoma:** Tumor is composed of spindle-shaped neoplastic epithelial cells, which may produce patterns resembling those of mesenchymal neoplasms such as storiform, fascicular and herring bone.
- **Ewing-like adamantinoma:** Tumor is composed of anastomosing cords of small round cells set in myxoid stroma.

Differential Diagnosis

Adamantinoma should be differentiated from oral-facial-digital syndrome, dedifferentiated adamantinoma, synovial sarcoma, epithelial hemangioendothelioma, and metastatic carcinoma to bone.

Immunohistochemistry Technique

Epithelial cells of tumor show positivity for pan cytokeratins. These cells exhibit a more specific subset profile, i.e. CK14 and CK19; CK5 and CK17.

Markers	Expression
▪ CK14 and CK19 ▪ CK5 and CK17	▪ Positive ▪ Positive

- **Prognosis and treatment:** Patient is treated by wide, local, limb-sparing resection of tumor. Radiotherapy and chemotherapy are ineffective. Local recurrence is reported in 90% of cases. It may metastasize to lung. Patient may have fatal outcome after surgical excision.

OSTEOCLASTIC GIANT CELL-RICH BONE TUMORS AND CYSTIC LESION

Osteoclastic giant cell-rich tumors according to recent 2020 WHO classification of bone tumors are given in Table 27.37.

Table 27.37 Osteoclastic giant cell-rich tumors according to recent 2020 WHO classification of bone tumors

Osteoclastic Giant Cell-rich Tumors
▪ Benign tumors • Giant cell tumor of the small bones
▪ Intermediate tumors (locally aggressive, rarely metastasizing) • Giant cell tumor of bone
▪ Giant cell tumor, malignant

GIANT CELL TUMOR OF BONE (OSTEOCLASTOMA)

Giant cell tumor of bone is potentially low-grade locally aggressive neoplasm, which is derived from monocyte-macrophage lineage. Tumor is composed of sheets of ovoid or spindled mononuclear cells interspersed with numerous osteoclast-like multinucleated giant cells.

Incidence and Locations

Giant cell tumor of bone accounts for 5% of all bone tumors, which originates from epiphysis or metaphysis of distal femur, proximal tibia and distal radius bones. Less common sites are sacrum and vertebral bodies. Tumor expands into the metaphysis of long bones resulting in erosion of the bone cortex. Tumor is confined proximally by growth plate, hence limited to metaphysis of the bone. As the tumor expands, it produces a bright rim of overlying reactive bone formation.

Age and Sex Predilection

Tumor occurs in mature skeleton mainly young adults during third to fourth decades of life with slight female predominance.

Clinical Features

Patient with giant cell tumor of bone presents with pain in the involved bone as a result of expansion of tumor near a joint. The weakened bone may undergo pathologic fracture. Clinical examination reveals tender swelling in the involved bone.

Radiologic Findings

- Radiograph shows osteolytic eccentric lesion with either well-defined without sclerotic margins or poorly differentiated margins giving '**soap bubble**' appearance.
- Aggressive giant cell tumor of bone may show cortical destruction and occasionally periosteal reaction.
- Soft tissue extension or recurrence of tumor shows marginal calcification giving 'egg-shell' appearance (Fig. 27.29).

Fig. 27.29: Giant cell tumor of femur in 56-year-old patient. Radiograph demonstrates a well-defined osteolytic lesion with narrow zone of transition with no sclerotic margins in lateral portion of lower femoral metaphysis extending into lateral femoral condyle. No periosteal reaction is noted. Findings are suggestive of giant cell tumor of femur shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

Surgical Pathology: Giant Cell Tumor of Bone

Gross Morphology

- Giant cell tumor of bone is large red brown, fleshy well-demarcated mass. Cut surface shows yellow and/or cystic areas.
- Areas of hemorrhage and necrosis are common. Hemosiderin deposition and reactive bone formation are demonstrated in the tumor. Gross morphology of giant cell tumor is shown in Fig. 27.30.

Light Microscopy

- Tumor is composed of ovoid mononuclear cells with indistinct cellular outlines growing in the form syncytium; interspersed with numerous osteoclast-like multinucleated giant cells containing >100 nuclei scattered among mononuclear cells. Mitotic figures are common in mononuclear cells.
- Morphologic features of nuclei of stromal mononuclear cells and osteoclast-like multinucleated giant cells are identical. There may be presence of aggregates of foam cells, focal osteoid or bone production, aneurysmal bone cyst like changes, storiform areas and necrosis (Fig. 27.31).

Differential Diagnosis

Giant cell tumor of bone should be differentiated from other bone tumors and tumor-like lesions showing multinucleated giant cells, which include aneurysmal bone cyst, chondroblastoma, benign fibrous histiocytoma, chondromyxoid fibroma, osteoblastoma, metaphyseal fibrous defect (nonossifying fibroma), brown tumor of hyperparathyroidism, malignant fibrous histiocytoma, fibrosarcoma of bone and giant cell variant of osteosarcoma. Bone tumors and tumor-like lesions show multinucleated giant cells are given in Table 27.38.

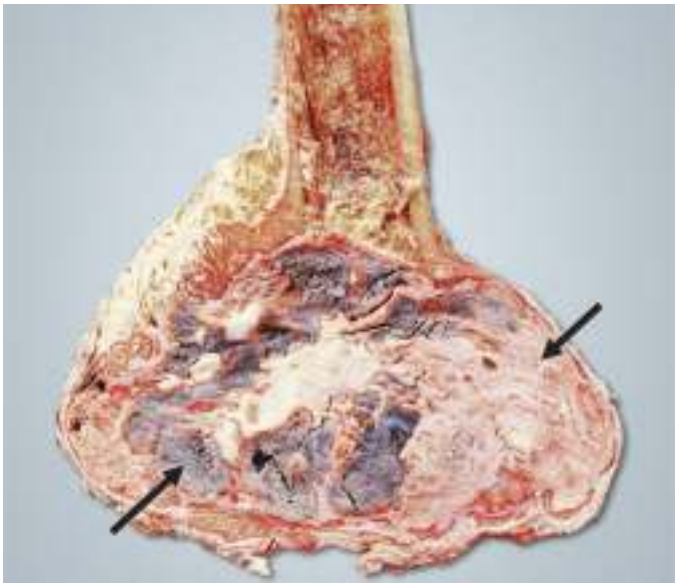

Fig. 27.30: Giant cell tumor of bone. Tumor of bone is large red brown, fleshy well-demarcated mass. Cut surface shows yellow and/or cystic areas. Areas of hemorrhage and necrosis are common. Hemosiderin deposition and reactive bone formation are demonstrated in the tumor (arrows). (*Courtesy:* Dr. Sujata Kanetkar, Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra).

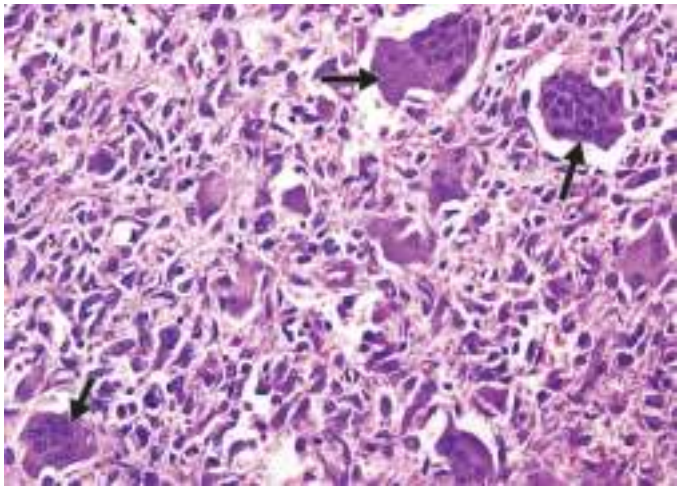

Fig. 27.31: Giant cell tumor of bone. Tumor is composed of ovoid mononuclear cells with indistinct cellular outlines growing in the form syncytium; interspersed with numerous osteoclast-like multinucleated giant cells containing >100 nuclei scattered among mononuclear cells. Mitotic figures are common in mononuclear cells. Morphological features of nuclei of stromal mononuclear cells and osteoclast-like multinucleated giant cells are identical. There may be presence of aggregates of foam cells, focal osteoid or bone production, aneurysmal bone cyst like changes, storiform areas and necrosis (400X).

Prognosis and Treatment

- Giant cell tumor of bone (osteoclastoma) is treated by surgical excision or curettage. Radiotherapy is advised inaccessible lesions. Recurrence most often occurs within two years of surgical intervention.

Table 27.38 Bone tumors and tumor-like lesions show multinucleated giant cells

Benign Bone Tumors and Tumor-like Lesions
Giant cell tumor of bone (osteoclastoma)
Aneurysmal bone cyst
Chondroblastoma
Benign fibrous histiocytoma
Chondromyxoid fibroma
Osteoblastoma
Metaphyseal fibrous defect (nonossifying fibroma)
Brown tumor of hyperparathyroidism
Malignant Bone Tumors
Malignant fibrous histiocytoma
Fibrosarcoma of bone
Giant cell variant of osteosarcoma

- Histologic examination does not predict the aggressiveness of the neoplasm. Lung metastasis is demonstrated in 2% of cases. Histologic features of giant cell tumor of bone are identical at primary site and metastatic site.
- Malignant transformation of giant cell tumor of bone may occur in 2% of cases. Prognosis is similar in malignant change in giant cell bone tumor and high-grade spindle cell sarcoma.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst (ABC) is a benign locally destructive non-neoplastic multiloculated blood filled cystic lesion. Aneurysmal bone cyst originates from metaphysis of long bone (femur, tibia), vertebral column and flat bones. ABC may arise in *de novo* (primary) or secondary in previously existing lesions. Aneurysmal bone cyst accounts for 2% of bone tumors. Precursor lesions for secondary aneurysmal cyst formation are given in Table 27.39.

Age and Sex Predilection

Aneurysmal bone cyst most often occurs during 5–20 years of age with equal sex distribution.

Clinical Features

Patient presents with painful swelling in the involved bone. Aneurysmal bone cyst in vertebral column may cause spinal cord compression.

Radiologic Findings

- Radiograph shows eccentric osteolytic lesion in the metaphyseal region of femur or tibia, balloon distension with cortical destruction exhibiting 'soap bubble appearance'. Periosteal eggshell appearance of bone is demonstrated.

Table 27.39 Precursor lesions for secondary aneurysmal cyst formation

Giant cell tumor of bone
Giant cell reparative granuloma
Osteoblastoma
Osteosarcoma
Chondroblastoma
Chondromyxoid fibroma
Chondrosarcoma
Nonossifying fibroma
Fibrous dysplasia
Eosinophilic granuloma
Hemangioma
Myositis ossificans
Malignant fibrous histiocytoma
Metastatic carcinoma
Hamartoma (rich vascular network)

- CT scan and MRI demonstrate multiloculated lesion in the bone often filled with fluid levels. Vertebral collapse is demonstrated in case of lesion in the vertebral column.

Surgical Pathology: Aneurysmal Bone Cyst

Gross Morphology

- Curettage fragments of aneurysmal bone cyst are red brown and soft in consistency.
- Resected specimen shows well demarcated lesion with blood filled cystic spaces of variable size and spongy in consistency. Well-defined margins with peripheral shell of bone are demonstrated. Gross morphology of aneurysmal bone cyst is shown in Fig. 27.32.

Light Microscopy

- Aneurysmal bone cyst is composed of variable sized blood spaces lined by thin membranous septae of loose fibrous tissue admixed with numerous osteoclast-like giant cells.
- Reactive bone trabeculae are lined by osteoblasts. Immature osteoid is arranged in a linear manner along septae. Irregular immature chondroid areas and calcification are demonstrated. There is no evidence of cytologic pleomorphism and cellular atypia.
- Solid areas with xanthogranulomatous appearance admixed with reactive bone trabeculae are also demonstrated (Fig. 27.33).

Differential Diagnosis

Aneurysmal bone cyst should be differentiated from telangiectatic osteosarcoma, giant cell tumor of bone, chondroblastoma, osteoblastoma, simple bone cyst and giant cell reparative granuloma.

Fig. 27.32: Aneurysmal bone cyst. Surgically resected specimen shows well-demarcated lesion with blood filled cystic spaces of variable size and spongy in consistency. Well-defined margins with peripheral shell of bone in aneurysmal bone cyst are demonstrated (arrows).

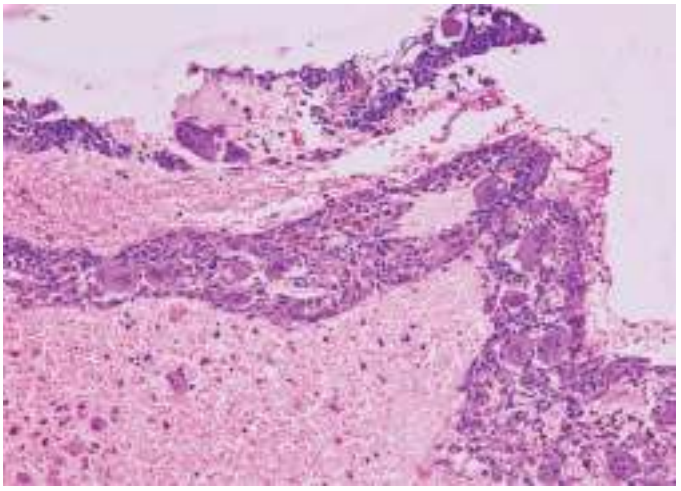

Fig. 27.33: Aneurysmal bone cyst. It is composed of variable sized blood spaces lined by thin membranous septae of loose fibrous tissue admixed with nemerous osteoclast-like giant cells. Reactive bone trabeculae are lined by osteoblasts. Immature osteoid is arranged in a linear manner along septae. Irregular immature chondroid areas and calcification are demonstrated. There is no evidence of cytologic pleomorphism and atypia. Solid areas with xanthogranulomatous appearance admixed with reactive bone trabeculae are also demonstrated (400X).

Prognosis and Treatment

Aneurysmal bone cyst is treated curettage or surgical resection. Bone grafting with preoperative embolization and or cryotherapy. Radiotherapy is advised for unresectable lesions. Prognosis is good in 90% of post-operative cases. Recurrence may occur after surgery in 20–70% of cases. Spontaneous malignant transformation is rare especially after post-radiation.

Table 27.40 Notochordal tumors classification according to recent 2020 World Health Organization classification of bone tumors

Notochordal Tumor: Histologic Variant	Behavior	Additional Comments
Conventional chordoma	Low malignant tumor	▪ Arising from sacrococcygeal region (35–50%), spheno-occipital region in the base of skull (30–40%), and vertebrae of mobile spine (20–30%) ▪ Slight risk for malignant transformation
Chondroid chordoma (conventional chordoma with chondroid component)	Malignant tumor	▪ Sporadic or familial tumor rising from base of skull ▪ Histologically closely resembles chondrosarcoma ▪ Immunohistochemical epithelial marker positive. Brachyury is a new marker for chondroid chordoma
Poorly differentiated chordoma	Malignant tumor	▪ Arising from base of skull in children and adolescents ▪ Highly cellular tumor with poor prognosis
Dedifferentiated chordoma	Malignant tumor	Some cases are associated with postradiotherapy

NOTOCHORDAL TUMORS

Notochordal tumors are classified according to old 2013 World Health Organization into four histologic variants: (a) conventional chordoma, (b) chondroid chordoma (conventional chordoma with chondroid component), (c) poorly differentiated chordoma, and (d) dedifferentiated chordoma. Notochordal tumors classification according to recent 2020 World Health Organization classification of bone tumors is given in Table 27.40.

CONVENTIONAL CHORDOMA

Notochord is a midline ectoderm derived structure in human beings. Degeneration of notochord begins during the development and completes by the second decade of life. Notochord remnants in adults are represented by nucleus pulposus in the intervertebral discs. Chordoma represents a low malignant mesenchymal neoplasm with distinct clinical and pathologic features and histologic similarities to notochord.

Incidence and Locations

Conventional chordoma accounts for 4% of malignant bone tumors. Various sites of conventional chordoma are sacrococcygeal region (35–50%), spheno-occipital region in the base of skull (30–40%), and vertebrae of mobile spine (20–30%).

- Nasopharyngeal chordoma arises from ectopic residues of chorda dorsalis.
- Extraosseous growth develops in the soft tissue around sacrum completely independent of origin from bone. But it is difficult to be sure that chordoma in either situation does not have a long filament osseous attachment. Locations and frequency of conventional chordoma in various age groups are given in Table 27.41.

Table 27.41 Locations and frequency of conventional chordoma in various age groups

Locations of Conventional Chordoma	Frequency	Age Group
Sacrococcygeal chordoma	30–50%	40–60 years
Spheno-occipital region in base of skull	30–40%	40–60 years
Vertebrae of mobile spine	20–30%	20–40 years

Age and Sex Predilection

Conventional chordoma occurs in infants and older persons. It most often affects 40–60 years of age group in sacrococcygeal and spheno-occipital region. It occurs in vertebrae of mobile spine in 20–40 years of age group.

Clinical Features

Patient with sacrococcygeal chordoma presents with low pain in the back region.

- Cranial chordoma presents with headache, visual disturbances (bilateral hemianopia) and symptoms related to multiple cranial palsies.
- Chordoma located in nasal cavity, paranasal sinuses and nasopharyngeal region presents respiratory difficulty.

Radiologic Findings

Radiograph shows osteolytic lesion. Rarely osteoblastic lesion is demonstrated.

Surgical Pathology: Conventional Chordoma

Gross Morphology

- Conventional chordoma has a characteristic lobulated structure. The lobules are separated by thin whitish septae.
- Cut surface of tumor is shiny, translucent and blue gray. Gross resection of tumor shows soft tissue extension with pushing border (Fig. 27.34).

Light Microscopy

- At low magnification, conventional chordoma demonstrates lobular growth pattern separated by thin collagenous septae. Majority of tumor volume is composed of abundant basophilic myxoid stroma.
- Tumor is composed of round to ovoid or polygonal neoplastic cells arranged in strands, cords and clusters. Tumor cells contain pale eosinophilic cytoplasm and central round nuclei.
- Numerous tumor cells contain one or several intracytoplasmic vacuoles creating bubbly appearance and small and central nuclei known as 'physaliphorous neoplastic cells'.
- Occasional tumor is composed of pleomorphic neoplastic cells with hyperchromatic nuclei, but retaining nuclear cytoplasmic ratio, which does not predict a worse prognosis.
- Areas of necrosis are demonstrated in 35% of cases. Mitotic activity is rare (Fig. 27.35).

Differential Diagnosis

Conventional chordoma should be differentiated from metastatic adenocarcinoma, giant notochordal rest, chondrosarcoma and extraskeletal myxoid chondrosarcoma.

Immunohistochemistry Technique

Conventional chordoma is positive for CK8, CK18, CK19, epithelial membrane antigen (EMA) and S-100 protein.

Markers	Expression
▪ CK8	▪ Positive
▪ CK18	▪ Positive
▪ CK19	▪ Positive
▪ EMA	▪ Positive
▪ S-100 protein	▪ Positive

Brachyury is a new marker for chondroid chordoma.

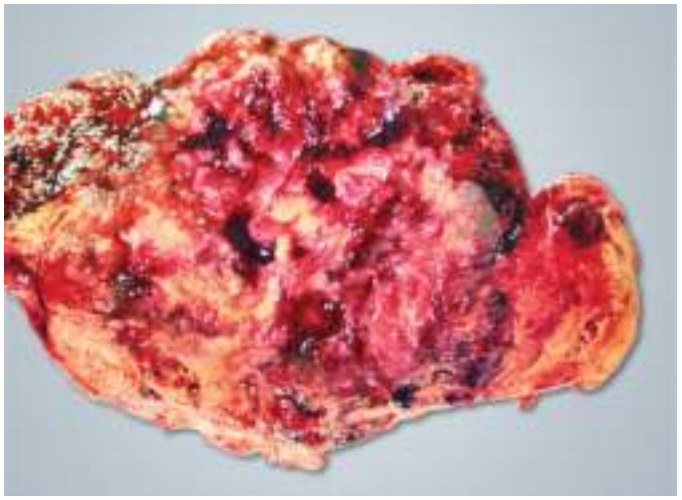

Fig. 27.34: Conventional chordoma. Tumor has a characteristic lobulated structure. The lobules are separated by thin whitish septae. Cut surface of tumor is shiny, translucent and blue gray. Gross resection of tumor shows soft tissue extension with pushing border.

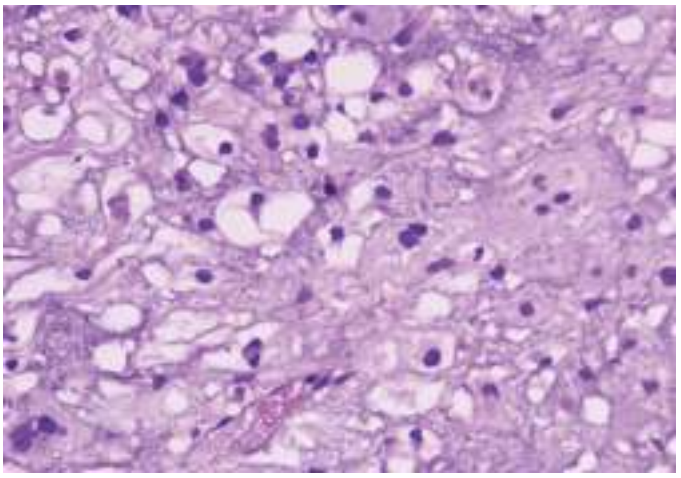

Fig. 27.35: Conventional chordoma. Tumor is composed of polygonal large cells with central round nuclei and abundant clear to eosinophilic cytoplasm that have a bubbly/vacuolated appearance (physaliphorous cells) and abundant vacuolated cytoplasm in myxoid stroma (400X).

Prognosis and Treatment

Conventional chordoma is treated by complete surgical resection with wide tumor-free margins. Cranial chordoma is treated by adjuvant radiation therapy followed by surgery. Metastases are demonstrated in ≤30% of cases. Morbidity and mortality occur due to destructive recurrence of conventional chordoma.

FIBROGENIC BONE TUMORS

Fibrogenic bone tumors are uncommon, which include desmoplastic fibroma and fibrosarcoma. Fibrogenic tumors classification according to recent 2020 WHO classification of bone tumors is given in Table 27.42.

DESMOPLASTIC FIBROMA OF BONE

Desmoplastic fibroma of bone is extremely rare benign locally aggressive intraosseous tumor due to proliferation of fibroblasts. This lesion is equivalent to soft tissue fibromatosis, which does not metastasize. But it may recur following incomplete surgical excision.

Incidence and Locations

Most common sites of tumor are distal femur, proximal tibia and pelvis. The other site is mandible.

Table 27.42 Fibrogenic tumors classification according to recent 2020 WHO classification of bone tumors

Fibrogenic Tumors
▪ Intermediate tumor (locally aggressive) • Desmoplastic fibroma of bone
▪ Malignant tumors • Fibrosarcoma of bone

Age and Sex Predilection

Tumor most often affects children and adolescents during 15–25 years of age. However, it may affect any age group between 20 months and 60 years of age.

Clinical Features

Patient presents with pain in the involved bone over years.

Radiologic Findings

Radiograph shows osteolytic lesion with multicystic pattern and destruction of cortex.

Surgical Pathology: Desmoplastic Fibroma of Bone	
Gross Morphology	
Desmoplastic fibroma of bone is gray and shining lesion measuring 3–10 cm in size.	
Light Microscopy	
▪ Histology of desmoplastic fibroma of bone is identical to soft tissue fibromatosis. ▪ Tumor is composed of spindle-shaped fibroblasts in a collagenized extracellular matrix. ▪ Spindle-shaped fibroblasts have bland oval or elongated nuclei usually without nucleoli. ▪ Proliferation of fibroblasts exhibits infiltrative growth pattern often entrapping native bone trabeculae.	
Differential Diagnosis	
Desmoplastic fibroma of bone should be differentiated from low-grade fibrosarcoma, fibrous dysplasia and nonossifying fibroma.	
Immunohistochemistry Technique	
Desmoplastic fibroma of bone shows positivity for vimentin.	
Marker	**Expression**
Vimentin	Positive

Prognosis and Treatment

Desmoplastic fibroma of bone is treated by surgical resection with tumor-free margin. Curettage of tumor may recur in 50% of cases.

FIBROSARCOMA OF BONE

Fibrosarcoma of bone is a rare spindle cell neoplasm of low to intermediate grade malignant tumor.

Incidence and Locations

Most common sites of fibrosarcoma of bone are distal femur and proximal tibia.

Age and Sex Predilection

Fibrosarcoma of bone most often affects adults. Peak incidence is seen in the fifth decade of life. It has also been reported in infants.

Clinical Features

Patient presents with pain in involved bone, which may produce pathologic fracture.

Radiologic Findings

Radiograph shows a poorly defined osteolytic lesion (permeative and destructive).

Surgical Pathology: Fibrosarcoma of Bone	
Gross Morphology	
Tumor is white soft tissue mass with firm consistency. It demonstrates replacement of cancellous and cortical bone.	
Light Microscopy	
▪ Tumor is composed of spindle cell arranged in a fascicular or 'herringbone' pattern. It also contains varying amount of collagen. ▪ Low-grade fibrosarcoma of bone is composed of uniform spindle cells with mild to moderate atypia. ▪ High-grade fibrosarcoma of bone is a highly cellular neoplasm composed of spindle cells with cytologic atypia and numerous mitotic figures (Fig. 27.36).	
Differential Diagnosis	
Fibrosarcoma of bone should be differentiated from desmoplastic fibroma of bone and malignant fibrous histiocytoma.	
Immunohistochemistry Technique	
Tumor shows positivity for vimentin. A few neoplastic cells may be weakly positive for smooth muscle actin.	
Markers	**Expression**
▪ Vimentin ▪ Smooth muscle actin	▪ Positive ▪ Positive (few neoplastic cells)

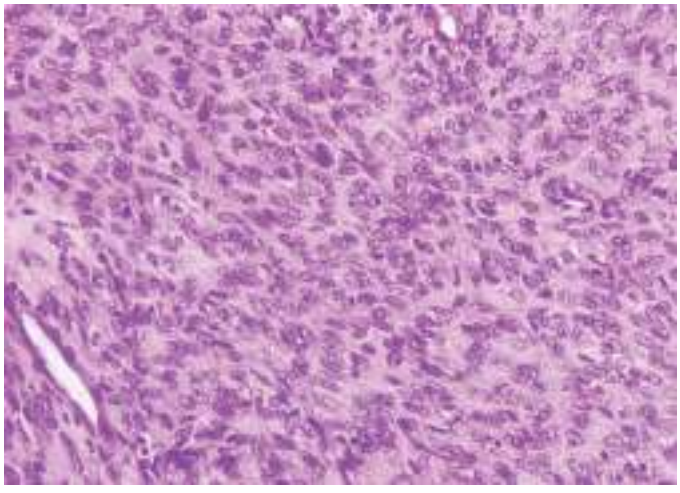

Fig. 27.36. Fibrosarcoma of bone. Tumor is composed of spindle cell with cytologic atypia and numerous mitotic figures arranged in a fascicular or 'herringbone' pattern. It also contains varying amount of collagen (400X).

Prognosis and Treatment

Fibrosarcoma of bone is treated by surgical ablation with disease-free margins. Low-grade fibrosarcoma of bone has a 10-year survival rate in 80% of cases. High-grade fibrosarcoma of bone has a lower survival rate.

FIBROHISTIOCYTIC TUMORS OF BONE

Fibrohistiocytic tumors of the bone include nonossifying fibroma (metaphyseal fibrous defect) of long bones, benign fibrous histiocytoma of flat bones and vertebrae, and malignant fibrous histiocytoma. The term benign fibrous histiocytoma of bone is only applied, when lesion affects flat bones and vertebrae. Tumor is composed of spindle cells arranged in storiform pattern, foam cells and multinucleated giant cells.

Fibrohistiocytic tumors classification according to revised 2020 WHO classification of bone tumors is given in Table 27.43.

BENIGN FIBROUS HISTIOCYTOMA/NONOSSIFYING FIBROMA (METAPHYSEAL FIBROUS DEFECT)

Benign fibrous histiocytoma/nonossifying fibroma (metaphyseal fibrous defect) of bone is a spindle cell neoplasm arising from the metaphyseal region of long bones (distal femur or proximal tibia, fibula, radius).

- Tumor occurs during skeletal growth due to exaggerated subperiosteal osteoclastic resorption of bone while modeling of the bone in the metaphyseal region.
- Osteoclastic resorption of bone most often begins at the site of tendon insertion. It never undergoes malignant transformation.

Incidence and Locations

Most common sites of benign fibrous histiocytoma/nonossifying fibroma of bone are distal femur or proximal tibia in 80% of cases. It may also occur in both ends of fibula and distal radius.

Age and Sex Predilection

Benign fibrous histiocytoma/nonossifying fibroma of bone affects equally male and female children during skeletal growth.

Table 27.43 Fibrohistiocytic tumors classification according to revised 2020 WHO classification of bone tumors

Fibrohistiocytic Tumors
▪ Benign tumors • Benign fibrous histiocytoma/nonossifying fibroma
▪ Malignant tumors • Malignant fibrous histiocytoma

Fig. 27.37: Benign fibrous histocytoma/nonossifying fibroma (metaphyseal fibrous defect) in right forearm radius bone in radiograph. Expansile osteolytic lesion is observed in lower radial diaphysis with a narrow zone of transition and mild sclerotic rim. There is marked thinning of overlying radial cortex. Chondroid matrix within lesion is absent. There is no break in the underlying cortex, and absence of periosteal reaction. Advised surgical biopsy and histological correlation are shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

Clinical Features

Patient is usually asymptomatic. Large size lesion may cause pain and pathologic fracture. Jaffe-Campanacci syndrome is characterized by formation of non-ossifying fibromas in multiple bones and *café au lait* spots on skin.

Radiologic Findings

Radiograph shows a well-defined eccentric osteolytic lesion in the metaphyseal region of a long bone. Margins of lesion are scalloped and surrounded by a sclerotic rim. Small lesion measuring 1–2 cm is regarded as fibrous cortical defect. Large lesion measuring 7 cm may undergo pathologic fracture due to cortical expansion (Fig. 27.37).

Surgical Pathology: Benign Fibrous Histiocytoma/ Nonossifying Fibroma (Metaphyseal Fibrous Defect)
Gross Morphology
Curettages of benign fibrous histiocytoma/nonossifying fibroma are friable, yellow brown and soft in consistency with an intact shell of overlying bone.
Light Microscopy
▪ Tumor is composed of spindle cell stroma with scattered a few to many multinucleated giant cells, hemosiderin pigment-laden macrophages and foam cells.

- Spindle cells of tumor are arranged in a whorled or storiform pattern. In occasional lesion, spindle cells have plump nuclei and typical mitotic figures. Reactive bone formation is most often demonstrated in older lesions (Fig. 27.38).

Differential Diagnosis

Benign fibrous histiocytoma/nonossifying fibroma should be demonstrated from giant cell tumor of bone, malignant fibrous histiocytoma and fibrous dysplasia.

Prognosis and Treatment

Benign fibrous histiocytoma/nonossifying fibroma can be left untreated. Large lesions are treated by curettage.

MALIGNANT FIBROUS HISTIOCYTOMA OF BONE

Malignant fibrous histiocytoma of bone is a high-grade neoplasm. Tumor is composed of fibrogenic spindle cells and histiocytic cells arranged in storiform pattern. It may also arise in pre-existing osseous lesions, Paget's disease of bone and cartilaginous neoplasms.

Incidence and Locations

Most common sites of tumor are femur in 33% of cases followed by tibia and humerus.

Age and Sex Predilection

Malignant fibrous histiocytoma of bone most often affects adults >40 years of age, which may also affect children and elderly persons of >75 years.

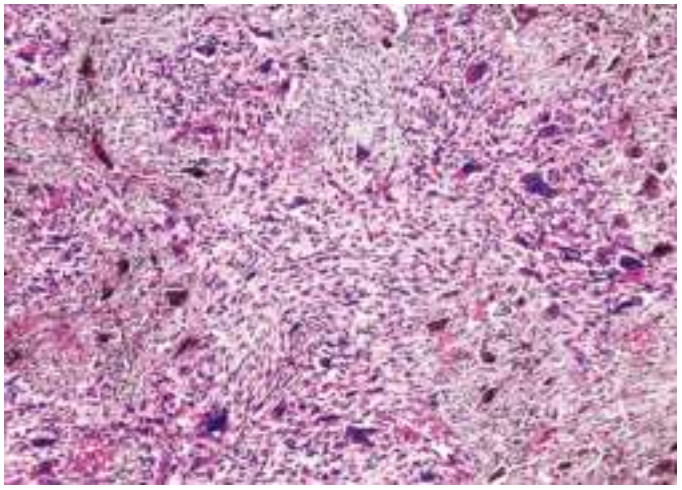

Fig. 27.38: Benign fibrous histiocytoma/nonossifying fibroma. Tumor is composed of spindle cell stroma with scattered a few to many multinucleated giant cells, hemosiderin pigment laden macrophages and foam cells. Spindle cells of lesion are arranged in a whorled or storiform pattern. In occasional lesion, spindle cells have plump nuclei and typical mitotic figures. Reactive bone formation is most often demonstrated in older lesions (400X).

Clinical Features

Patient presents with pain and swelling in tibia or humerus. Sometimes, pathologic fracture may occur in the involved bone.

Radiologic Findings

Radiograph shows poorly circumscribed osteolytic lesion with a permeative pattern of bone destruction. Cortex is most often destroyed.

Surgical Pathology: Malignant Fibrous Histiocytoma of Bone

Gross Morphology

Tumor is gray tan fleshy tumor. Cut surface shows larger areas of necrosis.

Light Microscopy

- Tumor is composed of spindle cells, round histiocyte-like cells or combination of both types of cells in varying proportions.
- Spindle cells contain oval nuclei with mild to moderate pleomorphisms. Spindle cells are arranged in a storiform pattern.
- Some malignant fibrous histiocytomas show histiocyte-like differentiation. Histiocyte-like cells contain large or lobulated nuclei and prominent nucleoli. Hemosiderin and lipid can be demonstrated in histiocyte-like cells. Multinucleated giant cells are most often present in the tumor (Fig. 27.39).

Differential Diagnosis

Malignant fibrous histiocytoma of bone should be differentiated from metastatic carcinoma especially renal cell carcinoma showing sarcomatoid growth pattern and osteosarcoma showing little osteoid production.

Immunohistochemistry Technique

Tumor cells show strong positivity for vimentin. Occasional tumor demonstrates positivity for α-actin, calponin, caldesmon, smooth muscle myosin heavy chain, cytokeratins and epithelial membrane antigen (EMA).

Markers	Expression
▪ Vimentin	▪ Positive (strong staining)
▪ α-Actin	▪ Positive/negative
▪ Calponin	▪ Positive/negative
▪ Caldesmon	▪ Positive/negative
▪ Smooth muscle myosin heavy chain (SMMHC)	▪ Positive/negative
▪ Cytokeratins	▪ Positive/negative
▪ Epithelial membrane antigen	▪ Positive/negative

Prognosis and Treatment

Malignant fibrous histiocytoma of bone is treated by complete surgical ablation with tumor-free margins and chemotherapy. Five-year survival rate is demonstrated in 35–50% of cases.

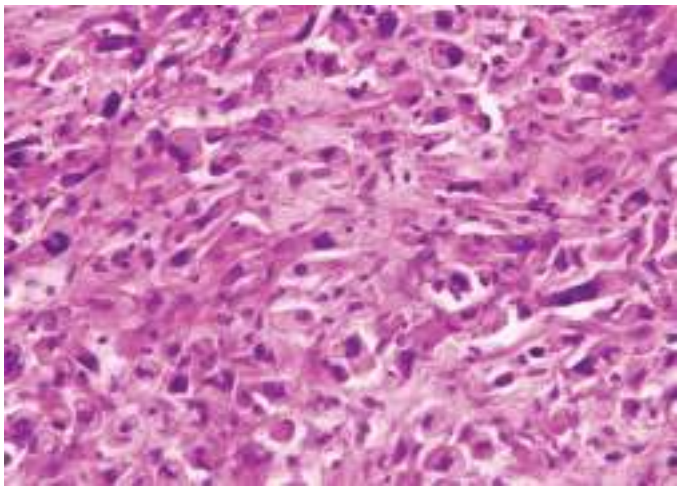

Fig. 27.39: Malignant fibrous histiocytoma of bone. Tumor is composed of spindle cells, round histiocyte-like cells or combination of both types of cells in varying proportions. Spindle cells contain oval nuclei with mild to moderate pleomorphisms. Spindle cells are arranged in a storiform pattern (400X).

HEMATOPOIETIC NEOPLASMS OF BONE

Lymphocytes and plasma cells reside in the company with hematopoietic elements of bone marrow. Therefore, malignant proliferation of lymphocytes and plasma cells occur in the center of the bone marrow and destroy bone marrow secondarily.

- Examples of hematopoietic neoplasms are plasma cell myeloma (multiple myeloma), solitary plasmacytoma of bone, non-Hodgkin's lymphoma and Hodgkin's disease. Solitary hematopoietic neoplasms confined to the bone marrow respond well to chemotherapy and radiotherapy and have excellent prognosis.
- Hematopoietic neoplasms can disseminate rapidly resulting in poor prognosis. These tumors most often occur in elderly persons, may also affect children. Hematopoietic neoplasms according to recent 2020 WHO classification of bone tumors are given in Table 27.44.

MULTIPLE MYELOMA

Multiple myeloma is monoclonal proliferation of plasma cells involving multiple sites in the skeleton.

Table 27.44 Hematopoietic neoplasms according to recent 2020 WHO classification of bone tumors

Hematopoietic Neoplasms
Malignant tumors
Plasma cell myeloma
Solitary plasmacytoma of bone
Primary non-Hodgkin's lymphoma of bone

Malignant plasma cells synthesize excess of monoclonal immunoglobulin that can be detected in the serum and urine. Monoclonal immunoglobulin, known as 'M-protein', is usually an IgG. Light chains released from the breakdown of monoclonal immunoglobulin is excreted in the urine, known as 'Bence Jones proteins' identified by urinary immunoelectrophoresis. Solitary plasmacytoma of bone is caused by neoplastic proliferation of plasma cells involving a solitary bone.

- Diagnosis of multiple myeloma rests on meeting specific diagnostic criteria including presence of ≥10% plasma cells on the bone marrow, increased M-protein in serum and urine, and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia or bone lesions).
- Majority of patients are diagnosed by clinical history, imaging of skeletal survey, hematologic findings (peripheral blood smear examination, erythrocyte sedimentation rate, bone marrow aspiration and trephine biopsy examination), serum calcium, blood urea, serum creatinine, and immunoelectrophoresis and immunofixation of serum and urine.

Incidence and Locations

Vertebral column is the most common site especially in lumbar region. The other bones affected in the descending frequency are skull, ribs, sternum, pelvis, femur, clavicle and scapula.

Age and Sex Predilection

Most cases of multiple myeloma occur during 50–80 years of age. Less than 2% of cases affect <40 years of age. Osteoclastic activating factor synthesized by monoclonal plasma cells cause osteolytic lesions in the skeleton. The lesion begins in the medullary cavity, erodes cancellous bone and progressively destroy the cortex of bone. Skeletal lesions are associated with bone pain and pathological fracture.

Clinical Features

Patient presents with bone pain (85%) and pathologic fracture of vertebrae and rib. Spine involvement causes compression of the spinal cord. Other presenting symptoms are recurrent bacterial infections, epistaxis, fever, anemia and weakness. Systemic complications due to M protein (myeloma protein) are renal insufficiency, hypercalcemia and amyloid deposition in the late stage disease.

Numerous other systems may be involved and known as **POEM syndrome** characterized by polyneuropathy, organomegaly, endocrinopathy and M protein. Myeloma kidney is caused by deposition of waxy casts of precipitated nephrotoxic monoclonal light chains

and blocking in the renal tubules. λ Light chains are more nephrotoxic then κ chains.

Radiologic Findings

Early involvement of bone in multiple myeloma shows only changes of osteoporosis. Well-developed skeletal lesions are usually multiple, discrete, punched out and radiolucent demonstrated on radiograph. Rarely, the skeletal lesion may be osteoblastic on skull radiograph, it shows multiple punched out osteolytic lesions as shown in Fig. 27.40.

Surgical Pathology: Multiple Myeloma

Gross Morphology

- Early skeletal lesion in multiple myeloma may show involvement of red bone marrow without destruction of cancellous bone.
- In advanced skeletal lesion, bone marrow is replaced by hemorrhagic friable soft tissue resembling 'currant jelly'. However, tissue fragments may show 'fish flesh' appearance. Humerus and femur involved by multiple myeloma is shown in Fig. 27.41.

Light Microscopy

- Trephine bone marrow biopsy fragments in multiple myeloma show replacement of bone marrow by diffuse sheets of plasma cells.
  - Plasma cells contain abundant blues to pink cytoplasm and eccentrically placed nuclei with clumped chromatin giving 'clock faced' appearance.
  - Sometime, plasma cells are poorly differentiated with large nuclei and prominent nucleoli (Fig. 27.42).
- Amyloid deposits (AL-amyloid) may be demonstrated in bone marrow and viscera in 10–15% of cases. Amyloid deposits in various sites indicate progression of the disease.

Differential Diagnosis

Multiple myeloma should be differentiated from malignant lymphoma, metastatic carcinoma and chronic osteomyelitis. Comparison of multiple myeloma and chronic osteomyelitis is given in Table 27.45.

Immunohistochemistry Technique

Neoplastic plasma cells consistently stain with specific marker CD138. These cells are also positive for κ or λ light chains.

Markers	Expression
▪ CD138	▪ Positive
▪ κ or λ light chains	▪ Positive

Prognosis and Treatment

Patient of multiple myeloma is treated with administration of chemotherapeutic agent melphalan and prednisone, and bone marrow transplantation.

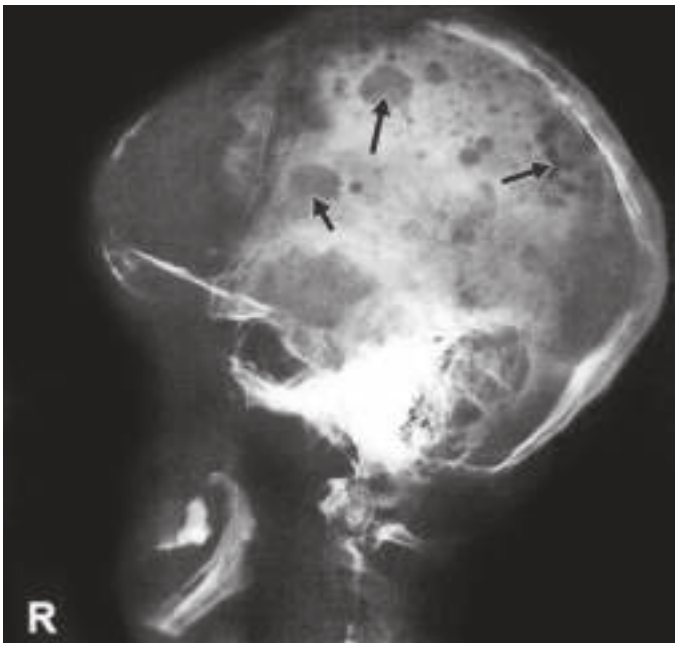

Fig. 27.40: Skull radiograph in multiple myeloma. Skull radiograph shows multiple punched out osteolytic lesions (arrows).

Fig. 27.41: Humerus and femur involved in multiple myeloma. Bone marrow cavity of humerus and femur bones is replaced by soft, gelatinous 'fish flesh hemorrhagic tissue. Patient presents with bone pain, lytic bone lesions (thoracic vertebrae most common, also ribs, skull, pelvis, femur); spinal cord compression and peripheral neuropathy are less common presenting symptoms, renal failure and recurrent infections shown by arrows.

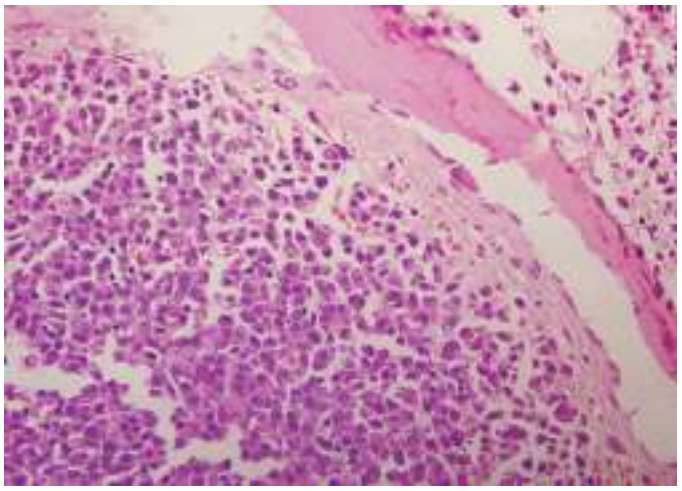

Fig. 27.42: Multiple myeloma. Trephine bone marrow biopsy fragments in multiple myeloma show replacement of bone marrow by diffuse sheets of plasma cells. Plasma cells contain abundant blues to pink cytoplasm and eccentrically placed nuclei with clumped chromatin giving 'clock faced appearance'. Sometime, plasma cells are poorly differentiated with large nuclei and prominent nucleoli (400X).

Radiotherapy is indicated in specific clinical situations. Median survival of multiple myeloma patients is three years. About 15% of solitary plasmacytoma cases experience progression to multiple myeloma after a median duration of three years.

PRIMARY BONE MARROW LYMPHOMA (PBML)

Lymphomas (non-Hodgkin's lymphoma and Hodgkin's disease) primarily involve lymph nodes, which may disseminate to other visceral organs and skeleton during course of disease. About 66% of lymphomas originate in other tissues (e.g. gastrointestinal tract, lung and bones) other than lymph nodes. About 5% of extra-nodal lymphomas are primary lymphomas of bone. Diagnostic criteria of primary bone marrow lymphoma include isolated bone marrow infiltration with no evidence of nodal or extranodal involvement, including bone and exclusion of leukemias/lymphomas that are considered to primarily involve bone marrow.

Incidence and Locations

Primary lymphoma of bone accounts for 7% of all malignant bone tumors. Most common sites are diametaphysis of femur and pelvis. It has aggressive pattern of osteolytic lesion associated with soft tissue mass. Other sites of bone tuomr are spine and other long bones. Involvement of solitary bone is demonstrated in 75% and multiple in 25% of cases.

Age and Sex Predilection

Primary lymphoma of bone most affects patients >40 years of age in 50% of cases. However, it may affect any age group. Precursor B cell lymphoblastic lymphoma affects children.

Clinical Features

Patient presents with symptoms depending on bone involved.

Radiologic Findings

Radiograph shows poorly defined lesion with permeative pattern of bone destruction. Primary lymphoma of bone marrow easily penetrates the cortex and invades soft tissue in 50% of cases. Some lesions show intraosseous reactive bone formation that can cause focal radiodensity. Pathologic fracture is demonstrated in 25% of cases.

Surgical Pathology: Primary Bone Marrow Lymphoma

Gross Morphology

Tumor is fleshy hemorrhagic due to bone destruction by primary bone marrow lymphoma.

Light Microscopy

Almost all primary bone marrow lymphomas are diffuse large B cell lymphoma (DLBCL). Others are immunoblastic lymphoma, anaplastic large T cell lymphoma, lymphoblastic lymphoma and Hodgkin's disease. Neoplastic cells diffusely infiltrate the bone marrow with intact bony trabeculae.

- **Diffuse large B cell lymphoma (DLBCL):** Majority of neoplastic cells display population of pleomorphic centroblasts with scant cytoplasm, hyperchromatic nuclei with finely clumped chromatic and two to three nucleoli. In occasional case tumor is composed of immunoblasts with round nuclei and abundant amphophilic cytoplasm.
- **Anaplastic large T cell lymphoma:** Tumor is composed of pleomorphic nuclei especially horseshoe nuclei.
- **Lymphoblastic lymphoma in children:** Tumor is composed of sheets of neoplastic cells with containing round nuclei with a fine stippled chromatin infiltration in the bone marrow.
- **Hodgkin's disease:** Tumor is composed of Reed-Sternberg cells admixed with population of inflammatory cells in mixed cellularity variant of Hodgkin's disease.

Differential Diagnosis

Primary bone marrow lymphoma should be differentiated from Ewing sarcoma, metastatic carcinoma, multiple myeloma and sarcomas with extensive fibrosis.

Immunohistochemistry Technique

Diffuse large B cell lymphoma (DLBCL) shows positivity for CD45, pan B cell markers (CD19, CD20, CD22, CD79a, PAX5). CD20 reactivity is lost in DLBCL treated by rituximab (anti-CD20 antibody), but reactivity is intact for CD19, CD22 and CD79a. There is variable expression of CD10, CD15, BCL-6, BCL-2, sIg and Ki-67 in diffuse large B cell lymphoma.

Markers	Expression
▪ CD45	▪ Positive
▪ Pan B cell markers (CD19, CD20, CD22, CD79a, PAX5)	▪ Positive
▪ CD10	▪ Positive (variable)
▪ CD15	▪ Positive (variable)
▪ BCL-6	▪ Positive (variable)
▪ BCL-2	▪ Positive (variable)
▪ sIg	▪ Positive (40–50%)
▪ Ki-67	▪ Positive (40–50%)

Prognosis and Treatment

Primary bone marrow lymphomas are treated with radiation and chemotherapy. Five-year survival rate is demonstrated in 50–90% of cases. Patients above 60 years of age have poor prognosis.

BONE TUMORS OF UNDEFINED NEOPLASTIC NATURE

A group of lesions that affect bone undergo into malignant neoplasms and have distinct histologic appearance and cytogenetic or molecular alterations, but the clinical behavior is suggestive of a non-neoplastic process. Tumors of undefined neoplastic nature according to recent 2020 WHO classification of bone tumors are given in Table 27.46.

SIMPLE BONE CYST

Simple bone cyst is a central intramedullary unilocular cystic cavity containing serous or serosanguineous fluid lined by a thin fibrovascular connective tissue membrane. It occurs in the metaphyseal region of immature skeleton of proximal femur and humerus, which may also occur in jaw.

Incidence and Locations

Simple bone cyst occurs in the metaphyseal region of immature skeleton of proximal femur and humerus. Its pathogenesis is unknown. But it is considered to be reactive or developmental lesion, probably be related to disturbance in the growth at the epiphyseal plate. It may also occur in jaw.

Age and Sex Predilection

Simple bone cyst occurs during first and second decades of life with male predominance.

Clinical Features

Simple bone cyst is detected as incidental finding on radiograph in majority of cases. Some patients may present with painful swelling and pathologic fracture.

Radiologic Findings

Simple bone cyst is a central intramedullary metaphyseal lesion. It is well circumscribed lucent lesion with

Table 27.45 Comparison of multiple myeloma and chronic osteomyelitis

Parameters	Multiple Myeloma	Chronic Osteomyelitis
Population of cells on histology	Plasma cells with abundant blue to pink cytoplasm with eccentrically placed nuclei with clumped chromatin giving 'clock faced appearance'	Plasma cells admixed with lymphocytes and neutrophils
Granulation tissue	Absent	Present
Immunohistochemistry	CD138 positive (monoclonal plasma cells)	CD138 positive (polyclonal plasma cells)

Table 27.46 Tumors of undefined neoplastic nature according to recent 2020 WHO classification of bone tumors

Tumors of Undefined Neoplastic Nature
Benign tumors
▪ Simple bone cyst ▪ Fibrous dysplasia ▪ Osteofibrous dysplasia ▪ Chondromesenchymal hamartoma ▪ Rosai-Dorfman disease
Intermediate tumors (locally aggressive)
▪ Aneurysmal bone cyst ▪ Langerhans cell histiocytosis (monostotic, polyostotic) (Letterer-Siwe disease, Hand-Schüller-Christian disease and eosinophilic granuloma) ▪ Erdheim-Chester disease

fine trabeculation with scalloped borders and cortical thinning; but without disruption, unless bone fracture has taken place. In some instances, a bony fragment within the cyst lumen known as 'fallen fragment' is demonstrated on radiograph.

Surgical Pathology: Simple Bone Cyst

Gross Morphology

- Thin translucent fibrous membrane <1 mm thick is demonstrated in minimal curettage material obtained in surgical specimen.
- Cyst is communicating directly with the medullary cavity of shaft of long bone.
- Intact simple bone cyst contains clear to yellowish fluid with or without internal septations.
- Presence of hemorrhagic fluid in the cyst may reflect prior bone fracture.

Light Microscopy

- Simple bone cyst is lined by a thin fibrovascular connective tissue membrane.
- There may be presence of scattered osteoclasts admixed with inflammatory cells and hemosiderin deposits in a case prior to bone fracture.
- Reactive bone formation is most often demonstrated in simple bone cyst following bone fracture. Cementum-like material is also demonstrated.

Differential Diagnosis

Simple bone cyst should be differentiated from aneurysmal bone cyst and intraosseous ganglion.

Prognosis and Treatment

Simple bone cyst is treated by curettage and bone grafting. It can be repeated in the rare event of recurrence of the lesion.

FIBROUS DYSPLASIA OF BONE

Fibrous dysplasia of bone is non-inherited dysplastic developmental disorder characterized by fibrous stroma with trabeculae of immature woven bone reflecting defective bone maturation due to post-zygotic GNAS1 gene mutation; which encodes G protein-coupled receptor activating adenyl cyclase resulting in excessive production of adenosine monophosphate that derives unrestricted cellular proliferation. Transformation of fibrous dysplasia of bone to osteosarcoma is rare.

Incidence and Locations

Fibrous dysplasia of bone accounts for 1% of bone tumors. Most common sites are neck of femur, tibia, humerus, craniofacial bones (maxilla, mandible) and ribs. It may involve single bone (monostotic) or multiple bones (polyostotic). Spine is rarely involved. Features of fibrous dysplasia of bone are given in Table 27.47.

- **Monostotic fibrous dysplasia:** It involves single bone and accounts for 70–75% of cases affecting older children and adolescents.
- **Polyostotic fibrous dysplasia:** It involves multiple bones and accounts for 25–30% of cases affecting children. Craniofacial involvement is demonstrated in 50% of cases.
  - Polyostotic fibrous dysplasia of bone is associated with McCune-Albright syndrome in 3–5% of cases affecting children; in the patient presents with precocious puberty and abnormal skin pigmentation (*café au lait* spots on skin).
  - Mazabraud syndrome is characterized by polyostotic fibrous dysplasia, skin lesions and hyperplasia of endocrinal glands.
  - Monomelic polyostotic fibrous dysplasia of bone involves unilateral one extremity and homolateral pelvis or scapula. On the other hand, polymelic polyostotic fibrous dysplasia involves widespread skeleton.

Age and Sex Predilection

Fibrous dysplasia of bone most often affects infants, children and adolescents <30 years of age. Monostotic

Table 27.47 Features of fibrous dysplasia of bone

Fibrous Dysplasia: Variants and Frequency	Age Group Distribution	Distribution of Lesions and Clinical Features
Monostotic fibrous dysplasia (70–75%)	Older children, adolescents	Single focus in femur, humerus, craniofacial bones, rib
Polyostotic fibrous dysplasia (25–30%)	Young children	▪ Multiple foci in several bones, i.e. femur, humerus, craniofacial bones and ribs ▪ Monomelic polyostotic fibrous dysplasia involves unilateral one extremity and homolateral pelvis or scapula ▪ Polymelic polyostotic fibrous dysplasia involves widespread skeleton
McCune-Albright syndrome	Young children	Polymelic polyostotic fibrous dysplasia with endocrinal abnormalities, i.e. precocious puberty in females, acromegaly, Cushing syndrome, hyperthyroidism, hyperparathyroidism
Mazabraud syndrome	Young persons	Polymelic polyostotic fibrous dysplasia associated with soft tissue myxoma

fibrous dysplasia occurs during second to third decades of life. On the other hand, polyostotic fibrous dysplasia occurs during first decade of life. Fibrous dysplasia of rib occurs during fourth to fifth decades of life.

Clinical Features

- **Monostotic fibrous dysplasia:** Patient is most often asymptomatic. Fibrous dyspasia of bone may be an incidental finding. Some patients present with deformity of craniofacial bones and long bone fracture.
- **Polyostotic fibrous dysplasia:** Patient with McCune-Albright syndrome may present with bone deformity, bone fracture and symptoms related to hyperplasia of endocrinal glands such as sexual precocity, acromegaly, hyperthyroidism, hyperparathyroidism, Cushing syndrome and hyperprolactinemia.

Radiologic Findings

Radiograph shows well circumscribed lesion with sclerotic rim of variable density giving 'ground glass appearance'. Lesion in femur, tibia and humerus is located in the metaphyseal region involving medullary cavity. Shepherd's crook deformity occurs in the femur, characterized by a coxa-vara angulation of the proximal femur. Lesion produces expansion in small bones (Fig. 27.43).

Surgical Pathology: Fibrous Dysplasia of Bone

Gross Morphology

- Fibrous dysplasia of long bones is well-defined showing thin cortex and expanded contours.
- Curettage shows tan gray fibrous tissue with gritty consistency.
- Areas of hemorrhage with or without cysts are demonstrated. Gross morphology of fibrous dysplasia is shown in Fig. 27.44.

Light Microscopy

- Fibrous dysplasia of bone is composed of irregular trabeculae of immature woven bone lacking osteoblastic rimming. The irregular trabeculae of immature woven bone are present in the stroma and giving 'storiform appearance'.
- There may be presence of foam cells, occasional stromal myxoid and/or cystic change. Sarcomatous transformation in fibrous dysplasia is rare (Fig. 27.45).

Differential Diagnosis

Fibrous dysplasia of bone should be differentiated from osteofibrous dysplasia, cemento-ossifying fibroma of gnathic bones (maxilla, mandible), desmoplastic fibroma, parosteal osteosarcoma, low-grade osteosarcoma and chondrosarcoma with prominent chondroid component.

Fig. 27.43: Fibrous dysplasia of fourth metacarpal bone. Radiograph of right hand demonstrates expansion of fourth metacarpal shaft due to an osteolytic lesion with ground glass density with cortical thinning with break in cortex on radial side. Other bones and joints appear normal. Soft tissue is normal. Findings are suggestive of fibrous dysplasia with pathological fracture shown by arrow. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

Prognosis and Treatment

Conservative treatment is recommended in monostotic fibrous dysplasia; because the lesion stabilizes after puberty.

- Prognosis is excellent in fibrous dysplasia involving single bone.
- In polyostotic fibrous dysplasia, prognosis depends on extent and severity of bone lesions and hyperplasia of endocrinal glands related symptoms

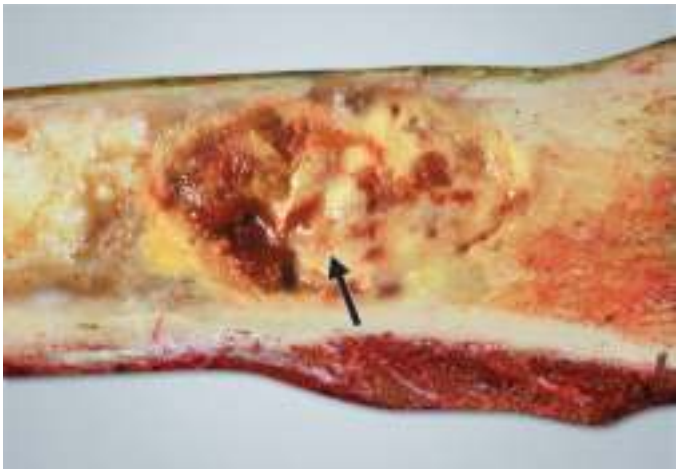

Fig. 27.44: Fibrous dysplasia of long bone. It is well-defined lesion showing thin cortex and expanded contours, tan gray fibrous tissue with gritty consistency. Areas of hemorrhage with or without cysts are demonstrated (arrow).

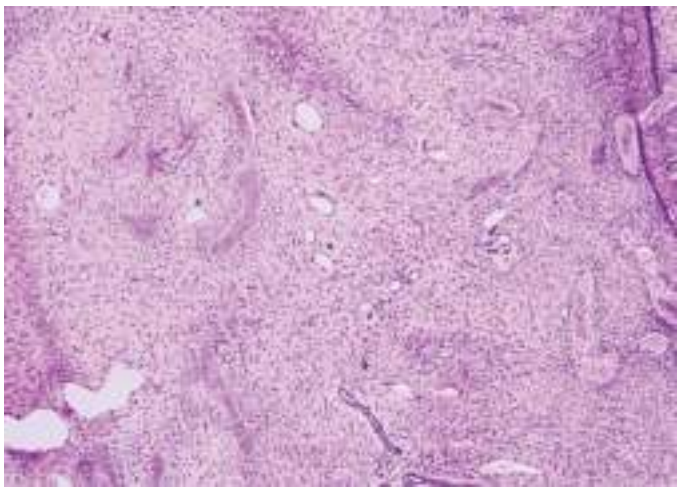

Fig. 27.45: Fibrous dysplasia. It is composed of irregular trabeculae of immature woven bone lacking osteoblastic rimming. The irregular trabeculae of immature woven bone are present in the stroma and giving 'storiform appearance'. There may be presence of foam cells, occasional stromal myxoid and/or cystic change (400X).

in McCune-Albright syndrome and Mazabraud syndrome.

OSTEOFIBROUS DYSPLASIA (OSSIFYING FIBROMA)

Osteofibrous dysplasia (also known as ossifying fibroma) is a benign intracortical lesion in the midshaft of tibia with or without involvement of fibula affecting children. Radius and ulna are rarely involved.

Incidence and Locations

Osteofibrous dysplasia most often occurs in the midshaft of tibia with or without involvement of fibula. Fibula alone is rarely involved. Rarely, radius and ulna may be involved.

Age and Sex Predilection

Osteofibrous dysplasia most often occurs in young children below the age of 15 years. Males and females are equally affected.

Clinical Features

Patient presents with painful swelling and deformity of tibia in the diaphyseal region.

Radiologic Findings

Radiograph shows several centimeters long intracortical radiolucent lesion in the diaphyseal region of tibia and sclerosis surrounding the lesion giving ground glass appearance. Involvement of medulla of bone results in narrowing of medullary cavity. Involved bone shows bowing. Lesion does not involve soft tissue.

Surgical Pathology: Osteofibrous Dysplasia

Gross Morphology

Osteofibrous dysplasia is confined to the cortex of tibia. It is gray white to yellow brown. Consistency is firm fibrous to gritty texture.

Light Microscopy

Osteofibrous dysplasia has zonal architecture, i.e. central and peripheral zones.

- **Central zone of osteofibrous dysplasia:** It is composed of loose fibrous tissue with myxoid appearance, arranged in storiform pattern admixed with immature woven bony trabeculae.
- **Peripheral zone of osteofibrous dysplasia:** It is composed of a mixture of mature lamellar bone and immature woven bone.
  - Mature lamellar bone merges with either the cortical bone or reactive sclerotic bone at the medullary aspect.
  - Bony trabeculae are rimmed by layer of osteoblasts throughout the lesion.

Differential Diagnosis

Osteofibrous dysplasia should be differentiated from fibrous dysplasia, osteofibrous dysplasia like differentiated lesion, classic adamantinoma with focal osteofibrous dysplasia like component.

Immunohistochemistry Technique

As osteofibrous dysplasia lacks epithelial cells, but shows positivity for cytokeratin AE1/AE3 in scattered cells within fibrous stroma. Cytokeratin profile is that of basal phenotype showing expression of CK14 and CK19. CK1 and CK5 are expressed in some lesions.

Markers	Expression
▪ CK14 (AE1/AE3)	▪ Positive
▪ CK19 (AE1/AE3)	▪ Positive
▪ CK1	▪ Positive (some cases)
▪ CK5	▪ Positive (some cases)

Prognosis and Treatment

Osteofibrous dysplasia regresses spontaneously after puberty in majority of cases. Lesion may recur after biopsy or surgical excision in 25% of cases. Severe bone deformity is treated by surgery.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH) is a spectrum of clinical syndromes characterized by proliferation of antigen-presenting dendritic cells derived from CD34 positive hematopoietic stem cells of bone marrow, which express major histocompatibility complex class II molecules and bear C3 receptors and CD1A.

Table 27.48 Clinical forms of Langerhans cell histiocytosis (LCH)

Clinical Forms	Age Group	Organs Involved	Prognosis
Letterer-Siwe disease (generalized diffuse)	Infancy	Bone, bone marrow, skin, lymph nodes, liver, spleen, thymus, lung	Usual fatal
Hand-Schüller-Christian disease (generalized diffuse)	Childhood, young adults	▪ *Adults:* Bone (ribs, ramus of mandible, vertebral bodies and orbit), lung, gastrointestinal tract, skin ▪ *Children:* Head and femur	Chronic disabling disease
Eosinophilic granuloma of bone (localized diffuse)	Childhood, young adults	Bone	Variable stable to remission
Eosinophilic granuloma of lung (localized diffuse)	Young adults	Lung	Variable stable to remission

- Langerhans cell histiocytosis contains tennis racket-shaped cytoplasmic 'Birbeck granules' demonstrated by electron microscopy, which have poor phagocytic activity.
- Langerhans cell histiocytosis is positive for S-100 protein, CD1a, CD207 (langerin) and CD68.
- Langerhans cell histiocytosis is classified into three clinical forms according to the extent of involvement of organs, i.e. skeletal and extraskeletal regions (lymph node, skin, lung, gastrointestinal tract), e.g. Letterer-Siwe disease, Hand-Schüller-Christian disease and eosinophilic granuloma. There can be unifocal or severe form multifocal involvement of organs. Clinical forms of Langerhans cell histiocytosis (LCH) are given in Table 27.48.

Langerhans Cell Histiocytosis (LCH): Clinical Forms

Letterer-Siwe Disease

Letterer-Siwe disease is an acute disseminated Langerhans cell histiocytosis, which affects infants and children. It has a rapid aggressive clinical course with fatal outcome.

- **Clinical Features:** Patient presents with painless yellow brown, maculopapular skin lesions over face (especially around eyes), mouth, trunk, perineum and axilla and recurrent infection as a result of widespread proliferation of Langerhans cell histiocytosis. Physical examination reveals hepatosplenomegaly, lymphadenopathy and pulmonary involvement (honeycomb appearance, pleural effusion and spontaneous pneumothorax).
- **Light Microscopy:** Histologic examination of the lesion shows numerous histiocytes lacking lipids and foci of necrosis.

Hand-Schüller-Christian Disease

Hand-Schüller-Christian disease is an acute onset disease followed by chronic clinical course as a result of proliferation of Langerhans cell histiocytosis, which affects infants, adolescents and elderly persons. It most often manifests before the age of 5 years. It has better prognosis than Letterer-Siwe disease.

- **Clinical Features:** Patient presents with clinical triad of manifestations: (a) skull lesions (orbit, tooth-bearing area of mandible, mastoid bone), (b) diabetes insipidus due to involvement of sella turcica, and (c) exophthalmos due to involvement of orbit. There may also be involvement of femur, pelvis, rubs, shaft of humerus. Hepatosplenomegaly and lymphadenopathy are demonstrated in 25% of cases.
- **Light Microscopy:** Histologic examination of the lesion (skull, liver, spleen, other tissues) is composed of histiocytes admixed with inflammatory cells.

Eosinophilic Granuloma

Eosinophilic granuloma is a rare benign-like disorder characterized by clonal proliferation of Langerhans cell histiocytosis. It is the most common variant of Langerhans cell histiocytosis. It may be unifocal or multifocal involvement of organs. It mainly involves skull, mandible, vertebrae, pelvis and ribs in children. It involves long bones, lung and gastrointestinal tract in adults.

- **Clinical Features:** Patient presents with bone pain, pathological fracture of long bone and vertebral collapse. Pulmonary manifestations are cough, breathlessness and pneumothorax. Gastrointestinal lesion may simulate polyp, duodenal ulcer and gastric carcinoma. Gastrointestinal lesion usually heals without treatment.
- **Light Microscopy:** Histologic examination of the eosinophilic granuloma is composed of numerous mononuclear histiocytes admixed with eosinophils and lymphocytes (Fig. 27.46).

Radiologic Findings

- Radiologic findings of clinical variants of Langerhans cell histiocytosis are variable. Radiograph shows geographic osteolytic lesion in the medullary region of long bones.
- Skull radiograph shows most often well defined 1–2 cm size nonsclerotic round or oval lesion with beveled edge. In long bones, radiograph demonstrates lesion reaching 6 cm in size within cortical region. Soft tissue involvement is well documented.

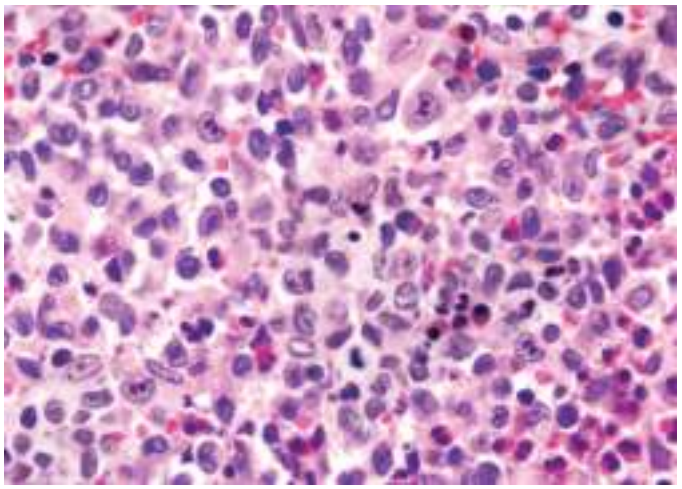

Fig. 27.46: Eosinophilic granuloma. It is composed of numerous mononuclear histiocytes admixed with eosinophils and lymphocytes (400X).

Surgical Pathology: Langerhans Cell Histiocytosis

Gross Morphology

- Gross morphology of curettage of Langerhans cell histiocytosis is gray yellow to tan or hemorrhagic depending on the proportion of these components.
- Small fragments are soft in consistency.
- Surgical excision of complete lesion is well circumscribed gray, yellow to red.
- Cortical destruction of long bone is most often demonstrated. Extension of the lesion into soft tissue is demonstrated.

Light Microscopy

- Langerhans cell histiocytosis lesion is composed of numerous histiocytes admixed with eosinophils, foamy macrophages, plasma cells, neutrophils, scattered osteoclast-like giant cells and scattered mitotic figures. Atypical cells and fibrous tissue in the background are absent.
- Histiocytes contain abundant eosinophilic to vacuolated cytoplasm and vesicular nuclei with well defined nuclear borders and prominent indentations giving 'coffee bean reniform' appearance. Binucleated and multinucleated forms are common (Fig. 27.47).

Electron Microscopy

Langerhans cell histiocytosis contains tennis racket-shaped cytoplasmic '**Birbeck granules**' demonstrated by electron microscopy.

Differential Diagnosis

Langerhans cell histiocytosis should be differentiated from osteomyelitis, granulation tissue, Hodgkin's disease, non-Hodgkin's lymphoma, Rosai-Dorfman disease and fibrohistiocytic tumor (nonossifying fibroma).

Immunohistochemistry Technique

Cells of Langerhans cell histiocytosis are positive for S-100 protein, CD1a, CD207 (langerin) and CD68. These cells are negative for CD45, AE1/AE3, CD15 and CD30.

Markers	Expression
S-100 protein	Positive
CD1a	Positive
CD207 (langerin)	Positive
CD68	Positive
CD45	Negative
AE1/AE3	Negative
CD15	Negative
CD30	Negative

Prognosis and Treatment

Prognosis of Langerhans cell histiocytosis depends on site and extent of lesion in the bones and other tissues. Localized lesion may regress spontaneously. Some lesions are treated by simple curettage or administration of steroids in the lesion. Multifocal systemic disease has a poor prognosis. Poor prognostic factors are hepatosplenomegaly, polyostotic disease, anemia, thrombocytopenia and affecting children of <3 years of age. Multiagent chemotherapy has been some success in treating these cases.

ERDHEIM-CHESTER DISEASE

Erdheim-Chester disease is a rare disseminated xanthogranulomatous and infiltrative disease of unknown etiology. It is characterized by involvement of bone and

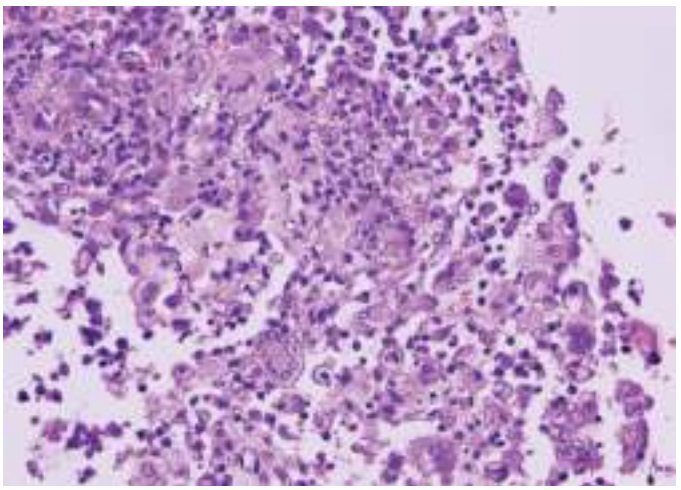

Fig. 27.47: Langerhans cell histiocytosis. It is composed of numerous Langerhans cell histiocytosis admixed with eosinophils, foamy macrophages, plasma cells, neutrophils, scattered osteoclast-like giant cells and scattered mitotic figures (400X).

systemic organs. Recent cytogenetic HUMARA (human androgen receptor-α)-PCR (polymerase chain reaction)-based studies suggest it a neoplastic disease.

Incidence and Locations

Erdheim-Chester disease involves skull, bilateral femur and tibia; heart, lung and retroperitoneum.

Age and Sex Predilection

Erdheim-Chester disease affects children to elderly persons between 7 and 84 years of age with slight male predominance. Peak incidence is observed during fifth to seventh decades of life.

Clinical Features

Involvement of orbit produces proptosis and exomphalos (birth defect of the abdominal wall). Involvement of pituitary gland manifests with diabetes insipidus. Cerebral and cerebellar involvement produces a multiple sclerosis-like syndrome. Involvement of myocardium and pericardium leads to cardiac failure. Pulmonary involvement produces interstitial lung disease. Bone marrow involvement occurs in bilateral distal femur, proximal tibia and fibula in the metaphyseal region.

Radiologic Findings

Radiograph shows bilateral symmetrical osteosclerotic lesions in the metaphyseal region of distal femur, proximal tibia and fibula. Epiphysis of bones is usually spared. Skull and ribs may demonstrate osteolytic lesions. In an occasional case, mixed sclerotic and osteolytic lesions may be demonstrated in distal femur, proximal tibia and fibula.

Surgical Pathology: Erdheim-Chester Disease

Gross Morphology

Biopsy fragments from lesion in Erdheim-Chester disease is composed of tan brown tissue with yellowish areas corresponding to xanthogranulomatous change.

Light Microscopy

- Osseous lesion of Erdheim-Chester disease is composed of numerous histiocytes admixed with multinucleated giant cells, Touton cells, lymphocytes and plasma cells lying in stroma.
- Thickening occurring in woven and lamellar bone may exhibit a pagetoid appearance.

Differential Diagnosis

Erdheim-Chester disease should be differentiated from chronic osteomyelitis, Langerhans cell histiocytosis and Rosai-Dorfman/sinus histiocytosis with massive lymphadenopathy.

Immunohistochemistry Technique

Osseous lesion of Erdheim-Chester disease is positive for CD68 and CD163 and negative for S-100 protein and CD1a.

Markers	Expression
▪ CD68	▪ Positive
▪ CD163	▪ Positive
▪ S-100 protein	▪ Negative
▪ CD1a	▪ Negative

Prognosis and Treatment

Prognosis of Erdheim-Chester disease depends on the extent of systemic involvement. Majority of patients have prolonged indolent course. Approximately 33% of cases have fatal outcome within 10 years from systemic effects. There is no definite treatment of the disease. Chemotherapy and corticoids are most often used to treat these cases.

CHONDROMESENCHYMAL HAMARTOMA

Chondromesenchymal hamartoma is a rare lesion in the rib cage of infants. It is composed of an admixture of spindle cells, cartilage and hemorrhagic cysts in variable proportion.

Incidence and Locations

Chondromesenchymal hamartoma most often occurs either in the medullary cavity or on the surface of rib cage. Lesion may be bilateral or multicentric.

Age and Sex Predilection

Chondromesenchymal hamartoma most often occurs in infants with male predominance, which rarely affects adults.

Clinical Features

Patient may be asymptomatic or having respiratory distress. Chondromesenchymal hamartoma may be detected incidentally as a palpable mass in the chest region.

Radiologic Findings

Radiograph and CT scan demonstrate an expansile mass with well-defined sclerotic margins, and areas of calcification and ossification. MRI shows solid and cystic components of the lesion.

Surgical Pathology: Chondromesenchymal Hamartoma

Gross Morphology

- Chondromesenchymal hamartoma can be of considerable size.
- Cut surface shows solid and cystic components with areas of hemorrhage. Cartilage is demonstrated in the solid component of the lesion.

Light Microscopy

- Solid component of chondromesenchymal hamartoma is composed of spindle cells with admixture of woven bone, cartilage and collagen in varying proportion. Enchondral ossification is frequently demonstrated.
- Cystic component of the lesion shows areas of hemorrhage. Its histologic features resemble aneurysmal bone cyst. Walls of septae of cystic component are composed of fibrous tissue, reactive bone and scattered osteoclast-like giant cells.

Differential Diagnosis

Chondromesenchymal hamartoma should be differentiated from aneurysmal bone cyst.

Molecular Genetic Alterations

Chondromesenchymal hamartoma arising in the nasal septum demonstrates chromosomal translocation t(12;17)(q24.1;q21).

Prognosis and Treatment

Chondromesenchymal hamartoma is treated by surgical excision. Asymptomatic patients can be managed by conservative treatment. Sporadic cases have fatal outcome due to respiratory insufficiency. Lesion may regress spontaneously.

ROSAI-DORFMAN DISEASE

Rosai-Dorfman disease is a rare disorder involving multiple organs and characterized by proliferation of histiocytes in the metaphyseal region of long bones and craniofacial bones.

Incidence and Locations

Most common sites of Rosai-Dorfman disease are long bones and craniofacial skeleton. Lesion is solitary in majority of cases. There may involvement of two or more separate bones in 20% of cases.

Age and Sex Predilection

Rosai-Dorfman disease affects 3–56 years of age group without sex predominance.

Clinical Features

Patient presents with pain in the localized area of involved bone.

Radiologic Findings

Radiograph shows well-defined osteolytic lesion and sometimes expansile separate mass. Cortical thickening and periosteal reaction are demonstrated in minority of cases.

Surgical Pathology: Rosai-Dorfman Disease

Gross Morphology

Osseous lesion of Rosai-Dorfman disease measures 1–7 cm in size. Osseous lesion measures <5 cm in diameter in majority of cases. Osseous lesion is well defined tan-gray and soft or gray gritty in consistency.

Light Microscopy

- Osseous lesion of Rosai-Dorfman disease is composed of numerous large size histiocytes admixed with plasma cells, lymphocytes, neutrophils, foamy macrophages and occasional eosinophils. Plasma cells most often contain Russell bodies.
- Large size histiocytes contain abundant eosinophilic cytoplasm and round or oval or kidney bean-shaped nuclei with fine or vesicular chromatin and prominent nucleoli. Microabscesses may be demonstrated in the lesion.

Immunohistochemistry Technique

Large size histiocytes show positivity for S-100 protein, CD8, CD163, and negative for CD1a.

Markers	Expression
S-100 protein	Positive
CD8	Positive
CD163	Positive
CD1a	Negative

Prognosis and Treatment

Rosai-Dorfman disease has a good prognosis. Approximately 40% of cases develop extraosseous foci of disease. Osseous lesions are treated by curettage.

ACHONDROPLASIA

Achondroplasia is an autosomal disorder characterized by short-limbed dwarfism and macrocephaly. Limb bones become short and thick. Anchondroplasia represents a failure of normal epiphyseal cartilage formation.

Pathogenesis

Achondroplasia occurs due to mutation of fibroblast growth factor receptor 3 (FGFR3) located at 4p16.3. FGFR3 gene mutation arrests chondrocyte proliferation, differentiation and development of epiphyseal plates.

Narrowing of epiphyseal plates, and bony sealing of the area between the epiphyseal plate and the metaphysis lead to failure of elongation of limb bones. A defective growth hormone receptor is responsible for rare cases of dwarfism (Laron dwarfism).

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is an autosomal dominant disorder and also known as brittle bone disease.

- **Physiologic state:** Normally, collagen genes (COLLA1 and COLLA2) encode α_1- and α_2-chains of type 1 procollagen fibers result in synthesis of collagen fibers, the major structural protein of bone.
- **Pathologic state:** Collagen genes (COLLA1 and COLLA2) lead to defective collagen synthesis in various organs such as skeleton (brittle bones), joints, ears, ligaments, teeth, sclerae, and skin.

Molecular genetic defects in four types of osteogenesis imperfecta are heterogeneous, but all adversely affect the synthesis of type 1 collagen fibers.

Clinical Features

Due to defective synthesis of collagen fibres in various organs (skeleton, joints, ligaments, sclerae, ear, teeth and skin, patients of osteogenesis imperfecta develop brittle bone disease, blue sclera, hearing loss and fractures during infancy and childhood.

OSTEOPETROSIS

Osteopetrosis is inherited disorder also known as marble disease or Albers-Schönberg disease, which occurs in two major clinical forms: an autosomal recessive variant of osteopetrosis that is usually fatal in infancy and a less severe autosomal dominant variant.

Age Group

Osteopetrosis affects infants and children, which occurs due to mutations in genes that govern osteoclast formation or function.

Pathology

Osteopetrosis results in increased bone density (thickened cortex), and lack of funnelization (funnel-like appearance) of the metaphysis and retention of the primary spongiosum with its cartilage cores. Decreased bone marrow space results in anemia.

- Due to narrowing of foramina results in blindness, deafness, due to pressure exerted on cranial nerves.
- Patient develops 'multiple fractures' in spite of increased bone density.
- Bone marrow transplant reverses many skeletal abnormalities. Human interferon gamma (IFN-γ) is administered in these patients.

Radiologic Findings

Long bones are shortened with loss of metaphyseal flare (Erlenmeyer, flask deformity, uniform opacity of pelvis and peripheral bones) alternating with normal bone cause a stippled appearance. It may cause spinal spondylolithiasis.

Surgical Pathology: Osteopetrosis

Gross Morphology

- Bones are solid and heavy without medullary canal.
- Long ends of bones are bulbous, small neural foramina, which compress the nerves.

Light Microscopy

- Osteopetrosis is primarily woven bone which does not undergo remodeling.
- Central core of the cartilage with dense and irregular bone trabeculae are formed.
- There is often presence of abundant osteoclasts.
- Reduced marrow space is present.
- Histology of osteopetrosis is seen in Fig. 27.48.
- Masson's trichrome stained section of osteopetrosis is shown in Fig. 27.49.

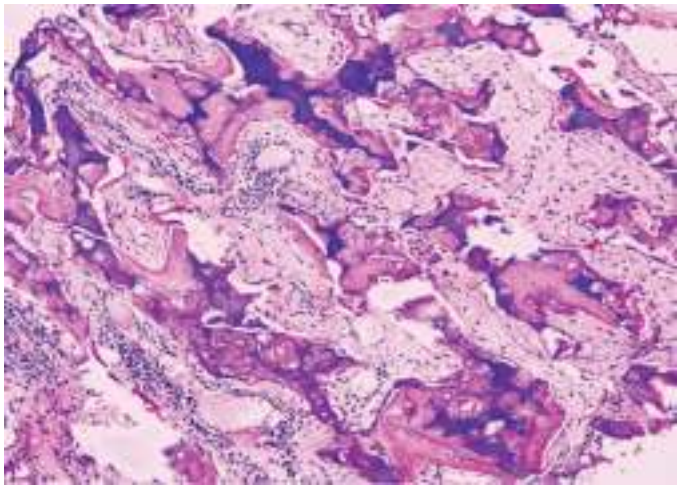

Fig. 27.48: Osteopetrosis. It shows increased bone density (thickened cortex) and decreased bone marrow space (100X).

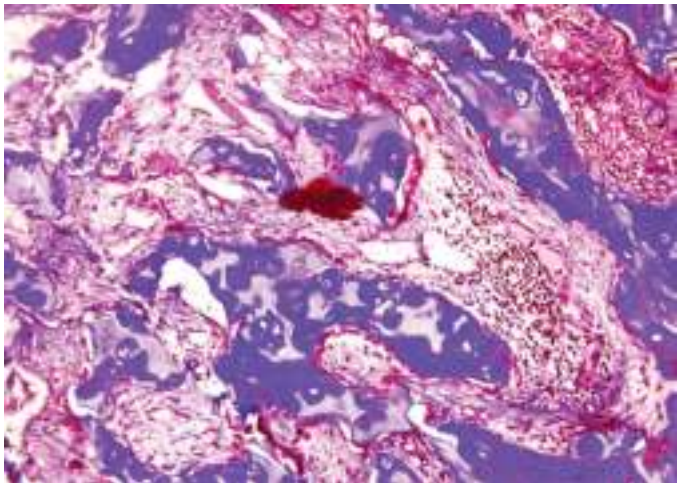

Fig. 27.49: Osteopetrosis. Masson's trichrome stain is demonstrated in osteopetrosis.

OSTEONECROSIS (AVASCULAR NECROSIS)

Osteonecrosis refers to the death of bone marrow in the absence of infection. Growing bones of children and adolescents are often affected.

Etiopathogenesis

Osteonecrosis is caused by trauma, thromboemboli, sickle cell anemia, decompression syndrome or the bends, in adults, which lead to interruption of blood supply to bone marrow. Causes of osteonecrosis are given in Table 27.49.

Pathologic Entities

- **Legg-Calvé-Perthes disease:** It refers to osteonecrosis in the femoral head in children. Collapse of the femoral head may lead to joint incongruity and severe osteoarthritis (Fig. 27.50).
- **Osgood-Schlatter disease:** It refers to osteonecrosis of tibial tubercle.
- **Köhler bone disease:** It refers to osteonecrosis of **navicular bone**.

Epiphyseal disorders

SECONDARY BONE TUMORS (METASTATIC BONE DISEASE)

Secondary bone tumors (metastatic bone disease) in various age groups are given in Table 27.50.

METASTATIC BONE DISEASE

Secondary bone involvement by a malignant tumor originating from another site is known as metastatic bone disease. After lung and liver, skeleton is the most common site of metastatic bone disease.

Fig. 27.50: Avascular necrosis of bilateral femoral heads. Radiograph and post-contrast magnetic resonance imaging demonstrate flattening and irregularity of articular surfaces of bilateral femoral heads. Areas altered marrow signal intensity are seen in bilateral femoral heads. There is involvement of almost entire right femoral head and around 40–50% of left femoral head. Few tiny degenerative changes and cystic areas are seen in right acetabulum. Left acetabulum reveals normal marrow signal. Findings are suggestive of avascular necrosis of bilateral femoral heads shown by arrows. (*Courtesy:* Dr. Vigyat and Dr. Anubhav, Dr. DY Patil Medical College, Pune, Maharashtra.)

Table 27.50 Secondary bone tumors (metastatic bone disease) in various age groups

Secondary Bone Tumors (Metastatic Bone Disease)	
Adult males	
▪ Prostatic carcinoma	▪ Lung carcinoma
Adult females	
▪ Breast carcinoma	▪ Endometrial carcinoma
▪ Thyroid carcinoma	▪ Cervical carcinoma
▪ Renal cell carcinoma	
Children (males and females)	
▪ Rhabdomyosarcoma	▪ Clear cell sarcoma of kidney
▪ Neuroblastoma	

- During course of primary carcinomas originating from breast, prostate, thyroid, lung, gastrointestinal tract, kidney, urinary bladder and melanoma; the adult patients have metastatic bone disease during fourth to seventh decades of life.
- In children, neuroblastoma, renal clear cell sarcoma, osteosarcoma, Ewing sarcoma/primitive neuroectodermal tumor (PNET), and rhabdomyosarcoma metastasize to the bones.
- Basal cell carcinoma, glioma and soft tissue sarcomas (except rhabdomyosarcoma) rarely metastasize to the bones.
- Immunohistochemistry technique is used to diagnose primary carcinoma involving bone.
- Combination of surgical procedures and radiation or other therapies is useful in the management of metastatic bone disease. Metastatic deposits in hematopoietic bone marrow in descending order are given in Table 27.51.

Bones Involvement: Mechanism

Primary malignancies invade bone by direct extension and lymphatic and hematogenous route including Batson paravertebral venous plexus. Skip metastasis or bone-to-bone metastasis has been reported.

- Batson paravertebral venous plexus has communication with vertebral venous plexus and vena cava.
- Vertebral venous plexus is extensive and valveless and having constant communication with breast, thyroid, lung and prostate gland.
- In addition, vertebral venous plexus has communication with dural sinus and vasa vasorum of humerus and femur. There are numerous inter-communications between vascular and lymphatic channels.

Table 27.51 Metastatic deposits in hematopoietic bone marrow in descending order

Metastatic Deposits in Bone Marrow
Vertebral column (most common site)
Pelvis
Ribs
Skull
Humerus proximal end
Femur proximal end

Skeletal metastases are uncommon below knee or elbow joints. Tumors rarely metastasizing to bones include basal cell carcinoma, gliomas and soft tissue sarcomas except embryonal rhabdomyosarcoma.

Solitary and Multifocal Bone Disease

Solitary and multifocal bone metastatic disease is given in Table 27.52.

- **Solitary bone metastatic disease:** It is an independent good prognostic factor. Patients with solitary metastatic bone disease live longer than with multifocal metastatic bone disease. Examples of solitary metastatic bone disease are lung carcinoma, renal cell carcinoma and well-differentiated thyroid carcinoma.
- **Multifocal bone metastatic disease:** Prognosis is poor in patient presenting with involvement of multiple bones by a malignant tumor. Examples of multifocal metastatic bone disease are mammary ductal carcinoma, gastric carcinoma, colorectal carcinoma and neuroblastoma.

Incidence and Locations

Metastatic bone disease is more common than primary malignant bone tumors. Metastases predominantly occur in the red bone marrow of vertebrae, cranium, ribs, sternum, sacrum, pelvic girdle, proximal femur and proximal humerus.

- Approximately 90% of patients have metastatic bone disease due to carcinoma originating from breast, lung, thyroid, prostate, stomach, colorectal region and malignant melanoma.
- Metastasis tends to involve the metaphysis of long bones.

Table 27.52 Solitary and multifocal bone metastatic disease

Bone Metastatic Disease	Example
Solitary metastatic bone disease	▪ Lung carcinoma ▪ Renal cell carcinoma ▪ Well differentiated thyroid carcinoma
Multifocal metastatic bone disease	▪ Mammary adenocarcinoma ▪ Gastric carcinoma ▪ Colorectal carcinoma ▪ Neuroblastoma

- Bone metastases are uncommon below knee or elbow joints. Metastases are rare in small bones of hands and feet.

Age and Sex Predilection

Metastatic bone disease most often occurs in adults 40–60 years of age; and children. Metastatic bone disease in adults and children is given in Table 27.53.

Clinical Features

Symptoms of metastatic bone disease are nonspecific. Patient presents with bone pain with or without swelling; and pathologic fracture. Metastases in vertebrae produce neurological symptoms.

- Hypercalcemia occurs due to osteolytic lesion produced by metastasis.
- Metastases involving skull base may cause Collet-Sicard syndrome characterized by combined and unilateral palsy of cranial nerves IX, X, XI and XII.

Table 27.53 Metastatic bone disease in adults and children

Metastases Involving Bone in Adults
Prostatic carcinoma
Mammary ductal carcinoma
Well-differentiated thyroid carcinoma
Renal cell carcinoma
Transitional cell carcinoma of urinary bladder
Lung adenocarcinoma
Serous cystadenocarcinoma of ovary
Gynecologic endometrioid carcinoma
Gastric carcinoma
Colorectal carcinoma
Hepatocellular carcinoma
Pancreatic carcinoma
Small cell lung carcinoma (neuroendocrine tumor)
Giant malignant pheochromocytoma (neuroendocrine tumor)
Paraganglioma (neuroendocrine tumor)
Malignant melanoma (melanocytic tumor)
Angiosarcoma
Rhabdomyosarcoma
Leiomyosarcoma
Liposarcoma
Malignant peripheral nerve sheath tumor
Alveolar soft part sarcoma
Synovial sarcoma
Undifferentiated pleomorphic sarcoma
Metastases Involving Bone in Children
Rhabdomyosarcoma
Osteosarcoma
Renal clear cell sarcoma

Radiologic Findings

Metastatic bone disease produces either osteolytic (destructive) or osteoblastic lesions. Less frequently, some tumors metastasizing to bone may produce osteolytic/osteoblastic mixed patterns.

- Neoplastic cells synthesize transforming growth factor β (TGF-β), fibroblastic growth factor (FGF), bone morphogenic proteins, prostaglandins, interleukin 1 (IL-1) and many other proteins, which modulate bone changes. Activity of the osteoblasts may also produce structural changes.
- Initial evaluation of metastatic bone disease should begin with conventional radiograph. Metastatic bone lesion in vertebrae may be detected by radiograph in 25% of cases; and CT scan and MRI in almost all cases. Radioisotope scintigram is done to detect multiple bone metastatic disease from carcinomas in almost all cases.

Osteolytic Lesions in Metastatic Bone Disease

Renal cell carcinoma, well-differentiated thyroid carcinoma, gastric adenocarcinoma, colorectal carcinoma, melanoma, non-Hodgkin's lymphoma and neuroblastoma metastasizing to the bone produce osteolytic and destructive lesions resulting in hypercalcemia and increased excretion of calcium in urine. Increased excretion of hydroxyproline containing peptide in urine indicates bone matrix destruction.

Osteoblastic Lesions in Metastatic Bone Disease

Prostatic adenocarcinoma, mammary ductal carcinoma and Hodgkin's disease metastasizing to the bone produce osteoblastic lesion.

- Prostatic adenocarcinoma metastasizing to the bone most often presents with osteoblastic lesion associated with periosteal reaction simulating primary bone sarcoma.
- Metastatic bone disease involving metaphysis can simulate primary bone sarcoma.
- Pathologic fracture in metastatic bone disease produces florid ossification demonstrated on radiograph may simulate osteosarcoma.
- Osteoblastic lesion in metastatic bone disease is associated with increased serum alkaline phosphatase and decreased serum calcium level.

Table 27.54 Osteolytic or osteoblastic lesion on radiograph in metastatic bone disease

Findings on Radiograph (Tumors Metastasizing to Bone)	Comments
Osteolytic and destructive lesion on radiograph	
▪ Renal cell carcinoma ▪ Well differentiated thyroid carcinoma ▪ Gastric adenocarcinoma ▪ Colorectal carcinoma ▪ Malignant melanoma ▪ Non-Hodgkin's lymphoma ▪ Neuroblastoma	▪ Increased serum calcium ▪ Increased excretion of calcium in urine ▪ Increased excretion of hydroxyproline containing peptide in urine indicates bone matrix destruction
Osteoblastic lesions on radiograph	
▪ Prostatic adenocarcinoma ▪ Mammary ductal carcinoma ▪ Hodgkin's disease	▪ Increased serum alkaline phosphatase ▪ Decreased serum calcium
Either osteolytic or osteoblastic lesion on radiograph	
▪ Small cell lung carcinoma ▪ Mammary ductal carcinoma	▪ Serum and urinary findings depend on type of lesion

Osteolytic/Osteoblastic Lesions in Metastatic Bone Disease

Small cell lung carcinoma and mammary ductal carcinoma metastasizing to the bone may produce either osteolytic or osteoblastic lesion on radiograph. Osteolytic or osteoblastic lesion on radiograph in metastatic bone disease is given in Table 27.54.

Surgical Pathology: Metastatic Bone Disease

Gross Morphology

- Gross morphologic features of metastatic bone disease are usually nonspecific simulating primary bone sarcomas.
- Metastatic bone disease lesions are osteolytic with soft in consistency and areas of hemorrhage.
- Desmoplastic reaction of stroma in metastatic bone disease produces grayish white lesion with firm in consistency.
- Prostatic adenocarcinoma metastasizing to the bone produces dense hard osteoblastic lesion.
- Periosteal new bone formation is infrequent.
- Extraosseous extension of metastatic bone disease may be demonstrated.

Light Microscopy

- Well-differentiated carcinoma from breast, prostate, kidney and thyroid gland metastasizing to bone resemble the histology of primary tumor.
- Undifferentiated or poorly differentiated tumors metastasizing to bone poses diagnostic difficulty on histologic examination.
- Sarcomatoid carcinomas of kidney, thyroid gland and lung lack apparent epithelial differentiation and therefore simulate spindle cell sarcoma of bone.
- Prostatic adenocarcinoma, mammary ductal carcinoma and neuroendocrine tumors produce reactive bone formation simulating osteosarcoma.
- Presence of numerous osteoclastic multinucleated giant cells in metastatic bone disease can be confused with giant cell tumor of bone.

Immunohistochemistry Technique

Immunohistochemistry technique plays an important role to differentiate metastatic bone disease and primary bone sarcomas.

- Immunostains for cytokeratins (AE1/AE3, CAM 5.2, CK7 and CK20) and epithelial membrane antigen (EMA) are most often positive in epithelial and negative in mesenchymal malignancies.
- In some cases, immune markers may be helpful to diagnose metastatic bone disease.
- Some examples are TTF-1 (thyroid transcription factor 1) for well differentiated thyroid carcinoma and lung adenocarcinoma; PSA (prostate-specific antigen) for prostatic adenocarcinoma, S-100 protein, MHB-45 and melan-A (A103) and MART-1 (melanoma-associated antigen recognized by T cells) for malignant melanoma.
- Other examples of immunohistochemical markers include NSE (neuron-specific enolase), synaptophysin and chromogranin A for neuroendocrine tumors; ER/PR, GCDFP (gross cystic disease fluid protein), mammaglobin and GATA3 for mammary ductal carcinoma, CDX2 and villin for gastric adenocarcinoma and colorectal carcinoma.
- Applications of immunohistochemistry technique in analysis of cytokeratins are given in Table 27.55. CK7 and CK20 immunohistochemistry technique expression profiles are given in Table 27.56. Role of immunohistochemistry technique in breast carcinoma is given in Table 27.57.

Table 27.55 Applications of immunohistochemistry technique in analysis of cytokeratins

Monoclonal Antibody Used	Analysis of Various Types of Cytokeratins
AE1 antibody	All acidic cytokeratins except CK9, CK12, CK17, CK18
AE3 antibody	All basic cytokeratins
AE1/AE3 antibody (pan-CK)	▪ Broad spectrum pan-cytokeratins antibody to identify both LMWCK and HMWCK ▪ AE1/AE3 antibody (pan-CK) is the first line marker, which detects both LMWCK and HMWCK present in squamous cell carcinoma, colon adenocarcinoma, prostatic carcinoma, hepatocellular carcinoma and renal cell carcinoma, adrenocortical neoplasms ▪ AE1/AE3 antibody reactivity is variable in neuroendocrine tumors. Therefore, precautions should be taken in interpretation of results
OSCAR, PANK (MNF-116) antibody	These are also broad spectrum cytokeratins similar to AE1/AE3 antibody used to identify both LMWCK and HMWCK
CAM 5.2 (34bH11) antibody	▪ CAM 5.2 (34βH11) antibody is a good complement to AE1/AE3 antibody (pan-CK). It detects those carcinomas missed by AE1/AE3 antibody (pan-CK) ▪ CAM 5.2 (34βH11) antibody demonstrates LMWCK (CK8, CK18) expressed by simple/non-squamous keratins in glandular epithelia (e.g. colon adenocarcinoma, prostatic adenocarcinoma); and visceral parenchyma (e.g. hepatocellular carcinoma, renal cell carcinoma)
CK903 (K903;34bE12) antibody and CK5/CK6 antibody	CK903 and CK5/CK6 antibodies demonstrate HMWCK (CK1, CK5, CK10, CK14) without LMWCK (CK1, CK5, CK10, CK14) expressed in keratinizing squamous epithelia and in majority of squamous cell carcinoma, however, some poorly differentiated non-keratinizing carcinomas show positivity for both HMWCK and LMWCK
Expression of cytokeratins (and EMA) is key diagnostic feature of carcinomas. Cytokeratin positivity may also be seen synovial sarcoma, epithelioid sarcoma, epithelioid angiosarcoma, non-seminomatous germ cell tumors (yolk sac tumor, embryonal carcinoma), trophoblastic tumors, mesothelioma, chordoma and thymoma, and aberrant expression of leiomyosarcoma, melanoma and peripheral nerve sheath tumor	
HMWCK (high molecular weight cytokeratin), LMWCK (low molecular weight cytokeratin)	

Table 27.56 CK7 and CK20 immunohistochemistry technique expression profiles

CK7 and CK20 Immunohistochemistry Technique	Location of Organs	Examples of Malignancy of Organs	
CK7+ and CK20–	Organs above the diaphragm	▪ Breast ▪ Lung and pleura ▪ Thyroid gland ▪ Salivary gland	▪ Kidney (renal papillary carcinoma) ▪ Female genital system (uterus and ovary)
CK7– and CK20+	Organs below the diaphragm	▪ Colon ▪ Rectum	▪ Merkel cell carcinoma
CK7+ and CK20+	Organs in peridiaphragmatic region	▪ Stomach ▪ Pancreas	▪ Biliary tree ▪ Urinary bladder
CK7– and CK20– (except colon)	Simple visceral epithelia	▪ Liver ▪ Kidney	▪ Prostate gland

Prognosis and Treatment

Prognosis of metastatic bone disease depends on the primary site of the tumor, histologic type and extent of disease. Aim of treatment of metastatic bone disease is to relieve pain and prevent pathologic fracture. Localized solitary metastatic deposit may be surgically resected. Radiotherapy and chemotherapy may be effective in controlling the symptoms. Specific therapies should be administered to the patients. ER/PR positive mammary ductal carcinoma is treated by tamoxifen. Herceptin is administered in HER2/neu positive mammary ductal carcinoma.

Table 27.57 Role of immunohistochemistry technique in breast carcinoma

Immunohistochemical Markers	Expression
Ductal carcinoma of breast in general	
▪ Estrogen/progesterone receptors (ER/PR) ▪ GCDFP-15 (gross cystic disease fluid protein 15) ▪ Mammoglobin ▪ HER2/neu growth factor receptor ▪ Ki-67 (proliferative marker) ▪ p53 ▪ CK7 ▪ GATA3	▪ Positive (nuclear staining in 50% of cases) ▪ Positive (cytoplasmic staining in 50% of cases) ▪ Positive (cytoplasmic staining in 50% of cases) ▪ Positive (membranous staining in 10–30% of cases) ▪ Positive ▪ Positive ▪ Positive (cytoplasmic staining) ▪ Positive
Lobular carcinoma of breast (*in situ* and invasive)	
▪ Loss of E-cadherin ▪ GCDFP-15 (gross cystic disease fluid protein 15)	▪ Positive ▪ Positive (cytoplasmic staining in 100% of cases)
Metaplastic carcinoma of breast	
▪ CK903 ▪ p63 ▪ CAM 5.2 (most reliable HMWCK marker) ▪ CK7 (most reliable HMWCK marker)	▪ Positive (cytoplasmic staining) ▪ Positive ▪ Positive (cytoplasmic staining) ▪ Positive (cytoplasmic staining)

DISORDERS OF JOINTS

CLASSIFICATION OF JOINTS

Joints are classified into three categories described as under:

- **Synarthroses joints:** Synarthroses joints are fibrous immovable joints, which do not allow any movement. Examples are coronal suture of skull and root of teeth in socket.
- **Amphiarthroses joints:** Amphiarthroses joints are cartilaginous or lightly movable joints. The bones are joined together with the help of cartilages, which permit limited movements. Examples are intervertebral joints and pubic symphysis.
- **Diarthroses synovial joints:** Diarthroses synovial joints contain synovial fluid in synovial cavity between the articulating surfaces of the two bones. Such an arrangement allows considerable free movements. Examples of synovial joints are given in Table 27.58.
  - Synovium is a glistening white membrane with villous projections. Synovium lines the inner surface of the joint capsule.
  - Factors affecting movement of diarthroses joints include structure or shape of the articulating bones, strength and tension of the joint ligaments and arrangement, and tension of the skeletal muscles around the joints (Fig. 27.51).

Table 27.58 Salient features of diarthroses synovial joints

Diarthroses Synovial Joints	Examples
Ball and socket joints	Shoulder joint (between humerus and pectoral girdle)
Hinge joint	Knee and elbow joints
Pivot joint	Atlas rotation around axis vertebrae
Gliding joint	▪ Joint between carpal bones of upper limb ▪ Joint between navicular and tarsus bone of foot
Saddle joint	Joint between trapezium and metacarpal of thumb
Condyloid joint	Joint between carpals and radius

Arthroscopy is a procedure that involves examination of the interior of joint especially knee to determine the nature and extent of injury.

ARTHRITIS OF PROBABLE AUTOIMMUNE ORIGIN

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic multisystem disorder of unknown cause. Its hallmark is persistent

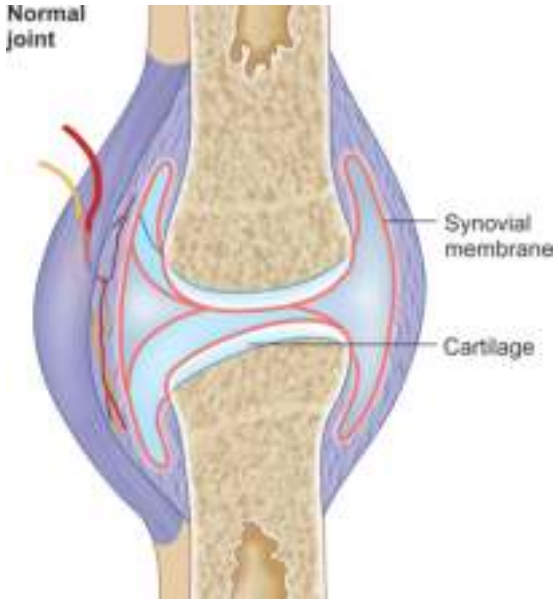

Fig. 27.51: Synovial joint is most common type of diarthrodial joints, which is covered by hyaline articular cartilage composed of collagen proteoglycans and water. This joint is enclosed in capsule. Joints are affected mostly by inflammatory and degenerative diseases.

inflammatory synovitis involving bilateral peripheral joints (proximal interphalangeal and metacarpophalangeal joints of the hands) in a symmetric distribution. Surrounding skeletal muscles, tendons, ligaments, blood vessels and knee joints may also be involved. Comparison of osteoarthritis and rheumatoid arthritis is given in Table 27.59.

Age Group

Rheumatoid arthritis is potentially crippling disease affecting more often women between 20 and 50 years of age. It occurs most often in HLA-DR4 positive individuals.

Hallmark of Rheumatoid Arthritis

Subcutaneous nodules and rheumatoid factor (autoantibodies principally IgM or IgG or IgA) are hallmarks of rheumatoid disease. These autoantibodies are directed against the Fc fragment of IgG.

- Rheumatoid factor (RF) is demonstrated in the serum in 80% of classic rheumatoid arthritis patients. Rheumatoid factor is useful in diagnosis.
- Significant titers of RF may also be demonstrated in related collagen vascular diseases, such as systemic lupus erythematosus (SLE), scleroderma, and dermatomyositis.

Pathologic Changes in Rheumatoid Arthritis

Pathologic changes in rheumatoid arthritis are shown in Fig. 27.52A and B.

Table 27.59 Comparison of osteoarthritis and rheumatoid arthritis

Feature	Osteoarthritis	Rheumatoid Arthritis
Joints involvement	▪ Weight bearing joints (hips, knees) ▪ Proximal interphalangeal (PIP) joints ▪ Distal interphalangeal (DIP) joints	Metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints, feet, wrists, ankles, elbow, knees
Morning stiffness of joints	<30 minutes	>1 hour
Clinical features	Pain occurs with movement of joints, feels better after rest	Stiffness and pain in joints after inactivity
Physical examination	Heberden and Bouchard lymph nodes	Rheumatoid nodules, radial deviation of wrist and ulnar deviation

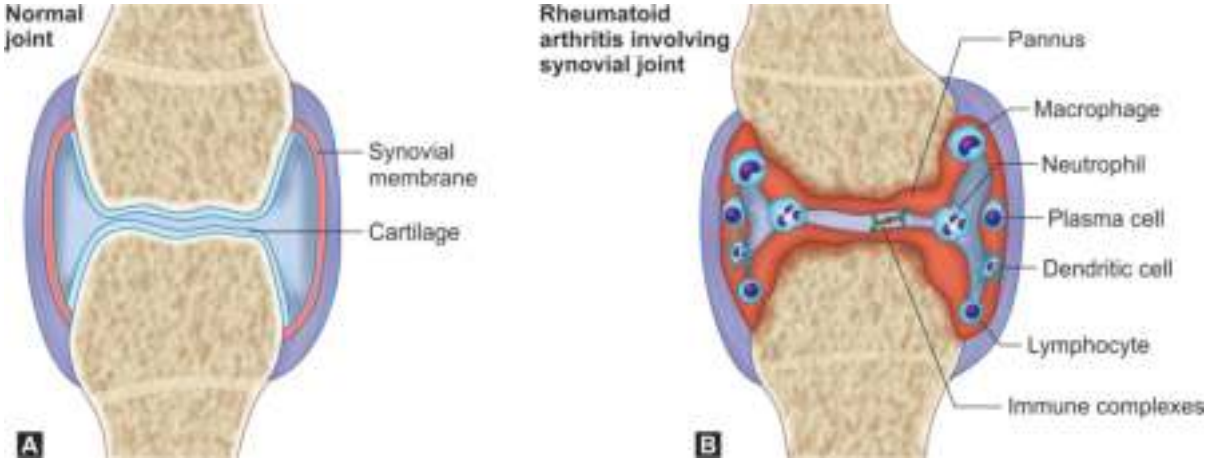

Fig. 27.52: Rheumatoid arthritis. (A) Normal synovial joint, (B) pathologic changes in rheumatoid arthritis.

- **Inflammatory stage:** Synovitis develops from congestion and edema of the synovial membrane and joint capsule. Initially, it shows acute inflammation followed by infiltration by lymphocytes and plasma cells. Synovial cells undergo hyperplasia and hypertrophy with formation of numerous villi and frond-like folds.
- **Formation of pannus (thickened layers of granulation tissue):** It covers and invades articular cartilage and subchondral bone, which eventually erodes and destroys the joint capsule and bone.
- **Fibrous ankylosis:** It occurs as a result of fibrous invasion of the pannus and scar formation that occludes the joint space. Bone atrophy and misalignment cause visible deformities and restrict movement, causing muscle atrophy, imbalance, and possibly partial dislocations.
- **Bony ankylosis:** Fibrous tissue calcifies, resulting in bony ankylosis (fixation of a joint) and total immobility. Pain associated with movement may restrict active joint use and resulting in fibrous or bony ankylosis, soft tissue contractures, and joint deformities. Subcutaneous nodules develop in approximately 33% of patients.

Clinical Features

- **Acute phase of disease:** Patient presents with fatigue, malaise, anorexia, weight loss, fever, and myalgia, bilateral symmetrical swelling and stiffness of joints especially in the morning or after inactivity.
- **Chronic phase of disease:** Patient develops flexion contracture of small joints of hands resembling curve of a swan-neck as a result of flexion of metacarpophalangeal joints and distal interphalangeal joints.
  - Boutonnière deformity occurs as a result of flexion of proximal interphalangeal joints with compensatory hyperextension of distal interphalangeal joints.
  - Patient develops ulnar deviation (drift) of fingers resulting from stretching of articular capsule and muscle imbalance. Minimal radial deviation of the wrist may occur. Rheumatoid nodules are formed in metacarpophalangeal joints and distal interphalangeal joints (Figs 27.53 and 27.54).

Extra-articular Manifestations

Extra-articular manifestations in rheumatoid arthritis include effusions (pleura, pericardium), vasculitis, and anemia of chronic disease, neurologic manifestations, lymphadenopathy and secondary reactive amyloidosis.

Association of Rheumatoid Arthritis

- **Sjögren syndrome:** Patient with Sjögren syndrome is associated with rheumatoid arthritis. Sjögren syndrome is a chronic inflammatory disease of the salivary (xerostomia) and lacrimal glands (keratoconjunctivitis sicca), which may be associated with a systemic collagen vascular disease. Malignant lymphoma is a frequent complication.

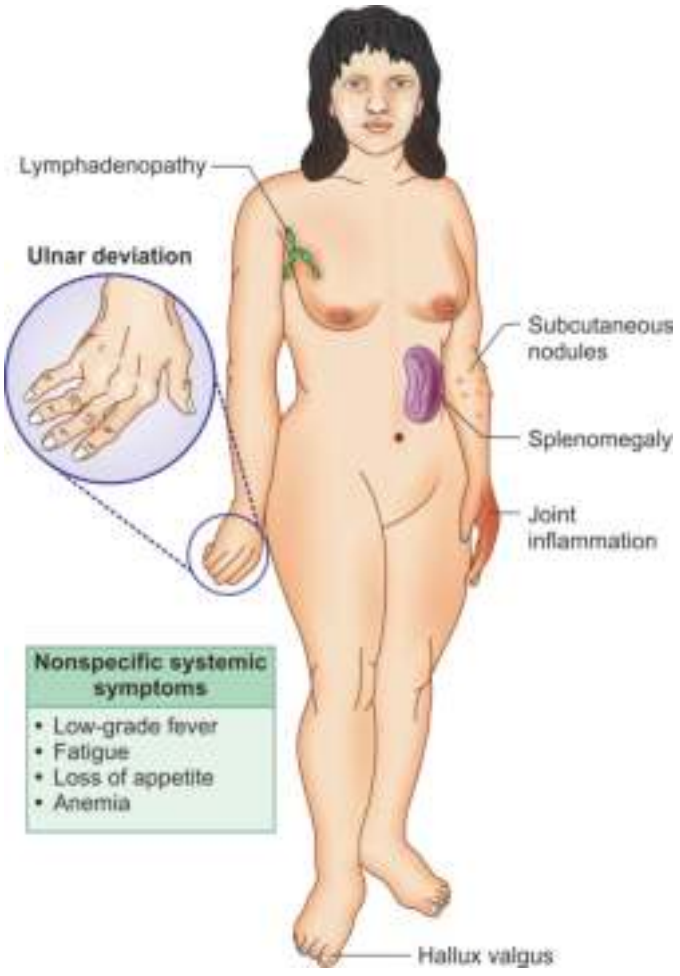

Fig. 27.53: Rheumatoid nodules over an interphalangeal joint of a patient with rheumatoid arthritis.

Fig. 27.54: Rheumatoid nodule (arrows).

- **Felty syndrome:** It is characterized by splenomegaly, neutropenia, and rheumatoid arthritis.
- **Still disease (juvenile rheumatoid arthritis):** Approximately 20% of children with juvenile arthritis (polyarticular) present with fever, rash, hepatosplenomegaly, lymphadenopathy, pleuritis, and anemia. Many children with juvenile arthritis develop ankylosing spondylitis, rheumatoid arthritis, psoriatic arthritis, and other connective tissue diseases.

Surgical Pathology: Rheumatoid Arthritis

Light Microscopy

- Histologic changes in rheumatoid arthritis occur due to destruction of the joint.
- Synovium undergoes hypertrophy and hyperplasia along with lymphocytes and plasma cells infiltration.
- Lymphoid follicles, acute fibrinous surface exudate, synovial giant cells may be seen.
- Destruction of cartilage and joint fusion (ankylosis) may occur due to formation of pannus.
- Pannus is composed of inflamed synovium and granulation tissue over the surface of overlying cartilage (Fig. 27.55).

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is probably autoimmune disorder with genetic component. It most often affects vertebral column and sacroiliac joints especially in young men. Bony fusion (ankylosis) causes rigidity and fixation of the spine (Fig. 27.56).

Etiopathogenesis

Ankylosing spondylitis occurs in various settings.

- **Genetic predisposition:** Almost all patients are positive for HLA-B27 antigen in 90% of cases.

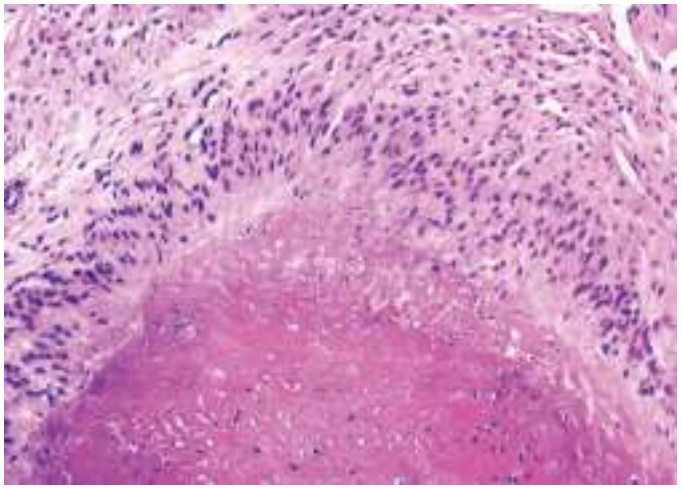

Fig. 27.55: Rheumatoid nodule. It is composed of lymphocytes, plasma cells, lymphoid follicles, acute fibrinous surface exudate, synovial giant cells may be seen (100X).

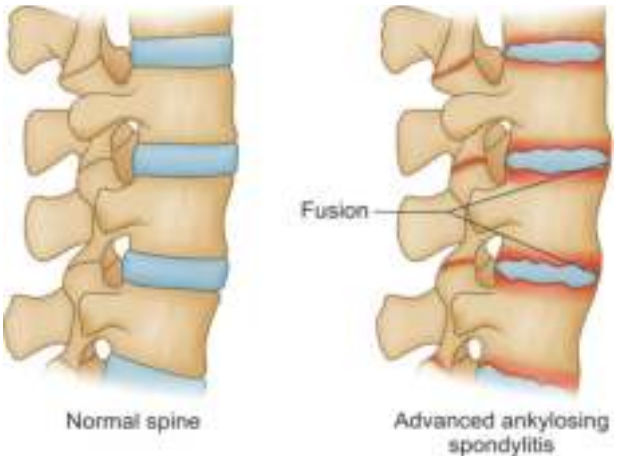

Fig. 27.56: Ankylosing spondylitis. It shows fusion of vertebrae.

- **Reiter syndrome:** It is triad that includes seronegative polyarthritis, conjunctivitis, and urethritis. It is often associated with venereal or bacillary dysentery in men. It is also associated with HLA-B27 antigen in up to 90% of patients.
- **Psoriatic arthritis:** It occurs in 10% of patients with psoriasis. Patient develops peripheral arthritis or ankylosing spondylitis complicating psoriasis.
- **Arthritis associated with inflammatory bowel disease:** Patient develops peripheral arthritis or ankylosing spondylitis complicating ulcerative colitis or Crohn's disease.

DEGENERATIVE DISEASE OF JOINTS

OSTEOARTHRITIS

Osteoarthritis is a slowly progressive destruction of the articular cartilage. Primary osteoarthritis is of unknown etiology and related to mechanical injury (wear-and-tear) and genetic predisposition. Secondary osteoarthritis occurs due to mechanical factors, ochronosis and inflammatory disorders.

Age Group

Osteoarthritis involves weight-bearing joints and interphalangeal joints especially in women more than 50 years of age.

Pathogenesis

Articular cartilage loses its elasticity resulting in fragmentation, which floats into synovial fluid. Floating cartilage erodes bone, which exhibits polished, ivory-like appearance (eburnation). It is accompanied by formation of new bone (osteocytes) subchondrally and at the margins of the affected joint.

Clinical Examination

Osteophytes (bony spurs) are formed at points of ligamental attachment to bone.

- Osteophytes formed at distal interphalangeal joints are known as Heberden nodes and Bouchard nodes at proximal interphalangeal joints.
- Osteophytes undergo fracturing and floating into synovial fluid known as joint mice.

Surgical Pathology: Osteoarthritis
Gross Morphology
▪ Gross examination reveals cartilaginous thinning, disruption of joints. ▪ There is complete loss of cartilage resulting in exposure of underlying bone exhibiting dense polished marble-like appearance.
Light Microscopy
▪ Histopathologic examination shows characteristic vertical clefts in the cartilage. ▪ There may be associated chronic inflammation of synovium and villus hyperplasia. ▪ Later findings should not be confused with rheumatoid arthritis.

ARTHRITIS OF METABOLIC ORIGIN

GOUTY ARTHRITIS

Gout is a metabolic disorder of disturbed purine metabolism, associated with elevated serum uric acid, which occurs primarily in men over 40 years of age.

- The deposition of monosodium urate crystals leads to formation of gouty tophi in metatarsophalangeal joint of the great toe (podagra), cartilage of helix and antihelix of the ear, and the Achilles tendon.
- Joint involvement is extremely painful in acute arthritis and bursitis.

Pathogenesis

When sodium urate crystals precipitate from supersaturated body fluids, which absorb fibronectin, complement, and other proteins on joint surfaces and initiate intense inflammatory reaction with opsonization of crystals by IgG.

- Neutrophils phagocytose urate crystals resulting in release of proteolytic lysosomal enzymes and oxygen-derived free radicals, which mediate tissue injury and promote an inflammatory response. It eventually leads to formation of nodular gouty tophi in the joints.
- Gouty tophus is an extracellular soft tissue deposit of urate crystals surrounded by fibrous connective tissue, foreign body giant cells and mononuclear cells.

Variants of Gout

- **Primary gout:** Primary gout is most common type of gout (85%) and is characterized by hyperuricemia without evident cause affecting middle-aged men.
- **Secondary gout:** Secondary gout is much less common and is characterized by hyperuricemia with evident cause, such as multiple myeloma, leukemia, myeloproliferative syndromes and chronic renal disease.
  - Patient with chronic renal disease has decreased urate excretion.
  - **Lesch-Nyhan syndrome** is an X-linked disorder due to deficiency of hypoxanthine-guanine phosphoribosyl transferase which produces hyperuricemia with severe neurological manifestations.

Clinical Features

Gouty arthritis is characterized by severe pain, redness and tenderness in joints often big toe. Severe attack of pain can occur suddenly often at night. During an acute attack, anti-inflammatory medication (NSAIDs) can help to reduce pain and shorten the duration of attack.

Patient presents with features due to acute gout arthritis and urate nephropathy described as under:

- **Acute gouty arthritis:** Acute gout usually involves first metatarsophalangeal joint. Clinical examination reveals redness, swelling, heat and extreme tenderness. In this characteristic location is known as podagra. A large meal or alcohol intake may increase hyperuricemia, often precipitates an exacerbation of the disorder.
- **Urate nephropathy:** Gout often leads to urate nephropathy characterized by interstitial deposition of urate crystals and obstruction of collecting tubules due to deposition of urate crystals and formation of urate and calcium stones.

Handling Fresh Specimen of Gouty Arthritis

In suspected cases of gout, fresh specimen should be handled carefully. Because sodium urate crystals are soluble in water component of 10% formalin preparation. Therefore preservation of sodium urate crystals is done by preparing touch preparation fixed in 100% alcohol.

Surgical Pathology: Gouty Arthritis
Light Microscopy
▪ Chronic accumulation of uric acid crystals leads to the formation of nodules (gouty tophi) in joint that contain granuloma-like aggregates of macrophages. ▪ Gouty tophus is composed of multiple irregular foci of amorphous pink stained material surrounded by foreign body giant cells reaction (Fig. 27.57). ▪ Gouty tophi may show secondary calcification and ossification. Gouty tophi may be demonstrated by De Galantha (silver impregnation) stain.

Laboratory Diagnosis

The diagnosis of gout is based on the finding of hyperuricemia along with urate crystals and neutrophils in synovial fluid or with biopsy evidence of tophaceous deposits. Urate crystals are needle-shaped and negatively birefringent under polarized light.

Autopsy Findings

During postmortem examination in suspected case of gout, one should expect gouty tophi, nephrolithiasis, white chalky paste-like material in synovium and joint deformity in long-standing gout.

CHONDROCALCINOSIS (PSEUDOGOUT)

Chondrocalcinosis (pseudogout) occurs due to deposition of calcium pyrophosphate dihydrate crystals in the synovial membranes (pseudogout), joint cartilage, ligaments, and tendon; which elicits an inflammatory reaction in cartilage.

- Under polarized light, these rhomboid-shaped crystals are positively birefringent.
- Pseudogout clinically resembles gout. It refers to self-limited attacks of acute arthritis lasting from 1 day to 4 weeks and involving one or two joints. It most often affects older than 85 years.

Clinical Features

Patient presents with acute onset of gout-like symptoms, manifesting as inflammation and swelling of knees, ankles, wrists, elbows, hips, or shoulders.

OCHRONOSIS OF JOINTS

Ochronosis is deposition of polymerized homogentisic acid, a black pigment, which is the product of incomplete degradation of tyrosine and phenylalanine occurring due to inborn defect of enzyme homogentisic acid oxidase.

Ochronosis may result in black discoloration of the tracheal rings, nephrolithiasis and vertebral ankylosis on postmortem examination.

Joints Involved

Homogentisic acid is deposited in articular cartilage of vertebral column and later hips, knees and shoulder joints.

Cartilage of nose and ears is also affected. Larger joints may be distended by noninflammatory effusions and hypertrophy of synovium.

Surgical Pathology: Ochronosis of Joints

Light Microscopy

Biopsy from tissue involved in ochronosis shows granular pigment in chondrocytes and matrix is diffusely stained. Synovium shows evidence of acute or chronic inflammation (Fig. 27.58).

INFECTIVE ARTHRITIS

Infective arthritis is characterized by purulent synovial fluid.

GONOCOCCAL ARTHRITIS

Gonococcal arthritis is caused by *Neisseria gonorrhoeae*. It is the most common form of bacterial arthritis (monoarticular). It most often involves knee joint. Other joints such as wrist and small joints of the hand may also be affected.

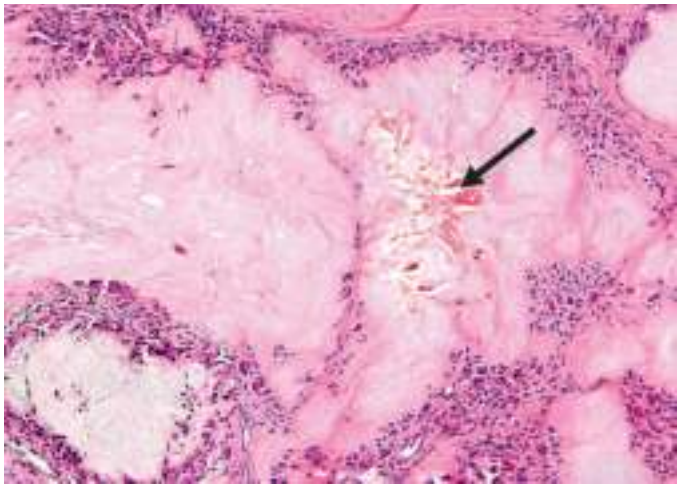

Fig. 27.57: Gouty tophus. It shows multiple irregular foci of amorphous pink stained material of surrounded foreign body giant cells reaction (arrow) (100X).

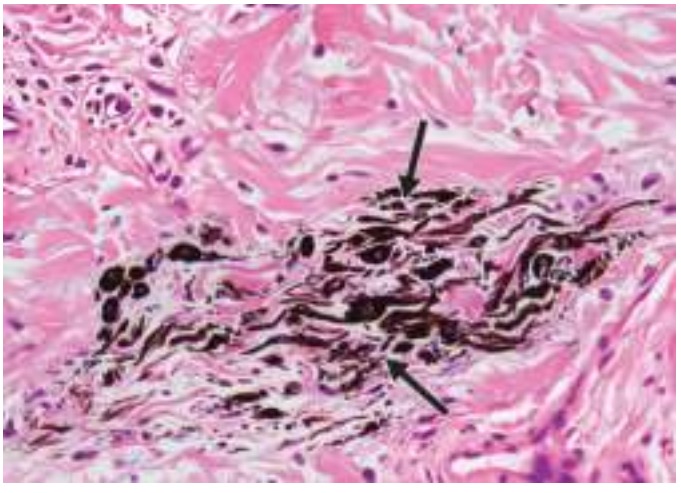

Fig. 27.58: Ochronosis. It occurs due to excessive deposition of homogentisic acid in connective tissues, cartilage and sclera. Histologic examination shows yellow-brown deposits in the cartilage (arrows).

LYME ARTHRITIS

Spirochete *Borrelia burgdorferi* transmitted by a tick causes Lyme disease. Lyme arthritis occurs when *Borrelia burgdorferi* enters joint tissue and induces inflammation. If Lyme arthritis left untreated permanent damage to the joint can occur.

Clinical Features

Patient presents with erythema chronicum migrans with central fading (bull's eye lesion), polyarticular arthritis involving larger joints (especially knee joints). It can also lead to myocardial, pericardial, or neurologic changes as late sequelae.

Laboratory Diagnosis

Lyme disease is diagnosed by demonstration of IgM serum antibodies to *Borrelia burgdorferi.*

Treatment

Response to early treatment with antibiotics is good.

TUBERCULAR ARTHRITIS

Tubercular arthritis is caused by the bacteria, *Mycobacterium tuberculosis*. Hip joint is most often involved in tuberculosis. There is fullness of groin and lower buttocks with loss of gluteal fold on affected side, flexion of hip or thigh and pain on pressure.

MISCELLANEOUS DISORDERS OF JOINTS

HYPERTROPHIC OSTEOARTHROPATHY

Hypertrophic osteoarthropathy is associated with systemic diseases such as chronic lung interstitial disease, congenital cyanotic heart disease, cirrhosis of liver, and inflammatory bowel disease.

- Patient develops clubbing of the fingers (most frequent), inflammation of distal end of the radius and ulna.
- Patient presents with painful swelling and tenderness of the peripheral joints.

GANGLION CYST

Ganglion cyst is small cystic and painless nodule arising in the tendon sheath or the joint capsule of wrist, which is thought to be caused by myxoid degeneration of connective tissue.

TIBIAL PSEUDOARTHROSIS

If a tibial fracture site does not heal, the condition is termed nonunion. Pseudoarthrosis occurs due to interposition of soft tissues at the fracture site, excessive motion, infection, and poor blood supply. Continued movement at the unhealed fracture may produce pseudoarthrosis. The joint-like material must be surgically excised for the fracture to heal properly.

Bone Specimen Handling in Surgical Pathology

Bone biopsies may be done to evaluate bone pain or tenderness, investigate an abnormality on radiographs, nature of bone tumor and find the cause of an unexplained inflammation. Magnetic resonance imaging is the gold standard for detailed evaluation of bone tumors and tumor-like lesions. Bone specimen requirements should be standardized and reported on every specimen. There are three main areas of grossing technology (i.e. tissue fixation, tissue sampling and embedding orientation for optimal microtomy), which can be beneficial to standardization of digital microscopic images of hematoxylin and eosin-stained tissue sections. Gross technology contributes to microslide images standardization.

- **Bone specimen collection and handling:** Patient's identity such as full name, age, sex, and identification number must be verified at the time of specimen collection. Specimen is labeled in the presence of the patient. All subsequent labeling of patient's blocks and slides must follow same patient-specific identifying process.
  - Recommended tissue fixative is 10% neutral buffered formalin for a minimum of six hours. Volume of the fixative to tissue ratio must be included in the collection/handling and submission procedures, i.e. 10% neural buffered formalin volume should be 15–20 times the volume of the tissue specimen.
  - Specimen must be placed in leak proof container properly labeled and transported to the laboratory immediately after collection. Containers should be rigid, impermeable, unbreakable, and non-reactive to fixative solutions.
  - All unfixed specimens should be placed in a sterile saline soaked sponge, transported to the pathology laboratory as soon as possible and refrigerated until placed into appropriate fixative. Written request for patient testing to include clinical history and all relevant investigations carried out.
- **Standard laboratory processing technique:** The use of surgical instruments should be avoided to prevent crushing or damaging the soft tissue attached to bone specimen. Adequate neutral buffered formalin fixative should be added to the specimen container as soon as possible. If insufficient tissue fixative is present when the specimen is received in the laboratory additional fixative should be added.
  - Pathologist determines correct orientation of bone specimen, immobilization, and appropriate cutting instrument. From grossing point of view, there are two types of bones: (a) compact bones (e.g. shaft of long bones, femoral head, and flat bones of skull), and (b) cancellous, trabecular, or spongy bones (e.g. vertebrae, ribs and epiphysis of long bones posing a challenge in the grossing room). Bone resections are performed for both benign and malignant tumors. Pathologist should review the results of prior biopsy along with the patient's clinical history and radiologic findings.

- Bone consists of osteocytes surrounded by a calcified matrix containing type 1 collagen fibers. In the calcified matrix, calcium is present in the form of hydroxyapatite crystals (i.e. calcium phosphate) deposited between the fibrous elements. Therefore, it is impossible to prepare in sections from 10% buffered neutral formalin-fixed paraffin-embedded tissue by standard microtomy without proper prior decalcification of the tissue containing bone, teeth, or calcifications.
- Decalcification technique removes minerals from the bone, so that good quality paraffin sections can be prepared that preserve all the essential microscopic elements. Decalcification is carried out by immersing the tissue in decalcification fluids (e.g. inorganic and organic acids, neutral fluid containing EDTA, and Bouin's fluid) after the surgical specimen has been thoroughly fixed and prior to routine processing to prepare paraffin block. Monitor the specimen frequently decalcification is detrimental to histologic quality.
- Scant bony fragments can be frozen fresh without decalcification and cut with cryostat. All heme bone core biopsies should be decalcified in ethylenediaminetetraacetic acid (EDTA), as the need for molecular genetic testing cannot always be predicted. Strong hydrochloric acid quickly decalcifies bone, but destroys nucleic acids. Formic acid slowly decalcifies bone, but also destroys nucleic acids. Chelating agent such as EDTA is the slowest, but also best at preserving nucleic acids.
- Cutting unform thin tissue sections 3–5 µm, with minimal artifacts is one of the most important steps in diagnostic pathology. Tissue sample should be submitted for light microscopy (histologic type, grade of bone tumor and adequacy of tumor margins), electron microscopy, cytogenetics, and flow cytometry.

Soft Tissue Tumors and Skeletal Muscle Non-Neoplastic Disorders

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

SOFT TISSUE TUMORS

- Soft tissue tumors: overview
  - Clinical history
  - Histopathologic examination
  - Immunohistochemistry technique
- Adipocytic tumors
  - Lipoma
  - Hibernoma
  - Well-differentiated liposarcoma/atypical lipomatous tumor
  - Dedifferentiated liposarcoma
  - Myxoid liposarcoma
  - Pleomorphic liposarcoma
- Fibroblastic/myofibroblastic tumors and other lesions
  - Keloid
  - Fibromatosis colli
  - Nodular fasciitis
  - Superficial fibromatosis (Dupuytren's disease or contracture)
  - Infantile fibrosarcoma (congenital fibrosarcoma)
  - Dermatofibrosarcoma protuberans
  - Conventional adult fibrosarcoma and other histologic variants
  - Myxofibrosarcoma
- Fibrohistiocytic tumors
  - Benign fibrous histiocytoma
  - Tenosynovial giant cell tumor localized type
  - Juvenile xanthogranuloma
  - Xanthoma
  - Atypical fibroxanthoma
  - Plexiform fibrohistiocytic tumor
  - Angiomatoid fibrous histiocytoma
  - Soft tissue giant cell tumor with low malignant potential
  - Undifferentiated pleomorphic sarcoma
- Smooth muscle tumors
  - Soft tissue leiomyoma
  - Soft tissue leiomyosarcoma
- Skeletal muscle tumors
  - Rhabdomyoma
  - Embryonal rhabdomyosarcoma
  - Alveolar rhabdomyosarcoma
  - Pleomorphic rhabdomyosarcoma
  - Adult sclerosing rhabdomyosarcoma
- Gastrointestinal stromal tumors
  - Gastrointestinal stromal tumors (benign/low-grade and malignant)
- Vascular tumors of soft tissue
- Pericytic/perivascular tumors
  - Hemangiopericytoma, solitary fibrous tumor of soft tissue and related lesions
  - Myopericytoma family of tumors
  - Glomus tumor
  - Atypical and malignant glomus tumors
- Neural and perineural tumors and other lesions
  - Traumatic neuroma
  - Granular cell tumor
  - Neurofibroma, neurofibromatosis type 1 and malignant change in neurofibroma
  - Schwannoma and neurofibromatosis type 2
  - Psammomatous melanocytic schwannoma
  - Perineuroma (sclerosing, intraneural, soft tissue and reticular perineuromas)
  - Nerve sheath myxoma
  - Malignant peripheral nerve sheath tumor
- Miscellaneous soft tissue tumors of uncertain lineage
  - Myxoma (intramuscular myxoma and juxta-articular myxoma)
  - Synovial sarcoma
  - Epithelioid sarcoma
  - Alveolar soft part sarcoma
  - Clear cell sarcoma of soft tissue
- Chondro-osseous tumors and other lesions
  - Myositis ossificans
  - Fibro-osseous pseudotumor of digits
  - Extraskeletal osteosarcoma
  - Soft tissue chondroma
  - Extraskeletal myxoid chondrosarcoma
  - Extraskeletal mesenchymal chondrosarcoma

NON-NEOPLASTIC DISORDERS OF SKELETAL MUSCLE

- Skeletal muscle: structure
- Myopathies
  - Inherited myopathies
    - Muscular dystrophies (Duchenne, Becker, myotonic, facioscapulohumeral, limb–girdle, Emery-Dreifuss, and oculopharyngeal muscular dystrophies)
    - Congenital myopathy (nemaline, central core, centronuclear, myotubular, and hyaline body myopathies)
    - Mitochondrial myopathy
    - Metabolic myopathies
  - Acquired myopathies
    - Inflammatory myopathies
    - Endocrine myopathies
    - Toxic myopathies
    - Autoimmune myopathies
  - Miscellaneous non-neoplastic disorders of skeletal muscle
    - Skeletal muscle atrophy
    - Myasthenia gravis
    - Lambert-Eaton myasthenic syndrome
    - Myositis ossificans
    - Rhabdomyolysis
    - Skeletal muscle hypertrophy

SOFT TISSUE TUMORS

SOFT TISSUE TUMORS: OVERVIEW

Soft tissue tumors comprise a group of entities exhibiting mesenchymal differentiation, which arise in skin, subcutis or deep soft tissue and are located in the deep soft tissues in the subfascial regions of extremities, shoulder, pelvis, thorax and intracranial regions. Similar tumors can occur in the viscera. According to revised 2020 World Health Organization (WHO), soft tissue tumors are categorized into adipocytic, fibrohistiocytic/myofibroblastic, fibrohistiocytic, smooth muscle, skeletal muscle, vascular, pericytic/perivascular, neural/perineural, chondro-osseous, miscellaneous tumors of uncertain origin and metastatic soft tissue tumors. Revised 2020 WHO classification of soft tissue tumors is given in Table 28.1. Based on clinical behavior, soft tissue tumors can be benign, intermediate and malignant. Most common metastatic tumors to soft tissues are given in Table 28.2.

Table 28.1 Revised 2020 World Health Organization classification of soft tissue tumors

Adipocytic Tumors

- Benign tumors
  - Lipoma and lipomatosis
  - Lipoblastoma
  - Lipomatosis of nerve
  - Lipoblastoma/lipoblastomatosis
  - Angiolipoma
  - Myolipoma
  - Chondroid lipoma
  - Extrarenal angiomyolipoma
  - Extra-adrenal myelolipoma
  - Spindle cells/pleomorphic lipoma
  - Hibernoma
- Intermediate (locally aggressive and recurrence after surgical excision) tumors
  - Atypical lipomatous tumor/well-differentiated liposarcoma
- Malignant tumors
  - Well differentiated liposarcoma: lipoma-like, sclerosing, inflammatory
  - Dedifferentiated liposarcoma
  - Myxoid liposarcoma/round cell liposarcoma
  - Pleomorphic liposarcoma
  - Mixed type liposarcoma
  - Liposarcoma, not otherwise specified

Fibroblastic/Myofibroblastic Tumors

- Benign tumors
  - Nodular fasciitis
  - Proliferative fasciitis
  - Proliferative myositis
  - Myositis ossificans and fibro-osseous pseudotumor of digits
  - Fibro-osseous pseudotumor of digits
  - Ischemic fasciitis
  - Elastofibroma
  - Fibrous hamartoma of infancy
  - Myofibroma/myofibromatosis
  - Fibromatosis colli
  - Juvenile hyaline fibromatosis
  - Inclusion body fibromatosis
  - Fibroma of tendon sheath
  - Desmoplastic fibroblastoma
  - Mammary-type fibroblastoma
  - Calcifying aponeurotic fibroma
  - Angiomyoblastoma
  - Cellular angiofibroma
  - Nuchal-type fibroma
  - Calcifying fibrous tumor
  - Giant cell angiofibroma
  - EWSR1-SMAD3 positive fibroblastic tumor (merging)
- Intermediate (locally aggressive and recurrence after surgical excision) tumors
  - Superficial fibromatosis (palmar/plantar)
  - Desmoid-type fibromatosis
  - Lipofibromatosis
  - Giant cell fibroblastoma
- Intermediate (rarely metastasizing) tumors
  - Dermatofibrosarcoma protuberans
    - Fibrosarcomatous dermatofibrosarcoma protuberans
    - Pigmented dermatofibrosarcoma protuberans
  - Solitary fibrous tumor
    - Solitary fibrous malignant tumor
  - Inflammatory myofibroblastic tumor
  - Myxoinflammatory fibroblastic sarcoma
    - Atypical myxoinflammatory fibroblastic sarcoma
  - Infantile fibrosarcoma
- Malignant tumors
  - Adult fibrosarcoma
  - Myxofibrosarcoma
  - Low-grade fibromyxoid sarcoma/hyalinizing spindle cell tumor
  - Sclerosing epithelioid fibrosarcoma

Fibrohistiocytic Tumors

- Benign tumors
  - Tenosynovial giant cell tumor (giant cell tumor of tendon sheath)
    - Localized tenosynovial giant cell tumor
    - Diffuse tenosynovial giant cell tumor
    - Malignant tenosynovial giant cell tumor
  - Deep benign fibrous histiocytoma
  - Juvenile xanthogranuloma
  - Xanthogranuloma

Contd...

Contd...

Table 28.1 Revised 2020 World Health Organization classification of soft tissue tumors (*Contd...*)

- Intermediate (rarely metastasizing) tumors
  - Atypical fibroxanthoma
  - Plexiform fibrohistiocytic tumor
  - Angiomatoid (malignant) fibrous histiocytoma
  - Giant cell tumor of soft tissue
- Malignant tumors
  - Undifferentiated pleomorphic sarcoma
  - Undifferentiated pleomorphic sarcoma with giant cells
  - Undifferentiated pleomorphic sarcoma with prominent inflammation

Smooth Muscle Tumors

- Benign tumors
  - Leiomyoma
    - Genital leiomyoma
    - Pilar leiomyoma
    - Leiomyoma of deep soft tissue
    - Vascular leiomyoma (angioleiomyoma)
    - Leiomyoma of retroperitoneal region
- Malignant tumors
  - Leiomyosarcoma
    - Leiomyosarcoma of deep soft tissue
    - Cutaneous leiomyosarcoma
    - Vascular leiomyosarcoma
    - Leiomyosarcoma of peritoneum
    - Epstein-Barr-associated smooth muscle tumor

Skeletal Muscle Tumors

- Benign tumors
  - Adult rhabdomyoma
  - Fetal rhabdomyoma
  - Genital rhabdomyoma
- Malignant tumors
  - Embryonal rhabdomyosarcoma
    - Conventional embryonal rhabdomyosarcoma
    - Spindle cell rhabdomyosarcoma (pediatric group)
    - Botryoid rhabdomyosarcoma
    - Anaplastic rhabdomyosarcoma
  - Alveolar rhabdomyosarcoma including solid alveolar rhabdomyosarcoma
  - Pleomorphic rhabdomyosarcoma
  - Spindle cell/sclerosing rhabdomyosarcoma (adult)

Vascular Tumors

- Reactive vascular hyperplasia
  - Papillary endothelial hyperplasia
  - Pyogenic granuloma (lobular capillary hemangioma)
  - Bacillary angiomatosis
  - Glomeruloid hemangioma
- Benign tumors
  - Capillary hemangioma
  - Cavernous hemangioma
  - Hemangioma of subcutaneous/deep soft tissue
  - Angiomatosis
  - Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia)
  - Intramuscular hemangioma
  - Spindle cell hemangioma
  - Lymphangioma
- Intermediate (borderline) malignant tumors
  - Kaposiform hemangioendothelioma
  - Dabska-type (papillary intralymphatic angioendothelioma) and retiform hemangioendothelioma
  - Kaposi sarcoma
- Malignant tumors
  - Angiosarcoma
  - Epithelioid hemangioendothelioma

Pericytic/Perivascular Tumors

- Benign tumors
  - Hemangiopericytoma and related tumors
    - Giant cell angiofibroma
    - Lipomatous hemangiopericytoma
  - Glomus tumor
    - Solid glomus tumor
    - Extra-tumoral perivascular sheathing by neoplastic glomus cells
    - Glomangiomyoma
    - Multiple glomus tumors
    - Glomus tumor with marked hemangiopericytic vessels
    - Symplastic glomus tumor
    - Glomus tumor with epithelioid cells
    - Glomus tumor with oncocytes
    - Glomus tumor with extensive myxoid change
    - Vascular invasion in otherwise benign glomus tumor
    - Glomangiomatosis
  - Myopericytic family of tumors
    - Infantile myofibromatosis
    - Solitary myofibroma in infants and children
    - Myopericytoma
    - Glomangiopericytoma
- Intermediate tumors
  - Glomus tumor of uncertain malignant potential
  - Atypical glomus tumor
- Malignant tumors
  - Malignant glomus tumor/glomangiosarcoma

Chondro-osseous Tumors

- Benign tumors/lesions
  - Soft tissue chondroma
  - Myositis ossificans
  - Fibro-osseous pseudotumor of digits
- Malignant tumors
  - Primary soft tissue osteosarcoma
  - Mesenchymal chondrosarcoma

Contd...

Table 28.1 Revised 2020 World Health Organization classification of soft tissue tumors (*Contd...*)

Gastrointestinal Stromal Tumors

- Benign tumors
  - Benign gastrointestinal stromal tumor
- Intermediate (locally aggressive) tumors
  - Gastrointestinal stromal tumor of uncertain malignant potential
- Malignant tumors
  - Malignant gastrointestinal stromal tumor

Neural and Perineural Tumors/Lesions

- Benign tumors
  - Neuromuscular hamartoma (benign Triton tumor)
  - Neuromas
    - Traumatic neuroma
    - Morton neuroma
  - Granular cell tumor
  - Schwannoma
    - Conventional schwannoma
    - Cellular schwannoma
    - Plexiform schwannoma
    - Melanotic schwannoma
    - Microcytic/reticular schwannoma
    - Other schwannomas
  - Neurofibroma
    - Circumscribed neurofibroma
    - Plexiform neurofibroma
    - Other neurofibromas
  - Perineuroma
    - Intraneural perineuroma
    - Soft tissue perineuroma
    - Sclerosing perineuroma
    - Reticular perineuroma
  - Hybrid peripheral nerve sheath tumor
- Intermediate tumors
  - Nerve sheath myxoma
  - Atypical granular tumor
- Malignant tumors
  - Malignant peripheral nerve sheath tumor (MPNST)
    - Low-grade malignant peripheral nerve sheath tumor
    - High-grade malignant peripheral nerve sheath tumor
    - Epithelioid peripheral nerve sheath tumor
    - MPNST ex-schwannoma
    - Malignant peripheral nerve sheath tumor
  - Synovial sarcoma
  - Malignant granular cell tumor
  - Malignant perineuroma
- Benign to malignant tumors
  - Paraganglioma of head and neck region
- Intermediate to malignant tumors
  - Ependymoma of soft tissue

Tumors of Uncertain Differentiation or Uncertain Lineage

- Benign tumors
  - Acral fibromyxoma
  - Intramuscular myxoma including cellular variant
  - Juxta-articular myxoma
  - Deep aggressive angiomyxoma
  - Ectopic hamartomatous thymoma
- Intermediate (locally aggressive) malignant tumors
  - Hemosiderotic fibrolipomatous tumor
- Intermediate (rarely metastasizing) malignant tumors
  - Atypical fibroxanthoma
  - Angiomatoid fibrous histiocytoma
  - Ossifying fibromyxoid tumor malignant
  - Mixed tumor, not otherwise specified
  - Mixed tumor, not otherwise specified malignant
  - Myoepithelioma
  - Myoepithelial carcinoma
  - Phosphaturic mesenchymal tumor usually benign
  - Phosphaturic mesenchymal tumor usually malignant
  - Pleomorphic hyalinizing angiectatic tumor
  - Hemosiderotic fibrolipomatous tumor
- Malignant tumors
  - Synovial sarcoma
    - Synovial sarcoma, spindle cell variant
    - Synovial sarcoma, biphasic
  - Epithelioid sarcoma
  - Alveolar soft part sarcoma
  - Clear cell sarcoma of soft tissue
  - Extraskeletal myxoid chondrosarcoma
  - Extraskeletal Ewing sarcoma
  - Desmoplastic small round cell tumor
  - Extrarenal rhabdoid tumor
  - Neoplasms with perivascular epithelioid cell differentiation (PEComa)
    - PEComa not otherwise specified, benign
    - PEComa not otherwise specified, malignant
  - Intimal sarcoma

Undifferentiated/Unclassified Sarcomas

- Undifferentiated spindle cell sarcoma
- Undifferentiated pleomorphic sarcoma
- Undifferentiated round cell sarcoma
- Undifferentiated epithelioid sarcoma
- Undifferentiated sarcoma, not otherwise specified

Metastatic Tumors of Soft Tissue

- Metastases in adult males
  - Lung carcinoma
  - Malignant melanoma
  - Renal cell carcinoma
  - Colon carcinoma
- Metastases in adult females
  - Lung carcinoma
  - Malignant melanoma
  - Renal cell carcinoma
  - Colon carcinoma
  - Breast carcinoma

Trunk, thigh, muscles, iliopsoas, paraspinal muscles are sites of metastases.

Contd...

Table 28.2 Most common metastatic tumors to soft tissues

Age Group and Gender	Most Common Metastatic Tumors to Soft Tissues	Most Common Soft Tissue Sites
Adult males	▪ Lung carcinoma ▪ Melanoma ▪ Renal cell carcinoma ▪ Colorectal carcinoma	▪ Trunk muscle ▪ Thigh muscle ▪ Iliopsoas muscle ▪ Paraspinal muscles
Adult females	▪ Melanoma ▪ Breast carcinoma ▪ Lung carcinoma ▪ Renal cell carcinoma	▪ Trunk muscle ▪ Thigh muscle ▪ Iliopsoas muscle ▪ Paraspinal muscles
Children (males and females)	No data available	No data available

- **Benign soft tissue tumors:** These tumors are cured by surgical excision. More superficial tumor <5 cm size can be excised.
- **Intermediate soft tissue tumors:** These tumors are locally aggressive. These can recur after surgical excision and rarely metastasize.
- **Malignant soft tissue tumors:** These tumors most often metastasize. Deep seated soft tissue tumors tend to be malignant than located in the superficial region. Large size soft tissue tumors tend to be malignant. Rapidly growing soft tissue tumors with infiltrative margins are malignant in nature. Deep seated tumors most often grow to a large size. These tumors are diagnosed for optimal management by clinical history, physical examination, radiologic examination, fine needle aspiration cytology, histologic examination (minimum of three biopsy cores), immunohistochemistry, electron microscopy, cytogenetic study and molecular analysis. Common diagnostic genetic chromosomal abnormalities in selected soft tissue tumors are given in Table 28.3.

Table 28.3 Common diagnostic genetic chromosomal abnormalities in selected soft tissue tumors

Histologic Type	Chromosomal Abnormalities	Fusion Gene or other Genetic Alteration
Adipocytic tumors		
Well-differentiated liposarcoma	12q14-15 amplification	MDM2/CDK4 amplification
Dedifferentiated liposarcoma	12q14-15 amplification	MDM2/CDK4 amplification
Myxoid/round cell liposarcoma	▪ t(12;16)(13;11) ▪ t(12;22)(13;12)	▪ FUS-DD1T3 ▪ EWSR1-DD1T3
Pleomorphic liposarcoma	Complex changes	Complex changes
Fibroblastic/histiocytic tumors		
Nodular fasciitis	t(17;22)	UPP6-MYH9
Tenosynovial giant cell tumor (giant cell tumor of tendon sheath)	t(1;2) (q13;q37)	COL6A3-CSF1
Solitary fibrous tumor	12q13	NAB2-STAT6
Inflammatory myofibroblastic tumor	Alterations of chromosome 2	Multiple translocations involving ALK
Dermatofibrosarcoma protuberans	t(17;22)	COL1A1-PDGFB
Infantile fibrosarcoma	t(12;15)	ETV6-NTRK3
Low-grade fibromyxoid sarcoma	▪ t(7;16) (q33;p11) ▪ t(11;16)(q33;p11)	▪ FUS-CREB3L2 (most common) ▪ FUS-CREB3L1 (exceptional)
Myxoinflammatory fibroblastic sarcoma	▪ t(1;10) (p22;q24) ▪ t(2;6) (p31;q21.3)	TGFBR3-MGEA5
Skeletal muscle tumors		
Alveolar rhabdomyosarcoma	t(X;17)	ASPSCR1-TFE3
Spindle cell rhabdomyosarcoma	t(6;8)	SRF-NCOA2

Contd...

Table 28.3 Common diagnostic genetic chromosomal abnormalities in selected soft tissue tumors (*Contd...*)

Histologic Type	Chromosomal Abnormalities	Fusion Gene or other Genetic Alteration
Vascular tumors		
Epithelioid hemangioendothelioma	t(1;3) or t(X;11)	WWTR1-CAMTA1 or YAPT1-TFE3
Gastrointestinal stromal tumors		
Clear cell sarcoma (GIT)	t(2;22)(q33;q12)	EWSR1-CREB1
Chondro-osseous tumors		
Extraskeletal mesenchymal chondrosarcoma	t(8;8)	HEY1-NCOA2
Extraskeletal myxoid chondrosarcoma	t(9;22)(q22;12)	EWS-NR4A3 fusion transcript
Soft tissue tumors of uncertain differentiation		
Myoepithelioma of soft tissue	Chromosome 22 translocations	Multiple chromosomal translocations involving EWSR1
Ossifying fibromyxoid tumor	t(6;12)	EP400-PHF1
Alveolar soft part sarcoma	t(X;17)	ASPSCR1-TFE3
Clear cell sarcoma of soft tissue	▪ t(12;22)(q13;q12) ▪ t(2;22)(q34;q12)	▪ EWSR1-ATF1 fusion transcript ▪ EWSR1-CREB1
Ewing's sarcoma/PNET	▪ t(11;22)(q24;q12) ▪ t(21;22)(q22;q12) ▪ t(7;22)(q22;q12) ▪ t(17;22)(q12;q12) ▪ t(2;22)(q33;q12) ▪ t(16;21)(p11;q22) ▪ t(2;16)(q35;p11)	▪ EWSR1-Flt-1 ▪ EWSR1-ERG ▪ EWSR1-ETV1 ▪ EWSR1-ETV4 ▪ EWSR1-FEV ▪ FUS-ERG ▪ FUS-FEV
Desmoplastic small round cell tumor	t(11;22)(p13;q12)	EWSR1-WT1 fusion transcript
Epithelioid sarcoma	Deletion 22q	Inactivation of SMARCB1
Extrarenal rhabdoid tumor	Deletion 22q	SMARCB1/INT1 mutation
Synovial sarcoma	▪ t(X;18)(p11,q11) ▪ t(X;20)(p11,q11)	▪ SSI8-SSX1 ▪ SSI8-SSX2
Extraskeletal myxoid chondrosarcoma	Chromosome 9 translocation	Multiple chromosomal translocations involving NR4A3
Angiomatoid fibrous histiocytoma	▪ t(12;22)(q11,q25) ▪ t(12;16)(q13,q11) ▪ t(2;22)(q33,q12)	▪ EWSR1-ATF1 ▪ FUS-ATF1 ▪ FUS-CRAB1
Myoepithelioma of soft tissue	▪ t(6;22)(p22;q12) ▪ t(19;22)(q13;q12)	▪ EWSR1-POU5F1 ▪ EWSR1-ZNF444

CLINICAL HISTORY

Before interpretation of the biopsy, attention should be given to the age of the patient, size, duration, location of soft tissue tumor including anatomical plane (e.g. cutaneous, subcutaneous, fascial or deep seated). Most benign soft tissue tumors occur in the superficial region. Myxofibrosarcoma, leiomyosarcoma, myxoinflammatory fibroblastic sarcoma and epithelioid sarcoma are less frequently demonstrated in the superficial region. Conversely, soft tissue tumor located in the deep tissue beneath fascia is most likely to be sarcoma. Radiological studies can additionally suggest the composition of soft tissue tumor.

HISTOPATHOLOGIC EXAMINATION

In children, majority of soft tissue tumors are benign. Diagnostic spectrum of benign and malignant tumors is different. Benign soft tissue tumors have pushing margins and less cellularity with pale uniform nuclei, fine chromatin and few mitoses but not atypical; but absence of necrosis. Some benign cellular lesions composed of pleomorphic neoplastic cells and numerous mitoses may simulate sarcoma. Malignant soft tissue tumors have invasive border, more cellularity with pleomorphic hyperchromatic neoplastic cells, abnormal mitoses, vascular invasion, foci of metastases, and presence of necrosis.

- Some benign soft tissue tumors located in the superficial regions can simulate malignant tumors (e.g. cellular fibrous histiocytoma, cellular myxoma, spindle cell lipoma, pleomorphic lipoma, chondroid lipoma, solitary fibrous tumor, extraskeletal chondroma and pleomorphic hyalinizing angiectatic tumor). Conversely, benign soft tissue tumors located in deep region poses diagnostic challenge to distinguish from cellular schwannoma, inflammatory myofibroblastic tumor and fibromatosis.
- Some malignant soft tissue tumors can be under-diagnosed due to their resemblance to benign counterpart (e.g. atypical lipomatous tumor and leiomyosarcoma). Similarly, some malignant tumors with deceptively bland nuclei can also be under-diagnosed (e.g. fibromyxoid sarcoma and myxofibrosarcoma).
- Many soft tissue tumors exhibit different cytomorphologic patterns (e.g. spindle cell, epithelioid cell, small round cell or pleomorphic), which need to be characterized further. Features of tumor architecture, cytomorphology, tumor–stromal interface, immunohistochemical, genetic and electron microscopic analysis are essential in establishing diagnosis.

Table 28.4 French Federation of Comprehensive Cancer Center Grading System of soft tissue tumors

Criterion	Score
Tumor differentiation according to Table 28.1	
Well-differentiated tumor closely resembling normal adult mesenchymal tissue	
▪ Sarcoma closely resembling normal adult mesenchymal tissue	▪ Score 1
▪ Moderately differentiated tumor of well-defined certain histogenetic types	▪ Score 2
▪ Poorly differentiated (undifferentiated) tumors and undefined histogenetic type	▪ Score 3
Mitotic count	
▪ 0–9/10 per high power fields	▪ Score 1
▪ 10–19/10 per high power fields	▪ Score 2
▪ ≥20/10 per high power fields	▪ Score 3
Tumor necrosis on histologic examination	
▪ No necrosis	▪ Score 0
▪ ≤50% tumor necrosis	▪ Score 1
▪ >50% tumor necrosis	▪ Score 2
Grades on histologic examination	**Sum of the above scores**
▪ Grade 1	▪ Total score 2 or 3
▪ Grade 2	▪ Total score 4 or 5
▪ Grade 3	▪ Total score 6, 7 or 8

- French Federation of Comprehensive Cancer Center Grading System is based on tumor differentiation, mitotic count, tumor necrosis and histologic grade of soft tissue tumor (Tables 28.4 and 28.5). Grade 1 bone tumors have better prognosis than grade 3. Grade 2 bone tumors have intermediate prognosis. French Federation of Comprehensive Cancer Center Grading System is based on multivariable analysis of tumor differentiation, mitotic count, tumor necrosis and grade on histologic examination.

IMMUNOHISTOCHEMISTRY TECHNIQUE

Immunohistochemistry technique is an essential adjunct in diagnosing soft tissue tumors. Some tumors express

Table 28.5 French Federation of Comprehensive Cancer Center Grading System of soft tissue sarcomas

Grade	Malignant Soft Tissue Tumors (Histologic Type)
Grade 1 soft tissue sarcomas	▪ Well-differentiated liposarcoma ▪ Well-differentiated fibrosarcoma ▪ Well-differentiated malignant peripheral nerve sheath tumor ▪ Extraskeletal well-differentiated chondrosarcoma
Grade 2 soft tissue sarcomas	▪ Myxoid liposarcoma ▪ Conventional fibrosarcoma ▪ Conventional malignant peripheral nerve sheath tumor ▪ Well-differentiated malignant hemangiopericytoma ▪ Myxofibrosarcoma ▪ Malignant fibrous histiocytoma with storiform pattern ▪ Extraskeletal myxoid chondrosarcoma ▪ Conventional angiosarcoma
Grade 3 soft tissue sarcomas	▪ Round cell liposarcoma ▪ Pleomorphic liposarcoma ▪ Dedifferentiated liposarcoma ▪ Poorly differentiated liposarcoma ▪ Epithelioid malignant schwannoma ▪ Malignant Triton tumor ▪ Conventional malignant hemangiopericytoma ▪ Giant cell and inflammatory malignant fibrous histiocytoma ▪ Poorly differentiated epithelioid/pleomorphic leiomyosarcoma ▪ Synovial sarcoma ▪ Rhabdomyosarcoma ▪ Mesenchymal chondrosarcoma ▪ Poorly differentiated/epithelioid angiosarcoma ▪ Extraskeletal osteosarcoma ▪ Extraskeletal Ewing sarcoma/PNET ▪ Alveolar soft part sarcoma ▪ Malignant rhabdoid tumor ▪ Clear cell sarcoma of soft tissue ▪ Undifferentiated sarcoma of soft tissue

specific antigens. However, a panel of antibodies (e.g. first line and second line) is required according to the broad cell-lineage. Monoclonal antibodies are almost never 100% specific or sensitive in soft tissue tumors. Hence, overreliance of a single marker needs to be avoided. The initial panel of antibodies depends on the morphologic features of tumor. First and second line panel of markers is given in Table 28.6. Immunohistochemistry of soft tissue tumors is given in Table 28.7.

Table 28.6 First and second line panel of markers

Line of Marker Purpose	Panel of Markers		
First line panel of markers			
Diagnosis of spindle cell sarcoma and pleomorphic sarcoma	▪ Desmin ▪ Smooth muscle actin ▪ S-100 protein ▪ CD34	▪ Epithelial membrane antigen (EMA) ▪ CK (AE1/AE3) and (CAM 5.2)	▪ MDM2 (pleomorphic sarcoma in abdomen) ▪ CDK4 (pleomorphic sarcoma in abdomen)
Clear cell sarcoma and epithelioid sarcoma	▪ Epithelial membrane antigen (EMA) ▪ CD34	▪ CD30 ▪ CD31 ▪ Desmin	▪ S-100 protein ▪ IN1 (BAF47)
Small round cell tumors	▪ CD99 ▪ S-100 protein ▪ Desmin ▪ CD99 ▪ CD56 ▪ CD45	▪ TdT ▪ Fli-1 ▪ WT1 ▪ TLE1 ▪ Myogenin	▪ NB84a ▪ Synaptophysin ▪ Chromogranin ▪ Neuron-specific enolase (NSE) ▪ Neurofilament
Second line panel of markers			
Epithelial cell, endothelial cell, smooth muscle, skeletal muscle, melanocytic, neural and other type of differentiation	▪ CK (AE1/AE3) and (CAM 5.2) ▪ Carcinoembryonic antigen (CEA) ▪ Calretinin ▪ Thrombomodulin ▪ BerErp4 ▪ TLE1 (transducin-like enhancer of split 1) ▪ Glial fibrillary acidic protein (GFAP) ▪ CD56 ▪ Chromogranin	▪ Synaptophysin ▪ Myogenin ▪ Smooth muscle myosin ▪ h-caldesmon ▪ Calponin ▪ β-Catenin ▪ BCL-2 ▪ TFE3 ▪ HMB4 ▪ Melan-A	▪ Inhibin ▪ CD31 ▪ Flt-1 ▪ HHV8 ▪ CD45 ▪ CD117 ▪ CD21 ▪ CD23 ▪ CD35

Table 28.7 Immunohistochemistry of soft tissue tumors

Immunohistochemical Marker	Expression
Adipocytic tumors	
Lipoma, lipomatosis and angiolipoma	S-100 protein, presence of abnormalities in the chromosome region 12q13–15 containing MDM2 and CDK4 genes in lipoma and lipomatosis but absent in well-differentiated liposarcoma
Neural fibrolipoma	S-100 protein (staining nerve and fat cells), EMA (staining perineural cells)
Lipoblastoma	Presence of PLAG gene mutation on chromosome 8, but absence of DD1T3 gene mutation due to chromosomal translocation t(12;16)
Hibernoma	S-100 protein
Chondroid lipoma	S-100 protein, chromosomal translocation (11;16) (q13; p12-13)
Spindle cell and pleomorphic lipoma	CD34 (hematopoietic progenitor cell antigen)

Contd...

Table 28.7 Immunohistochemistry of soft tissue tumors (*Contd...*)

Immunohistochemical Marker	Expression
Well-differentiated liposarcoma	Amplification of MDM2, CDK4 present in the region on chromosome 12(12q–15) confirmed by FISH studies
Atypical lipomatous tumor	Amplification of MDM2, CDK4 present in the region on chromosome 12(12q–15) confirmed by FISH studies
Dedifferentiated liposarcoma	Amplification of MDM2, CDK4 present in the region on chromosome 12(12q–15) confirmed by fluorescence *in situ* hybridization (FISH) studies
Myxoid and round cell liposarcoma	Translocation involving the DDT gene on chromosome 12; and FUS gene on chromosome 22 confirmed by FISH studies, and alternate translocation involving the DDT gene on chromosome 12; and EWS gene on chromosome 22 in 10% confirmed by FISH studies
Pleomorphic type liposarcoma	S-100 protein (50%)
Fibroblastic and myofibroblastic tumors	
Nodular fasciitis	SMA (smooth muscle actin), calponin, CD68, chromosomal translocation involving USP6 gene product but caldesmon is negative in leiomyoma and positive in leiomyosarcoma
Proliferative myositis and proliferative fasciitis	Vimentin, SMA (smooth muscle actin), MSA (muscle-specific actin)
Ischemic fasciitis	Vimentin, CD34, CD68, SMA (smooth muscle actin)
Postoperative spindle cell nodule	Cytokeratin (+++), vimentin, SMA (smooth muscle actin), desmin (variable staining)
Elastofibroma	Vimentin, Verhoeff-Van Gieson elastic stain
Hypertrophic scar	α-Smooth muscle actin (70%)
Fibrous hamartoma of infancy	Vimentin (fibrous and immature areas), actin (trabecular component), desmin (trabecular component sometimes)
Gardner fibroma	Cyclin D1 (100%), β-catenin (64%), c-Myc
Nuchal fibroma	CD34, CD99, vimentin
Fibromatosis colli	Vimentin, SMA (smooth muscle actin)
Calcifying aponeurotic fibroma	MSA (muscle-specific actin) (50%), SMA (smooth muscle actin), vimentin, CD68, CD69, S-100 protein
Fibroma of tendon sheath	Vimentin, MSA (muscle-specific actin), SMA (smooth muscle actin), factor XIIIa, CD34
Superficial fibromatosis	Vimentin, MSA (muscle-specific actin) (variable staining), SMA (smooth muscle actin) (variable staining)
Deep fibromatosis	Vimentin, MSA (muscle-specific actin), β-catenin, desmin (rare case)
Inclusion body fibromatosis	Desmin, cytokeratins (CKs), calponin, CD99, α-SMA, vimentin, CD117 (occasional case)
Fibromatosis (myofibroblastic differentiation)	β-Catenin, SMA (smooth muscle actin)
Myofibroblastoma (mammary type)	Desmin, SMA (smooth muscle actin), CD34
Inflammatory myofibroblastic tumor (IMT)	ALK (anaplastic lymphoma kinase) protein (35%), SMA (smooth muscle actin) (80%), desmin (40%), vimentin, ALK gene rearrangement (detected by *in situ* hybridization in 50%), cytokeratin (+/–)
Myofibroma and myofibromatosis	Vimentin, SMA (smooth muscle actin), HHF35 pan-actin
Intranodal myofibroblastoma	Vimentin, SMA (smooth muscle actin)
Myofibroblastoma sarcoma	SMA (smooth muscle actin), MSA (muscle-specific actin), calponin
Reticulohistiocytoma	CD68, CD31 (variable staining), α_1-antitrypsin (variable staining)
Juvenile xanthogranuloma	Factor XIIIa, CD68, HAM56, CD4, Ki-MIP, vimentin

Contd...

Table 28.7 Immunohistochemistry of soft tissue tumors (*Contd...*)

Immunohistochemical Marker	Expression
Benign fibrous histiocytoma	Factor XIIIa, HMGA1, HMGA2
Angiomatoid fibrous histiocytoma	Desmin (50%), CD99 (50%), EMA (epithelial membrane antigen) (40%), CD68
Plexiform fibrohistiocytic tumor	Vimentin, SMA (smooth muscle actin), CD68
Superficial acral fibromyxoma	CD34 (hematopoietic progenitor cell antigen) (75%), EMA (epithelial membrane antigen) (50%), CD99
Superficial angiomyxoma	CD34 (hematopoietic progenitor cell antigen in most cases), cytokeratins (CKs in some cases), S-100 protein in some cases), desmin (rarely positivity), SMA (smooth muscle actin—rare positivity)
Dermatofibrosarcoma protuberans (DFSP)	CD34 (hematopoietic progenitor cell antigen (diffuse staining)
Desmoplastic small round cell tumor	WT1, CKs, EMA, desmin, NSE (neuron-specific enolase)
Giant cell fibroblastoma	CD34 (hematopoietic progenitor cell antigen), α_1-antitrypsin
Fibrosarcoma arising in dermatofibrosarcoma protuberans	CD34 (hematopoietic progenitor cell antigen), COL1A (PDGF-β gene fusion), MIB-1 labeling index, p53
Fibrosarcoma adult type	Vimentin, SMA (smooth muscle antigen)
Fibrosarcoma infantile type	Vimentin, SMA (smooth muscle antigen in rare case)
Fibrosarcoma sclerosing epithelioid type	Vimentin, SMA (smooth muscle antigen) (50%)
Fibromyxoid sarcoma low-grade	Vimentin, SMA (smooth muscle antigen—focal staining in occasional case)
Atypical fibroxanthoma	Vimentin
Intramuscular myxoma	Vimentin, CD34 (hematopoietic progenitor cell antigen—variable staining), desmin (variable staining), SMA (smooth muscle actin—variable staining), mucoid matrix stains (Alcian blue, mucicarmine, colloidal iron)
Myxofibrosarcoma	Vimentin, SMA (smooth muscle actin—focal staining), MSA (muscle-specific actin—focal staining)
Fibrohistiocytic tumors	
Tenosynovial giant cell tumor	Desmin, CD68
Benign fibrous histiocytoma	CD68, factor XIIIa, HMGA1, HMGA2
Juvenile xanthogranuloma	CD68 (clones of KPI and PGM1), CD31, factor XIIIa, HAM56, HHF35, CD4, Ki-MIP, vimentin
Atypical xanthogranuloma	CD99 (+++75%), SMA (smooth muscle actin—focal staining)
Plexiform fibrohistiocytic tumor	Vimentin, SMA (smooth muscle actin), CD68
Angiomatous (malignant) fibrous histiocytoma	Desmin (50% cases), CD68 (50% cases), CD99 (50%), EMA (40%)
Soft tissue giant cell tumor with low malignant potential	CD68 (100% cases), SMA (smooth muscle actin) (75% cases)
Undifferentiated pleomorphic sarcoma	SMA (smooth muscle actin)
Smooth muscle tumors	
Angioleiomyoma	MSA (muscle-specific actin), desmin, heavy caldesmon (h-caldesmon)
Pilar leiomyoma	MSA (muscle-specific actin), desmin, heavy caldesmon (h-caldesmon)
Leiomyoma deep soft tissue	MSA (muscle-specific actin), desmin, heavy caldesmon (h-caldesmon), ER (retroperitoneal leiomyoma)
Leiomyosarcoma soft tissue	MSA (muscle-specific actin), desmin, heavy caldesmon (h-caldesmon), CAM 5.2 (aberrant reactivity in leiomyosarcoma)
Vascular leiomyosarcoma	MSA (muscle-specific actin), desmin, heavy caldesmon (h-caldesmon—more specific marker)
Epstein-Barr virus-associated smooth muscle cell tumor	MSA (muscle-specific actin), desmin, heavy caldesmon (h-caldesmon), CD3 (stains T cells), EBA-DNA (demonstrated by *in situ* hybridization)

Contd...

Table 28.7 Immunohistochemistry of soft tissue tumors (*Contd...*)

Immunohistochemical Marker	Expression
Skeletal muscle tumors	
Rhabdomyoma adult type	MSA (muscle-specific actin), desmin, myoglobin, PTAH, SMA (smooth muscle actin—rare/focal staining), S-100 protein (rare/focal staining)
Rhabdomyoma fetal type	MSA (muscle-specific actin), desmin, myoglobin, PTAH, SMA (smooth muscle actin—rare/focal staining), S-100 protein (rare/focal staining)
Genital rhabdomyoma	MSA (muscle-specific actin), desmin, myoglobin
Alveolar rhabdomyosarcoma	MSA (muscle-specific actin), desmin (patchy cytoplasmic staining), myogenin, MyoD1 (focal nuclear staining pattern) in embryonal rhabdomyosarcoma) and (diffuse staining pattern) in alveolar rhabdomyosarcoma), PAX5, PAX3-FKHR, PAX7-FKHR
Embryonal rhabdomyosarcoma	MSA (muscle-specific actin), desmin (patchy cytoplasmic staining), vimentin (patchy cytoplasmic staining), myogenin (focal nuclear staining pattern) in embryonal rhabdomyosarcoma), MyoD1 (focal nuclear staining pattern) in embryonal rhabdomyosarcoma, cytokeratins (focal staining), S-100 protein (focal staining), CD99 (15%)
Pleomorphic rhabdomyosarcoma	Myoglobin, MyoD1, myogenin, desmin, MSA (muscle-specific actin—variable staining), SMA (smooth muscle actin—variable staining), sarcomeres (Z-bands by electron microscopy)
Gastrointestinal stromal tumors (GISTs)	
Gastrointestinal stromal tumors	c-KIT (95% diffuse staining), CD34 (75%), DOG1, BCL-2, mitotic index—high
Vascular tumors of soft tissue	
Lymphangioma	D2–40 (podoplanin)
Cavernous hemangioma	CD31, CD34, Flt-1, vWF
Spindle cell hemangioma	CD31, CD34 (hematopoietic progenitor cell antigen), desmin, MSA (smooth muscle actin)
Deeply located hemangioma including angiomatosis	CD31, CD34 (hematopoietic progenitor cell antigen), Fli-1, von Willebrand factor (vWF)
Pyogenic granuloma	CD31, CD34 (hematopoietic progenitor cell antigen), Fli-1
Arteriovenous malformation	CD31, CD34 (hematopoietic progenitor cell antigen)
Kaposiform hemangioendothelioma	CD31, CD34 (hematopoietic progenitor cell antigen), Fli-1, von Willebrand factor (vWF)
Dabska-type papillary intralymphatic angioendothelioma and retiform hemangioendothelioma	CD31, CD34 (hematopoietic progenitor cell antigen), VEGFR3, D2–40 (podoplanin)
Kaposi sarcoma	CD31 (PECAM1), CD34 (hematopoietic progenitor cell antigen in 40%), D2–40 (podoplanin), factor VIII-related antigen (demonstrated by immunoperoxidase method). Ulex europaeus 1, Flt-1, Flt-4, VEGFR3 (vascular endothelial growth factor receptor 3), CD141 (thrombomodulin in some cases), HHV8 LANA protein (most sensitive marker)
Epithelioid hemangioendothelioma	CD31, CD34 (hematopoietic progenitor cell antigen), Flt-1, von Willebrand factor (vWF), cytokeratins (low-molecular weight: 25%)
Angiosarcoma	CD31 (PECAM1), CD34 (hematopoietic progenitor cell antigen), D2–40 (some cases), Flt-1, Flt4, CD141 (thrombomodulin), von Willebrand factor (vWF), factor VIII-related antigen (demonstrated by immunoperoxidase method), Ulex europaeus 1 (positive in some cases), VEGFR3 (positive in some cases), cytokeratins (low-molecular weight: 25%)
Pericytic/perivascular tumors	
Glomus tumor	SMA (smooth muscle actin), MSA (muscle-specific actin), calponin, caldesmon, pericellular type 4 collagen, desmin (positive in some cases)
Glomuvenous malformation	Vimentin, pericellular type 4 collagen, SMA (smooth muscle actin), laminin, type 4 collagen

Contd...

Table 28.7 Immunohistochemistry of soft tissue tumors (*Contd...*)

Immunohistochemical Marker	Expression
Myopericytoma	SMA (smooth muscle actin), CD34 (hematopoietic progenitor cell antigen), heavy caldesmon (h-caldesmon)
Hemangiopericytoma	CD34 (hematopoietic progenitor cell antigen), BCL-2
Atypical or malignant glomus tumor	SMA (smooth muscle actin), collagen IV (pericellular staining)
Nerve and nerve sheath tumors	
Traumatic neuroma	S-100 protein (stains Schwann cell), neurofilament (stains axons), EMA (epithelial membrane antigen) (stains perineural cells)
Schwannoma, cellular type	S-100 protein (++++), GFAP (glial fibrillary acidic protein—variable staining), Leu7 (CD57) (variable staining), laminin (pericellular staining), collagen IV (pericellular staining)
Schwannoma, ancient type	S-100 protein, GFAP (glial fibrillary acidic protein—variable staining), Leu7 (CD57) (variable staining)
Ganglioneuroma	Synaptophysin (ganglion cells), neurofilament (ganglion cells), tubulin (ganglion cells), NSE (neuron-specific enolase—ganglion cell marker), S-100 protein (ganglion cells), GFAP (glial fibrillary acidic protein—Schwann cell marker)
Neurothekeoma	NKIC3 (also positive in cellular neurothekeoma), S-100 protein (positive except in cellular neurothekeoma), PGP9.5, MITF (microphthalmia-asspcoated transcription factor), SMA (smooth muscle actin)
Cellular schwannoma	S-100 protein (++++), GFAP (glial fibrillary acidic protein—variable), Leu7 (CD57)
Neurofibroma	S-100 protein (staining less diffuse than in schwannoma), Leu7 (CD57), CD34 (hematopoietic progenitor cell antigen—variable staining), factor X111-related antigen (variable staining)
Plexiform neurofibroma	S-100 protein (staining less diffuse than in schwannoma), Leu7 (CD57), CD34 (hematopoietic progenitor cell antigen—variable staining), factor X111-related antigen (variable staining)
Perineuroma	EMA (epithelial membrane antigen), S-100 protein, GLUT1 (glucose transporter protein isoform 1), claudin, laminin (outlines the basal lamina around individual cells or small group of cells), type 4 collagen (outlines the basal lamina around individual cells or small group of cells)
Malignant peripheral nerve sheath tumor (MPNST)	S-100 protein (diffuse staining) in epithelioid variant of MPNST, Leu7 (CD57 in 30–40%)
Malignant triton tumor	S-100 protein (diffuse staining in 50%), Leu7 (CD57 in 30–40%), cytokeratins (CKs), desmin
Granular cell tumor (benign)	CD68 (++++ strong staining), S-100 protein, SMA (smooth muscle actin), inhibin, NSE (neuron-specific enolase), laminin, myelin P0, myelin P2PAS-D (cytoplasmic granules), mitotic index—low
Granular cell tumor (malignant)	S-100 protein, neuron-specific enolase (NSE), vimentin, PAS-D (cytoplasmic granules)
Neuroglial heterotopia	S-100 protein (stains glial tissue), GFAP (glial fibrillary acidic protein—stains glial tissue), synaptophysin, chromogranin, NSE (neuron-specific enolase), neurofilamaent, N-Myc amplification (FISH analysis), chromosome 1p deletion (cytogenetic analysis)
Esthesioneuroblastoma	Synaptophysin, chromogranin, NSE (neuron-specific enolase), neurofilament, S-100 protein (staining at periphery of tumor, CD56)
Paraganglioma	Synaptophysin (chief cells), chromogranin (chief cells), NSE (neuron-specific enolase—chief cells), neurofilament, peptide hormones (calcitonin, somatostatin in chief cells), S-100 protein (sustentacular cells), GFAP (glial fibrillary acidic protein in sustentacular cells)
Melanocytic neuroectodermal tumor of infancy	Cytokeratins (CKs), HMB-45, NSE (neuron-specific enolase), synaptophysin

Immunohistochemical Marker	Expression
Tumors of uncertain differentiation	
Synovial sarcoma (SS)	TLE1 (novel immunohistochemical marker for synovial sarcoma), BCL-2, calponin, S-100 protein (30%), cytokeratins (CKs—focal staining), EMA (epithelial membrane antigen—focal staining)
Epithelioid sarcoma	Cytokeratins (50% strong staining), EMA (epithelial membrane antigen), CEA (carcinoembryonic antigen—focal staining), vimentin
Alveolar soft part sarcoma	TFE3 (nuclear staining), desmin (50% focal staining), SMA (smooth muscle actin in 10%), S-100 protein, PAS/diastase resistant, rhomboid cytoplasmic crystals demonstrated by electron microscopy
PEComas (neoplasms with perivascular epithelioid cell differentiation)	SMA (smooth muscle actin), Melan-A (A103), MART-1 (melanoma-associated antigen recognized by T cells 1), HMB-45 (human melanoma black 45) marker of immature melanocytes, MITF (microphthalmia-associated transcription factor), c-KIT, cathepsin K, TFE3 (rearrangements or amplification in a subset), desmin (+/–), S-100 protein (+/–)
Ewing sarcoma/PNET extraskeletal origin	CD99, cytokeratin (CKs—focal staining in 20% cases), synaptophysin, chromogranin A, NSE (neuron-specific enolase), CD56 (neuronal cell adhesion molecule)
Chondro-osseous tumors	
Extraskeletal osteosarcoma	Osteocalcin (neoplastic cells and neoplastic matrix), vimentin (neoplastic cells and neoplastic matrix), SMA (smooth muscle actin—focal staining), desmin (focal staining), S-100 protein (focal staining)
Soft tissue chondrosarcoma	Vimentin, S-100 protein
Extraskeletal myxoid chondrosarcoma	Vimentin (diffuse staining pattern), S-100 protein (<50%), NSE (neuron-specific enolase), synaptophysin
Mesenchymal chondrosarcoma	Vimentin (small blue cells and chondrocytes components), CD99 (small blue cell component), S-100 protein (cartilaginous component)

Neural and perineural tumors are described in detail in Chapter 30; Nervous System.

First Line of Panel of Monoclonal Antibodies

First line of panel of monoclonal antibodies is used to diagnose spindle cell sarcoma and pleomorphic sarcoma. Immunohistochemical markers for soft tissue tumors include desmin, smooth muscle actin, broad spectrum cytokeratins (AE1/AE3 and CAM 6.2), S-100 protein and CD34.

- **Pleomorphic liposarcoma:** Immunohistochemical markers for pleomorphic liposarcoma located in abdomen are positive for MDM2 and CDK4.
- **Clear cell and epithelioid soft tissue tumors:** Immunohistochemical markers for clear cell and epithelioid soft tissue tumors are positive for EMA (epithelial membrane antigen), CD34, CD30, CD31, desmin, S-100 protein and INI (selected cases).
- **Round cell tumors:** Immunohistochemical markers for round cell tumors are positive for cytokeratins, CD99, S-100 protein, desmin, CD99, CD56, CD45 and TdT, FLI-1, WT1, TLE1, myogenin, NB84a, synaptophysin, chromogranin, neuron-specific enolase (NSE), neurofilament and other markers as indicated.

Second Line of Panel of Monoclonal Antibodies

Second line of panel of monoclonal antibodies is specific for epithelial cell, endothelial cell, smooth muscle, skeletal muscle, melanocytic, neural and other type of differentiation. Immunohistochemical markers include: CK (AE1/AE3) and (CAM 5.2), CEA (carcinoembryonic antigen), calretinin, thrombomodulin, BerErp4, TLE, GFAP (glial fibrillary acidic protein), CD56, chromogranin, synaptophysin, myogenin, smooth muscle myosin, h-caldesmon, calponin, β-catenin, BCL-2, TFE3, HMB4, Melan-A, inhibin, CD31, FLI-1, HHV8, CD45, CD117, CD21, CD23 and CD35.

ADIPOCYTIC TUMORS

Adipocytic tumors share variable features of lipomatous differentiation. These tumors represent the most common group of mesenchymal lesions. Besides most common lipoma tumor, adipocytic tumors range from benign, intermediate and malignant neoplasms (liposarcomas). Liposarcoma is the most common soft tissue sarcoma

Table 28.8 Adipocytic tumors according to revised 2020 WHO classification of soft tissue tumors

Adipocytic Tumors	
Benign tumors	
▪ Lipoma and lipomatosis	▪ Chondroid lipoma
▪ Lipoblastoma	▪ Extra-renal angiomyolipoma
▪ Lipomatosis of nerve	▪ Extra-adrenal myelolipoma
▪ Lipoblastoma/ lipoblastomatosis	▪ Spindle cells/pleomorphic lipoma
▪ Angiolipoma	▪ Hibernoma
▪ Myolipoma	
Intermediate (locally aggressive and recurrence after surgical excision) tumors	
Atypical lipomatous tumor/well-differentiated liposarcoma	
Malignant tumors	
▪ Dedifferentiated liposarcoma	
▪ Myxoid liposarcoma/round cell liposarcoma	
▪ Pleomorphic liposarcoma	
▪ Mixed type liposarcoma	
▪ Liposarcoma, not otherwise specified	

comprising 25% of all soft tissue sarcomas. According to revised 2020 WHO classification of soft tissue tumors, the adipocytic tumors are categorized into benign, intermediate (locally aggressive) and malignant neoplasms (Table 28.8).

LIPOMA

Lipoma is the most common benign mesenchymal tumor of mature adipocytes, which most often occurs during fifth to seventh decades of life without sex predominance. Most common sites of lipoma are superficial or subcutaneous lump in the region of shoulder, back, neck, abdomen and extremities. Infrequently, large well circumscribed lipoma may be present in the intramuscular compartment of arm, thigh or thorax.

Clinical Features and Management

Patient presents with painless, soft and mobile lump in the shoulder, back, neck, abdomen or extremities. Lipoma is treated by surgical excision.

Surgical Pathology: Lipoma

Gross Morphology

Lipoma shows yellow and translucent adipose tissue. Tumor is encapsulated. Gross morphology of lipoma is shown in Fig. 28.1.

Light Microscopy

- Lipoma is indistinguishable from normal adipose tissue. Tumor is composed of lobules of well-differentiated unremarkable adipocytes with inconspicuous eccentrically located nuclei. Adipocytes lack pleomorphism.
- Sometimes, focal areas of fat necrosis are demonstrated. Adipocytes do not show nuclear atypia.
- In occasional lipoma, there may be presence of areas of bone formation (osteolipoma), abundant fibrous tissue (fibrolipoma) or cartilage (chondrolipoma). Histology of lipoma is shown in Fig. 28.2.

Immunohistochemistry Technique

Lipoma shows positivity for S-100 protein.

Marker	Expression
S-100 protein	Positive

Fig. 28.1: Lipoma. Tumor is encapsulated, well circumscribed, mass of uniform, yellowish adipose tissue with mottled tan areas and a soft consistency. Cut surface shows white/yellow, translucent, homogeneous and lobulated appearance.

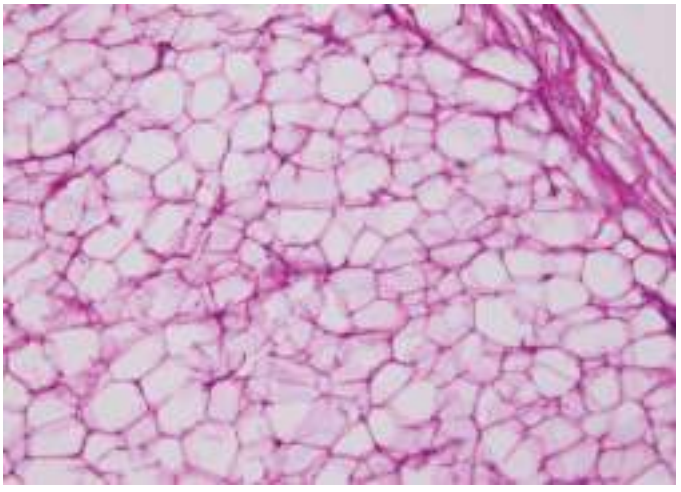

Fig. 28.2: Histology of lipoma. Tumor is indistinguishable from normal adipose tissue. It is composed of lobules of well-differentiated unremarkable adipocytes with inconspicuous eccentrically located nuclei. Adipocytes lack pleomorphism (400X).

Molecular Genetic Alterations

Conventional lipoma often shows rearrangement of HMG2 gene located on chromosome 12q13.15, 6p and 13q. Spindle cell lipoma and pleomorphic lipoma show rearrangement of 16q and 13q.

HIBERNOMA

Hibernoma is a rare benign adipocytic tumor, which arises from remnants of fetal brown adipose tissue. It is indistinguishable from malignant neoplasm taking into consideration of clinical history and radiologic findings, hence, it emphasizes its inclusion in the differential diagnosis. It usually affects young adults during third and fourth decades of life. However, cases have been reported in the age group of three months of age to fifty years. Hibernoma shows breakpoints in 11q12.21 with many chromosomal translocations.

Clinical Features

Patient presents with large painful lump in axilla, back, mediastinum, shoulder, thigh, head and neck regions; abdominal cavity, arm, breast and spermatic cord. Hibernoma is treated by surgical excision. It has no significant potential for recurrence after surgery.

Radiologic Findings

Hibernoma is indistinguishable from malignant neoplasm taking into consideration of clinical history and radiologic findings.

Surgical Pathology: Hibernoma

Gross Morphology

- Hibernoma is a lobulated well demarcated large tumor with tan-yellow to red brown in color.
- Cut surface is brown with spongy consistency. Gross morphology of hibernoma is shown in Fig. 28.3.

Light Microscopy

- Tumor is composed of large number of brown adipocytes with small centrally located nuclei and multivacuolated cytoplasm; and admixed with normal adipocytes.
- Areas of necrosis and mitoses are absent in the neoplasm. Histology of hibernoma is shown in Fig. 28.4.

Histochemistry

Oil red O and Sudan black demonstrate adipocytes in hibernoma.

Differential Diagnosis

Hibernoma should be differentiated from well-differentiated liposarcoma, conventional lipoma and residual brown fat around cervical and axillary lymph nodes.

Immunohistochemistry Technique

Hibernoma shows positivity for immunomarker S-100 protein in 85% of cases and CD31.

Markers	Expression
▪ S-100 protein	▪ Positive (85%)
▪ CD31	▪ Positive

WELL-DIFFERENTIATED LIPOSARCOMA/ATYPICAL LIPOMATOUS TUMOR

Well-differentiated liposarcoma occurs as a result of proliferation of mature adipocytes exhibiting marked variation in size with at least focal nuclear atypia. It represents 40–45% of all liposarcomas.

- Most common sites of liposarcoma are retroperitoneum, limbs, mediastinum and spermatic cord.
- Peak incidence is seen during sixth decade of life with male predominance. The tumor may affect children associated with Li-Fraumeni syndrome. It shows no potential for metastasis unless tumor undergoes dedifferentiation.

Fig. 28.3: Hibernoma. Tumor is a lobulated well demarcated large tumor with tan-yellow to red brown in color. Cut surface is brown with spongy consistency.

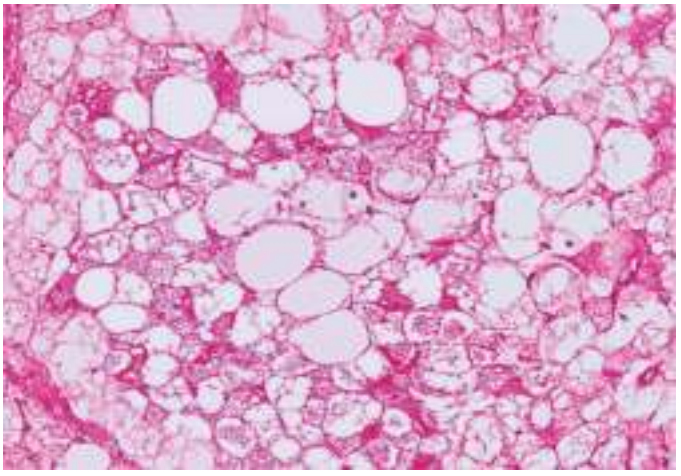

Fig. 28.4: Hibernoma. Tumor is composed of large number of brown adipocytes with small centrally located nuclei and multivacuolated cytoplasm; and admixed with normal adipocytes. Areas of necrosis and mitoses are absent in the neoplasm (400X).

- Atypical lipomatous tumor term is employed for lesion arising at surgically amenable locations in the limbs and trunk.
- Complete surgical excision of tumor is curable. Incomplete excision of well-differentiated liposarcoma without dedifferentiation and located in the mediastinum and retroperitoneal region causes recurrence and metastasis.
- According to recent 2020 WHO classification of soft tissue tumors and well-differentiated liposarcoma are of four subtypes, i.e. adipocytic, sclerosing, inflammatory and spindle cell liposarcomas.

Clinical Features

Patient presents with slow-growing painless lump in retroperitoneum, limbs, mediastinum and spermatic cord.

Surgical Pathology: Well-differentiated Liposarcoma/ Atypical Lipomatous Tumor

Gross Morphology

- Well-differentiated liposarcoma is a large well circumscribed lobulated mass. Rarely, an infiltrative growth pattern may be encountered.
- Cut surface of tumor varies from yellow to white with firm in consistency depending on the presence of variable amount of fibrous and/or myxoid components. Areas of fat necrosis are common in the large tumor (Fig. 28.5A).

Light Microscopy

According to recent 2020 WHO classification of soft tissue tumors and well-differentiated liposarcoma are of four subtypes, i.e. adipocytic, sclerosing, inflammatory and spindle cell liposarcomas. Presence of more than one morphologic pattern is common in the same lesion especially located in the retroperitoneal region.

- **Well-differentiated adipocytic subtype of liposarcoma:** Tumor is composed of mature adipocytes of variable size and shape associated with nuclear atypia in adipocytes or spindle cells in the tumor. Spindle cells containing hyperchromatic nuclei tend to be more numerous within fibrous septa. There is presence of varying number of monovacuolated or multivacuolated lipoblasts. It is worth mentioning that mere presence of lipoblasts is not essential to establish its diagnosis. Histology of well-differentiated adipocytic type of liposarcoma is shown in Fig. 28.5B.
- **Well-differentiated sclerosing subtype of liposarcoma:** Tumor tends to occur in the retroperitoneum and paratesticular region. Tumor is composed of scattered distinctive bizarre stromal cells with hyperchromatic nuclei admixed with occasional multivacuolated lipoblasts in a fibrillary collagenous background.
- **Well-differentiated inflammatory subtype of liposarcoma:** Tumor represents a rare variant of well-differentiated liposarcoma. It occurs in the retroperitoneum. Adipocytic nature of the neoplasm is obscured due to presence of chronic inflammatory infiltrate composed of polyphenotypic aggregates of lymphocytes and plasma cells. When the adipocytic component is sparse, the presence of bizarre multinucleated stromal cells represents a useful diagnostic tool.
- **Well-differentiated spindle cell subtype of liposarcoma:** Tumor is composed of bland neural-like spindle cells in a background of fibrous and/or myxoid tissue admixed with lipoblasts. Occasional tumor may contain osseous element, well-differentiated smooth or skeletal muscle component.

Differential Diagnosis

- Well-differentiated liposarcoma/atypical lipomatous tumor should be differentiated from conventional lipoma, spindle cell lipoma and pleomorphic lipoma. Presence of fat necrosis in conventional lipoma or multinucleated giant cells in spindle cell lipoma and pleomorphic lipoma may be mistaken for well-differentiated liposarcoma.
- Conventional lipoma, spindle cell lipoma and pleomorphic lipoma occur in superficial regions and lack MDM2 amplification analyzed by fluorescence *in situ* hybridization.
- Well-differentiated liposarcoma/atypical lipomatous tumor should also be differentiated from extrarenal angiomyolipoma. It occurs in the retroperitoneum. Neoplastic cells of angiomyolipoma show positivity for HMB-45 or MRT1. On the other hand, well-differentiated liposarcoma is negative for HMB-45 or MRT1.

Immunohistochemistry Technique

- Well-differentiated adipocytic type of liposarcoma shows positivity for S-100 protein, MDM2 and or CDK4. Amplification of MDM2 gene on chromosome 12q13.15 is demonstrated in well-differentiated liposarcoma by fluorescence *in situ* hybridization technique.
- Histiocytes and lipoma undergoing necrosis show positivity for MDM2.
- Well-differentiated spindle cell type of liposarcoma is negative for MDM2.

Markers	Expression
S-100 protein	Positive
MDM2	Positive
CDK4	Positive

Molecular Genetic Alterations

Quantitative profile of chromosome 12 sequences obtained by array comparative genomic hybridization (CGH) in well-differentiated liposarcoma/atypical lipomatous tumor shows discontinuous high level amplification in the region 12q14.15. Amplification of genes on chromosomes 12q13, 12q23, and 12q24.13 is also demonstrated in these cases. Amplification of MDM2 gene on chromosome 12q13.15 is demonstrated in well-differentiated liposarcoma by fluorescence *in situ* hybridization (FISH).

Fig. 28.5A: Liposarcoma in retroperitoneal region. Primary liposarcoma arises in the retroperitoneal space, but not from the retroperitoneal organs. Cut surface reveals well demarcated retroperitoneal mass having yellow cut surface. (*Courtesy*: Department of Pathology, Sher-E-Kashmir Institute of Medical Sciences, Srinagar, Jammu & Kashmir.)

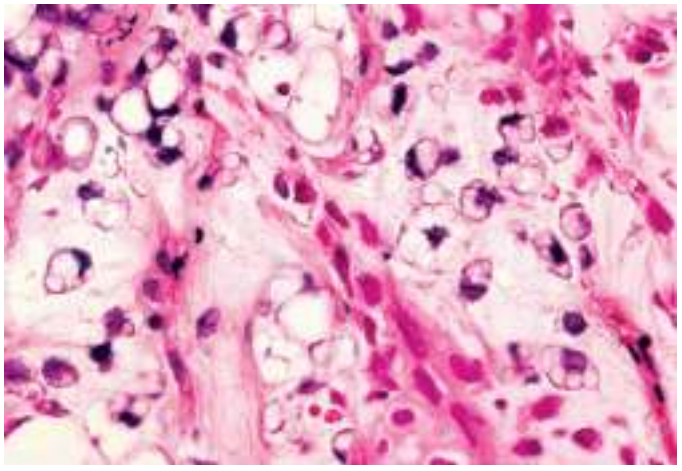

Fig. 28.5B: Well-differentiated adipocytic type of liposarcoma. Tumor is composed of mature adipocytes of variable size and shape associated with nuclear atypia in adipocytes or spindle cells in the tumor. Spindle cells containing hyperchromatic nuclei tend to be more numerous within fibrous septa. There is presence of varying number of monovacuolated or multivacuolated lipoblasts. It is worth mentioning that mere presence of lipoblasts is not essential to establish the diagnosis (400X).

Prognosis and Treatment

Anatomical location of well-differentiated liposarcoma/atypical lipomatous tumor is most important prognostic factor. Wide surgical excision of tumor located in superficial region does not recur. Surgical excision of tumor located in retroperitoneum and spermatic cord can recur or metastasize. Tumor located in retroperitoneum may transform to high-grade dedifferentiated liposarcoma.

DEDIFFERENTIATED LIPOSARCOMA

Dedifferentiated liposarcoma refers to a previously well-differentiated liposarcoma that has lost its adipocytic nature and transformed to aggressive neoplasm with metastatic potential. Peak incidence is seen during sixth decade of life with male predominance. It may affect children associated with Li-Fraumeni syndrome.

- Amplification of MDM2 gene on chromosome 12q13.15 is demonstrated in both well-differentiated liposarcoma and dedifferentiated liposarcoma by fluorescence *in situ* hybridization technique.
- Most common site of tumor is retroperitoneum. Other sites are spermatic cord, head and neck and trunk regions. Rare site is subcutaneous region.

Clinical Features

Patient presents with slow growing painless lump in retroperitoneum, head and neck and trunk regions.

Radiologic Findings

Imaging techniques demonstrate co-existence of both fatty and non-fatty solid components in the retroperitoneum.

Surgical Pathology: Dedifferentiated Liposarcoma

Gross Morphology

- Dedifferentiated liposarcoma is a large nodular yellow mass. Cut surface shows discrete solid tan gray dedifferentiated areas.
- Transformation between the lipomatous and dedifferentiated areas may sometimes be gradual (Fig. 28.6).

Light Microscopy

- In dedifferentiated liposarcoma, there is abrupt transition between well-differentiated liposarcoma and non-lipogenic high-grade areas of neoplasm. Morphology of these components of the neoplasm most often overlaps.
- Low-grade dedifferentiated liposarcoma tumor is composed of uniform fibroblastic spindle cells with nuclear atypia and arranged in a fascicular pattern.
- Dedifferentiated liposarcoma tumor may exhibit heterologous differentiation in 10% of cases. Heterologous elements include osseous, chondroid and angiomatous components. But presence of heterologous components does not affect clinical course (Fig. 28.7).

Differential Diagnosis

Dedifferentiated liposarcoma refers to previously well-differentiated liposarcoma that has lost its adipocytic nature and transformed to more aggressive neoplasm with metastatic potential. It should be differentiated from undifferentiated high-grade pleomorphic liposarcoma and high-grade liposarcoma with infiltrating benign adipose tissue component.

- Amplification of MDM2 gene on chromosome 12q13.15 is demonstrated in both well-differentiated liposarcoma and dedifferentiated liposarcoma by fluorescence *in situ* hybridization. Amplification of MDM2 gene on chromosome 12q13.15 is absent in undifferentiated liposarcoma.

- Most dedifferentiated liposarcomas retain the morphological features of residual well-differentiated liposarcoma in the tumor. This finding differentiates it from other high-grade liposarcoma infiltrating benign adipose tissue.

Immunohistochemistry Technique

Amplification of MDM2 gene on chromosome 12q13.15 is demonstrated in dedifferentiated liposarcoma by fluorescence *in situ* hybridization.

Marker	Expression
MDM2	Positive

Prognosis and Treatment

Dedifferentiated liposarcoma is treated by wide surgical excision and adjuvant chemotherapy.

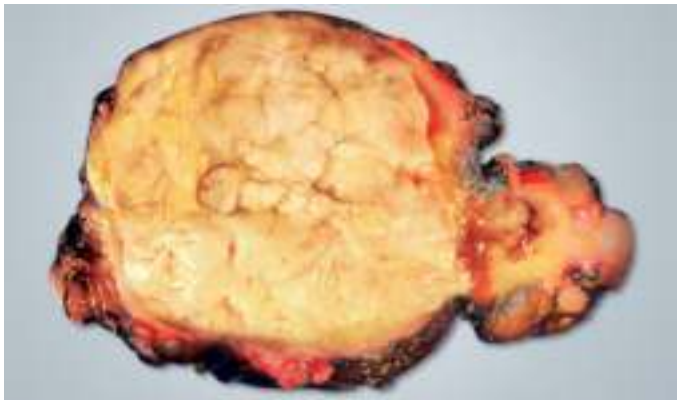

Fig. 28.6: Dedifferentiated liposarcoma. Tumor is large nodular yellow mass. Cut surface shows discrete solid tan gray dedifferentiated areas. Transformation between the lipomatous and dedifferentiated areas may sometimes be gradual.

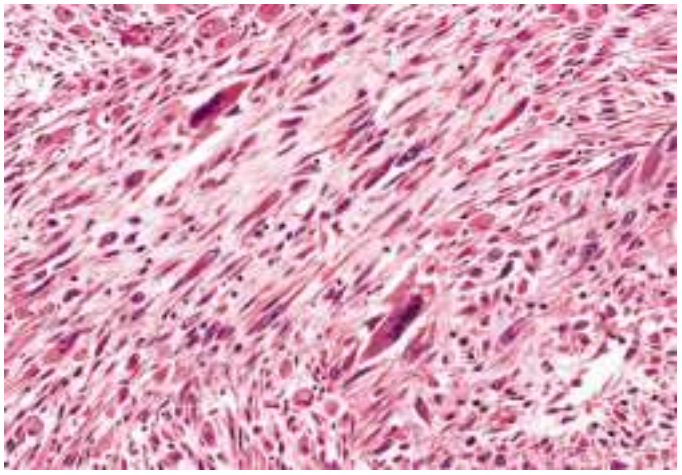

Fig. 28.7: Dedifferentiated liposarcoma. In dedifferentiated liposarcoma, there is abrupt transition between well-differentiated liposarcoma and nonlipogenic high-grade areas of neoplasm. Low-grade dedifferentiated liposarcoma is composed of uniform fibroblastic spindle cells with nuclear atypia and arranged in a fascicular pattern. Dedifferentiated liposarcoma may exhibit heterologous differentiation (osseous, chondroid and angiomatous components) in 10% of cases (400X).

MYXOID LIPOSARCOMA

Myxoid liposarcoma most often affects young adults and children with equal sex distribution and accounts for 15–20% of all liposarcomas. Most common site is deep soft tissue of the extremities especially thigh region in 66% of cases. Rare sites are retroperitoneum and subcutaneous tissue.

- Tumor is composed of uniform round to oval primitive (nonlipogenic) cells admixed with signet ring monovacuolated lipoblasts in a myxoid stroma along and plexiform vascularized myxoid stroma.
- The tumor consistently demonstrates translocation of chromosome 12 involving DDIT3 gene and chromosome 16 involving FUS gene. It may also demonstrate alternate translocation of chromosome 12 involving DDIT3 gene and chromosome 22 involving EWS gene. Fluorescence *in situ* hybridization (FISH) technique is performed to establish its diagnosis.

Clinical Features

Patient presents with large painless lump within the deep soft tissue of the extremities especially thigh region. Tumor metastasizes to retroperitoneum, opposite extremity or axilla, spine and lungs leading to clinical manifestations.

Surgical Pathology: Myxoid Liposarcoma

Gross Morphology

- Myxoid liposarcoma is well circumscribed multinodular intramuscular tumor. Gross evidence of tumor necrosis is uncommon.
- Cut surface is glistening and gelatinous in low-grade myxoid liposarcoma. It is fleshy in high-grade myxoid liposarcoma.

Light Microscopy

- Tumor is composed of uniform round to oval primitive (nonlipogenic) cells admixed with signet ring monovacuolated lipoblasts in a myxoid stroma along and plexiform vascularized myxoid stroma. Histology of myxoid liposarcoma is shown in Fig. 28.8.
- High-grade myxoid liposarcoma is composed of overlapping round cells with enlarged nuclei and prominent nucleoli arranged in solid nests.

Differential Diagnosis

Myxoid liposarcoma should be differentiated from well-differentiated liposarcoma with myxoid change, extraskeletal myxoid chondrosarcoma, lipoblastoma and myxofibrosarcoma.

- Atypical hyperchromatic tumor cells are absent in myxoid liposarcoma, but present in myxofibrosarcoma and well-differentiated liposarcoma.
- Myxoid liposarcoma never occurs during first decade of life. Morphological features of lipoblastomas and myxoid liposarcoma are identical.

- Fluorescence *in situ* hybridization (FISH) study is done to establish diagnosis showing translocation of chromosome 12 involving DDIT3 gene and chromosome 16 involving FUS gene. It may also demonstrate alternate translocation of chromosome 12 involving DDIT3 gene and chromosome 22 involving EWS gene.

Prognosis and Treatment

Myxoid liposarcoma metastasizes to distant organs in 33% of cases.

- Presence of significant population of round cells with vesicular nuclei constituting >5% of cell population in myxoid liposarcoma is associated with metastasis and poor prognosis. Patient is treated by wide surgical excision, radiotherapy and chemotherapy.
- High-grade myxoid liposarcoma with >5% round cell component has evidence of necrosis in tumor, TP53 and CDKN2A gene alterations are predictors of poor prognosis in localized myxoid liposarcoma.
- Low-grade myxoid liposarcoma has metastatic potential in <10% of cases.

PLEOMORPHIC LIPOSARCOMA

Pleomorphic liposarcoma is a high-grade neoplasm. Tumor is composed of variable number of pleomorphic lipoblasts and complex genomic profile. It most often affects adults in later life with male predominance. Peak incidence is seen during seventh decade of life. It accounts for 5% of all liposarcomas. Most common site is lower and upper extremities in decreased frequency in 66% of cases. Less frequent sites are trunk wall, retroperitoneum (25%) and spermatic cord.

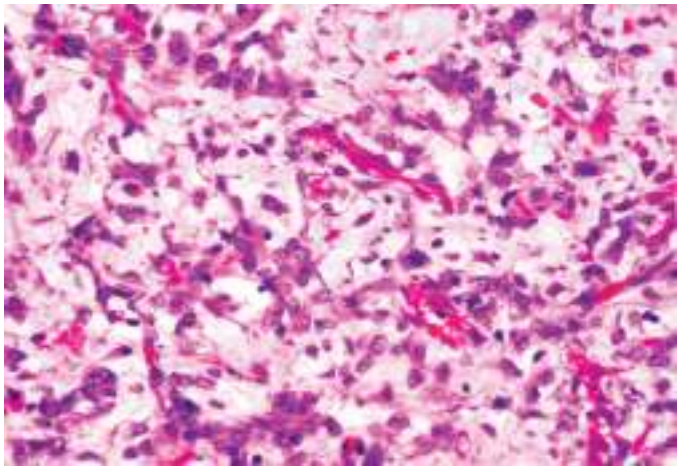

Fig. 28.8: Myxoid/round cell sarcoma. Tumor is composed of uniform round to oval primitive (nonlipogenic) cells admixed with signet ring monovacuolated lipoblasts in a myxoid stroma along and plexiform vascularized myxoid stroma (400X).

Clinical Features

Patient presents with rapidly growing mass with or without pain and symptoms related to the location of tumor over 3–6 months duration.

Surgical Pathology: Pleomorphic Liposarcoma

Gross Morphology

- Pleomorphic liposarcoma is well circumscribed tumor measuring 8–10 cm in diameter. Some tumors may be multinodular or infiltrative.
- Cut surface is white to yellow. Myxoid changes and foci of necrosis are demonstrated.

Light Microscopy

- Pleomorphic liposarcoma is composed of pleomorphic lipoblasts in variable proportion in a background of a high-grade sarcomatous element.
  - The presence of pleomorphic lipoblasts is essential for diagnosis.
  - Mitotic rate is variable. A median of 19–25 mitoses per high power field and necrosis are demonstrated in >50% of tumors.
- In most tumors, nonlipogenic component resembles undifferentiated pleomorphic liposarcoma, and shows spindle cells, multinucleated giant cells, neoplastic cells with vacuolated cytoplasm and hyaline droplets. Histology of pleomorphic liposarcoma is shown in Fig. 28.9.

Differential Diagnosis

- Pleomorphic liposarcoma should be differentiated from dedifferentiated liposarcoma, undifferentiated liposarcoma, high-grade pleomorphic liposarcoma and renal cell carcinoma.
- Pleomorphic liposarcoma and dedifferentiated liposarcoma have identical histologic features. Amplification of MDM2 gene on chromosome 12q13.15 is demonstrated in dedifferentiated liposarcoma by fluorescence *in situ* hybridization (FISH). On the other hand, pleomorphic liposarcoma lacks amplification of MDM2 gene on chromosome 12q13.15.
- Poorly differentiated carcinoma shows positivity for cytokeratins, on the other hand, pleomorphic liposarcoma lacks positivity for cytokeratins.

Immunohistochemistry Technique

Pleomorphic liposarcoma shows positivity for S-100 protein.

Markers	Expression
S-100 protein	Positive
Cytokeratin	Negative

Molecular Genetic Alterations

Pleomorphic liposarcoma is a high-grade neoplasm distinct from well-differentiated liposarcoma and myxoid liposarcoma. Like other liposarcomas, pleomorphic liposarcoma lacks translocation of chromosome 12 involving DDIT3 gene and chromosome 16 involving FUS gene analyzed by FISH. Tumor may also demonstrate alternate translocation of chromosome 12

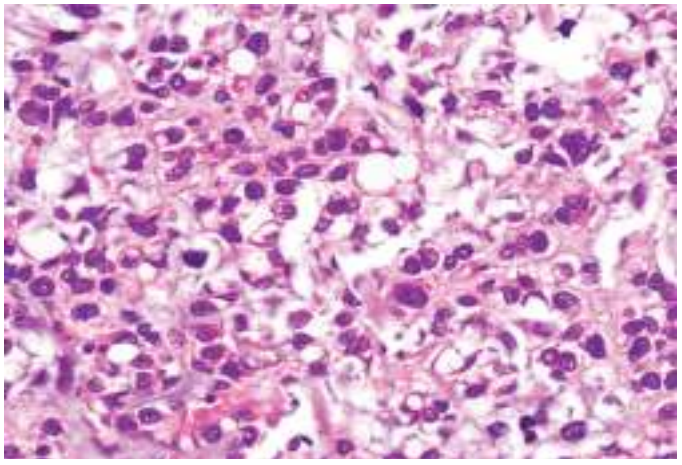

Fig. 28.9: Pleomorphic liposarcoma. Tumor is composed of pleomorphic lipoblasts in variable proportion in a background of a high-grade sarcomatous element. The presence of pleomorphic lipoblasts is essential for diagnosis. Mitotic rate is variable. A median of 19–25 mitoses per high power field and necrosis are demonstrated in >50% of tumors (400X).

involving DDIT3 gene and chromosome 22 involving EWS gene. On the other hand, these findings are present in myxoid liposarcoma.

Prognosis and Treatment

Pleomorphic liposarcoma is treated by wide surgical excision and adjuvant chemotherapy. Local recurrence and metastases in lungs and pleura are demonstrated in 30–50% of cases. Centrally located neoplasm in deep soft tissue and high mitotic index are associated with poor prognosis. Five-year survival rate is seen in 60% of cases.

Pathology Pearls: Adipocytic Tumors

- Pleomorphic lipoma and spindle cell lipoma occur in the subcutaneous tissue of neck and back regions, which may demonstrate atypical appearing multinucleated giant cells.
- Hibernoma is benign adipocytic tumor composed of brown adipocytes admixed with mature white adipose tissue.
- Angiolipoma is benign tumor composed of numerous capillaries admixed adipose tissue. Patient presents with painful nodule in subcutaneous region of young adults. It is essential to differentiate well-differentiated liposarcoma from lipoma.
- All adipocytic tumors located in retroperitoneum should be assessed for features of well-differentiated liposarcoma.
- Well-differentiated liposarcoma and dedifferentiated liposarcoma consistently demonstrate amplification of MDM2 gene located on chromosome 12 analyzed by fluorescence *in situ* hybridization.
- Pleomorphic liposarcoma is composed of bizarre lipoblasts, which lacks amplification of MDM2 gene located on chromosome 12 analyzed by fluorescence *in situ* hybridization.
- Myxoid liposarcoma and dedifferentiated liposarcoma have metastatic potential and recurrence after surgical excision.

FIBROBLASTIC/MYOFIBROBLASTIC TUMORS AND OTHER LESIONS

Fibroblastic/myofibroblastic tumors are grouped together and essentially composed of fibroblasts and myofibroblasts in varying proportion. Fibroblasts and myofibroblasts are able to contract due to the presence of myofilaments. Myofibroblasts participate in the early stages of wound healing and inflammation. According to recent 2020 World Health Organization of soft tissue tumors, fibroblastic/myofibroblastic tumors are categorized into benign tumors (cured by surgical excision), intermediate tumors (locally aggressive or rarely metastasizing) and malignant tumors (metastasizing to distant sites) in nature (Table 28.9).

Table 28.9 Fibroblastic/myofibroblastic tumors according to recent 2020 WHO classification of soft tissue tumors

Benign Tumors (Cures after Surgical Excision)

- Nodular fasciitis
- Proliferative fasciitis
- Proliferative myositis
- Myositis ossificans
- Fibro-osseous pseudotumor of digits
- Ischemic fasciitis
- Elastofibroma
- Fibrous hamartoma of infancy
- Myofibroma/myofibromatosis
- Fibromatosis colli
- Juvenile hyaline fibromatosis
- Inclusion body fibromatosis
- Fibroma of tendon sheath
- Desmoplastic fibroblastoma
- Mammary-type fibroblastoma
- Calcifying aponeurotic fibroma
- Angiomyoblastoma
- Cellular angiofibroma
- Nuchal-type fibroma
- Calcifying fibrous tumor
- Giant cell angiofibroma
- EWSR1-SMAD3 positive fibroblastic tumor (merging)

Intermediate (Locally Aggressive with Recurrence) Tumors

- Superficial fibromatosis (palmar/plantar)
- Desmoid-type fibromatosis
- Lipofibromatosis
- Giant cell fibroblastoma

Intermediate (Rarely Metastasizing) Tumors

- Dermatofibrosarcoma protuberans (DFSP)
  - Fibrosarcomatous dermatofibrosarcoma protuberans
  - Pigmented dermatofibrosarcoma protuberans
- Solitary fibrous tumor
  - Solitary fibrous tumor malignant
- Inflammatory myofibroblastic tumor
- Myxoinflammatory fibroblastic sarcoma
  - Atypical myxoinflammatory fibroblastic sarcoma
- Infantile fibrosarcoma

Malignant Tumors (Metastases Frequent)

- Adult fibrosarcoma (conventional)
- Myxofibrosarcoma
- Low-grade fibromyxoid sarcoma/hyalinizing spindle cell tumor
- Sclerosing epithelioid fibrosarcoma

KELOID

Keloid is an exaggerated response to injury to skin due to ear piercing or surgical wounds especially in dark persons. It is characterized by exuberant proliferation of fibroblasts and synthesis of abundant collagen bundles resulting in formation of large nodular scar. Keloid may recur after surgical excision.

Locations and Age Distribution

Most common sites of keloid are hands, ear lobe, neck, sternum, chest and shoulder. It most often in females on the ear lobe secondary to ear piercing during 10–30 years of age.

Clinical Features

Patient presents with large nodular scar on the upper back, shoulder, pre-sternal region and ear lobe. Keloid is most often asymptomatic. Sometimes, keloid may be tender, pruritic or painful. On clinical examination, keloid is elevated and protruding surrounding skin.

Surgical Pathology: Keloid

Gross Morphology

Keloid is nodular firm mass with curving contours with well defined borders. It varies in color, i.e. pink, red, gray or brown pigmented.

Light Microscopy

- Mature keloid is elevated and protruding surrounding skin and composed of homogenous, broad, eosinophilic fibrillary collagen bundles arranged in haphazardly array. Increased number of fibroblasts are found arrayed with an orientation that parallel the accompanying collagen bundles.
- Vascularity is diminished within keloid. Overlying epidermis is most often thinned out. Histology of keloid is shown in Fig. 28.10.

Differential Diagnosis

Keloid is differentiated from dermatofibroma, benign fibrous histiocytoma, lobomycosis (blastomycosis of skin) and hypertrophic scar. Comparison of keloid and hypertrophic scar is given in Table 28.10.

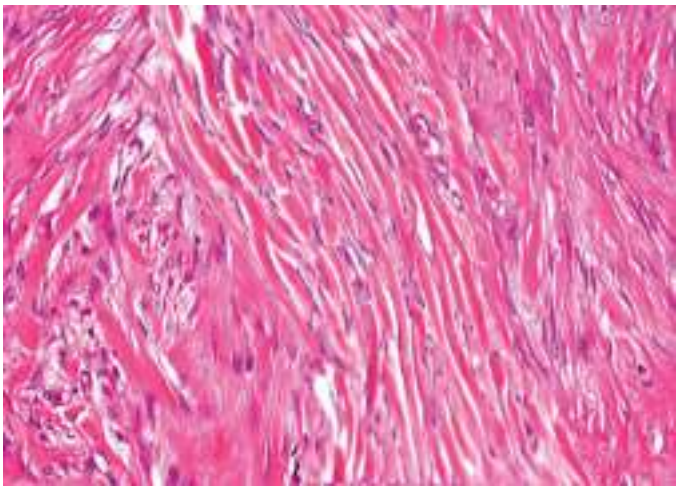

Fig. 28.10: Keloid scar. Keloid scar is composed of homogenous, broad, eosinophilic fibrillary collagen bundles arranged in haphazardly array. Increased number of fibroblasts are found arrayed with an orientation that parallel the accompanying collagen bundles. Vascularity is diminished within the lesion. It is worth mentioning that overlying epidermis is most often thinned out.

FIBROMATOSIS COLLI

Fibromatosis colli is a benign soft tissue lesion, which occurs due to proliferation of fibrous tissue resulting in thickened sternocleidomastoid muscle. It is recognized early in life as clinical torticollis (congenital muscular torticollis of sternocleidomastoid muscle tumor of infancy) possibly related to birth trauma.

Locations and Age Distribution

Most common site of fibromatosis colli is right sternocleidomastoid muscle. Diagnosis is established by the age of six months of life. Fibromatosis colli accounts for 0.4% of live births and more often affects male infants.

Clinical Features

About 20–25% present with neonatal torticollis (muscular tightening and resultant turning of the head toward the ipsilaterally involved shoulder). Within first few days to weeks of life, lesion is recognized as palpable, firm, non-tender mass at the base of the sternocleidomastoid muscle. Almost all cases show unilateral involvement of sternocleidomastoid muscle. Rarely, bilateral sternocleidomastoid muscles are involved.

Surgical Pathology: Fibromatosis Colli

Gross Morphology

- Fibromatosis colli is a small, firm gray-tan mass measuring 1–2 cm in diameter.
- Cut surface is gray white and glistening. It melts smoothly within the surrounding skeletal muscle.

Light Microscopy

- Fibromatosis colli is composed of plump fibroblasts and myofibroblasts resulting in partially displacing and replacing the skeletal muscle.
- Spindle cells contain nuclei without mitoses and arranged in long fascicles. The residual fibers show degeneration.
- Scar-like collagen fibers remain in the skeletal muscle leaving degenerating and regenerating skeletal fibers. Histology of fibromatosis colli is shown in Fig. 28.11.

Differential Diagnosis

Fibromatosis colli should be differentiated from fibromatosis, fibrodysplasia ossificans progressive and proliferative myositis.

Table 28.10 Comparison of keloid and hypertrophic scar

Features	Keloid	Hypertrophic Scar
Locations	Hands, ear lobe, neck, sternum, chest and shoulder	No predilection
Age and sex predominance	Females 10–30 years of age	No age and sex predominance
Clinical features	Asymptomatic to tender, pruritic or painful in smooth lesions	Asymptomatic
Extension beyond the margins of antecedent trauma	Present	Absent
Gross morphology	Mature keloid nodular firm mass with curving contours with well-defined borders elevated above skin and varying in color, i.e. pink, red, gray or brown pigmented	No definite gross morphology
Light microscopy	Early stage of keloid is cellular, and later mature keloid is composed of homogenous, broad, eosinophilic fibrillary collagen bundles arranged in haphazardly array. Increased number of fibroblasts are found arrayed with an orientation that parallel the accompanying collagen bundles, diminished vascularity within the lesion with thinning of overlying epidermis	Hypertrophic scar persists as a cellular fibrous tissue composed of collagen bundles but not undergoing hyalinization
Recurrence	Recurrence common after surgical excision	Recurrence after surgical excision

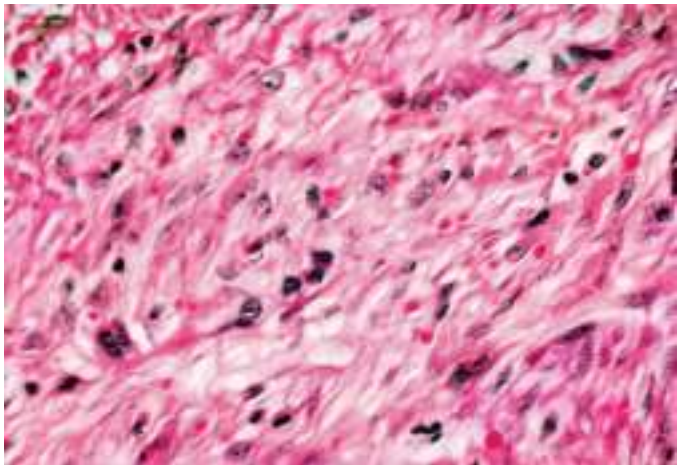

Fig. 28.11: Fibromatosis colli. Fibromatosis colli is composed of plump fibroblasts and myofibroblasts resulting in partially displacing and replacing the skeletal muscle. Spindle cells contain nuclei without mitoses and arranged in long fascicles. The residual fibers show degeneration. Scar-like collagen fibers remain in the skeletal muscle leaving degenerating and regenerating skeletal fibers.

Prognosis and Treatment

Fibromatosis colli is treated by stretching and physiotherapy resulting in resolution of lesion in 66% of cases. Some cases require surgical excision.

NODULAR FASCIITIS

Nodular fasciitis is a self-limited rapidly growing pseudosarcomatous reactive process, which occurs in the subcutaneous tissue of trunk and extremities. It affects young adults during first three decades of life. Nodular fasciitis is composed of fibroblasts and myofibroblasts, which may be associated with traumatic injury to the superficial fascia. Recurrence of nodular fasciitis is occasional observed after incomplete surgical excision.

Clinical Features

Patient presents with lump of 2–3 cm in subcutaneous tissue of trunk or extremities over a period of 3–6 weeks. Large lesion is unusual. It eventually regresses.

Surgical Pathology: Nodular Fasciitis

Gross Morphology

- Nodular fasciitis lesion is poorly circumscribed or infiltrative 2–3 cm mass without a capsule.
- Cut surface shows myxoid and fibrous tissue.

Light Microscopy

- Histologically, vast array of patterns is observed in nodular fasciitis: (a) cellular phase with myxoid changes, (b) fibrotic phase, (c) presence of ganglion-like cells, (d) presence of ossification (ossifying nodular fasciitis), and (e) presence of ischemic change (ischemic nodular fasciitis).
- Nodular fasciitis in cellular phase is composed of fibroblasts and myofibroblasts growing along fibrous septa of hypodermis. Early lesion of nodular fasciitis is composed of myxoid stroma and numerous mitoses (not abnormal mitoses). Long-standing lesion is composed of abundant collagen fibers and extracellular matrix.
- Inflammation is prominent around nodular fasciitis. Small blood vessels are numerous simulating granulation tissue. Osteoclast-like multinucleated giant cells are demonstrated in 10% of cases (Fig. 28.12).

Differential Diagnosis

Diagnostic difficulty occurs due to presence of vast array of histologic patterns in nodular fasciitis.

- Nodular fasciitis (cellular phase with myxoid change) should be differentiated from myxoma, myxofibrosarcoma, myxoid dermatofibrosarcoma and malignant nerve sheath tumor.
- Nodular fasciitis (cellular phase and without myxoid change): should be differentiated from cellular schwannoma, fibrous histiocytoma, leiomyosarcoma, fibrosarcoma, spindle cell melanoma and spindle cell carcinoma.
- Nodular fasciitis (fibrotic phase) should be differentiated from fibroma, neurofibroma and desmoplastic fibroblastoma.
- Ossifying nodular fasciitis should be differentiated from osteosarcoma.
- Nodular fasciitis with ganglion-like cells should be differentiated from rhabdomyosarcoma, ganglioneuroblastoma and pleomorphic sarcoma.
- Ischemic nodular fasciitis should be differentiated from myxofibrosarcoma and epithelioid sarcoma.

Immunohistochemistry Technique

Myofibroblasts show diffuse positivity for immunomarkers smooth muscle actin, muscle-specific actin (clone HHF35) and calponin, and focal positivity for desmin. Myofibroblasts are negative for h-caldesmon and S-100 protein.

Markers	Expression
Smooth muscle actin	Positive (diffuse staining)
Muscle-specific actin (clone HHF35)	Positive (diffuse staining)
Calponin	Positive (diffuse staining)
Desmin	Positive (focal staining)
h-caldesmon	Negative
S-100 protein	Negative

SUPERFICIAL FIBROMATOSIS (DUPUYTREN'S DISEASE OR CONTRACTURE)

Superficial fibromatosis is a benign recurring but non-metastasizing, infiltrative lesion as a result of fibroblastic proliferation in the soft tissue of palmar, plantar or penile regions. Immunohistochemistry technique and electron microscopy indicate that lesion is composed of myofibroblasts.

Locations and Age Distribution

Superficial fibromatosis most often occurs in the soft tissue of palmar, plantar or penile regions. It affects middle to advanced aged persons with male predominance. Superficial fibromatosis in plantar region is demonstrated in children and adolescents. It is more common in North Europeans.

Clinical Features

Patient presents with slow-growing subcutaneous nodules, plaques or cord-like lesions involving dermis or underlying fascia of ulnar side of palm resulting in contracture of fourth and fifth fingers. Superficial fibromatosis in plantar region is demonstrated in children and adolescents. Dupuytren's disease or contracture may be bilateral in 50% of cases with involvement of soles of feet, known as 'Ledderhose disease'.

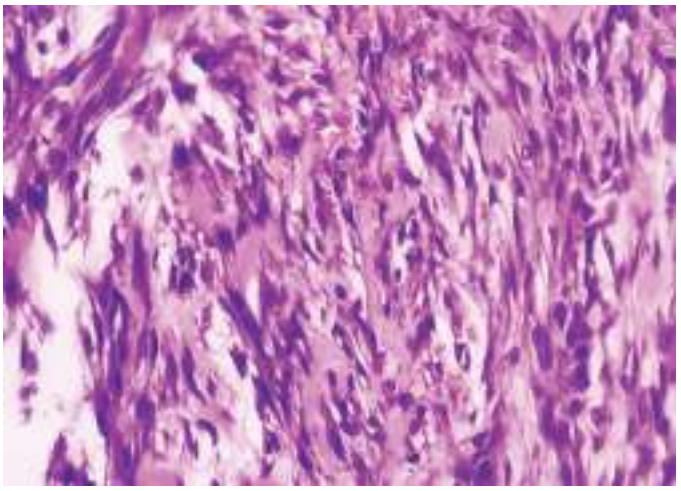

Fig. 28.12: Nodular fasciitis. Nodular fasciitis in cellular phase is composed of fibroblasts and myofibroblasts growing along fibrous septa of hypodermis. Early lesion of nodular fasciitis is composed of myxoid stroma and numerous mitoses (not abnormal mitoses). Long-standing lesion is composed of abundant collagen fibers and extracellular matrix. Inflammation is prominent around nodular fasciitis. Small blood vessels are numerous simulating granulation tissue. It is worth mentioning that osteoclast-like multinucleated giant cells are demonstrated in 10% of cases.

Surgical Pathology: Superficial Fibromatosis

Gross Morphology

- Superficial fibromatosis may be single or multiple measuring 0.5–2 cm in diameter.
- Cut surface is gray white with firm in consistency.

Light Microscopy

Superficial fibromatosis is composed of uniform nontypical fibroblasts arranged in monotonous fascicular fashion surrounded by abundant collagen fibers in long-standing lesion. Mitotic figures may be demonstrated. Hypercellularity is frequent in plantar superficial fibromatosis.

Differential Diagnosis

Superficial fibromatosis should be differentiated from synovial sarcoma, malignant peripheral nerve sheath tumor (MPNST), fibrosarcoma and desmoid type fibromatosis.

Immunohistochemistry Technique

Superficial fibromatosis shows positivity for vimentin and smooth muscle actin, and negative for CD34, cytokeratins, epithelial membrane antigen (EMA) and S-100 protein.

Markers	Expression
▪ Vimentin	▪ Positive
▪ Smooth muscle actin (SMA)	▪ Positive (focal staining)
▪ CD34	▪ Negative
▪ Cytokeratins	▪ Negative
▪ EMA	▪ Negative
▪ S-100 protein	▪ Negative

Molecular Genetic Alterations

Trisomy of 7 and 8; and loss of Y are demonstrated in Dupuytren's disease or contracture. Trisomy 8 and trisomy 14 are demonstrated in 'Ledderhose disease'.

Prognosis and Treatment

Superficial fibromatosis is treated by fasciectomy/aponeurectomy followed by skin grafting. It has strong tendency to recur after surgical intervention.

DEEP FIBROMATOSIS (DESMOID TYPE)

Deep fibromatosis (desmoid type) is a benign infiltrative fibroblastic/myofibroblastic neoplasm, which tends to recur after surgery. It does not metastasize.

Locations and Age Distribution

Deep fibromatosis is divided into abdominal, extra-abdominal and intra-abdominal types.

- **Abdominal wall deep fibromatosis:** It develops from musculoaponeurotic structures of the abdominal wall. It occurs in young women during pregnancy or within one year of childbirth, which suggests role of hormones in the pathogenesis of deep fibromatosis.
- **Extra-abdominal deep fibromatosis:** It most often occurs in skeletal muscles and aponeurosis of shoulder girdle, pelvic girdle, chest wall, thigh, head and neck regions affecting children, young and middle-aged persons. In children, most common sites are head and neck regions. The lesion tends to be more cellular and aggressive in children. Lesion may be multicentric in 5% of cases.
- **Intra-abdominal deep fibromatosis:** Trauma plays an important role in the pathogenesis of intra-abdominal deep fibromatosis in patient with prior abdominal surgery. Most common sites of deep fibromatosis are mesentery, retroperitoneum and pelvis. Pelvic deep fibromatosis is most often misdiagnosed as an ovarian tumor. Mesenteric deep fibromatosis is the commonest, which may be sporadic or associated with Gardner's syndrome.

Clinical Features

Patient presents with slow-growing painless deep-seated lump measuring 5–10 cm. Compression of structures by the tumor produce other symptoms. Abdominal deep fibromatosis occurs in young women during pregnancy or within one year of childbirth. Intra-abdominal deep fibromatosis may be sporadic or associated with Gardner's syndrome.

Radiologic Findings

Radiologic studies in deep fibromatosis reveal homogenous mass with infiltrative borders. Erosion of the underlying bone may be demonstrated. Myxoid change in the lesion may be demonstrated in some lesions.

Surgical Pathology: Deep Fibromatosis

Gross Morphology

- Deep fibromatosis is usually a solitary well circumscribed mass with infiltrative margin and soft in consistency measuring 5–10 cm in diameter.
- Cut surface shows fascicular white surface. Myxoid and cystic areas may be demonstrated in intra-abdominal deep fibromatosis. Areas of necrosis are absent.

Light Microscopy

- Deep fibromatosis is composed of spindle shape fibroblasts and myofibroblasts arranged in uniform fascicular architecture. Storiform growth pattern may be demonstrated in focal areas of the lesion.
- Abundant collagenous extracellular matrix is present. Blood vessels in muscle are well formed and showing gaping.
- Mesenteric deep fibromatosis may sometimes demonstrate keloid collagen. Myxoid change may be demonstrated in an occasional lesion (Fig. 28.13).

Differential Diagnosis

Deep fibromatosis should be differentiated from nodular fasciitis, fibrosarcoma, neurofibroma, low-grade malignant peripheral nerve sheath tumor, monophasic synovial sarcoma and scar tissue.

Immunohistochemistry Technique

Deep fibromatosis shows diffuse positivity for smooth muscle actin (SMA), variable expression of desmin and β-catenin. Lesion is negative for CD34, cytokeratins, EMA (epithelial membrane antigen) S-100 protein, and CD117.

Markers	Expression
▪ SMA	▪ Positive (diffuse staining)
▪ Vimentin	▪ Positive (focal staining)
▪ β-Catenin	▪ Positive (focal staining)
▪ CD34	▪ Negative
▪ Cytokeratins	▪ Negative
▪ EMA	▪ Negative
▪ S-100 protein	▪ Negative
▪ CD117	▪ Negative

Molecular Genetic Alterations

Trisomy 8 or 20 or both is/are demonstrated in 30% cases of deep fibromatosis. APC gene mutation is

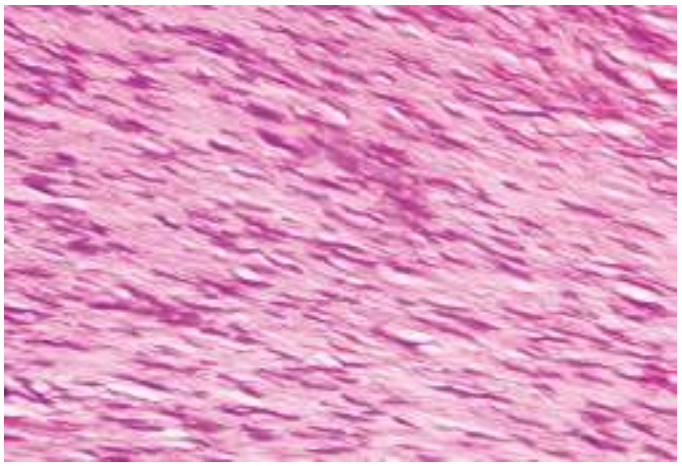

Fig. 28.13: Deep fibromatosis (desmoid type). Deep fibromatosis is composed of spindle shape fibroblasts and myofibroblasts arranged in uniform fascicular architecture. Storiform growth pattern may be demonstrated in focal areas of the lesion. Abundant collagenous extracellular matrix is present. Blood vessels in muscle are well formed and showing gaping. Mesenteric deep fibromatosis may sometimes demonstrate keloid collagen. Myxoid change may be demonstrated in an occasional lesion.

demonstrated in deep fibromatosis associated with Gardner's syndrome. Cellular abnormality of APC/β-catenin pathway, RB gene and TP53 gene mutations may be demonstrated in deep fibromatosis.

Prognosis and Treatment

Deep fibromatosis is a benign recurring but non-metastasizing lesion treated by wide surgical excision. Symptomatic patients are treated by low dose of chemotherapy and adjuvant irradiation.

INFANTILE FIBROSARCOMA (CONGENITAL FIBROSARCOMA)

Infantile fibrosarcoma (congenital fibrosarcoma) is an unusual neoplasm affecting infants and young children. Histology of infantile fibrosarcoma resembles classic adult fibrosarcoma. Tumor predominantly involves distal region of upper and lower extremities.

Locations and Age Distribution

Most common sites of infantile fibrosarcoma are superficial and deep tissues of lower extremity (foot, ankle, lower leg) and upper extremity (wrist, hand and forearm). Rare sites are trunk, head and neck region. Tumor is observed at birth in 30–40% of cases. It affects infants and children with slight male predominance.

Clinical Features

Patient presents with rapidly growing large painless mass in the distal regions of upper and lower extremities. Local examination reveals overlying skin reddened or ulcerated.

Surgical Pathology: Infantile Fibrosarcoma

Gross Morphology

- Infantile fibrosarcoma is a poorly circumscribed lobular mass measuring 5–15 cm in diameter.
- Cut surface shows grayish fleshy appearance. Areas of hemorrhage, necrosis and/or myxoid change may be demonstrated.

Light Microscopy

- Tumor is composed of densely packed monotonous spindle cells arranged in intersecting bundles. Nuclear pleomorphism is usually absent. Neoplastic cells are infiltrating the surrounding tissues.
- Numerous atypical mitoses and interstitial lymphocytes are demonstrated in the tumor. Hemangiopericytoma-like vascular pattern is most often present.

Differential Diagnosis

Infantile fibrosarcoma should be differentiated from conventional adult fibrosarcoma, malignant tumor of peripheral nerve sheath tumor, infantile fibromatosis (cellular variant) and spindle cell rhabdomyosarcoma.

Immunohistochemistry Technique

Infantile fibrosarcoma tumor cells show positivity for vimentin (diffuse staining), smooth muscle actin (variable staining), desmin (occasional case), CD34 (occasional case), S-100 protein (occasional case) and cytokeratins (occasional case). It is negative for epithelial membrane antigen.

Markers	Expression
Vimentin	Positive (diffuse staining)
SMA	Positive (variable staining)
Desmin	Positive (occasional case)
CD34	Positive (occasional case)
S-100 protein	Positive (occasional case)
Cytokeratins	Positive (occasional case)
EMA	Negative

Molecular Genetic Alterations

Reciprocal chromosomal translocation t(12;15) (p13;26) involves ETV6 gene on chromosome 12 and NTRK3 gene (a receptor tyrosine kinase gene) on chromosome 15q resulting in formation of ETV6-NTRK3 fusion protein; demonstrated in paraffin-embedded tissue or frozen tissue using RT-PCR (reverse transcriptase-polymerase chain reaction) or fluorescence *in situ* hybridization (FISH) technique. Trisomy of chromosomes 11, 20, 17 and 8 are demonstrated in infantile fibrosarcoma.

Prognosis and Treatment

Infantile fibrosarcoma is treated by complete surgical excision with or without adjuvant chemotherapy. Local recurrence after surgical excision is demonstrated in 5–50% of cases. Distant metastases are observed in <10% of case. Median five-year survival rate is observed in 75–80% of cases.

DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans (DFSP) is a solitary slow growing highly infiltrative, locally aggressive and rarely metastasizing neoplasm. However, wide surgical excision with tumor margins is most often curative.

Locations and Age Distribution

Frequent sites of dermatofibrosarcoma protuberans are trunk, proximal upper extremity and lower extremity. It usually affects 20–50 years of age group.

Clinical Features

Patient presents with plaque-like thickening of skin and steadily progressing to form subcutaneous nodular mass over the course of several years.

Surgical Pathology: Dermatofibrosarcoma Protuberans

Gross Morphology

- Dermatofibrosarcoma protuberans is a solitary multinodular mass measuring several centimeters in diameter with average 5 cm.
- Although the neoplasm is highly infiltrative, yet it may appear as circumscribed mass (Fig. 28.14A).

Light Microscopy

- Dermatofibrosarcoma protuberans is composed of bland-appearing spindled fibroblasts arranged in an irregularly whorled or storiform pattern, which infiltrates into the periphery of tumor entrapping fat resulting in thinned out epidermis.
- Overlying epidermis may be normal, atrophic or ulcerated. plastic cells show mild atypia and occasional mitosis.
- Occasional tumor can have a more aggressive component, where neoplastic spindle cells are arranged in fascicular pattern. This variant of neoplasm is known as fibrosarcomatous variant of dermatofibrosarcoma protuberans (Fig. 28.14B).

Differential Diagnosis

- Dermatofibrosarcoma protuberans should be differentiated from fibrous histiocytoma (dermatofibroma).
- Unlike dermatofibrosarcoma protuberans, fibrous histiocytoma tends to be limited to the dermis.
- Analysis of COLLA1-PDGFB fusion protein by fluorescence *in situ* hybridization (FISH) technique can be helpful in diagnosing neoplasm in difficult cases.
- It is worth mentioning that storiform pattern may be demonstrated in dermatofibrosarcoma protuberans, malignant fibrous histiocytoma, liposarcoma, peripheral nerve sheath tumor and nodular fasciitis.

Immunohistochemistry Technique

Dermatofibrosarcoma protuberans shows positivity for CD34.

Marker	Expression
CD34	Positive

Fig. 28.14A: Dermatofibrosarcoma protuberans. Tumor is multinodular mass measuring several centimeters with average 5 cm. Although, tumor is highly infiltrative, however it may appear as circumscribed mass. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

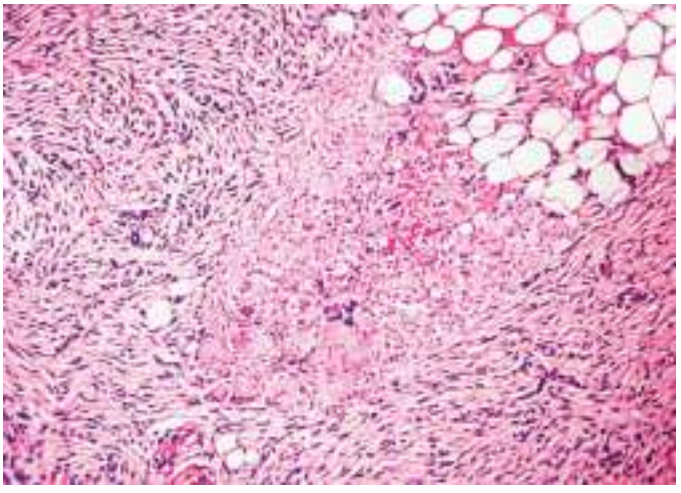

Fig. 28.14B: Dermatofibrosarcoma protuberans (DFSP). Dermatofibrosarcoma protuberans is composed of bland-appearing spindled fibroblasts arranged in an irregularly whorled or storiform pattern, which infiltrate into the periphery of tumor entrapping fat resulting in thinned out epidermis. Overlying epidermis may be normal, atrophic or ulcerated. Neoplastic cells show mild atypia and occasional mitosis. Occasional tumor can have a more aggressive component, where neoplastic spindle cells are arranged in fascicular pattern. This variant of neoplasm is known as fibrosarcomatous variant of dermatofibrosarcoma protuberans (400X).

Molecular Genetic Alterations

- Dermatofibrosarcoma protuberans exhibits chromosomal translocation t(17;22) (q22;q13) resulting in formation of COLLA1-PDGFB fusion protein analyzed by fluorescence *in situ* hybridization.
- Supernumerary ring chromosome in dermatofibrosarcoma protuberans may contain centromere of chromosome 22 and sequences from chromosomes 17 and 22.

Prognosis and Treatment

Prognosis of dermatofibrosarcoma protuberans is excellent after surgical excision of tumor. Recurrence of tumor is demonstrated in 11–33% of cases. Tumor may metastasize to lymph node in 1% and distant organs in 5% of cases.

CONVENTIONAL ADULT FIBROSARCOMA AND OTHER HISTOLOGIC VARIANTS

Conventional adult fibrosarcoma is a malignant neoplasm composed of fibroblasts and variable amount of collagen synthesis giving 'herringbone' architecture.

- Histologic variants of adult fibrosarcoma are conventional fibrosarcoma, low-grade fibromyxoid sarcoma, sclerosing epithelioid fibrosarcoma and myxofibrosarcoma.
- Low-grade fibromyxoid sarcoma shows reciprocal chromosomal translocation t(7;16) or ring chromosomes with material from chromosomes 7 and 17.

Incidence, Age Distribution and Clinical Features

- **Conventional adult fibrosarcoma:** Most common sites of tumor in decreased frequency are lower extremity (thigh region) and trunk. It most affects occurs young adults during 30–60 years of age with male predominance. Patient presents with large slow growing, deep-seated solitary lump at the site of prior burns, injury or radiotherapy site.
- **Low-grade fibromyxoid sarcoma variant of adult fibrosarcoma:** Most common sites of tumor are lower extremities and trunk. It most often affects young adults with male predominance. Patient presents with deep-seated slow-growing painless lump in the lower extremities and trunk.
- **Sclerosing epithelioid fibrosarcoma variant of adult fibrosarcoma:** Most common sites of tumor are lower extremities and limb girdles. It most often affects elderly persons during 50–70 years of age without sex predominance. Patient presents with deep-seated painless/painful lump in the lower extremities and limb girdles.
- **Myxofibrosarcoma variant of adult fibrosarcoma:** Most common sites of tumor are deep dermis, subcutaneous region of extremities and limb girdles. It most often affects adults with/without sex predominance. Patient presents with slow growing painless mass in lower dermis or deep to fascia in extremities and limb girdles.

Surgical Pathology: Adult Fibrosarcoma

Gross Morphology

- **Conventional adult fibrosarcoma:** Tumor is well circumscribed. Cut surface gives whitish and fleshy appearance with areas of hemorrhage and necrosis.
- **Low-grade fibromyxoid sarcoma variant of adult fibrosarcoma:** Tumor is well circumscribed or lobulated. Cut surface shows homogenous appearance.
- **Sclerosing epithelioid fibrosarcoma variant of adult fibrosarcoma:** Tumor is well circumscribed or lobulated measuring 7–10 cm in diameter. Cut surface shows whitish appearance with firm in consistency and areas of calcification or cystic/myxoid change.
- **Myxofibrosarcoma variant of adult fibrosarcoma:** Tumor is multinodular in the subcutaneous region. Cut surface shows multiple whitish glistening nodules. Deep-seated tumor is solitary poorly circumscribed with areas of hemorrhage and necrosis.

Light Microscopy

- **Conventional adult fibrosarcoma:** Tumor is composed of monotonous uniform bipolar neoplastic spindle cells with scanty cytoplasm, tapered nuclei and variable collagen stroma. Neoplastic cells are arranged in long, sweeping bundles showing 'herringbone' architecture. Mitotic activity is moderate in the neoplasm (Fig. 28.15).
- **Low-grade fibromyxoid sarcoma variant of adult fibrosarcoma:** Tumor is composed of an admixture of collagenous and myxoid zones. Tumor is composed of bland spindle cells with oval nuclei and eosinophilic cytoplasm arranged in fascicles or whorls in the collagenous zone. Myxoid zone of tumor contains plexiform blood vessels. Mitotic activity is low.
- **Sclerosing epithelioid fibrosarcoma variant of adult fibrosarcoma:** Tumor is composed of epithelioid or clear cells with uniform round or oval nuclei arranged in strands and nests. Dense collagenous stroma is present in the background. Tumor may be cellular and resembling conventional fibrosarcoma. Mitotic activity is low.
- **Myxofibrosarcoma variant of adult fibrosarcoma:** Tumor is composed of neoplastic cells containing hyperchromatic pleomorphic nuclei. Variable amount of myxoid areas is present in the background. There is presence of thin-walled blood vessels. Mitotic activity is low.

Immunohistochemistry Technique

- Conventional adult fibrosarcoma, low-grade fibromyxoid sarcoma, myxofibrosarcoma variants show positivity for vimentin and smooth muscle actin, and negative for cytokeratins and epithelial membrane antigen.
- Sclerosing epithelioid fibrosarcoma shows positivity for vimentin, BCL-2, p53, S-100, cytokeratins and epithelial membrane antigen.

Markers	Conventional Adult Fibrosarcoma Variant	Low-grade Fibromyxoid Sarcoma Variant	Myxofibrosarcoma Variant	Sclerosing Epithelioid Fibrosarcoma
▪ Vimentin	▪ Positive (constant staining)	▪ Positive (constant staining)	▪ Positive (constant staining)	▪ Positive (constant staining)
▪ Smooth muscle actin	▪ Positive	▪ Positive	▪ Positive	▪ Positive (90% cases)
▪ Cytokeratins	▪ Negative	▪ Negative	▪ Negative	▪ Positive (few cases)
▪ Epithelial membrane antigen	▪ Negative	▪ Negative	▪ Negative	▪ Positive (few cases)
▪ BCL-2	▪ Negative	▪ Negative	▪ Negative	▪ Positive (few cases)
▪ p53	▪ Negative	▪ Negative	▪ Negative	▪ Positive (few cases)
▪ S-100 protein	▪ Negative	▪ Negative	▪ Negative	▪ Positive (few cases)

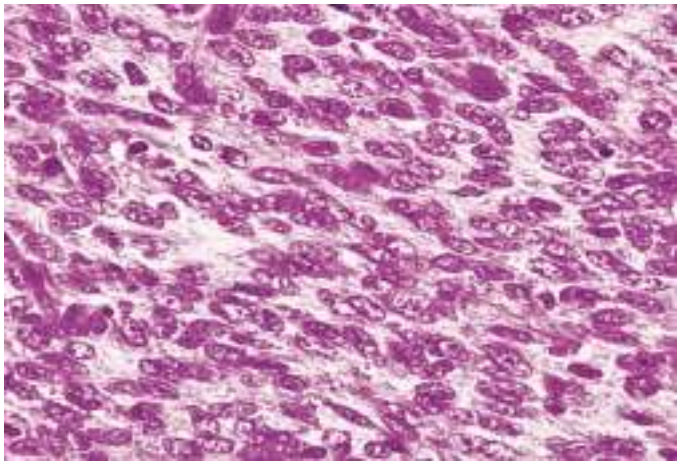

Fig. 28.15: Fibrosarcoma. Conventional fibrosarcoma is composed of monotonous uniform bipolar neoplastic spindle cells with scanty cytoplasm, tapered nuclei and variable collagen stroma. Neoplastic cells are arranged in long, sweeping bundles showing 'herringbone' architecture. Mitotic activity is moderate in the neoplasm.

Prognosis and Treatment

All histologic variants of adult fibrosarcoma are treated by wide surgical excision with tumor-free margins, radiotherapy and chemotherapy. Local recurrence and distant metastasis are demonstrated. Patients have five-year survival.

- **Conventional adult fibrosarcoma:** Adverse prognostic factors include high cellularity, high histologic grade, numerous atypical mitoses (>20 mitoses per 10 high power field), tumor size >5 cm in diameter, deep-seated location and presence of necrosis in the neoplasm.
- **Low-grade fibromyxoid sarcoma variant of adult fibrosarcoma:** Adverse prognostic factors include high-grade tumor and recurrence due to marginal surgical resection.
- **Sclerosing epithelioid fibrosarcoma variant of adult fibrosarcoma:** Adverse prognostic factors include large tumor, proximal location of tumor and male sex distribution.
- **Myxofibrosarcoma variant of adult fibrosarcoma:** Adverse prognostic factors include deep-seated location of tumor, high-grade of tumor and local recurrence within one year of treatment.

MYXOFIBROSARCOMA

Myxofibrosarcoma originates from fibroblasts in the dermis or subcutaneous tissue. Low-grade myxofibrosarcoma is composed of pleomorphic neoplastic cells admixed with myxoid stroma. Poorly differentiated high-grade myxofibrosarcoma resembles unclassified pleomorphic sarcoma. Low-grade myxofibrosarcoma shows t(17;16) cytogenetic abnormality.

Locations and Age Distribution

Most common sites of myxofibrosarcoma are shoulder and pelvic girdles followed by lower and upper extremities. It usually affects adults during sixth to eighth decades of life.

Clinical Features

Patient presents with soft tissue mass in shoulder girdle, pelvic girdle and extremities. Lung and bone metastases may occur.

Surgical Pathology: Myxofibrosarcoma
Gross Morphology
Myxofibrosarcoma demonstrates mucoid appearance.
Light Microscopy
Myxofibrosarcoma tumor can be low-grade, intermediate grade and high-grade. ▪ **Low-grade myxofibrosarcoma:** Tumor is composed of myxoid material that surrounds a conspicuous network of curved blood vessels and pleomorphic neoplastic cells containing hyperchromatic nuclei and poorly defined vacuolated cytoplasm. ▪ **High-grade myxofibrosarcoma:** Tumor is composed of numerous pleomorphic neoplastic cells with hyperchromatic nuclei arranged in clusters or sheets-like pattern.
Differential Diagnosis
Myxofibrosarcoma should be differentiated from low-grade fibromyxoid sarcoma, myxoid liposarcoma and intramuscular myxoma.

Prognosis and Treatment

Low-grade myxofibrosarcoma located in the superficial soft tissue of cutis has good prognosis. However, low-grade myxofibrosarcoma tumor >5 cm in diameter has metastatic potential. Incomplete surgical excision of tumor may recur. Intermediate/high-grade myxofibrosarcoma is most likely to recur after surgical resection. High-grade myxofibrosarcoma located in deep-seated region is more likely to metastasize to distant organs.

FIBROHISTIOCYTIC TUMORS

Fibrohistiocytic tumors according to revised 2020 WHO classification of tumors are given in Table 28.11.

BENIGN FIBROUS HISTIOCYTOMA

Benign fibrous histiocytoma is a benign tumor and characterized by proliferation of fibroblasts and histiocytes in the dermis or subcutis or both. Tumor is composed of fibroblasts and histiocytes arranged in sheets or short fascicles admixed with chronic inflammatory cells, multinucleated giant cells and hemosiderin laden macrophages. Most common sites of tumor are dermis or subcutis or both. It affects early to middle-aged persons during 20–40 years of age with female predominance.

Clinical Features

Patient presents with solitary slow-growing papule measuring <1 cm in size in the dermis or subcutis. Lesion in the deep soft tissue presents with painless measuring >5 cm in size.

Table 28.11 Fibrohistiocytic tumors according to revised 2020 WHO classification of tumors

Fibrohistiocytic Tumors	
Benign tumors	

▪ Tenosynovial giant cell tumor (giant cell tumor of tendon sheath)
  • Localized tenosynovial giant cell tumor
  • Diffuse tenosynovial giant cell tumor
  • Malignant tenosynovial giant cell tumor
▪ Deep benign fibrous histiocytoma
▪ Juvenile xanthogranuloma
▪ Xanthogranuloma	

Intermediate (rarely metastasizing) tumors	
▪ Atypical fibroxanthoma ▪ Plexiform fibrohistiocytic tumor	▪ Angiomatoid fibrous histiocytoma ▪ Giant cell tumor of soft tissue
Malignant tumors	
▪ Undifferentiated pleomorphic sarcoma ▪ Undifferentiated pleomorphic sarcoma with giant cells ▪ Undifferentiated pleomorphic sarcoma with prominent inflammation	

Surgical Pathology: Benign Fibrous Histiocytoma

Gross Morphology

- Benign fibrous histiocytoma is a plaque or nodule well circumscribed usually measuring <1 cm in diameter.
- Cut surface shows circumscribed yellow or whitish mass. Focal areas of hemorrhage may be demonstrated.

Light Microscopy

Histologic variants of benign fibrous histiocytoma are polymorphic, cellular, lipidized and variant located in the deep tissue, aneurysmal and epithelioid types.

- **Benign fibrous histiocytoma polymorphic variant:** Tumor is composed of monomorphic population of spindle cells arranged in fascicular and storiform patterns admixed with multinucleated giant cells (Touton giant cells), foamy macrophages, hemosiderin laden macrophages and interstitial fibrosis. Cutaneous lesion tends to be confined to dermis and sparing epidermis and subcutis.
- **Benign fibrous histiocytoma cellular variant:** Tumor is composed of numerous spindle cells arranged in fascicular pattern rather than storiform pattern. Multinucleated giant cells and hemosiderin laden macrophages are absent. Tumor shows numerous mitoses >3 per 10 high power fields.
- **Benign fibrous histiocytoma lipidized variant:** Tumor is composed of numerous xanthogranuloma cells admixed with a smaller number of spindle cells.
- **Benign fibrous histiocytoma in deep tissue variant:** Tumor is composed of numerous xanthogranuloma cells and few multinucleated giant cells arranged in diffusely storiform pattern.
- **Benign fibrous histiocytoma aneurysmal variant:** Tumor is composed of numerous large blood-filled spaces lined by discohesive neoplastic fragments, abundant hemosiderin deposits and mitotic activity near areas of hemorrhage. Growth of tumor is rapid due to hemorrhage.
- **Benign fibrous histiocytoma epithelioid variant:** Tumor is composed of large round to polygonal cells with abundant eosinophilic cytoplasm resembling the cells of reticulocytoma.

Differential Diagnosis

Benign fibrous histiocytoma should be differentiated from nodular fasciitis, neurofibroma, epithelioid sarcoma, dermatofibrosarcoma protuberans and Spitz nevus (epithelioid variant).

Immunohistochemistry Technique

Benign fibrous histiocytoma tumor cells show positivity for immunomarkers CD68, factor XIIIa, HMGA1, and HMGA2. It is negative for CD34, S-100 protein, CD1a and cytokeratins.

Markers	Expression
▪ CD68	▪ Positive
▪ Factor XIIIa	▪ Positive
▪ HMGA1	▪ Positive
▪ HMGA2	▪ Positive
▪ CD34	▪ Negative
▪ S-100 protein	▪ Negative
▪ CD1a	▪ Negative
▪ Cytokeratins	▪ Negative

Prognosis and Treatment

Benign fibrous histiocytoma located in dermis and subcutis regions is treated by surgical resection. Recurrence is demonstrated in <5% of cases. Tumor located in the deep soft tissue may recur after surgical resection in 50% of cases.

TENOSYNOVIAL GIANT CELL TUMOR LOCALIZED TYPE

Tenosynovial giant cell tumor localized type is also known as giant cell tumor of tendon sheath. It is well circumscribed benign lesion arising from hands and feet close to interphalangeal joints or synovium of tendon sheath.

- On the other hand, tenosynovial giant cell tumor diffuse type is known as pigmented villonodular tenosynovitis, which originates from articular space of knee or hip joints and soft tissue of wrists, thigh and feet in persons <40 years of age. Tenosynovial giant cell tumor diffuse type is more aggressive and tender than localized type.
- Histology of both localized and diffuse types is identical. It affects adults during fourth to sixth decades of life.
- Tenosynovial giant cell tumor localized type is treated by surgical excision. Recurrence may occur in 10% of cases. Forms of pigmented villonodular synovitis are given in Table 28.12.

Locations and Age Distribution

Tenosynovial giant cell tumor localized type is well circumscribed benign lesion arising from hands and feet close to interphalangeal joints or synovium of tendon sheath. It most often affects adults between 30 and 50 years of age.

Clinical Features

Patient presents with well circumscribed nodule in the interphalangeal joints of hands and feet in proximity to tendon sheath.

Surgical Pathology: Tenosynovial Giant Cell Tumor Localized Type

Gross Morphology

- Tenosynovial giant cell tumor localized type is well circumscribed and lobulated mass.
- Cut surface is whitish to variably yellow tan.

Light Microscopy

- Tenosynovial giant cell tumor localized type is composed of mononuclear cells with eosinophilic cytoplasm, osteoclast-like multinucleated giant cells and foamy histiocytes.
- Sometimes, cholesterol clefts may be demonstrated. Hemosiderin pigment may be identified (Fig. 28.16).

Differential Diagnosis

Tenosynovial giant cell tumor localized type should be differentiated from fibroma of tendon sheath.

Immunohistochemistry Technique

Mononuclear cells of tenosynovial giant cell tumor localized type show positivity for desmin and CD68. But immunohistochemistry is rarely used to establish diagnosis.

Markers	Expression
▪ Desmin	▪ Positive
▪ CD68	▪ Positive

JUVENILE XANTHOGRANULOMA

Juvenile xanthogranuloma is a self-limited benign histiocytic disorder, which arises from non-Langerhans histiocytes present in dermis or superficial cutis or both on head region; or deep soft tissue, viscera and eyes (iris).

Table 28.12 Forms of pigmented villonodular synovitis

Location and Types	Comments
Intra-articular location of pigmented villonodular synovitis	
Diffuse type	Diffuse involvement of joint synovium
Localized type	Localized (polypoid or nodular) joint synovial lesion
Extra-articular location of pigmented villonodular synovitis	
Diffuse type	Diffuse multifocal involvement of extra-articular synovial membrane (tendon)
Localized type	Localized extra-articular nodular lesion, also referred to as giant cell tumor of the tendon sheath

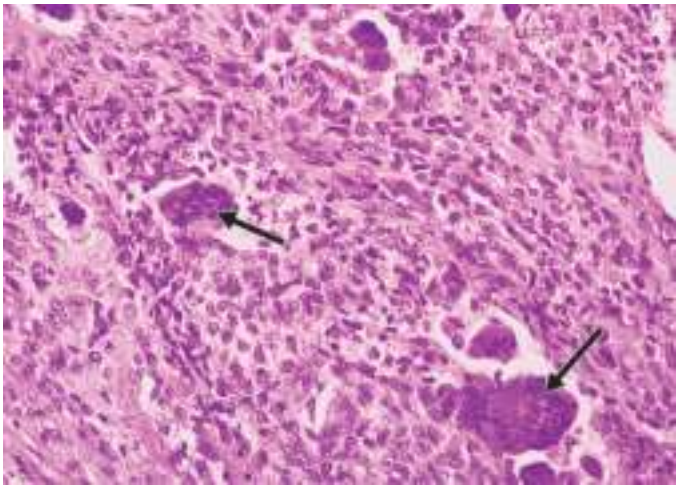

Fig. 28.16: Giant cell tumor of tendon sheath. Tenosynovial giant cell tumor localized type is composed of mononuclear cells with eosinophilic cytoplasm, osteoclast-like multinucleated giant cells and foamy histiocytes. Sometimes, cholesterol clefts may be demonstrated. Hemosiderin pigment may be identified (arrows) (400X).

Locations and Age Distribution

Most common sites of juvenile xanthogranuloma are dermis or superficial cutis or both on head region; or deep soft tissue, viscera and eyes (iris). Disorder usually affects infants and children. Cutaneous lesions have slight male predominance. Extracutaneous lesions are demonstrated in 4% of cases. Congenital juvenile xanthogranuloma is demonstrated in 10–35% of cases. Most lesions resolve by the age of five years.

Clinical Features

Most patients remain asymptomatic. Patient presents with multiple slightly raised skin papules on head region, or ocular lesion involving iris. Approximately 50% of patients with systemic involvement are accompanied by cutaneous involvement.

Surgical Pathology: Juvenile Xanthogranuloma

Gross Morphology

Juvenile xanthogranuloma is red yellow or brown papule or nodule measuring ≤1.5 cm in dimeter.

Light Microscopy

- **Cutaneous juvenile xanthogranuloma:** It is composed of histiocytes laden with lipid, eosinophils and Touton multinucleated giant cells in variable proportions. Fibrosis is demonstrated in long-standing cases.
- **Deep-seated juvenile xanthogranuloma:** It is more cellular neoplasm composed of monomorphic histiocytes laden with less lipid and a few Touton multinucleated giant cells.

Differential Diagnosis

Juvenile xanthogranuloma should be differentiated from dermatofibroma especially lipidized variant, Langerhans cell histiocytosis, mastocytosis, Spitz nevus and cutaneous xanthogranuloma.

Immunohistochemistry Technique

Juvenile xanthogranuloma shows positivity for CD68 (clones of KPI and PGM1), CD31, factor XIIIa, HAM56, HHF35, CD4, Ki-MIP, vimentin. It is negative for CD1a and S-100 protein.

Markers	Expression
CD68 (clones of KPI and PGM1)	Positive
CD31	Positive
Factor XIIIa	Positive
HAM56	Positive
HHF35	Positive
CD4	Positive
Ki-MIP	Positive
Vimentin	Positive
CD1a	Negative
S-100 protein	Negative

Prognosis and Treatment

Juvenile xanthogranuloma is self-limited benign disorder. Cutaneous, ocular lesions and systemic lesions are treated by surgical excision. Systemic corticosteroids can be used to shrink problematic visceral lesions.

XANTHOMA

Xanthoma represents a localized yellow lesion due to accumulation of lipid (cholesterol) within skin. It is associated with familial and secondary hyperlipidemia.

Locations and Age Distribution

- **Cutaneous xanthoma:** Lesions can be eruptive, plain and tuberous. Tuberous lesions present as nodules on the elbow, knee and buttock, associated with familial dysbetalipoproteinemia. These lesions resolve by treating underlying cause of hyperlipidemia. Disorder may occur in persons of any age.
- **Xanthoma in eyelid:** It is known as xanthelasma and not associated with hyperlipidemia. Xanthelasmas usually occur in persons older than 50 years.
- **Xanthoma in deep tissue:** It occurs in tendon sheath or synovium of fingers, wrist, and ankle (Achilles tendon) as a painless lesion and associated with hyperlipidemia. It may occur in persons of any age.
- **Xanthoma disseminatum:** Systemic lesions are demonstrated. Disorder occurs before the age of 25 years in 66% of cases.

Clinical Features

Patient presents with well circumscribed most often multiple masses in cutaneous regions, eyelid, deep tissues such as tendon sheath or synovium, elbow, knee and buttock regions.

Surgical Pathology: Xanthoma

Gross Morphology

Xanthoma is well circumscribed white or yellow to brown masses.

Light Microscopy

- Tuberous xanthoma and xanthogranuloma in tendons are composed of admixture of foamy macrophages, cholesterol clefts, foreign body of giant cells, lymphoid aggregates and fibrosis.
- Xanthelasma is predominantly of xanthogranuloma cells with little fibrosis.

Differential Diagnosis

Deep-seated xanthoma may be mistaken clinically for a sarcoma. However, histologic features and existence of hyperlipidemia are diagnostic of xanthogranuloma.

Prognosis and Treatment

Surgical excision of xanthoma is indicated in case of compromised joint function. Hyperlipidemia should be treated. Recurrence may occur unless hyperlipidemia is treated.

ATYPICAL FIBROXANTHOMA

Atypical fibroxanthoma is a low-grade superficial sarcoma that frequently presents as a red nodule or plaque on sun-exposed skin in the region of head and neck. Ultraviolet light appears to play a significant role since most lesions appear on the sun-exposed head and neck regions. Genetic factors are also linked to development of atypical fibroxanthoma. Other predisposing factors include trauma to the skin, radiation therapy and immunosuppression.

Locations and Age Distribution

Atypical fibroxanthoma almost occurs on sun-exposed skin in the region of head and neck. It affects elderly persons without sex predominance.

Clinical Features

Patient presents with small nodule <2 cm in diameter. Lesion may undergo ulceration.

Surgical Pathology: Atypical Fibroxanthoma

Gross Morphology

Atypical fibroxanthoma is solitary and small cutaneous nodule with or without ulceration measuring <2 cm in diameter.

Light Microscopy

- Atypical fibroxanthoma is composed of spindle to pleomorphic cells with hyperchromatic nuclei set in a variably collagenized matrix.
- Mononucleated and multinucleated tumor giant cells and mitoses including atypical mitoses are demonstrated. Solar elastosis of adjacent skin is present. Tumor necrosis is absent. Lesion is not extending into subcutis.

Differential Diagnosis

Atypical fibroxanthoma should be differentiated from spindle cell/sarcomatoid carcinoma, malignant fibrous histiocytoma, melanoma and spindle cell angiosarcoma (scalp region).

Immunohistochemistry Technique

Atypical fibroxanthoma shows positivity for CD99 and smooth muscle actin. It is negative for desmin, CD34, S-100 protein and cytokeratins.

Markers	Expression
CD99	Positive (diffuse staining in 75%)
Smooth muscle actin	Positive (focal staining)
Desmin	Negative
CD34	Negative
S-100 protein	Negative
Cytokeratins	Negative

Prognosis and Treatment

Atypical fibroxanthoma is treated by surgical excision. Local recurrence may occur in lesion invading deep soft tissue. Metastasis may be observed in exceptional case.

PLEXIFORM FIBROHISTIOCYTIC TUMOR

Plexiform fibrohistiocytic tumor is a mesenchymal tumor with intermediate malignant potential. Tumor is composed of fibroblasts, myofibroblasts and histiocytes. Most common site of tumor is deep dermis or subcutis of upper and lower extremities. It exclusively affects children and young adults with female predominance.

Clinical Features

Patient presents with painless slow-growing relatively ill-defined lump measuring 3 cm in diameter.

Surgical Pathology: Plexiform Fibrohistiocytic Tumor

Gross Morphology

Plexiform fibrohistiocytic tumor is multinodular firm and poorly defined dermal or subcutaneous mass measuring ≤3 cm in diameter.

Light Microscopy

- Plexiform fibrohistiocytic tumor is composed of fibroblasts, myofibroblasts and histiocytes arranged in short fascicular pattern. Multinucleated giant cells may be present.
- Spindle cell component branches out into the soft tissue and creating a plexiform or infiltrative architecture.
- Nuclear atypia, mitotic activity and necrosis are absent in the tumor. Vascular invasion may be demonstrated in minority of cases.

Differential Diagnosis

Plexiform fibrohistiocytic tumor should be differentiated from giant cell tumor of soft tissue, granulomatous inflammation, fibrous histiocytoma and fibromatosis.

Immunohistochemistry Technique

Plexiform fibrohistiocytic tumor shows positivity for vimentin, smooth muscle actin and CD68. It is negative for NK1/C.

Markers	Expression
Vimentin	Positive (spindle cell component)
Smooth muscle actin (SMA)	Positive (spindle cell component)
CD68	Positive (mononuclear cells and multinucleated osteoclasts like giant cells)
NK1/C	Negative

Prognosis and Treatment

Plexiform fibrohistiocytic tumor is treated by surgical excision. Local recurrence after marginal or incomplete surgical excision is demonstrated in 10–50% of cases. There is limited risk for metastases in the regional lymph nodes or distant organs. Metastasis may be demonstrated in the lymph node and lung in <1% of cases.

ANGIOMATOID FIBROUS HISTIOCYTOMA

Angiomatoid fibrous histiocytoma is a slow-growing tumor of intermediate malignant potential with a partially myxoid phenotype. Tumor occurs in the deep dermis and subcutis of extremities, trunk, head and neck. Most common sites of tumor are in the deep dermis and subcutis of extremities, trunk, head and neck in decreased frequency. Tumor may also originate from lymph node. Tumor affects children and young adults with mean age 20 years without sex predominance.

Clinical Features

Patient presents with painless lump in the deep dermis and subcutis of extremities, trunk, head and neck; and lymph node in decreased frequency.

Surgical Pathology: Angiomatoid Fibrous Histiocytoma

Gross Morphology

- Angiomatoid fibrous histiocytoma is a nodular cystic and hemorrhagic mass measuring 7–12 cm with median size >3 cm in diameter.
- Cut surface shows blood filled cystic spaces and red brown color due to hemosiderin deposit.

Light Microscopy

- Angiomatoid fibrous histiocytoma consists of a dense fibrous capsule with lymphoid infiltrate in the periphery of tumor.
- Tumor is composed of neoplastic cells with bland histoid to spindle cells arranged in short fascicles, whorls and sheets. Neoplastic cells contain hemosiderin deposits. Blood filled pseudovascular spaces are demonstrated in >50% of cases. Cellular atypia may be demonstrated in occasional tumor.

Differential Diagnosis

Angiomatoid fibrous histiocytoma should be differentiated from aneurysmal bone cyst, benign fibrous histiocytoma, metastatic tumor in lymph node, follicular dendritic tumor and rhabdomyosarcoma.

Immunohistochemistry Technique

Angiomatoid fibrous histiocytoma tumor cells show positivity for immunomarkers desmin, CD68, CD99 and epithelial membrane antigen (EMA). Tumor is negative for smooth muscle actin (SMA), myogenin, CD21, CD31, CD34, S-100 protein, HMB-45 and cytokeratins.

Markers	Expression
▪ Desmin	▪ Positive (50% cases)
▪ CD68	▪ Positive (50% cases)
▪ CD99	▪ Positive (50% cases)
▪ EMA	▪ Positive (40% cases)
▪ SMA	▪ Negative
▪ Myogenin	▪ Negative
▪ CD21	▪ Negative
▪ CD31	▪ Negative
▪ CD34	▪ Negative
▪ S-100 protein	▪ Negative
▪ HMB-45	▪ Negative
▪ Cytokeratins	▪ Negative

Molecular Genetic Alterations

Majority of cases with angiomatoid fibrous histiocytoma harbor one of three chromosomal translocations, i.e. t(12;16) (FUS-ATF1), t(12;22) (EWS:ATF1) and t(2;22) (EWS:CREB4).

Prognosis and Treatment

Angiomatoid fibrous histiocytoma is treated by wide surgical excision. Local recurrence is demonstrated in 2–10% of cases. It may metastasize to regional lymph nodes in 1% of cases.

SOFT TISSUE GIANT CELL TUMOR WITH LOW MALIGNANT POTENTIAL

Soft tissue giant cell tumor with low malignant potential is the counterpart of giant cell tumor of bone. It is now considered a fibrohistiocytic tumor of intermediate malignant potential according to recent 2020 WHO classification of soft tissue tumors.

Locations and Age Distribution

Soft tissue giant cell tumor with low malignant potential occurs as a multinodular mass in the skin or subcutis of the extremities. Tumor may also present as deep-seated mass in children. It most often affects young and middle-aged adults. It may also affect children.

Clinical Features

Patient presents with multinodular lump in dermis or subcutis of extremities. Children may present with deep-seated mass.

Surgical Pathology: Soft Tissue Giant Cell Tumor with Low Malignant Potential

Gross Morphology

- Soft tissue giant cell tumor with low malignant potential appears as small nodules in the dermis and subcutis measuring <5 cm in diameter.
- Cut surface shows foci of hemorrhage with gritty in consistency.

Light Microscopy

- Histology of soft tissue giant cell tumor with low malignant potential is identical to giant cell tumor of bone.
- Tumor is composed of bland mononuclear cells, spindle cells admixed with osteoclast-like giant cells. Spindle cells are arranged in short fascicular pattern. Mitoses without cytologic atypia are demonstrated in the tumor. Vascular invasion by neoplastic cells is demonstrated.

- Other histologic changes present in the tumor include metaplastic bone, vascular spaces, proliferation of fibroblasts and histiocytes and rarely cartilage.

Differential Diagnosis

Soft tissue giant cell tumor with low malignant potential should be differentiated from osteoclast-rich sarcomas, carcinoma, melanoma, lymphomas, tenosynovial giant cell tumor and intravascular nodular fasciitis.

Immunohistochemistry Technique

Soft tissue giant cell tumor with low malignant potential shows positivity for CD68 and smooth muscle actin (SMA). It is negative for immunomarkers CD31, CD34, S-100 protein, desmin and cytokeratins.

Markers	Expression
▪ CD68	▪ Positive (100% cases)
▪ SMA	▪ Positive (75% cases)
▪ CD31	▪ Negative
▪ CD34	▪ Negative
▪ S-100 protein	▪ Negative
▪ Desmin	▪ Negative
▪ Cytokeratins	▪ Negative

Prognosis and Treatment

Soft tissue giant cell tumor with low malignant potential is treated by surgical excision with wide tumor-free margins. Local recurrence may be demonstrated due to incomplete surgical excision of tumor in 10–50% of cases. Distant metastasis is demonstrated in <1% of cases.

UNDIFFERENTIATED PLEOMORPHIC SARCOMA

Undifferentiated pleomorphic sarcoma is the term designated for those tumors, in which melanotic and lymphoid differentiation have been excluded. Histologic variants of undifferentiated pleomorphic sarcoma include: (a) undifferentiated pleomorphic sarcoma with giant cells (so-called giant cell malignant fibrous histiocytoma) and (b) undifferentiated pleomorphic sarcoma with prominent inflammation (known as inflammatory malignant fibrous histiocytoma).

Locations and Age Distribution

- Undifferentiated pleomorphic sarcoma with giant cells variant (so-called giant cell malignant fibrous histiocytoma) occurs in deep soft tissue of extremities and trunk. It affects middle and advanced aged persons with male predominance.
- Undifferentiated pleomorphic sarcoma with prominent inflammation variant (known as inflammatory malignant fibrous histiocytoma) occurs in the retroperitoneum. This histologic variant is now considered as inflammatory form of dedifferentiated liposarcoma.

Clinical Features

Patient presents with deep-seated lump in extremities and trunk. Rapidly growing tumor is painful.

Surgical Pathology: Undifferentiated Pleomorphic Sarcoma

Gross Morphology

- Undifferentiated pleomorphic sarcoma is well circumscribed tumor measuring 5–15 cm in diameter.
- Cut surface shows areas of hemorrhage, myxoid and/or necrosis.

Light Microscopy

- Cellularity of undifferentiated pleomorphic sarcoma is variable. Tumor is composed of admixture of spindle cells and pleomorphic cells with nuclear atypia, multilobulated nuclei, mitoses, tumor giant cells, histiocytic-like foamy cells and areas of necrosis. Extracellular matrix may be collagenous to myxoid.
- Undifferentiated pleomorphic sarcoma with giant cells variant shows numerous osteoclasts like multinucleated giant cells.
- Undifferentiated pleomorphic sarcoma with prominent inflammation variant shows numerous xanthogranuloma cells, neutrophils and few tumor cells.

Differential Diagnosis

- Undifferentiated pleomorphic sarcoma should be differentiated from metastatic carcinoma or melanoma, lymphoma, dedifferentiated liposarcoma in retroperitoneum, rhabdomyosarcoma, leiomyosarcoma, malignant tumor of peripheral nerve sheath tumor and high-grade myxofibrosarcoma.
- Undifferentiated pleomorphic sarcoma with giant cells variant should be differentiated from giant cell-rich extraskeletal osteosarcoma, giant cell-rich leiomyosarcoma and giant cell tumor of soft tissue.
- Undifferentiated pleomorphic sarcoma with prominent inflammation variant should be differentiated from lymphoma, inflammatory myoblastic tumor and abscess.

Immunohistochemistry Technique

Undifferentiated pleomorphic sarcoma shows positivity for smooth muscle actin. It is negative for desmin, h-caldesmon, S-100 protein, epithelial membrane antigen and cytokeratins.

Markers	Expression
▪ Smooth muscle actin (SMA)	▪ Positive
▪ Desmin	▪ Negative
▪ h-caldesmon	▪ Negative
▪ S-100 protein	▪ Negative
▪ Epithelial membrane antigen (EMA)	▪ Negative
▪ Cytokeratins (CKs)	▪ Negative

Prognosis and Treatment

Undifferentiated pleomorphic sarcoma is treated by wide surgical excision followed by radiotherapy.

Adjuvant chemotherapy may be administered in selected young persons. Undifferentiated pleomorphic sarcoma with prominent inflammation variant shows a more indolent course. Five-year survival is observed in 30–50% of patients.

SMOOTH MUSCLE TUMORS

Smooth muscle tumors according to revised 2020 WHO classification of tumors are given in Table 28.13.

SOFT TISSUE LEIOMYOMA

Leiomyoma is a benign mesenchymal tumor with smooth muscle differentiation. Extra-uterine leiomyomas are classified according to their site of origin, i.e. pilar leiomyoma, genital leiomyoma, vascular leiomyoma, deep soft tissue leiomyoma and retroperitoneal leiomyoma. Diagnostic criteria of leiomyomas in non-gynecologic sites include minimal cytologic atypia, absence of coagulative necrosis, and mitoses not more than 1 per 50 high power fields. Complete surgical excision of leiomyoma is curative.

Locations, Age Distribution and Clinical Features

- **Pilar leiomyoma:** It is relatively a rare tumor, which arises from arrector pili smooth muscle is the subcutis region. Most common sites are extremities and trunk. Familial leiomyoma is associated with increased incidence of uterine leiomyoma and renal cell carcinoma. It affects adolescents and young adults without sex predominance. Patient presents with single or multiple painful red brown papules in the cutaneous regions of extremities and trunk regions.

Table 28.13 Smooth muscle tumors according to revised 2020 WHO classification of tumors

Smooth Muscle Tumors
Benign tumors
▪ Leiomyoma
• Genital leiomyoma
• Pilar leiomyoma
• Leiomyoma of deep soft tissue
• Vascular leiomyoma (angioleiomyoma)
• Leiomyoma of retroperitoneal region
Malignant tumors
▪ Leiomyosarcoma
• Leiomyosarcoma of deep soft tissue
• Cutaneous leiomyosarcoma
• Vascular leiomyosarcoma
• Leiomyosarcoma of peritoneum
• Epstein-Barr-associated smooth muscle tumor

- **Genital leiomyoma:** Tumor occurs in the dartos muscle in scrotum and deep muscles of vulva. It most often affects adults with female predominance. Patient presents with lump in labia majora most often misinterpreted as Bartholin cyst.
- **Deep soft tissue leiomyoma:** Tumor is extremely rare. Most common site of tumor is extremities. It affects young and middle-aged persons without sex predominance. Patient presents with solitary nodular lump in the extremities of young and middle-aged persons.
- **Vascular leiomyoma (angioleiomyoma):** Tumor most often occurs in the subcutis region. Rarely, it may occur in dermis.
  - **Solid variant of vascular leiomyoma:** It affects middle-aged to elderly adults with female predominance. Patient with solid variant of vascular leiomyoma presents with painful solitary nodule in the extremities.
  - **Venous variant of vascular leiomyoma:** It occurs in adults with male predominance. Patient with venous variant of vascular leiomyoma presents with painless lump in the head region.
- **Retroperitoneal leiomyoma:** Tumor is relatively common in the retroperitoneal region in perimenopausal women. It also occurs in retroperitoneal region in males. Patient presents with painful lump in the retroperitoneal region.

Surgical Pathology: Soft Tissue Leiomyoma

Gross Morphology

- Leiomyoma is a well circumscribed to infiltrative tumor with rubbery texture.
- Cut surface shows gray white and whorled surface. Areas of hemorrhage, cystic change, myxoid change and calcification may be demonstrated in the tumor.

Light Microscopy

- **Pilar leiomyoma:** Tumor may be infiltrative or well-circumscribed. Tumor is composed of bundles and fascicles of well-differentiated smooth muscle cells containing eosinophilic cytoplasm and blunt ended cigar-shaped nuclei arranged in an irregular manner in the reticular dermis (Fig. 28.17).
- **Genital leiomyoma, deep soft tissue leiomyoma, vascular leiomyoma (angioleiomyoma) and retroperitoneal leiomyoma:** Tumor is well-circumscribed to focally infiltrative having identical features in these regions.
- **Mitotic index in extra-uterine leiomyomas:** All type leiomyomas except vulvar leiomyoma show no significant nuclear atypia and mitotic index ≤1 mitosis per 50 high power fields. Vulvar leiomyoma may show up to 3 mitoses per 50 high power fields or coagulative necrosis in the tumor.

Differential Diagnosis

- Pilar leiomyoma should be differentiated from benign fibrous histiocytoma.
- Genital leiomyoma should be differentiated from cellular angiofibroma and hyperplasia of scrotal smooth muscle tumor.
- Deep soft tissue leiomyoma should be differentiated from schwannoma and leiomyosarcoma.
- Vascular leiomyoma (angioleiomyoma) should be differentiated from glomangiopericytoma.
- Retroperitoneal leiomyoma should be differentiated from leiomyosarcoma and cellular leiomyoma.

Immunohistochemistry Technique

Tumor cells leiomyoma shows positivity for immunomarkers desmin, smooth muscle actin, muscle-specific actin, calponin, h-caldesmon and smooth muscle myosin heavy chain.

Markers	Expression
Desmin	Positive
Smooth muscle actin (SMA)	Positive
Muscle-specific actin (MSA)	Positive
Calponin	Positive
h-caldesmon	Positive
Smooth muscle myosin heavy chain (SMMHC)	Positive

Prognosis and Treatment

Complete surgical excision of extra-uterine leiomyoma is curative.

SOFT TISSUE LEIOMYOSARCOMA

Extra-uterine leiomyosarcoma is a malignant mesenchymal tumor with smooth muscle differentiation. It accounts for 10% of soft tissue sarcomas. Depending on the site of origin of tumor, extra-uterine leiomyosarcomas are categorized into various groups: cutaneous leiomyosarcoma, deep soft tissue leiomyosarcoma, vascular leiomyosarcoma, retroperitoneal leiomyosarcoma, and EBV (Epstein-Barr virus) infection associated smooth muscle tumors.

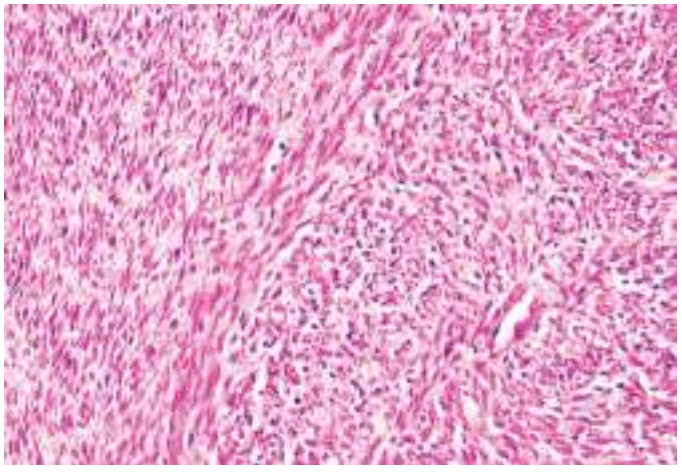

Fig. 28.17: Soft tissue leiomyoma. Pilar leiomyoma may be infiltrative or well circumscribed. Tumor is composed of bundles and fascicles of well-differentiated smooth muscle cells containing eosinophilic cytoplasm and blunt ended cigar-shaped nuclei arranged in an irregular manner in the reticular dermis (400X).

Locations and Age Distribution

- **Cutaneous leiomyosarcoma:** Tumor arises from the arrector pili muscle of skin on the extensor surface of extremities. It may also arise from dartos muscle of scrotum. It most often affects young adults with male predominance. Patient presents with slow growing lumps in these regions.
- **Deep soft tissue leiomyosarcoma:** Tumor occurs in the lower extremities. It most often affects middle-aged persons without sex predominance. Patient presents with slow growing lumps in these regions.
- **Vascular leiomyosarcoma:** Tumor arises from inferior vena cava (IVC) and large veins of the lower extremities. It most often affects adults with female predominance. Patient presents with tumor obstructing inferior vena cava and edema of lower extremities.
- **Retroperitoneal leiomyosarcoma:** Tumor originates from retroperitoneum. It most often affects adults with female predominance. Patient presents with slow growing lumps in these regions.
- **Epstein-Barr virus (EBV) infection associated smooth muscle tumors:** Immunocompromised AIDS patients and patients undergoing organ transplantation may acquire EB virus infection and develop multifocal smooth muscle cell tumors in endocrine glands, central nervous system, lung and liver. These can affect all age groups without sex predominance. These are slow growing tumor. These may be detected as incidental finding related to surveillance.

Surgical Pathology: Soft Tissue Leiomyosarcoma

Gross Morphology

- Leiomyosarcoma is poorly circumscribed fleshy red-tan.
- Cut surface shows areas of necrosis, cystic areas myxoid change (Fig. 28.18A).

Light Microscopy

Mitotic index in leiomyosarcoma is >4 per high power fields.

- **Cutaneous leiomyosarcoma:** Tumor is well to moderately differentiated and composed of atypical spindle cells and brisk mitoses. It can be either well-differentiated of diffusely infiltrative.
- **Deep soft tissue leiomyosarcoma:** Tumor is moderately differentiated and composed of atypical spindle cells arranged intersecting fascicles and brisk mitoses. Mitotic index is as low as 1 per 50 high power fields.

- **Vascular leiomyosarcoma:** Tumor is well to poorly differentiated and highly cellular with areas of necrosis. Cytoplasmic and perinuclear vacuolation are demonstrated in the neoplastic cells. Extensive myxoid change is uncommon in the tumor.
- **Retroperitoneal leiomyosarcoma:** Tumor is composed of spindle cells arranged in intersecting fascicles exhibiting a variable degree of cytologic atypia, mitotic activity and necrosis. Areas of cytoplasmic vacuolation in neoplastic cells are frequent (Fig. 28.18B).
- **EBV infection associated smooth muscle tumor:** Tumor is composed of dual population of well-differentiated spindle cells and small primitive round cells with prominent lymphocytic infiltrate. Areas of necrosis are uncommon.

Differential Diagnosis

- Leiomyosarcoma should be differentiated from spindle cell tumors, i.e. leiomyoma, gastrointestinal stromal tumors, cellular schwannoma and undifferentiated high-grade pleomorphic sarcoma. Immunohistochemistry plays important role to establish diagnosis.
- Leiomyosarcoma shows positivity for desmin, smooth muscle actin, muscle-specific actin, calponin, h-caldesmon, smooth muscle myosin heavy chain and EBV-RNA.
- Leiomyosarcoma has more cytologic atypia, mitotic index and areas of necrosis than leiomyoma.
- Unlike leiomyosarcoma, gastrointestinal stromal tumors show positivity for CD117. Schwannoma shows positivity for S-100 protein.
- Retroperitoneal leiomyosarcoma is very aggressive tumor with metastatic potential and poor prognosis.

Immunohistochemistry Technique

Leiomyosarcoma shows positivity for desmin, smooth muscle actin, muscle-specific actin, calponin, h-caldesmon, smooth muscle myosin heavy chain and EBV-RNA.

Markers	Expression
Desmin	Positive
Smooth muscle actin	Positive
Muscle-specific actin	Positive
Calponin	Positive
h-caldesmon	Positive
Smooth muscle myosin heavy chain	Positive
EBV-RNA	Positive

Prognosis and Treatment

Leiomyosarcoma is treated by wide surgical excision and radiotherapy. Chemotherapy is administered for metastatic disease.

SKELETAL MUSCLE TUMORS

Skeletal muscle tumors are classified into benign (rhabdomyoma) and malignant (rhabdomyosarcoma). Rhabdomyosarcoma affects children and adults. Accurate subclassification of rhabdomyosarcoma is essential in view of prognostic implications. Skeletal muscle tumors according to revised 2020 WHO classification of tumors are given in Table 28.14.

Fig. 28.18A: Leiomyosarcoma in retroperitoneal region. Primary leiomyosarcoma arises in the retroperitoneal space, but not from the retroperitoneal organs. Cut surface reveals poorly demarcated tumor having variegated appearance with areas of hemorrhage. (*Courtesy*: Department of Pathology, Sher-E-Kashmir Institute of Medical Sciences, Srinagar, Jammu & Kashmir.)

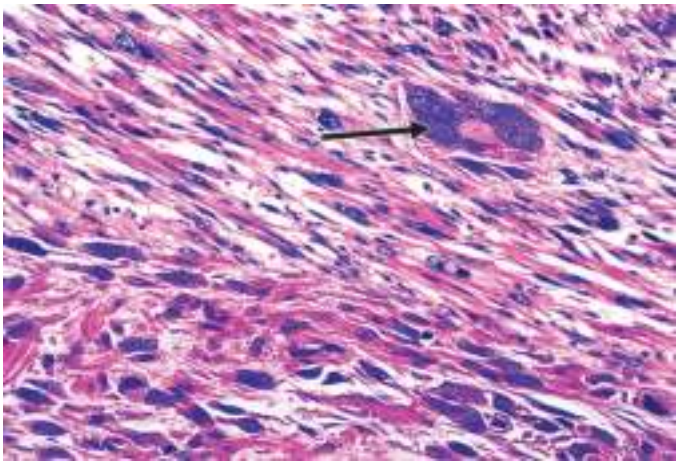

Fig. 28.18B: Leiomyosarcoma in retroperitoneal region. Tumor is composed of spindle cells arranged in intersecting fascicles exhibiting a variable degree of cytologic atypia, mitotic activity and necrosis. Areas of cytoplasmic vacuolation in neoplastic cells are frequent (arrow) (400X).

RHABDOMYOMA

Rhabdomyoma is a rare mesenchymal tumor. It is classified into cardiac and noncardiac types. Depending on the degree of differentiation, noncardiac rhabdomyoma is further categorized into adult rhabdomyoma, fetal rhabdomyoma, and genital rhabdomyoma. Genital rhabdomyoma is well-differentiated tumor. It is difficult to differentiate rhabdomyoma and rhabdomyosarcoma. Cardiac rhabdomyoma is discussed in Chapter 16. Noncardiac rhabdomyoma is treated by surgical excision.

Table 28.14 Skeletal muscle tumors according to revised 2020 WHO classification of tumors

Skeletal Muscle Tumors
Benign tumors
▪ Rhabdomyosarcoma • Adult rhabdomyosarcoma • Fetal rhabdomyosarcoma • Genital rhabdomyosarcoma
Malignant tumors
▪ Embryonal rhabdomyosarcoma • Conventional embryonal rhabdomyosarcoma • Spindle cell rhabdomyosarcoma (pediatric) • Botryoid rhabdomyosarcoma • Anaplastic rhabdomyosarcoma ▪ Alveolar rhabdomyosarcoma including solid alveolar rhabdomyosarcoma ▪ Pleomorphic rhabdomyosarcoma ▪ Spindle cell/sclerosing rhabdomyosarcoma (adult)

Locations and Age Distribution

Most common sites of adult and fetal rhabdomyoma are head and neck regions, mucosal surface of oral cavity, larynx and pharynx.

- **Adult rhabdomyoma:** Tumor is multinodular or even multicentric. It most often affects adults. Mean age is 60 years with male predominance.
- **Fetal rhabdomyoma:** Tumor may be associated with nevoid basal cell carcinoma syndrome. It affects children. Median age is 4 years. It may also affect adults.
- **Genital rhabdomyoma:** Tumor resembles a benign polyp in vagina. It exclusively affects women between 30–48 years of age.

Clinical Features

Patient presents with mass and obstruction with signs and symptoms related to location of tumor.

Surgical Pathology: Rhabdomyoma

Gross Morphology

- **Adult rhabdomyoma:** Tumor is well delineated, nodular mass measuring 1.5–8 cm in diameter. Cut surface is glistening.
- **Fetal rhabdomyoma:** Tumor is also well delineated solitary mass measuring 1–13 cm in diameter. Cut surface is more glistening than adult rhabdomyoma.

Light Microscopy

- **Adult rhabdomyoma:** Tumor is composed of lobules of closely packed large polygonal cells with abundant eosinophilic granular/or vacuolated cytoplasm and vesicular nuclei. Cell outlines are well defined. Intercellular stroma is usually scant. Mitotic figures are absent.
- **Fetal rhabdomyoma:** Tumor has two histologic variants: (a) classic immature fetal rhabdomyoma, and (b) intermediate fetal rhabdomyoma. Classic immature fetal rhabdomyoma is composed of primitive spindle cells, myotubules and myxoid stroma. Intermediate fetal rhabdomyoma is composed of numerous spindled rhabdomyoblasts arranged in fascicular pattern. Mitoses are absent in both histologic variants.
- **Genital rhabdomyoma:** Tumor is composed of rhabdomyoblasts haphazardly arranged embedded in fibrous stroma.

Histochemistry

In adult rhabdomyoma, PAS stain demonstrates abundant glycogen in the cytoplasm of neoplastic cells. Masson trichrome or phosphotungstic acid hematoxylin (PTAH) stain shows striations/inclusions in the cytoplasm of neoplastic cells.

Differential Diagnosis

- Adult rhabdomyoma should be differentiated from granular cell tumor, crystal-storing histiocytes and alveolar soft part sarcoma.
- Fetal rhabdomyoma should be differentiated from embryonal rhabdomyosarcoma.
- Genital rhabdomyoma should be differentiated from vagina; stromal polyp and embryonal rhabdomyosarcoma.

Immunohistochemistry Technique

Rhabdomyoma shows always positivity for desmin, muscle-specific actin, MyoD1 and myoglobin.

Markers	Expression
▪ Desmin	▪ Positive
▪ Muscle-specific actin	▪ Positive
▪ MyoD1	▪ Positive
▪ Myoglobin	▪ Positive

EMBRYONAL RHABDOMYOSARCOMA

Embryonal rhabdomyosarcoma is a primitive soft tissue sarcoma showing phenotypic and variable degree of embryonic skeletal muscle differentiation. Histologic variants of embryonal rhabdomyosarcoma include conventional, botryoid, spindle cell and anaplastic types.

Locations and Age Distribution

Embryonal rhabdomyosarcoma affects children during 5–15 years of age with male predominance.

- **Conventional embryonal rhabdomyosarcoma:** Most common sites of tumor are orbit, eyelid, oropharynx, parotid gland, middle ear, auditory canal, nose, paranasal sinuses, tongue and cheek.
- **Botryoid rhabdomyosarcoma:** Most common sites of tumor are wall of hollow organs or beneath mucosal lining of urinary bladder, vagina, nasopharynx and middle ear. Cystoscopy shows grape-like polypoidal masses in the urinary bladder.
- **Spindle cell rhabdomyosarcoma:** It occurs in the scrotal region.

Clinical Features

Patient presents with painful or painless mass, obstruction and/or bleeding depending on the site of involvement.

Surgical Pathology: Embryonal Rhabdomyosarcoma

Gross Morphology

- **Embryonal rhabdomyosarcoma:** It is poorly circumscribed fleshy tumor measuring 1–32 cm in diameter.
- **Botryoid rhabdomyosarcoma:** It resembles cluster of grapes.
- **Spindle cell rhabdomyosarcoma:** It is relatively firm and more fibrous in consistency.

Light Microscopy

- **Conventional embryonal rhabdomyosarcoma:** Tumor is composed of variable density neoplastic cells ranging from undifferentiated to classic rhabdomyoblasts arranged in sheets. Neoplastic cells contain round eccentric nuclei and eosinophilic cytoplasm. Interstitial matrix may be sparse or abundant, and myxoid in nature (Fig. 28.19).
- **Botryoid rhabdomyosarcoma:** Tumor is composed of round to oval cells admixed with spindle cells in loose myxoid stroma. A cambium layer of tightly packed undifferentiated neoplastic cells is demonstrated beneath mucosal lining (Fig. 28.20).
- **Spindle cell rhabdomyosarcoma:** Tumor is composed of spindle cells with eosinophilic cytoplasm, cigar-shaped blunt ended nuclei. Tumor contains >50% of spindle cells are arranged in whorls, fascicles and storiform pattern.
- **Anaplastic rhabdomyosarcoma:** Tumor is composed of anaplastic cells with hyperchromatic nuclei and numerous mitoses, the size of nuclei three times larger than the surrounding cells. Anaplastic cells may be arranged in diffuse or multifocal pattern.

Differential Diagnosis

- Embryonal rhabdomyosarcoma is a blue round cell tumor. It should be differentiated from other blue round cell tumors, e.g. Ewing sarcoma/primitive neuroectodermal tumor (PNET), neuroblastoma, nephroblastoma, desmoplastic small round cell tumor, small cell synovial sarcoma, lymphoma, rhabdoid tumor, rhabdomyoma and alveolar rhabdomyosarcoma.
- Spindle cell variant of embryonal rhabdomyosarcoma should be differentiated from leiomyosarcoma, myofibromatosis and infantile fibromatosis.

Immunohistochemistry Technique

- Embryonal rhabdomyosarcoma shows positivity for desmin, muscle-specific actin (MSA), myogenin and α-sarcomere actin.
- Desmin is universal immunohistochemical marker of smooth and striated muscle. Its expression in rhabdomyoblasts is variable.
- Muscle-specific actin (MSA) is also universal immunohistochemical marker of smooth and striated muscle.
- MyoD1 and myogenin are transcriptional factors specific to striated muscle. These immunomarkers are applied to differentiate rhabdomyosarcoma (positive for immunohistochemical markers) from leiomyosarcoma (negative for immunohistochemical markers). Embryonal rhabdomyosarcoma shows focal positivity.

Markers	Expression
Desmin	Positive (cytoplasmic staining)
Muscle-specific actin (MSA)	Positive
MyoD1 (specific immunohistochemical markers for striated muscles)	Positive (nuclear staining)
Myogenin (specific immunohistochemical markers for striated muscles)	Positive (nuclear staining)
PAX3-FOXO1A fusion transcript	Absent
PAX7-FOXO1A fusion transcript (better prognosis)	Absent

PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts are demonstrated in alveolar rhabdomyosarcoma. On the other hand, embryonal rhabdomyosarcoma lacks these PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts.

Molecular Genetic Alterations

Embryonal rhabdomyosarcoma does not show consistent cytogenetic abnormality. Extra copies of chromosomes 2, 8 and 13 are frequent. Allelic loss in the chromosomal region 11p15 has also been reported.

Prognosis and Treatment

- Embryonal rhabdomyosarcoma is treated by surgery, chemotherapy and radiotherapy. It may metastasize to lungs and lymph nodes.

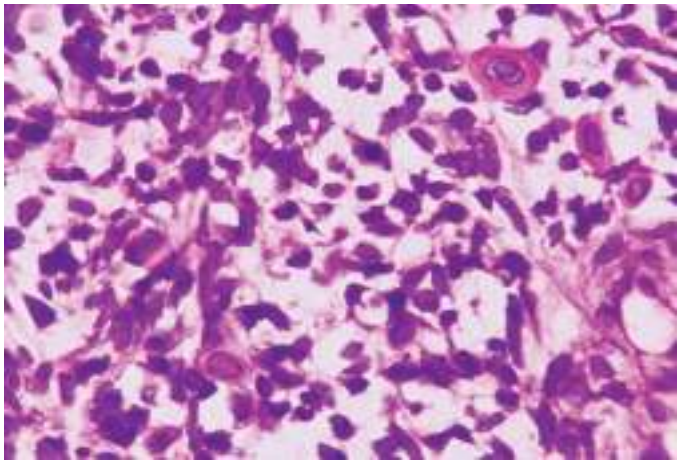

Fig. 28.19: Conventional embryonal rhabdomyosarcoma. Tumor is composed of variable density neoplastic cells ranging from undifferentiated to classic rhabdomyoblasts arranged in sheets. Neoplastic cells contain round eccentric nuclei and eosinophilic cytoplasm. Interstitial matrix may be sparse or abundant, and myxoid in nature (400X).

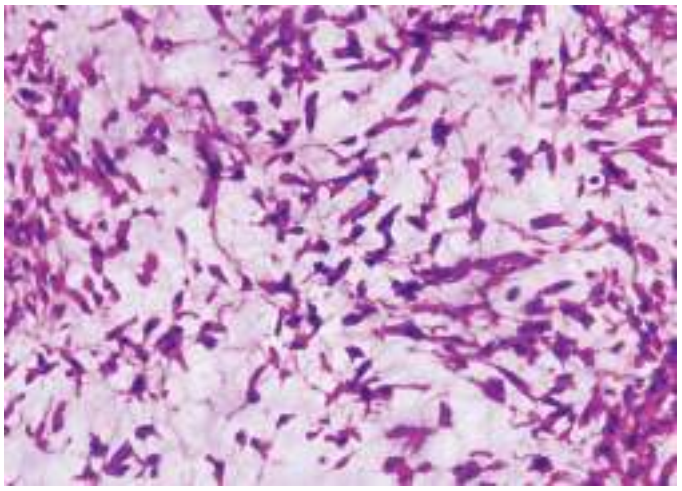

Fig. 28.20: Botryoid rhabdomyosarcoma. Tumor is composed round to oval cells admixed with spindle cells in loose myxoid stroma. A cambium layer of tightly packed undifferentiated neoplastic cells is demonstrated beneath mucosal lining (400X).

- Botryoid rhabdomyosarcoma and spindle cell rhabdomyosarcoma in paratesticular region have good prognosis in >90% of cases.
- Conventional embryonal rhabdomyosarcoma and spindle cell rhabdomyosarcoma in non-paratesticular region have intermediate prognosis in >70% of cases.
- Embryonal rhabdomyosarcoma in head and neck, orbit and genitourinary regions have better prognosis.

ALVEOLAR RHABDOMYOSARCOMA

Alveolar rhabdomyosarcoma is a high-grade round cell sarcoma, which shows alveolar and solid growth patterns with variable skeletal muscle differentiation. Most common sites of tumor are deep soft tissues of extremities. Other sites are paraspinal region, perineal region, head and neck, trunk and pelvis. It affects young adults during 2–25 years of age without sex predominance.

Clinical Features

Patient presents with rapidly growing painless lump in deep soft tissues of extremities, paraspinal region, perineal region, head and neck, trunk and pelvis. Other signs and symptoms, i.e. compression and obstruction depend on location of tumor.

Surgical Pathology: Alveolar Rhabdomyosarcoma

Gross Morphology

- Alveolar rhabdomyosarcoma is fleshy tumor measuring 2–8 cm in diameter.
- Cut surface shows variable amount of fibrous tissue and hemorrhage.

Light Microscopy

Alveolar rhabdomyosarcoma is a round cell sarcoma. Histologic variants of alveolar rhabdomyosarcoma are conventional alveolar rhabdomyosarcoma and solid variant of alveolar rhabdomyosarcoma.

- **Conventional alveolar rhabdomyosarcoma:** Tumor is composed of large neoplastic cells with large nuclei, eosinophilic cytoplasm, showing rhabdomyoblastic differentiation admixed with multinucleated giant cells. Nests of neoplastic cells are separated by fibrovascular septa that separate nests of neoplastic cells. Neoplastic cells line or cover fibrovascular septa and tend to shed in a discohesive manner into the center of alveolar spaces. Rhabdomyoblasts occasionally show clear cytoplasm, anaplastic features or rhabdoid features (Fig. 28.21).
- **Solid variant of alveolar rhabdomyosarcoma:** Tumor poses diagnostic challenge as fibrovascular septa in the tumor are hardly demonstrated. Neoplastic cells lack discohesive growth pattern, but show identical cell morphology demonstrated in conventional alveolar rhabdomyosarcoma.

Fine Needle Aspiration Cytology

Alveolar rhabdomyosarcoma is composed of neoplastic cells dispersed individually and loosely cohesive nests. Most often, a striking uniformity of the round neoplastic cells is evident. Rhabdomyoblastic differentiation may be demonstrated.

Differential Diagnosis

- Alveolar rhabdomyosarcoma should be differentiated from Ewing sarcoma, desmoplastic round cell tumor, alveolar soft part sarcoma and poorly differentiated carcinoma. Immunohistochemistry plays important role to establish diagnosis.
- PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts are demonstrated in alveolar rhabdomyosarcoma. On the other hand, embryonal rhabdomyosarcoma lacks these PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts. Prognosis of alveolar rhabdomyosarcoma showing PAX7-FOXO1A fusion transcript is better than PAX3-FOXO1A fusion transcript.
- Ewing sarcoma/primitive neuroendocrine tumor (PNET) and desmoplastic round cell tumor show EWSR1 gene mutation.
- Poorly differentiated carcinoma shows positivity for cytokeratins but lacks immunoreactivity for desmin, myogenin, MyoD1 and muscle-specific actin (MSA).
- Alveolar soft part sarcoma also has alveolar pattern but lacks multinucleated giant cells. Tumor shows positivity for desmin, myogenin, MyoD1 and MSA. PAS-diastase stain shows characteristic crystalline cytoplasmic inclusions.

Immunohistochemistry Technique

- Alveolar rhabdomyosarcoma cells show positivity for desmin, myogenin, MyoD1 and muscle-specific actin (SMA). Myogenin expression is more diffuse in alveolar rhabdomyosarcoma than embryonal rhabdomyosarcoma.

- PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts are demonstrated in alveolar rhabdomyosarcoma. On the other hand, embryonal rhabdomyosarcoma lacks PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts. Prognosis of alveolar rhabdomyosarcoma showing PAX7- FOXO1A fusion transcript is better than PAX3-FOXO1A fusion transcript.

Markers	Expression
▪ Desmin	▪ Present (cytoplasmic staining)
▪ Myogenin	▪ Present (nuclear diffuse staining)
▪ MyoD1	▪ Present (nuclear staining)
▪ Muscle-specific actin (MSA)	▪ Present
▪ PAX3-FOXO1A fusion transcript	▪ Present
▪ PAX7-FOXO1A fusion transcript (better prognosis)	▪ Present

PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts are demonstrated in alveolar rhabdomyosarcoma. On the other hand, embryonal rhabdomyosarcoma lacks these PAX3-FOXO1A and PAX7-FOXO1A fusion transcripts.

Molecular Genetic Alterations

- About 60% of alveolar rhabdomyosarcomas demonstrate chromosomal translocation t(2;13)(q35;q14) resulting in formation of PAX3-FOXO1A fusion transcript.
- About 20% of alveolar rhabdomyosarcomas manifest chromosomal translocation t(1;3)(p36,q14) resulting in formation of X7-FOXO1A fusion transcript.

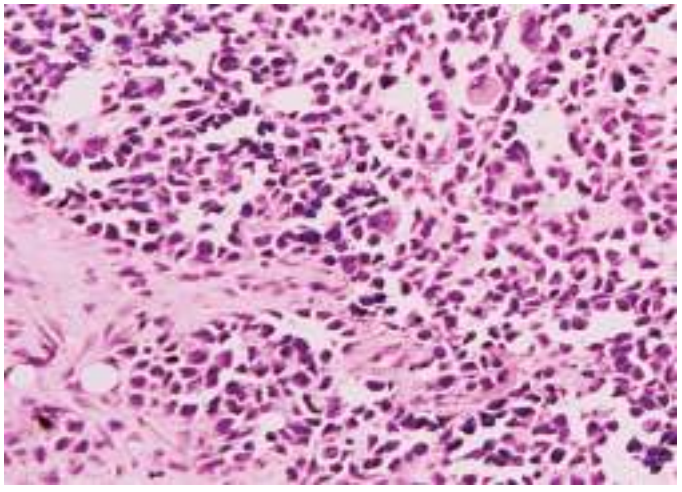

Fig. 28.21: Conventional alveolar rhabdomyosarcoma. Tumor is composed of large neoplastic cells with large nuclei, eosinophilic cytoplasm, showing rhabdomyoblastic differentiation admixed with multinucleated giant cells. Nests of neoplastic cells are separated by fibrovascular septa that separate nests of neoplastic cells. Neoplastic cells line or cover fibrovascular septa and tend to shed in a discohesive manner into the center of alveolar spaces. Rhabdomyoblasts occasionally show clear cytoplasm, anaplastic features or rhabdoid features (400X).

Prognosis and Treatment

No effective therapy is available to treat alveolar rhabdomyosarcoma. Prognosis depends on the stage of tumor. Tumor is more aggressive than embryonal rhabdomyosarcoma. It may metastasize to lungs and lymph nodes. Prognosis of patient with alveolar rhabdomyosarcoma showing PAX7-FOXO1A fusion transcript is better than PAX3-FOXO1A fusion transcript.

PLEOMORPHIC RHABDOMYOSARCOMA

Pleomorphic rhabdomyosarcoma is a high-grade soft tissue sarcoma, which most often displays skeletal muscle differentiation demonstrated by immunohistochemistry and electron microscopy. Most common site of tumor is deep soft tissues of lower extremities. It usually affects adult men during sixth and seventh decades of life.

Clinical Features

Patient presents with rapidly growing painful lump in the lower extremities.

Surgical Pathology: Pleomorphic Rhabdomyosarcoma

Gross Morphology

- Pleomorphic rhabdomyosarcoma is well circumscribed enclosed in pseudocapsule.
- Cut surface shows fleshy appearance with areas of hemorrhage and necrosis (Fig. 28.22).

Light Microscopy

- Pleomorphic rhabdomyosarcoma is composed of spindle to bizarre polygonal atypical neoplastic cells with abundant eosinophilic cytoplasm and vesicular hyperchromatic nuclei arranged in sheets, arranged in storiform pattern or without definite pattern.
- Atypical mitoses and necrosis are frequently demonstrated in the tumor. Neoplastic cells lack cross striations in the cytoplasm (Fig. 28.23).

Electron Microscopy

Electron microscopy demonstrates rudimentary sarcomere formation indicative of skeletal muscle differentiation.

Differential Diagnosis

Pleomorphic rhabdomyosarcoma should be differentiated from embryonal rhabdomyosarcoma, alveolar rhabdomyosarcoma, pleomorphic leiomyosarcoma, dedifferentiated liposarcoma and malignant triton tumor.

- Embryonal rhabdomyosarcoma and alveolar rhabdomyosarcoma can have focal areas of pleomorphic cells limited to a portion of tumor.
- Dedifferentiated liposarcoma shows positivity for MDM2.

- Malignant triton tumor is relatively rare aggressive neoplasm composed of both schwannoma cells and malignant rhabdomyoblasts. It classified as malignant peripheral nerve sheath tumor with rhabdomyosarcomatous differentiation.

Immunohistochemistry Technique

Pleomorphic rhabdomyosarcoma shows focal positivity for desmin, myogenin, MyoD1 and muscle-specific actin (MSA).

Markers	Expression
▪ Desmin	▪ Present (cytoplasmic staining)
▪ Myogenin	▪ Present (nuclear diffuse staining)
▪ MyoD1	▪ Present (nuclear staining)
▪ Muscle-specific actin	▪ Present

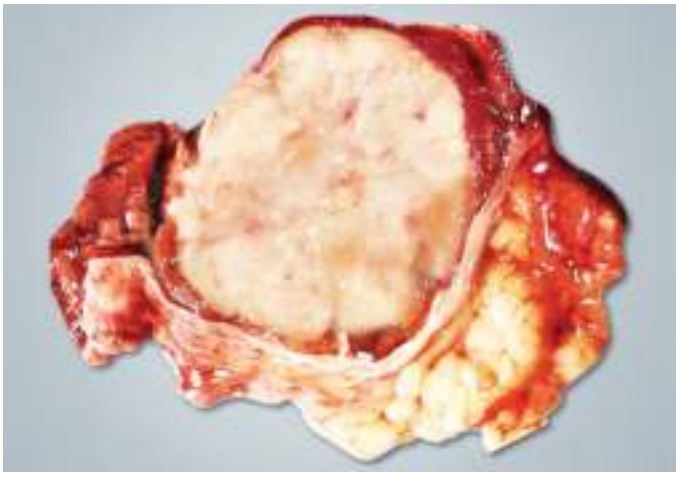

Fig. 28.22: Pleomorphic rhabdomyosarcoma. Tumor is well circumscribed enclosed in pseudocapsule. Cut surface shows fleshy appearance with areas of hemorrhage and necrosis.

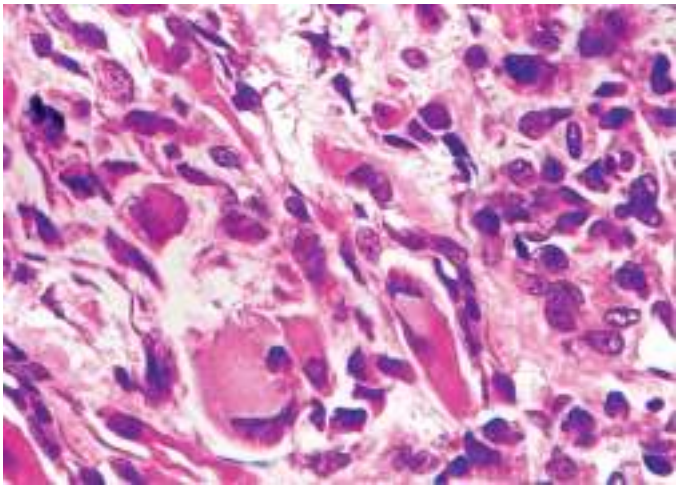

Fig. 28.23: Pleomorphic rhabdomyosarcoma. Tumor is composed of spindle to bizarre polygonal atypical neoplastic cells with abundant eosinophilic cytoplasm and vesicular hyperchromatic nuclei arranged in sheets, arranged in storiform pattern or without definite pattern. Mitoses and necrosis are frequently demonstrated in the tumor. Neoplastic cells lack cross striations in the cytoplasm (400X).

Prognosis and Treatment

Pleomorphic rhabdomyosarcoma has poor prognosis. Majority of patients die of disseminated disease especially to lungs within one year of diagnosis.

ADULT SCLEROSING RHABDOMYOSARCOMA

Recently, seven cases of rhabdomyosarcoma have been reported under the named 'adult sclerosing rhabdomyosarcoma' and pseudovascular rhabdomyosarcoma. It is not clear that this tumor either represent separate entity or unusual presentation of embryonal rhabdomyosarcoma. The tumor lacks cytogenetic changes, which are demonstrated in alveolar rhabdomyosarcoma such as chromosomal translocation t(2;13)(q35;q14) with formation of PAX3-FOXO1A fusion transcript and chromosomal translocation t(1;3)(p36,q14) resulting in formation of X7-FOXO1A fusion transcript. Differences among various histologic variants of rhabdomyosarcomas are given in Table 28.15.

Locations and Age Distribution

Most common sites of adult sclerosing rhabdomyosarcoma are extremities, orbit, nasopharynx, jaw and sacrum. It affects persons during 18–56 years of age.

Clinical Features

Patient presents with rapidly growing mass in extremities, orbit, nasopharynx, jaw and sacrum and related symptoms depending on location of tumor.

Surgical Pathology: Adult Sclerosing Rhabdomyosarcoma

Gross Morphology

- Adult sclerosing rhabdomyosarcoma is poorly circumscribed fleshy tumor.
- Cut surface is firm in consistency and showing fibrous appearance.

Light Microscopy

- Adult sclerosing rhabdomyosarcoma is composed of neoplastic cells arranged in nests, and abundant hyaline matrix resembling primitive osteoid or chondroid elements.
- Neoplastic cells may show focal areas of alveolar or pseudoalveolar pattern.

Immunohistochemistry Technique

Pleomorphic rhabdomyosarcoma shows focal positivity for desmin, myogenin, MyoD1 and muscle-specific actin (MSA).

Markers	Expression
▪ Desmin	▪ Present (cytoplasmic focal staining)
▪ Myogenin	▪ Present (nuclear diffuse staining)
▪ MyoD1	▪ Present (nuclear staining)
▪ Muscle-specific actin (MSA)	▪ Present

Table 28.15 Differences among various histologic variants of rhabdomyosarcomas

Histologic Variants	Age Group	Features	Immunohistochemistry
Embryonal rhabdomyosarcoma	Children	Some resemblance to developing muscle	Desmin, vimentin, MyoD1, myoglobin
Botryoid rhabdomyosarcoma	Children	Term botryoid (grape-like) polypoid mass with myxoid consistency in mucosa lined organs	Desmin, MyoD1, myoglobin
Alveolar rhabdomyosarcoma	Children and teenagers (10–20 years)	Located in extremities. Small cells arranged in sheets or nests separated by fibrous septa	Myogenin positivity
Pleomorphic rhabdomyosarcoma	6th–7th decades	Lower extremities (usually intramuscular)	Desmin, MyoD1, myogenin

Prognosis and Treatment

Adult sclerosing rhabdomyosarcoma is treated by surgical excision with wide margin. It has tendency to recur and metastasize.

GASTROINTESTINAL STROMAL TUMORS

Gastrointestinal stromal tumors (GISTs) according to revised 2020 World Health Organization are given in Table 28.16.

GASTROINTESTINAL STROMAL TUMORS (BENIGN/LOW-GRADE AND MALIGNANT)

Gastrointestinal stromal tumors are most common mesenchymal neoplasms that originate primarily in the wall of gastrointestinal tract. Clinical behavior ranges from benign/low-grade to malignant tumors. Malignant gastrointestinal stromal tumors can disseminate to liver and intra-abdominal structures resulting in fatal outcome. Instead of dividing GISTs into benign/low-grade to malignant; risk for progression to malignant is based on anatomic location, size and mitotic activity of gastrointestinal stromal tumors.

Locations and Age Distribution

Most common sites of gastrointestinal stromal tumor are stomach (60%), small intestine (30%), colon, appendix (10%), rectum and gallbladder. Rare sites of extra-gastrointestinal stromal tumors are omentum, mesentery, retroperitoneum and pelvis. It usually affects adult males with median age of 58 years. It can affect children and young adults in the setting of Carney's syndrome.

Table 28.16 Gastrointestinal stromal tumors according to revised 2020 World Health Organization

Gastrointestinal Stromal Tumors
▪ Benign tumors • Benign gastrointestinal stromal tumor
▪ Intermediate (locally aggressive) tumors • Gastrointestinal stromal tumor of uncertain malignant potential
▪ Malignant tumors • Malignant gastrointestinal stromal tumor

Clinical Features

Patient presents with anemia due to ulceration and bleeding of tumor, fatigue, pain abdomen and distension abdomen. GIST is detected as incidental finding in surgical specimens such as gastrectomy for gastric carcinoma. Carney's syndrome is characterized by Carney's triad (gastric GIST, extra-adrenal paraganglioma and pulmonary chondroma) in children.

Radiologic Findings

CT scan and MRI are performed to diagnose gastrointestinal stromal tumor. Endoscopy and ultrasonography are useful diagnostic techniques.

Surgical Pathology: Gastrointestinal Stromal Tumor

Gross Morphology

- Gastrointestinal stomal tumor is either unilobular or multilobular with smooth circumscribed borders. Ulceration is commonly demonstrated. Pedunculated lesion in serosa may be demonstrated.
- Cut surface is fleshy and cystic with areas of hemorrhage and necrosis.

Light Microscopy

Gastrointestinal stomal tumors (GISTs) are composed of either epithelioid or spindle-shaped cells. Majority of GISTs show combined cytomorphologic features of epithelioid and spindle-shaped cells. Cardinal diagnostic features of GISTs include lack of pleomorphism and low mitoses.

- **Epithelioid GIST:** Tumor is composed of epithelioid neoplastic cells with round-elongated nuclei, fine chromatin, inconspicuous nucleoli and abundant fibrillary cytoplasm; and arranged in either in sheets or nests.
- **Spindle cell GIST:** Tumor is composed of spindle-shaped neoplastic cells with round-elongated nuclei, fine chromatin, inconspicuous nucleoli, abundant fibrillary cytoplasm, and arranged in fascicular pattern. Spindle cell GIST may show nuclear palisading resembling schwannoma.

Electron Microscopy

Analysis of gastrointestinal stromal tumors shows lack of differentiation, i.e. incomplete differentiation or neuroaxonal differentiation.

Histochemistry

A small set of GISTs has acellular collagen bundles known as 'skeinoid fibers', that are demonstrated by PAS stain.

Differential Diagnosis

Gastrointestinal stromal tumor should be differentiated from leiomyoma, leiomyosarcoma, schwannoma, desmoid fibromatosis, malignant melanoma and carcinoma.

Immunohistochemistry Technique

Gastrointestinal stomal tumors show positivity for c-KIT (CD117), CD34 (75%), and smooth muscle actin (40%). c-KIT (CD117) staining is most often diffuse and strong membranous, cytoplasmic or paranuclear globular staining pattern. About 5% of GISTs are negative for c-KIT (CD117). Majority of these tumors are of epithelioid GISTs showing PDGFRA gene mutations.

Markers	Expression
▪ c-KIT (CD117)	▪ Positive (90%)
▪ CD34	▪ Positive (75%)
▪ Smooth muscle actin (SMA)	▪ Positive (40%)
▪ DOG1	▪ Positive
▪ BCL-2	▪ Positive
▪ Mitotic index	▪ High
▪ Desmin	▪ Negative
▪ S-100 protein	▪ Negative

Molecular Genetic Alterations

Loss of material from the short arm of chromosome 1 and monosomy for chromosome 14 and chromosome 22 is most common cytogenetic profile in gastrointestinal stromal tumor. Loss of material from the short arm of chromosomes 9 and 11 is less common and associated with aggressive clinical course.

Prognosis and Treatment

Majority of GISTs exhibit benign clinical course. Recurrence and metastases are demonstrated in 50% of cases. GISTs have tendency for intra-abdominal spread and metastasize to liver. Lymph node metastasis is extremely rare. Lungs are the most common site of metastasis outside the abdomen.

VASCULAR TUMORS OF SOFT TISSUE

Vascular tumors of soft tissue occur in the deep subfascial soft tissue and/or subcutis. Some vascular tumors occurring in the dermis may involve deep soft tissue. Vascular tumors according to revised 2020 World Health Organization classification of soft tissue tumors are given in Table 28.17. Kindly refer to Chapter 15 for vascular tumors discussed in details.

Table 28.17 Vascular tumors according to revised 2020 WHO classification of soft tissue tumors

Vascular Tumors

- Reactive vascular hyperplasia
  - Papillary endothelial hyperplasia
  - Pyogenic granuloma (lobular capillary hemangioma)
  - Bacillary angiomatosis
  - Glomeruloid hemangioma
- Benign tumors
  - Capillary hemangioma
  - Cavernous hemangioma
  - Hemangioma of subcutaneous/deep soft tissue
  - Angiomatosis
  - Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia)
  - Intramuscular hemangioma
  - Spindle cell hemangioma
  - Lymphangioma
- Intermediate (borderline) malignant tumors
  - Kaposiform hemangioendothelioma
  - Dabska-type (papillary intralymphatic angioendothelioma) and retiform hemangioendothelioma
  - Kaposi sarcoma
- Malignant tumors
  - Angiosarcoma
  - Epithelioid hemangioendothelioma

PERICYTIC/PERIVASCULAR TUMORS

Pericytic/perivascular tumors according to revised 2020 WHO classification of soft tissue tumors are given in Table 28.18. Pericytic/perivascular tumors may be benign, intermediate (borderline) and malignant.

HEMANGIOPERICYTOMA, SOLITARY FIBROUS TUMOR OF SOFT TISSUE AND RELATED LESIONS

According to revised 2020 World Health Organization of soft tissue tumors, hemangiopericytoma and solitary fibrous tumor of soft tissue are considered closely related. Hemangiopericytoma is a benign neoplasm showing uncertain line of differentiation (not true microvascular pericytes). Solitary fibrous tumor of soft tissue is also a benign tumor.

Locations and Age Distribution

Both hemangiopericytoma and solitary fibrous tumor of soft tissue affect adults without male predominance.

- Most common sites of hemangiopericytoma are retroperitoneum and abdomen.

Table 28.18 Pericytic/perivascular tumors according to revised 2020 WHO classification of soft tissue tumors

Pericytic/Perivascular Tumors
Benign tumors
▪ Hemangiopericytoma and related tumors • Giant cell angiofibroma • Lipomatous hemangiopericytoma ▪ Glomus tumor • Solid glomus tumor • Extra-tumoral perivascular sheathing by neoplastic glomus cells • Glomangiomyoma • Multiple glomus tumors • Glomus tumor with marked hemangiopericytic vessels • Symplastic glomus tumor • Glomus tumor with epithelioid cells • Glomus tumor with oncocytes • Glomus tumor with extensive myxoid change • Vascular invasion in otherwise benign glomus tumor • Glomangiomatosis ▪ Myopericytic family of tumors • Infantile myofibromatosis • Solitary myofibroma in infants and children • Myopericytoma • Glomangiopericytoma
Intermediate tumors
▪ Glomus tumor of uncertain malignant potential ▪ Atypical glomus tumor
Malignant tumors
Malignant glomus tumor/glomangiosarcoma

- Solitary fibrous tumor of soft tissue occurs in the thoracic cavity and abdomen.

Clinical Features

Patient presents with non-specific soft tissue mass and hypoglycemia induced by the tumor.

Surgical Pathology: Hemangiopericytoma and Solitary Fibrous Tumor

Gross Morphology

- Both hemangiopericytoma and solitary fibrous tumor of soft tissue are large well delineated soft tissue mass measuring 5–8 cm in superficial, deep soft tissue and mesothelial lining surface.
- Cut surface is gray white and firm in consistency.

Light Microscopy

- **Hemangiopericytoma:** Tumor is composed of staghorn vasculature with perivascular hyalinization, around which are present bland spindle to ovoid cells arranged without a definite pattern. Occasional tumor may demonstrate pseudovascular spaces lined by multinucleated giant cells and termed giant cell angiofibroma. It shows mitoses 1–3 per 10 high power fields.
- **Solitary fibrous tumor of soft tissue:** Histologic features are identical to hemangiopericytoma. In addition, tumor shows broad areas of collagenization and proliferation of bland fibroblastic spindle cells arranged without a definite pattern. Occasional tumor may demonstrate pseudovascular spaces lined by multinucleated giant cells and termed giant cell angiofibroma. It shows mitoses 1–3 per 10 high power fields.
- **Malignant hemangiopericytoma and malignant solitary fibrous tumor of soft tissue:** Tumors exhibit hypercellularity with pleomorphic neoplastic cells containing hyperchromatic nuclei, areas of necrosis and >4 mitoses per high power fields including atypical mitoses.

Differential Diagnosis

Both hemangiopericytoma and solitary fibrous tumor of soft tissue should be differentiated from synovial sarcoma, low-grade fibromyxoid sarcoma, malignant peripheral nerve sheath tumor, desmoplastic mesothelioma, well-differentiated liposarcoma and giant cell fibroblastoma (giant cell rich hemangiopericytoma and solitary fibrous tumor of soft tissue).

Immunohistochemistry Technique

Both hemangiopericytoma and solitary fibrous tumor of soft tissue neoplastic cells show positivity for CD34, CD99, epithelial membrane antigen (EMA), BCL-2 and smooth muscle actin. These are negative for desmin, CD117 and cytokeratins.

Markers	Expression
▪ CD34	▪ Positive (90–95%)
▪ CD99	▪ Positive (70%)
▪ Epithelial membrane antigen (EMA)	▪ Positive (33%)
▪ BCL-2	▪ Positive (33%)
▪ Smooth muscle actin	▪ Positive (33%)
▪ Desmin	▪ Negative
▪ CD117	▪ Negative
▪ Cytokeratins	▪ Negative

Prognosis and Treatment

Both hemangiopericytoma and solitary fibrous tumor of soft tissue are treated by wide surgical excision.

- Tumors with uncertain malignant potential may metastasize in occasional case.
- Malignant hemangiopericytoma and malignant solitary fibrous tumor of soft tissue metastasize to distant organs in 15–20% of cases. These patients are treated by wide surgical excision, radiotherapy or chemotherapy or both.

MYOPERICYTOMA FAMILY OF TUMORS

Myopericytoma denotes group of histologically overlapping lesions described as infantile myofibromatosis,

infantile myofibroma and adult myofibroma. These are usually benign tumors derived from true microvascular pericytes related to glomus tumor.

Locations and Age Distribution

Most common sites of myofibroma are subcutaneous region of head and neck, soft tissue, bone and viscera. Lesions may be either solitary or multiple.

- Infantile myofibroma affects children with male predominance.
- Adult myofibroma and myopericytoma affect adults of any age with sex predominance.

Clinical Features

Infantile myofibromatosis presents as multicentric lesions in soft tissue, skin, bone and viscera. Solitary myofibroma and myopericytoma present as small lesions in the skin.

Surgical Pathology: Myopericytoma Family of Tumors

Gross Morphology

- Infantile myofibromatosis, infantile myofibroma and adult myofibroma are soft tissue masses.
- Cut surface of myofibroma shows areas of necrosis and calcification.

Light Microscopy

- **Myofibroma:** Tumor shows central and peripheral zones. Peripheral zone of the tumor is composed of hyalinized myxoid appearing spindled cells. Central zone of the tumor is composed of primitive appearing round to short spindled cells with vasculature of hemangiopericytoma, areas of necrosis and calcification resembling sarcoma.
- **Adult myofibroma:** Tumor shows central and peripheral zones. It most often shows reversal of zones. Peripheral zone of the tumor is composed of primitive appearing round to short spindled cells with vasculature of hemangiopericytoma, areas of necrosis and calcification resembling sarcoma. Central zone of the tumor is composed of hyalinized myxoid appearing spindled cells.
- **Infantile myofibroma:** Histologic features correspond to the central zone of tumor with minimal atypia. Central zone of the tumor is composed of primitive appearing round to short spindled cells with vasculature of hemangiopericytoma, areas of necrosis and calcification resembling sarcoma.
- **Myopericytoma:** Tumor is composed of myxoid appearing short spindled cells arranged around small blood vessels, vascular pattern of hemangiopericytoma and glomus-like areas (glomangiopericytoma).

Differential Diagnosis

Myopericytoma family of tumors should be differentiated from infantile fibrosarcoma, glomus tumor, hemangiopericytoma and angioleiomyoma.

Immunohistochemistry Technique

Infantile myofibromatosis, infantile myofibroma and adult myofibroma show positivity for smooth muscle actin. These are negative for desmin and CD34.

Markers	Expression
▪ Smooth muscle actin	▪ Positive
▪ Desmin	▪ Negative
▪ CD34	▪ Negative

Prognosis and Treatment

Myopericytoma family of tumors is treated by surgical excision. Solitary myofibroma in children may spontaneously regress. Malignant myopericytoma is locally aggressive tumor. Multicentric myofibroma in infants involving viscera has fatal outcome. Low dose of chemotherapy may be beneficial in treating these tumors.

GLOMUS TUMOR

Glomus tumor is a mesenchymal neoplasm that differentiates along the lines of glomus cells, which resemble modified smooth muscle of normal glomus having thermoregulatory body.

Locations and Age Distribution

Most common sites of glomus tumor are subungual region, hands, wrist and foot. Rare sites are deep soft tissue and viscera in young adults without sex predominance. Glomus tumor in subungual region most often affects females. Glomuvenous malformation (glomangioma) affects children.

Clinical Features

Clinical manifestations are variable depending on location of benign glomus tumor. Cutaneous tumor usually presents as red-blue colored small nodule. Subungual tumor presents as discoloration of beneath nail associated with pain and cold sensitivity. Deep soft tissue tumor is asymptomatic.

Surgical Pathology: Glomus Tumor

Gross Morphology

- Surgical specimen of glomus tumor from cutaneous and subungual regions is red-blue colored nodule <1 cm in diameter.
- Surgical specimen of glomus tumor from deep soft tissue appears as non-specific soft tissue mass.

Light Microscopy

Typical glomus tumors are classified depending on the relative prominence of glomus cells, smooth muscle and blood vessels described as under:

- **Solid glomus tumor:** It is the most common histologic variant accounting for 75% of glomus tumors.

- Tumor is composed of small, round and uniform glomus cells with centrally placed round nucleus and amphophilic to lightly eosinophilic cytoplasm.
- Glomus cells are arranged in nests surrounding capillary sized blood vessels.
- Each glomus cell is surrounded by basal lamina demonstrated by PAS and toluidine blue stains.
- The stroma of the tumor may show hyalinization or myxoid change (Fig. 28.24).

- **Glomuvenous malformation:** Tumor is poorly circumscribed lesion and composed of proliferation of cavernous hemangioma-like vascular channels surrounded by small cluster of glomus cells.
- **Glomangiomyoma:** Tumor shows a transition from typical glomus cells to elongated mature smooth muscle cells.

Histochemistry

In glomus tumor, glomus cell is surrounded by basal lamina demonstrated by PAS and toluidine blue stains.

Differential Diagnosis

Typical glomus tumor should be differentiated from myopericytic tumors, hemangiopericytoma, solitary fibrous tumor, spindle cell malignant glomus tumor and other round cell sarcomas.

Immunohistochemistry Technique

Glomus tumor cells show positivity for smooth muscle actin and pericellular collagen IV. It is negative for desmin, CD34, S-100 protein and cytokeratins.

Markers	Expression
▪ Smooth muscle actin	▪ Positive
▪ Pericellular collagen IV	▪ Positive
▪ Desmin	▪ Negative
▪ CD34	▪ Negative
▪ S-100 protein	▪ Negative
▪ Cytokeratins (CKs)	▪ Negative

Molecular Genetic Alterations

Multiple inherited glomuvenous malformations occur due to glomulin gene mutation on chromosome 1p21-22. During embryogenesis, glomulin gene is normal component of vascular smooth muscle.

Prognosis and Treatment

Benign glomus tumor and glomuvenous malformations are treated by wide surgical excision. Glomus tumor located in the deep soft tissue and viscera are of uncertain malignant potential and treated by complete surgical excision. Patients should be followed closely for lung metastasis.

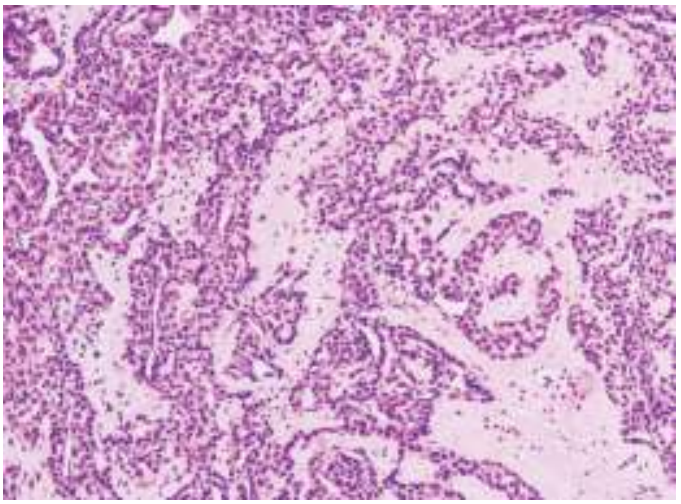

Fig. 28.24: Glomus tumor. Tumor is composed of small, round and uniform glomus cells with centrally placed round nucleus and amphophilic to lightly eosinophilic cytoplasm. Glomus cells are arranged in nests surrounding capillary sized blood vessels. Each glomus cell is surrounded by basal lamina demonstrated by PAS and toluidine blue stains. The stroma of the tumor may show hyalinization or myxoid change (400X).

ATYPICAL AND MALIGNANT GLOMUS TUMORS

Unusual glomus tumors display unique features such as large size tumor in deep location, infiltrative growth, mitotic activity, nuclear pleomorphism and necrosis. Authors studied previously diagnosed as atypical or malignant glomus tumors by virtue of nuclear atypia and mitotic activity; and evaluated size of tumor, depth of tumor, growth pattern, cellularity, nuclear grade, number of mitoses per 50 high power fields, atypical mitotic figures, vascular invasion and necrosis to define criteria for malignancy in glomus tumor.

Classification scheme of atypical and malignant glomus tumors based on histologic features is given in Table 28.19.

Table 28.19 Classification scheme of atypical and malignant glomus tumors based on histologic features

Atypical and Malignant Glomus Tumor Variants	Histologic Features
Malignant glomus tumor	Neoplastic cells with high nuclear grade plus mitotic activity or atypical mitotic activity
Symplastic glomus tumor	Neoplastic cells showing marked nuclear atypia (mitoses <1 per 50 high power fields)
Glomus tumor of uncertain malignant potential	Neoplastic cells not fulfilling diagnostic criteria for malignancy, i.e. absence of atypia or mitoses, but presence of large size tumor measuring >2 cm in diameter in the deep soft tissue

Surgical Pathology: Atypical and Malignant Glomus Tumors

Light Microscopy

Histologic variants of atypical and malignant glomus tumors are malignant glomus tumor (type 1 and 2), symplastic glomus tumor and glomus tumor of uncertain malignant potential.

- **Malignant glomus tumor type 1:** Tumor is composed of a component of previously pre-existing benign glomus tumor in the center of the tumor, surrounded by a nodule of cytologically atypical mitotically active spindle cells resembling features of fibrosarcoma or leiomyosarcoma.
- **Malignant glomus tumor type 2:** Tumor is usually lacking a component of previously pre-existing benign glomus tumor. Tumor retains the histologic features similar to benign glomus tumor. Malignant component of the tumor is composed of highly malignant pleomorphic neoplastic cells with high nuclear grade and numerous mitoses.
- **Symplastic glomus tumor:** Tumor is composed of marked nuclear atypia believed to be degenerative phenomenon. Mitoses >1 per 50 high power fields are demonstrated in the tumor.
- **Glomus tumor of uncertain malignant potential:** Tumor does not fulfill the diagnostic criteria of malignancy without cytologic atypia and mitotic activity. Characteristic feature is deep-seated large size tumor.

Immunohistochemistry Technique

Benign, atypical and malignant glomus tumors show positivity for smooth muscle actin and pericellular collagen IV. It is negative for desmin, CD34, S-100 protein and cytokeratins.

Markers	Expression
Smooth muscle actin (SMA)	Positive
Pericellular collagen IV	Positive
Desmin	Negative
CD34	Negative
S-100 protein	Negative
Cytokeratins (CKs)	Negative

Prognosis and Treatment

Glomus tumor of uncertain malignant potential is treated by wide surgical excision. Malignant glomus tumors metastasize to distant organs resulting in fatal outcome.

NEURAL AND PERINEURAL TUMORS AND OTHER LESIONS

Nerve sheath and neuroectodermal tumors are derived from the neural crest or neuroectodermal tissue of the developing embryo.

- Normal nerve is composed of axons surrounded by Schwann cells. Endoneurium is composed of axons, Schwann cells, fibroblasts, mast cells, capillaries and collagen fibers. Group of axons and their Schwann cells are surrounded by perineurium forming a fascicle. A group of fascicles is surrounded by epineurium. Normal structure of a nerve helps to understand origin of tumors from nerve.
- Neuromas are mainly reactive lesions of existing nerves. Neurofibromas arise from within the nerve or axon. Schwannomas are derived from Schwann cells than encase of the axons. Neural and perineural tumors and lesions of soft tissue according to revised 2020 WHO classification of soft tissue tumors are given in Table 28.20.

Table 28.20 Neural and perineural tumors and lesions of soft tissue according to revised 2020 WHO classification of soft tissue tumors

Neural and Perineural Tumors and Lesions of Soft Tissue
Benign tumors
▪ Neuromuscular hamartoma (benign triton tumor)
▪ Neuromas
• Traumatic neuroma
• Morton neuroma
▪ Granular cell tumor
▪ Schwannoma
• Conventional schwannoma
• Cellular schwannoma
• Plexiform schwannoma
• Melanotic schwannoma
• Microcytic/reticular schwannoma
• Other schwannomas
▪ Neurofibroma
• Circumscribed neurofibroma
• Diffuse and massive soft tissue neurofibroma
• Plexiform neurofibroma
• Other neurofibromas
▪ Perineuroma
• Intraneural perineuroma
• Soft tissue perineuroma
• Sclerosing perineuroma
• Reticular perineuroma
▪ Hybrid peripheral nerve sheath tumor
Intermediate tumors
▪ Nerve sheath myxoma
▪ Atypical granular tumor
Malignant tumors
▪ Malignant peripheral nerve sheath tumor (MPNST)
▪ Low-grade malignant peripheral nerve sheath tumor
▪ High-grade malignant peripheral nerve sheath tumor
▪ Epithelioid peripheral nerve sheath tumor
▪ Malignant peripheral nerve sheath tumor ex-schwannoma
▪ Malignant granular cell tumor
▪ Malignant perineuroma
Benign to malignant tumors
Paraganglioma of head and neck region
Intermediate to malignant tumors
Ependymoma of soft tissue

TRAUMATIC NEUROMA

Traumatic neuroma occurs in response to injury or surgical amputation of limb. It is characterized by painful disorganized proliferation of nerves. It can affect persons of all age groups.

Locations

Traumatic neuroma occurs as a painful nodule in response to injury or surgical amputation of limb and digits.

Clinical Features

Patient presents with firm painful nodule at the site of nerve injury.

Radiologic Findings

Traumatic neuroma is demonstrated by the presence of nerve terminating into a bulbous mass.

Surgical Pathology: Traumatic Neuroma
Gross Morphology
Traumatic neuroma is firm gray white nodule measuring <5 cm in diameter.
Light Microscopy
▪ Traumatic neuroma is composed of haphazardly arranged small nerve fascicles containing Schwann cells, perineural cells surrounded by fibrous tissue. ▪ Myxoid traumatic neuroma is composed of collagen bundles, cellular architecture in the center of lesion and scattered mast cells.
Differential Diagnosis
Traumatic neuroma should be differentiated from neurofibroma, Morton's neuroma of toe and mucosal neuroma.

Prognosis and Treatment

Traumatic neuroma is treated by surgical excision and prior reapproximating of nerve endings or re-embedding of proximal nerve stump in an area far away from scar.

GRANULAR CELL TUMOR

Granular cell tumor is a benign tumor rarely with malignant behavior. Tumor is derived from Schwann cell. Neoplastic cells contain cytoplasmic granules representing aggregates of lysosomes.

Locations and Age Distribution

Most common sites of granular cell tumor are dermis/subcutaneous region of upper extremities, gastrointestinal tract and respiratory tract. Granular cell tumor affects persons during second to fourth decades of life. However, it may affect any age group with female predominance.

Clinical Features

Patient presents with painless solitary mass in the dermis/subcutaneous region of upper extremity, gastrointestinal tract and respiratory tract over <6 months of duration. Multiple tumors may be demonstrated in 15–20% of cases.

- Benign granular cell tumor occurs in the superficial or deep tissue of upper extremity.
- Malignant cell tumors arise in *de novo*, but not from benign granular cell tumor.

Surgical Pathology: Granular Cell Tumor	
Gross Morphology	
▪ **Benign granular cell tumor:** Tumor is poorly delineated measuring <3 cm in diameter. Cut surface shows pale yellow color. ▪ **Malignant granular cell tumor:** Tumor is poorly delineated measuring of large size with mean 4 cm in diameter. Cut surface shows pale yellow color.	
Light Microscopy	
▪ **Benign granular cell tumor:** Tumor is composed of large polygonal cells containing eosinophilic granular cytoplasm, dark ovoid nuclei, inconspicuous nucleoli and showing minimal mitotic activity. Distinctive cytoplasmic aggregates of lysosomes surrounded by a clear halo are demonstrated in the neoplastic cells. ▪ **Atypical granular cell tumor:** Tumor should have one or two of the histologic features such as sarcomatoid spindling, necrosis, mitoses >2 per high power fields, high nuclear to cytoplasmic ratio, pleomorphic neoplastic cells, vesicular nuclei with macronucleoli. ▪ **Malignant granular cell tumor:** Tumor should have at least three and most often five to six of the histologic features: sarcomatoid spindling, necrosis, mitoses >2 per high power field (HPF), high nuclear to cytoplasmic ratio, pleomorphic neoplastic cells, vesicular nuclei with macronucleoli.	
Electron Microscopy	
Neoplastic cells of granular cell tumor contain cytoplasmic granules representing aggregates of lysosomes. Some neoplastic cells contain large boat-shaped cytoplasmic crystals.	
Differential Diagnosis	
Granular cell tumor should be differentiated from other granular cell tumors.	
Immunohistochemistry Technique	
Granular cell tumor shows positivity for immunomarkers S-100 protein, CD68 and α-inhibin.	
Markers	**Expression**
▪ S-100 protein ▪ CD68 ▪ α-Inhibin	▪ Positive ▪ Positive ▪ Positive

Prognosis and Treatment

Benign granular cell tumor is treated by surgical excision. Malignant granular cell tumor behaves like high-grade sarcoma.

NEUROFIBROMA, NEUROFIBROMATOSIS TYPE 1 AND MALIGNANT CHANGE IN NEUROFIBROMA

Neurofibroma is a benign tumor, which arises from within a peripheral nerve. Solitary neurofibroma is relatively common. It can be associated with neurofibromatosis type 1. Neurofibromatosis type 1 presents with multiple neurofibromas. Café au lait spots, optic iris hamartoma, sphenoid bone dysplasia, macrocephaly, short stature and mental retardation.

Diagnostic Criteria of Neurofibromatosis Type 1

Patient presents with two or more neurofibromas or one plexiform neurofibroma, six or more café au lait macules >5 mm (pubertal) or >15 mm (post-pubertal), ocular iris hamartomas, sphenoid bone dysplasia and first degree relative with neurofibromatosis type 1. Out of these clinical manifestations, patient must have at least two or more clinical features.

Locations and Age Distribution

Solitary neurofibroma is relatively a common tumor. Plexiform neurofibroma associated with neurofibromatosis type 1 is relatively uncommon. Both tumors originate from peripheral nerve especially in the scalp region and lower extremities. Neurofibroma usually affects persons of 20–40 years of age. Neurofibroma associated with neurofibromatosis type 1 affects children and adolescents with male predominance.

Clinical Features

Patient with neurofibromatosis type 1 presents with solitary or multiple neurofibromas, Café au lait spots, optic iris hamartoma, sphenoid bone dysplasia, macrocephaly, short stature and mental retardation. Clinical photograph of patient is shown in Fig. 28.25.

Surgical Pathology: Neurofibroma, Neurofibromatosis Type 1 and Malignant Change in Neurofibroma

Gross Morphology

- **Solitary neurofibroma:** Tumor is well delineated and fusiform shaped mass measuring 1–2 cm in diameter.
- **Diffuse neurofibroma:** Tumor is gray plaque-like thickening of dermis with soft in consistency.
- **Plexiform neurofibroma:** Tumor is large soft tissue mass giving 'bag of worms' appearance.

Light Microscopy

- **Neurofibromatosis type 1:** Cellular and stromal milieu in neurofibromatosis type 1 includes Schwann cells, intraneural fibroblasts, collagen bundles and myxoid change and increased cellularity in the center of neurofibroma, when compared with edematous appearance in the peripheral region of neurofibroma.
- **Solitary neurofibroma:** Tumor is composed of spindle cells arranged in storiform pattern with abundant intervening collagen fibers. Intraneural growth is extending into the surrounding tissue (Fig. 28.26).
- **Diffuse neurofibroma:** Tumor is composed of small round to spindle cells associated with fibrillar and myxoid background. It infiltrates subcutaneous fat in a honeycomb pattern. Presence of 'Wagner-Meissner bodies' is the hallmark of diffuse neurofibroma.
- **Plexiform neurofibroma:** Tumor is tortuous distension of peripheral nerve showing plexiform architecture demonstrated on imaging technique, gross morphology and histologic features with multiple intraneural nodules of tumor separated by epineurium and stroma. It can involve the subcutis or skeletal structures or both. Clinicopathologic diagnosis is established due to its 'bag of worms' appearance.
- **Low-grade malignant peripheral nerve sheath tumor (low-grade MPNST):** Neurofibroma may undergo early malignant transformation. Low-grade malignant peripheral nerve sheath tumor resembles neurofibroma but with increased cellularity with pleomorphism and arranged in fascicular architecture and scattered mitotic activity in the deep area of tumor.

Differential Diagnosis

Neurofibroma should be differentiated from schwannoma, malignant peripheral nerve sheath tumor (MPNST), benign fibrous histiocytoma and desmoplastic malignant melanoma.

Immunohistochemistry Technique

Neurofibroma and neurofibromatosis type 1 may undergo early malignant transformation show positivity for S-100 protein (Schwann cells), epithelial membrane antigen (EMA), CD34 (intraneural fibroblasts), neurofilament protein (NFP) and glial fibrillary acidic protein (GFAP).

Markers	Expression
S-100 protein	Positive
Epithelial membrane antigen	Positive
CD34	Positive
NFP	Positive
GFAP	Positive (occasional)

Molecular Genetic Alterations

Neurofibromatosis type 1 occurs due to germline mutation of NF1 tumor suppressor gene located on

Fig. 28.25: Neurofibroma. On clinical examination, patient showed multiple neurofibromas.

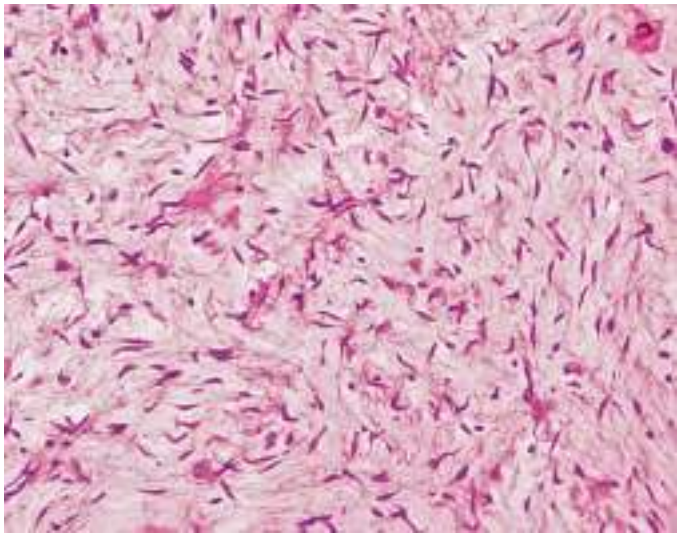

Fig. 28.26: Neurofibroma. Solitary neurofibroma is composed of spindle cells arranged in storiform pattern with abundant intervening collagen fibers. Intraneural growth is extending into the surrounding tissue (400X).

chromosome 17. NF1 gene encodes protein product known as 'neurofibromin', homologous to the GTPase-activating (GAP) for members of the p21 (RAS) family protein that affects cell cycle by downregulating the p21 (RAS) gene. Malignant transformation of neurofibroma is common in these patients. Neurofibromatosis type 1 presents with multiple neurofibromas, café au lait spots, optic iris hamartoma, sphenoid bone dysplasia, macrocephaly, short stature and mental retardation.

Prognosis and Treatment

Solitary neurofibroma, diffuse neurofibroma and plexiform neurofibroma may be associated with neurofibromatosis type 1. These tumors are treated by surgical excision. Recurrence is common in diffuse neurofibroma after surgical excision. Early malignant peripheral nerve sheath tumor in a case of neurofibromatosis type 1 is treated similar to low-grade sarcoma. High-grade malignant transformation in neurofibroma is treated similar to high-grade sarcoma.

SCHWANNOMA AND NEUROFIBROMATOSIS TYPE 2

Schwannoma is a benign tumor of peripheral nerve sheath tumor, which commonly involves the vestibular division of eighth cranial nerve.

- Schwannoma accounts for 8% of intracranial tumors and 28% of primary spinal tumors. Most common sites are head and neck region. Other sites are extensor aspect of extremities, vestibular division of eighth cranial nerve, bone and gastric region.
- Schwannoma usually affects persons of 20–50 years of age except in the setting of neurofibromatosis type 2 (NF2), which occurs due to germline NF2 gene mutation located on chromosome 22 encoding aberrant protein 'Merlin'.

Diagnostic Criteria of Neurofibromatosis Type 2

Diagnostic criteria of neurofibromatosis type 2 include bilateral vestibular schwannomas or family history of neurofibromatosis type 2 in first degree relative and unilateral vestibular schwannoma in below 30 years of age and any two of the lesions, i.e. meningioma, schwannoma, glioma, posterior subcapsular lenticular opacities/juvenile cortical cataract. Comparison of neurofibromatosis type 1 and neurofibromatosis type 2 is given in Table 28.21.

Clinical Features

Patient with neurofibromatosis type 2 presents with tinnitus, hearing loss, acoustic bilateral schwannoma and facial paresthesia. Patient with schwannoma in peripheral region presents with mass.

Radiologic Findings

Radiograph demonstrates intracranial calcification in neurofibromatosis type 2. Radiologic study demonstrates mass eccentric to nerve involved in a case of schwannoma.

Table 28.21 Comparison of neurofibromatosis type 1 and neurofibromatosis type 2

Parameters	Neurofibromatosis Type 1 (NF1)	Neurofibromatosis Type 2 (NF2)
Germline gene mutation	NF1 gene mutation on chromosome 17p11 by deletion	NF2 gene mutation on chromosome 22q12.2 by deletion or nonsense mutation
Encoded protein by NF1 and NF2 genes	Neurofibromin 1	Merlin
Encoded protein function by NF1 and NF2 genes	Neurofibromin type 1 homologous to GAP protein, that influences cell cycle by downregulating p21 RAS gene (RAS/MAP-kinase signaling pathway)	Merlin stabilizes skeleton membrane linkage
Diagnostic criteria of NF1 and NF2	Patient presents with two or more neurofibromas or one plexiform neurofibroma, six or more café au lait macules >5 mm (pubertal) or >15 mm (postpubertal), ocular iris hamartomas, sphenoid bone dysplasia and first degree relative with neurofibromatosis type 1	Diagnostic criteria of neurofibromatosis 2 include bilateral vestibular schwannomas or family history of neurofibromatosis type 2 in first degree relative and unilateral vestibular schwannoma in below 30 years of age and any two of the lesions, i.e. meningioma, schwannoma, glioma, posterior subcapsular lenticular opacities/juvenile cortical cataract

Surgical Pathology: Neurofibroma and Neurofibromatosis Type 2

Gross Morphology

- Classic schwannoma is encapsulated tan-yellow mass measuring 2–10 cm in diameter.
- Sinonasal and intracranial schwannomas are not encapsulated.

Light Microscopy

Classic schwannoma is encapsulated and composed of alternating Antoni A cellular component with Verocay bodies (cellular areas surrounded by nuclear palisading), and Antoni B hypocellular component with myxoid architecture.

- **Antoni A cellular component of schwannoma:** It is cellular component and composed of monomorphic spindle-shaped Schwann cells containing poorly defined cytoplasm, pointed basophilic nuclei set in a variably collagenous stroma showing nuclear palisading surrounding pink areas known as 'Verocay bodies'.
- **Antoni B cellular component of schwannoma:** It is composed of Schwann cells containing inconspicuous cytoplasm and nuclei suspended in abundant myxoid microcystic matrix.

Differential Diagnosis

Schwannoma should be differentiated from neurofibroma, nevomelanocytic lesions, leiomyosarcoma, gastrointestinal stromal tumor and malignant peripheral nerve sheath tumor (MPNST).

Immunohistochemistry Technique

Schwannoma shows strong positivity for S-100 protein.

Marker	Expression
S-100 protein	Positive

Molecular Genetic Alterations

NF2 gene located on chromosome 22 encodes protein 'Merlin'. Merlin stabilizes skeleton membrane linkage. Neurofibromatosis type 2 is caused by germline NF2 gene mutation due to deletion or nonsense mutation, which encodes aberrant protein '**Merlin**'.

Prognosis and Treatment

Benign schwannoma is treated by surgical excision. Neurofibromatosis type 2 due to germline NF2 gene mutation is difficult to treat.

PSAMMOMATOUS MELANOTIC SCHWANNOMA

Psammomatous melanocytic schwannoma is a melanin pigmented neural neoplasm, which arises from sympathetic nervous system. It differs from conventional schwannoma. About 50% of psammomatous melanotic schwannoma have been associated with autosomal dominant Carney's complex, which is characterized by spotty skin pigmentation, Cushing's syndrome, acromegaly, sexual precocity, atrial myxomas and angiomyxomas.

Locations and Age Distribution

Most common sites of psammomatous melanotic schwannoma are spinal nerve roots, soft tissue of extremities and trunk region. Uncommon sites are intestine, skin, bronchus, heart, liver and bone. It affects persons of 20–40 years of age.

Clinical Features

About 50% of psammomatous melanotic schwannoma have been associated with autosomal dominant

Carney's complex,which is characterized by spotty skin pigmentation, Cushing's syndrome, acromegaly, sexual precocity, atrial myxomas and angiomyxomas.

Surgical Pathology: Psammomatous Melanotic Schwannoma

Gross Morphology

- Psammomatous melanocytic schwannoma is a well-circumscribed fusiform shaped gray-black tumor measuring 1–10 cm in diameter with mean 5 cm in size.
- Cut surface shows cystic appearance.

Light Microscopy

- Psammomatous melanocytic schwannoma is composed of tightly packed spindled cells containing dark brown melanin pigment obscuring nuclear and cytoplasm morphology.
- Calcified psammomatous bodies are demonstrated in nearly all cases.
- Spindled cells are arranged in fascicular, solid or whorled growth patterns. Nuclei may show mild atypia. Presence of marked nuclear atypia, mitotic activity and necrosis are indicative of malignant phenotype.

Differential Diagnosis

- Psammomatous melanocytic schwannoma should be differentiated from malignant melanoma and blue nevus.
- Psammoma bodies are not demonstrated in malignant melanoma.
- Blue nevus shows small cutaneous lesions with lesser degree of nuclear atypia and absence of psammomatous bodies.

Immunohistochemistry Technique

Psammomatous melanocytic schwannoma shows positivity for S-100 protein, HMB-45 (human melanoma black 45) and glial fibrillary acidic protein (GFAP). It is essential to bleach the sections to observe immunoreactivity.

Markers	Expression
S-100 protein	Positive
HMB-45	Positive
GFAP	Positive (occasional)

Prognosis and Treatment

Benign psammomatous melanocytic schwannoma is treated by wide surgical resection. Malignant psammomatous melanocytic schwannoma may metastasize to lungs, pleura, liver and spleen in 10% of cases.

PERINEUROMA (SCLEROSING, INTRANEURAL, SOFT TISSUE AND RETICULAR PERINEUROMAS)

Perineuroma is usually a benign tumor composed of perineural cells counterpart of meningeal cells of intracranial pia–arachnoid membranes.

- Tumor may arise in the superficial or deep regions. Cytogenetic analysis reveals monosomy of chromosome 26.
- Perineuroma is of following types in decreased frequency:
  - Sclerosing perineuroma of soft tissue is the most common histologic type of perineuroma.
  - Intraneural perineuroma usually involves peripheral nerves of the extremities.
  - Soft tissue perineuroma occurs in soft tissue. It does not involve peripheral nerves.
  - Reticular perineuroma is uncommon.

Incidence and Locations

- Intraneural perineuroma usually involves peripheral nerves of the extremities.
- Soft tissue perineuroma occurs in soft tissue. It does not involve peripheral nerves.

Age and Sex Predilection

- Intraneural perineuroma affects adolescents and young adults without sex predominance.
- **Soft tissue perineuroma** affects adults with female predominance.

Clinical Features

- Intraneural perineuroma: Patient with intraneural perineuroma presents with muscular weakness as a result of nerve involvement.
- Soft tissue perineuroma does not involve nerve. Patient presents with soft tissue mass.

Surgical Pathology: Perineuroma

Gross Morphology

- **Intraneural perineuroma:** Tumor shows segmental enlargement of nerves up to 10 cm or longer. Cut surface is gray white and gelatinous with firm in consistency.
- **Soft tissue perineuroma:** Tumor is solitary well-circumscribed mass measuring 1.5–2 cm in greater dimension. Cut surface is gray-white to gelatinous with firm in consistency.

Light Microscopy

- **Intraneural perineuroma:** Tumor is composed of bulb-like perineural cells arranged in concentric pattern giving 'onion skin' appearance. Perineural cells are present around residual nerve twigs. The lesion may be hyalinized.
- **Soft tissue perineuroma:** Sclerosing perineuroma of soft tissue is the most common histologic type of perineuroma. Tumor is composed of uniform perineural cells arranged in whorls embedded collagenized stroma. But typical soft tissue perineuroma is composed of spindled shaped, waxy, perineural cells embedded in collagenized stroma. Some cells are arranged in whirling pattern.

Differential Diagnosis

Intraneural perineuroma has quite distinctive histology.

- Typical soft tissue perineuroma should be differentiated from neurofibroma, low-grade fibromyxoid sarcoma, solitary fibrous tumor, dedifferentiated liposarcoma with meningothelial like whorls and malignant peripheral nerve sheath tumor (MPNST).
- Sclerosing soft tissue perineuroma should be differentiated from benign fibrous histiocytoma, glomus tumor and myoepithelial tumor.

Immunohistochemistry Technique

- Intraneural perineuroma: It demonstrates epithelial membrane antigen (EMA) positive perineural cells. Surrounding residual Schwann cells show positivity for S-100 protein. Axons of the nerve fibers show positivity for neurofilament protein (NFP).
- Soft tissue perineuroma (typical and sclerosing types): Both histologic variants of tumor show positivity for EMA. This tumors are negative for S-100 protein. Both histologic variants can be positive for claudin 1 and GLUT-1 (glucose transporter protein 1).

Component of Perineuroma	Markers	Expression
Intraneural perineuroma		
▪ Perineural cells ▪ Schwann cells ▪ Residual axons of nerve fibers	▪ Epithelial membrane antigen (EMA) ▪ S-100 protein ▪ Neurofilament protein (NFP)	▪ Positive ▪ Positive ▪ Positive
Soft tissue perineuroma (typical and sclerosing types)		
Perineural cells	▪ Epithelial membrane antigen (EMA) ▪ Claudin 1 ▪ Glucose transporter protein 1 (GLUT-1) ▪ S-100 protein	▪ Positive ▪ Positive ▪ Positive ▪ Negative

Molecular Genetic Alterations

Cytogenic analysis reveals monosomy of chromosome 26 in perineuroma.

Prognosis and Treatment

Most histologic variants of benign perineuroma are treated by surgical excision. Malignant perineuroma should be treated similar to sarcomas.

NERVE SHEATH MYXOMA

Nerve sheath myxoma is a benign tumor not associated with neurofibromatosis type 1 or type 2.

Locations and Age Distribution

Most common sites of nerve sheath myxoma are in the subcutaneous and dermis of extremities, head and neck region. It rarely involves deep soft tissue. It affects children and young adults without sex predominance.

Clinical Features

Patient with nerve sheath myxoms presents with small mass of 0.5–2 cm size in the dermis or subcutaneous region of extremities, head and neck region.

Surgical Pathology: Nerve Sheath Myxoma

Gross Morphology

Nerve sheath myxoma is small multinodular mucoid mass measuring 0.5–2 cm.

Light Microscopy

- Nerve sheath myxoma is composed of well demarcated myxoid lobules of variable size. Myxoid lobules are separated by fibrous septa containing stellate, spindled cells and rarely epithelioid cells with dark nuclei. Cells are showing little pleomorphism or mitotic activity.
- Occasional nerve sheath myxoma may demonstrate scattered enlarged cells with hyperchromatic nuclei.

Differential Diagnosis

Nerve sheath myxoma should be differentiated from angiomyxoma, myxofibroma, myxoid schwannoma and myxoid neurofibroma.

Immunohistochemistry Technique

Nerve sheath myxoma shows positivity for S-100 protein, collagen type 4 and epithelial membrane antigen (EMA).

Markers	Expression
▪ S-100 protein ▪ Collagen type 4 ▪ EMA	▪ Positive ▪ Positive ▪ Positive

Prognosis and Treatment

Nerve sheath myxoma is treated by surgical excision. Prognosis is excellent.

MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

Malignant peripheral nerve sheath tumor (MPNST) can originate in *de novo* or in the setting of neurofibroma and neurofibromatosis type 1.

Locations and Age Distribution

Most common sites of malignant peripheral nerve sheath tumor are buttock, thigh, brachial plexus, upper arm and paraspinal regions. Sporadic malignant nerve sheath tumor affects adults during second to fifth decades of life. On the other hand, malignant nerve sheath tumor originating in the setting of neurofibromatosis type 1 affects persons during third to sixth decades of life.

Clinical Features

Patient presents with signs and symptoms depending on location of malignant nerve sheath tumor.

Radiologic Findings

Malignant peripheral nerve sheath tumor poses diagnostic difficulty to differentiate from benign nerve sheath tumor on radiologic techniques. Tumor size >5 cm with irregular borders and presence of necrosis are suggestive of MPNST.

Surgical Pathology: Malignant Peripheral Nerve Sheath Tumor

Gross Morphology

- Tumor is creamy gray and fusiform shaped measuring >5 cm in diameter.
- Cut surface shows areas of hemorrhage and necrosis.

Light Microscopy

- Tumor exhibits diverse histologic patterns resembling marble-like appearance with alternating zones of hypercellularity and hypocellularity.
- Tumor is composed of neoplastic cells with waxy or buckled hyperchromatic nuclei and moderate amount of lightly eosinophilic cytoplasm.
  - Neoplastic cells are arranged in long fascicles.
  - In occasional area of the tumor, neoplastic cells may be arranged in storiform pattern.
  - Hemangiopericytoma like vascular pattern may also be demonstrated.
- Heterologous differentiation, e.g. skeletal muscle, cartilage, bone, blood vessels and glands is demonstrated in few cases of neurofibromatosis type 1 related MPNST.

Differential Diagnosis

Malignant peripheral nerve sheath tumor (MPNST) should be differentiated from synovial sarcoma, fibrosarcoma, malignant solitary fibrous tumor and malignant melanoma.

Electron Microscopy

Malignant peripheral nerve sheath tumor (MPNST) shows melanosomes combined with schwannian features of well-developed basement membranes and complex processes.

Immunohistochemistry Technique

- Spindled malignant peripheral nerve sheath tumor shows positivity for HMB-45 and S-100 protein (weak and focal staining).
- Epithelioid malignant peripheral nerve sheath tumor shows positivity for HMB-45 and S-100 protein (strong staining).
- Malignant peripheral nerve sheath tumor with rhabdoblastic differentiation shows positivity for desmin, myogenin, MyoD1 and HMB-45.

Markers	Expression
Spindled malignant peripheral nerve sheath tumor	
▪ HMB-45 ▪ S-100 protein	▪ Positive ▪ Positive (weak and focal staining)
Epithelioid malignant peripheral nerve sheath tumor	
▪ S-100 protein ▪ HMB-45	▪ Positive (strong staining) ▪ Positive
Malignant peripheral nerve sheath tumor with rhabdoblastic differentiation	
▪ Desmin ▪ Myogenin ▪ MyoD1 ▪ HMB-45	▪ Positive ▪ Positive ▪ Positive ▪ Positive

Prognosis and Treatment

- Malignant peripheral nerve sheath tumor arising *de novo* and in the setting of neurofibromatosis type 1 has five-year survival rate in 85% of cases.
- Malignant peripheral nerve sheath tumor of head and neck region is a low-grade tumor associated with best prognosis.

MISCELLANEOUS SOFT TISSUE TUMORS OF UNCERTAIN LINEAGE

Soft tissue tumors of uncertain differentiation or uncertain lineage are given in Table 28.22.

MYXOMA (INTRAMUSCULAR MYXOMA AND JUXTA-ARTICULAR MYXOMA)

Myxoma is a benign mesenchymal tumor. Tumor is composed of bland stellate to spindled cells embedded in hypovascular abundant myxoid matrix.

Locations and Age Distribution

- Intramuscular myxoma arises from large skeletal muscles of thigh and buttock region in women. Mazabraud syndrome is characterized by myxoma and fibrous dysplasia.

Table 28.22 Soft tissue tumors of uncertain differentiation or uncertain lineage

Benign Tumors
▪ Acral fibromyxoma ▪ Intramuscular myxoma including cellular variant ▪ Juxta-articular myxoma ▪ Deep aggressive angiomyxoma ▪ Ectopic hamartomatous thymoma
Intermediate (Locally Aggressive) Malignant Tumors
Hemosiderotic fibrolipomatous tumor
Intermediate (Rarely Metastasizing) Malignant Tumors
▪ Atypical fibroxanthoma ▪ Angiomatoid fibrous histiocytoma ▪ Ossifying fibromyxoid tumor malignant ▪ Mixed tumor, not otherwise specified ▪ Mixed tumor, not otherwise specified, malignant ▪ Myoepithelioma ▪ Myoepithelial carcinoma ▪ Phosphaturic mesenchymal tumor, benign ▪ Phosphaturic mesenchymal tumor, malignant ▪ Pleomorphic hyalinizing angiotectic tumor ▪ Hemosiderotic fibrolipomatous tumor
Malignant Tumors
▪ Synovial sarcoma • Synovial sarcoma, spindle cell variant • Synovial sarcoma, biphasic ▪ Epithelioid sarcoma ▪ Alveolar soft part sarcoma ▪ Clear cell sarcoma of soft tissue ▪ Extraskeletal myxoid chondrosarcoma ▪ Extraskeletal Ewing sarcoma ▪ Desmoplastic small round cell tumor ▪ Extra-renal rhabdoid tumor ▪ Neoplasms with perivascular epithelioid cell differentiation (PEComa) • PEComa, not otherwise specified, benign • PEComa, not otherwise specified, malignant ▪ Intimal sarcoma

- Juxta-articular myxoma occurs in the region of knee joint, shoulder and hip regions. It affects men especially in region of degenerative joint disease.

Clinical Features

Patient presents with painless soft tissue mass in the skeletal muscles of thigh, buttock, knee, shoulder and hip regions.

Surgical Pathology: Myxoma

Gross Morphology

- Myxoma is a well circumscribed soft tissue mass.
- Cut surface is gelatinous with areas of cystic change.

Light Microscopy

- Tumor is composed of stellate to spindled cells embedded in hypovascular abundant myxoid matrix.
- Cellular myxoma located in juxta-articular region is a highly cellular tumor composed of stellate to spindled cells arranged in fascicular pattern.
- Numerous blood vessels are present in the tumor.

Differential Diagnosis

Myxoma should be differentiated from myxofibrosarcoma, myxoid liposarcoma, myxoid chondrosarcoma, myxoid desmoid-type fibromatosis and myxoid nodular fasciitis.

Immunohistochemistry Technique

Myxoma cells show strong positivity with vimentin. It is negative for smooth muscle actin.

Markers	Expression
▪ Vimentin ▪ Smooth muscle actin (SMA)	▪ Positive ▪ Negative

Prognosis and Treatment

Myxoma is cured by surgical excision.

SYNOVIAL SARCOMA

Synovial sarcoma is a highly malignant mesenchymal tumor, which displays variable degree of epithelial differentiation and formation of glandular structures. Tumor originates in the region of a joint rather within joint cavity, which has no etiologic or direct anatomic relation to the synovium. Demonstration of chromosomal translocation t(X;18)(p11;q11) is characteristic finding in synovial sarcoma in 95% of cases.

Locations and Age Distribution

Most common sites of synovial sarcoma are deep soft tissue of lower and upper extremities in the juxta-articular regions in 70% of cases. Other sites are trunk region (15%) and head and neck region (7%). Unusual sites are sex organs, kidney, adrenal glands, retroperitoneum, viscera, mediastinum, bone, central nervous system and peripheral nerves. Tumor usually affects adolescents and young adults during 20–50 years of age without sex predominance.

Clinical Features

Patient presents with painful and tender slowly growing mass in the vicinity of knee joint and parapatellar regions. Tumor may occur in other unusual sites.

Surgical Pathology: Synovial Sarcoma

Gross Morphology

- Synovial sarcoma is a well circumscribed tumor measuring 3–10 cm in diameter. Tumor in hands and feet measures 1 cm in diameter.
- Cut surface is gray-yellow or pink with soft in consistency depending on proportion of cellularity, collagenization, myxoid change or hemorrhage, multinodular and multicystic areas. Tumor may show areas of calcification, metaplastic ossification and necrosis. Synovial sarcoma in amputated leg is shown in Fig. 28.27.

Light Microscopy

Synovial sarcoma shows two histologic patterns depending on the presence of epithelial and spindle cell components in varying proportions: (a) monophasic variant (containing spindle cell component without epithelial differentiation) or (b) biphasic (containing both epithelial and spindle cell components). Biphasic synovial sarcoma usually shows areas of calcification and ossification and contains both epithelial and spindle cell components.

- **Epithelial component of biphasic synovial sarcoma:** Epithelial component of biphasic synovial sarcoma resembles that predominates in epithelial malignancy.
  - Epithelial component cells are arranged in solid cords or nests or glandular, tubular, sometimes alveolar or papillary architecture.
  - Glandular architecture is lined by epithelial cuboidal or columnar cells containing vesicular nuclei and abundant pale eosinophilic cytoplasm.
  - Mucin is demonstrated in glandular lumen.
  - Epithelial keratinization, metaplasia and glandular change may be demonstrated in occasional tumor.
  - Epithelial cells show positivity for cytokeratins (AE1/AE3) and epithelial membrane antigen.
- **Spindle cell component of biphasic synovial sarcoma:** Spindle cell component of biphasic synovial sarcoma resembles that predominates in monophasic synovial sarcoma.
  - Tumor is composed of small and uniform neoplastic spindle cells with sparse cytoplasm and ovoid hyperchromatic nuclei, granular chromatin, inconspicuous nucleoli, and high nucleocytoplasmic ratio.
  - Spindle cells are arranged in dense cellular sheets or vague fascicles, with occasional nuclear palisading or herringbone pattern.
  - Collagen is present in variable proportions. Poorly differentiated synovial sarcoma shows severe nuclear atypia and high mitotic activity >15 per high power field (HPF) in the spindle cell component. Histology of biphasic synovial sarcoma is shown in Fig. 28.28.

Histochemistry

Epithelial cell component of synovial sarcoma is outlined by PAS stain, Alcian blue stain and colloidal iron.

Electron Microscopy

- Epithelial cell component of synovial sarcoma shows microvilli, tonofilaments and cell junctions; surrounded by basement membrane similar to demonstrated in adenocarcinoma. These ultrastructural features are frequently demonstrated in biphasic synovial sarcoma.
- Monophasic synovial sarcoma shows fewer specific features.

Immunohistochemistry Technique

Epithelial cell component of biphasic synovial sarcoma shows positivity for CD99, BCL-2, cytokeratins, epithelial membrane antigen (EMA) and TLE-1. It is negative for CD34. Spindle cell component of synovial sarcoma shows positivity for vimentin.

Markers	Expression
Epithelial cell component of synovial sarcoma	
▪ CD99 (membranous staining) ▪ BCL-2 ▪ Cytokeratins (7, 8, 14, 18, 19) by AE1/AE3 ▪ Epithelial membrane antigen (EMA) ▪ TLE-1 (nuclear staining) ▪ CD34	▪ Positive ▪ Positive ▪ Positive (70–80%) ▪ Positive (70–80%) ▪ Positive (80%) ▪ Negative
Spindle cell component of synovial sarcoma	
Vimentin	Positive

Molecular Genetic Alterations

Demonstration of chromosomal translocation t(X;18)(p11,q11) is characteristic finding in 95% of synovial

Fig. 28.27: Synovial sarcoma. Amputated surgical specimen of synovial sarcoma. Cut surface revealed gray-yellow or pink with soft in consistency depending on proportion of cellularity, collagenization, myxoid change or hemorrhage. It showed multinodular and multicystic areas. It may show areas of calcification, metaplastic ossification and necrosis.

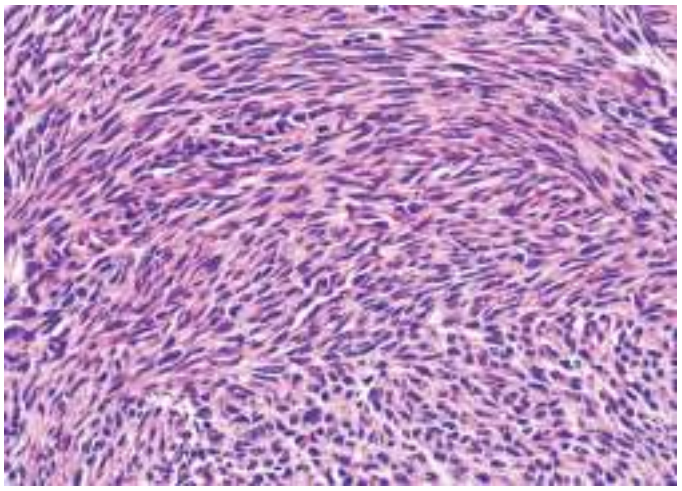

Fig. 28.28: Synovial sarcoma. Tumor shows two histologic patterns depending on the presence of epithelial and spindle cell components in varying proportions: (a) monophasic variant (containing spindle cell component without epithelial differentiation) and (b) biphasic (containing both epithelial and spindle cell components). Biphasic synovial sarcoma usually shows areas of calcification and ossification (400X).

sarcoma cases. As a result of chromosomal translocation t(X;18) (p11,q11), SS18 gene (also known as SYT or SSXT) fuses with one of the SSX genes (SSX1, SSX2, SSX4) on X chromosome. Molecular genetic alterations in synovial sarcoma are given in Table 28.23.

Prognosis and Treatment

Synovial sarcoma has variable prognosis depending on the age of patient, size of the tumor, histologic features, i.e. differentiation of tumor, mitotic activity, nuclear grading, vascular invasion and clinical stage. Prognostic factors of synovial sarcoma are given in Table 28.24.

- **Poor prognostic factors:** Synovial sarcoma >5 cm in diameter with necrosis in trunk, head and neck region, presence of 10 mitoses per 10 high power fields in a patient above 40 years of age most often metastasizes to lungs and bone resulting in fatal outcome. Synovial sarcoma with >20% poorly differentiated histology has aggressive behavior. Prognosis is poor in synovial sarcoma showing vascular invasion on histologic examination.
- **Good prognostic factors:** Prognosis is excellent in patients with small size synovial sarcoma measuring <1 cm in diameter in extremities and tumor <5 cm in diameter without necrosis and <10 mitoses per 10 high power fields. Prognosis is better in children than adults.

Table 28.23 Molecular genetic alterations in synovial sarcoma

Fusion Protein	Frequency
SS18-SSX1	66%
SS18-SSX2	33%
SS18-SSX4	1%

EPITHELIOID SARCOMA

Epithelioid sarcoma is a malignant mesenchymal tumor showing epithelial differentiation with epithelioid cytomorphology. Two clinicopathological subtypes of epithelioid sarcoma have been described in Table 28.25.

Locations and Age Distribution

- **Conventional or classic distal subtype of synovial sarcoma:** Common sites of tumor are upper extremity (fingers and hands) in dermis or subcutis region or deep soft tissue. It affects children and young adults (10–40 years).
- **Proximal subtype of synovial sarcoma:** Common sites of tumor are pelvis, perineum, genital, inguinal region, buttock, hip, thigh, head, neck, distal extremity and axilla in dermis or subcutis region or deep soft tissue. It affects children and adults.

Table 28.24 Prognostic factors of synovial sarcoma

Parameters	Good Prognostic Factors	Poor Prognostic Factors
Clinical features		
▪ Age of the patient ▪ Location of tumor ▪ Size of tumor ▪ Stage	▪ Children ▪ Extremities ▪ <5 cm (excellent if <1 cm) ▪ Stage I	▪ Adults ▪ Trunk, head and neck ▪ >5 cm ▪ Advanced stage with distant metastasis in lungs and bone
Gross morphology		
Necrosis in large tumor	Absent	Present
Histologic features		
▪ Tumor differentiation ▪ Vascular invasion ▪ Calcification in tumor ▪ Mitoses	▪ Well-differentiated tumor ▪ Absent ▪ Present ▪ <10 mitoses per 10 high power fields	▪ Tumor with >20% poorly differentiated histology ▪ Present ▪ Absent ▪ >10 mitoses per 10 high power fields

Table 28.25 Clinicopathological subtypes of epithelioid sarcoma

Parameters	Conventional or Classic Distal Subtype of Synovial Sarcoma	Proximal Subtype of Synovial Sarcoma (Large Cell Variant)
Clinical history		
Location of tumor	Upper extremity (fingers and hands) in dermis or subcutis region or deep soft tissue	Pelvis, perineum, genital, inguinal region, buttock, hip, thigh, head, neck, distal extremity and axilla in dermis or subcutis region or deep soft tissue
Age group	Children and young adults (10–40 years)	Children and young adults
Gross morphology		
Tumor	Few mm to 5 cm in diameter in superficial region (solitary or multiple nodules) and up to 15 cm in deep soft tissue	1–20 cm in diameter (solitary or multiple nodules)
Cut surface	Gray-white or gray tan, glistening surface	Gray-white with areas of hemorrhage and necrosis

Clinical Features

Patient presents with slow-growing painless firm solitary or multiple nodules in dermis or subcutis region or deep soft tissue. Tumor usually metastasizes to regional lymph nodes.

Surgical Pathology: Epithelioid Sarcoma

Gross Morphology

- **Conventional or classic distal subtype of synovial sarcoma:** Tumor excised from dermis and subcutaneous region is ill-defined nodule measuring few mm to 5 cm in diameter.
  - Tumor excised from tendon and fascia in the deep-seated region is multinodular measuring 1–15 cm in diameter.
  - Cut surface is gray-white or gray-tan with glistening surface.
- **Proximal subtype of synovial sarcoma:** Tumor is solitary or multiple whitish nodule measuring 1–20 cm in diameter. Cut surface shows areas of hemorrhage and necrosis.

Light Microscopy

- Epithelioid sarcoma is composed of epithelioid cells admixed with distinct elongated spindle cells. Epithelioid cells small to large contain uniform hyperchromatic nuclei. Presence of bland nuclear features in association with central necrosis may closely resemble a granulomatous process termed necrobiotic granuloma. There is presence of lymphocytes surrounding neoplastic cells.
- Some epithelioid sarcomas are entirely composed of spindle cells resembling benign fibrous histiocytoma and fibrosarcoma.

Differential Diagnosis

Epithelioid sarcoma should be differentiated from necrobiotic granuloma, cutaneous squamous cell carcinoma and adnexal carcinoma, benign fibrous histiocytoma, fibrosarcoma and epithelioid angiosarcoma (pseudoalveolar variant).

Immunohistochemistry Technique

Epithelioid sarcoma shows co-expression of cytokeratins and vimentin. It shows positivity for CD34 and epithelial membrane antigen (EMA). Loss of INI-1 is demonstrated in 90% of cases.

Markers	Expression
▪ Cytokeratins (low and high molecular weight)	▪ Positive
▪ Vimentin	▪ Positive
▪ CD34	▪ Positive (50%)
▪ Epithelial membrane antigen (EMA)	▪ Positive
▪ Loss of INI-1	▪ Positive (90%)

Molecular Genetic Alterations

Genetic chromosomal alterations of 22q11.12 have been implicated in the pathogenesis of epithelioid sarcoma. Alterations in tumor suppressor gene SMARCB1 (HSSn5, INI-1) have been demonstrated in epithelioid sarcoma.

Prognosis and Treatment

Epithelioid sarcoma is treated by surgical excision, i.e. amputation of extremity, radiotherapy and chemotherapy.

- Local recurrence after surgery occurs in 70% of cases. Tumor metastasizes to regional lymph nodes and lungs in 50% of cases.
- Adverse prognostic factors are elderly persons, deep-seated tumor, tumor size >5 cm in diameter with extensive necrosis, multifocal involvement, high mitotic activity, lymph node and distant metastasis and proximal type of epithelioid sarcoma associated with presence of rhomboid cells.

ALVEOLAR SOFT PART SARCOMA

Alveolar soft part sarcoma (ASPS) is a rare slow-growing malignant tumor. Tumor is composed of large uniform epithelioid cells with well-defined borders, centrally placed bland nuclei and abundant eosinophilic cytoplasm somewhat granular and rod-shaped intracytoplasmic inclusions.

- Neoplastic cells are arranged in solid nests and/or alveolar structures and separated by delicate

fibrovascular septa. Presence of ASPSCR1-TFE3 fusion protein is highly specific for alveolar soft part sarcoma. However, it is also demonstrated in renal cell carcinoma affecting young persons.

- Alveolar soft part sarcoma is defined by a specific cytogenetic alteration, der(17) t(X;17) (p11;q25) resulting in the formation of fusion protein ASPSCR1-TFE3. ASPSCR1 located on 17q25 fuses with TFE transcription factor gene located on Xp11.

Locations and Age Distribution

Most common sites of alveolar soft part sarcoma are deep soft tissue of thigh, buttock region, popliteal region, chest and forearm in decreased frequency in adults.

- In children and infants, most common sites are head and neck, tongue and orbit.
- Unusual sites are lung, breast, stomach, liver, bone, larynx, heart, urinary bladder, uterine cervix and another region of female genital tract.
- Alveolar soft part sarcoma most often affects 15–35 years of age. However, it can occur at any age. Tumor rarely affects children below 5 years and adults above 50 years of age. Males are more affected than females during first three decades of life. But after 30 years of age, females are more affected than males.

Clinical Features

Patient presents with slow-growing painless mass within soft tissue in the region of thighs, buttock, popliteal region, chest, trunk, head and neck, and female genital system. Orbital lesion presents with proptosis and lid swelling. Vaginal bleeding occurs due to tumor in female genital tract.

Surgical Pathology: Alveolar Soft Part Sarcoma

Gross Morphology

- Alveolar soft part sarcoma is a poorly circumscribed tumor.
- Cut surface is pale gray with soft in consistency.
- Areas of hemorrhage and necrosis are demonstrated in large tumor.

Light Microscopy

- Alveolar soft part sarcoma is composed of large uniform epithelioid cells with well-defined borders, centrally placed bland nuclei and abundant eosinophilic cytoplasm somewhat granular and rod-shaped intracytoplasmic inclusions.
- Tumor cells are arranged in solid nests and/or alveolar structures and separated by delicate fibrovascular septa (Fig. 28.29).
- Loss of cellular cohesion and necrosis of the neoplastic cells in the central region of nests of tumor cells gives pseudoalveolar pattern.

Histochemistry

Neoplastic cells of alveolar soft part sarcoma demonstrate rhomboid or rod-shaped intracytoplasmic inclusions, and variable amount of glycogen and diastase resistant granules demonstrated by PAS stain.

Electron Microscopy

- Most distinctive feature of alveolar soft part sarcoma is the presence of membrane bound rhomboid or rectangular crystals composed of periodic lattice work of rigid fibrils with 5–7 nm in diameter.
- Cytoplasmic granules associated with formation of crystals contain monocarboxylate transporter protein 1 and its cellular chaperone CD147.

Differential Diagnosis

Alveolar soft part sarcoma.

Immunohistochemistry Technique

Alveolar soft part sarcoma shows strong nuclear positivity for TFE3 retained in the fusion protein.

Marker	Expression
TFE3	Positive

Molecular Genetic Alterations

- Alveolar soft part sarcoma is defined by a specific cytogenic alteration, der(17) t(X;17) (p11;q25) resulting in the formation of fusion protein ASPSCR1-TFE3. ASPSCR1 located on 17q25 fuses with TFE transcription factor gene located on Xp11.

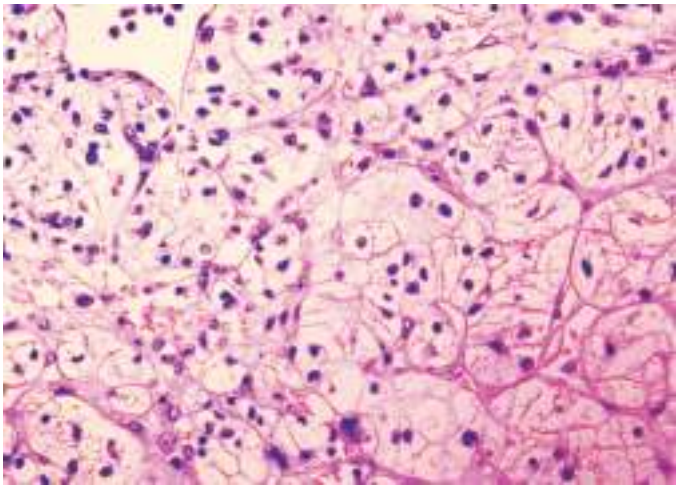

Fig. 28.29: Alveolar soft part sarcoma. Tumor is composed of large uniform epithelioid cells with well-defined borders, centrally placed bland nuclei and abundant eosinophilic cytoplasm somewhat granular and rod-shaped intracytoplasmic inclusions. Neoplastic cells are arranged in solid nests and/or alveolar structures and separated by delicate fibrovascular septa. Loss of cellular cohesion and necrosis of the neoplastic cells in the central region of nests of tumor cells gives pseudoalveolar pattern (400X).

- Presence of ASPSCR1-TFE3 fusion transcript is highly specific for alveolar soft part sarcoma. However, it is also demonstrated in renal cell carcinoma affecting young persons.

Prognosis and Treatment

Alveolar soft part sarcoma is treated by surgical excision. Tumor may recur after surgical resection of tumor. Before detection of primary tumor, metastases can be observed in lung, bone and brain. Metastases in lymph nodes are uncommon. Factors influencing prognosis are age of the patient, tumor size and metastases to distant organs.

CLEAR CELL SARCOMA OF SOFT TISSUE

Clear cell sarcoma of soft tissue is also known as malignant melanoma of soft tissue, which most often occurs in the deep soft tissue of the extremities in proximity to tendons and aponeurotic structures.

- Tumor shows nested growth pattern of neoplastic cells, consistent melanocytic differentiation and recurrent EWSR1-ATF1 fusion protein in majority of cases.
- Reciprocal chromosomal translocation t(12;22)(q13,q12) leads to formation of EWSR1-ATF1 fusion transcript in >90% of cases.

Locations and Age Distribution

Most common site of clear cell sarcoma is foot/ankle of deep region intimately associated with tendons and aponeurosis without involving skin in 40% of cases. Uncommon sites are head and neck, trunk, retroperitoneum, viscera, bone and gastrointestinal tract especially small intestine in decreased frequency. It usually affects young adults with equal sex distribution. Peak incidence of tumor is during third and fourth decades of life.

Clinical Features

Patient presents with slow-growing mass most often in foot/ankle region over weeks to several years' duration. Pain and tenderness is present in 50% of cases. Lymph node metastasis is frequent.

Surgical Pathology: Clear Cell Sarcoma of Soft Tissue

Gross Morphology

- Tumor is well-circumscribed soft tissue mass measures <5 cm in diameter. However, tumor >10 cm has been reported.
- Cut surface shows a lobulated gray white tumor with pushing margin. Rarely, areas of pigmentation, necrosis and cystic areas are demonstrated.

Light Microscopy

- Under low magnification, tumor shows nested growth pattern with collagenous fibrous bands dividing the tumor into distinct compartments. Neoplastic cells display predominantly epithelioid morphology.
- Tumor is composed of epithelioid cells containing vesicular nuclei and amphophilic cytoplasm.
- Scattered wreath-like multinucleated giant cells are most often demonstrated. Melanin is demonstrated in 66% of tumors. Average 4 mitoses per high power fields are demonstrated.

Histochemistry

Melanin is demonstrated in clear cell sarcoma of soft tissue by Masson-Fontana stain in 66% of cases.

Electron Microscopy

Melanosomes are demonstrated in majority of cases in clear cell sarcoma of soft tissue.

Immunohistochemistry Technique

Clear cell sarcoma of soft tissue shows positivity for S-100 protein, HMB-45 (human melanoma black 45) and MITF (microphthalmia transcription factor).

Markers	Expression
S-100 protein	Positive
HMB-45 (human melanoma black 45)	Positive
MITF (microphthalmia transcription factor)	Positive

Molecular Genetic Alterations

Genetic hallmark of clear cell sarcoma of soft tissue is reciprocal chromosomal translocation t(12;22)(q13,q12) resulting in the formation of EWSR1-ATF1 fusion transcript in >90% of cases.

Prognosis and Treatment

Clear cell sarcoma of soft tissue is treated by wide margin surgical excision. Local recurrence of tumor occurs after surgical excision. Poor prognostic factors include tumor size >5 cm, presence of necrosis, local recurrence after surgical excision, and metastases to regional lymph nodes, lungs and bones. Clear cell sarcoma of gastrointestinal tract usually metastasizes to lymph nodes, peritoneum and liver.

CHONDRO-OSSEOUS TUMORS AND OTHER LESIONS

Normally, somatic soft tissue lacks mature osteoblasts and chondrocytes. Therefore, somatic soft tissue does not contain bone or cartilage. However, under certain circumstances, undifferentiated mesenchymal cells are stimulated to develop into bone or cartilage producing tumors. Chondro-osseous tumors according to recent 2020 WHO classification of soft tissue tumors are shown in Table 28.26.

Table 28.26 Chondro-osseous tumors according to recent 2020 WHO classification of soft tissue tumors

Chondro-osseous Tumors
Benign tumors/lesions
▪ Soft tissue chondroma ▪ Myositis ossificans ▪ Fibro-osseous pseudotumor of digits
Malignant tumors
▪ Primary soft tissue osteosarcoma ▪ Mesenchymal chondrosarcoma

MYOSITIS OSSIFICANS

Myositis ossificans is a non-neoplastic reactive bone and cartilage producing pseudotumor developing in the skeletal muscle.

Locations and Age Distribution

Most common sites of myositis ossificans are large muscles of the proximal extremities of persons during second and third decades of life. Males and females are equally affected.

Clinical Features

Patient presents with short history of pain and swelling of the affected extremity. Localized erythema is rarely seen.

Radiologic Findings

Conventional radiograph and magnetic resonance imaging initially demonstrate a soft tissue mass. In mature lesion of myositis ossificans demonstrates areas of ossification.

Surgical Pathology: Myositis Ossificans

Gross Morphology

- Myositis ossificans most often measures <5 cm in diameter.
- Early lesion of myositis ossificans is ill-defined soft tissue mass, that may exhibit focal gritty calcifications of mineralized bone.
- As the lesion matures, mass is completely ossified appearing solid bone and easily demarcated from the skeletal muscle.

Light Microscopy

- **Early lesion of myositis ossificans:** It is composed of plump myofibroblastic cells arranged in sheets and fascicles.
  - Myofibroblastic cells contain oval nuclei with vesicular chromatin and eosinophilic nucleoli; embedded within a myxoid to collagenous ground substance.
  - Mitotic figures are usually demonstrated. Necrosis is absent.
- **Mature lesion of myositis ossificans:** It is composed of well-organized more mature bone (lamellar cortical and lamellar bone containing hematopoietic marrow).
  - Intersecting fibrillary eosinophilic lace-like woven bone trabeculae appear to originate from the spindle cells.
  - Transition of immature foci of woven bone to thicker mineralized woven bone trabeculae showing prominent osteoblastic rimming is termed 'zoning phenomenon' (Fig. 28.30).

Differential Diagnosis

- Myositis ossificans should be differentiated from fibro-osseous pseudotumor (non-muscular soft tissue mass) of hand, nodular fasciitis and extraskeletal osteosarcoma.
- Extraskeletal osteosarcoma affects adults during fifth and six decades of life. Tumor measures >5 cm in diameter. Tumor is composed of pleomorphic cells with cytologic atypia.

Immunohistochemistry Technique

Early lesion of myositis ossificans composed of spindle cells shows positivity for smooth muscle actin and muscle-specific actin reflecting their myofibroblastic morphology.

Markers	Expression
▪ Smooth muscle actin (SMA) ▪ Muscle-specific actin (MSA)	▪ Positive ▪ Positive

Prognosis and Treatment

Myositis ossificans is cured by surgical excision. Recurrence is extremely uncommon, even when resection margins are positive.

FIBRO-OSSEOUS PSEUDOTUMOR OF DIGITS

Fibro-osseous pseudotumor of digits is a non-neoplastic reactive bone and cartilage producing pseudotumor in the soft tissue of digits. It is clinicopathologic analogous to myositis ossificans.

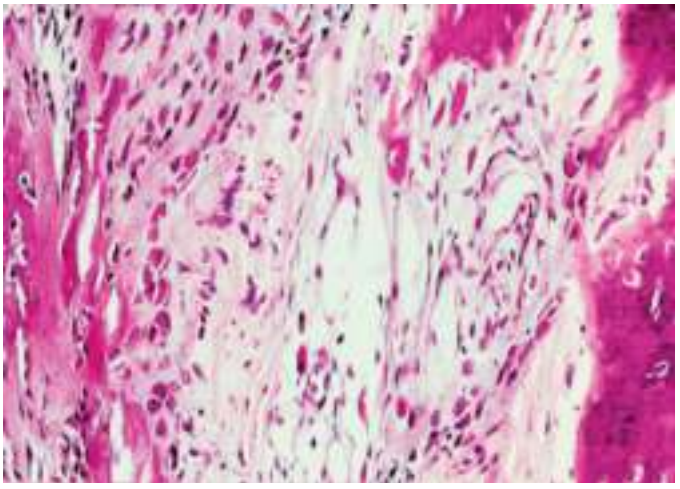

Fig. 28.30: Myositis ossificans. Myositis ossificans is a non-neoplastic reactive bone and cartilage producing pseudotumor developing in skeletal muscle. As the lesion matures, it becomes less cellular and shows osteoid and chondroid formation in the skeletal muscle (400X).

Locations and Age Distribution

Most common sites of fibro-osseous pseudotumor are soft tissue surrounding the small tubular bones of hands and feet in decreased frequency. It most common affects adults during second and third decades of life. Males and females are equally affected.

Clinical Features

Patient presents with swelling digits over short duration especially history of trauma in <50%.

Radiologic Findings

Radiograph demonstrates soft tissue swelling with or without linear periosteal bone formation affecting the underlying bone.

Surgical Pathology: Fibro-osseous Pseudotumor of Digits
Gross Morphology
Fibro-osseous pseudotumor is firm, tan and rubbery measuring <3 cm in diameter.
Light Microscopy
▪ Histology of fibro-osseous pseudotumor of digits is identical to myositis ossificans. Fibro-osseous pseudotumor is composed of plump spindle cells admixed with osseocartilaginous tissue. Zoning phenomenon, i.e. transition of immature foci of woven bone to thicker mineralized woven bone trabeculae with prominent osteoblastic rimming is absent in fibro-osseous pseudotumor. ▪ Typical mitotic figures are demonstrated. High-grade nuclear atypia and necrosis are absent.
Differential Diagnosis
Fibro-osseous pseudotumor of digits should be differentiated from myositis ossificans, soft tissue chondroma and fracture callus.

Prognosis and Treatment

Fibro-osseous pseudotumor of digits is cured by surgical excision. Recurrence is uncommon, even when margins are positive. Aggressive destructive growth does not occur.

EXTRASKELETAL OSTEOSARCOMA

Extraskeletal osteosarcoma originates in somatic soft tissue, in which the neoplastic cells produce osteoid and/or bone matrix.

Locations and Age Distribution

Extraskeletal osteosarcoma accounts for 1–2% of soft tissue sarcomas. Most common sites of extraskeletal osteosarcoma are the deep soft tissue of the thigh and buttock regions. It usually affects adults during fifth and sixth decades with male predominance.

Clinical Features

Patient presents with soft tissue painless mass in the thigh or buttock regions.

Radiologic Findings

Most of extraskeletal osteosarcomas have nonspecific imaging features identical to other high grade soft tissue sarcomas. Mineralization tends to be minimal.

Surgical Pathology: Extraskeletal Osteosarcoma	
Gross Morphology	
▪ Tumor is large heterogenous well circumscribed tumor measuring >10 cm in diameter. ▪ Mineralized bone is not demonstrated on gross examination. ▪ Cut surface shows areas of hemorrhage and necrosis.	
Light Microscopy	
▪ Tumor is composed of spindle to epithelioid neoplastic cells forming neoplastic lace-like eosinophilic osteoid and/or bone. Mineralized osteoid (bone) is relatively uncommon. ▪ Lobules of cellular atypical hyaline cartilage may be demonstrated. ▪ All histologic patterns of osseous osteosarcoma including small cell, telangiectatic and undifferentiated spindle cell sarcoma patterns may be demonstrated in extraskeletal osteosarcoma.	
Differential Diagnosis	
Extraskeletal osteosarcoma should be demonstrated from osseous osteosarcoma (primary or metastatic and recurrent) and other non-matrix producing soft tissue sarcomas.	
Immunohistochemistry Technique	
▪ Tumor cells show identical pattern of staining to skeletal osteosarcoma. ▪ Diffuse strong vimentin staining is demonstrated in extraskeletal osteosarcoma. ▪ Focal staining for S-100 protein, desmin, and smooth muscle actin may also be demonstrated. ▪ Antibody to the bone matrix osteocalcin is specific for both neoplastic cells and neoplastic bone/osteoid matrix.	
Markers	**Expression**
▪ Osteocalcin	▪ Positive (neoplastic cells and neoplastic matrix)
▪ Vimentin	▪ Positive (diffuse strong staining)
▪ Smooth muscle actin	▪ Positive (focal staining)
▪ Desmin	▪ Positive (focal staining)
▪ S-100 protein	▪ Positive (focal staining)

Prognosis and Treatment

Extraskeletal osteosarcoma is a high-grade sarcoma treated by wide surgical excision with systemic

chemotherapy. Tumor has high rate of metastases to distant organs.

SOFT TISSUE CHONDROMA

Soft tissue chondroma is a benign tumor composed of mature chondrocytes, associated with well-formed hyaline cartilage.

Locations and Age Distribution

Most common sites of soft tissue chondroma are distal extremities especially fingers and wrist region. It most affects adults during fourth to seventh decades of life with male predominance.

Clinical Features

Patient presents with painless soft tissue mass in fingers or wrist.

Radiologic Findings

Radiograph shows nonspecific appearance. Lesion is not attached to the underlying skeleton.

Surgical Pathology: Soft Tissue Chondroma

Gross Morphology

- Tumor is well circumscribed tumor measuring <2 cm in diameter. It is easily removed from the surrounding structures.
- Cut surface shows pearly white, chalk-like areas of calcification.

Light Microscopy

- Tumor is composed of mature chondrocytes arranged in clusters embedded within well formed hyaline cartilage. Chondrocytes may demonstrate mild nuclear irregularity and nucleoli. Mitotic figures are rarely demonstrated. Overall cellularity of chondroma is greater than normal hyaline cartilage.
- Tumor is lobulated and well demarcated from adjacent soft tissue. It shows microscopic calcification with or without enchondral ossification.
- Few chondromas show increased cellularity, and are composed of more plump epithelioid chondrocytes and clusters of multinucleated osteoclast-like giant cells. Such tumors are designated as 'chondroblastoma-like' soft tissue chondromas.

Differential Diagnosis

Chondroma should be differentiated from synovial chondromatosis, fibro-osseous pseudotumor of digits and soft tissue chondrosarcoma.

Immunohistochemistry Technique

Chondroma shows positivity for vimentin and S-100 protein.

Markers	Expression
▪ Vimentin	▪ Positive
▪ S-100 protein	▪ Positive

Prognosis and Treatment

Soft tissue chondroma is treated by surgical excision. Recurrence is demonstrated in 20% of cases.

EXTRASKELETAL MYXOID CHONDROSARCOMA

Extraskeletal myxoid chondrosarcoma is a soft tissue tumor composed of spindle and epithelioid neoplastic cells associated with extracellular matrix, that resembles cartilage on histological and histochemical examination. The majority of neoplasms exhibit the chromosomal translocation t(9;22)(q22;q12) involving the EWS and CHN genes. These tumors are distinct from osseous chondrosarcomas on histological, histochemical and immunohistochemical analysis.

Locations and Age Distribution

Extraskeletal myxoid chondrosarcoma accounts for 2.5% of all soft tissue sarcomas. Most common sites of tumor are deep soft tissue of proximal extremities and trunk. However, it may occur at any site. It affects adults during fourth to seventh decades of life with male predominance.

Clinical Features

Patient presents with painless soft tissue mass in the deep soft tissue of the proximal extremity or trunk. Rarely, patient may present with lung metastasis and an occult primary tumor.

Surgical Pathology: Extraskeletal Myxoid Chondrosarcoma

Gross Morphology

- Tumor is a lobulated mass measuring >5 cm in diameter.
- Cut surface is gray and gelatinous with soft in consistency.

Light Microscopy

- Tumor demonstrates a lobular growth pattern under low power examination.
- Tumor is composed of uniform oval to spindled cells with uniform dark staining nuclei and indistinct nucleoli arranged in nests, cords and clusters, and embedded within flocculent basophilic matrix.
- Individual lobules of the tumor are separate by fibrous bands. Blood vessels are indistinct.
- In recent years, the existence of cellular matrix-poor regions of extraskeletal chondrosarcoma has been recognized. In these areas, there is presence of large neoplastic cells with hyperchromatic nuclei, nuclear atypia, high nuclear/cytoplasmic ratio and mitoses.

Histochemistry

Alcian blue histochemical staining is positive at pH 4.0 and 1.0, suggesting the presence of chondroitin sulfate in the tumor.

Differential Diagnosis

Extraskeletal myxoid chondrosarcoma should be differentiated from soft tissue sarcoma, osseous chondrosarcoma with soft tissue extension, ossifying fibromyxoid tumor and myoepithelioma/mixed tumor of soft tissue.

Immunohistochemistry Technique

Extraskeletal myxoid chondrosarcoma cells show diffuse positivity for vimentin, S-100 (<50%), neuron-specific enolase (NSE) and synaptophysin.

Markers	Expression
▪ Vimentin	▪ Positive (diffuse staining pattern)
▪ S-100 protein	▪ Positive (<50%)
▪ Neuron-specific enolase	▪ Positive
▪ Synaptophysin	▪ Positive

Prognosis and Treatment

Extraskeletal myxoid chondrosarcoma is treated by surgical excision. Five-year survival rate is demons trated in >80% of cases. Late metastasis may occur in lungs.

EXTRASKELETAL MESENCHYMAL CHONDROSARCOMA

Extraskeletal mesenchymal chondrosarcoma is a high-grade biphasic sarcoma composed of undifferentiated small blue cells and islands of well-formed hyaline cartilage.

Locations and Age Distribution

Extraskeletal mesenchymal chondrosarcoma accounts for <1% of soft tissue sarcomas. Most common sites of tumor are craniospinal axis soft tissues, meninges and paraspinal musculature, which may occur at any age, although most cases are diagnosed in adults during second to fourth decades of life. Males and females are equally affected.

Clinical Features

Patient with extraskeletal mesenchymal chondrosarcoma presents with painless within soft tissues of craniospinal axis or paraspinal musculature. Patient with meningeal mesenchymal chondrosarcoma presents with focal neurologic signs depending on location of intracranial tumor.

Radiologic Findings

Radiograph demonstrates soft tissue mass and focal cartilaginous-type calcification.

Surgical Pathology: Extraskeletal Mesenchymal Chondrosarcoma

Gross Morphology

- Tumor is well defined measuring <5 to >30 cm in diameter.
- Cut surface is tan gray. Focal areas of hemorrhage or necrosis are demonstrated. Gritty areas representing the calcified cartilage are usually demonstrated.

Light Microscopy

- Tumor is composed of undifferentiated 'small blue cell' component.
- Neoplastic cells are arranged in sheets, vague nests or both. Characteristic feature of tumor is the presence of a supporting capillary network that has acute angle branching resulting in a 'hemangiopericytoma-like' growth pattern.
- The blue cells are associated with bands of eosinophilic hyalinized collagen fibers that may resemble the 'rope-like' collagen of solitary fibrous tumor.
- Islands of well-formed hyaline cartilaginous matrix with embedded well-differentiated chondrocytes exhibiting granular purple mineralization of the matrix are demonstrated.

Differential Diagnosis

- Extraskeletal mesenchymal chondrosarcoma should be differentiated from other blue cell sarcomas such as Ewing sarcoma/primitive neuroectodermal tumor (PNET) and small cell osteosarcoma.
- Ewing sarcoma is characterized by recurrent balanced chromosomal translocations in almost all cases. Reciprocal translocation between chromosomes 11 and 22 results in fusion of the amino terminus of EWSR1 gene and Flt-1 gene, which encodes a nuclear transcription factor resulting in unrestricted cellular proliferation.
- Solitary fibrous tumor and synovial sarcoma demonstrate sheets of small, rather undifferentiated appearing cells often associated with a hemangiocytoma-like vascular pattern. These tumors do not show hyaline cartilage.

Immunohistochemistry Technique

Small blue cells and chondrocytes of extraskeletal mesenchymal chondrosarcoma show positivity for vimentin. Small blue cells are positive for CD99. Cartilaginous component of the tumor shows positivity for S-100 protein.

Markers	Expression
▪ Vimentin	▪ Positive (small blue cells and chondrocytes components)
▪ CD99	▪ Positive (small blue cell component)
▪ S-100 protein	▪ Positive (cartilaginous component)

Prognosis and Treatment

Extraskeletal mesenchymal chondrosarcoma is highly aggressive tumor treated by a combination of surgery and chemotherapy. Five-year survival is demonstrated in 50% of cases.

NON-NEOPLASTIC DISORDERS OF SKELETAL MUSCLE

SKELETAL MUSCLE: STRUCTURE

Skeletal muscle is a specialized tissue of mesodermal origin, which has special properties like excitability, contractibility and elasticity.

- Each skeletal muscle is composed of numerous muscle fibers bundled together and wrapped in a connective tissue sheath called epimysium. Fascia, connective tissue outside the epimysium surrounds and separates the skeletal muscle fibers. Portions of the epimysium project inward to divide the skeletal muscle into compartments. Each bundle of skeletal muscle fiber is called fasciculus and surrounded by a connective tissue called perimysium. Within the fasciculus, each skeletal muscle fiber is surrounded by connective tissue called endomysium.
- Skeletal muscles have an abundant supply of blood vessels and nerves. Skeletal muscle fiber contains a specialized smooth endoplasmic reticulum called sarcoplasmic reticulum, that stores, releases and retrieves calcium ions (Ca^{++}).
- Skeletal muscle fiber is composed of many myofibrils, which contain sarcomeres with light and dark regions that give the cell, its striated appearance, and surrounded by a plasma membrane called sarcolemma (Greek word '*sarco*' means 'flesh'), which contains cytoplasm called sarcoplasm.
- The sarcomere, the region from one Z line to the next Z line, is the fundamental functional unit of a skeletal muscle fiber. When sarcomere contracts, the Z lines move close together and the I band (light band) becomes smaller. The A band (dark band) stays the same width. At full contraction, the thick filaments and thin overlap. Contractile thick and thin filaments are present in the sarcoplasm.
  - Contractile thick filaments possess myosin component, which has a tail and head (actin binding site). Myosin head has contractile property as well as ATPase like action. Contractile thin filaments possess troponin, actin and tropomyosin. Troponin masks the active sites on the F-actin.
- Skeletal muscle fibers contain two types of fibers: slow-twitch (type 1) and fast twitch (type 2). Slow-twitch skeletal muscle fibers support long distance endurance activities like marathon running. Fast-twitch skeletal muscle fibers support quick, powerful movements such as sprinting or weight-lifting. Comparison of type 1 and type 2 skeletal muscle fibers is given in Table 28.27.

Table 28.27 Comparison of type 1 and type 2 skeletal muscle fibers

Features	Type 1 (Red) Skeletal Muscle Fibers	Type 2 (White) Skeletal Muscle Fibers
Prototype muscle	Soleus muscle	Pectoral muscle
Action and duration	Sustained movement with force and prolonged duration action	Sudden movement and short duration action
Contraction rate	Contraction rate slow	Contraction rate fast
Glycogen content	Scant amount of glycogen	Abundant amount of glycogen
Lipid content	Abundant amount	Scant amount
Staining properties	▪ ATPase at pH 4.2 dark staining ▪ ATPase at pH 9.4 light staining ▪ NADH-tetrazolium reductase dark staining	▪ ATPase at pH 4.2 light staining ▪ ATPase at pH 9.4 dark staining ▪ NADH-tetrazolium reductase light staining
Myoglobin	Present	Absent
Ultrastructure findings	▪ Many mitochondria ▪ Z-band wide	▪ Lesser mitochondria ▪ Z-band narrow
Physiology	Slow-twitch	Fast-twitch
Aerobic energy production	Aerobic energy production high	Aerobic energy production low
Anaerobic energy production	Low	High
Fatigue	Slow-onset fatigue	Rapid-onset fatigue
Energy utilization	Energy utilization low	Energy utilization high
Color of muscle fiber	Red color	White color
Function	Weight bearing	Purposeful motion

NADH-TR: Nicotinamide adenine dinucleotide tetrazolium reductase.

MYOPATHIES

Myopathy refers to skeletal and cardiac muscle dysfunction unrelated to any disorder of innervation or neuromuscular junction. Disruption of the structural integrity and metabolic processes of skeletal muscle cells can result from genetic abnormalities, inflammation, infection, toxins and hormonal and electrolyte imbalance.

- **Clinical features:** Patients typically present with proximal skeletal muscle weakness of legs more than arms with motor nerve involvement and without sensory nerve involvement. Myopathy can also affect the respiratory muscles, which can lead trouble breathing. Other symptoms of myopathy may include: skeletal muscle cramps, stiffness, muscle pain, low energy and fatigue and exercise intolerance. Over time, patients may also experience skeletal muscle wasting.
- **Classification of myopathies:** Age of clinical presentation, duration of illness, and distribution of weakness of skeletal muscles are helpful in determining the classification and etiology of myopathy. Myopathies can be divided into two main categories: inherited and acquired myopathies. Clinical course, the pattern of muscle weakness, and the absence of a family history of myopathy help in distinguishing between the inherited and acquired types.
  - **Inherited myopathies:** An early age of onset with a relatively longer duration of the disease suggests an inherited myopathy, which occurs due to transmission of an abnormal gene mutation from parents to children resulting in disruption of structural integrity and function of skeletal muscles, which can be further subclassified as muscular dystrophies, congenital myopathies, mitochondrial myopathies and metabolic myopathies. Inherited myopathies are given in Table 28.28.
  - **Acquired myopathies:** Acquired myopathies can be subclassified as inflammatory myopathies, toxic myopathies, and myopathies associated with systemic disorders. Treatment options for myopathy depends on the type and severity. Acquired myopathies are given in Table 28.29.

Table 28.28 Inherited myopathies

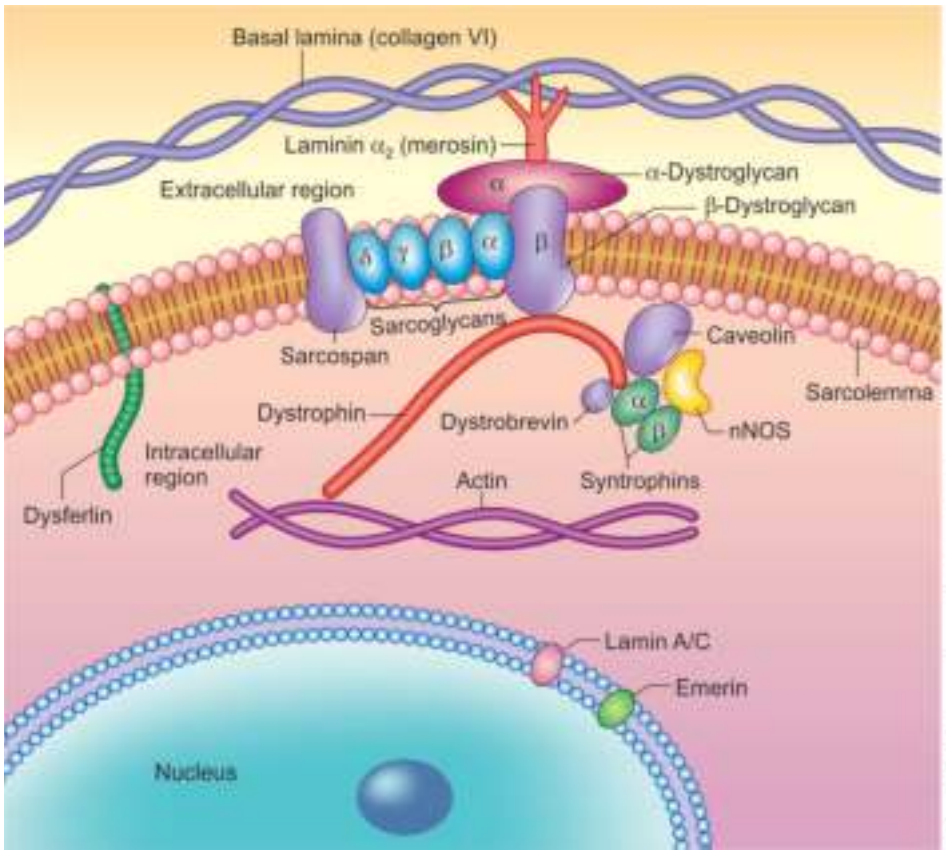
Skeletal Muscle Dystrophy
Duchenne muscular dystrophy (severe dystrophinopathy)
Becker muscular dystrophy (less severe dystrophinopathy)
Myotonic dystrophy
Emery-Dreifuss muscular dystrophy
Facioscapulohumeral dystrophy
Oculopharyngeal muscular dystrophy
Limb girdle muscular dystrophy
Congenital Myopathy
Nemaline myopathy
Central core myopathy
Centronuclear myopathy
Myotubular myopathy
Congenital fiber-type disproportion myopathy
Hyaline body myopathy
Mitochondrial Myopathy
Myoclonic epilepsy and ragged red fibers (MERRF)
Mitochondrial myopathy, lactic acid and strokes (MELAS)
Mitochondrial neurogastrointestinal encephaolpathy (MNGIE)
Progressive external ophthalmoplegia (PEO)
Metabolic Myopathy
Acid maltase or acid alpha-1,4-glucosidase deficiency (Pompe disease)
Glycogen storage disorders 1–11
Carnitine palmitoyl transferase deficiency

Table 28.29 Acquired myopathies

Autoimmune Myopathy
Polymyositis
Dermatomyositis
Myositis associated with antisynthetase syndrome
Immune-mediated necrotizing autoimmune myopathy
Inclusion body myositis
Infectious Myopathy
Viral infections (Epstein-Barr virus, influenza virus, human immunodeficiency virus)
Bacterial infections (pyomyositis due to *Staphylococcus aureus* and Streptococci)
Spirochete (Lyme disease)
Parasitic infections (trichinosis, cysticercosis, toxoplasmosis)
Fungal infections (Candida, Coccidioidomycosis)
Toxic Myopathy
Medications (corticosteroids, checkpoint inhibitor immunosuppressive agents, cholesterol-lowering medicines, i.e. statins, amiodarone, colchicine chloroquine, tryptophan, omeprazole)
Toxic agents (alcohol consumption, toluene vapor in spray paint inhalation)
Myopathy Associated with Systemic Disorders
Endocrine disorders (dysfunction of thyroid, parathyroid, pituitary and adrenal glands)
Systemic autoimmune disorders (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, Sjögren's syndrome, sarcoidosis and mixed connective tissue disease)
Amyloidosis [primary amyloidosis, familial amyloidosis (TTR mutation)]
Critical illness myopathy (nonpolarizing neuromuscular blocking agents, steroids)

- **Laboratory evaluation of myopathy:** Screening testing which indicates skeletal muscle damage, includes creatine phosphokinase (CPK), aldose, lactate dehydrogenase (LDH), and liver enzymes.
  - **Screening panel of laboratory tests:** Serologic testing, electromyography, skeletal muscle biopsy and genetic testing are helpful diagnostic tools in identifying the presence of myopathy and determining the etiology. A screening panel of laboratory tests should be performed to rule out more common causes of myopathy, which include: identification of etiology (complete blood count, metabolic panel, thyroid function tests, parathormone assay, C-reactive protein), identification of inflammation etiology (myositis-specific autoantibodies, anti-double-stranded DNA antibody, anti-Scl70 antibody, anti-SSA and SSB antibodies, rheumatoid factor, anti-PM1 antibody, angiotensin-converting enzyme levels), and identification of mitochondrial pathway, or metabolic pathway (serum lactate, pyruvate, ammonia, carnitine levels).
  - **Commercially available genetic tests:** Genetic tests are performed to detect gene mutation to diagnose myopathy, which include: (a) mutation in dystrophin gene in 'Duchenne muscular dystrophy' and Becker muscular dystrophy, (b) mutation in emerin gene in 'Emery-Dreifuss muscular dystrophy', (c) mutation in gene coding for lamin A/C, calpain, dysferlin and Fukutin-related protein in limb–girdle muscular dystrophy, (d) mutation in D4Z4 gene (deletion) in 'facio-scapulohumeral muscular dystrophy', (e) mutation in poly(A)-binding protein 2 gene coding for GCG repeat expansion in 'oculopharyngeal muscular dystrophy', (f) mutation in DMK gene for type 1 and CNBP (ZNF3) gene for type 2 are demonstrated in 'myotonic muscular dystrophy' type 1 and 2, (g) specific mutation in mitochondrial DNA (mitochondrial DNA**)** gene in 'mitochondrial myopathy', (h) mutation in transthyretin gene in 'familial amyloid myopathy', and (i) mutation in SLCO1B1 gene indicates increased susceptibility to 'statin myopathy'.
- **Management:** Management is largely supportive for an inherited myopathy. In acquired myopathies, treatment is targeted toward the underlying etiology. Treatment of statin myopathy is dependent on creatine phosphokinase levels and degree of skeletal muscle symptoms. Consider and lower doses when initiation of statin therapy.

INHERITED MYOPATHIES



Genetic abnormalities cause inherited myopathies that cause progressive weakness and degeneration of skeletal muscles used during voluntary movement. Inherited myopathies are differentiated by age of onset, skeletal muscle groups involved, and mode of inheritance.

- Inherited myopathies primarily affect the skeletal muscles caused by mutations in different genes coding for proteins that normally maintains skeletal muscle structure and function. Skeletal muscle weakness and hypotonia are classic clinical presentations in most common inherited myopathies.
- Some inherited myopathies result from irregularities in the mitochondria of the cells, and these are called mitochondrial myopathies, which can cause weakness of skeletal muscles of face and neck muscles including slurred speech, difficulty in swallowing and drooping upper eyelids (ptosis).
- Metabolic myopathies affect the genes that normally code for the enzymes responsible for normal skeletal muscle function. Patient presents with exercise intolerance and exertional muscle pain. Skeletal muscle biopsy is helpful in distinguishing muscle dystrophies from abnormalities secondary to denervation.

Muscular Dystrophies

Muscular dystrophy is a group of diseases that cause progressive weakness of skeletal muscles and loss of muscle mass. In muscular dystrophy, abnormal genes (mutations) interfere with the production of proteins needed for normal structure and function of muscles. The main sign of muscular dystrophy is progressive muscle weakness. Specific signs and symptoms begin at different ages and in different skeletal muscle groups depending on the type of muscular dystrophy. Having a family history of myopathy increases the likelihood to inherit an abnormal gene (mutation) that causes inherited myopathy. Muscular dystrophies include dystrophinopathy (Duchenne muscular dystrophy, Becker muscular dystrophy), 'myotonic dystrophy', 'facioscapulohumeral dystrophy, 'oculopharyngeal muscular dystrophy' and 'limb–girdle muscular dystrophy'. Patterns of inheritance of myopathies can be X-linked, autosomal dominant and autosomal recessive. Dystrophin associated protein complex and other proteins involved in skeletal muscular dystrophies is shown in Fig. 28.31. Salient features of skeletal muscular dystrophies are given in Table 28.30.

- **X-linked (sex-linked) recessive inheritance:** X-linked (sex-linked) recessive inheritance of muscular dystrophies occurs when as mother carries the defective gene on one of her two X chromosomes and transmitting it to her sons, as males always inherit an X chromosome from mother and the Y chromosome from their father, while daughters inherit an X chromosome from each parent.

Protein alteration	Muscular dystrophies
Dystrophin	DMD (Duchenne muscular dystrophy)
Dystrophin	BMD (Becker muscular dystrophy)
Laminin α_2 (merosin)	CMD (congenital muscular dystrophy)
Sarcoglycan subtypes	LGMD (limb–girdle muscular dystrophy)
α	LGMD
β	LGMD
γ	LGMD
δ	LGMD
Caveolin	LGMD1C
Dysferlin	LGMD2B (Miyoshi myopathy)
Collagen IV	CMD
Lamin A/C	Emery-Dreifuss MD (AD) Emery-Dreifuss MD (AR)
Emerin	Emery-Dreifuss MD (X-linked)

- **DMD:** Duchenne muscular dystrophy
- **CMD:** Congenital muscular dystrophy
- **LGMD:** Limb–girdle muscular dystrophy

Fig. 28.31: Dystrophin associated protein complex and other proteins involved in skeletal muscular dystrophies.

Table 28.30 Salient features of skeletal muscular dystrophies

Myopathy	Pattern of Inheritance	Genetic Defects	Distribution of Muscular Weakness	Other Systemic Manifestations
Duchenne muscular dystrophy	X-linked recessive	Dystrophin gene (Xp21)	Symmetrical proximal shoulder and pelvic girdles weakness, calf pseudohypertrophy, ankle contractions	Low intelligence, cardiomyopathy, gastrointestinal tract, muscle involvement, kyphoscoliosis, cognitive impairment
Becker muscular dystrophy	X-linked recessive	Dystrophin gene (Xp21)	Slowly progressive weakness of girdle muscles (minor variant of Duchenne's type)	Cardiomyopathy
Emery-Dreifuss muscular dystrophy	X-linked recessive, autosomal dominant or autosomal recessive	Emerin gene	Slowly progressive contractures of the Achilles tendon, elbow, neck and spine	Cardiomyopathy
Limb–girdle muscular dystrophy	Autosomal dominant or autosomal recessive	Lamin A/C, calpin, dysferlin, Fukutin-related protein	Slowly progressive weakness of proximal pelvic girdle followed by shoulder girdle, calf hypertrophy, scapular winging	Cardiomyopathy, cardiac arrhythmias, respiratory muscle weakness
Facioscapulohumeral dystrophy	Autosomal dominant	D4Z4 gene	Slowly-progressive weakness of facial, scapular and upper arm muscles, scapular winging	Hearing loss, retinal telangiectasis, hypertension

Contd...

Table 28.30 Salient features of muscle dystrophies (*Contd...*)

Myopathy	Pattern of Inheritance	Genetic Defects	Distribution of Muscular Weakness	Other Systemic Manifestations
Oculopharyngeal muscular dystrophy	Autosomal dominant	Short GCG repeat expansion in the poly(A)-binding protein 2 gene (PABP2 gene)	Slowly progressive weakness of extraocular eyelids, face and pharyngeal muscles	Ophthalmoparesis, bulbar weakness, dysarthria and dysphagia
Myotonic dystrophy type 1 and type 2 (DM1, DM2)	Autosomal dominant	Myotonic dystrophy type 1 (DMPK gene), type 2 (CNBP, i.e. CNF9 gene)	▪ Slowly progressive myotonic stiffness or spasm after a forceful, muscle contraction ▪ Myotonic dystrophy type 1 (distal muscle weakness) ▪ Myotonic dystrophy type 2 (proximal muscle weakness)	Cataracts, frontal balding, cardiac conduction defects, cardiac arrhythmias, mental impairment, diabetes mellitus, pregnancy and delivery related complications, eyelid ptosis without extra-articular muscle weakness, gonadal atrophy
Mitochondrial myopathy	Maternally inherited (some autosomal dominant or autosomal recessive)	Specific point mutation analysis for diseases like MELAS, POLG1 sequencing for MERRF available and South blot analysis for mtDNA deletions and mtDNA sequencing	Skeletal muscle weakness, hypotonia, exercise intolerance, feeding problems ▪ Infant symptoms (encephalomyopathy, respiratory muscle weakness, hypotonia and feeding difficulty) ▪ Children symptoms (progressive external ophthalmoplegia, drooping of upper eyelids, mild visual impairment)	Extraocular muscle weakness (drooping of upper eyelids), peripheral neuropathy, ataxia, deafness, cardiac conduction system defects
Acid alpha glucosidase, i.e. acid maltase deficiency (glycogen storage disorder type 2, i.e. Pompe disease)	Autosomal recessive	Gene mutation causing acid alpha glucosidase (acid maltase deficiency)	Proximal girdle weakness	Macroglossia, hepatomegaly in infancy, severe ventricular muscle weakness with adult presentation, cardiomyopathy
Statin-associated myopathy	Unknown	SLCO1B1 gene	Mild-to-moderate muscular weakness, muscle pain	Potentially life-threatening rhabdomyolysis

MELAS: Mitochondrial myopathy, lactic acid and strokes
MERRF: Myoclonic epilepsy and ragged red fibers
MNGIE: Mitochondrial neurogastrointestinal encephalopathy
PEO: Progressive external ophthalmoplegia

- Sons of carrier mothers have a 50% chance of inheriting the X-linked recessive disorder. Daughters also have a 50% chance of inheriting the defective gene, but usually are not affected since the healthy X chromosome they receive from their father can offset (less noticeable) the defective gene received from their mother.
- Affected fathers cannot transmit an X-linked recessive disorder to their sons but their daughters will be carriers of the disorder. Carrier females occasionally can exhibit milder symptoms of skeletal muscular dystrophy.

▪ **Autosomal dominant inheritance:** Autosomal dominant inheritance of muscular dystrophies occurs when as child receives a normal gene from one parent and defective gene from the other parent. Autosomal dominant inheritance means only one parent needs to transmit an abnormal gene to the child in order to cause the disorder. In families, where one parent carries a defective gene, each child has a 50% chance of inheriting the gene and therefore suffers from this disorder. Both males and females are equally at risk and the severity of the disorder can differ from person to person.

▪ **Autosomal recessive inheritance:** Autosomal recessive inheritance of muscular dystrophies means that both parents must carry faulty gene and transmit to their children. The parents each have one defective gene but are not affected by genetic disorder. Children in these families have a 25% chance of inheriting both copies of defective gene at a 50% chance of inheriting one gene and therefore becoming a carrier, able to transmit along the defective gene to their children. Children of

either sex can be affected by autosomal recessive inheritance.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is most common and severe form of X-linked recessive genetic disorder in boys characterized by progressive skeletal muscle degeneration and weakness. Although girls can be carriers and mildly affected.

- **Molecular genetic alterations:** Duchenne muscular dystrophy is caused by mutations of the dystrophin gene (DMD gene) mapped on chromosome Xp21 due to in-frame deletion of one or many exons leading to incomplete translation of dystrophin protein.
  - Loss of dystrophin protein leads to recurrent myofiber damage, progressive muscle fiber fibrosis and weakness, and dysfunction of muscle stem cells during muscle contractions.
  - Normal dystrophin protein links the subsarcolemmal cytoskeleton to the exterior of the cell of muscle fiber through a transmembrane complex of proteins that normally helps in keeping skeletal muscle cells intact against the mechanical and contractile stresses by inhibiting calcium (Ca^{++}) from entering the cell membrane of muscle fiber, affecting signaling of the cell, and water enters the mitochondria that causes muscular cell burst.
- **Clinical features:** Skeletal muscle weakness of arms, shoulder girdle, pelvic girdle and thighs may present initially with difficulty in independent ambulation but progressively advances to such an extent that affected patients are unable to carry out activities of daily living and must use wheelchairs. Patient has difficulty in rising from the floor, climbing stairs, maintaining balance and raising the arms. Orthopedic and cardiac complications are common and death occurs in the twenties due to respiratory insufficiency caused by muscular weakness or cardiac arrhythmia due to myocardial involvement. Duchenne skeletal muscle dystrophy involving proximal muscles of the extremities is shown in Fig. 28.32.
- **Laboratory diagnosis:** Laboratory diagnosis of Duchenne muscular dystrophy can usually be made after careful review of clinical history and examination of affected boys presenting with developmental delay, proximal skeletal muscle weakness, and marked elevated serum levels of creatine phosphokinase (CPK) plus confirmation by muscle biopsy and genetic testing (dystrophin gene mutation).
- **Management:** Current therapy is focused on treatment of Duchenne muscular dystrophy with glucocorticoids and physiotherapy to prevent onset of orthopedic complications. New emerging treatment includes viral-mediated microdystrophin gene replacement, exon skipping to restore frame, and nonsense expression therapy to allow translation and production of modified dystrophin protein.

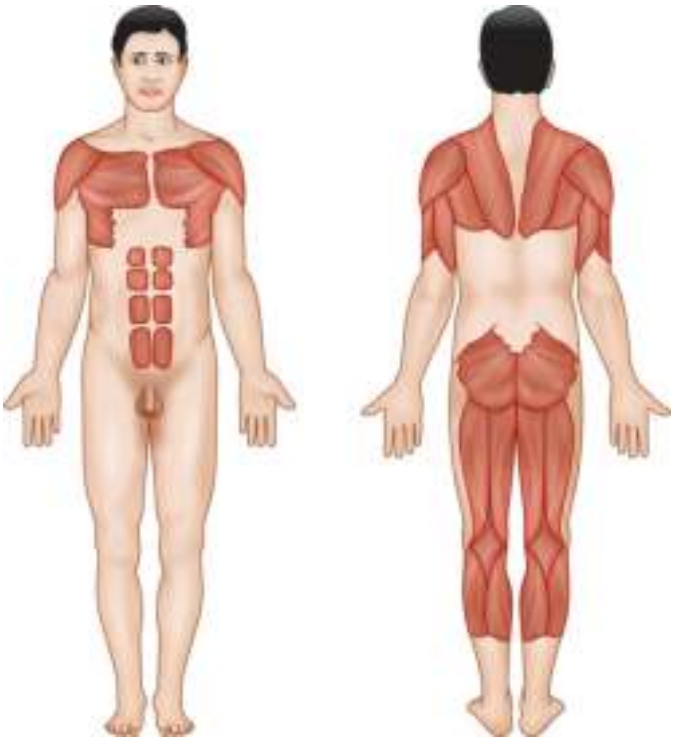


Fig. 28.32: Duchenne skeletal muscular dystrophy. It is X-linked recessive disorder involving proximal muscles of the extremities, progressing to muscle necrosis, wasting, muscle contracture with fatal outcome in their teens.

Becker Muscular Dystrophy

Becker muscular dystrophy (BMD) is an X-linked recessive inherited disorder characterized by slowly progressing skeletal muscle weakness of the legs and pelvis. BMD is generally milder and less severe muscle weakness than Duchenne skeletal muscular dystrophy. The affected maternal uncles with BMD continue to be ambulatory after age 15–20 years.

- **Molecular genetic alterations:** Becker muscular dystrophy is caused by mutation in the dystrophin gene located on the short arm of the X chromosome (Xp21) as a result of segmental deletion of dystrophin gene. It does not cause a coding frameshift, which encodes dystrophin protein.
- **Clinical features:** Signs and symptoms of Becker muscular dystrophy are clinically similar to those of Duchenne muscular dystrophy in boys, but tend to be milder, less severe, slower, less predictable and progress more slowly. Symptoms generally begin in the teens and might not occur until the mid-20s or later. Generalized weakness first affects skeletal muscles of hips, pelvis, thighs and shoulders. Calves are enlarged. There can be significant cardiac involvement. Patients can usually live at least for

30 years. The principal cause of death in patients with BMD is cardiac failure due to dilated cardiomyopathy.

- **Management:** Physical, occupational, speech and recreational therapy can all play in management of Becker muscular dystrophy.

Myotonic Muscular Dystrophy

Myotonic muscular dystrophy is an adult-onset, most common autosomal dominant disorder characterized by an inability to relax muscles after use following prolonged muscle contractions, progressive wasting of skeletal muscle, smooth muscles (gastrointestinal tract), cardiac electric conduction system defects, testes, atrophy and cataract.

- **Molecular genetic alterations:** Myotonic muscular dystrophy is caused by an increased number of trinucleotide repeats (50–1000) in the myotonin protein kinase gene (normal is <30 nucleotides).
- **Major types of myotonic muscular dystrophy:** There are two major types of myotonic muscular dystrophy, i.e. type 1 (mild and congenital variants) and type 2 (milder variant).
  - **Type 1 (mild and congenital) variant myotonic muscular dystrophy:** Type 1 mild variant of myotonic muscular dystrophy becomes apparent in mid-to-late adulthood with features of mild myotonia (lower legs, hands, neck and face) and cataract. Type 1 congenital variant of myotonic muscular dystrophy is apparent at birth with features of myotonia (lower legs, hands, neck and face), cataract clubfoot, breathing problems, delayed development and intellectual disability and other life-threatening health problems.
  - **Type 2 (milder) variant of myotonic muscular dystrophy:** It is caused by mutations in different genes, which involve skeletal muscles of the neck, shoulders, elbows and hips.
- **Clinical features:** Primary symptom of myotonic muscular dystrophy is myotonic stiffness or spasm following muscle contraction. Patient is unable to relax muscles once contracted.

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant disorder characterized by slowly-progressive skeletal muscle weakness and wasting of the face, scapular region, and upper arm with normal life expectancy. The shoulder blade might stick out like wings when arms are raised. Signs and symptoms usually appear in adolescence.

- **Molecular genetic alterations:** Facioscapulohumeral muscular dystrophy may be inherited through either father or mother or it may occur without a family history. FSHD is caused by insufficient repeat-mediated epigenetic repression of the D_4Z_4 gene microsatellite repeat array on chromosome 4q35 resulting in variegated expression of the D_4Z_4 retrogene, encoding double homeobox protein 4 (transcription factor) in skeletal muscle.
- **Clinical features:** However, onset and severity of FSHD disorder varies widely. Milder cases may not become noticeable until later in life. Severe cases present with muscular weakness with a descending progression starting in the face and scapular muscles then progressing to humeral muscles, foot dorsiflexor muscles and finally, proximal lower extremity of skeletal muscles during infancy or early childhood. Facioscapulohumerous skeletal muscular dystrophy is shown in Fig. 28.33.

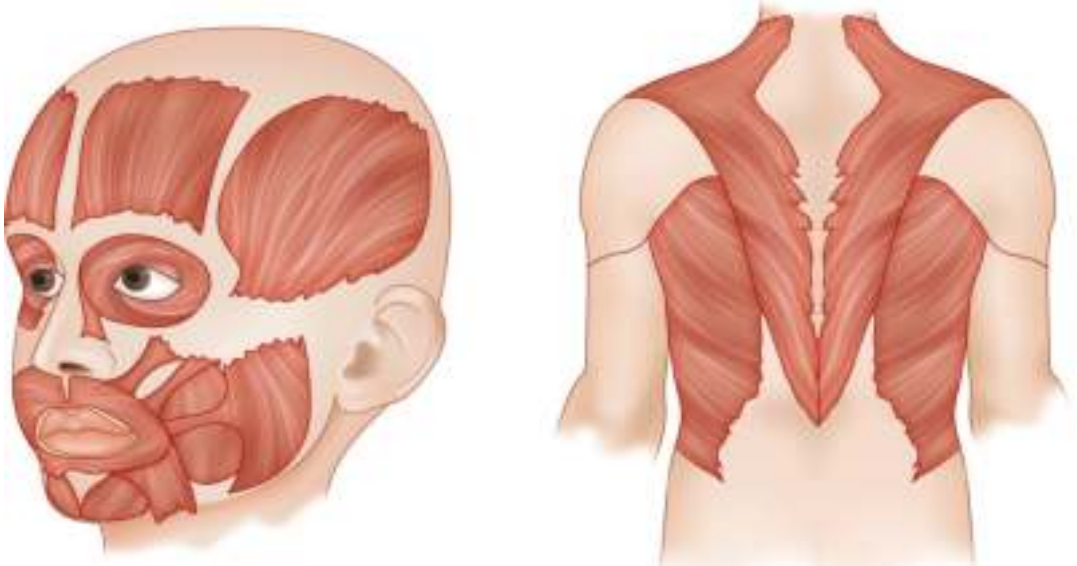

Fig. 28.33: Facioscapulohumerous skeletal muscular dystrophy. It is an autosomal dominant disorder involving skeletal muscles of the face, scapular region and upper arm.

Limb–Girdle Muscular Dystrophy

Limb–girdle muscular dystrophy is a genetic disorder (autosomal dominant or autosomal recessive) characterized by progressive weakness of skeletal muscles of upper arms, shoulder girdle, pelvic girdle and thighs during childhood or adolescence.

- **Molecular genetic alterations:** Limb–girdle muscular dystrophy is caused by different genes coding for aberrant proteins needed for maintenance and repair of skeletal muscles. Type 1 limb–girdle muscular dystrophy is an autosomal dominant disorder. Type 2A and 2B limb–girdle muscular dystrophy is an autosomal recessive disorder (CAPN3 gene mutation in type 2A and DYFS gene mutation in type 2B). Sarcoglycanopathies are forms of limb–girdle muscular dystrophy caused by mutations in the SGCA, SGCB, SGCG and SGCD genes.
- **Clinical features:** Patients might have difficulty in lifting the front part of the foot and so might trip frequently and may eventually require wheelchair assistance. Patients may develop cardiomyopathy. However, clinical manifestations remain mild in some cases. Limb–girdle muscular dystrophy involves skeletal muscles of the upper arms, shoulder, pelvic girdle and thighs is shown in Fig. 28.34.
- **Laboratory diagnosis:** Laboratory diagnosis of limb–girdle muscular dystrophy is based on clinical history, family history, physical examination, and supporting laboratory studies.

Fig. 28.34: Limb–girdle muscular dystrophy. It is genetic disorder involving skeletal muscles of the upper arms, shoulder, pelvic girdle and thighs.

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy (EDMD) is a genetic disorder with inheritance patterns (X-linked, or autosomal dominant or autosomal recessive), that primarily affects skeletal muscles of the elbows, ankle joints and cardiac muscle. Among the earliest features of the disorder are joint deformities called contractures of elbows, ankle joints (Achilles tendon), neck and spine during childhood.

- **Molecular genetic alterations:** Emery-Dreifuss muscular dystrophy is caused by absence of some protein functions in the cell's nucleus (emerin, lamin A, lamin C). Small protein called emerin is normally present in the cell membrane that surrounds each cell's nucleus. Untreated patients have fatal outcome as a result of defects in cardiac electric conduction.
- **Clinical features:** Patient presents with joint contractures that begin in early childhood, slowly progressive muscle weakness and wasting initially in humeroperoneal muscles that later extends to the scapular muscles and pelvic girdle muscles. There may be cardiac involvement in these cases.
- **Diagnosis:** Genetic testing is commercially available for the genes associated with Emery-Dreifuss muscular dystrophy: EMD, LMNA, HSH1, SYN1, SYNE2, TMEM43, SUN1, SUN2 and TTN.

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy (OPMD) is an autosomal dominant disorder characterized by weakness of skeletal muscles of upper eyelids (drooping of upper eyelids) and pharynx (dysphagia) in both men and women. OPMD is more common in people of French-Canadian descent, Hispanic people in Northern New Mexico and Ashkenazi Jewish. Patient presents with problems related to vision swallowing and talking.

- **Molecular genetic alterations:** Oculopharyngeal muscular dystrophy is caused by mutation in PABPN1 gene that codes for protein called polyadenylate-binding protein nuclear 1 (PABPN1). Either one copy or two copies (one from each parent) of defective gene is transmitted from parents to their children. Mutation in gene leads to buildup of aberrant PABPN1 protein in skeletal muscle cells. The PABPN1 clumps inside the skeletal muscle cells and may cause cells to die leading to skeletal muscle weakness.

- **Clinical features:** Patient presents with weakness of skeletal muscles of upper eyelids (drooping of upper eyelids) and pharynx (dysphagia) in both men and women.
- **Laboratory diagnosis:** Oculopharyngeal muscular dystrophy is diagnosed by family history, DNA analysis, swallowing tests, nerve conduction studies and electromyography and skeletal muscle biopsy for OPMD-PABPN1 clumps.

Congenital Myopathy

Congenital myopathy is term applied to distinct primary neuromuscular disorders that may be present at birth in both boys and girls. Symptoms may not appear until adolescence. Three common types of congenital myopathy include central core myopathy, nemaline myopathy and centronuclear myopathy. Other types include microtubular myopathy, multi-mini core myopathy, congenital muscle-fiber type disproportion myopathy and hyaline body myopathy. Different types of congenital myopathy are distinguished primarily by their clinical manifestations, skeletal muscle biopsy, MRI of skeletal muscles and DNA testing. Treatment of congenital myopathy is supportive and includes physiotherapy.

Nemaline Myopathy

Nemaline myopathy is a genetic disorder (autosomal dominant or autosomal recessive) caused by mutations in about 10 genes that encode thin filament proteins. Severe disease results in weakness of respiratory muscles and respiratory failure. Moderate disease manifests with progressive weakness of skeletal muscles of the face, trunk, and feet, but life expectancy may be normal. Mild disease is nonprogressive and life expectancy is normal. Skeletal muscle biopsy demonstrates tangles of small rod-shaped granules, predominantly in type 1 fibers.

Central Core Myopathy

Central core myopathy is a genetic disorder (autosomal recessive) caused by mutation in PYR_1 gene. Sporadic cases are also observed.

- Neonates develop hypotonia and mild proximal skeletal muscle weakness, but sometimes clinical manifestations do not manifest until adulthood. The affected infants eventually become ambulatory. Many patients also have nonprogressive skeletal muscle weakness of face.
- Life expectancy is normal, but some patients are severely affected and require a wheelchair. The gene mutation associated with central core myopathy is also associated with increased susceptibility to malignant hyperthermia.
- Skeletal muscle biopsy specimen lacks oxidative enzyme staining in the region (core). The regions may be peripheral, or central, focal, multiple, or extensive. A loss of mitochondria and other organelles occur in the central portion of type 1 muscle fibers.

Centronuclear Myopathy

Centronuclear myopathy is a genetic disorder (autosomal dominant or autosomal recessive or X-linked recessive inheritance) caused by mutations in genes that code for membrane-trafficking proteins. Skeletal muscle biopsy demonstrates an abundance of central nuclei.

- Autosomal dominant form of centronuclear myopathy typically manifests in adolescence or adulthood with exercise-induced myalgia, bifacial weakness, ptosis (drooping of upper eyelids) and external ophthalmoplegia.
- X-linked recessive inheritance form of centronuclear myopathy is most common and severe affecting children, which do not survive beyond the first year of life.

Myotubular Myopathy

Myotubular myopathy is a rare form of congenital myopathy affecting boys. Mother notices reduced movements of the weak and floppy baby in her womb during pregnancy.

- Floppy infant syndrome is marked by hypotonia and skeletal muscle weakness at birth or during the neonatal period and in some cases, delayed motor development later in childhood.
- Newborns usually have significant difficulties in respiration and swallowing. Many children do not survive. This order is also associated with osteopenia.

Congenital Fiber-type Disproportion Myopathy

Congenital fiber-type disproportion myopathy is a rare form of congenital myopathy that begins with floppiness, limb and facial weakness and respiratory problems.

Hyaline Body Myopathy

Hyaline body myopathy is a rare form of congenital myopathy characterized by the specific appearance on the microscopic examination of skeletal muscle tissue. Hyaline body myopathy has several different causes. Because of this, the clinical manifestations are quite variable.

Mitochondrial Myopathy

Mitochondrial myopathy is mediated by maternally transmitted mitochondrial DNA (mtDNA) abnormalities (most often deletions in mitochondrial DNA) affecting predominantly the skeletal muscle.

- Mitochondria regulate the production of cellular energy and carry the genetic blueprints for this process within their own unique DNA (mtDNA).
- Mitochondrial myopathy often affects more than one organ system of the body such as high energy tissues like skeletal muscle, cardiac muscle and brain.
- Kearns-Sayre syndrome is characterized by ophthalmoplegia, pigmentary retinopathy, heart conduction system block, cerebellar ataxia, and an exclusively maternal mode of transmission.
- Skeletal muscle biopsy demonstrates ragged red appearance due to various mitochondrial enzyme or coenzyme defects. In most mitochondrial disorders, abnormally high numbers of defective mitochondria are present in the cells of the body.

Metabolic Myopathies

Metabolic myopathies are disorders of muscle energy metabolism arising from specific enzymatic defects due to defective genes that result in skeletal muscle dysfunction.

- Enzymatic defects adversely affect glycogen breakdown, glucose utilization (glycolysis), fatty acid transport and oxidation to maintain adequate energy and adenosine triphosphate (ATP) production along the mitochondrial pathway.
- Cardiac and systemic metabolic dysfunction may coexist. Symptoms are often intermittent and provoked by exercise or changes in the supply of carbohydrate and lipid fuels.
- Evaluation of metabolic myopathies often requires provocative testing, which may include ischemic forearm exercise aerobic cycle exercise (failure to elevate lactate in blood confirming an abnormality of glycolytic metabolism), and 31P magnetic resonance spectroscopy with exercise.

Carnitine Palmitoyltransferase Deficiency Associated Myopathy

Patients with carnitine palmitoyltransferase deficiency cannot metabolize long-chain fatty acids because of an inability to transport these lipids into the mitochondria, where they undergo β-oxidation.

- **Clinical features:** Patient presents with skeletal muscular pain after prolonged exercise, which may progress to myoglobinuria. After such an episode, fibers regenerate and restore skeletal muscle structure.
- **Laboratory diagnosis:** Laboratory diagnosis depends on the biochemical assay for carnitine palmitoyltransferase activity. Skeletal muscle biopsy shows no microscopic abnormalities.

Pompe Disease Associated Myopathy

Pompe disease is an autosomal recessive glycogen storage disorder characterized by an inability to degrade glycogen due to acid maltase (acid alpha-1,4-glucosidase) deficiency. It is the most severe form of disease, which adversely affects skeletal muscle, cardiac muscle, central nervous system, and liver in the neonates or infants. Patient presents with severe hypotonia and absence of reflex (areflexia). Sometimes, the patient has an enlarged tongue and cardiomegaly and die of cardiac failure. Child usually dies within the first 2 years of life.

ACQUIRED MYOPATHIES

Acquired myopathies can be subclassified as inflammatory myopathies, toxic myopathies, and myopathies associated with systemic disorders such as autoimmune etiology (systemic lupus erythematosus, rheumatoid arthritis) or inflammation, infectious, endocrine hormonal imbalance etiology (hypothyroidism, hyperthyroidism, hyperparathyroidism, Cushing syndrome) and toxic agents. An electrolyte imbalance (hypokalemia, hyperkalemia) can also interfere with a muscle's ability to contract and relax as it should.

Inflammatory Myopathies

Inflammatory myopathies represent a heterogeneous group of acquired disorders, which are immune-mediated process triggered by environmental factors (tobacco smoke, infections, ultraviolet radiation) in a genetically susceptible person. Infectious myopathies occur as a result of infections that affect skeletal muscle function due to viruses (Epstein-Barr virus, human immunodeficiency virus, and influenza virus), bacteria, parasites (trichinosis, toxoplasmosis, cysticercosis) and fungi (Candida and Coccidioidomycosis) and Lyme disease.

- **Pathology:** Inflammatory myopathies are characterized by symmetric proximal skeletal muscle weakness, increased serum levels of muscle-derived enzymes, and nonsuppurative inflammation, necrosis and phagocytosis of skeletal muscle fibers, and a mixture of regenerating and atrophic fibers, and fibrosis.
- **Clinical features:** Patient presents with subacute to chronic onset of proximal muscle weakness manifested by difficulty with rising from a chair, climbing stairs, lifting objects and combing hair.
- **Laboratory diagnosis:** Laboratory diagnosis of inflammatory myopathies is based on clinical history, physical examination, electrodiagnosis and blood samples for skeletal muscle enzymes analysis. Muscle biopsy remains the gold standard for diagnosis. Skin biopsy can show changes in the skin associated with dermatomyositis. Goals of treatment are to eliminate inflammation, restore muscle performance, reduce morbidity and improve quality of life. Most

commonly used medicines are corticosteroids, immunosuppressants and immunoglobulin therapy.

Endocrine Myopathies

Endocrine myopathies occur when hormones interfere with skeletal muscle function in an overt endocrinopathy, i.e. disorders of thyroid gland (hyperthyroidism or hypothyroidism), parathyroid glands (hyperparathyroidism), and adrenal glands (Cushing syndrome and Addison disease). All the patients with neuromuscular complaints should be investigated for endocrine causes. In endocrine myopathy type 2, fast twitch skeletal muscle fibers are more severely affected than type 1 muscle fibers. Myopathies caused by endocrine disorders are mainly due to alterations in the protein and carbohydrate metabolism. Either deficiency or excess of hormones produced by the endocrine glands can cause muscle dysfunction that can be reversed by starting hormone replacement therapy.

Thyroid Gland Dysfunction Associated Myopathy

Thyrotoxicosis produces myopathy caused by protein catabolism, accelerated basal metabolic rate and impaired carbohydrate metabolism.

- In thyrotoxicosis, shortening of skeletal muscle contraction time may result from accelerated myosin ATPase activity and increased calcium uptake by the sarcoplasmic reticulum. Depolarization of the muscle fiber and impaired Na^+-K^+ activity in muscle may predispose to thyrotoxic paralysis. Neuromuscular presynaptic impairment may account for worsening of myasthenia gravis by thyrotoxicosis.
- In hypothyroidism, impaired energy metabolism, deduction in myosin ATPase activity and impaired Na^+-K^+ activity, impaired calcium uptake by sarcoplasmic reticulum in skeletal muscle may limit the force generation leading to slow contraction and relaxation of muscles. Treatment of thyroid disorders associated myopathy is restoration of euthyroid state.

Parathyroid Glands Dysfunction Associated Myopathy

Primary hyperparathyroidism and secondary hyperparathyroidism are always associated with proximal muscle weakness and fatigability. Myopathy is improved with restoration of normal parathormone levels and vitamin D replacement.

Adrenal Gland Dysfunction Associated Myopathy

Corticosteroid therapy and excess of ACTH (Cushing syndrome) cause myopathy having a pattern of proximal muscle weakness affecting the legs more than the arms. Steroid myopathy is not apparent until other signs of excess corticosteroid are present. Adrenal gland insufficiency (Addison disease) produces generalized skeletal muscle weakness, muscle cramps and fatigue in about 50% of cases.

Toxic Myopathies

Toxic myopathy is characterized by skeletal muscle weakness, myalgia, blood creatine kinase elevation or myoglobinuria that can occur in patients without muscle disease when they are exposed to certain drugs (corticosteroids, check point inhibitor immunosuppressive agents, cholesterol-lowering medicines, i.e. statins, amiodarone, colchicine chloroquine, tryptophan, omeprazole) and toxins (alcohol consumption, toluene vapor in spray paint inhalation). Early recognition of toxic myopathies is important as they potentially are reversible on removal of the offending drug or toxin, with greater likelihood of complete resolution the sooner this is achieved.

Autoimmune Myopathies

Autoimmune myopathies consist of dermatomyositis (most common in children), polymyositis (more common in females), myositis associated with antisynthetase syndrome, immune-mediated necrotizing autoimmune myopathy and inclusion body myositis (males) in the settings of systemic lupus erythematosus, rheumatoid arthritis, and sarcoidosis.

- In patients with suspected autoimmune myopathy, muscle imaging, electrophysiologic examination and serologic studies can be performed to confirm diagnosis. When present, dermatomyositis-specific autoantibodies may help to identify patients with different disease subtypes.
- Histologic features of dermatomyositis are perifascicular atrophy and perivascular inflammation. Histologic features of immune-mediated necrotizing myopathy are prominent myofiber necrosis. Histologic features of polymyositis are non-necrotic muscle fibers surrounded by lymphocytes.

MISCELLANEOUS NON-NEOPLASTIC DISORDERS OF SKELETAL MUSCLE

Skeletal Muscle Atrophy

Skeletal muscle atrophy is defined as a decrease in muscle mass and occurs when protein degradation exceeds protein synthesis leading to adverse functional consequences. Skeletal muscle atrophy occurs due to disuse of skeletal muscles (e.g. denervation, prolonged immobilization), starvation, aging and cachexia.

- Denervation skeletal muscle atrophy involves both type 1 and type 2 fibers. Disuse skeletal muscle atrophy fibers in prolonged immobilization involves type 2. Decrease in protein synthesis and increase in

protein degradation have been observed to contribute to skeletal muscle protein loss due to disuse.

- Recent studies have delineated elements of both synthetic and proteolytic processes. It has become evident that interactions among known proteolytic pathways (ubiquitin-proteasome, lysosomal, and calpain) are involved in skeletal muscle proteolysis during skeletal muscle atrophy.
- Tumor necrosis factor-α, glucocorticoids, myostatin and reactive oxygen species can induce skeletal muscle protein loss under specified conditions. It has become apparent that transcription factor NF-κB is a key intracellular signal inducer in disuse skeletal muscle atrophy.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder more frequent in women than in men. Disorder is characterized by breakdown of normal communication between nerves and muscles arising from production of autoantibodies to postsynaptic acetylcholine receptors of the neuromuscular junction (motor end-plate) involving extraocular and facial muscles, muscles of the extremities, and other muscle groups.

- **Pathogenesis:** Thymoma or thymic hyperplasia plays an important role in the pathogenesis of myasthenia gravis. Surgical removal of thymoma tumor is often curative in 40% of patients.
- **Clinical features:** Patient presents with drooping of one or both upper eyelids (ptosis), double vision (diplopia), difficulty in chewing, swallowing or speaking, and weakness of neck, arm and legs. Myasthenia gravis can be complicated by respiratory failure due to diaphragmatic weakness. Patient improves dramatically with administration of drugs with anticholinesterase activity.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome is a paraneoplastic disorder is characterized by muscular weakness of pelvic girdles, muscular wasting, and fatigability of the proximal limbs and trunk. Although it is most commonly associated with small cell lung carcinoma, yet it may also occur in patients with other malignant diseases. The pathogenic IgG autoantibodies recognize voltage sensitive calcium channels that are expressed both in motor nerve terminals and in the cells of the lung cancer. The calcium (Ca^{++}) channels, which are necessary for release of acetylcholine, are greatly reduced in the presynaptic membrane in these patients, thereby interfering with neuromuscular transmission. Patients respond to treatment with corticosteroids.

Myositis Ossificans

Myositis ossificans most often affects young persons. It is a benign condition but mimics a malignant neoplasm. The lesion typically results from blunt trauma to the muscle and soft tissues, usually of the lower limb. Over a short time, peripheral revascularization occurs in the hematoma results in formation of bone spicules in the soft tissue. It often occurs near a bone on radiography and may be misdiagnosed as a malignant bone-forming tumor.

Rhabdomyolysis

Rhabdomyolysis refers to the dissolution of skeletal muscle fibers and the release of myoglobin into the circulation, an event that may result in myoglobinuria and acute renal failure.

- Rhabdomyolysis may occur due to heat stroke or malignant hyperthermia after administration of an anesthetic such as halothane.
- Skeletal muscle biopsy shows active, non-inflammatory myopathy, with scattered necrosis of muscle fibers and varying degrees of degeneration and regeneration.
- Rhabdomyolysis may be acute, subacute, or chronic. During acute phase, the muscles are swollen, tender, and profoundly weak.

Skeletal Muscle Hypertrophy

Skeletal muscle hypertrophy of type 2 fibers occurs due to androgenic steroids. Stimulation of skeletal muscle type 2 fibers elicits a faster, shorter, and more powerful contraction than occurs in type 1 fibers.

- Skeletal muscle type 2 fibers rapidly contract for brief duration and react to strength training with hypertrophy.
- Skeletal muscle hypertrophy does not respond to an increased workload by increasing the number of fibers (hyperplasia).

Soft Tissue Tumor Specimen Handling in Surgical Pathology

- Soft tissues of the body connect, support, and other body parts and organs, which include: bone, cartilage, skeletal muscles, tendons, adipose tissue, blood vessels, lymphatic channels, nerves, and synovial tissue.
- According to WHO classification, soft tissue tumors are classified into three categories: benign tumors, intermediate tumors (locally aggressive and rarely metastasizing potential), and malignant tumors.
- Benign soft tissue tumors are common than malignant tumors. Soft tissue sarcomas can form anywhere in the body in the head, neck, arms, legs, trunk, abdomen, and retroperitoneum.

- Soft tissue tumors are diagnostically challenging group of neoplasms with a diverse spectrum and overlapping clinical features, radiologic and histologic features that can have varying lines of differentiation. Accurate diagnosis is essential for appropriate treatment and prognostication.
- Benign soft tissue tumors are common and treated with surgery alone. Surgery (wide surgical excision) is a common treatment for soft tissue sarcoma. External radiation therapy and internal radiation therapy, targeted therapy with receptor tyrosine kinase inhibitor (RTKI), and chemotherapy may be used to treat soft tissue sarcoma. Advances in molecular oncology have improved diagnostic, prognostic, and treatment protocols for patients with soft tissue high-grade sarcomas.
- Risk factors for soft tissue sarcoma include various inherited disorders: Li-Fraumeni syndrome (TP53 mutation), von Recklinghausen disease (neurofibromatosis type 1 (NF1) mutation), Gardner's syndrome (APC, nevoid basal cell carcinoma syndrome (Gorlin syndrome, PTCH1 mutation), and Werner syndrome (adult progeria, WRN mutation). Acquired risk factors for soft tissue sarcomas include: prior treatment with radiotherapy, persistent lymphedema in the arms or legs, exposure to thorium dioxide, vinyl chloride or arsenic, and being infected with HIV and human herpesvirus 8 (HHV8).
- Tests and procedures used to diagnose soft tissue sarcomas include imaging diagnostic tools (X-rays, CT scan, MRI scan and positron emission tomography), might help show the size and location of the tumor, biopsy procedures (core needle biopsy and surgical biopsy such as marginal resection, wide resection, and radical resection), molecular genetic tests, gross morphology of surgical specimen, histologic examination, and immunohistochemistry technique.
- Upon receipt of the surgical specimen in the pathology laboratory, it is essential to know clinical history, radiologic findings, staging, and prior chemotherapy or radiotherapy. Pathologist must evaluate gross morphologic features of surgical specimen such as unifocal/multifocal tumor, tumor site, tumor size in greatest dimension, cut surface appearance of tumor. Following the neutral buffered formalin fixation, representative thin slice of surgical specimen is processed and ultimately immersed in paraffin wax, termed a 'paraffin block'. Tissue sections are stained with hematoxylin and eosin stain and examined under the light microscope.
- Pathologist must follow reporting protocol such as histologic examination, tumor grading, mitotic rate, macroscopic or macroscopic necrosis, lymphovascular invasion, tumor margin status, regional lymph node status and distant metastasis status. Special studies are performed such as immunohistochemistry, cytogenetics, and molecular genetics.

CHAPTER

29

Skin

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

SKIN HISTOLOGY AND SKIN DISORDERS

- Skin histology
  - Epidermis
  - Dermis and subcutaneous tissue
  - Nails structure
- Skin disorders

INFECTIOUS DERMATITIS

- Bacterial skin infections
  - Eczematous dermatitis
  - Impetigo
  - Neurodermatitis
  - Scabies
  - Leprosy (Hansen's disease)
- Viral skin infections
  - Molluscum contagiosum
  - Common warts (verrucous vulgaris)
  - Dermatitis herpetiformis (herpes simplex virus II skin infection)
  - Varicella zoster virus skin infection (chickenpox)
- Fungal skin infections
  - Dermatophytosis (superficial fungal skin infections)
  - *Candida albicans* skin infection
  - Deep subcutaneous fungal infections (mycetoma, mucormycosis)

INFLAMMATORY DERMATITIS

- Inflammatory dermatitis: overview
- Inflammatory dermatitis: clinical entities
  - Psoriasis
  - Erythema multiforme
  - Lichen planus
- Pemphigus vulgaris
- Bullous pemphigoid

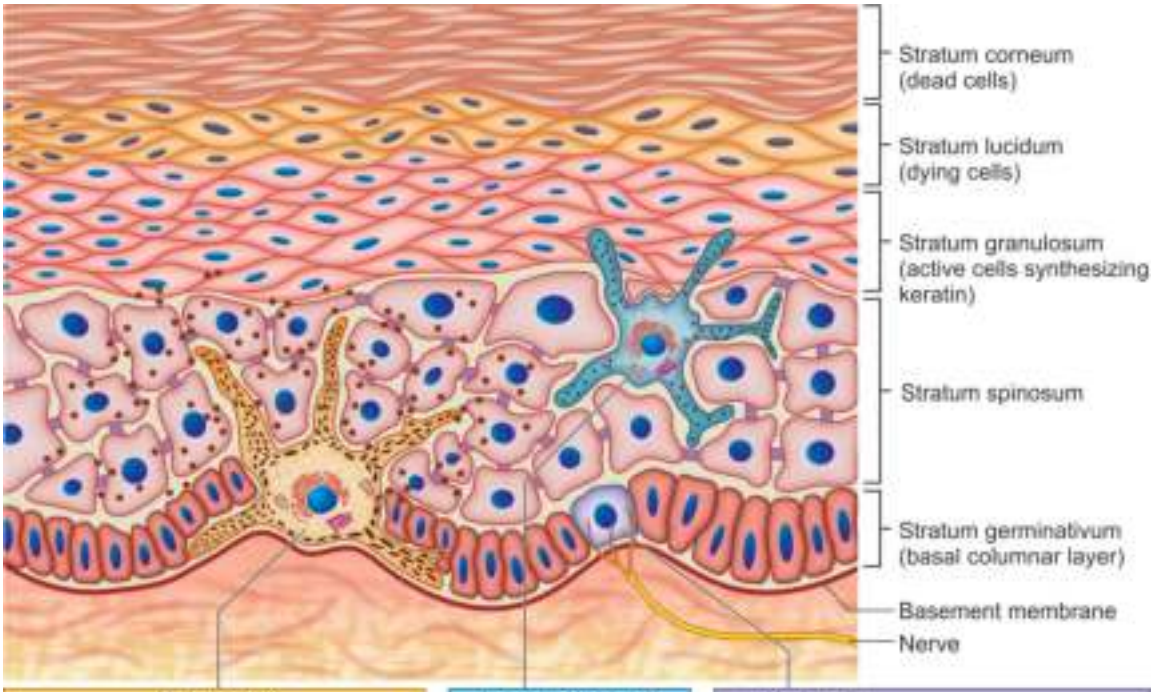
NON-NEOPLASTIC MELANOCYTIC DISORDERS AND MELANOCYTIC NEOPLASMS

- Non-neoplastic melanocytic disorders
  - Albinism
  - Vitiligo
  - Freckle (ephelis)
  - Lentigo simplex
- Melanocytic neoplasms
  - Congenital melanocytic nevi
  - Melanocytic nevus (common mole)
    - Dysplastic melanocytic nevus
    - Lentigo maligna
    - Blue nevus
    - Spitz nevus
  - Melanoma

NONMELANOCYTIC CUTANEOUS NEOPLASMS

- Carcinogenesis of skin cancers
  - Genomic instability
  - Chemical carcinogenesis
  - Ultraviolet radiation in carcinogenesis
- Epidermis tumors
  - Epithelial precancerous lesions
    - Actinic keratosis
    - Arsenical keratosis
    - Viral-associated epithelial precancerous lesions (bowenoid papulosis, epidermodysplasia verruciformis)
  - Bowen disease (squamous cell carcinoma *in situ*)
  - Squamous cell carcinoma of skin
  - Keratoacanthoma of skin
  - Basal cell carcinoma of skin
  - Basal cell nevus syndrome
  - Seborrheic keratosis
- Neuroendocrine tumors
  - Merkel cell carcinoma
- Skin appendageal tumors and hamartomatous of the skin
  - Nodular hidradenoma
  - Eccrine spiradenoma
  - Chondroid syringoma
  - Pilomatrixoma
- Dermis and subcutaneous fat: tumors
  - Dermatofibroma
  - Dermatofibrosarcoma protuberans
- Vascular tumors of skin
  - Capillary hemangioma
  - Kaposi sarcoma
  - Cutaneous angiosarcoma
- Neural tumors of skin
  - Plexiform neurofibroma
  - Traumatic neuroma
- Cutaneous metastases

MISCELLANEOUS SKIN DISORDERS



- Acne vulgaris
- Fibroepithelial polyp
- Epidermal keratinous cyst
- Acanthosis nigricans
- Xanthomas
- Granuloma pyogenicum
- Keloid

SKIN HISTOLOGY AND SKIN DISORDERS

SKIN HISTOLOGY

Skin consists of three layers: epidermis (outermost layer), dermis, and hypodermis (Fig. 29.1). Skin performs many functions: sensation, thermoregulation, protection, and metabolism (Table 29.1). Cells in the epidermis and dermis are given in Table 29.2.

- Epidermis is lined by stratified squamous epithelium that contains 4–5 layers depending on location: stratum basalis (basal layer close to dermis), stratum

Cells and structures in the epidermis and dermis

Skin layer	*Cells*	*Other structures*
Epidermis	• Keratinocytes • Melanocytes • Langerhans' cells • Merkel cell	Hair follicles, apocrine glands and sweat glands are derived from epidermis and extended to dermis
Dermis	• Fibroblasts • Mast cells • Histiocytes • Macrophages • Lymphocytes	Matrix of polysaccharides and proteins

Fig. 29.1: Schematic representation of structure of epidermis and dermis. Epidermis shows stratum germinativum, stratum spinosum, stratum granulosum, stratum lucidum and stratum corneum. The basal cells in the stratum germinativum undergo mitosis producing keratinocytes that change their size as they move upward, replacing cells that are lost during normal cell shedding. Schematic representation demonstrates melanocytes, Langerhans' cells and Markel cells in epidermis.

spinosum (prickle cell layer), stratum lucidum (present only in soles and palms), and stratum corneum (keratinized layer). Keratinocytes make up about 85% of cells in the epidermis.

- Dermis is a thick layer of connective tissue consisting of collagen, elastin, nerve endings, blood vessels, and adnexal structures such as hair shafts, sweat glands, and sebaceous glands. Hypodermis consists of adipose tissue.

EPIDERMIS

The epidermis rests on a basement membrane, a thin, acellular film of protein, which separates the epidermis from the dermis.

- Epidermis is composed of stratum germinativum (basal cells), stratum spinosum (prickle layer), stratum granulosum and stratum corneum. Stratum lucidum is present between stratum corneum and stratum granulosum.

Table 29.1 Functions of the skin

There are four main functions of the skin: sensation, thermoregulation, protection, and metabolism:

- **Sensation:** The skin contains many types of different receptors that sense temperature, pain, pressure, and touch.
- **Thermoregulation:** Hair and sweat glands participate in the regulation of body temperature to maintain homeostasis.
- **Protection:** The skin serves as the barrier between the inside and outside of the body against infection, chemical stress, thermal stress, and UV light.
- **Metabolism:** Adipose tissue in the hypodermis is vital in the production of vitamin D and lipid storage.

Table 29.2 Cells in the epidermis and dermis

Cells in the Epidermis
Melanocytes: The epidermis also contains melanocytes, which are derived from the embryonic nervous system (neural crest), present among the basal cells on the basement membrane. These synthesize melanin. A single melanocyte associates with a number of keratinocytes forming an epidermal melanin unit. Schematic representation of signaling pathways in melanogenesis is shown in Fig. 29.2
Langerhans' cells (dendritic cells): These specialized immune system cells are voracious phagocytes, which trap microbes and other alien materials that manage to cross the basement membrane. Langerhans' cells then present captured antigen to immune system lymphocytes. Schematic representation of Langerhans' cell functions is shown in Fig. 29.3
Merkel cells: Merkel cells are found in normal epidermis and act as transducers for fine touch
Cells in the Dermis
Fibroblasts: The main cell in the dermis is the fibroblast, that produces the collagen and elastin fibers and account for skin toughness and resiliency
Dermal dendritic cells: These are similar to epidermal Langerhans' cells

- As the epidermal cells mature, these cells undergo flattening with accumulation of keratin to form stratum corneum, which acts as barrier to infectious agents. Epidermis is very thin in most of regions, which may be 10–20 cells thick in some. It is considerably thicker on the palms and soles because of the extra thickness of the surface layer of dead cells of the stratum corneum.

Stratum Germinativum (Basal Cell Layer)

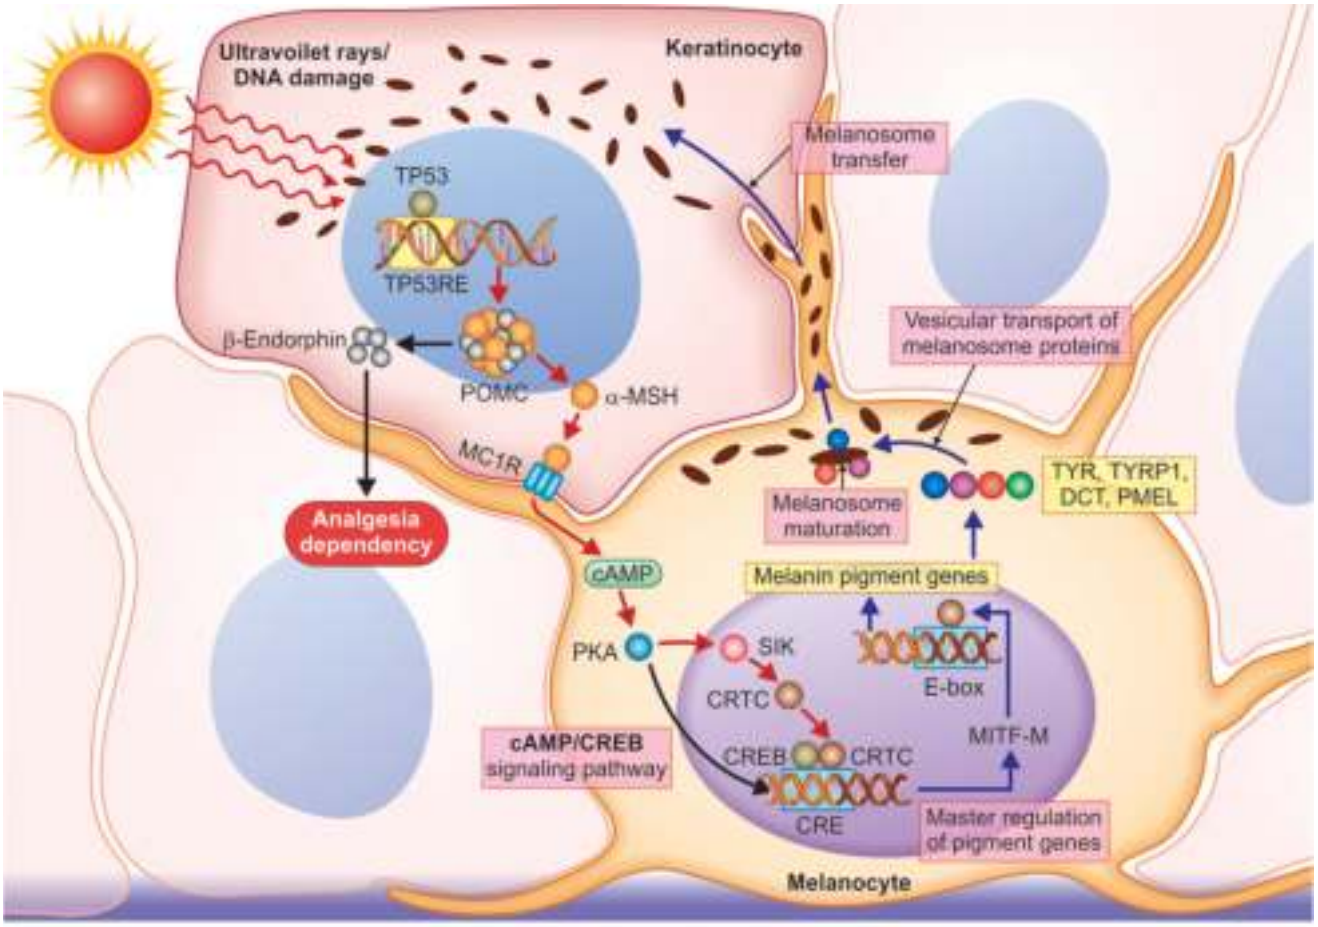
Stratum germinativum layer, the deepest mitotically active layer, that rests on a basement membrane, which attaches it to the underlying dermis. It contains melanin producing melanocytes, a single row of keratinocytes, and epidermal stem cells with progressive keratinization.

- Stratum germinativum provides the germinal cells necessary for the regeneration of the layers of epidermis.
- Keratinocytes from basal cell layer evolve and mature as they travel outward/upward to create the remaining layers of epidermis. Stratum germinativum is characterized by cuboidal or low columnar cells with basophilic cytoplasm and melanocytes in H&E-stained sections.
- Melanocytes are present as rounded cell bodies with clear cytoplasm and slender cytoplasmic processes.

Stratum Spinosum (Prickle Cell Layer)

Stratum spinosum layer comprises most of the epidermis, which contains several layers of keratinocytes connected by desmosomes. The desmosomes allow cells to remain tightly bound to one another and resemble 'spines' architecturally.

- Desmosomes are composed of transmembrane desmocollin-desmoglein pairs, which bind to the tonofilaments via desmoplakins, plakoglobin (Dsg-1 and Dsg-3) and plakophilin-1. Desmoglein-1 (Dsg-1) is expressed in the upper epidermis, while desmoglein-3 (Dsg-3) is mostly expressed in the basal epidermis.
- Stratum spinosum layer comprises desmosomes attached to polyhedral-shaped keratinocytes with round to oval nuclei and prominent nucleoli. Desmosome junctions appear as spines between cells of stratum spinosum in H&E-stained sections.



Stratum Granulosum (Granular Cell Layer)

Stratum granulosum layer consists of several layers of cells, which contain lipid-rich lamellar granules.

- Stratum granulosum layer synthesizes glucosylceramides, phospholipids, cholesterol, free fatty acids, which help in the barrier function. In this layer, cells begin to immortalize and lose their nuclei, as they move away from the nutrients located in the deeper tissue. Stratum granulosum also participates in process of keratinization.
- The process of maturation of cells with change in quality and type of keratins is called keratinization. Keratins (from the Greek *keras* meaning horn) are the main intermediate filaments in epithelial cells, which are of two types—basic and acidic and are always in pairs.
- Different keratins are found at different levels of the epidermis depending on the stage of differentiation and disease. Normal basal cells make keratins 5 and 14, but terminally differentiated suprabasal cells make keratins 1 and 10. Keratins 6 and 16 become prominent in hyperproliferative states, i.e. psoriasis. Stratum granulosum layer is characterized by keratinocytes with dense, ovoid, and basophilic keratohyalin granules in H&E-stained sections.

Stratum Lucidum

Stratum lucidum layer only exists in the thick skin of soles and palms and consists of mostly immortalized dead skin cells in the epidermis, and is named for its translucent appearance. Stratum lucidum contains a clear substance called eludin, which eventually becomes keratin. This layer is only found on the soles and palms. Stratum lucidum layer is characterized by a thin homogenous eosinophilic zone that is difficult to identify in H&E sections.

Signaling pathways in melanogenesis

1. Melanin is produced in the melanosomes (pigment granules or organelles) within melanocytes derived from neural crest.
2. Exposure of keratinocytes to UV light causes DNA mutations.
3. DNA damage stimulates p53 protein, which increases expression of proopiomelanocortin (POMC), a precursor protein to α-melanocyte-stimulating hormone (α-MSH).
4. α-MSH binds MCIR, which increases cAMP and microphthalmia associated transcription factor (MITF), which is transcriptional activator of several genes (TYR, TYRP1, DCT and PMEL) that encode melanosome localized proteins involved in synthesis of melanin and melanosomes and in melanoma biogenesis and transport.
5. Dopamine tautomerase (DCT) is a type 1 membrane protein involved in melanin synthesis.
6. Melanocyte is in contact with many keratinocytes through their processes forming an epidermal melanin unit.
7. Processes of the melanocyte 'dock' with keratinocyte, allowing transfer of the melanosome.
8. Once in the keratinocyte, the melanosome degranulates and releases melanin pigment, which protects the nucleus from UV light by dissipating the ultraviolet rays as heat (i.e. internal conversion).
9. Disorders related to melanin production include vitiligo, albinism, freckles, nevi and malignant melanoma.

Fig. 29.2: Signaling pathway in melanogenesis. Melanogenesis is a process by which the melanin pigment is produced in melanosomes by melanocytes. Cirsimaritin induces melanogenesis by stimulating the expression of TYR and TRP1 through the cyclic AMP/PKA cascade and subsequent activation of CREB and MITF in B16F10 cells.

Stratum Corneum (Keratin Layer)

Stratum corneum serves as protective outermost layer of the epidermis and contains flattened dead cells (corneocytes) without nuclei and separated by lipids and the mortar—in the intercellular space. Due to keratinization and lipid content, stratum corneum allows for the regulation of water loss by preventing internal fluid evaporation. This layer also prevents invasion by infectious agents and toxic chemical agents.

Pathology Pearls: Desmosomal Cadherins—Desmocollin and Desmoglein

- Desmosomes are intercellular junctions that tether intermediate filaments to the plasma membrane. Desmosomes contain two specific cadherins (**desmocollin** and **desmoglein**).
- Extracellular domains of desmocollin and desmoglein mediate extracellular adhesion of desmosome junctions of adjacent cells, whereas the cytoplasmic tails of desmosomal

cadherins associate with desmosomal plaque proteins such as plakoglobin, desmoplakin, and plakophilin.

- There are seven desmosomal cadherins, i.e. three desmocollins and four desmogleins. In human beings, desmocollin-2 and desmoglein-2 are the primary isoforms at the intercalated discs identified.
- Mutations in cadherins superfamily members are associated with hereditary diseases of epidermis, mucosal membranes and cardiomyocytes.

DERMIS AND SUBCUTANEOUS TISSUE

Dermis lies deep to the epidermis, which is a thick layer of connective tissue composed of collagen fibers and elastin. Collagen fibers provide strength and elastin gives elasticity to the skin.

- The dermis also contains nerve endings, blood vessels and adnexal structures such as hair shafts, sweat glands and sebaceous glands.
- The apical layer of dermis folds to form papillae that extend into the epidermis. The lower layer of dermis is referred to as the reticularis dermis.
- The hypodermis is the third deepest layer consisting mainly of adipose tissue. Below subcutaneous fat is a layer of dense fascia that sheaths the entire body and covers bone, muscle, and other deep structures.

NAILS STRUCTURE

The hard keratin of the nail plate is formed in the nail matrix, which lies in an invagination of the epidermis (nail fold) on the back of the terminal phalanx of each digit.

- The nail matrix runs from the proximal end of the floor of the nail fold to the distal margin of the lunula. From this region, the nail plate grows forward over the nail bed, ending in a free margin at the tip of the digit.
- The cuticle acts as a seal to protect the potential space of the nail fold from chemicals and from infection. The nails provide strength and protection for the terminal phalanx. The presence of nails helps with fine touch and handling of small subjects. Schematic

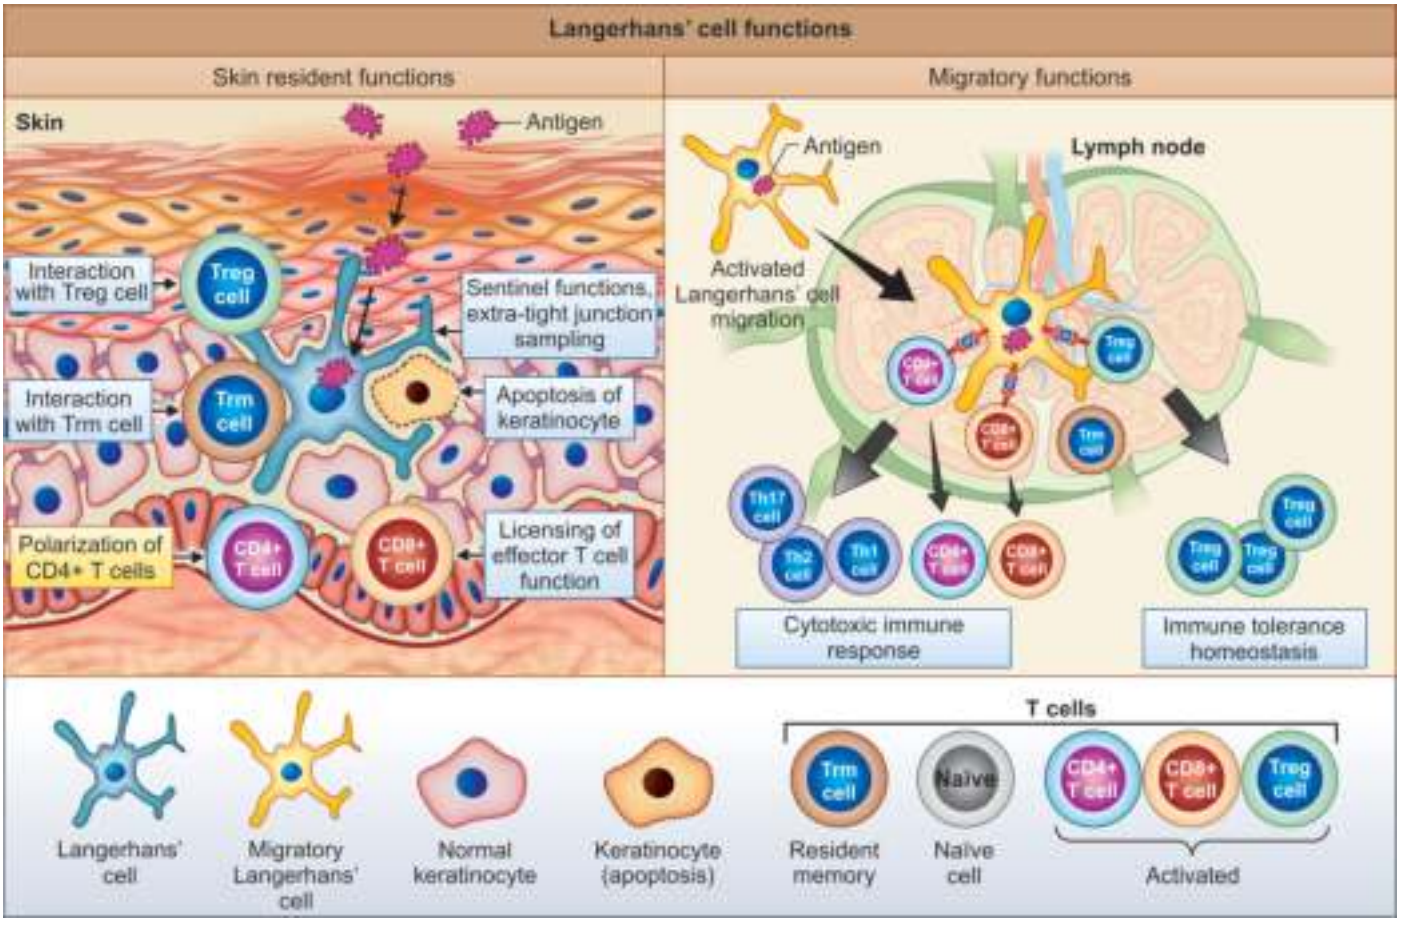


Fig. 29.3: Schematic representation of Langerhans' cells and their functions, Langerhans' cells populate across the epidermis of the skin from the early stage of development, but which have the ability to migrate from the epidermis to draining lymph nodes. These cells provide act as first line of defense against pathogens encountered via the skin.

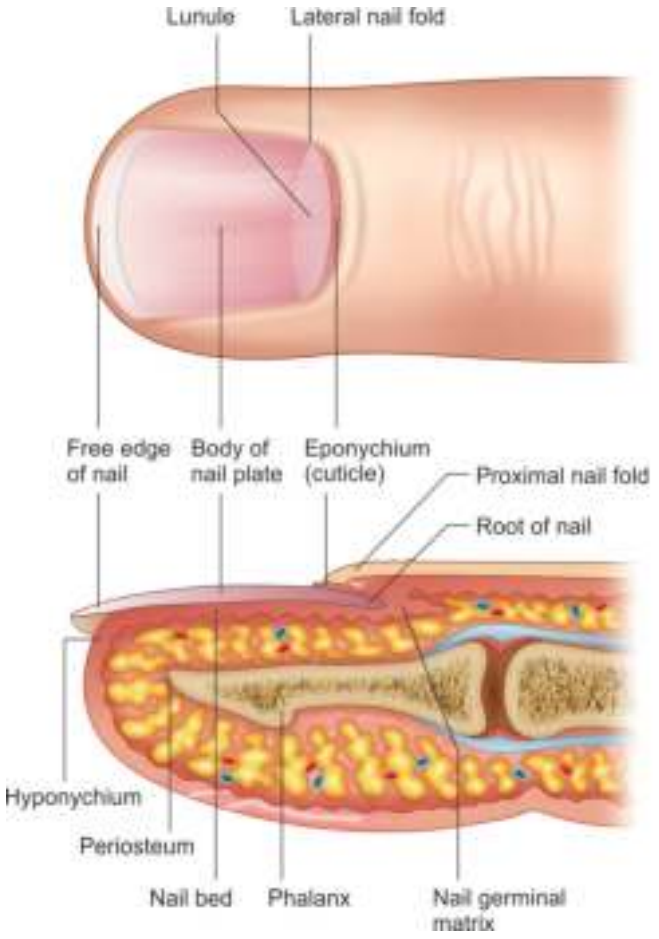

Fig. 29.4: Structure of the nail. The nail structure is divided into six parts: root, nail bed, nail plate, eponychium, paronychium and hyponychium. The nail bed contains blood vessels, nerves and melanocytes that produce melanin. The nail functions by protecting the digits and contributing to tactile sensation.

representation of structure of the nail and nail bed is shown in Fig. 29.4.

SKIN DISORDERS

Skin disorders may be primary or secondary. Primary disorders of the skin include inflammatory, pigment disorders, autoimmune disorders, dermatoses, thermal injuries, and skin cancers (squamous cell carcinoma, basal cell carcinoma and malignant melanoma). Clinical and histologic terms used in dermatopathology are given in Table 29.3. Classification of skin disorders based on histologic examination is given in Table 29.4. Categorization of skin disorders based on etiology is given in Table 29.5. Skin manifestations in systemic disorders are given in Table 29.6. Immunofluorescence patterns and skin disease association are given in Table 29.7. Revised 2024 WHO classification of skin tumors with new entities is given in Table 29.8.

Table 29.3 Clinical and histologic terms used in dermatopathology

Term	Description
Clinical terms used in dermatopathology	
Macule	Flat skin lesion recognized by discoloration <1 cm
Papule	Smaller palpable skin lesion <1 cm
Patch	Flat skin lesion recognized by discoloration >1 cm
Nodule	Elevated skin lesion, 'marble-like' >1 cm in width and depth
Induration	Firmness to palpation
Plaque	▪ Large palpable skin lesion >1 cm ▪ Coalescent papules
Lichenification	Palpable, visibly thickened skin with accentuated skin markings
Scale	▪ Visibly altered stratum corneum ▪ Scales are dry and whitish
Vesicle	Small blister filled with clear fluid <1 cm
Pustule	Visible collection of pus in blister
Bulla	Blister filled with clear fluid >1 cm
Crust formation	Dried exudate (serum, blood or pus) on the skin surface
Histologic terms used in dermatopathology	
Hyperkeratosis	Increased thickness of stratum corneum due to an abnormal increase in keratin in eczema, warts and corns
Parakeratosis	Retention of nuclei in the stratum corneum, and is a sign of increased cell turnover in psoriasis
Acanthosis	Thickening of the epidermis due to hyperplasia of stratum spinosum in 'acanthosis nigricans'
Acantholysis	Loss of keratinocyte cell-to-cell adhesion (separation of epidermal cells) resulting in round rather than polygonal appearing cells in 'pemphigus vulgaris'
Atrophy	Thinning; reduction in size
Hypergranulosis	Increased thickness of stratum granulosum in lichen planus
Spongiosis	Intercellular edema between the intercellular spaces of keratinocytes of the spinous layer in eczematous dermatitis
Lichenification	Hyperkeratosis, hypergranulosis, acanthosis and fibrosis of the capillary dermis corresponding to clinical skin thickening
Lichenoid	A band-like inflammatory infiltrate (usually lymphocytes) below the dermal-epidermal junction
Orthokeratosis	Stratum corneum without retention of nuclei
Pedunculated lesion	A papule connected to the skin by a stalk thinner than the lesion itself
Psoriasiform	Inflammatory pattern: epidermis with thickening and elongation of rete ridges
Vacuolar alteration	Alteration including vacuole formation in cells of the basal layer

Table 29.4 Classification of skin disorders based on histologic examination

Skin Layer	Skin Disorders	
Epidermis	▪ Psoriasis	▪ Pemphigus vulgaris
Dermal-epidermal interface	▪ Bullous pemphigoid ▪ Erythema multiforme	▪ Lupus erythematosus
Superficial and deep vascular bed	▪ Cutaneous vasculitis	▪ Contact dermatitis
Dermal connective tissue	Systemic sclerosis	
Panniculus adiposus	▪ Erythema nodosum	▪ Erythema induratum

Table 29.5 Categorization of skin disorders based on etiology

Categories	Skin Disorders	
Infectious disorders	▪ Impetigo ▪ Cellulitis, verruca	▪ Molluscum contagiosum
Inflammatory dermatoses	▪ Eczema ▪ Psoriasis ▪ Acne vulgaris	▪ Lichen planus ▪ Contact dermatitis
Blistering dermatoses	▪ Pemphigus vulgaris ▪ Bullous pemphigoid	▪ Dermatitis herpetiformis
Disorders of pigmentation and melanocytes	▪ Vitiligo ▪ Albinism	▪ Nevus ▪ Melanoma
Epithelial tumors arising from keratinocytes	▪ Basal cell carcinoma ▪ Basal cell nevus syndrome (BCNS) ▪ Bowen disease (*in situ* squamous cell carcinoma)	▪ Squamous cell carcinoma ▪ Keratoacanthoma ▪ Markel cell carcinoma

Table 29.6 Skin manifestations in systemic disorders

Systemic Disorders	Skin Manifestations	
Sarcoidosis	▪ Erythema nodosum	▪ Lupus pernio causing severe cosmetic disfigurement
Scleroderma	▪ Thickened tight skin especially of fingers ▪ Skin telangiectasias	▪ Calcified nodules
Hyperlipidemia	▪ Xanthelasmas (eyelids)	▪ Xanthomas (elbows, knuckles, buttock, soles, palms and Achilles tendon)
Diabetes mellitus	▪ Necrobiosis lipoidica (symmetric plaques on shins with atrophic yellow appearance and waxy feel, cutaneous)	▪ Candida infection ▪ Ulcers on feet
Cushing's syndrome	Purple striae, thin skin, easy bruising	
Inflammatory bowel disease (ulcerative colitis and Crohn's disease)	Pyoderma gangrenosum (large ulcer)	
Dermatomyositis	Edema and mauve discoloration of eyelid, erythema of the knuckles and other bony points, such as elbow and shoulder to photosensitive butterfly rash on face	
Cancers	Acanthosis nigricans—brown velvet-like thickening of skin in axilla, and groin-thickening or painless ichthyosis—fish-like skin appearance	

Table 29.7 Immunofluorescence patterns and skin disease association

Disease	Antibodies	Immunofluorescence Patterns	Histologic Manifestations
Pemphigus vulgaris	Antidesmosal antibody	Intercellular chicken-wire IgG in the epidermis	Suprabasal vesiculation
Bullous pemphigoid	▪ Antiepithelial BM antibody ▪ Anti-hemidesmosome (collage XII-BP180) antibody	Linear IgG along BM; in salt-split skin, reactivity along roof	Subepithelial vesiculation
Epidermolysis bullosa acquisita (EBA)	EBA antibody	Linear IgG along BM; in salt-split skin, reactivity along floor	Subepithelial vesiculation
Dermatitis herpetiformis	Antigluten antibody	Granular IgA, especially in tips of dermal papillae	Subepithelial vesiculation

Table 29.8 Revised 2024 WHO classification of skin tumors with new entities

Type of Skin Tumor relating to Origin	Representative Skin Tumors	
Keratinocytic/epidermal (nonmelanoma) origin	▪ Basal cell carcinoma ▪ Basal cell carcinoma with sarcomatoid differentiation ▪ Bowen disease (squamous cell carcinoma *in situ*) ▪ Squamous cell carcinoma ▪ Clear cell squamous cell carcinoma ▪ Lymphoepithelioma-like carcinoma	▪ Squamous cell carcinoma with sarcomatoid differentiation ▪ Squamous cell carcinoma with osteoclastic-like giant cells ▪ Epidermolytic actinic keratosis ▪ Merkel cell carcinoma
Melanocytic origin	▪ Combined BAP1-inactivated nevus/melanocytoma	▪ Malignant melanoma
Appendageal tumors	▪ Malignant tumors with eccrine and apocrine differentiation ▪ Malignant tumors with follicular differentiation ▪ Sebaceous carcinoma ▪ Adnexal adenocarcinoma NOS ▪ Endocrine mucin-producing sweat gland carcinoma ▪ Squamoid eccrine ductal carcinoma ▪ Syringocystadenocarcinoma papilliferum ▪ Secretory carcinoma	▪ Cribriform carcinoma ▪ Signet-ring cell histiocytoid carcinoma ▪ Trichoblastic carcinoma ▪ Trichoblastic carcinosarcoma ▪ Trichilemmal carcinoma ▪ Melanocytic matricoma ▪ Adenocarcinoma of anogenital mammary-like glands ▪ Fibroadenoma of anogenital mammary-like glands ▪ Phyllodes tumor of mammary-like glands
Soft tissue tumors	▪ Adipocytic tumors (liposarcoma) ▪ Fibroblastic, myofibroblastic and fibrohistiocytic tumors ▪ Vascular tumors (Kaposi sarcoma, angiosarcoma)	▪ Myopericytic tumors ▪ Neural tumors (malignant peripheral nerve sheath tumor) ▪ Tumors of uncertain differentiation
Uncertain differentiation	▪ Pleomorphic dermal sarcoma ▪ Epithelioid sarcoma ▪ Myxo-fibrosarcoma	▪ Dermal clear cell sarcoma ▪ Ewing sarcoma
Hematologic and lymphoid origin	▪ Mycosis fungoides ▪ CD30+ T cell lymphoproliferative disorders ▪ Skin T cell leukemia/lymphomas (primary/secondary) ▪ Skin B cell leukemia/lymphomas (primary/secondary) ▪ B-lymphoblastic leukemia ▪ Blastic plasmacytoid dendritic cell neoplasia	▪ T-lymphoblastic leukemia ▪ Skin determination in myeloid leukemia ▪ Lymphomatoid papulosis subtype D, E and DUSP22 ▪ Primary cutaneous gamma-delta T cell lymphoma ▪ Primary cutaneous acral CD8+ T cell lymphoma ▪ Erdheim-Chester disease
Inherited tumor syndromes associated with skin malignancies	▪ Familial melanoma ▪ Gorlin syndrome (nevoid basal cell carcinoma syndrome) ▪ BAP1 tumors predisposition syndrome	▪ Skin cancers linked to xeroderma pigmentosum ▪ Muir-Torre syndrome

INFECTIOUS DERMATITIS

BACTERIAL SKIN INFECTIONS

Bacterial skin infections include erythrasma and related disorders, impetigo, ecthyma, folliculitis, erysipelas and cellulitis. While there are certainly other bacterial skin infections, which are either uncommon or result from systemic illness. Bacterial skin infections are given in Table 29.9.

Table 29.9 Bacterial skin infections

Disorder	Bacteria	Age Group	Clinical Features
Impetigo	*Staphylococcus aureus, Streptococcus* pyogenes	Children and immuno-compromised persons	Nonbullous impetigo on nose associated with lymph-adenopathy to bullous impetigo 1–2 cm with fever
Staphylococcal-scalded skin syndrome	*Staphylococcus aureus*	Young children (newborn to 2 years of age)	Blistering desquamative eruption, sheet-like desqua-mation and positive Nikolsky sign, fever, malaise
Necrotizing fasciitis	*Staphylococcus aureus*	Adults (median age 40)	Rapidly progressive bacterial infection, begins as ill-defined erythema and tenderness
Ecthyma	Group A (β-hemolyticus *Streptococcus pyogenes*)	Children and elderly persons	Ulcerative skin lesions, punched out, discrete ulcer with thick overlying crust on lower extremities
Bacillary angiomatosis	*Bartonella henselae* and *Bartonella quintana* gram-negative bacilli	Immunocompromised persons	Erythematous, papules or nodules (solitary/multiple), fever, lymphadenopathy, weight loss, visceral lesions in bones, liver, spleen, lungs, and brain
Actinomycosis	*Actinomyces israelii* (filamentous gram-positive bacteria)	All ages	Fistulae, sinus tracts and multiple abscesses, fever, weight loss and five subtypes: cervicofacial (mandible), abdomen, thoracic, female pelvic and mycetoma foot (sinus tracts)
Granuloma inguinale	*Calymmatobacterium granulomatis* gram-negative bacteria (sexual transmission)	20–40 years both males and females	Painless expansive ulcer with a clean beefy red base and rolled margins, may be verrucous lesion in male (penis, scrotum, perianal, inguinal) and female (labia minora, fourchette, clitoris, cervix); and lymphadenopathy due to secondary infection
Anthrax	*Bacillus anthracis* gram-positive bacteria	Adults	Cutaneous anthrax erythematous papule with extensive surrounding edema; pulmonary anthrax occurs due to inhalation of spores with involvement of lymph nodes and systemic dissemination, gastrointestinal tract anthrax due to ingestion of infected meat
Corynebacterium infections (erythrasma and trichomycosis)	*Corynebacterium minutissimum* gram-positive filamentous bacillus	All ages	Erythrasma (asymptomatic erythematous macular eruption with distinct border in axilla, inguinal folds, interdigital web spaces); and trichomycosis (concretions yellow, red, black especially in axilla and pubic area)
Syphilis	*Treponema pallidum* spirochete (sexual transmission)	Young persons (30–40 years)	Primary syphilis (painless chancre on penis or labia), secondary syphilis (macular, erythematous, symmetrical eruptions on trunk and proximal extremities); tertiary syphilis (syphilitic aortitis, dementia, tabes dorsalis, meningitis, ataxia and skin nodules)
Lupus vulgaris	*Mycobacterium tuberculosis*	Any age	Erythematous, scaly papules and nodules, peripheral exten-sion with scarring, ulcerative and verrucous lesions may erode into cartilage (skin lesion due to lymphovascular spread)
Leprosy	*Mycobacterium leprae* with varied immunological response	All ages	▪ Tuberculoid leprosy patient has good cell-mediated granulomatous response and develops hypopigmented center and raised erythematous border ▪ Lepromatous leprosy patient has poor immunological response and develops macules, papules and plaques, but firm nodules may also be seen in the face ▪ Borderline leprosy is an intermediate form between tuberculoid and lepromatous leprosy and patient develops hypopigmented macules

ECZEMATOUS DERMATITIS

Eczematous dermatitis, also known as atopic dermatitis, is the most common form of dermatitis in children, who have history of hay fever or bronchial asthma. It can be seen in adults. Genetic as well as environmental factors (chemical agents such as hair dye) are thought to play role in its pathogenesis. Patient presents with dry skin that leads to a skin rash as a result of scratching or rubbing. The skin rash is prone to infection. The most important treatment of eczematous dermatitis is skin hydration followed by topical steroids for flare-ups.

Pathogenesis

Recent research demonstrates that there is a genetic component to eczematous dermatitis. Filaggrin gene encodes a protein responsible for maturation of skin by creating the tough, flat corneocytes tightly packed in an organized manner that form the outermost protective layer of skin. Filaggrin gene mutation has been observed in eczematous dermatitis.

- A patient with filaggrin gene mutation will have a dysfunctional skin barrier due to the haphazard organization of the skin cells, which allows water loss and decreased protection from harmful substances. Persons with eczematous dermatitis also have reduced levels of β-defensins (host defense peptides) in the skin against certain bacteria, viruses and fungi. Decreased levels of β-defensins (host defense peptides) leads to increased colonization of bacteria and infection, especially with *Staphylococcus aureus*.
- Chemical agents can directly injure skin or may act as antigens. Type 4 cell-mediated hypersensitivity reaction plays a key role in eczematous dermatitis due to contact chemical agent resulting from cooperation of skin macrophages (Langerhans' cells) and helper T cells. The skin manifestations in atopic patients are most often caused by type 4 rather than type 1 hypersensitivity reaction. Patient presents with itching, erythema and oozing following use of hair dye.

Clinical Features

Patient presents with intensely pruritic, dry scaly, skin rash with erythematous papules and small excoriations.

- Continuous rubbing of itching skin rash leads to eczematous dermatitis over face, especially the cheeks in children. Later, the children develop skin lesions on the extensor surfaces of wrist, elbows, ankles and knees; and flexor surfaces on antecubital and popliteal fossa.
- Clinical examination of face may reveal '**Dennie-Morgan lines**' (crease-like wrinkles just below the lower lid) in 25% of patients with eczematous dermatitis. Clinical photograph of eczematous dermatitis is shown in Fig. 29.5.

Fig. 29.5: Clinical photograph of eczematous dermatitis. A patient with itching, erythema and oozing following use of hair dye (arrow).

Surgical Pathology: Eczematous Dermatitis

Light Microscopy

- Morphology of the eczematous dermatitis depends on the activity of disease.
- In acute stage of eczematous dermatitis, skin lesion demonstrates spongiosis with vesicle formation. In chronic stage, skin lesion shows acanthosis, hyperkeratosis, lichenification, and focal lymphocytic dermal infiltrates.
- In subacute stage of eczematous dermatitis, skin lesion shows intermediate changes between acute and chronic; less spongiosis and vesiculation than in acute; less acanthosis and hyperkeratosis than in chronic eczematous dermatitis.

Treatment

Eczematous dermatitis is treated by hydration skin moisturizing and ointment and topical anti-inflammatory medicines. An ointment is preferred over a cream due to the high proportion of oil to water in lotions.

IMPETIGO

Impetigo is a common highly contagious infection of the superficial layers of the epidermis on sun exposed skin (face, hands) in pediatric age group (2–5 years), or any age group; and most commonly caused by gram-positive bacteria (*Staphylococcus aureus* or group A Streptococcus). Children younger than two years of age account for 90% of cases of bullous impetigo caused by *Staphylococcus aureus*. Nonbullous impetigo is caused by *Staphylococcus aureus* and group A β-hemolytic streptococci.

Pathophysiology

Impetigo can be classified as either primary or secondary. Primary impetigo involves previously normal skin by

bacterial invasion into epidermis. Secondary impetigo involves skin at a previous skin wound site.

- Disturbance in the skin barrier leads to access to *Staphylococcus aureus* and group A Streptococcus, which bind to fibronectin receptors for colonization.
- Predisposing factors for breakdown of skin barrier include trauma, insect bites, surgery, atopic dermatitis, burns and varicella. Incidence of impetigo is increased in immunocompromised persons, overcrowding, diabetes mellitus and poor hygiene.

Clinical Features

- Patient with nonbullous impetigo usually develops a vesicle or a pustule, which later ruptures resulting in purulent exudate forming honey-colored crust, which are often multiple lesions on the face and extremities in areas of disruption of skin barrier. Mild regional lymphadenopathy is a common associated finding. Systemic symptoms such as fever are typically absent in nonbullous impetigo.
- Bullous impetigo in patient begins with fewer small vesicles on nose, that become flaccid bullae 1–2 cm in diameter than in nonbullous impetigo containing a clear or yellow fluid which eventually progresses to become purulent. Surrounding erythema and edema are typically absent.
  - Bullous impetigo does not form a dried serum giving honey-colored crust. If the crust is not removed, new lesions form about the periphery and extensive epidermal damage may ensue.
  - Patient presents with skin lesions in the intertriginous regions, and unlike nonbullous impetigo, may occur in the buccal membranes.
  - Regional lymphadenopathy is absent. Systemic symptoms, such as fever, are more common than in nonbullous impetigo.
- Development of impetigo in the deep tissue is known as exthyma, that occurs due to penetration of ulcerative lesion through the epidermis and deep into the dermis. The lesions appear as 'punched out' with violaceous margins. Clinical photograph of impetigo is shown in Fig. 29.6.

Surgical Pathology: Impetigo

Light Microscopy

Impetigo lesion shows subcorneal cleft in the stratum granulosus, vesicle contains neutrophils and gram-positive bacteria, acantholytic cells, intradermal perivascular neutrophils and lymphocytes. Superficial dermal inflammation accompanies these findings.

Treatment

Treatment of impetigo involves topical and oral antibiotics and symptomatic care. Localized uncomplicated non-bullous impetigo is treated by topical antibiotics by prior removal of the crust. Bullous impetigo in skin or oral mucosa with lymphadenopathy is treated by systemic administration of antibiotics.

Fig. 29.6: Clinical photograph of impetigo. A child with lesions of impetigo on the face with the serum giving rise to the classic golden-yellow, "honey-crusted" lesion (arrows).

NEURODERMATITIS

Neurodermatitis is also known as lichen simplex chronicus, that presents as dry, patchy areas of skin that are scaly and thick. Neurodermatitis occurs in the settings of psychological stress or cutaneous pruritic diseases such as eczema or psoriasis due to chronic, habitual rubbing and scratching. This lesion is clinically indistinguishable from chronic eczematous dermatitis.

Clinical Features

Patient presents with well-defined hyperpigmented to erythematous leathery single or multiple plaques with exaggerated skin lines (lichenification) on head, scalp, posterior neck, genitalia, extensor aspect of arms and legs. The most common symptom of neurodermatitis is itching.

- Repeated scratching of the skin lesion leads to formation of leathery plaques of variable sizes (3–10 cm) and potentially thickened skin lesions.
- Center region of skin lesions has different shades of yellow or a deep reddish brown. However, with the respective age of the lesion, this color may transform into a leucodermic center with a darker zone surrounding the lesion. Clinical photograph of neurodermatitis is shown in Fig. 29.7.

Laboratory Diagnosis

Skin biopsies can be performed to exclude skin disorders such as psoriasis or mycosis fungoides. Blood tests may be performed. Elevated serum immunoglobulin E levels support the diagnosis of an underlying atopic diathesis linked to allergic disorders.

Fig. 29.7: Clinical photograph of neurodermatitis. Chronic scratching leads to a thick raised plaque with increase in surface markings (lichen simplex chronicus) (arrows).

SCABIES

Scabies is caused by female mite Sarcoptes scabiei. Its transmission occurs by close personal contact: mother–child, siblings, or sexual partners.

- Female mites burrow in the epidermis just below the stratum corneum and deposit eggs and feces in the interdigital spaces, sides of the hands and feet, flexural surface of the wrist, anterior axillary line, genital skin, and nipples. The first infestation remains asymptomatic for a period of weeks, until an immune response develops and then pruritus results.
- Upon re-infestation, the symptoms appear within a few days. Patient presents with intense skin itching at night. Immune reaction of type 4 to mites leads to both pruritus and diffuse exanthema. Typical sites of scabies are thighs, buttocks, and trunk. Clinical photograph of scabies is shown in Fig. 29.8.

Fig. 29.8: Clinical photograph of scabies. Pathognomonic involvement of the web spaces in a case of scabies (arrows).

LEPROSY (HANSEN'S DISEASE)

Leprosy, also known as **Hansen's disease**, is a chronic infectious disease caused by obligate intracellular gram-positive and weakly acid-fast *Mycobacterium leprae*, a microorganism that has a predilection for the skin and nerves. The complexity of presentation is related to the varied immunologic responses.

- *Mycobacterium leprae* are transmitted from human body by nasal discharge and digital impregnation of skin, as bacilli can be carried under nails and are inoculated under the skin by scratching. The incubation period is usually 3–5 years. Skin and peripheral nerves are commonly involved.
- *Mycobacterium leprae* target Schwann cells (SCs) leading to injury of the nerve, demyelination, loss of axonal conductance and consequent disability. The pathogen can invade the Schwann cells by a specific laminin-binding protein known as PGL-1.

Leprosy Classification

Based on clinical, histologic and immunologic status, leprosy is classified within two poles of the disease with transition into five forms: tuberculoid polar leprosy (TT), borderline tuberculoid (BT), mid-borderline (BB), borderline lepromatous (BL), and lepromatous polar leprosy (LL). Schematic representation of Ridley-Jopling and WHO classification of leprosy is shown in Fig. 29.9.

Indian Leprosy Classification

According to Indian classification, leprosy is classified into five categories: indeterminate, tuberculoid, borderline, lepromatous and pure neuritic leprosy. Pure neuritic leprosy (PNL) constitutes a significant proportion of cases in India. It is essential to pay more attention to this form of leprosy to diagnose and treat patients earlier to prevent deformities and sequelae of nerve damage.

Myrid Leprosy Classification

According to Myrid classification, leprosy is classified into two categories: immunological stable (lepromatous and tuberculoid leprosy) and immunological unstable (indeterminate and borderline leprosy). The most widely accepted scheme of classification is Ridley-Jopling classification.

WHO Leprosy Classification

According to WHO leprosy classification, patients are divided into two groups for therapeutic purposes: paucibacillary (TT, BT) and multibacillary (mid-borderline (BB), BL, LL).

- Paucibacillary (PB) leprosy is characterized by 1–5 skin lesions, one nerve involvement and slit skin smear negative for AFB.

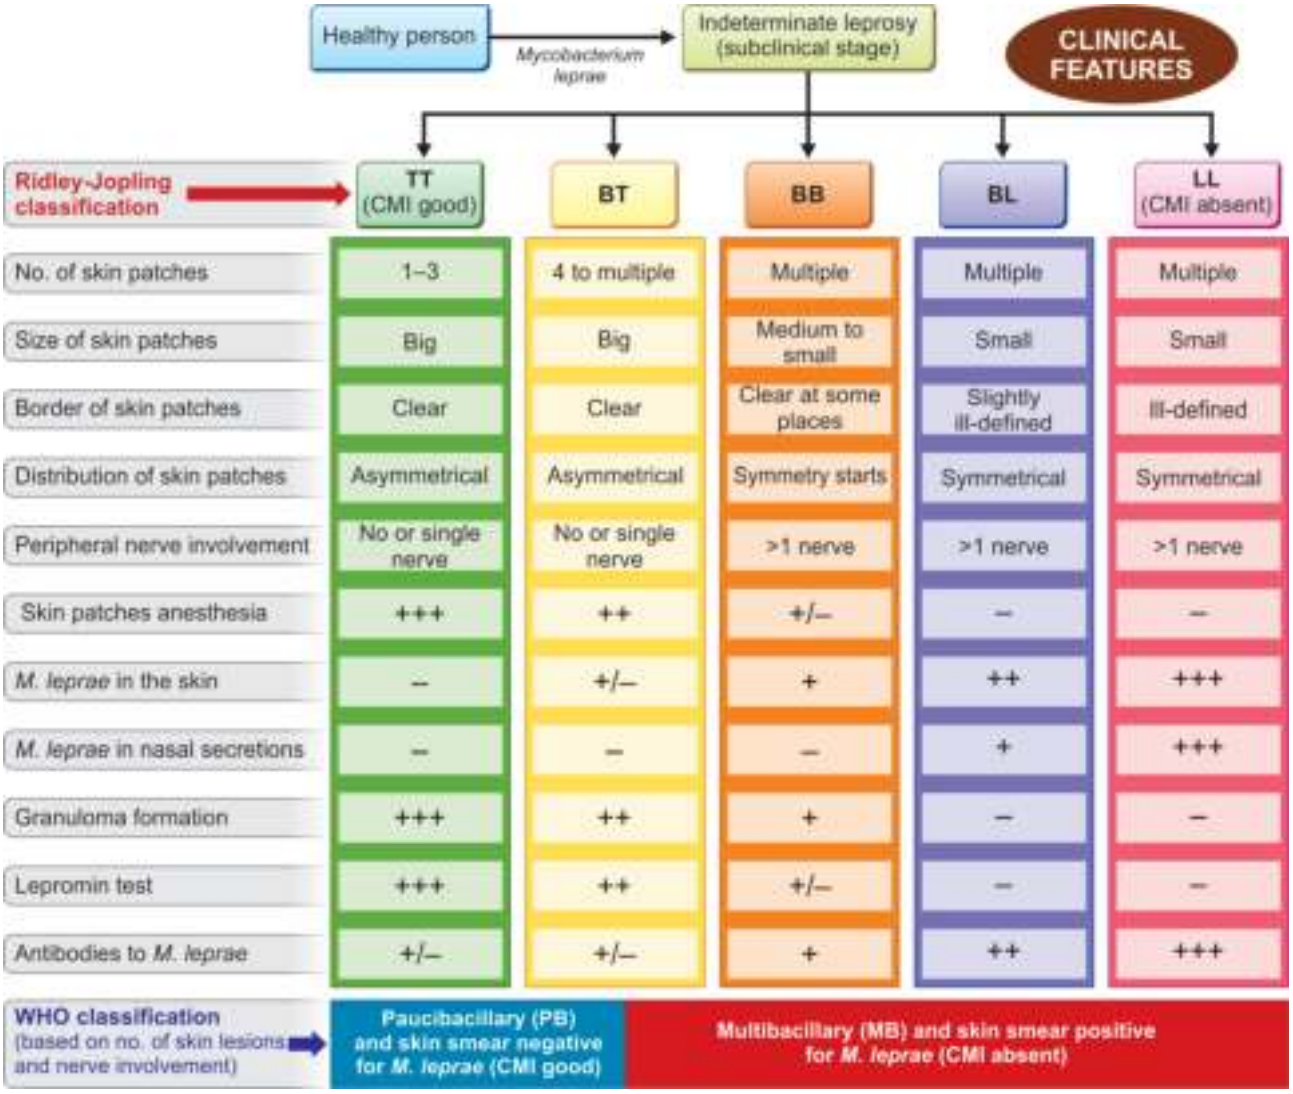

Fig. 29.9: Schematic representation of Ridley-Jopling and WHO classification of leprosy.

- Multibacillary (MB) leprosy is characterized by 6 or more skin lesions, involvement of more than two nerves and slit skin smear positive for AFB.

Ridley-Jopling Leprosy Classification

Ridley-Jopling leprosy classification is based on a combination of clinical findings, bacteriological index (BI), immunological reactivity (lepromin test) and the histologic findings. This leprosy classification ranges from a spectrum of high- to low-resistance pattern. Borderline leprosy includes borderline tuberculoid leprosy, mid-borderline leprosy, borderline lepromatous leprosy, tuberculoid leprosy, and lepromatous leprosy.

- **Borderline tuberculoid leprosy (BT):** Patient presents with multiple large anesthetics less-defined discrete; satellite papules similar to those seen in tuberculoid leprosy. Several peripheral nerve trunks are symmetrically enlarged and neuropathy often occurs. Bacterial index ranges from zero to 2.
- **Mid-borderline leprosy (BB):** Patient presents with numerous asymmetrical annular dimorphic plaques with poorly-defined outer borders and sharply defined central 'punched out' skin lesions, which exhibit both tuberculoid and lepromatous lesions. These patients may develop nerve hypertrophy and/or neuritis. Bacterial index ranges from 3 to 4.
- **Borderline lepromatous leprosy (BL):** Majority of patients have variable immunological response. BL patients do not fall into polar group. Borderline tuberculoid leprosy tends to be more towards tuberculoid leprosy and borderline lepromatous leprosy towards lepromatous leprosy. Patient presents with dimorphic, symmetrical, bilateral widespread small macules, papules and nodules of variable sizes and shapes on skin including symmetric peripheral nerve involvement. Bacterial index is 4 or 5.

- **Tuberculoid leprosy (TT):** Tuberculoid leprosy is characterized by presence of immunological response against *Mycobacterium leprae*. Patient develops large macular lesions on cooler parts especially nose, outer ears, testes and superficial nerve endings. There is presence of cell-mediated immune response. Infectivity is low in tuberculoid leprosy.
- **Lepromatous leprosy (LL):** Lepromatous leprosy has least capacity to mount immunological response against *Mycobacterium leprae*. Patient develops extensive erythematous macules, papules or nodules with extensive destruction of skin. Immune response is severely depressed. There is high infectivity in lepromatous leprosy.

Immune Status in Leprosy

Cell-mediated and humoral immunity have been implicated in leprosy. T cells participate in cell-mediated immunity. Increased titers of IgG, IgA and IgM have been demonstrated in these patients, which are not protective. Tuberculoid leprosy occurs in persons with good cell-mediated immunity; patients develop granulomatous response. Lepromatous leprosy occurs in persons with poor cell-mediated immunity; does not develop a granulomatous response. Borderline leprosy is an intermediate form between tuberculoid and lepromatous leprosy.

- **High-immune response in indeterminate, tuberculoid leprosy (TT) and borderline tuberculoid leprosy (BT):** Patient presents with few well-defined skin lesions with regular borders with asymmetrically distribution pattern and nerve enlargement. Slit skin smear may show scant *Mycobacterium leprae*. Lepromin test is positive.
- **Low-immune response in borderline lepromatous (BL) and lepromatous leprosy (LL):** Patient presents with symmetrical distribution of numerous skin lesions ranging from macules–papules with ill-defined margins. These skin lesions may be hypoanesthetic. Lepromin test is negative.
- **Mid-immune response in mid-borderline leprosy (BB):** Patient shows features of both the spectrums of leprosy. This mid-borderline leprosy is immunologically unstable, and hence prone to immune reactions.

Clinical Features

Activity of leprosy disease is assessed by various signs: erythema/infiltration, extension or appearance of new lesions, extension/new appearance of anesthesia, paresis and paralysis, tenderness and pain in nerves, morphological index and occurrence of immune reaction. Even though the nerves affected in leprosy are mixed motor and sensory nerves, the sensory loss is more marked compared to motor dysfunction.

Indeterminate Leprosy

Indeterminate leprosy is a prelude to the determinate form of leprosy. The initial cutaneous manifestations of leprosy are subtle and not specific, which are most common cutaneous lesions in Indian children. Most cases resolve, but some advance into more severe disease.

- Patient develops an ill-defined, bizarre hypopigmented macule(s) with a smooth or scaly surface. The sensations over the macule may or may not be impaired. The nerve proximal to the patch may or may not be thickened.
- Histologic examination of indeterminate leprosy shows scant lymphocytes and histiocytes in the superficial and deep in the dermis with some tendency to localize around skin appendages; and increased mast cells. Histology of indeterminate leprosy is shown in Fig. 29.10.

Tuberculoid Leprosy

Tuberculoid leprosy is a milder, less severe form of leprosy (called paucibacillary leprosy), which occurs in patients with robust cell-mediated immune response with prompt granulomatous inflammation. Tuberculoid leprosy is characterized by infiltration of dermis and subcutaneous fat by noncaseating granulomas predominantly centered around small cutaneous nerves.

- Nerves are completely destroyed in the process and replaced by noncaseating epithelioid granulomas. There is preponderance of CD4+ helper T cells over CD4+ suppressor T cells and without antibody response to *Mycobacterium leprae*. Cell-mediated

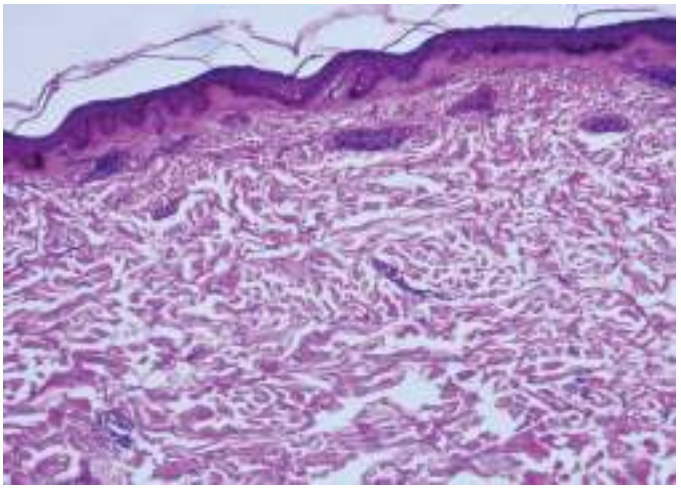

Fig. 29.10: Histology of indeterminate leprosy. Histologic examination of indeterminate leprosy shows scant lymphocytes and histiocytes around neurovascular bundles in the superficial and deep in the dermis with some tendency to localize around appendages; and increased mast cells (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

hypersensitivity reaction eradicates bacteria from the tuberculoid leprosy lesion in tissue. Therefore, the *Mycobacterium leprae* bacilli are scarce and usually not identified with modified Ziehl-Neelsen acid-fast stain (Wade-Fite stain).

- Most skin lesions have no identifiable bacteria; hence diagnosis is achieved using real-time polymerase chain reaction (PCR) to amplify *Mycobacterium leprae* specific DNA sequence and to detect serum antibodies specific to *Mycobacterium leprae* antigens.
- Patient presents with only single or multiple flat or well-circumscribed hypoanesthetic and hypopigmented plaque with raised erythematous border on extremities, buttock and face, thickened nerves, loss of sensation and diminished sweating. All patients have nerve involvement. Inflammation of Schwann cells leads to thickening of peripheral nerves. Clinical course is generally benign.
- On histologic examination, tuberculoid leprosy demonstrates noncaseating granuloma, Langhans giant cells, CD4+ helper T lymphocytic infiltration, and involvement of peripheral nerve. The close association of granulomatous response with the cutaneous nerves is a helpful diagnostic feature in tuberculoid leprosy. Tuberculoid leprosy is less contagious than other forms of leprosy. Histology of tuberculoid leprosy is shown in Fig. 29.11.

Borderline Leprosy

Borderline leprosy is an intermediate form between tuberculoid and lepromatous leprosy. Patient has hypopigmented macules and involvement of nerves exhibiting onion-skin appearance.

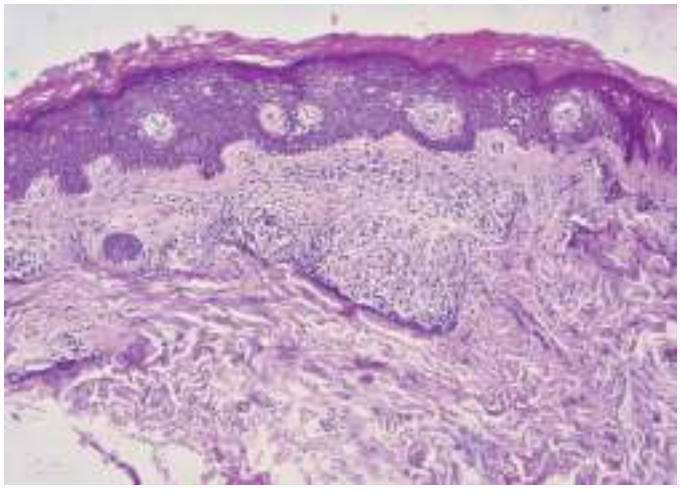

Fig. 29.11: Histology of tuberculoid leprosy. Hematoxylin and eosin-stained section shows noncaseating epithelioid granuloma, Langhans giant cells, T-helper lymphocytic infiltration, and involvement of peripheral nerve (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

- **Borderline tuberculoid leprosy (BT):** Borderline tuberculoid leprosy is characterized by granulomas and numerous lymphocytes in dermis. Diagnosis of borderline tuberuloid leprosy is achieved using real-time polymerase chain reaction (PCR) to amplify *Mycobacterium leprae* specific DNA sequence and to detect serum antibodies specific to *Mycobacterium leprae* antigens. Clinical photograph of borderline tuberculoid leprosy is shown in Fig. 29.12. Histology of borderline tuberculoid leprosy is shown in Fig. 29.13.
- **Borderline lepromatous leprosy:** Majority of borderline lepromatous leprosy patients have variable

Fig. 29.12: Clinical photograph of borderline tuberculoid leprosy. Clinical examination shows more widespread and less sharply defined lesions than in tuberculoid form. These are usually symmetrical on trunk but may be asymmetric on face. These are less likely to have scale with sharply raised border seen over right elbow. Nerve involvement less prominent. (*Courtesy*: Dr. Krishna Deb Barman, Director Professor of Dermatology, Maulana Azad Medical College and Associated Lok Nayak Hospital, New Delhi.)

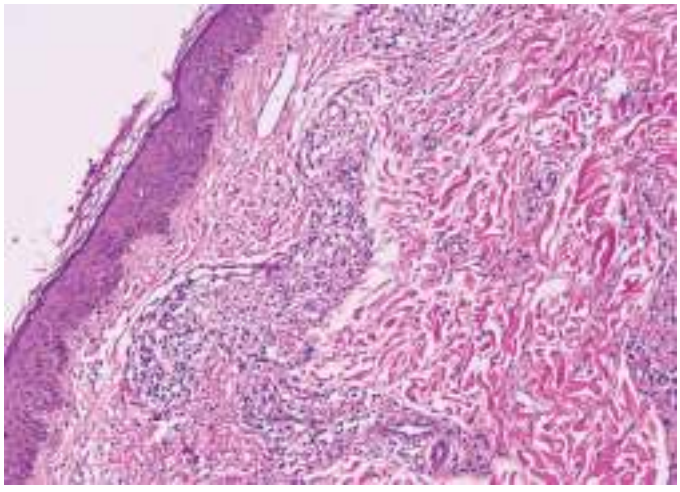

Fig. 29.13: Histology of borderline tuberculoid leprosy. Hematoxylin and eosin-stained section shows formation of epithelioid granulomas (400X).

immunological response. BL patients do not fall into polar group. Borderline tuberculoid leprosy tends to be more towards tuberculoid leprosy and borderline lepromatous leprosy towards lepromatous leprosy. Patient presents with dimorphic, symmetrical, bilateral widespread, small macules, papules and nodules of variable sizes and shapes on skin including symmetric peripheral nerve involvement. Bacterial index is 4 or 5. Clinical photograph of borderline lepromatous leprosy is shown in Fig. 29.14. Histology of borderline lepromatous leprosy is shown in Fig. 29.15.

Lepromatous Leprosy

Patients with lepromatous leprosy develop numerous macules, papules, plaques or firm nodules on nose and ears in symmetric distribution, later involve cooler parts (face, ears, wrists, elbows, buttocks, and knees) sparing inguinal and axillary regions. Facial lesions can be markedly swollen with loss of eyebrows (Lucio sign). Facial nerve involvement, hoarseness, loss of eyebrows and eyelashes, and nasal collapse (saddle nose) secondary to nasal septal perforation may occur in advanced cases of disease. Nasal secretions are rich in *Mycobacterium leprae* organism. Differences between tuberculoid and lepromatous leprosy are given in Table 29.10.

Fig. 29.14: Clinical photograph of borderline lepromatous leprosy. Clinical examination shows symmetric bilateral widespread, well-defined, hypopigmented to erythematous hypoesthetic small macules, papules and nodules of variable sizes and shapes with downward slopping edges seen over the back. Small satellite lesion is also in the periphery of skin lesions. These skin lesions are mostly lepromatous in nature but also contain aspects of tuberculoid lesions. (*Courtesy*: Dr. Krishna Deb Barman, Director Professor of Dermatology, Maulana Azad Medical College and Associated Lok Nayak Hospital, New Delhi.)

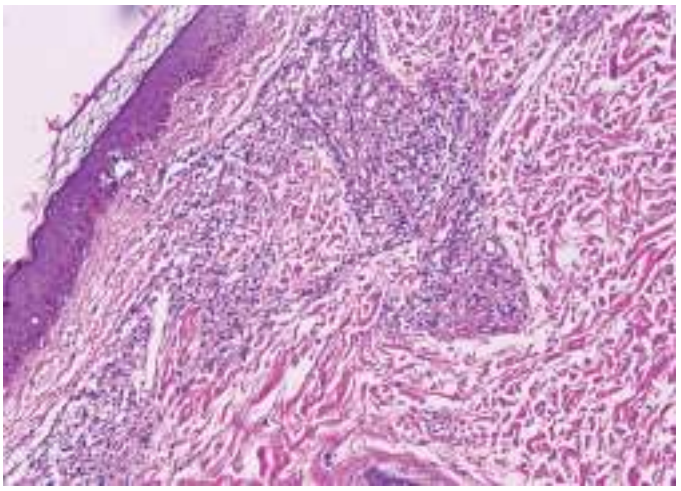

Fig. 29.15: Histology of borderline lepromatous leprosy. Hematoxylin and eosin-stained section shows formation of epithelioid granulomas (400X).

- The predominant histologic feature in lepromatous leprosy is a diffuse histiocytic infiltrate in the dermis that is not necessarily centered around nerves. A grenz zone of sparing is usually present in the papillary dermis. There are no discrete granulomas in the dermis. The histiocytes are arranged in poorly circumscribed clusters. Lymphocytes are scarce and those are present usually CD4+ suppressor T cells. The histiocytes may demonstrate vacuolated or foamy cytoplasm with a grayish-blue tinge on hematoxylin and eosin-stained sections due to clusters of *Mycobacterium leprae* bacilli. With modified Ziehl-Neelsen acid-fast (Wade-Fite) stain, *Mycobacterium leprae* bacilli can be visualized in large numbers in histiocytes surrounding cutaneous nerves, blood vessels and eccrine glands. In some cases of lepromatous leprosy, histiocytes are spindle-shaped and arranged in storiform pattern mimicking fibrous histiocytoma, which is referred to as histoid leprosy. Histology of histoid leprosy a type of lepromatous leprosy is shown in Fig. 29.16. Ziehl-Neelsen (Wade-Fite) stained section demonstrates numerous *Mycobacterium leprae* bacilli as shown in Fig. 29.17.
- Histoid leprosy is a rare variant of lepromatous leprosy characterized by unique clinical, histopathologic, and morphologic features. Histiocytes in lepromatous leprosy are spindle-shaped and arranged in a storiform pattern. This variant is called histoid leprosy. Patient presents with cutaneous and

Table 29.10 Differences between tuberculoid and lepromatous leprosy

Characteristics	Tuberculoid Leprosy	Lepromatous Leprosy
Host resistance	Present	Absent
T cell immunity	Present	Absent
Lepromin test	Strongly positive	Negative
Fernandez reaction (24–48 hours)	Positive	Negative
Mitsuda reaction (3–4 weeks)	Positive	Negative
Skin lesions	▪ Macular lesions with central depressed areas and hypopigmented margins ▪ Asymmetrical lesions not involving both sides	▪ Macular/papular/nodular lesions on hand and face (leonine face) ▪ Symmetrical lesions involving both sides
Touch sensation	Hypoanesthetic/ anesthetic lesions	Absent (anesthetic patches)
Clinical appearance	Disfigurement minimal	Disfigurement maximum (leonine facies, claw hands and pendulous ear lobes)
Nerves involved	Ulnar, facial and peroneal nerves	Ulnar and peroneal nerves
Other organs involved	Other organs are not involved	Anterior chamber eye, upper respiratory tract, testes, lymph nodes, liver, spleen and gynecomastia in males
Infectivity	Low infectivity	Very high infectivity
Skin histology	▪ Epidermis becomes nonatrophic ▪ Rete ridges are present ▪ Dermal papillae are normal ▪ Clear zone between epidermis and dermis is absent ▪ Epithelioid cell granulomas are present ▪ CD4+ helper T cells: Present at the periphery of granulomas ▪ CD4+ suppressor T cells: Very few at the center of lesion ▪ Fite stain: AFB (*M. leprae* bacilli) few (4–5) in macrophages	▪ Epidermis becomes atrophic ▪ Rete ridges are absent ▪ Dermal papillae become flattened ▪ Clear zone between epidermis and dermis is present ▪ Epithelioid cell granulomas are absent ▪ CD4+ helper T cells are absent ▪ CD4+ suppressor T cells are present in large number in diffuse manner ▪ Fite stain: AFB (*M. leprae* bacilli) abundant in macrophages
Complications	These are related to nerve damage like paralysis, distinct sensory losses	Antigen–antibody complex mediated erythema nodosum, leprosum, vasculitis, glomerulonephritis besides nerve related
Prognosis	Milder disease, hence good prognosis	Extensive progressive disease, hence poor prognosis

subcutaneous nodules. Histoid leprosy patients represent probable residual bacilli and a highly active lepromatous leprosy process. These cases may act as reservoirs of the disease and lead to further spread of leprosy. Continual occurrence of these cases does not bode well (favorable) for eradication of leprosy.

Erythema Nodosum Leprosum

Erythema nodosum leprosum (ENL) is an immune-mediated complication, which affects 50% of patients with lepromatous leprosy (LL) and 10% of borderline lepromatous leprosy (BL).

- Erythema nodosum leprosum is characterized by the presence of tender red plaques and nodules together with areas of erythema over skin, fever, malaise, arthritis, neuritis and lymphadenitis, orchitis, dactylitis, osteitis, lymphadenitis, facial mutilation, eye inflammation, neurotrophic ulcers, flexion contractures of hands, foot drop and nephritis. The eruption is generally widespread and accompanied by fever, malaise and arthralgia. Clinical photograph of erythema nodosum leprosum (ENL) is shown in Fig. 29.18.
- Erythema nodosum leprosum is treated mainly with corticosteroids. Prolonged administration of corticosteroids can cause morbidity and mortality.
- Histologic examination of H&E-stained sections demonstrates an inflammatory neutrophilic infiltrate,

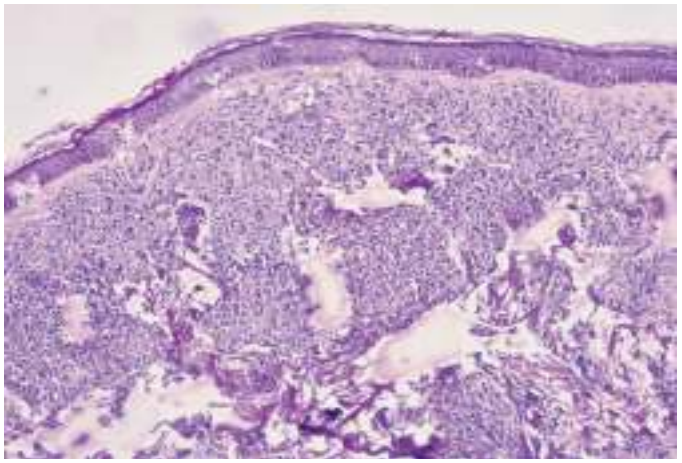

Fig. 29.16: Histology of histoid leprosy is a type of lepromatous leprosy. In some cases of lepromatous leprosy, histiocytes are spindle-shaped and arranged in storiform pattern mimicking fibrous histiocytoma around blood vessels and adnexal structures (400X). Fig. 29.19: Histology of erythema nodosum leprosum. Histologic examination of H&E-stained sections demonstrates an inflammatory neutrophilic infiltrate, vasculitis and/or panniculitis, immune-complex deposit and complement deposit associated with antigens of *Mycobacterium leprae* (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

vasculitis and/or panniculitis, immune-complex deposit and complement deposit associated with antigens of *Mycobacterium leprae*. Histology of erythema nodosum leprosum is shown in Fig. 29.19.

- The clinical course of erythema nodosum leprosum is prolonged with recurrent episodes of *Mycobacterium leprae* over a period of 12–24 months or even longer than seven years in some cases.

Lepromin Test

Lepromin test is used to demonstrate immune status in leprosy patients. Antigenic extract obtained from *Mycobacterium leprae* is administered by intradermal route. The injection site is evaluated at 1–2 days and 3 weeks. Lepromin test is positive in tuberculoid leprosy. Delayed hypersensitivity is demonstrated in tuberculoid leprosy (TT). Lepromin test is negative in lepromatous leprosy (LL). Lepromin positive reaction is of two types: Fernandez reaction and Mitsuda reaction.

- **Fernandez reaction:** Fernandez reaction occurs within first 2 days and represents a delayed hypersensitivity reaction to intradermally injected heat-killed leprosy bacilli. Patient develops skin induration within 24–48 hours at the site of injection.

- **Mitsuda reaction:** Mitsuda reaction measures the granulomatous immune response to intradermally injected heat-killed leprosy bacilli. A positive Mitsuda reaction is described as an indurated skin lesion of more than 4 mm that histologically shows epithelioid cell granuloma formation after 3–4 weeks at the site of injection. A positive reaction corresponds to the acquisition of cell-mediated immunity against the *Mycobacterium leprae* and occurs in tuberculoid leprosy patients. Borderline leprosy patients show an indurated skin lesion of less than 3 mm.

VIRAL SKIN INFECTIONS

Viral skin infections account for a significant percentage of skin disorders across world, which include verruca vulgaris, verruca plantaris, verruca plana, condyloma acuminatum, molluscum contagiosum, herpes simplex, varicella zoster. Viral skin disorders and morphologic features are given in Table 29.11.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is self-limited viral infection of the skin caused by molluscum contagiosum virus (MCV), a double-stranded DNA virus, that belongs to the Poxviridae family. MCV has four genotypes: MCV1 (75–95%), MCV2, MCV3 and MCV4. MCV1 is transmitted by direct skin-skin contact or sharing infected clothes. MCV2 is transmitted via sexual contact in adults and immunocompromised individuals.

- MCV infects the epidermis and replicates in the cytoplasm of cells with a variable incubation period

Table 29.11 Viral skin disorders and morphologic features

Disorder	Virus	Age Group	Clinical Features	Histologic Features
Verruca vulgaris	HPV: 2, 4 followed by types 1, 3, 27, 29 and 57	Children and adults	Discrete white to tan flat, papules or plaques (0.1 to 1.0 cm) with a rough, pebble-like surface on hands, fingers, feet and toes	Epidermal squamous differentiation with papillomatosis, hyperkeratosis, koilocytic change within stratum granulosum
Verruca plantaris (plantar wart)	HPV: 1, 2, 4, 63 (traumatic skin transmission)	Children and teenagers	Verrucous hyperkeratotic, papule, nodule of variable size (1 to 2 cm), asymptomatic/ painful	Hyperkeratosis with parakeratosis, acanthosis with papillomatosis, keratohyaline aggregates, koilocytic changes within epidermis, blood vessels dilated with thrombosis
Verruca plana (plane wart)	HPV: 3, 10, 28	Children and adults	Thin papules on face, dorsal surface of hands, arms and knees	Orthokeratosis (basket wave), hypergranulosis area, acanthosis, focal koilocytic change within epidermis prickle cell and granular cell layer
Condyloma acuminatum	HPV: 6,11 (sexual transmission)	Adolescents and young adults	Cauliflower-like pruritus, tender or bleeding lesions on genitalia and perianal regions	Bullous papillomatous acanthosis with exoendophytic growth pattern, parakeratosis, hyperkeratosis, koilocytic change within epidermis, coarse keratohyaline granules, occasional mitoses in lower epidermis
Molluscum contagiosum	Poxvirus (sexual transmission)	Children and young adults	Skin-colored to erythematous papule with central keratinous core ≤1 cm, can be associated with eczematous dermatitis	Bullous acanthosis with central crateriform invagination extending deep into the dermis, intracytoplasmic oval bodies (Henderson-Patterson bodies) within wall of squamous proliferation
Herpes simplex	HSV:1, 2 (DNA virus)	General population with immunosuppression	Recurrent painful clustered vesicles in oral, genital and anal regions	Epidermal intracytoplasmic edema, epidermal necrosis and intraepithelial vesicle, multinucleated giant cells, follicular involvement
Varicella zoster virus (VZV)	Varicella zoster (chickenpox) lies dormant within nerve ganglion	Children and older persons	Vesicles few mm to 2 cm evolving through pustular and crusted phases leaving shallow scar	Features identical to HSV infections, epidermal intracytoplasmic edema, epidermal necrosis and intraepithelial vesicle, multinucleated giant cells, follicular involvement
ORF (ecthyma contagiosum)	Parapoxvirus (infection from sheep, goat)	Male adults	Evolving lesion as macule, papule, erythematous on hands	Intraepithelial vesiculation, pseudoepitheliomatous hyperplasia, epidermal vacuolation and necrosis

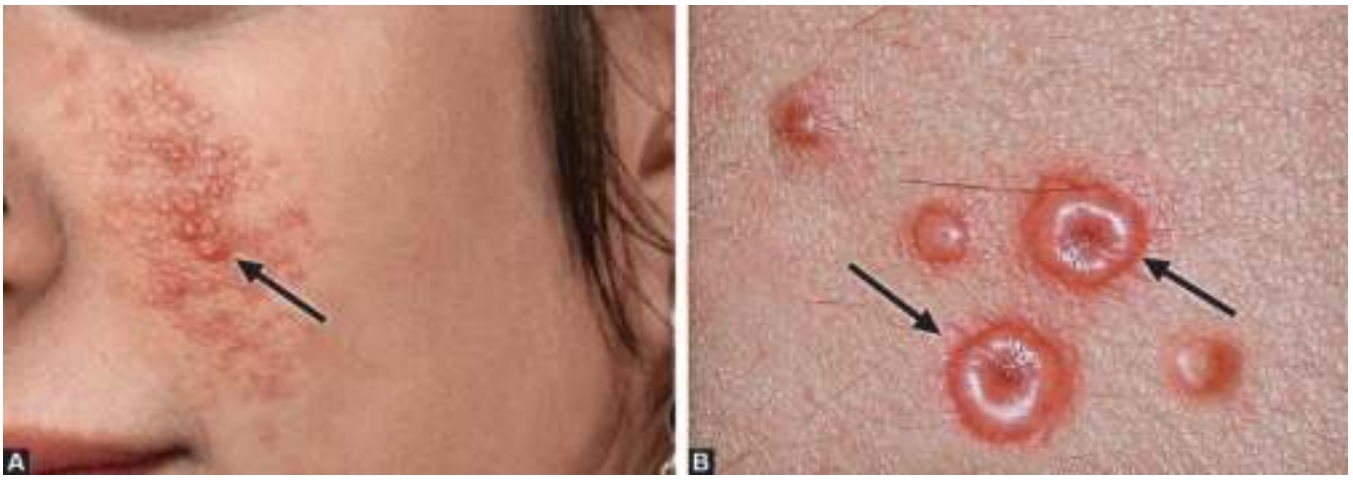

Fig. 29.20: Clinical photograph of molluscum contagiosum. Typical distribution of lesions is present on a child's face. Note the lesions in the eyelid (arrows). The lesion is a skin infection caused by a poxvirus (molluscum contagiosum), that produces benign raised lesions on the upper layer of skin. The lesion may appear anywhere on the body. (A) The lesions are distributed on a child's face. Note the eyelid lesions (arrow). (B) Close up of the lesion is dome-shaped pearly painless papule with central umbilication (arrows).

between two and six weeks. Four viral genes have been identified that code proteins that would alter the activation of the nuclear factor κB (NF-κB): MC159, MC160, MC132, and MC005. MCV most often affects children and adolescents.

- In children, the main affected areas include skin, over trunk, extremities, intertriginous regions, genitalia (mainly due to autoinoculation and not pathognomonic of sexual abuse), and face, except palms and soles; rare involvement of oral mucosa.
- In adults, lesions are most frequently located in the lower abdomen, thighs, genitalia, and perianal area. Patient presents with umbilicated, dome-shaped papules, 2–5 mm size pink or skin-colored over body, arms and legs. Pruritus may be present. Lesions may be single or multiple. Umbilication of skin lesion occurs as a result of intracytoplasmic viral inclusions extruding infected cell on the surface with central pore. Clinical photograph of molluscum contagiosum is shown in Fig. 29.20A and B.

Surgical Pathology: Molluscum Contagiosum

Light Microscopy

- In molluscum contagiosum, epidermis grows deeper down into the dermis and form closely packed lobules. Epidermal cells contain large intracytoplasmic eosinophilic stained inclusion bodies known as molluscum bodies.
- The molluscum bodies displace the nuclei at the periphery of epidermal cells. In the center of the lesion, stratum corneum disintegrates and release the molluscum bodies together with keratinous debris resulting in formation of central crater.
- Dermis shows prominent acute and chronic inflammatory infiltrate and foreign body giant cells. Histology of molluscum contagiosum is shown in Fig. 29.21.

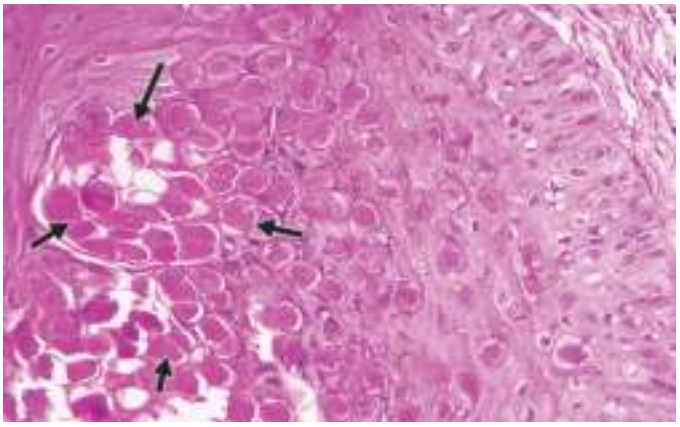

Fig. 29.21: Histology of molluscum contagiosum. Hematoxylin and eosin-stained section demonstrates epidermal cells containing large intracytoplasmic eosinophilic stained inclusion bodies containing virus particles in keratinocytes of stratum spinosum and stratum granulosum, and these are known as Henderson-Patterson bodies (molluscum bodies) shown by arrows. Skin histologic examination also reveals epidermal lobular acanthosis with inverted epidermal hyperplasia (400X).

COMMON WARTS (VERRUCOUS VULGARIS)

Common warts (verrucous vulgaris) are benign lesions that occur on mucosa and skin of persons of all ages with equal sex predilection. Verrucocus vulgaris is caused by human papillomavirus (HPV), with over 100 serotypes of HPV identified. Transmission involves direct contact between individuals, or autoinoculation.

- The primary clinical manifestations of HPV infection include common warts (HPV types 1, 2), genital warts, flat warts (HPV types 3, 10, 28), deep palmoplantar warts (HPV type 1), focal epithelial hyperplasia (HPV types 13, 32), epidermodysplasia verruciformis (HPV types 3, 5, 8, 20, and 47), butcher's wart (HPV type 7); and plantar cystic wart (HPV type 60).

- Generally, warts are self-limited lesions, which most often regress spontaneously within six months to two years. These strains are distinct from HPV strains associated with gynecologic neoplasms. Clinical photograph of common warts (verrucous vulgaris) is shown in Fig. 29.22.

Surgical Pathology: Common Warts (Verrucous Vulgaris)

Light Microscopy

- **Common warts:** Skin biopsy in common warts (verruca vulgaris) demonstrates acanthosis, digitated epidermal hyperplasia, papillomatosis, compact orthokeratosis, hypergranulosis, tortuous capillaries within the dermal papillae, and vertical tiers of parakeratotic cells with red blood cells entrapped above the tips of the digitations. Elongated rete ridges may point radially toward the center of the lesion. Koilocytic cells are pathognomonic. Koilocytes are large HPV-infected keratinocytes with prominent condensed keratohyaline granules, abundant eosinophilic cytoplasm and vacuoles; and small wrinkled-appearing pyknotic nuclei as a result of viral cytopathic effects. Histology of verruca vulgaris is sown in Fig. 29.23.
- **Filiform warts:** Filiform warts appear similar to common warts, but they may have prominent papillomatosis.
- **Warts with focal epithelial hyperplasia:** Skin biopsy shows acanthosis, blunting, hyperplastic mucosa with thin parakeratotic stratum corneum, anastomosis of rete ridges, and whiteness of epidermal cells due to intracellular edema. Some may have prominent keratohyaline granules, and vacuolated cells may be present.
- **Deep palmoplantar warts:** Histologic features of deep palmoplantar warts are similar to common warts except the lesion lies deep to the plane of the skin surface. The endophytic epidermal growth is composed of polygonal, refractile-appearing, eosinophilic, cytoplasmic inclusions made up of keratin filaments, forming ring-like structures. Basophilic parakeratotic cells loaded with virions and basophilic nuclear inclusions and may be in the upper layers of the epidermis.
- **Flat warts:** Histologic features of flat warts are similar to common warts. Skin lesion is composed of cells with prominent perinuclear vacuolization around pyknotic, basophilic, centrally located nuclei can be in the granular layer. These are referred to as 'owl's eye cells.
- **Cystic warts:** Cystic warts are filled with horny material. The wall of cystic wart is composed of basal, granular, and squamous cells. Many epithelial cells have large nuclei and clear cytoplasm with eosinophilic inclusion bodies. The cyst may rupture causing a foreign body granuloma.

DERMATITIS HERPETIFORMIS (HERPES SIMPLEX VIRUS II SKIN INFECTION)

Dermatitis herpetiformis is an intensely pruritic inflammatory cutaneous eruption disease related to gluten sensitivity caused by herpes simplex virus II (HSV-II) in 20–40 years of age and most often immunocompromised elderly patients.

Fig. 29.22: Clinical photograph of common warts (verrucous vulgaris). The lesion is caused by localized infection with human papillomavirus (DNA virus). The common warts are especially common among children and adolescents and may occur on any mucocutaneous surface. This patient has multiple common warts with flesh colored and rough surface (arrows).

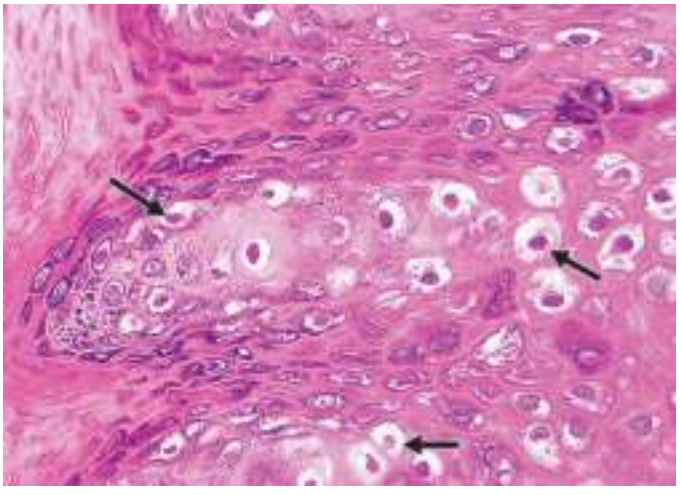

Fig. 29.23: Histology of verruca vulgaris. Hematoxylin and eosin-stained section demonstrates vacuolization of the epidermal cells (koilocytotic change) in this verruca vulgaris is seen. It indicates the viral origin of this lesion. One type of human papillomavirus (HPV) is associated with appearance of warts (arrows) (400X).

- Dermatitis herpetiformis has chronic relapsing course, pruritic polymorphic lesions, and typical histopathologic and immunopathologic findings.
- Patient presents with urticaria-like plaques and vesicles over the extensor surfaces of knees and elbows, scalp, upper back, and sacral area.
- Patient improves when patients are placed on gluten-free diets. Clinical photographs of dermatitis herpetiformis are shown in Figs 29.24 and 29.25.

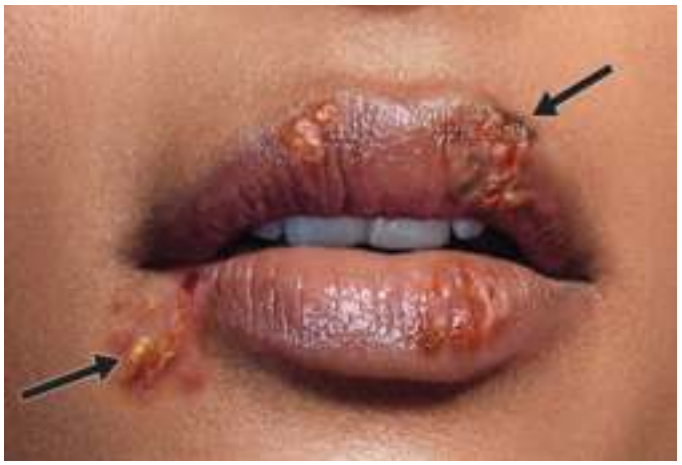

Fig. 29.24: Clinical photograph of dermatitis herpetiformis. The disease is a persistent immunobullous disease that has been linked to coeliac disease, gluten-sensitive enteropathy. The name dermatitis herpetiformis is derived from the tendency for blisters to appear in clusters resembling herpes simplex virus (HSV). However, dermatitis herpetiformis is not due to HSV infection. Dermatitis herpetiformis is also known as Duhring-Brocq disease. Clinical photograph of a female shows erythematous blisters (vesicles) on the face. Patient has recurrent HSV infection on the face in a female with grouped vesicles (arrows).

Fig. 29.25: Clinical photograph of dermatitis herpetiformis. Grouped, erythematous, vesicles are seen here in a zosteriform distribution (arrows).

Pathogenesis

IgA antibodies formed against gluten in the intestine gain access to the circulation and get deposited in the skin. Release of lysosomal enzymes by inflammatory cells cleave the epidermis from the dermis.

- According to several studies, dermatitis herpetiformis is considered the specific cutaneous manifestation of celiac disease (CD). Both dermatitis herpetiformis and celiac disease disorders occur in gluten-sensitive persons, share same HLA haplotypes (DQ2 and DQ8).
- These patients improve following the administration of a gluten-free diet. Small intestinal biopsy performed in dermatitis herpetiformis demonstrates villous atrophy to augmented presence of intraepithelial lymphocytes in all the cases, as well as the generation of circulating autoantibodies to tissue transglutaminase (tTG).
- Patient contracting herpes simplex virus I (HSV-I) infection presents with tender lip, tongue, or buccal sores. Another pattern produced by herpes zoster (also called varicella zoster virus) is the appearance of painful, clear vesicles on large areas of skin, usually on a dermatomal distribution.

Laboratory Diagnosis

Diagnosis of dermatitis herpetiformis is based on clinical history, physical examination, histologic examination, demonstration of granular IgA deposits along the dermal–epidermal junction or at the papillary tips by direct immunofluorescence (DIF) assay and positive anti-tissue transglutaminase antibody.

- Gluten-free diet for weeks to months leads to disappearance of skin lesions.
- IgA anti-endomysium antibodies (EMAs), IgA and IgG anti-deamidated synthetic gliadin-derived peptides, and IgA anti-epidermal transglutaminase (eTG) antibodies are considered specific and sensitive serologic markers for dermatitis herpetiformis.

Surgical Pathology: Dermatitis Herpetiformis (Herpes Simplex Virus II Infection)

Light Microscopy

- Histologic examination of skin lesion demonstrates subepidermal vesicles and blisters with dead keratinocyte, multinucleated giant cells with large nuclei having viral inclusions associated with accumulation of neutrophils at the papillary tips.
- Sometimes, eosinophils can be demonstrated within the inflammatory infiltrate, making difficult to the differential diagnosis with bullous. Histology of dermatitis herpetiformis is shown in Fig. 29.26.

Immunofluorescence Microscopy

- Deposits of IgA are demonstrated at the tips of dermal papillae of skin lesion.

VARICELLA ZOSTER VIRUS SKIN INFECTION (CHICKENPOX)

Chickenpox is a contagious disease of childhood caused by the varicella zoster virus (VZV). Symptoms begin 10–21 days after exposure, but the average incubation period is about two weeks. The disease is more severe in adults than in children.

- Chickenpox typically starts with vesicular eruptions (skin rashes), that form small, itchy blisters on the chest, back, and face then spreads all over body leading to scab formation. Complications of

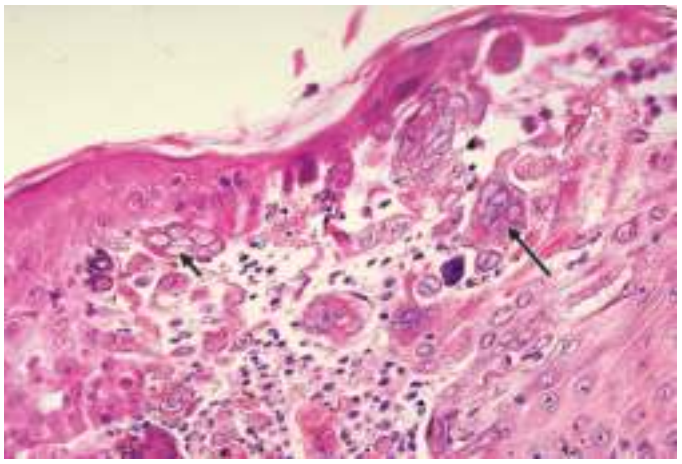

Fig. 29.26: Histology of dermatitis herpetiformis. It is caused by herpes simplex viral infection. On H&E-stained section, histologic examination of skin lesion demonstrates subepidermal vesicles and blisters with dead keratinocyte, multinucleated giant cells with large nuclei having viral inclusions (long arrow) associated with accumulation of neutrophils at the papillary tips; and steel gray to mauve inclusions (short arrow) typical for herpes simplex infection (400X).

Fig. 29.27: Clinical photographs of chickenpox (varicella zoster infection). The disease is caused by varicella zoster virus (DNA virus) especially in children. The virus stays in the sensory nerve ganglia as a latent infection. Patient develops generalized vesicular eruptions (erythematous rashes) also termed the dewdrop on a rose petal (arrows).

chickenpox include pneumonia, brain inflammation, and bacterial skin infections.

- Exposure to varicella zoster virus (VZV) causes the production of host immunoglobulins such as IgG, IgM, and IgA. IgG antibodies persist and confer life-long immunity. Cell-mediated immune responses are important in limiting the duration of primary varicella infection. Following overt varicella zoster infection, varicella zoster virus can remain latent for years in dorsal root ganglia. Clinical photographs of chickenpox or varicella zoster infection are shown in Figs 29.27 and 29.28.

FUNGAL SKIN INFECTIONS

Fungal infections of skin are categorized into dermatophytosis (superficial), angioinvasive and traumatic implanted fungi (dematiaceous fungus).

- Superficial fungal infections are caused by dermatophytes such as Microsporum, Trichophyton and Epidermophyton. These fungi reside in stratum corneum of epidermis, hair and nails.
- Tinea infections are named according to the Latin term that designates the anatomic site of infection, such as tinea capitis (scalp), tinea corporis (body), tinea manuum (hand), tinea cruris (groin), tinea pedis (foot) and tinea unguium (nail).
- Immunocompromised person with angioinvasive fungi presents with necrotic papules/plaques.
- Traumatic implanted fungus/dematiaceous fungus causes scaly and erythematous nodules at the site of trauma. Fungal infections of skin are given in Table 29.12.

Fig. 29.28: Clinical photographs of chickenpox or varicella zoster infection. The disease is caused by varicella zoster virus (DNA virus) especially in children. Patient develops generalized vesicular eruptions (erythematous rashes) also termed the dewdrop on a rose petal at higher magnification. The virus stays in the sensory nerve ganglia as a latent infection.

DERMATOPHYTOSIS (SUPERFICIAL FUNGAL SKIN INFECTIONS)

Dermatophytosis (superficial fungal infections) is caused by dermatophytes such as Microsporum, Trichophyton and Epidermophyton, which resides in stratum corneum of epidermis, hair and nails. Tinea infections are named according to the Latin term that designates the anatomic site of infection, such as tinea capitis (scalp), tinea corporis (body), tinea manuum (hand), tinea cruris (groin), tinea pedis (foot), and tinea unguium (nail). A diagnosis of tinea infection may be suspected on the basis of clinical history and examination.

Table 29.12 Fungal infections of skin

Disorder	Organism	Age Group	Clinical Features	Histologic Features
Dermatophytosis	*Trichophyton, Microsporum, Epidermophyton* species	Children and adults	Hyperkeratotic, inflamed lesions present on various sites: tinea corporis (trunk, limbs except hands and feet), tinea capitis (scalp), tinea pedis (feet), tinea magnum (hands), tinea faciei (face), tinea inguinalis/cruris (groin), tinea unguium (nails)	Key histologic feature is the presence of dermatophytes: fungal forms in the stratum corneum of the epidermis, nail plate, or hair shaft
Tinea versicolor	*Malassezia globosa* (*Malassezia furfur*)	30–40 years	Fine scaly, erythematous patches to thin plaques over trunk	Key histologic feature is the 'spaghetti and meatballs' appearance of intracorneal hyphae and yeast forms, hyperkeratosis, parakeratosis and slight acanthosis
Candidiasis	*Candida albicans*	Children and elderly persons especially immunocompromized persons	Papules, pustules and ulcers, red erosive skin lesions; satellite arrangement of papulopustular lesions classical presentation	Epidermal hyperplasia and spongiosis, *Candida albicans* pseudohyphae, acute and chronic inflammatory cells
Pityrosporum folliculitis	*Malassezia globosa* (*Malassezia furfur*)	Adolescents and middle-aged	Pruritic, erythematous papules and pustules on chest, back, neck, upper arms	Hair follicle dilated with yeast forms and keratin plugs, surrounding chronic inflammatory cells; follicular rupture with neutrophils
Mycetoma	*Pseudoallescheria boydii* and Medurella	Middle-aged persons	Cutaneous infection with 'granules' of fungi (eumycetoma) involving foot after trauma; nodules and draining abscesses	Key histologic features are collection of granules of organisms in the dermis and subcutaneous tissue surrounded by acute and chronic inflammatory cells
North American blastomycosis (Gilchrist disease)	Blastomycosis dermatitis (droplet infection)	Adult men	Usually disseminated disease (genitourinary tract, bone and skin); skin lesions such as hyperkeratotic nodules, plaques, ulcers with heaped up margins <1 to several centimeteres	Epidermal pseudoepitheliomatous hyperplasia with neutrophilic abscess; presence of a broad-based budding yeast with a thick cell wall and multiple nuclei, neutrophils, lymphocytes and histiocytes; granulomatous component with multinucleated giant cells in older lesion
Histoplasmosis	*Histoplasma capsulatum* (bird droppings)	Immunocompetent and immunocompromised persons	Disseminated disease (liver, adrenal gland, reticuloendothelial system, meninges, skin and mucous membranes), skin lesions such as papules, nodules, plaques and punched-out ulcers	The yeast small 2–4 μm, intracellular surrounded by clear space (pseudocapsule), tuberculoid caseating granulomas
Cryptococcosis	*Cryptococcus neoformans* (bird droppings)	Immunocompromised persons	Widespread papules, pustules, nodules and ulcers on head and neck regions	Histologic variants granulomatous, gelatinous and suppurative lesions. Organism is 3–6 μm yeast surrounded by thick mucoid capsule of cryptococcosis include

Contd...

Table 29.12 Fungal infections of skin (*Contd...*)

Disorder	Organism	Age Group	Clinical Features	Histologic Features
Coccidioidomycosis	*Coccidioides immitis*	Immunocompromised persons	Pustules, nodules, plaques and often verrucous after pulmonary involvement	Fungus containing numerous organisms, pseudoepitheliomatous hyperplasia, microabscesses, neutrophils, lymphocytes and histiocytes, sometimes foci of necrosis
Paracoccidioidomycosis (South American blastomycosis)	*Paracoccidioides brasiliensis*	Adults	Pulmonary infection involving skin with ulcers and plaques on face with subcutaneous involvement	Fungus resembles ship's wheel with central large thick-walled yeast form with multiple narrow based buddings, pseudoepitheliomatous hyperplasia, microabscesses and granulomatous inflammation
Chromoblastomycosis (chromomycosis)	*Cladosporium, Fonsecaea, Exophiala* and *Philophora* species	Adult men	Verrucous papules, nodules, plaques, ulcerations and scarring at subcutaneous trauma on leg and foot	Presence of small, round, thick walled, septate, brown yeast of 5–12 µm, pseudoepitheliomatous hyperplasia, neutrophils, lymphocytes, histiocytes, granulomas, microabscesses
Phaeohyphomycosis	*Cladosporium, Fonsecaea, Waniella, Bipolaris, Culvularia, Philophora* species	Healthy persons following trauma/ immunocompromised persons	Nodules, pustules and hemorrhagic plaques on extremities or cystic lesion	Mixed suppurative and granulomatous inflammation, brown yeasts and hyphae (narrow, septate and branching)
Sporotrichosis	*Sporothrix schenckii* (in decaying plants)	Adult men (gardeners)	Papules, nodules and ulcers following subcutaneous trauma	Pseudoepitheliomatous hyperplasia with neutrophilic microabscesses, mixed granulomatous and suppurative dermal inflammation, 4–6 µm yeast forms in center of microabscesses or giant cells, yeasts may be surrounded by eosinophilic material (Splendore-Hoeppli phenomenon)
Aspergillosis	*Aspergillus fumigatus* (most common), *Aspergillus flavus, Aspergillus niger* (otitis media)	Immunocompromised persons due to neutropenia	Lung involvement resulting in skin lesions such as papules, nodules and ulcers especially in venous injection site and burns	Fungus with septate hyphae with branching at 45°, intense acute chronic inflammatory infiltrate, less evident in neutropenic persons; and granulomas in primary infections
Zygomycosis	*Rhizopus, Absidia* and *Mucor* species	Immunocompromised persons	Erythematous macules/ patches with dusky center, which ulcerate	Fungus with thick nonseptate hyphae that branch at right angles, mixed chronic granulomatous suppurative inflammatory infiltrate

- Tinea infection can be diagnosed by using light microscopy and culture, which allows for fungal specification and viability assessment. Skin scrapings and nail clippings are performed on KOH (potassium hydroxide) and examined under microscope to demonstrate fungi. Fungal culture can take up to four to six weeks and but has a false-negative rate of at least 30% for nail samples. Repeat culture should be performed if there is a high index of clinical suspicion of superficial fungal infections.
- The mode of treatment depends on the extent and location of the tinea infection.
  - Topical antifungal shampoos for tinea capitis can reduce the risk for fungal transmission to others but are ineffective in treating the infection. Most cases of tinea corporis, tinea cruris and tinea pedis are

amenable to topical therapy. Recommended first-line topical therapy is terbinafine 1% cream once or twice daily for one to two weeks. Topical treatments are usually ineffective against onychomycosis.

- Onychomycosis is treated by systemic administration of antifungal therapy. Overview of various sites affected with superficial fungal infections is shown in Fig. 29.29.

Surgical Pathology: Dermatophytosis

Light Microscopy

- A skin scraping with KOH mount can be utilized to identify these fungi. Fungal cell walls are rich in mucopolysaccharides and stained with PAS stain, which gives bright pink to red appearance. Involved areas of skin and nails may fluoresce under ultraviolet light.
- The fungi are present in the anucleate cornified layer of skin, hair, or nails. Therefore, scrapings are taken for fungi culture and definite classification. Reactive epidermal changes may produce a pattern that mimics a mild eczematous dermatitis.

Tinea Capitis

Tinea capitis is a dermatophyte infection of the scalp and hair in prepubertal children. There are three main clinical presentations of tinea capitis: (a) scaly patches with alopecia, (b) alopecia with black dots at the folliular opening and (c) diffuse scalp scaling with subtle hair loss. Severe form of tinea capitis is known as 'kerion', which is characterized by a tender plaque with pustules and crusting. Cervical lymphadenopathy is a common associated finding in patients with tinea capitis.

Tinea Corporis and Tinea Cruris

Tinea corporis is commonly referred to as ringworm, annular or ring-like eruption on the skin, other than face, hands, feet or groin. It most commonly occurs in children and young adults. It may spread from other infected humans. It may be autoinoculated from other areas of the body infected by tinea pedis or tinea capitis. Another common mode of transmission of tinea corporis is noted in wrestlers.

- Tinea cruris is also known as 'jock itch' and occurs in the groin fold and is more frequent in adult men.

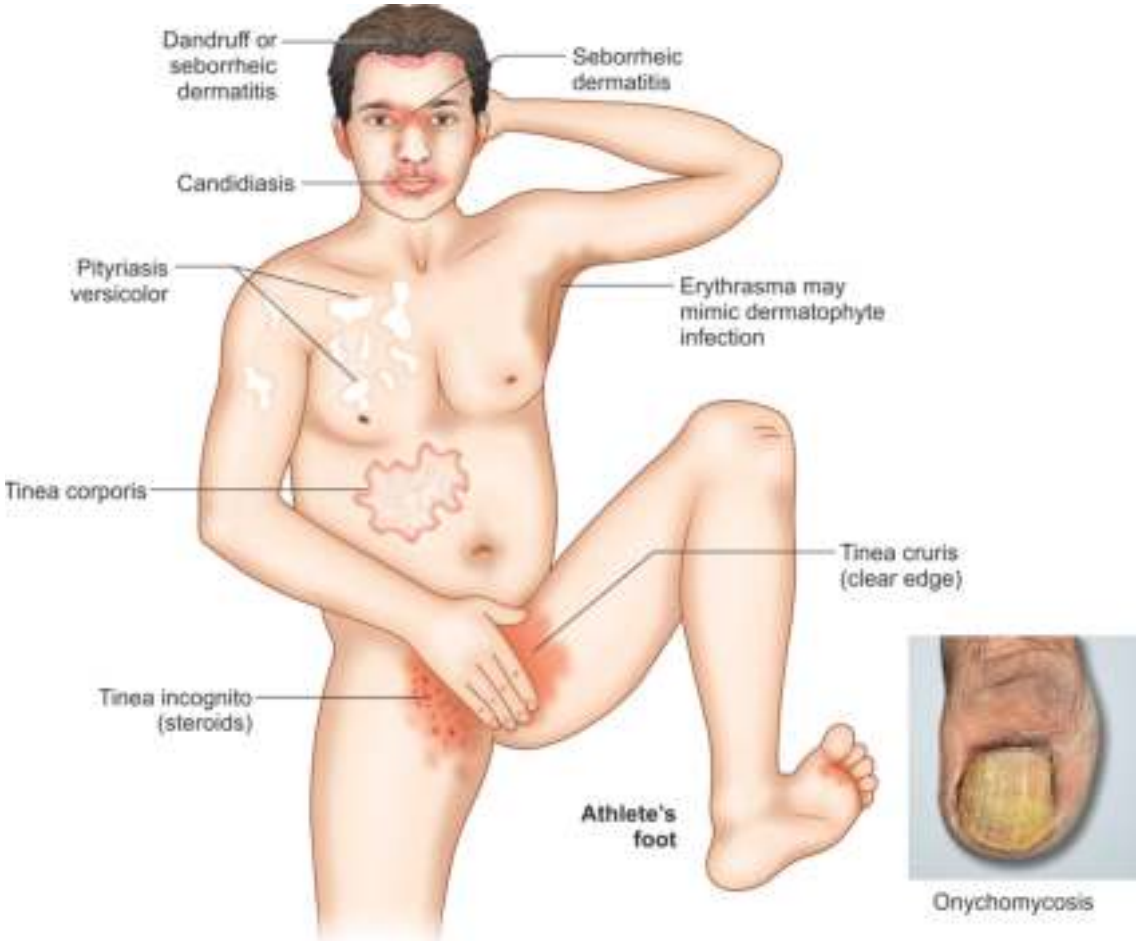

Fig. 29.29: Overview of various sites affected with superficial fungal infection.

Tinea corporis and tinea cruris classically present as annular plaques with central clearing and leading scale. Skin lesions may be single or multiple and of varying sizes, which may coalesce. Pustules or vesicles can sometimes occur at the active edge.

- While tinea may be suspected on the basis of clinical grounds, it is important to be aware of the various conditions considered in the differential diagnosis that may mimic tinea infections.
- Annular skin rash in tinea capitis and tinea cruris should be differentiated from discoid eczema, annular psoriasis, pityriasis rosea, subacute cutaneous lupus erythematosus and erythema annulare centrifugum.
- Topical and systemic antifungal modalities are available and are selected on the basis of the subtypes and severity of tinea infection. Untreated, tinea can cause significant morbidity and predispose to complications, including cellulitis and ulcers on the feet and alopecia on the scalp. Clinical photograph of tinea corporis is shown in Fig. 29.30.

Tinea Pedis

Tinea pedis, known as 'athlete foot', is the most common dermatophyte infection in young persons, but rare in children. Predisposing factors are exposure to occlusive footwear and sweating.

- The interdigital subtype is the most common form of tinea pedis, which manifests as maceration or scales between toes.

Fig. 29.30: Clinical photograph of tinea corporis. A classic case of tinea corporis showing erythematous raised scaly advancing margins with central clearing showing increased activity of the fungus at the margins and presence of host immune response which clears the fungus from the center.

Fig. 29.31: Clinical photograph of tinea unguium. It demonstrates proximal and distal pharynx onychomycosis.

- Another subtype of tinea pedis known as chronic hyperkeratotic (moccasin-type), that spares dorsal surface is characterized by chronic plantar erythema with scaling involving the lateral and plantar surfaces of the foot.
- Recurrent tinea pedis may be due to a reservoir of untreated tinea in the nails.

Tinea Unguium

Tinea unguium, also known as onychomycosis, is a dermatophyte infection of the nails in elderly persons over age of 70 years. About 50% of patients have concomitant fungal skin infections, most commonly tinea pedis.

- Distal lateral subungual onychomycosis is the most common subtype and characterized by yellowish or brownish discoloration associated with onycholysis and subungual hyperkeratosis.
- The other common subtype is the white superficial onychomycosis characterized by white spots on the nail plate that can involve the entire nail if not treated.
- Onychomycosis should be differentiated from nail psoriasis, lichen planus, yellow nail syndrome, traumatic onychodystrophy, alopecia areata and age-related nail dystrophies. Immunocompromised and diabetic persons are at greater risk for fungal and bacterial infections. Clinical photograph of tinea unguium is shown in Fig. 29.31.

CANDIDA ALBICANS SKIN INFECTION

Candida albicans is an opportunistic human fungal pathogen, which can switch from an oval yeast form to a filamentous hyphal form, which is characteristic

of filamentous fungi. It affects children and immunocompromised elderly persons.

- Patient presents with papules, pustules and ulcers, red erosive skin lesions, and satellite arrangement of papulopustular lesions.
- Histologic examination of skin lesion shows epidermal hyperplasia and spongiosis, *Candida albicans* pseudohyphae, acute and chronic inflammatory cells. Clinical manifestations of *Candida albicans* and oral candidiasis by *Candida albicans* are shown in Figs 29.32 and 29.33.

DEEP SUBCUTANEOUS FUNGAL INFECTIONS

Majority of cases in clinical practice are seen due to superficial fungal infections. Invasive subcutaneous mycoses are important to recognize and treat, as deep fungal infections often have significant morbidity and mortality. Deep fungal infections demonstrate species-specific syndromes, which may be identified by clinical and histologic features in addition to serological evaluation and culture.

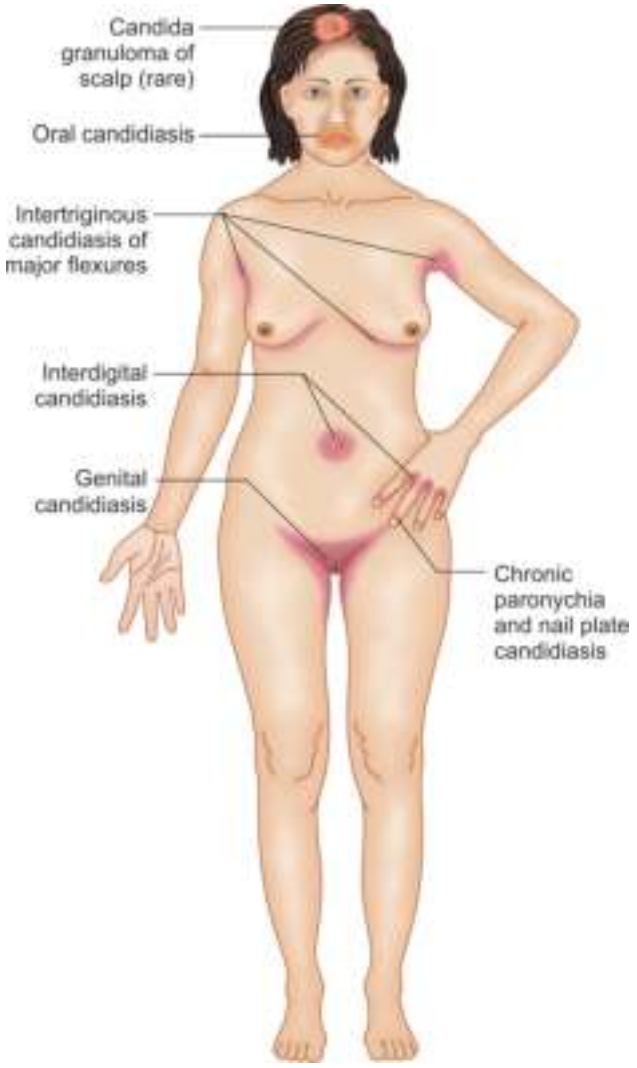

Fig. 29.32: Clinical manifestations of *Candida albicans*. It depicts the sites of involvement in candidiasis.

Fig. 29.33: Oral candidiasis by *Candida albicans*. Oral mucosa shows white deposits present on the labial mucosa and tongue, which on removal leaves an erythematous mucosal surface.

- Identification of the common inoculation subcutaneous mycoses, as well as those associated with pulmonary primary infection and dissemination to the skin is important, as treatments vary due to causative organism and clinical settings.
- Deep fungal infections include mycetoma, chromoblastomycosis, sporotrichosis, zygomycosis, mucormycosis and phaeohyphomycosis.

Mycetoma

Mycetoma is a localized chronic, suppurative, and deforming granulomatous inflammation of subcutaneous tissue, skin and bones, mainly of feet.

- Diagnosis of mycetoma can be made by the classic triad of painless soft tissue swelling, draining sinus tracts and extrusion of grains depending on causative organisms. Mycetoma is caused by various species of fungi and bacteria, which occur as saprophytes in soil or on the plants.
- Actinomycotic mycetoma is caused by aerobic species of gram-positive actinomycetes belonging to genera *Nocardia asteroides*, *Nocardia brasiliensis*, *Actinomedura medurae* and *Streptomyces somaliensis*.
- Gram-negative eumycotic mycetoma is associated with a variety of fungi, the most common being *Madurella mycetomatis*, that extrudes black to brown granules through sinus tracts. Fungi causing mycetoma and the type of granules produced are given in Table 29.13.

Table 29.13 Fungi causing mycetoma and the type of granules produced

Causative Organisms	Color of Granules
Actinomycotic mycetoma	
Actinomadura medurae	White
Actinomadura pelletieri	Red to pink
Streptomyces somaliensis	White to yellow
Nocardia asteroides	White
Nocardia brasiliensis	White
Nocardia otitidiscaviarum	White
Eumycotic mycetoma	
Madurella mycetomatis	Black to brown
Madurella grisea	Black to brown

Pathogenesis

The fungus is usually implanted after a penetrating injury while performing agricultural work barefoot or through preexisting abrasions, which leads to invasive and widespread infection. Predisposing factors are poor general health, diabetes, and malnutrition.

- Neutrophil degranulation and adherence to the grain surface, resulting in gradual disintegration of the grain. Outside the zone of neutrophils is a zone of granulation tissue containing macrophages, lymphocytes, and plasma cells.
- After disappearance of the neutrophils, macrophages participate in clearance of granules, which is followed by formation of epithelioid cell granulomas. T cell response plays an important part in the development of mycetoma. Most common sites of mycetoma are lower extremities commonly in the foot (70%) followed by hand, head, neck, chest, shoulder, and arm.

Clinical Features

Patient presents with small, painless, subcutaneous nodule at the site of injury, which over time softens and ulcerates to form draining sinuses to discharge a viscous, purulent, or serosanguineous fluid containing characteristic granules on the skin surface. Clinical photograph of mycetoma foot is shown in Figs 29.34 and 29.35.

Mucormycosis

Mucormycosis is a serious but rare fungal infection caused by a group of molds called mucoromycetes.

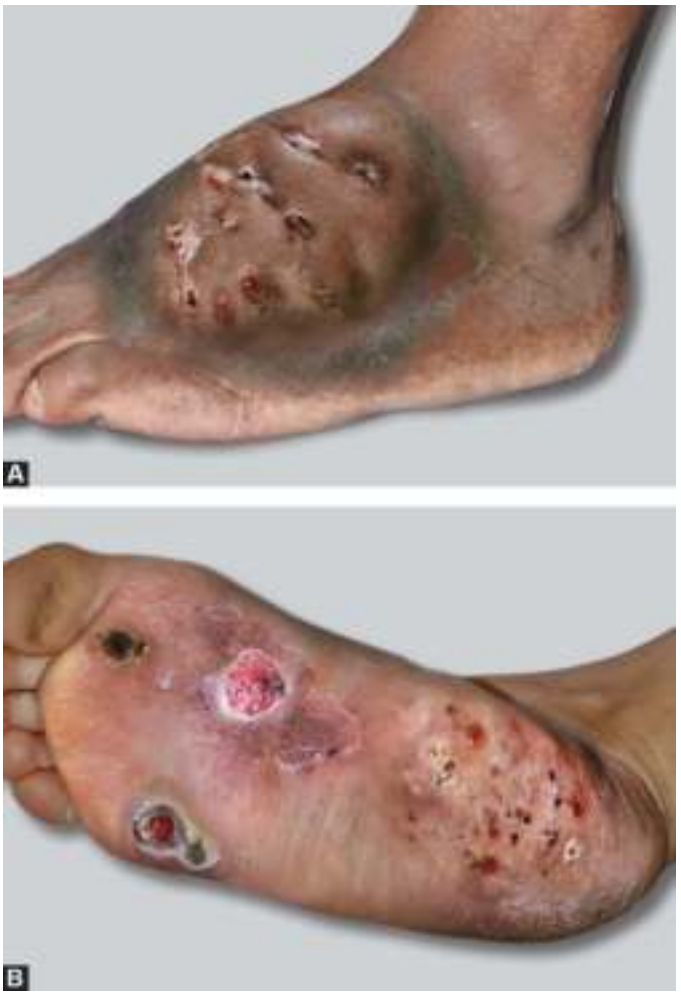

Fig. 29.34: Clinical photograph of mycetoma foot. (A) A case of eumycetoma with chronic swelling of the dorsum of the foot and sinuses, (B) a case of eumycetoma with visible black granules.

Fig. 29.35: Gross morphology of mycetoma foot. Cut surface of mycetoma foot shows black granules. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

- Mucormycosis is characterized by hyphae growing in and around blood vessels, resulting in formation of blood clots and surrounding tissue death due to ischemia, which can be potentially life-threatening in severely immunocompromised (HIV) or uncontrolled diabetic individuals, organ transplant, chronic kidney disease, long-term corticosteroid and immunosuppressive therapy.
- Angioinvasion of fungus is common and may elicit intravascular thrombus. There is often a marked inflammatory response, which may be neutrophils and formation of epithelioid cell granulomas. The fungus most commonly affects the sinuses, brain or the lungs after inhalation of fungal spores from the air, or the skin after the fungus enters the skin through a cut, burn, or other type of skin injury.
- Infection of the oral cavity or brain is the most common site; however, the fungus can also infect gastrointestinal tract, skin, and other organ system. Histology of mucormycosis is shown in Fig. 29.36.

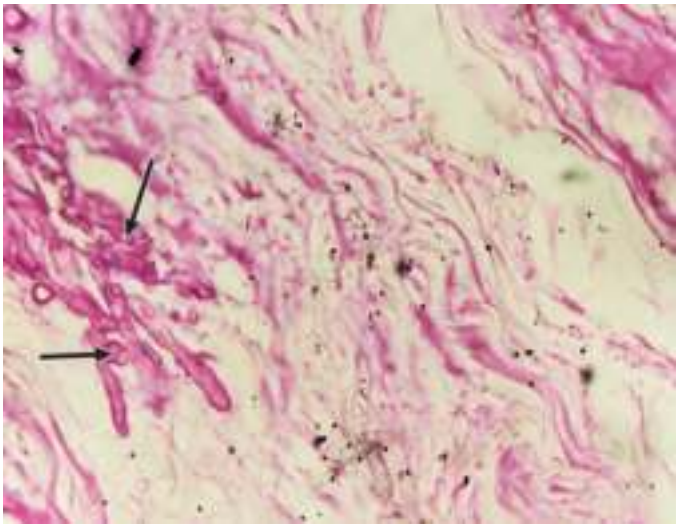

Fig. 29.36: Histology of mucormycosis. Hematoxylin and eosin-stained section demonstrates broad, irregular nonseptate hyphae of mucormycosis. Angle of the branching is greater than other organs. There is often a marked inflammatory response which may be neutrophils and granulomas (arrows) (400X).

INFLAMMATORY DERMATITIS

INFLAMMATORY DERMATITIS: OVERVIEW

Cutaneous inflammation can lead to many skin disorders. Lichenoid/interface dermatoses are characterized lymphocytic infiltration in the upper dermis leading to damage to basal keratinocytes. Psoriasiform dermatoses are characterized by expanded space between adjacent keratinocytes of the spinous layer of epidermis. Vesicobullous dermatoses are characterized by vesicles or bullae formation. Granulomatous dermatoses are characterized by granulomatous inflammation. Vasculopathic dermatoses are characterized by damage to endothelial cells, which become dysfunctional. Panniculitis dermatoses are characterized by inflammatory changes to the septa or lobules of the subcutaneous adipose tissue. Inflammatory dermatoses terminology and examples are given in Table 29.14. Nine basic patterns of inflammatory skin disorders are given in Table 29.15. Blistering diseases of the skin are given in Table 29.16.

Table 29.14 Inflammatory dermatoses terminology and examples

Histologic Features	Skin Disorders	Comments
Lichenoid/interface dermatoses		
Damage to basal keratinocytes	Lichen planus	Multiple papules and plaques on skin, hair, nails and mucous membrane
Lymphocytic infiltration in the upper dermis	▪ Lichen planus like keratosis ▪ Erythema multiforme (Stevens-Johnson syndrome) ▪ Lupus erythematosus ▪ Graft-versus-host disease	▪ Single red scaly plaque on sun-exposed regions ▪ Symmetrical cutaneous sloughing lesions on palms and soles ▪ Butterfly-shaped skin lesions and organs involvement ▪ Acute GVHD: Eruptions on palms, soles, head and neck ▪ Chronic GVHD: It may resemble lichen planus or lichen morphea

Contd...

Table 29.14 Inflammatory dermatoses terminology and examples (*Contd...*)

Histologic Features	Skin Disorders	Comments
Psoriasiform dermatoses		
Expanded space between adjacent keratinocytes of the spinous layer of epidermis	▪ Eczema/atopic dermatitis ▪ Pityriasis rosea ▪ Eosinophilic spongiosis	▪ Erythematous scaly plaques with variable distribution ▪ Erythematous scaly plaques (Christmas tree-like pattern) on back ▪ Lesions vary based on etiology
Vesicobullous dermatoses		
Vesicles or bullae formation	▪ Bullous pemphigoid ▪ Pemphigus vulgaris ▪ Porphyria cutanea tarda ▪ Epidermolysis bullosa acquisita ▪ Dermatitis herpetiformis	▪ Generalized tense blisters on erythematous base in elderly ▪ Painful oral erosions and flaccid cutaneous blisters that extend with lateral pressure (Nikolsky's sign) ▪ Blistering of skin-exposed on hand and face ▪ Blisters on site of trauma ▪ Pruritic small vesicles
Granulomatous dermatoses		
Epithelioid cell granuloma	▪ Necrobiotic granuloma (e.g. granuloma annulare) ▪ Necrobiosis lipoidica ▪ Sarcoidosis	▪ Erythematous plaques or subcutaneous nodules on localized or generalized sites ▪ Plaques with depressed yellow center in diabetes mellitus ▪ Variable lesions (annular, hypopigmented spots, ichthyosis-like, alopecia, subcutaneous nodules)
Vasculopathic dermatoses		
Damage to endothelial cells (dysfunctional endothelial cells)	▪ Acute vasculitis of small blood vessels (leukocytoclastic vasculitis) ▪ Granuloma faciale ▪ Lymphocytic vasculitis ▪ Vaso-occlusive vasculopathies ▪ Neutrophilic dermatosis (Sweet's syndrome) ▪ Urticaria ▪ Pigmented purpuric dermatosis	▪ Palpable purpura on extremities ▪ Reddish brown plaques on face ▪ Variable morphology ▪ Purpura, ulcer or infarct ▪ Abrupt onset of erythematous plaques on head, neck and upper extremities ▪ Pruritic wheals ▪ Multiple clinical variants
Panniculitis dermatoses		
Inflammatory changes to the septa or lobules of the subcutaneous adipose tissue	▪ Erythema nodosum (septal) ▪ Erythema induratum/nodular fasciitis ▪ Subcutaneous fat necrosis of the newborn ▪ Membranous lipodystrophy	▪ Single or multiple painful erythematous nodules on anterior leg (shin) ▪ Multiple erythematous plaques on posterior leg (calf) ▪ Firm, nodular areas of body ▪ Variable lesions on lower extremities

Table 29.15 Nine basic patterns of inflammatory skin disorders

▪ Superficial and deep perivascular dermatitis	▪ Intraepidermal vesicular and pustular dermatitis
▪ Vasculitis	▪ Perifolliculitis and folliculitis
▪ Nodular and diffuse dermatitis	▪ Fibrosing dermatitis
	▪ Panniculitis

Contd...

Table 29.16 Blistering diseases of the skin

Feature	Bullous Pemphigoid	Pemphigus Vulgaris	Dermatitis Herpetiformis
Epidemiology	Peak >60 years of age, most common bullous autoimmune disease	Peak incidence 40–60 years of age	Peak 15–40 years of age
Skin areas involved	Extremities, axillae and groin; oral mucosa in 10–15%	Oral mucosa (prominent >50% of cases), scalp, face and chest	Extensor surfaces; buttocks
Clinical features	Initially urticarial lesions resulting in large blisters, intensely pruritic lesions	Painful, flaccid intradermal blisters resulting in rupture, pruritus absent	Pruritic eruption on buttocks and extensor surface
Antibody target	Hemidesmosomes (bullous pemphigoid antigen of the epithelial membrane antigen)	IgG antibodies directed against desmoglein-3 and desmoglein-1 in desmosomes	Gliadin and reticulin (associated with HLA-DR3 and HLA-DQ2)
Histology	Subdermal clefting and blistering	Intradermal suprabasal clefting and blistering just above basal layer of the epidermis	Subdermal clefting and blistering
Pattern of immunofluorescence	Linear pattern of IgG and C3 along dermoepidermal junction	Deposition of IgG in intercellular spaces of the dermis giving net-like pattern	IgA positive clusters at tips of dermal papillae
Nikolsky sign	Negative	Positive	Negative
Tzanck test	Negative	Positive	Negative
Treatment	Topical steroids (first-line), systemic glucocorticoids (second-line)	Topical steroids (first-line), immunosuppressive drugs (second-line)	Gluten-free diet, dapsone (first-line), topical steroids and low intake of iodine
Prognosis	Benign disease, usually responds to treatment	Often fatal without treatment	Lifelong disorder requiring treatment

Nikolsky sign refers to slight rubbing of the skin resulting in exfoliation of the outermost layer.

INFLAMMATORY DERMATITIS: CLINICAL ENTITIES

PSORIASIS

Psoriasis is a chronic inflammatory multisystem non-pruritic disease affecting skin, nails, and musculocutaneous system. Psoriasis is characterized by persistent epidermal hyperplasia resulting in well-demarcated erythematous papules and plaques covered with silvery white scales commonly on the dorsal extensor cutaneous surfaces of the elbows and knees, as well as the scalp and sacral region.

- Psoriasis has complex pathogenesis include genetic (Cw6 gene mutation strongest association, HLA-B27, HLA-B13, and HLA-DR7), and autoimmune disorder. On histologic examination, psoriatic lesion is made of acanthosis, perivascular inflammation, dilated vessels in the papillary dermis and thinning of the suprapapillary plates.
- Scratching of silvery white scaly lesion causes rupture of small blood vessels in the suprapapillary thinned plates resulting in pinpoint hemorrhages known as 'Auspitz sign'. Clinical photograph of psoriasis is shown in Fig. 29.37.

Fig. 29.37: Clinical photograph of psoriasis. Multiple erythematous plaques of psoriasis are demonstrated (arrows). (*Courtesy*: Dr. Krishna Deb Barman, Director Professor of Dermatology, Maulana Azad Medical College and Associated Lok Nayak Hospital, New Delhi.)

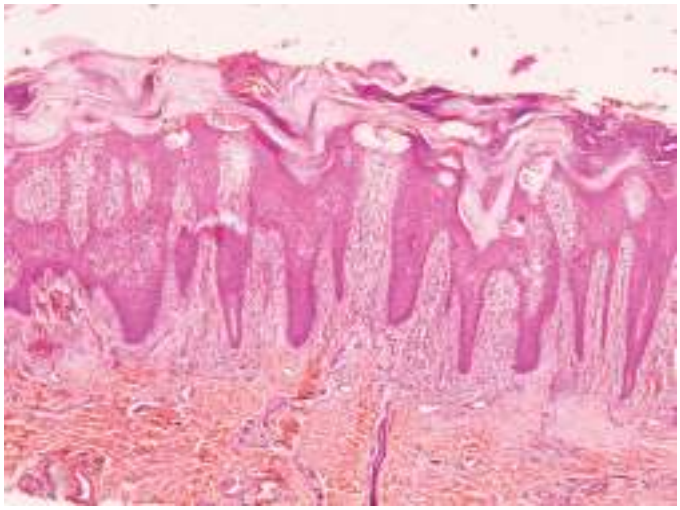

Fig. 29.38: Histology of psoriasis. Psoriasis is characterized by downward elongation of the rete ridges with thinning of overlying stratum granulosum, with parakeratosis above this. Small aggregates of neutrophils with surrounding spongiform change are seen in the superficial epidermis. Capillaries within dermal papillae are brought close to the surface (400X).

Surgical Pathology: Psoriasis

Light Microscopy

- Skin biopsy from patient with psoriasis shows thickening of epidermis, several folds, hyperkeratosis, parakeratosis, regular acanthosis and suprapapillary thinning (portion of epidermis over papillae thinned out).
- Neutrophils may become localized in the epidermal spinous layer or in small '*Munro microabscesses*' in the stratum corneum.
- The dermis below the papillae exhibits a varying number of mononuclear inflammatory cells around the superficial vascular plexuses. The capillaries of the papillae are dilated and tortuous. Histology of psoriasis is shown in Fig. 29.38.

ERYTHEMA MULTIFORME

Erythema multiforme (EM) is a cutaneous and mucosal hypersensitivity reaction with characteristic lesions in target triggered by certain antigenic stimuli. It is interface dermatitis, in which primary pathology is related to the dermoepidermal junction involving basal layer and the papillary dermis. Erythema multiforme is associated with herpes simplex virus infection.

- *Mycoplasma pneumoniae*, drugs, autoimmune disorders (concomitant connective tissue disorders) and malignancy have been implicated in pathogenesis of erythema multiforme.
- Erythema multiforme mainly involves the skin (macules, papules, bullous and necrotic lesions) and sometimes the mucosa. Skin lesions can be isolated, recurrent, or persistent. Disorder can affect young adults and children.

Clinical Features

Patient presents with symmetrical <3 cm of skin lesions on the extensor surface of the extremities (palms, and back of hands and feet without involvement of trunk) and spread centripetally.

- Typical skin lesion of erythema multiforme is round and regular three concentric circles and a well-defined border. The peripheral ring is erythematous, sometimes microvesicular, middle zone is clear, edematous and palpable; and the central zone is erythematous, covered by a blister. In erythema multiforme, skin lesions are typically fixed for a minimum of seven days.
- Mucosal lesions with fibrin-whitish coating occur in mouth (cheek, palate), ocular mucous membrane and genitalia. Initial mucosal lesions are bullous, then quickly turn into painful erosions. Mucosal lesions are frequently painful, whereas skin lesions painless.
- Pulmonary lesions occur due to *Mycoplasma pneumoniae* and manifest as cough and dyspnea. Erythema multiforme is most often associated with a target lesion resembling an archer's bull's eye. Clinical photograph of erythema multiforme is shown in Fig. 29.39.

Treatment

Erythema multiforme is treated by topical steroids or antihistamines and treating the underlying etiology. Recurrent erythema multiforme associated with the herpes simplex virus is treated by prophylactic antiviral therapy. Severe mucosal erythema multiforme can require hospitalization for intravenous fluids and repletion of electrolytes.

Fig. 29.39: Clinical photograph of erythema multiforme. Typical lesion of erythema multiforme is round and regular three concentric circles and a well-defined border. The peripheral ring is erythematous, sometimes microvesicular, middle zone is clear, edematous and palpable; and the center zone is erythematous and covered by a blister. Center cyanosis surrounded by red ring in this case (arrows).

LICHEN PLANUS

Lichen planus (LP) is an inflammatory disorder of the skin and mucous membranes of unknown etiology.

- Patient presents with pruritic, violaceous papules and plaques on the inner side of the wrist or blisters on palms, lower back, ankles and soles. A lattice-like network of white lines called Wickham striae overlies the lesions in oral mucosa, drug-induced lichen planus, or lichenoid drug eruption, may be indistinguishable from idiopathic lichen planus.
- Clinical course of lichen planus varies significantly. Cutaneous lesions clear within 1–2 years after initial presentation in majority of the patients, however, recurrences are common and the residual cutaneous lesions become hyperpigmented. While oral mucosal lesions may or may not remit.
- Drug-induced lichen planus gradually undergoes resolution after withdrawal of the causative therapeutic agents.

Pathogenesis

Pathogenesis of lichen planus is not known. It is "considered to be autoimmune disorder mediated by T cells.

- Prevailing theory is that lichen planus occurs due to exposure to viruses (HCV), drugs or contact allergens, which cause alteration of epidermal self-antigens and activation of CD8+ cytotoxic T cells. The altered self-antigens cross-react with normal self-antigens present on the basal keratinocytes resulting in CD8+ cytotoxic T cells targeting and apoptosis.
- More commonly associated drugs linked to lichen planus include antimalarials, NSAIDs, thiazide diuretics, angiotensin converting enzyme inhibitors (ACEIs), quinidine, β-blockers, tumor necrosis factor-α (TNF-α) inhibitors, and gold. Oral lichen planus is correlated with contact metal allergens (mercury, copper, gold) used in dental restorations. Removal of the sensitizing metal leads to clearance of oral lesions.

Clinical Features

Lichen planus can display a variety of lesion types. Patient usually presents with purple, polygon-shaped, pruritic papules of few mm wide and covered in fine white lines known as Wickham striae. Lesions are firm on palpation. Hypertrophic lichen planus is usually present on shins and ankles, and is red, red-brown, or yellow-grey papules and plaques that coalesce with a thickened or verrucous surface. Ulcerative lichen planus is seen on foot and between toes. Bullous lichen planus is seen on legs.

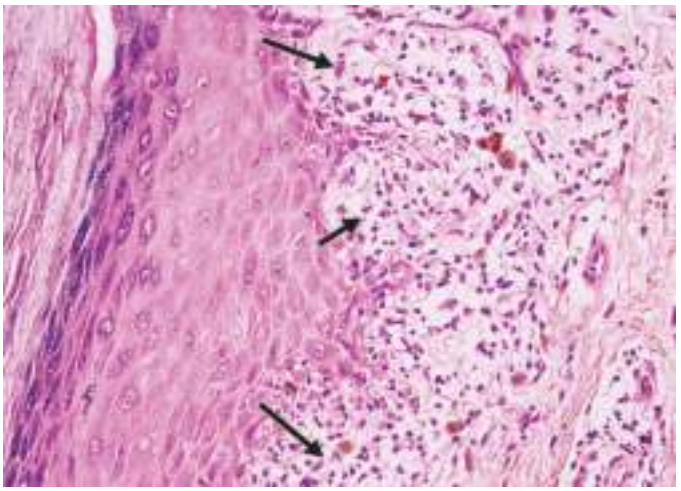

Fig. 29.40: Histology of lichen planus. Hematoxylin and eosin-stained section shows lymphoid aggregates along epidermis–dermis junction destroying basal layer of epidermis (arrows) (400X).

Surgical Pathology: Lichen Planus

Light Microscopy

- Histologic examination of lichen planus lesion on skin or oral and genital mucosa shows thickening of stratum corneum without nuclei, hyperkeratosis without parakeratosis, alteration or loss of rete ridges resulting in a sawtooth appearance, dense band-like lymphoid infiltrates along the epidermal–dermal junction, destroying the basal layer of the epithelium.
- Apoptotic keratinocytes are often demonstrated near the basal layer and are termed colloid or civatte bodies. Histology of lichen planus is shown in Fig. 29.40.

Immunofluorescence Microscopy

Direct staining by immunofluorescence microscopy may display colloid bodies with irregular deposits of IgA, IgM, IgG, or C3.

Treatment

Cutaneous lichen planus typically clears within 1–2 years. Treatment is focused on reducing pruritus by topical steroids for 2–4 weeks. Intralesional steroid injection and oral steroids are administered in patients with inadequate response to topical steroids tapered over 2–6 weeks.

PEMPHIGUS VULGARIS

Pemphigus vulgaris, an autosomal acantholytic disease, is associated with IgG antibodies against desmosomal glycoprotein desmoglein-3 and less commonly desmoglein-1, which is part of cadherin family of cell–cell adhesion molecules present in desmosomes.

- Antigen–antibody complex results in acantholysis (loss of cell–cell adhesion between keratinocytes) and formation of severe intraepidermal bullae as a result of loss of cell-to-cell adhesion of epithelial cells in lower epidermis or mucosa. It is augmented by the release of plasminogen activator (plasmin), that causes proteolysis of intercellular substance and dyshesion. Disease most often occurs in persons 30–60 years of age.
- Desmoglein-3 is a calcium-binding transmembrane glycoprotein component of desmosomes in epithelial cells in lower epidermis and mucosa, primarily responsible for maintaining intercellular adhesion in stratified squamous epithelia, such as the skin and oral mucosa.
- Patient initially develops lesions in the oral mucosa followed by extensive involvement of skin, which often rupture, leaving large denuded surfaces subject to secondary infection.

Pathology Pearls: Pathophysiology of Pemphigus Vulgaris

Pemphigus can be classified into three major forms: pemphigus vulgaris, pemphigus foliaceus and paraneoplastic pemphigus. Pemphigus vulgaris and pemphigus foliaceus are the originally characterized as classic forms of pemphigus. On histologic examination, pemphigus vulgaris blisters develop deep in the epidermis or oral epithelium above the basal layer, whereas pemphigus foliaceus blisters occur in the superficial layers of the epidermis, mostly in the granular layer.

- **Pemphigus vulgaris:** In pemphigus vulgaris, the lesions are present as mucosal dominant, mucocutaneous, and cutaneous.
  - Mucosal lesions are characterized by formation of blisters in the deep layers of the oral mucosa owing to anti-desmoglein-3 IgG autoantibodies.
  - Cutaneous lesions are characterized by formation of blisters in the deep layers of the epidermis owing to anti-desmoglein-1 and pathogenically weak anti-desmoglein-3 IgG autoantibodies. Clinical photograph of pemphigus vulgaris is shown in Fig. 29.41.
- **Pemphigus foliaceus:** Pemphigus foliaceus is caused by humoral autoimmune response; no apparent mucosal involvement blisters in the superficial layers of epidermis owing to anti-desmoglein-1 IgG autoantibodies.
- **Paraneoplastic pemphigus:** Paraneoplastic pemphigus is distinguished by the presence of a known-associated or occult-associated neoplasm, usually of lymphoid tissue and caused by humoral and cellular responses.
  - Paraneoplastic pemphigus is characterized by formation of blisters in the deep epithelial layers of mucosal and cutaneous regions owing to anti-desmoglein-3 and anti-desmoglein-1 IgG autoantibodies in combination interface dermatitis (vacuolization of basal cells, apoptosis of keratinocytes and abnormal keratinization, and inflammatory infiltrate owing to self-reacting T cells).
  - The patients also develop IgG autoantibodies against other several proteins (protease inhibitor and cytoplasmic proteins of the plakin family).

Surgical Pathology: Pemphigus Vulgaris

Light Microscopy

In pemphigus vulgaris, distinctive rounded keratinocytes (termed acantholytic cells) are shed into the vesicle during the process of dyshesion. Skin lesion shows prominent intra-epidermal acantholysis with intact basal layer as a floor and the remaining epidermis as a roof. The skin blister contains lymphocytes, macrophages, eosinophils, and neutrophils. Histology of pemphigus vulgaris is shown in Fig. 29.42.

Immunofluorescence Microscopy

Immunofluorescence microscopy shows deposition of IgG and C3 around cell membranes highlighting intercellular pattern of staining exhibiting honeycomb appearance.

BULLOUS PEMPHIGOID

Bullous pemphigoid is the most common autoimmune subepidermal vesicular (blisters) dermatitis in elderly persons of 60–80 years. It represents 80% of subepidermal blister forming disorders. Complement-fixing IgG antibodies are directed against basement membrane proteins, BPAG1 and BPAG2.

- Bullous pemphigoid resembles pemphigus vulgaris, but of less severity. Acantholysis is absent in bullous pemphigoid but present in pemphigus vulgaris.
- Before skin blisters develop, pruritus, and urticarial lesions may be present. The blisters tend to develop

Fig. 29.41: Clinical photograph of pemphigus vulgaris. Raw, erythematous and crusted lesions of pemphigus vulgaris are seen.

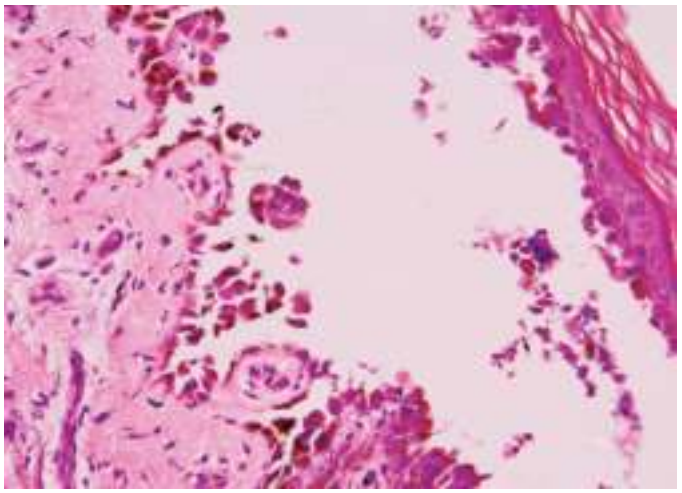

Fig. 29.42: Histology of pemphigus vulgaris. Hematoxylin and eosin stained section shows prominent intraepidermal acantholysis with intact basal layer as a floor and the remaining epidermis as a roof. The blister contains lymphocytes, macrophages, eosinophils, and neutrophils (400X).

in these regions. Since the entire epidermis forms the blister roof, hence the blisters become very stable and tense, due to fluid level, and can reach 10 cm in diameter. Oral mucosal involvement occurs in 20%; rarely presenting sign.

- Patient presents with tense bullae and intense generalized pruritus. Skin biopsy for hematoxylin and eosin staining demonstrates a subepidermal split with eosinophils.
- Direct immunofluorescence microscopy shows the autoantibodies against the basement membrane zone. Enzyme-linked immunosorbent assay (ELISA) testing is also useful in diagnosing bullous pemphigoid. Treatment depends on the severity of the disease.

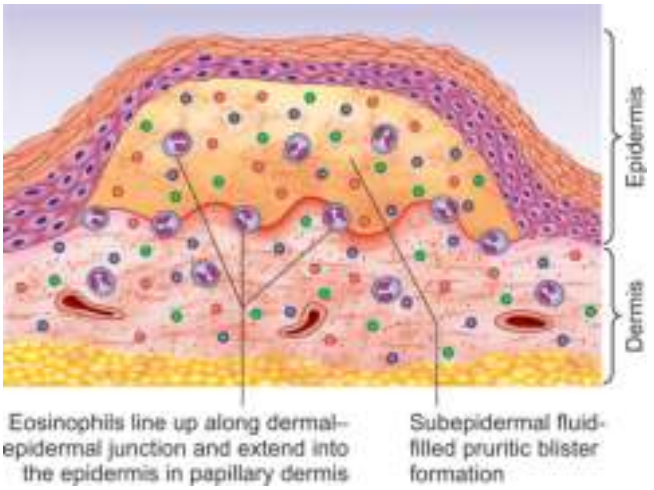

Fig. 29.44A: Schematic representation of bullous pemphigoid. This autoimmune disorder occurs due to autoantibodies against hemidesmosomal antigen, bullous antigens 1 and 2 with subepidermal fluid-filled pruritic blister formation and eosinophilic spongiosis.

- Standard treatment involves topical or systemic immunosuppressive agents. Prognosis is variable hence long-term monitoring is essential. Clinical photograph of bullous pemphigoid is shown in Fig. 29.43. Schematic representation of bullous pemphigoid is shown in Fig. 29.44A.

Surgical Pathology: Bullous Pemphigoid
Light Microscopy
Skin biopsy in bullous pemphigoid shows subepidermal bullae, with a characteristic inflammatory infiltrate of eosinophils in the surrounding dermis. Histology of bullous pemphigoid is shown in Fig. 29.44B.
Immunofluorescence Microscopy
In contrast to pemphigus vulgaris, immunofluorescence microscopy demonstrates deposition of C3 and IgG along the epidermal basement membrane in bullous pemphigoid.

Fig. 29.43: Clinical photograph of bullous pemphigoid. Tense blisters are present on an erythematous base in this case.

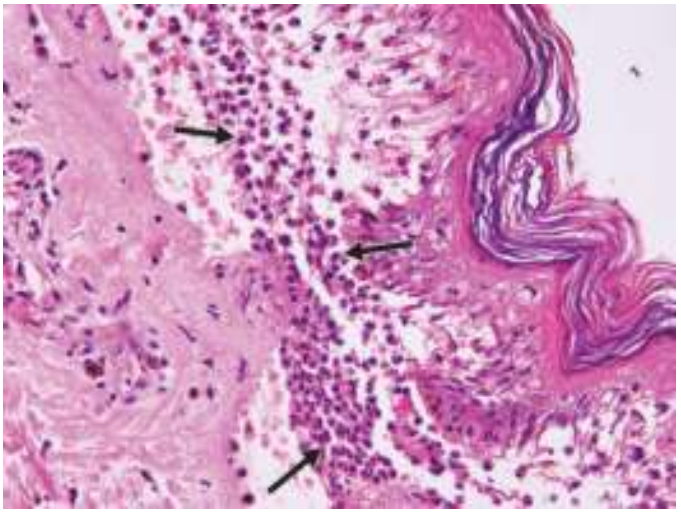

Fig. 29.44B: Histology of bullous pemphigoid. Hematoxylin and eosin-stained section shows subepidermal bullae, with a characteristic inflammatory infiltrate of eosinophils in the surrounding dermis (arrows) (400X).

NON-NEOPLASTIC MELANOCYTIC DISORDERS AND MELANOCYTIC NEOPLASMS

NON-NEOPLASTIC MELANOCYTIC DISORDERS

Biology of melanoblasts, melanocytes and melanosomes are discussed below.

- **Melanoblasts:** These cells are derived from neural crest. Melanoblasts migration/differentiation/survival in the epidermis is influenced by numerous signaling molecules synthesized by neighboring cells, which include Wnt, endothelin, bone morphogenic proteins, stem cell factor, c-KIT factor and hepatocyte growth factors. The growth factors bind to cognate cell surface receptors and induce intracellular signaling to influence gene transcription and protein synthesis. Endothelin mutation results in Hirschsprung disease and Waardenburg syndrome.
- **Melanocytes:** These cells populate the epidermis, hair follicle, eye, meninges, cochlea. Melanocytes synthesize melanin, an indole derivative of 1-3,4 dihydroxyphenylalanine (DOPA). Melanocyte stem cells are present in the hair follicle bulge. Melanocytes stain positive for TRP-2, an early marker of commitment to the melanocytic lineage, but negative for Ki-67 proliferative marker. Melanocytic lineage characterizes melanocytes migrating down to the dermal papilla during the anagen phase of cell cycle.
- **Melanosomes:** These cells are organized into supranuclear 'caps' within keratinocytes and demonstrated by Fontana-Masson stain. These cells display four maturation stages. Melanosomes contain structural matrix proteins, pH maintaining proteins, melanogenic enzymes, and free-radical scavengers.
  - Melanosomes are transported to epidermal keratinocytes and melanocyte dendritic tips.
  - Melanosomes absorb ultraviolet radiation in the skin against photodamage.
  - Melanosomes synthesize two types of melanins: (a) eumelanin dark brown-black and insoluble; and (b) phaeomelanin-light red-yellow sulfur-containing and soluble.
  - Melanin biosynthesis begins with the amino acid tyrosine that is converted to DOPA (3,4-dihydroxyphenylalanine) in the rate-limiting step of melanin biosynthesis. Melanin is stored in melanosomes.

ALBINISM

Albinism is usually inherited recessive trait disorder. It occurs due to failure of pigment synthesis by otherwise intact melanocytes as a result of failure of conversion of tyrosine to dihydroxyphenylalanine (DOPA). Clinical features of albinism include lightly pigmented or nonpigmented skin and silver-white or light color hair. Ocular nystagmus and reduced visual acuity are important features of albinism. Albinism occurs in two ocular and oculocutaneous variants.

- Ocular albinism is a melanin dysfunction that is limited to the eyes.
- Oculocutaneous albinism is an autosomal recessive disorder characterized by melanin synthetic defect that involves the eyes, skin, and hair. Risk of development of actinic keratosis, basal cell carcinoma, squamous cell carcinoma, and malignant melanoma is increased due to sensitivity of skin to sunlight.
  - **Oculocutaneous albinism type 1:** It occurs due to loss of function of the melanocyte enzyme tyrosinase resulting from mutation of the TYR gene on chromosome 11q21.
  - **Oculocutaneous albinism type 2:** It occurs due to OCA2 (P) gene mutation mapped on chromosome 15q.
  - **Oculocutaneous albinism type 3:** It occurs due to OCA3 (OMIM) gene mutation located on chromosome 9p23.
  - **Oculocutaneous albinism type 4:** It occurs due to MATP gene mutation mapped on chromosome 5p.

VITILIGO

Vitiligo is the most frequent depigmented acquired disorder involving multiple genes and environmental factors. It is characterized by progressive autoimmune mediated destruction of epidermal melanocytes in discrete areas of skin. It is sometimes associated with autoimmune disorders, such as Graves' disease and Addison disease. Antimelanocyte antibodies are sometimes demonstrated. Toxic substances may cause destruction of melanocytes resulting in vitiligo.

Clinical Features

Patient presents with acquired milk-white macules with fairly homogenous depigmentation and well-defined borders.

- **Vitiligo vulgaris:** It is characterized by multiple scattered lesions distributed in a more or less symmetrical pattern.
- **Acrofacial vitiligo:** It affects the distal end of fingers and facial orifices in a circumferential pattern.
- **Mixed vitiligo:** It is a combination of acrofacial and vulgaris, or segmental and acrofacial types.
- **Vitiligo universalis:** It is the severe form of vitiligo and characterized by complete or nearly complete depigmentation of the whole body.

- **Mucosal vitiligo:** It is confined to mucous membrane.
- **Focal vitiligo:** It is characterized by the presence of one/few macules in one area.

Clinical Course

Clinical course of any type of vitiligo is unpredictable and gradually progressive. It is difficult to control the disease with therapy.

Treatment

First-line treatment for vitiligo includes topical corticosteroids, calcineurin and ultraviolet B, systemic psoralen and ultraviolet A (PUVA). Second-line treatment includes topical calcineurin, topical PUVA and excimer laser.

FRECKLE (EPHELIS)

Freckle is produced by an increase in number of intraepidermal melanocytes laden with melanin pigment within basal keratinocytes. Freckle occurs on the sun-exposed skin areas like the cheeks, nose, and forehead in children and older adults. Newly developed lasers produce excellent results with minimal complications.

LENTIGO SIMPLEX

Lentigo simplex is a benign hyperpigmented macule located anywhere on the body in early life. Lesion results from a mild hyperplasia of melanocytes in the epidermis producing increased amounts of melanin not associated with sun exposure. Lesion occasionally forms in cutaneous scars and may be associated with psoralen/ultraviolet light therapy.

Clinical Features

Patient presents with asymptomatic, well-circumscribed, symmetric, homogeneous, light brown to black single or multiple macules measuring <5 mm in size on the trunk, extremities, genitalia, and mucous membranes. Lesion on mucous membranes can appear irregular with increased size, irregular borders, and heterogeneous pigmentation. Lentigo simplex may evolve into junctional nevi, which does not progress melanoma. Multiple lesions in lentigo simplex are associated with rare genetic disorders given in Table 29.17.

Table 29.17 Multiple lesions in lentigo simplex are associated with rare genetic disorders

Genetic Disorder	Clinical Features
Carney complex	Lentigines, atrial myxoma, mucocutaneous myxoma, and nevi
Peutz-Jeghers syndrome	Lentigines (perioral and oral), multiple gastrointestinal polyps, and visceral tumors (pancreas, ovary, testes)
Xeroderma pigmentosum	Lentigines on sun-exposed skin and multiple skin cancers
Cronkhite-Canada syndrome	Lentigines (buccal mucosa, face, palmoplantar), alopecia, nail dystrophy, and intestinal polyps

MELANOCYTIC NEOPLASMS

CONGENITAL MELANOCYTIC NEVI

Congenital melanocytic nevi are observed at birth represent a developmental abnormality of normal melanocytic development. These lesions occur presumably due to N-RAS gene mutation that occur in the progenitor cell, that result in the abnormal extensive accumulation of cutaneous melanocytic cells along migration pathways during normal development of melanoblasts in 1% of newborns. Congenital melanocytic nevi are formed between 5 and 24 weeks of gestation and present at birth or become apparent within the first year of life.

Clinical Features

The appearance of skin lesions varies considerably on the basis of morphology, texture, location, and size. Initially newborns present with nevi light in color, flat, or hairless; that can become round or oval with smooth, well-defined borders, more pigmented, raised papule or rugose, or verrucous and acquire long, coarse hairs measuring 2–20 cm in diameter.

- Congenital melanocytic nevi can appear anywhere on the body. The most common anatomic location for a giant congenital melanocytic nevus is the posterior trunk, followed by the legs, arms, head, and neck.
- The lifetime risk for malignant transformation of congenital melanocytic nevi depends largely on size of the skin lesion.

Treatment

Congenital melanocytic nevi are treated by observation of lesions, dermabrasion, chemical peel, laser ablation, and complete excision. The primary aim of management is to remove the risk for malignant transformation while minimizing functional deformity and improving cosmesis. Approach to the patient with congenital melanocytic nevi is given in Table 29.18.

MELANOCYTIC NEVUS (COMMON MOLE)

The benign melanocytic nevus (common mole) is the most common tumor, which rarely transforms to melanoma. Ultraviolet radiation (UVR) is involved in the etiology of a subset of nevi.

Table 29.18 Approach to the patient with congenital melanocytic nevi

Skin Lesion	Approach
Pigmented macular, popular or extension at birth	Small biopsy indicated in case of differential diagnosis of café' au lait macule (CALM), dermal melanocytosis (Mongolian spot) or epidermal nevus
Cranial or midline large lesions with increased risk of neurocutaneous/leptomeningeal involvement	MRI performed
One must analyze risk of melanoma	Excision of the lesion
One must analyze change in color of nonuniform lesion	Excision of the lesion

- Melanocytes are special dendritic cells derived from neural crest that have the ability to spread over the entire surface of the body.
- Nevus cells derived from melanocytes and ordinarily occur in clusters or nests.
- Depending on the involvement of skin layer melanocytic nevi are of three types: (a) junctional nevus—nevus cells are confined to the epidermal–dermal junction, (b) compound nevus—nevus cells are confined both at the epidermal–dermal junction and in the dermis; (c) intradermal nevus—nevus cells are nonpigmented and confined within the dermis.
- Patient presents with pigmented, and tan to brown, uniformly pigmented, small, 1 cm areas of elevated skin (papules, or moles) with well defined, rounded borders. Histology of intradermal nevus is shown in Fig. 29.45.

Surgical Pathology: Melanocytic Nevus

Light Microscopy

Melanocytic nevus is composed of round to oval melanocytes forming either round aggregates arranged in nests or sheets of cells in the epidermis in junctional nevus, dermis in dermal nevus or both in compound nevus.

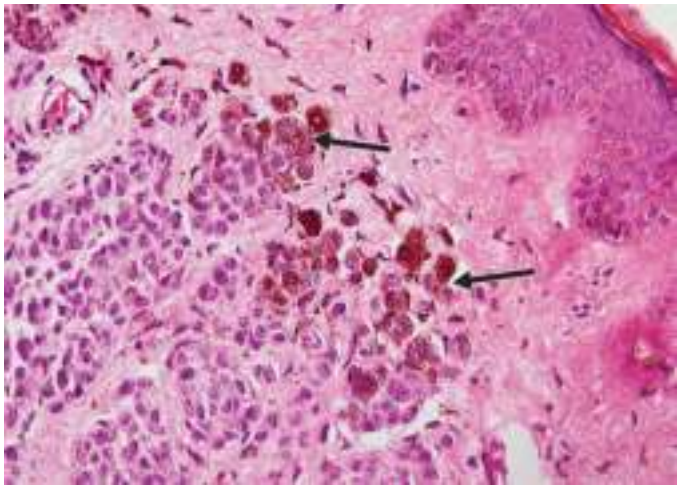

Fig. 29.45: Histology of intradermal nevus. Hematoxylin and eosin-stained section shows aggregates of melanocytes (arrows) (400X).

Dysplastic Melanocytic Nevus

Dysplastic melanocytic nevus is an atypical and irregular pigmented lesion with disorderly proliferation of melanocytes, dermal fibrosis, and lymphocytic infiltration. A clinical diagnosis of dysplastic melanocytic nevi is based on the presence of following features: skin lesion (fried egg appearance) <5 mm with ill-defined borders and color variation. Most of the atypical nevi are biopsied as these are concerning for atypical moles or melanoma.

- Dysplastic melanocytic nevus may transform into malignant melanoma. Etiology of dysplastic melanocytic nevus is not clear. However, phenotype expression is related to genetic and environmental factors. Predisposing risk factors include ultraviolet (UV) sunlight exposure especially in children, freckles, family history of dysplastic nevus syndrome, fair skin tone, light hair and light color eyes.
- Unlike patients with familial melanoma who often demonstrate a CDKN2A gene mutation, dysplastic melanocytic nevus does not commonly display CDKN2A gene mutation. Recent studies revealed that dysplastic melanocytic nevi are clonal like common nevi and some have BRAF, p16, or TP53 genetic alterations in expression.

Surgical Pathology: Dysplastic Melanocytic Nevus

Light Microscopy

- Histologic examination of dysplastic melanocytic nevus shows four characteristic features: intraepidermal lentiginous hyperplasia of melanocytes, cytologic atypia of melanocytes, lamellar and concentric fibroplasia (stromal response), and architectural atypia.
- Compound dysplastic nevus usually has 'shoulder sign' in which component extends beyond the 'shoulders' the dermal component.
- The dysplastic cells contain vesicular nuclei and prominent nuclei. The cytologic atypia is random and graded as mild, moderate or severe.

Lentigo Maligna

Lentigo maligna was first described by Hutchinson in 1890 and referred to as 'Hutchinson's melanotic

freckle'. It is characterized by atypical melanocytes at the epidermal–dermal junction. It is a precursor to lentigo maligna melanoma.

- Patient presents as an irregular brown macule on chronically ultraviolet radiation-damaged skin, particularly the head and neck, in the elderly persons.
- Ultraviolet radiation exposure causes oxidative damage and produce signature gene mutations, which in turn alter genes involved in the PI3K and MAPK pathways including BRAF, N-RAS, and KIT.
- Secondary gene mutations in CCND1, CDKN2A, and/or TP53 then result in transformation into malignant tumor.

Blue Nevus

Blue nevus can present clinically as blue, gray, brown, or black highly pigmented solitary nodules or plaques on the skin since birth. Histologically, blue nevus represents dermal pigmented dendritic melanocytes derived from embryonal precursors of melanocytes. Genetically, blue nevus harbors mutations in G protein-coupled receptor subunits, GNAQ and GNA11. Progression of blue nevus to malignant blue nevus is associated with additional gene mutations and partial gains and losses of chromosomal material.

Spitz Nevus

Spitz nevus is most often characterized by spindled and/or epithelioid nevomelanocytes, which most often affects children. Younger age is associated with more likely benign behaving Spitz nevus. Comparison of classic Spitz nevus and atypical Spitz nevus is given in Table 29.19.

MELANOMA

Melanoma is produced by the malignant transformation of melanocytes present in the basal layer of the skin derived from the neural crest, which can arise in other locations where neural crest cells migrate to brain and gastrointestinal tract. It is most often associated with excessive exposure to ultraviolet radiation.

- Clinically, melanomas are classified according to their depth: thin (≤1 mm), moderate (1–4 mm) and thick (>4 mm).
- Melanoma has two growth patterns: radial and vertical. During radiation growth, neoplastic cells grow in a radial fashion in the epidermis.
- With time, most melanomas progress to the vertical growth in which neoplastic cells invade underlying dermis and develop the ability to metastasize via lymphatic route to regional lymph nodes and via homogenous routine to distant organs (lung, liver, bone, brain). The five-year survival rate for patients with stage 0 melanoma is 97%, when compared with about 10% for patients with stage IV disease.

Table 29.19 Comparison of classic Spitz nevus and atypical Spitz nevus

Clinical Features	Classic Spitz Nevus	Atypical Spitz Nevus
Age group	<10 years	10–20 years
Location	Extremities, face, neck	Back
Size of lesion	<5–6 mm	>1 cm
Shape of lesion	Symmetrical or dome-shaped	Asymmetrical
Border	Well-defined	Irregular
Surface	Smooth	Irregular
Color	Pink, red	Irregular
Family history	No	Yes

Predisposing Factors

Melanoma is caused by combination of environmental and genetic factors. Risk factors for melanoma include ultraviolet radiation exposure, dysplastic melanocytic nevi, immunosuppressive states (hematological malignancies, transplantation patients) and positive family history, mutation in p16, BRAF, or MICR, blue eyes, fair complexion.

- Melanoma may develop in *de novo* (without evidence of precursor lesion) or precursor lesions (acquired nevus, dysplastic nevus, congenital nevus, cellular nevus). Solar irradiation predisposes to melanoma, basal cell carcinoma and squamous cell carcinoma. Melanoma may occur on unexposed areas of the skin, including the palms, soles, and perineum.
- UVB radiation spectrum (290–320 nm) induces two major DNA lesions at dipyrimidine sites: cyclobutene pyrimidine dimers and pyrimidine and pyrimidone photoproducts. UVB radiation induced DNA damage adversely affects signaling pathways resulting in impairment of cell cycle arrest, DNA repair and apoptosis. UV radiation causes TP53 and PTCH gene mutations, classical UVB signature mutations C→T (CC-TT) and dipyrimidine sites, UVA signature and oxidative mutations; and TNF-α released by exposed skin diminishes immune response. TNF-α induces dimer formation between neighboring thymine pairs in DNA.
- Depending on time and dose rate exposure to ultraviolet radiation leaves characteristic gene mutations that participate by molecular and cellular alterations in skin melanoma. Ultraviolet radiation-induced molecular changes are prevented by DNA repair, apoptosis and signaling pathways. Skin melanoma risk is increased due to genetic polymorphisms in genes for DNA repair, melanin and oxygen-derived free radical scavenging.

Table 29.20 Environmental agents associated with the development of human skin cancers

Environmental Agent	Persons at Risk	Route of Exposure to Agent	Associated Sporadic Skin Cancer
General exposure to environmental agents			
Ultraviolet radiation (UVB:290–320 nm), p53 gene mutation and induces dimer formation between neighboring thymine pairs in DNA	General population	Topical exposure	▪ Melanoma ▪ Squamous cell carcinoma ▪ Basal cell carcinoma ▪ Bowen disease ▪ Skin cancers in xeroderma pigmentosum
Therapeutic agents administered in patients			
Psoralen (PUVA)	Psoriasis patient	Topical exposure or systemic system	▪ Melanoma ▪ Squamous cell carcinoma ▪ Basal cell carcinoma

- Educational and behavioral approaches are keys to minimize skin melanoma rates. Inflammation, immunosuppression and oxidative stress enhance UV-induced carcinogenesis by causing DNA mutations.
- Clonal expansion of mutant cells increases opportunities to receive additional gene mutations for development and progression of skin melanoma. Environmental agents associated with the development of human skin cancers are given in Table 29.20.

Molecular Genetic Alterations: Melanoma

Most cases of melanoma are sporadic. It means that acquired somatic mutations in the melanocytes during a person's lifetime give rise to melanoma. Oncogenes and tumor suppressor genes in cutaneous melanoma and other human cancers are given in Table 29.21.

- Somatic germline mutations in the BRAF and CDKN2A genes are demonstrated in some cases and most common in sporadic melanoma. In about 10% of cases, melanoma occurs in multiple members of the same family. Unlike sporadic melanoma, familial melanomas are caused by inherited germline mutations in CDKN2A and MCIR genes.
- The CDKN2A gene plays important role in regulating cell senescence. MCIR gene influences skin pigmentation. In people with germline CDKN2A and MCIR gene mutations, changes in other genes, together with environmental and lifestyle factors contribute to possible development of melanoma.
  - **CDKN2A-CDK4-TP53 pathway disruption:** Germline mutations in cyclin-dependent kinase inhibitor 2A (CDKN2A) tumor suppressor gene account for 40% of hereditary melanoma and pancreatic carcinoma. CDKN2A gene is a regulator of cell division. Mutations in CDKN2A gene are the most common cause of inherited melanoma. The risk of melanoma in CDKN2A mutation carriers is approximately 14% by age 50 years, 24% by age 70 years and 28% by age 80 years.
  - **RAS signaling pathway disruption:** Somatic mutation in the BRAF gene is demonstrated in 66% of melanomas occurring on skin subject to intermittent ultraviolet radiation.
  - **Microphthalmia associated transcription pathway disruption:** Recently somatic amplifications of the microphthalmia (MITF) gene has been detected in a subset of melanomas. Overexpression of MITF in conjunction with BRAF can result in melanocytic transformation.
  - **KIT tyrosine kinase receptor mutation:** KIT tyrosine kinase receptor has been demonstrated to be mutated or amplified in a subset of melanomas predominantly in acral and mucosal sites. Tyrosine kinase receptor inhibitor 'imatinib' may be useful in the treatment of c-KIT mutated melanomas.
  - **Melanocortin 1 receptor mutation:** Recently mutations in the melanocortin 1 receptor (MCIR) increase the risk of melanoma.
  - **Xeroderma pigmentosum gene mutation:** Xeroderma pigmentosum is an autosomal recessive disorder. Mutations of XP genes increase the risk of melanoma.
  - **Breast cancer susceptibility gene mutation:** Carriers of the breast cancer susceptibility gene (BRCA) increase risk for melanoma.

Melanoma: Clinical Variants

Clinical variants of melanomas include superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma and acral lentiginous melanoma. Clinical variants of melanomas are shown in Fig. 29.46A to D and clinical variants of melanomas are given in Table 29.22.

- **Superficial spreading melanoma:** It accounts for 70% of melanomas and occurs on trunk and extremities. Patient initially develops a flat growth in a radial fashion with irregular border and variegated dark brown pigmentation resulting in about 2 cm growth with variegated colors, as well as peripheral notches, indentations, or both.
- **Nodular melanoma:** It accounts for 15–30% of melanoma diagnoses. Patient presents with blue-black tumor (sometimes lacking pigmentation) on head, neck and trunk, that grows in vertical fashion. This variant has the poorest prognosis of the clinical variants.

Table 29.21 Oncogenes and tumor suppressor genes in cutaneous melanoma and other human cancers

Gene	Locus	Function	Tumor Type	
Oncogenes				
H-RAS	11p15.5	Cell cycle, survival	▪ Melanoma	▪ Squamous cell carcinoma
K-RAS	1p13.2	Cell cycle, survival	▪ Melanoma	▪ Squamous cell carcinoma
BRAF	7q34	Cell cycle, survival	▪ Melanoma ▪ Leukemia	▪ Colon carcinoma
CDK4	q13–15	Cell cycle during G1/S transition by inhibiting RB1 protein	▪ Melanoma ▪ Glioblastoma multiforme	▪ Sarcoma
FGFR3'INT2	Unknown	Regulation of cell growth, division, angiogenesis and embryo development	Melanoma	
Tumor suppressor genes				
p16 (INK4A)	9p21	Cyclin-dependent kinase inhibitor	▪ Melanoma ▪ Squamous cell carcinoma	▪ Mesotheliomas ▪ Astrocytoma
APC	5p21	APC inhibits Wnt signaling activator pathway, thus prevents nuclear transcription. It degrades catenin	▪ Melanoma ▪ Familial polyposis coli with malignant transformation ▪ Colon carcinoma	▪ Gastric carcinoma ▪ Pancreatic carcinoma ▪ Thyroid carcinoma
PTEN	10q23.3	Phosphatase	▪ Melanoma	▪ Trichoepithelioma

Unknown gene mutation on Xq24-q27 may cause basal cell carcinoma. Unknown gene mutation on 9q31 can cause keratoacanthoma.

Fig. 29.46: Melanoma variants: (A) Superficial spreading melanoma *in situ*, (B) nodular malignant melanoma, (C) lentigo maligna presents as hyperpigmented lesion with irregular borders located on the head, (D) acral variant of melanoma.

Table 29.22 Clinical variants of melanomas

Clinical Variant	Frequency	Locations	Median Age	Features
Superficial spreading melanoma	70%	Trunk and extremities	47 years	Initially flat pigmented growth in a radial fashion attaining 2 cm
Nodular melanoma	4–10%	Head, neck and trunk	50 years	Tumor with vertical growth pattern associated with poorest diagnosis
Lentigo maligna melanoma	2–8% (Whites) 35–60% (dark-skinned)	Nose and cheek	70 years	Large pigmented 3 cm macule with marked notching of the borders
Acral lentiginous melanoma	2–8%	Palms, soles, and subungual regions	61 years	Flat, tan, or brown stained growth with irregular borders

- **Lentigo maligna melanoma:** It represents 4–10% of melanomas. It is also known as Hutchinson melanotic freckle. Initially, patient presents with large pigmented 3 cm macule with marked notching of the borders on nose and cheek.
- **Acral subungual and mucosal lentiginous melanoma:** Acral lentiginous melanoma accounts for 2–8% in Whites and 35–60% in dark-skinned people. Patient presents with flat, tan, or brown stained growth with irregular borders on palms, soles, and subungual regions. Subungual lentiginous melanoma can be brown or black, with ulcerations in later stages. A similar tumor occurs on the mucous membranes known as mucosal lentiginous melanoma.

Surgical Pathology: Melanoma

Gross Morphology

Gross morphology of malignant melanoma in skin with lymph node metastasis is shown in Fig. 29.47A and B.

- **Superficial spreading melanoma:** Tumor occurs on trunk and extremities. Initially, tumor is flat growth in a radial fashion with irregular border and variegated dark brown pigmentation resulting in about 2 cm growth with variegated colors, as well as peripheral notches, indentations, or both.
- **Nodular melanoma:** Tumor is blue-black tumor (sometimes lacking pigmentation) on head, neck and trunk, that grows in vertical fashion. This variant has the poorest prognosis of the clinical variants.
- **Lentigo maligna melanoma:** Tumor is large pigmented 3 cm macule with marked notching of the borders on nose and cheek.
- **Acral subungual and mucosal lentiginous melanoma:** Acral lentiginous melanoma is flat, tan, or brown stained growth with irregular borders on palms, soles, and subungual regions. Subungual lesions can be brown or black, with ulcerations in later stages. A similar tumor occurs on the mucous membranes known as mucosal lentiginous melanoma.

Light Microscopy

- **Dermoepidermal melanoma:** Melanoma cells are usually considerably larger than nevus cells. Tumor cells contain large nuclei with irregular contours with eosinophilic nuclei. Chromatin is clumped at the periphery of the nuclear membrane.

All melanomas start as *in situ* lesion involving only the epidermis. Nests of melanoma cells are present at the dermoepidermal junction. Histology of malignant melanoma is shown in Fig. 29.48. Cytology of malignant melanoma metastasizing to lymph node is shown in Fig. 29.49.

- **Pagetoid spread melanoma:** The lesion progresses to involve all layers of the epidermis known as epidermal tropism or Pagetoid spread.
- **Radial growth melanoma:** As melanoma cells expand laterally (so-called radial growth phase), the area of involved skin enlarges. Tumor grows in all directions predominantly lateral within epidermis and papillary zone of the dermis. There is presence of numerous lymphocytes. This variant does not metastasize; hence prognosis is good.
- **Vertical growth melanoma:** Eventually, melanoma cells invade the dermis and the so-called vertical growth phase begins (which indicates the progression from *in situ* to invasive melanoma), which extends into the reticular dermis or beyond. Prognosis depends on depth of the lesion. It may spread by lymphatic and hematogenous routes.

Electron Microscopy

Sometimes a melanoma will not be well-differentiated enough to show the typical melanin pigmentation. Electron microscopy shows oval premelanosome structures.

Immunohistochemistry Technique

Panel of markers is applied on histologic sections in melanoma.

Melanoma *in situ*	
Melan-A (A103) or also known as melanoma antigen recognized by T cells 1 (MART-1)	Positive (80–100%)
Human melanoma black 45 (HMB-45)	Positive (60–90%)
S-100 protein (calcium-binding protein)	Positive
Microphthalmia transcription factor (MITF)	Positive

Melanoma (epithelioid variant)	
Melan-A (A103) or also known as melanoma antigen recognized by T cells 1 (MART-1)	Positive (80–100%)
Human melanoma black 45 (HMB-45)	Positive (60–90%)
Ki-67 proliferative marker	Positive

▪ S-100 (calcium-binding protein)	▪ Positive
▪ Microphthalmia transcription factor (MITF)	▪ Positive
▪ SOX 100	▪ Positive
▪ PNL2	▪ Positive
▪ MUM1	▪ Positive
Melanoma (desmoplastic variant)	
▪ S-100 protein (calcium-binding protein)	▪ Positive
▪ Melan-A (A103) or also known as melanoma antigen recognized by T cells 1 (MART-1)	▪ Negative
▪ Human melanoma black 45 (HMB-45)	▪ Negative
▪ Microphthalmia transcription factor (MITF)	▪ Negative
▪ SOX 100	▪ Negative
▪ PNL2	▪ Negative
▪ MUM1	▪ Negative

Prognostic Factors

The most important prognostic indicator is tumor thickness. Superficial variant of melanoma has better prognosis than vertical variant. Ulceration, high mitotic rate, absence of significant lymphocytic response are poor prognostic indicators.

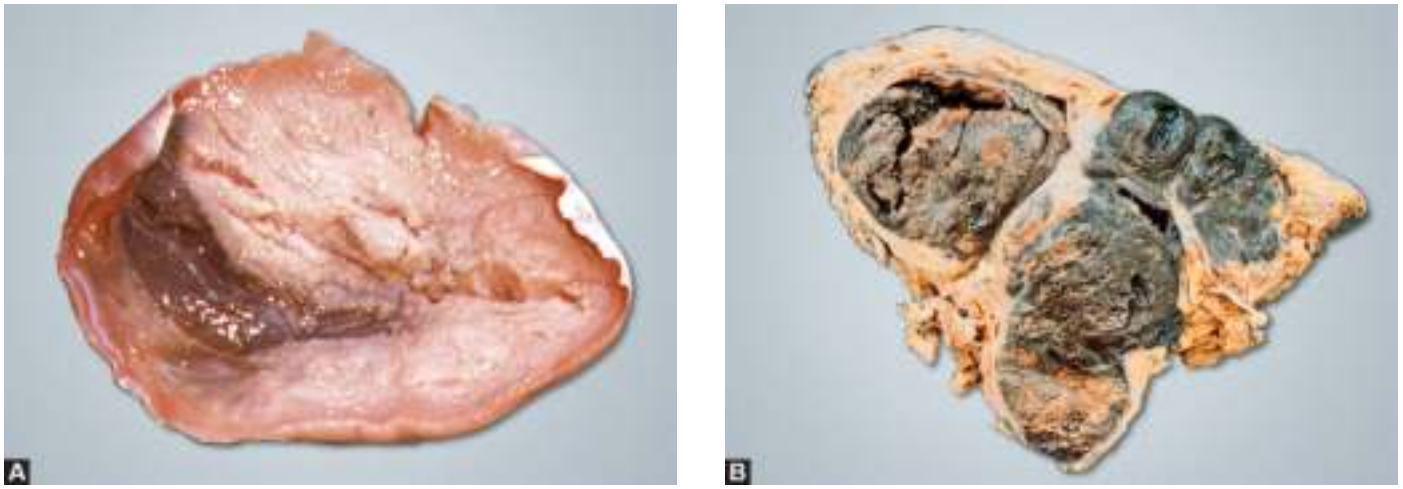

Fig. 29.47: Malignant melanoma. (A) Tumor arises from skin. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka) and (B) melanoma metastases in lymph node. (*Courtesy*: Dr. Sujata Kanetkar, Professor and Head of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

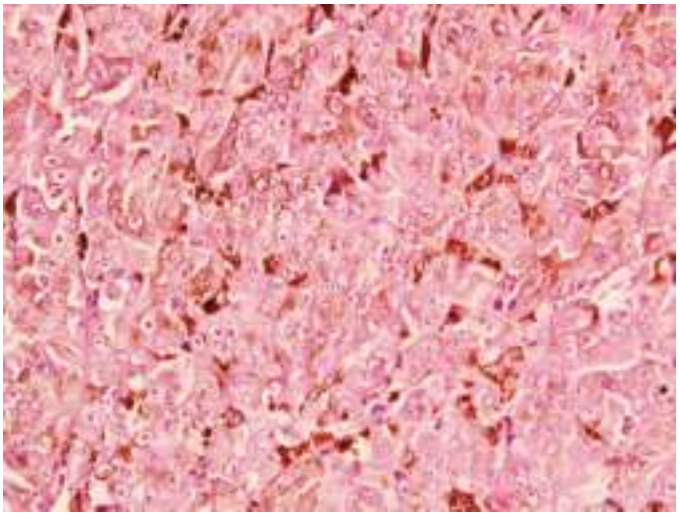

Fig. 29.48: Histology of malignant melanoma. Melanoma cells are usually considerably larger than nevus cells. Tumor cells contain large nuclei with irregular contours. Chromatin is clumped at the periphery of the nuclear membrane. All melanomas start as *in situ* lesion involving only the epidermis. Nests of melanoma cells are present at the dermoepidermal junction (400X).

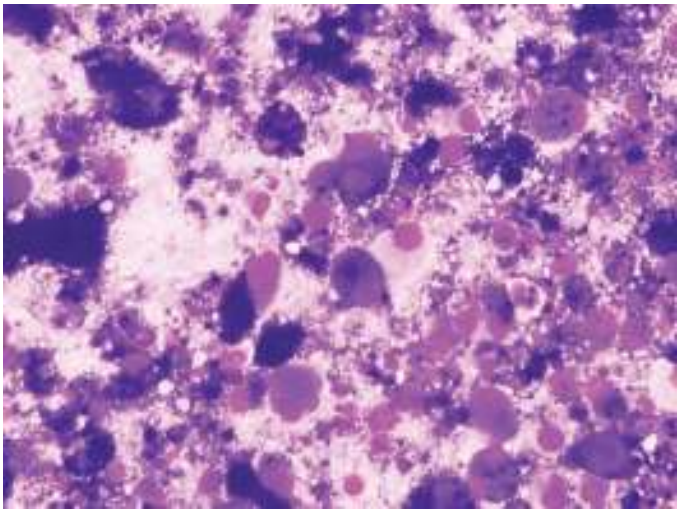

Fig. 29.49: Fine needle aspiration cytology of malignant melanoma metastasizing to lymph node. Malignant melanoma is produced by the malignant transformation of melanocytes derived from neural crest. Positive family history, exposure to UVA and UVB radiation, and atypical mole syndrome are linked to malignant melanoma. Tumor can metastasize via lymphatic and hematogenous routes (400X).

NONMELANOCYTIC CUTANEOUS NEOPLASMS

Skin cancer is the most common type of malignancy worldwide. Possible risk factors include exposure to sunlight or UV radiation, human papillomavirus (HPV), fair skin type, presence of large numbers or certain types of nevi (moles), exposure to arsenic, immunosuppression, certain genetic conditions (e.g. xeroderma pigmentosum), and family history of skin cancer.

- Epithelial neoplasms of skin include basal cell carcinoma, basal cell nevus syndrome, Bowen disease (squamous cell carcinoma *in situ*), squamous cell carcinoma and keratoacanthoma. Melanocytic neoplasms include nevi and melanoma discussed under disorders of pigmentation and melanocytes.
- Tumors of the cutaneous appendages arising from hair follicle, eccrine glands, sebaceous glands include chondroid syringoma, nodular hidradenoma and pilomatrixoma. Merkel cell carcinoma arises from neuroendocrine cell. Fibrohistiocytic tumors include dermatofibroma and dermatofibrosarcoma protuberans. Vascular tumors include capillary hemangioma, spindle cell hemangioma, kaposiform hemangioendothelioma, Dabska-type papillary intralymphatic angioendothelioma and retiform hemangioendothelioma, Kaposi sarcoma and angiosarcoma.

CARCINOGENESIS OF SKIN CANCERS

Carcinogenesis is a multistep process of formation of malignant tumor growth; whereby normal cells are transformed to malignant cells. Carcinogenesis process is characterized at the cellular, genomic and epigenetic levels and abnormal cell division.

GENOMIC INSTABILITY

Integrity of the genome is constantly threatened by exogenous agents (ultraviolet radiation, ionization radiation, tobacco smoke, chemical agents) or endogenous agents (reactive oxygen species, DNA-damaging agents).

- DNA damage can cause changes in DNA sequence due to alterations in the structure of nucleotides, DNA double-strand breaks, DNA cross-links, incorrect nucleotide base pairing, and DNA adducts.
- The ability of cells with DNA damage to repair and maintain the genomic stability is important in prevention of malignant transformation. Different agents induce different types of DNA damage, which in turn require different cellular responses and repair pathways.
- Many hereditary disorders are characterized by genomic stability due to defects in genes involved in cellular DNA repair or DNA repair defects. Inherited or acquired genomic instability is associated with an increased risk for development of cancer. Oncogenes and tumor suppressor genes in human cutaneous cancers are given in Table 29.23.

CHEMICAL CARCINOGENESIS

Chimney sweep has been linked with environmental exposure and cutaneous scrotal carcinoma. Chemical agents, such as arsenic and hydrocarbons, have been implicated in human skin cancers. Chemical

Table 29.23 Oncogenes and tumor suppressor genes in human cutaneous cancers

Gene	Locus	Function	Tumor Type
Oncogenes			
H-RAS	11p15.5	Cell cycle, survival	▪ Squamous cell carcinoma ▪ Melanoma
K-RAS	1p13.2	Cell cycle, survival	▪ Squamous cell carcinoma ▪ Melanoma
SMO	7q31–q32	Hedgehog signaling pathway receptor	Basal cell carcinoma
BRAF	7q34	Cell cycle, survival	▪ Melanoma ▪ Leukemia ▪ Colon carcinoma
CDK4	q13–15	Cell cycle during G1/S transition by inhibiting RB1 protein	▪ Melanoma ▪ Glioblastoma multiforme ▪ Sarcoma
CTNNB1	3p22–p21.3	Cell-cell adhesion, transcription	Pilomatricoma (pilomatrixoma)
LEF1	4q23–q25	Transcription	Sebaceous tumors

Table 29.23 Oncogenes and tumor suppressor genes in human cutaneous cancers (*Contd...*)

Gene	Locus	Function	Tumor Type
FGFR3/INT2	Unknown	Regulation of cell growth, division, angiogenesis and embryo development	Melanoma
Tumor suppressor genes			
TP53	17p13.1	DNA repair, cell cycle regulation, apoptosis	▪ Squamous cell carcinoma ▪ Basal cell carcinoma
p16 (INK4A)	9p21	Cyclin-dependent kinase inhibitor	Squamous cell carcinoma
Melanoma			
APC	5p21	APC inhibits Wnt signaling activator pathway, thus prevents nuclear transcription. It degrades β-catenin	▪ Melanoma ▪ Familial polyposis coli with malignant transformation ▪ Colon carcinoma ▪ Gastric carcinoma ▪ Pancreatic carcinoma ▪ Thyroid carcinoma
PTCH1	9p22.3	Hedgehog signaling pathway receptor	▪ Basal cell carcinoma ▪ Trichoepithelioma
PTEN	10q23.3	Phosphatase	▪ Melanoma ▪ Trichoepithelioma
CYLD	16q12–q13	NF-κβ inhibitor	Cylindroma
▪ MSH2 ▪ MLH1	▪ 2p22–p21 ▪ 3p21.3	Mismatch repair	Sebaceous gland carcinoma
FLCN	17p11.2	Ribosomal protein S6 modulator	Fibrofolliculoma

Unknown gene mutation on Xq24-q27 may cause basal cell carcinoma. Unknown gene mutation on 9q31 can cause keratoacanthoma.

carcinogenic agents linked to human cancers are classified as tumor initiators, promoters, or 'complete carcinogens'. Incomplete chemical carcinogens act as promoters in the carcinogenesis.

- Tumor initiation, associated with gene mutations permanently alter the cellular biological responsiveness, is irreversible change. Tumor promotion process does not produce gene mutations, that provides a selective growth at early stages; genotoxic carcinogenic agents that facilitate malignant progression.
- Most chemical carcinogens must undergo metabolic activation, which involves cellular enzymes involved in xenobiotic metabolism, including cytochrome p-450 enzymes and glutathione S-transferase. Presence of additional risk factors such as UV exposure including polymorphisms influence the susceptibility to develop human cancers.

ULTRAVIOLET RADIATION CARCINOGENESIS

Ultraviolet (UV) radiation from the sun is most important carcinogen in human beings. There is continuous increase in the incidence of development of all types of skin cancers (squamous cell carcinoma, basal cell carcinoma, melanoma and skin cancers in xeroderma pigmentosum; Merkel cell carcinoma is also induced by polyomavirus). Exposure of the skin to UV radiation has multiple cellular and clinical effects including development of skin cancers.

- UVB radiation spectrum (290–320 nm) induces two major DNA lesions at dipyrimidine sites: cyclobutene pyrimidine dimers and pyrimidine and pyrimidone photoproducts. UVB radiation-induced DNA damage adversely affects signaling pathways resulting in impairment of cell cycle arrest, DNA repair and apoptosis. UV radiation causes p53 and PTCH gene mutations, classical UVB signature mutations C→T (CC-TT) and dipyrimidine sites, UVA signature and oxidative mutations; and TNF-α released by exposed skin diminishes immune response. UVB radiation induces dimer formation between neighboring thymine pairs in DNA.
- Depending on time and dose rate exposure to ultraviolet radiation leaves characteristic mutations that participate by molecular and cellular alterations in skin cancers. Ultraviolet radiation-induced molecular changes are prevented by DNA repair, apoptosis and signaling pathways. Skin cancer risk is increased due to genetic polymorphisms in genes for DNA repair, melanin and oxygen-derived free radical scavenging.
- Educational and behavioral approaches are keys to minimize skin cancer rates. Inflammation,

immunosuppression and oxidative stress enhance UV-induced carcinogenesis by causing DNA mutations.

- Clonal expansion of mutant cells increases opportunities to receive additional mutations for development and progression of skin cancers. Environmental agents associated with the development of human skin cancers are given in Table 29.24. Panel of immunohistochemical markers applied in assessment of selected skin tumors is given in Table 29.25.

Table 29.24 Environmental agents associated with the development of human skin cancers

Environmental Agent	Persons at Risk	Route of Exposure to Agent	Associated Sporadic Skin Cancer
General exposure to environmental agents			
Ultraviolet radiation (UVB:290–320 nm) causes p53 gene mutation and induces dimer formation between neighboring thymine pairs in DNA	General population	Topical	▪ Squamous cell carcinoma ▪ Basal cell carcinoma ▪ Melanoma ▪ Bowen disease ▪ Skin cancers in xeroderma pigmentosum
Tobacco smoke	Tobacco smokers	Topical, systemic	Squamous cell carcinoma
Soot	Chimney sweep	Topical	Squamous cell carcinoma
Occupational exposure			
Coat tar, pitch	Coker of coal, steel worker	Topical	Squamous cell carcinoma
Petroleum oils	Machinist, textile worker	Topical	Squamous cell carcinoma
Arsenic	Agriculture worker, soil contamination, living in areas of high groundwater	Topical, systemic	▪ Squamous cell carcinoma ▪ Basal cell carcinoma ▪ Bowen disease
4,4'-Bipyridyl	Pesticide manufacturer	Topical	▪ Squamous cell carcinoma ▪ Bowen disease
Polychlorinated biphenyl	Petrochemical worker	Topical, systemic	Melanoma
Dry cleaning agents	Dry cleaner	Topical, systemic	Basal cell carcinoma
Fiberglass	Insulator	Topical	Basal cell carcinoma
Therapeutic agents administered in patients			
Psoralen (PUVA)	Psoriasis patient	Topical, systemic	▪ Squamous cell carcinoma ▪ Basal cell carcinoma ▪ Melanoma
Nitrogen mustard	Cutaneous T cell lymphoma	Topical	Squamous cell carcinoma
Immunosuppressants	Transplant recipients	Systemic	▪ Squamous cell carcinoma ▪ Basal cell carcinoma
Ionizing radiation	Cancer therapy patient	Topical	▪ Squamous cell carcinoma ▪ Basal cell carcinoma

EPIDERMIS TUMORS

Skin is composed of squamous cells, basal cells, and melanocytes. Cancers arise from these skin cells are called squamous cell carcinoma, basal cell carcinoma and melanoma respectively. Squamous cell carcinoma and basal cell carcinoma are the most common types of skin cancer.

EPITHELIAL PRECANCEROUS LESIONS

Epithelial precancerous lesions for skin epidermis carcinomas include actinic keratosis, arsenical keratosis and viral-associated lesions (Bowenoid papulosis, epidermodysplasia verruciformis).

Actinic Keratosis

Actinic keratosis is a precancerous lesion on a spectrum from ultraviolet radiation-induced skin damage to squamous cell carcinoma. With time, actinic keratoses may evolve into squamous cell carcinoma *in situ*, and finally, resulting in invasive squamous cell carcinoma.

- However, actinic keratosis lesion may remain stable or regress. It is strongest predictor of subsequent development of skin melanoma.
- Risk factors for development of actinic keratoses include individual susceptibility (e.g. elderly male gender, fair skin, light-colored eyes), cumulative ultraviolet radiation exposure, immunosuppression, prior history of actinic keratoses, squamous cell carcinomas, basal cell carcinoma, and melanoma; genetic syndromes (xeroderma pigmentosum, Bloom syndrome, Rothmund-Thompson syndrome).

Clinical Features

Actinic keratoses can affect elderly and young persons in the significant sun-exposed regions of body such as head, neck, forearms and dorsal hands. Patient presents with pruritus, burning or stinging pain, bleeding in the scaly erythematous papules of 2–6 mm size or nodules. Clinical photograph of actinic keratoses is shown in Fig. 29.50.

Molecular Genetic Alterations

Ultraviolet radiation-induced TP53 gene mutation provides selective growth advantage to neighboring cells, which leads to clonal expansion in the epithelium in 50% of cases. Actinic keratoses also demonstrate overexpression of cyclin D1 and RAS genes and loss of heterozygosity on chromosomes 9p, 9q, 13q, 17p and 17q. Human papillomavirus (HPV) has been detected in 40% of cases.

Fig. 29.50: Actinic keratosis. Actinic keratosis (AK) is a lesion that arises as a result of excessive exposure to solar radiation and appearing predominantly on Fitzpatrick phototype I and II skin. Lesion of actinic keratosis is present on the lip (arrow).

Light Microscopy

Histologic examination of actinic keratoses demonstrates atypical cells along the basal layer with sparing of adnexal epithelium, shows patchy parakeratosis and agranulosis. Dyskeratotic cells are sometimes present. Dysplasia does not involve full thickness of the epidermis. Solar elastosis is most often seen.

Prognosis

The prognosis of actinic keratoses includes persistence, regression or malignant transformation into invasive squamous cell carcinoma in 1–20% of cases. The relative risk for progression to squamous cell carcinoma depends on period of exposure to ultraviolet radiation and immune status.

Treatment

Treatment modalities for actinic keratoses include liquid nitrogen cryotherapy, curettage with or without electrosurgery, shave excision, topical agents (5-fluorouracil cream and solution, imiquimod cream, 3% diclofenac cream), photodynamic therapy, cryopeeling, dermabrasion, medium-depth chemical peel and laser resurfacing.

Arsenical Keratosis

Arsenical keratosis is precancerous lesion associated with chronic arsenical exposure due to occupational, medicinal and environmental exposure. Chronic arsenicism is associated with Bowen disease, squamous cell carcinoma, basal cell carcinoma and internal malignancies. Bowen disease tends to persist for many years and progression to invasive squamous cell carcinoma. Most lesions are followed clinically or treated

symptomatically. Treatment modalities for arsenical keratoses include surgical excision, cryosurgery, curettage with or without topical electrosurgery, CO_2 laser treatment and topical chemotherapy.

Viral-associated Epithelial Precancerous Lesions

Viral-associated epithelial precancerous lesions are Bowenoid papulosis caused by HPV-16, HPV-18; and epidermodysplasia verruciformis caused by HPV-5, HPV-8. Lesions caused by HPV-16 include vulvar intraepithelial neoplasia (VIN), anal intraepithelial neoplasia (AIN), perianal intraepithelial neoplasia (PaIN), penile intraepithelial neoplasia (PIN) and digital or periungual Bowen disease.

- **Bowenoid papulosis of the genitalia:** It is caused by human papillomavirus (HPV), especially types 18 and 33. The lesion may regress spontaneously, persist or rarely progresses to Bowen disease or squamous cell carcinoma. Sexual partners of the patients must be examined and followed for the development of penile carcinoma, cervical carcinoma and valvular carcinoma. Patients with Bowenoid papulosis are treated by topical imiquimod, curettage, excision and laser vaporization.
- **Epidermodysplasia verruciformis (EV):** It is a rare lesion associated with mutations in EVER1 and EVER2 genes. Affected persons are prone to acquired HPV infections (HPV-5, HPV-8). Patient presents with widespread flat, wart-like papules in childhood. The patients are prone to develop squamous cell carcinoma. These patients are advised to avoid sun exposure, use sun-protective measures, regular follow-up and screening of family members.

BOWEN DISEASE (SQUAMOUS CELL CARCINOMA *IN SITU*)

Bowen disease is a squamous cell carcinoma *in situ* with the potential to progress to invasive squamous cell carcinoma. Predisposing factors for Bowen disease include UV radiation exposure, ionizing radiation exposure, chronic arsenicism, immunosuppression, HPV infection and previous psoralen therapy. Clinical variants of Bowen disease include pigmented intertriginous, periungual and subungual Bowen disease. The lesions of Bowen disease progress to invasive carcinomas in 3–5% of cases. Extragenital Bowen disease harbors HPV DNA in 30% of cases.

Clinical Features

Patient presents with discrete, slow-growing pink to erythematous macule or thin plaque with well-demarcated, irregular borders overlying scale or crust on skin exposed regions on face and legs especially in fair skinned person.

Molecular Genetic Alterations

TP53 gene mutation has been observed in majority of cases. Allelic deletion of one or more chromosome has been detected in occasional cases. Hyperkeratotic and verrucous surface changes may be demonstrated. Pigmented Bowen disease has been reported in 2% of cases.

Surgical Pathology: Bowen Disease

Light Microscopy

- In Bowen disease, epidermis exhibits full-thickness (stratum corneum to basal layer) cytologic atypia in the intraepidermal portions of adnexal structures.
- Basement membrane of epidermis remains intact. Epidermis shows presence of parakeratosis, hyperkeratosis, acanthosis, dyskeratosis, mitoses and loss of maturation.
- Numerous pleomorphic keratinocytes with hyperchromatic nuclei and eosinophilic cytoplasm are present throughout full-thickness of the epidermis.
- The upper dermis is infiltrated by numerous lymphocytes, plasma cells and histiocytes.

Bowen Disease: Histologic Variants

- **Psoriasiform Bowen disease:** It shows parakeratoses and marked acanthosis with broad, sometimes, fused rete ridges of epidermis.
- **Atrophic Bowen disease:** It shows thinned epidermis with cellular atypia in full-thickness of epidermis with lack of cellular maturation as well as adnexal involvement.
- **Acantholytic Bowen disease:** It shows marked acantholysis in the epidermis.
- **Epidermolytic Bowen disease:** It shows epidermolytic hyperkeratosis.
- **Pagetoid Bowen disease:** It shows nests of atypical cells within the epidermis.

Treatment

Patient with Bowen disease is treated by excision and Mohs micrographic surgery, curettage with or without electrosurgery, liquid nitrogen cryosurgery, topical therapies, laser ablation, radiotherapy, and photodynamic therapy. Histopathologic evaluation of biopsy is essential to rule out invasive carcinoma. Curettage treatment may miss appendageal involvement.

SQUAMOUS CELL CARCINOMA OF SKIN

Squamous cell carcinoma of skin is a common malignant locally invasive neoplasm derived from suprabasal dermal keratinocytes. Most common sites are lower part of face and back of the hands. Predisposing factors for squamous cell carcinoma of skin are ultraviolet radiation exposure actinic keratosis, Bowen disease, scars/chronic scarring, burns or long-term heat exposure, exposure to

environmental carcinogens. inflammatory dermatoses, human papillomavirus (HPV) infection, albinism, xeroderma pigmentosum, epidermolysis bullosa and porokeratosis.

- UVB radiation spectrum (290–320 nm) induces two major DNA lesions at dipyrimidine sites: cyclobutene pyrimidine dimers and pyrimidine and pyrimidone photoproducts. UVB radiation-induced DNA damage adversely affects signaling pathways resulting in impairment of cell cycle arrest, DNA repair and apoptosis.
- UVB radiation causes TP53 and PTCH gene mutations, classical UVB signature mutations C→T (CC-TT) and dipyrimidine sites, UVA signature and oxidative mutations; and TNF-α released by exposed skin diminishes immune response. It induces dimer formation between neighboring thymine pairs in DNA. Treatment options are excision, Mohs micrographic surgery and radiation. Predisposing factors for squamous cell carcinoma of skin are given in Table 29.26. Environmental agents associated with the development of squmous cell carcinoma of skin are given in Table 29.27.

Table 29.26 Predisposing factors for squamous cell carcinoma of skin

Precursor lesions (actinic keratosis, Bowen disease)
Ultraviolet radiation exposure
Scars and underlying diseases (chronic osteomyelitis sinuses, granuloma inguinale, lupus vulgaris, discoid lupus erythematosus)
Burns or long-term heat exposure
Exposure to environmental carcinogens (arsenic, aromatic hydrocarbons, insecticides, herbicides)
Immunosuppressive state
Inflammatory dermatoses
Human papillomavirus (HPV) infection
Albinism
Xeroderma pigmentosum
Epidermolysis bullosa
Porokeratosis
Third degree burns
Sinuses in chronic osteomyelitis

Table 29.27 Environmental agents associated with the development of squamous cell carcinoma of skin

Environmental Agent	Persons at Risk	Route of Exposure to Agent	Associated Sporadic Skin Cancer
General exposure to environmental agents			
Ultraviolet radiation (UVB:290–320 nm) causes p53 gene mutation and induces dimer formation between neighboring thymine pairs in DNA	General population	Topical	Squamous cell carcinoma
Tobacco smoke	Tobacco smokers	Topical, systemic	Squamous cell carcinoma
Soot	Chimney sweep	Topical	Squamous cell carcinoma
Occupational exposure			
Coal tar, pitch	Coker of coal, steel worker	Topical	Squamous cell carcinoma
Petroleum oils	Machinist, textile worker	Topical	Squamous cell carcinoma
Arsenic	Agriculture worker, soil contamination, living in areas of high groundwater	Topical, systemic	Squamous cell carcinoma
4,4'-Bipyridyl	Pesticide manufacturer	Topical	Squamous cell carcinoma
Therapeutic agents administered in patients			
Psoralen (PUVA)	Psoriasis patient	Topical, systemic	Squamous cell carcinoma
Nitrogen mustard	Cutaneous T cell lymphoma	Topical	Squamous cell carcinoma
Immunosuppressants	Transplant recipients	Systemic	Squamous cell carcinoma
Ionizing radiation	Cancer therapy patient	Topical	Squamous cell carcinoma

Clinical Features

Patient initially presents with firm or erythematous nodules, which later become shallow ulcers with firm elevated or indurated surroundings, sometimes with crust or scale especially in fair-skin persons as well as immunocompromised adults. High-risk squamous cell carcinoma of skin is given in Table 29.28.

Molecular Genetic Alterations

Development of squamous cell carcinoma of skin from normal keratinocytes begins with mutations in the cellular DNA and genetic instability. Molecular alterations in gene expression results in loss of growth controls, penetration of the basement membrane, and ultimately invasion into surrounding tissue. Along the pathway to squamous cell carcinoma, keratinocytes become resistant to apoptosis and immune attack.

- Genetic changes associated with development of squamous cell carcinoma of skin occurs by multistage evolution. In the early lesions, mutations of TP53, K-RAS, H-RAS occur in the normal keratinocyte induced by ultraviolet light rays. Later changes are associated with genomic instability due to loss of heterozygosity (17p, 17q, 9p, 9q, 3p, 13q), INK4A-ARF mutation (9pq), TP53 mutation (17p21), upregulation of telomerase and amplification of EGFR in the development of squamous cell carcinoma *in situ*, then invasive squamous cell carcinoma.
- Mutations of DNA repair genes allow cells with lethal damage to proliferate, which increases the risk of cancer. Oncogenes and tumor suppressor genes in cutaneous squamous cell carcinoma, basal cell carcinoma and melanoma are given in Table 29.29.

Table 29.28 High-risk squamous cell carcinoma of skin

Diameter of tumor >2 cm
Depth of tumor >4 mm, and Clark levels IV and V (based on depth and invasion)
Tumor involving muscle, nerve and bone
Location of tumor on ear and lip
Tumor arising in scar tissue
Broders grade 3 and 4
Immunosuppressive state
Absence of inflammatory infiltrate in tumor

With respect to depth and invasion, tumors <4 mm is rated as Clark levels I–III.

Surgical Pathology: Squamous Cell Carcinoma of Skin

Gross Morphology

- Diagnosis of squamous cell carcinoma of skin is always made by skin biopsy, that should include sufficient depth in invasive tumor. Superficial shaving technique is applied in flat or minimally elevated lesion <1 mm. Punch biopsy is taken from elevated tumor.
- The margins of tumor may be indistinct. Large tumor is firm in consistency. Progressive invasion of the tumor results in fixation of tumor to underlying soft tissue.
- Presence of enlarged lymph node indicates tumor metastases. Gross morphology of squamous cell carcinoma of skin is shown in Fig. 29.51.
- Squamous cell carcinoma of skin is a firm, flesh colored or erythematous, keratotic papule or plaque. Tumor may be pigmented or ulcerated or smooth nodule or a thick cutaneous horn or verrucous. Tumor may be present as an abscess in periungual location.

Light Microscopy

- Invasive squamous cell carcinoma of skin shows variable degree of differentiation. Highly atypical cells are demonstrated at all levels of the epidermis beneath basement membrane.
- Tumor is composed of polygonal cells arranged in orderly lobules and exhibiting numerous large zones of keratinization forming squamous or keratin pearls to highly anaplastic, rounded cells with foci of necrosis and only abortive, single-cell keratinization (dyskeratosis). Histology of cutaneous squamous cell carcinoma is shown in Fig. 29.52.

Table 29.29 Oncogenes and tumor suppressor genes in cutaneous squamous cell carcinoma, basal cell carcinoma and melanoma

Gene	Locus	Function	Tumor Type
Oncogenes			
H-RAS	11p15.5	Cell cycle, survival	▪ Squamous cell carcinoma ▪ Melanoma
K-RAS	1p13.2	Cell cycle, survival	▪ Squamous cell carcinoma ▪ Melanoma
Tumor suppressor genes			
TP53	17p13.1	DNA repair, cell cycle regulation, apoptosis	▪ Squamous cell carcinoma ▪ Basal cell carcinoma
p16 (INK4A)	9p21	Cyclin-dependent kinase inhibitor	▪ Squamous cell carcinoma ▪ Melanoma

Unknown gene mutation on Xq24–q27 may cause basal cell carcinoma. Unknown gene mutation on 9q31 can cause keratoacanthoma.

Squamous Cell Carcinoma of Skin: Histologic Variants

- Histologic variants of squamous cell carcinoma of skin include: SCC (NOS), keratoacanthoma (low-grade variant), verrucous variant, acantholytic variant, adenosquamous variant, spindle cell variant, basaloid variant, clear cell variant, signet-ring variant, pseudoglandular variant and other rare variants (lymphoepithelial-like SCC, pseudovascular SCC, and SCC with sarcomatoid differentiation).
- Keratoacanthoma exhibits as symmetric keratin-filled crater, with the epidermis on each side extending over to form a distinct lip.
- In verrucous squamous cell carcinoma of skin, superficial component resembles verruca vulgaris with prominent acanthosis and papillomatosis; and the deeper component extends downward, displacing collagen bundles.
- Spindle cell variant of squamous cell carcinoma of skin reveals spindle-shaped atypical cells.
- Adenoid (pseudoglandular) variant of squamous cell carcinoma of skin shows glandular microscopic pattern and keratinocyte acantholysis.
- In clear cell variant of squamous cell carcinoma of skin keratinocytes exhibit hydropic cytoplasmic swelling and accumulation of lipid vacuoles.
- Signet-ring variant of squamous cell carcinoma of skin is rare and characterized by concentric rings composed of keratin and large vacuoles corresponding to markedly dilated endoplasmic reticulum.
- Basaloid variant of squamous cell carcinoma of skin is another histologic subtype.

Immunohistochemistry Technique

Panel of markers used for squamous cell carcinoma (spindle cell variant) of skin is mentioned below.

Markers	Expression
▪ Cytokeratins	▪ Positive
▪ p63	▪ Positive
▪ Actin	▪ Negative/positive
▪ Desmin	▪ Negative/positive

Treatment and Clinical Course

Squamous cell carcinoma of skin causes local tissue destruction. Metastasis tends to occur in patient with large tumors that invade deep structures or cutaneous nerves in <5% of cases.

- Large tumors are discovered early and cured by nonexcisional ablative therapy for *in situ* carcinoma, Mohs micrographic surgery, conventional surgical excision, topical therapy for *in situ* carcinoma and radiation therapy.
- Indications of Mohs micrographic surgery are infiltrative growth with poorly defined clinical margins on lip, ear, nail bed, nasal tip, eyelid and genitalia; history of radiation at site, immunosuppression state, recurrence of large tumor, verrucous carcinoma and tumor arising from chronic scarring conditions.

Fig. 29.51: Squamous cell carcinoma of skin. Gross examination shows cauliflower-like growth. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

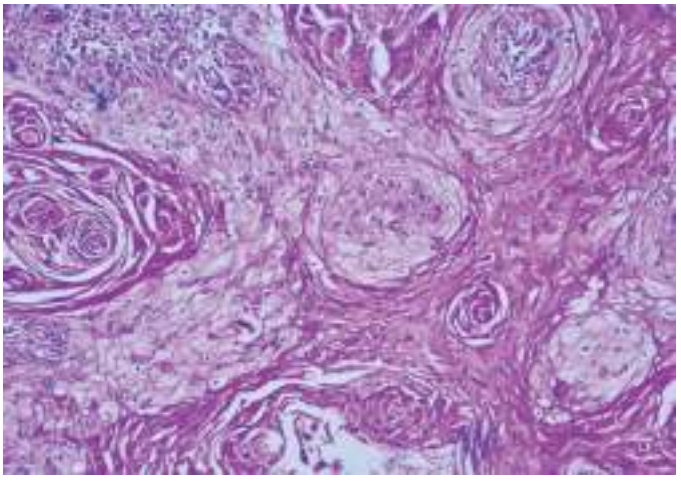

Fig. 29.52: Histology of squamous cell carcinoma of skin. Tumor is composed of solid nests of polygonal-shaped cells with distinct borders, intercellular bridges, pink keratinized cytoplasm and keratin formation (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

KERATOACANTHOMA OF SKIN

Keratoacanthoma is a low-grade squamous cell carcinoma of skin characterized by initial rapid growth with central keratin plug followed by a period of variable tumor stability and spontaneous regression. Tumor originates from pilosebaceous unit and shares histopathologic features with squamous cell carcinoma (SCC) requiring treatment.

- Cytologic pleomorphism is less common in keratoacanthoma, which has glassy pale eosinophilic cytoplasm. There is an abrupt transition between the tumor and adjacent epidermis.
- Keratoacanthoma has predilection for cheeks, nose, ears, and dorsa of hands on sun-exposed areas. The peak incidence of solitary keratoacanthoma is

between 50 and 69 years of age. They occur more frequently in men with a male to female ratio of 2:1.

Molecular Pathogenesis

Predisposing factors for keratoacanthoma include ultraviolet (UV) radiation, exposure to chemical carcinogens, immunosuppression, human papillomavirus (HPV), recent trauma or surgery to the location, mutations of TP53 or H-RAS; Hedgehog pathway inhibitors for basal cell carcinoma and use of BRAF inhibitors in melanoma. Keratoacanthoma can be associated with autosomal dominant disorders such as Muir-Torre syndrome, Ferguson-Smith syndrome or multiple keratoacanthoma of Witten-Zak; autosomal recessive xeroderma pigmentosum; and X-linked dominant incontinentia pigmenti.

Clinical Features

Most common sites of keratoacanthoma are hair-bearing areas and sun-exposed hair-bearing areas with the face, head, neck, and dorsum of extremities; within the mouth, lip, gingiva, hard palate, and other mucosal surfaces. Keratoacanthoma has three stages: (a) proliferation stage—rapid growth of flesh-colored, dome-shaped nodule of 1–2 cm with a central crater filled with keratinaceous material with a central crater filled with keratinaceous material within 6–8 weeks, (b) maturation stage—lasts for several weeks to months where the keratoacanthoma maintains its crateriform appearance, and (c) involution stage—heals spontaneously after several weeks leaving atrophic scar without treatment.

Surgical Pathology: Keratoacanthoma

Gross Morphology

Keratoacanthoma is solitary nodule with central keratin plug. The lesion is solitary nodule with central keratin plug.

Light Microscopy

- Exoendophytic keratoacanthoma is composed of central, keratin-filled crater, surrounded by keratinizing well differentiated squamous epithelium. There is marked acanthosis and hyperkeratosis.
- Cells in the center of lesion have glassy eosinophilic appearance of cytoplasm, which extend upward over the sides of the crater and downward into the dermis as irregular tongues or nests of squamous cells. Prominent inflammatory cells are present around the lesion. Microabscesses are present at the edge of tumor.
- Tumor does not extend beyond sweat glands. Perineural and vascular invasion may be present. Histology of keratoacanthoma is shown in Fig. 29.53.

Keratoacanthoma: Histologic Variants

Histologic subtypes of keratoacanthoma include solitary keratoacanthoma, subungual keratoacanthoma, mucosal keratoacanthoma, giant keratoacanthoma, keratoacanthoma centrifugum marginatum, generalized eruptive keratoacanthoma of Grzybowski, and multiple keratoacanthomas in Ferguson-Smith syndrome.

Treatment and Prognosis

While keratoacanthoma is a low-grade squamous cell carcinoma of skin, hence treatment is recommended due to the relation to squamous cell carcinoma. Tumor should be excised with 4 mm margins. Tumor <2 cm on extremities is treated by electrodesiccation and curettage. Aggressive tumor >2 cm in cosmetically sensitive areas require tissue sparing and should consider Mohs micrographic surgery. Mohs micrographic surgery is the treatment of choice for tumor with perineural invasion. Keratoacanthoma has an excellent prognosis after surgical excision.

BASAL CELL CARCINOMA OF SKIN

Basal cell carcinoma of skin is the most common slow growing locally destructive malignant tumor in persons with fair skin that rarely metastasizes. It is caused by exposure to ultraviolet light radiation; associated with PTCH gene mutation.

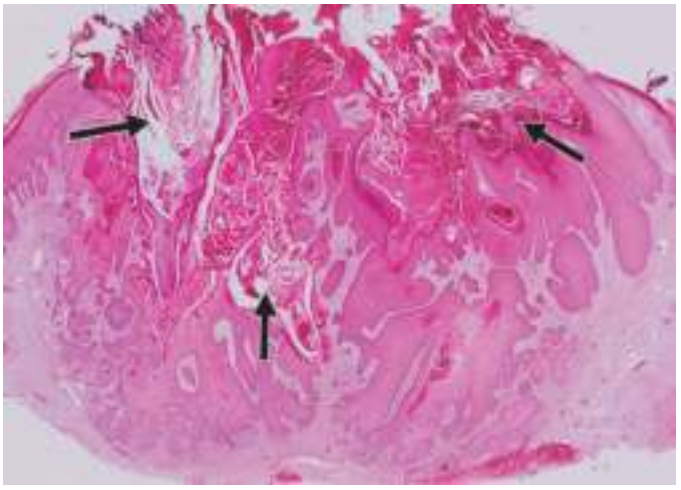

Fig. 29.53: Histology of keratoacanthoma. Tumor is composed of central, keratin-filled crater, surrounded by keratinizing well differentiated squamous epithelium. There is marked acanthosis and hyperkeratosis. Cells in the center of lesion have glassy eosinophilic appearance of cytoplasm. These cells extend upward over the sides of the crater and downward into the dermis as irregular tongues or nests of squamous cells. Prominent inflammatory cells are present around the lesion. Microabscesses are present at the edge of lesion. Tumor does not extend beyond sweat glands. Perineural and vascular invasion may be present (arrows) (400X).

- There is a direct correlation between total exposure to sunlight on head and neck region resulting in basal cell carcinoma, squamous cell carcinoma and melanoma of skin. In contrast to squamous cell carcinoma, it tends to involve the upper part of the face. Incidence is increasing in younger populations.
- The great danger of basal cell carcinoma of skin results from local invasion rather than metastases. The doubling time is estimated to be between six months to one year. Metastases of basal cell carcinoma occur rarely to regional lymph nodes and lungs.
- Metastases of basal cell carcinoma of skin to the bone marrow have been reported. Lethal extension to the central nervous system from aggressive basal cell carcinoma on scalp has been reported.
- Basal cell carcinoma of skin is treated by surgical excision, electrodesiccation and curettage, Mohs micrographic surgery, and occasionally radiation.

Pathogenesis

Solar ultraviolet radiation causes basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), which often appear on sun-exposed regions of skin. Ultraviolet B-radiation dose influences the induction of apoptosis and TP53 gene in human keratinocytes. Two main DNA lesions in keratinocytes formed by exposure to UVB radiation are cyclobutene pyrimidine dimers (CPD) and 6–4 pyrimidine pyrimidone photoproducts (6–4PPs), and their Dewar isomers at dipyrimidine sites.

- Cutaneous absorption of ultraviolet B (UVB) radiation (290–320 nm) induces mutations in TP53 gene, PTCH gene and UV signature genes, which directly interferes with the bonding between the nucleotide base pairs in the DNA, resulting in impairment of cell cycle arrest, DNA repair and apoptosis.
- The cellular response to ultraviolet radiation is dependent upon the induced expression of many genes including TP53 tumor suppressor gene. Increased expression of p53 protein is cell-type specific and activation is due to an alteration in transcription, translation or conformation. Once expression of TP53 tumor suppressor gene is activated, p53 protein can bind directly to single-stranded DNA, interact with DNA replication machinery and regulate the transcription of genes involved in both cell cycle arrest DNA repair and apoptosis.
- Environmental agents associated with the development of basal cell carcinoma of skin and other cancers are given in Table 29.30. Heritable disorders predisposing to multiple basal cell carcinomas of skin are given in Table 29.31.

Molecular Genetic Alterations

Mutations of PTCH1 gene on chromosome 9q22.3 and SMD gene on chromosome 7q31–32 involved in Hedgehog signaling pathway have been demonstrated in sporadic basal cell carcinoma. Oncogenes and tumor suppressor genes in basal cell carcinoma of skin are given in Table 29.32.

Table 29.30 Environmental agents associated with the development of basal cell carcinoma of skin and other cancers

Environmental Agent	Persons at Risk	Route of Exposure to Agent	Associated Sporadic Skin Cancer
General exposure to environmental agents			
Ultraviolet radiation (UVB:290–320 nm) uses p53 gene mutation and induces dimer formation between neighboring thymine pairs in DNA	General population	Topical	▪ Basal cell carcinoma ▪ Squamous cell carcinoma ▪ Melanoma ▪ Bowen disease ▪ Skin cancers in xeroderma pigmentosum
Occupational exposure			
Arsenic	Agriculture worker, soil contamination, living in areas of high groundwater	Topical, systemic	▪ Basal cell carcinoma ▪ Squamous cell carcinoma ▪ Bowen disease
Dry cleaning agents	Dry cleaner	Topical, systemic	Basal cell carcinoma
Fiberglass	Insulator	Topical	Basal cell carcinoma
Therapeutic agents administered in patients			
Psoralen (PUVA)	Psoriasis patient	Topical, systemic	▪ Basal cell carcinoma ▪ Squamous cell carcinoma ▪ Melanoma
Immunosuppressants	Transplant recipients	Systemic	▪ Basal cell carcinoma ▪ Squamous cell carcinoma
Ionizing radiation	Cancer therapy patient	Topical	▪ Basal cell carcinoma ▪ Squamous cell carcinoma

Table 29.31 Heritable disorders predisposing to multiple basal cell carcinomas of skin

Heritable Disorder	Comments
Nevoid basal cell carcinoma syndrome (NBCCS)	PTCH gene mutation, associated with multiple basal cell carcinomas >100 broad nasal root, borderline intelligence jaw cysts, palmar pits, multiple skeletal abnormalities
Bazex syndrome	X-linked disorder, associated with multiple basal cell carcinomas, follicular atrophoderma, dilated follicular ostia, with ice scars, hypotrichosis, hypohidrosis
Rombo syndrome	Autosomal dominant disorder associated with multiple basal cell carcinomas, atrophoderma, milia, hypertrichosis, trichoepitheliomas, peripheral vasodilation

Table 29.32 Oncogenes and tumor suppressor genes in basal cell carcinoma of skin

Gene	Locus	Function	Tumor Type
Oncogenes			
SMO	7q31–q32	Hedgehog signaling pathway receptor	Basal cell carcinoma
Tumor suppressor genes			
TP53	17p13.1	DNA repair, cell cycle regulation, apoptosis	▪ Basal cell carcinoma ▪ Squamous cell carcinoma
PTCH1	9p22.3	Hedgehog signaling pathway receptor	▪ Basal cell carcinoma ▪ Trichoepithelioma

Clinical Features

Patient presents with friable, nonhealing translucent lesion, pearly papules with areas of ulceration, telangiectasias (subepidermal dilated blood vessels) and presence of rolling border on the sun-exposed areas of head and neck. It is locally aggressive tumor extending in facial tissues, including underlying bone.

- Clinical features may vary in different clinical subtypes, which may include nodular, pigmented (similar to nevi or melanomas), superficial, morpheaform (sclerosing) and fibroepithelioma of Pinkus (FEP). The anatomical location of basal cell carcinoma may favor the occurrence of a particular clinical subtype.
- Basal cell carcinoma of skin almost never metastasizes. Tumor is usually curable by surgical resection. Clinical photograph of basal cell carcinoma of skin is shown in Fig. 29.54.

Surgical Pathology: Basal Cell Carcinoma of Skin

Gross Morphology

Gross morphology of basal cell carcinoma of skin depends on the clinical subtypes. Tumor is pearly papule or nodule, often with central ulceration, and overlying telangiectatic vessels.

- **Nodular basal cell carcinoma:** It is most common clinical subtype, which occurs on unexposed regions of head and neck as translucent papule or nodule depending on duration of tumor. Large tumor undergoing central necrosis is called 'rodent ulcer'.
- **Pigmented basal cell carcinoma:** It is also clinical subtype of nodular subtype and presents as hyperpigmented translucent papule undergoing erosion.
- **Superficial basal cell carcinoma:** It usually occurs on trunk as erythematous patch that resembles eczema.
- **Morpheaform basal cell carcinoma:** It presents as ivory-white small scar-like or small lesion of morphea in the absence of pervious surgical procedure or trauma. Fibroepithelioma of Pinkus basal cell carcinoma presents as papule on the lower back; and expresses androgen receptors.

Light Microscopy

Tumor is composed of infiltrative deeply basophilic epithelial (basaloid) cells with narrow rims of cytoplasm arranged in clusters. Tumor cell clusters are attached to the epidermis and protruding into the subjacent papillary dermis. Nuclei in the periphery of the clustered cells are arranged in palisading manner. Mitotic figures are absent. Frequently, slit-like retraction of stroma from tumor islands is present creating lacunae. Histology of basal cell carcinoma of skin is shown in Fig. 29.55. Histology of basal cell carcinoma with squamous differentiation of skin is shown in Fig. 29.56.

- **Nodular basal cell carcinoma:** Tumor is composed of discrete nests of basaloid cells in either the papillary or reticular dermis.
- **Pigmented basal cell carcinoma:** Tumor contains melanocytes in 75% of cases. In 25% cases, tumor contains large amounts of melanin.
- **Superficial basal cell carcinoma:** Tumor contains buds of malignant cells extending into the dermis from basal layer of the epidermis. Tumor cells show palisading pattern in the peripheral region of tumor. There is minimal epidermal atrophy and dermal invasion. Upper dermis shows chronic inflammatory infiltrate.

- **Morpheaform basal cell carcinoma:** Tumor is composed of cells arranged in packed columns. Recurrent basal cell carcinoma may show tumor cells arranged in nests embedded within the dense fibrous stroma of scar.
- **Fibroepithelioma of Pinkus:** Tumor is composed of long strands of interwoven basaloid cells embedded in fibrous stroma with abundant collagen fibers.
- **Basosquamous carcinoma:** Tumor is a form of aggressive basal cell carcinoma composed of cells arranged in infiltrating jagged tongues admixed with squamous intercellular bridges and cytoplasmic keratinization.

Treatment

Basal cell carcinoma of skin is treated by surgical excision, radiotherapy, cryotherapy, curettage, electrodesiccation and Mohs micrographic surgery. Recurrence rate for non-Mohs modalities is nearby four times higher than Mohs micrographic surgery.

- Nonaggressive basal cell carcinoma on trunk and extremities are treated by surgical excision. Aggressive basal cell carcinoma on trunk and extremities are treated by surgical excision or Mohs micrographic surgery.
- Recurrent tumor or tumor located in canthus, nasolabial fold, periorbital or postocular region are treated by Mohs micrographic surgery. The 5-year recurrence rate for Mohs micrographic surgery is approximately 6%.

BASAL CELL NEVUS SYNDROME

Basal cell nevus syndrome (BCNS) is an autosomal dominant disorder with complete penetrance but variable expression of traits. It is characterized by developmental anomalies and postnatal tumors especially multiple basal cell carcinomas in young persons, and medulloblastoma, pits of the palms and soles; and odontogenic cysts of the jaw. Other related findings include enlarged body habitus, calcifications of the falx cerebri, and skeletal abnormalities of the ribs. Histologic features of basal cell carcinomas and medulloblastoma are identical to those seen in tumors.

Molecular Genetic Alterations

Basal cell nevus syndrome carries tumor suppressor gene mutations of PTCH1 on long arm of chromosome 9. PTCH1 plays a central role in Hedgehog signaling pathway, that is essential for the development of normal body. Basal cell nevus syndrome patients

inherit one defective PTCH1 gene allele and tumors demonstrate somatic mutations. Basal cell nevus syndrome may also occur by two-hit gene mutations.

SEBORRHEIC KERATOSIS

Seborrheic keratosis is the most common benign epidermal tumor. It usually begins as well-circumscribed, dull, flat, tan or brown scaly patches with pseudohorn cysts and rapidly progressing to symptomatic or atypical lesions over years with velvety to granular surface on the head, neck, trunk, and extremities of middle-aged to older individuals.

- Rapidly growing growth should be biopsied to rule out basal cell carcinoma, squamous cell carcinoma or melanoma of skin.
- Clinical and histologic variants of seborrheic keratoses include common seborrheic keratosis, clonal seborrheic keratosis, stucco keratosis, reticulated keratosis, irritated keratosis, seborrheic keratosis with squamous atypia, melanoacanthoma and dermatosis papulosa nigra. The sudden appearance of numerous seborrheic keratosis has been associated with internal malignancies (sign of Leser-Trelat), especially gastric adenocarcinoma.

Surgical Pathology: Seborrheic Keratosis

Gross Morphology

- Seborrheic keratosis tumor measures few millimeters to several centimeters in size. It may be single or multiple.
- Tumor is soft, tan-black with greasy surface, sharply demarcated pigmented lesion that protrudes above surface of skin. It appears stuck to skin. Gross morphology of seborrheic keratitis is shown in Fig. 29.57.

Light Microscopy

- Hematoxylin and eosin-stained section in a case of seborrheic keratosis shows broad anastomosing cords of mature stratified squamous epithelium with abrupt area of acanthotic proliferations of small cuboidal keratinocytes without cytologic atypia, hyperkeratosis, papillomatosis and small 'horn pseudocysts' (round intralesional cysts of loose keratin).
- Clonal seborrheic keratosis is characterized by intraepidermal proliferation of keratinocytes (basaloid to epithelioid cells) without horn pseudocysts. String sign refers to lesion extends to a uniform depth and one could draw a horizontal line parallel to the epidermal surface underlying the lesion. Histology of seborrheic keratosis is shown in Fig. 29.58.

Fig. 29.57: Gross morphology of seborrheic keratosis. Gross morphology of tumor is soft, tan-black with greasy surface, sharply demarcated pigmented lesion that protrudes above surface of skin. It appears stuck to skin (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

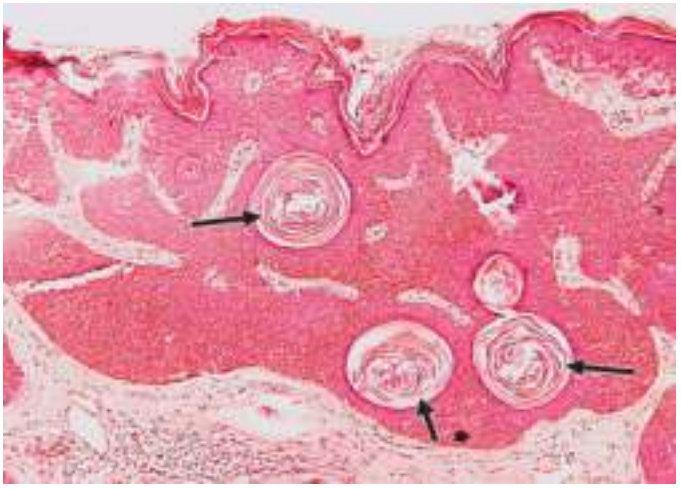

Fig. 29.58: Histology of seborrheic keratosis. Hematoxylin and eosin-stained sections from skin biopsy of seborrheic keratosis shows broad anastomosing cords of mature stratified squamous epithelium with abrupt area of acanthosis, hyperkeratosis, papillomatosis and small pseudohorn keratin cysts (arrows) (400X).

NEUROENDOCRINE TUMORS

Neuroendocrine tumors (NETs) are neoplasms that rise from cells of nervous system and endocrine system. These tumors may contain higher-than-normal quantity of hormones into the blood in response to a signal from the nervous system which can cause various clinical manifestations.

- Neuroendocrine tumors may arise at almost any anatomical site, including paraganglia and are distributed throughout the body in organs including soft tissues.
- Some examples of neuroendocrine tumors are prostatic neuroendocrine tumor, carcinoid tumors in intestine, pancreatic islet cell tumors, medullary thyroid carcinoma, pheochromocytoma, neuroendocrine carcinoma of the skin (Merkel cell carcinoma), small cell lung carcinoma and large cell lung carcinoma.

- Three grading parameters of prognostic relevance in neuroendocrine tumors are the mitotic index, Ki-67 labeling index and presence or absence of necrosis defined by morphological criteria.
- Immunohistochemical stains for neuroendocrine differentiation include neuron-specific enolase, chromogranin A, chromogranin B, synaptophysin and CD56 as well as site specific markers such as hormones and transcription factor.

MERKEL CELL CARCINOMA

Merkel cell carcinoma (MCC) is an uncommon primary cutaneous aggressive neuroendocrine cancer associated with a high-risk of local recurrence, lymph nodal metastasis, and distant metastases. Tumor most commonly occurs on ultraviolet (UV) radiation exposed regions (head, neck) of white elderly patients >65 years of age especially in immunosuppressive state and Merkel cell polyomavirus infection (80%).

- Five-year survival is 51% for localized disease and as low as 14% for distant disease. Sentinel lymph node, surgery and radiation are indicated in many cases.
- On clinical examination, tumor appears as a red or violaceous nodule or plaque.
- Advances in molecular genetics and immunology are helpful to understand pathophysiology and treatment of Merkel cell carcinoma. Deletion of chromosome 1p36 and trisomy 6 are most often demonstrated.

Clinical Features

Patient presents with nontender, firm, red, purple, or skin colored papule or nodule; on the ultraviolet radiation exposed regions such as head and neck of <2 cm at the time of diagnosis in immunocompromised elderly persons. Growth may expand rapidly within three months.

Surgical Pathology: Merkel Cell Carcinoma

Gross Morphology

Tumor is fleshy tan brown nodule or ill-defined lesion showing variable ulceration.

Light Microscopy

- Markel cell carcinoma is composed of dermal proliferation of small, blue cells with indistinct borders arranged in sheets, nests or a trabecular array.
- Tumor cells contain scant cytoplasm and vesicular round nuclei containing finely granular chromatin and inconspicuous nucleoli.
- Numerous mitotic figures are present. Tumor may demonstrate vascular invasion, perineural invasion, or cellular necrosis. Tumor cells invade dermis and cutis. Histology of Merkel cell carcinoma is shown in Fig. 29.59.

Immunohistochemistry Technique

- Immunohistochemistry technique differentiates Merkel cell carcinoma (MCC) from other dermal, blue cell tumors such as lymphoma, Ewing sarcoma, neuroblastoma, melanoma, and small cell lung carcinoma.
- In addition to immunostaining for neuroendocrine markers (synaptophysin, chromogranin), perinuclear dot-like staining with cytokeratin 20 is characteristic.

Markers	Expression
Cytokeratin 20	Positive (highly sensitive)
Neuron-specific enolase (NSE)	Positive
Chromogranin	Positive
Synaptophysin	Positive
Epithelial membrane antigen (EMA)	Positive
Cytokeratin CAM 5.2	Positive
S-100 protein	Negative
Thyroid transcription factor 1 (TTF-1)	Negative

Staging and Prognosis

According to the new American Joint Committee on cancer, there are four stages for Merkel cell carcinoma. Survival after a diagnosis of Merkel cell carcinoma is highly dependent on the stage of presentation. Survival decreases markedly with lymph node involvement and metastatic disease. Unlike melanoma, Merkel cell carcinoma recurs rapidly.

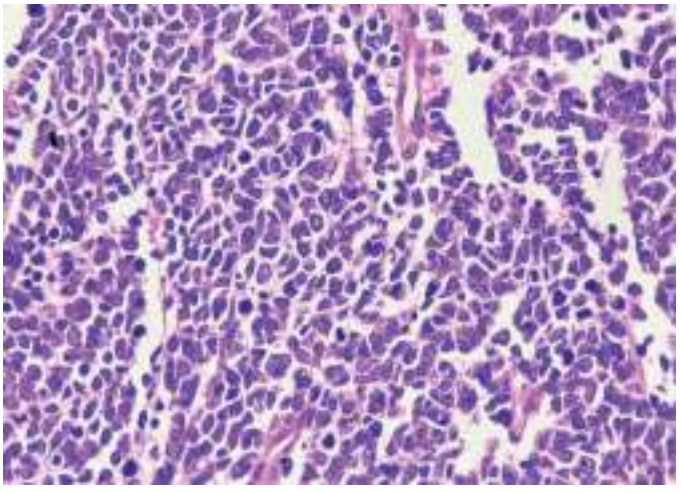

Fig. 29.59: Histology of Merkel cell carcinoma. Hematoxylin and eosin-stained section reveals a dermal proliferation of small, blue cells with indistinct borders arranged in sheets, nests or a trabecular array. Tumor cells contain scant cytoplasm and vesicular round nuclei containing finely granular chromatin and inconspicuous nucleoli. Numerous atypical mitotic figures are present. Tumor may demonstrate vascular invasion, perineural invasion, or cellular necrosis. Tumor cells invade dermis and cutis (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

SKIN APPENDAGEAL TUMORS AND HAMARTOMATOUS OF THE SKIN

Skin appendageal tumors comprise a wide spectrum of benign and malignant tumors that exhibit morphological differentiation from cutaneous adnexal structures found in normal skin. Majority of the tumors are benign and clinically asymptomatic. Classification of skin appendageal tumors is given in Table 29.33.

- Skin appendages arise from pluripotent stem cells that are undifferentiated and present within the epidermis or the appendageal structures.
- Patients can present with papules and nodules. The most important tool for diagnosing and classifying skin appendageal tumors is histopathology. Immunohistochemical analysis has been of little value in diagnosing skin appendageal tumors.
- Skin appendages are represented by three histologically distinct structures: (a) the pilosebaceous unit (hair follicle and sebaceous glands); (b) the eccrine sweat glands; and (c) the apocrine glands.
  - **Pilosebaceous unit:** The sebaceous glands are present in the opening shaft of hair. Palms of the hands or the soles of the feet lack sebaceous glands. These glands secrete an antibacterial moisture known as sebum fluid, that also softens the hands. The secretion activity is related to hormonal release. Blockage of sebaceous ducts results in acne.
  - **Eccrine sweat glands:** The eccrine sweat glands arise from epidermal epithelial germs protruding into the dermis similar to those of pilosebaceous units, but contain less mesenchymal condensation. These are distributed all over the body except nipples and outer genital organs. Although the nipples do have the mammary glands, these are known as modified sweat glands.
  - **Apocrine glands:** The apocrine glands are present mainly in the axillae, groin, pubic and perineal regions. In contrast with eccrine glands, apocrine glands develop from an upper bulge in hair follicles that are in the early bulbous peg stage.

NODULAR HIDRADENOMA

Nodular hidradenoma (synonym: eccrine acrospiroma) is usually a solitary, well-circumscribed and solid tumor measuring 0.5–≥2.0 cm with few of them exhibiting cystic changes on the scalp and axilla. Tumor arises from sweat gland distal excretory duct.

- Long-standing nodular hidradenoma has been reported to undergo malignant transformation. No local recurrence or metastasis has been observed within one year.

Table 29.33 Classification of skin appendageal tumors

Origin	Hamartomas, Hyperplasias and Cysts	Benign Skin Appendageal Neoplasms	Malignant Skin Appendageal Neoplasms
Hair and hair follicle	▪ Hair follicle nevus ▪ Basaloid follicular hamartoma	▪ Trichofolliculoma ▪ Pilar sheath acanthoma ▪ Dilated pore of Winer ▪ Fibrofolliculoma ▪ Trichodiscoma ▪ Fibrous papule ▪ Trichoblastoma ▪ Trichoepithelioma ▪ Desmoplastic trichoepithelioma ▪ Trichoadenoma ▪ Pilomatricoma ▪ Trichilemmoma ▪ Tumor of the follicular infundibulum ▪ Proliferating trichilemmal cyst	▪ Pilomatrical carcinoma ▪ Malignant proliferative trichilemmal tumor ▪ Trichilemmal carcinoma ▪ Trichoblastic carcinoma
Sebaceous glands	▪ Nevus sebaceous ▪ Sebaceous hyperplasia	▪ Sebaceous adenoma ▪ Sebaceoma/sebaceous epithelioma	▪ Sebaceous carcinoma ▪ Basal cell; carcinoma with sebaceous differentiation
Apocrine	▪ Apocrine hidrocystoma ▪ Apocrine nevus	▪ Apocrine fibroadenoma ▪ Erosive adenomatosis of the nipple ▪ Hidradenoma papilliferum ▪ Syringocystadenoma	▪ Apocrine adenocarcinoma ▪ Hidradenocarcinoma ▪ Syringocystadenocarcinoma papilliferum ▪ Cylindrocarcinoma

- The tumor is composed of tubules of various sizes along with papillary projections that are lined by an outer layer of myoepithelial cells and inner layer of cuboidal cells. Solid portions of the tumor show nodules composed of clear and polygonal cells. Tumors have no predilection.

Clinical Features

Patient presents with slow-growing, solitary, firm, flesh-colored or red to blue, mobile, solid or cystic nodule measuring 1–2 cm in diameter on scalp, face and trunk.

Surgical Pathology: Nodular Hidradenoma

Gross Morphology

Majority of tumors are solitary, circumscribed, and non-encapsulated, solid and cystic, dermal, symmetrical, lobulated tumors. Cut surface shows pinkish or bluish or red-blue or brownish nodules with cystic areas.

Light microscopy

- Nodular hidradenoma tumor is composed of round, fusiform or polygonal cells with clear to eosinophilic cytoplasm and a regular oval grooved nucleus and a small inconspicuous nucleolus. Tumor cells arranged in sheet-like and papillary architecture.
- Squamous differentiation is an important feature, especially of an infundibular type of keratinization. Sebaceous differentiation is also common. The stroma varies from fine to dense fibrous tissue to dense hyalinized collagen fibers to myxoid. Cystic spaces may be due to degeneration of tumor cells. Histology of nodular hidradenoma is shown in Fig. 29.60.

Immunohistochemistry Technique

Panel of markers is used in nodular hidradenoma.

Markers	Expression
▪ Cytokeratin	▪ Positive
▪ EMA	▪ Positive
▪ CEA	▪ Positive
▪ S-100 protein	▪ Positive
▪ Vimentin	▪ Positive

Treatment and Clinical Course

Nodular hidradenoma is treated by surgical excision with clear margins. Incomplete surgical excision, nodular hidradenoma has recurrence rate. Mohs micrographic surgery is employed for margin control in irregular tumor.

ECCRINE SPIRADENOMA

Eccrine spiradenoma is an extremely painful slowly growing solitary pink gray benign tumor with eccrine differentiation that may occur anywhere in the body on trunk, scalp and female genital area (vulva, clitoris, labia majora). It may be derived from the secretory coil. It may rarely undergo high-grade malignant transformation.

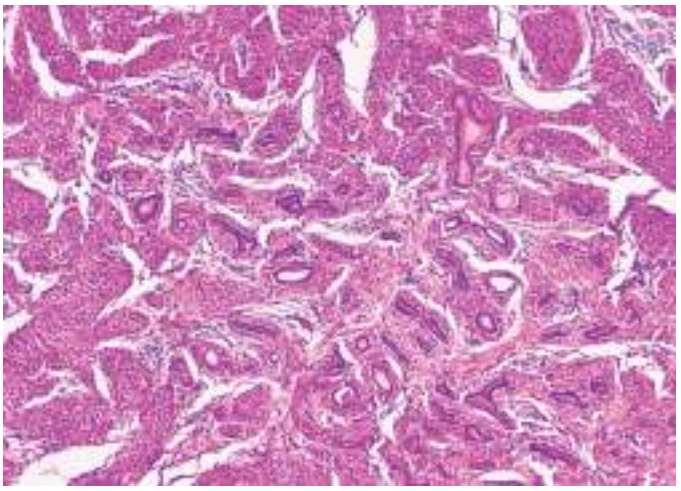

Fig. 29.60: Nodular hidradenoma. Tumor cells are round, fusiform or polygonal exhibiting squamous appearance (400X).

- Tumor is composed of round to oval cells in dermis or subcutaneous tissue with small basaloid cells on the outside and larger polygonal cells with vesicular nuclei and prominent nucleoli towards the center.
- Prognosis is excellent unless malignant transformation with features of rapid growth, distortion and ulceration.

Surgical Pathology: Eccrine Spiradenoma

Gross Morphology

Tumor is usually solitary measuring >1 cm, with pink to gray or tan nodule.

Light Microscopy

- Tumor has delicate fibrovascular capsule. Tumor is composed of round to oval cells in dermis or subcutaneous tissue.
- Small basaloid cells on the outside and larger polygonal cells with vesicular nuclei and prominent nucleoli towards the center.
- Lymphocytes are common throughout the lesion. Histology of eccrine spiradenoma is shown in Fig. 29.61.

CHONDROID SYRINGOMA

Chondroid syringoma, or mixed tumor of the skin is a benign slow-growing tumor of sweat glands with a mucoid stroma showing cartilaginous metaplasia in dermis or subcutaneous region. Though tumor is usually benign, malignant counterpart (malignant chondroid syringoma) does exist and should be ruled out on morphologic features on histologic examination.

- Morphologically, it is identical to pleomorphic adenoma. Tumor is composed of both epithelial cells and mesenchymal cells. Epithelial cells are arranged in solid nests, small clusters and ducts in the myxoid, chondroid or fibrous stroma. It most often seen in middle aged men; mean age at presentation is 48 years.

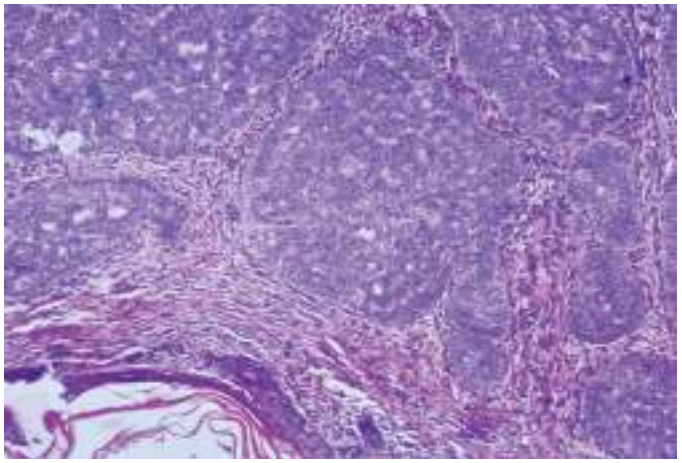

Fig. 29.61: Histology of eccrine spiradenoma. Tumor is composed of round to oval cells in dermis or subcutaneous tissue. Small basaloid cells on the outside and larger polygonal cells with vesicular nuclei and prominent nucleoli towards the center (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

- Most common sites of chondroid syringoma in decreasing frequency are nose, cheek, upper lip, face, head and neck extremities, trunk and back. Chondroid syringoma can easily confused with epidermal cyst and pilomatricoma.

Molecular Genetic Alterations

Chondroid syringoma is positive for gene rearrangement of PLAG1 in largest study to date, but lacks the characteristic translocations of PLAG1 seen in pleomorphic adenoma of salivary gland.

Surgical Pathology: Chondroid Syringoma

Gross Morphology

Chondroid syringoma is well circumscribed but unencapsulated, multilobulated tumor in deep dermis or subcutaneous fat with a prominent chondroid or myxoid stroma.

Light Microscopy

- Major diagnostic criteria of chondroid syringoma include chondroid matrix, tubuloalveolar structures lined by a bilayered epithelium, ductal structures lined by a single epithelium, nests of polygonal cells and the presence of keratinous cysts.
- Tumor is biphasic with both epithelial and stromal components. Epithelial cells are elongated branching tubular structures with two cell layers. Outer layer is cuboidal or columnar with mild nuclear pleomorphism; inner layer is columnar with eosinophilic cytoplasm.
- Lobules are separated by fibrous septae of varying thickness. Features suggestive of malignancy include severe cytologic atypia, markedly increased cellularity, numerous mitoses, destruction of surrounding tissue and tumor necrosis. Histology of chondroid syringoma is shown in Fig. 29.62.

Immunohistochemistry Technique

Panel of markers are used to demonstrate inner epithelial cells and outer myoepithelial cells in benign chondroid syringoma.

Markers	Expression
Inner epithelial cells	
▪ EMA	▪ Positive
▪ CEA	▪ Positive
▪ GCDFP	▪ Positive
▪ Actin	▪ Positive
▪ Cytokeratin 15	▪ Positive
Outer myoepithelial cells	
▪ Vimentin	▪ Positive
▪ GFAP	▪ Positive
▪ SMA	▪ Positive
▪ Calponin	▪ Positive
▪ p63	▪ Positive

p16 is negative in benign syringoma in contrast to strong nuclear. p16 is positive in malignant chondroid syringoma.

PILOMATRIXOMA

Pilomatrixoma is also known as calcifying epithelioma of Malherbe, which arises from pilosebaceous unit. The most sites are head (cheek, periorbital, scalp) and neck region, followed by the upper extremities, trunk and the lower extremities in descending order. Although pilomatrixoma can occur at any age two peaks of presentation, the first and the sixth decades. It is associated with activating mutations in β-catenin, a mediator in the Wnt signaling pathway.

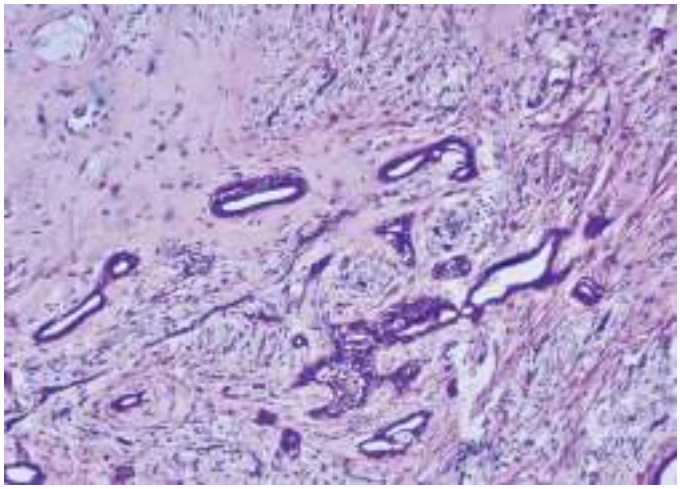

Fig. 29.62: Histology of chondroid syringoma. Tumor consists of chondroid matrix, tubuloalveolar structures lined by a bilayered epithelium, ductal structures lined by a single epithelium, nests of polygonal cells and the presence of keratinous cysts. Tumor is biphasic with both epithelial and stromal components. Lobules are separated by fibrous septae of varying thickness (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

Clinical Features

Patient presents with firm, nontender, solitary cutaneous skin-colored or bluish, firm nodule, cystic to firm in consistency measuring 1–2 cm with adherence to the overlying normal or hyperemic skin but not to the underlying structure on the head and neck, and upper extremities especially during childhood. Overlying epidermal atrophy is common.

- Giant pilomatrixoma has been associated with hypercalcemia and elevated parathyroid hormone-related protein (PTH-rp).
- Multiple pilomatrixomas are demonstrated in Gardner's syndrome, Turner syndrome, myotonic dystrophy, Rubinstein-Taybi syndrome.

Surgical Pathology: Pilomatrixoma
Light Microscopy
▪ Pilomatrixoma is sharply demarcated in the lower dermis most often the subcutis. It is composed of two types of cells: basaloid and shadow (ghost) cells. ▪ The ghost cells have well-defined cell borders, abundant pale eosinophilic cytoplasm, distinct cell borders and no nuclear staining with a central portion of the tumor and may later calcify to give a bony hard consistency to the lesion. ▪ Basaloid cells resemble the cells of basal cell carcinoma of skin. The basaloid cells are deep blue stained, round-to-ovoid cells with ill-defined cell borders having minimal cytoplasm. ▪ Shadow cells have eosinophilic cytoplasm, distinct cell borders and no nuclear staining. Calcification can be present. Histology of pilomatrixoma is shown in Fig. 29.63.

Treatment

Pilomatrixoma is treated by surgical excision. It rarely recurs after surgery. Rare malignant transformation to pilomatrical carcinoma has been reported on head, neck, upper extremities and buttocks. Metastases to regional lymph nodes and distant sites are seen in 10% of patients. Malignant tumor rarely arises *de novo*.

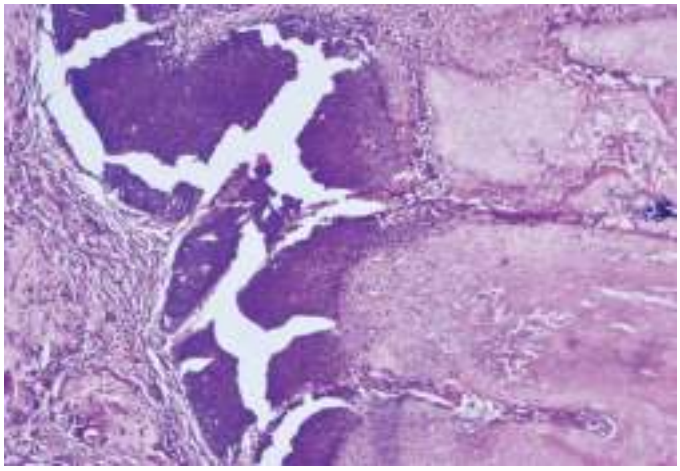

Fig. 29.63: Histology of pilomatrixoma. Tumor is composed of small epithelial cells arranged in solid nests, small clusters and ducts in the mesenchymal components (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

DERMIS AND SUBCUTANEOUS FAT: TUMORS

DERMATOFIBROMA

Skin lesions in dermatofibroma are tan to brown, firm dermal papules. Clinical photograph of dermatofibroma is shown in Fig. 29.64.

Surgical Pathology: Dermatofibroma
Gross Morphology
Tumor is well circumscribed. Cut surface is gray white. Gross morphology of dermatofibroma is shown in Fig. 29.65.
Light Microscopy
On histologic examination, tumor is composed of homogenous spindle-shaped fibroblasts, histiocytes and blood vessels. At the periphery, collagen bundles are surrounded by fibroblasts. The overlying epidermis shows acanthosis, basal keratinocyte hyperpigmentation and broad flattened rete ridges or basaloid proliferation, which may be mistaken for basal cell carcinoma. Histology of dermatofibroma is shown in Fig. 29.66.
Immunohistochemistry Technique
Tumor cells show positivity for factor XIIIa, but negative with CD34.

DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans (DGSP) is slow growing, solitary or multiple polypoid infiltrative, locally aggressive and rarely metastasizing neoplasm on the trunk, proximal upper extremity and lower extremity of 20–50 years of age group.

Fig. 29.64: Clinical photograph of dermatofibroma. Child shows dermatofibroma on the abdominal wall (arrow).

Fig. 29.65: Gross morphology of dermatofibroma. Tumor is well circumscribed. Cut surface is gray white. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Benguluru, Karnataka.)

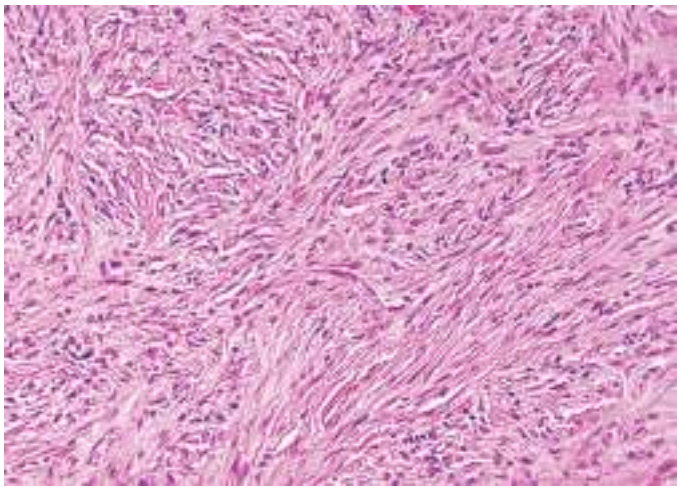

Fig. 29.66: Histology of dermatofibroma. Tumor is composed of homogenous spindle-shaped fibroblasts, histiocytes and blood vessels. At the periphery, collagen bundles are surrounded by fibroblasts (400X).

Clinical Features

Patient presents with plaque-like thickening of skin and steadily progressing to form subcutaneous nodular mass over the course of several years. However, wide surgical excision with generous tumor margins is most often curative.

Surgical Pathology: Dermatofibrosarcoma Protuberans

Gross Morphology

Dermatofibrosarcoma protuberans is a solitary multinodular mass measuring several centimeters with average 5 cm. Although the neoplasm is highly infiltrative, yet it may appear as circumscribed mass. Gross morphology of dermatofibrosarcoma protuberans is shown in Fig. 29.67.

Light Microscopy

- Dermatofibrosarcoma protuberans is composed of bland appearing spindled fibroblasts arranged in an irregularly whorled or storiform pattern or cartwheel pattern; which infiltrate between adnexa, extending into the subcutis with trapping of fat resulting in thinned out epidermis.
- Overlying epidermis may be normal, atrophic or ulcerated. Neoplastic cells show mild atypia and occasional mitosis.
- Occasional tumor can have a more aggressive component, where neoplastic spindle cells are arranged in fascicular pattern. This variant of neoplasm is known as fibrosarcomatous variant of dermatofibrosarcoma protuberans. Histology of dermatofibrosarcoma protuberans is shown in Fig. 29.68.

Differential Diagnosis

Dermatofibrosarcoma protuberans should be differentiated from fibrous histiocytoma (dermatofibroma). Unlike dermatofibrosarcoma protuberans, fibrous histiocytoma tends to limited to the dermis. Analysis of COL1A1-PDGFB fusion protein by fluorescence *in situ* hybridization can be helpful in diagnosing neoplasm in difficult cases. It is worth mentioning that storiform pattern may be demonstrated in dermatofibrosarcoma protuberans, malignant fibrous histiocytoma, liposarcoma, peripheral nerve sheath tumor and nodular fasciitis.

Immunohistochemistry Technique

Dermatofibrosarcoma protuberans shows positivity for CD34.

Markers	Expression
▪ CD34	▪ Positive
▪ Factor XIIIa	▪ Negative

Fig. 29.67: Gross morphology of dermatofibrosarcoma protuberans is a solitary multinodular mass measuring several centimeters with average 5 cm. Although the neoplasm is highly infiltrative, yet it may appear as circumscribed mass. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

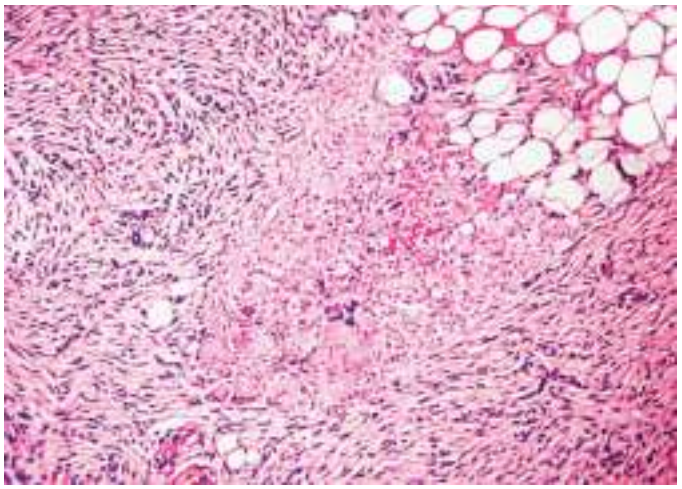

Fig. 29.68: Histology of dermatofibrosarcoma protuberans (DFSP). Tumor is composed of bland-appearing spindled fibroblasts arranged in an irregularly whorled or storiform pattern; which infiltrate into the periphery of tumor entrapping fat resulting in thinned out epidermis. Overlying epidermis may be normal, atrophic or ulcerated. Neoplastic cells show mild atypia and occasional mitosis. Occasional tumor can have a more aggressive component, where neoplastic spindle cells are arranged in fascicular pattern. This variant of neoplasm is known as fibrosarcomatous variant of dermatofibrosarcoma protuberans (400X).

Molecular Genetic Alterations

Dermatofibrosarcoma protuberans exhibits t(17;22)(q22;q13) chromosomal translocation resulting in formation of COL1A1-PDGFB fusion protein analyzed by fluorescence *in situ* hybridization. Supernumerary ring chromosome in dermatofibrosarcoma protuberans may contain centromere of 22 and comprise sequences from chromosomes 17 and 22.

Prognosis and Treatment

Prognosis is excellent after surgical excision of dermatofibrosarcoma protuberans. Recurrence is demonstrated in 11–33% of cases. Tumor may metastasize to lymph node in 1% and distant organs in 5% of cases.

VASCULAR TUMORS OF SKIN

CAPILLARY HEMANGIOMA

Capillary hemangioma is a regressing benign neoplasm of vascular endothelial cells. It is the most common tumor of soft tissue either present at birth or during infancy in 15–20% of cases and children. Initially, it grows rapidly followed by stabilization and involution. Familial capillary hemangioma may show abnormality of chromosome 5.

Age, Sex Predilection and Locations

Capillary hemangioma affects infants and children without sex predominance. Most common sites of hemangioma are skin and mucosal surface followed by viscera. Large hemangioma in infants on the head and neck region occurs as a part of PHACE syndrome (posterior fossa refers to possible abnormal structure in the brain especially cerebellum, hemangiomas of the cervicofacial region, abnormalities of arteries, cardiac and ocular region). Lumbosacral hemangioma occurs in infants with occult spinal malformations.

Clinical Features

Patient with small superficial hemangioma presents with red macules, usually level with the surface of the skin or slightly elevated. Large capillary hemangioma appears as firm, blue-violet torturous mass. Some capillary hemangiomas are associated with Sturge-Weber syndrome and von Hippel-Lindau syndrome. Clinical photograph of capillary hemangioma is shown in Fig. 29.69.

- **Port-wine stain:** It is flat, purple-red birthmark on the face or neck on face of infants. It is composed of large vascular channels frequently interspersed with small capillaries.
- **Cherry hemangioma:** It is small, dome-shaped red papule.
- **Sturge-Weber syndrome:** It is characterized by port-wine stain of face, ipsilateral glaucoma, vascular lesions of choroidal tissue and extensive hemangiomatous involvement of meninges. Patient presents with convulsions, mental retardation and retinal detachment.

Fig. 29.69: It is most common benign vascular tumor in head and neck region of children and infants (arrow).

- **von Hippel-Lindau syndrome:** It is characterized by multiple vascular tumors, other tumors and cysts widely scattered in many organ systems.

Surgical Pathology: Capillary Hemangioma

Gross Morphology

Capillary hemangioma is well circumscribed but lacking capsule. Gross morphology of capillary hemangioma varies depending on its size and location. Small sized capillary hemangioma in the superficial region appears as red macules. Capillary hemangioma located in deep tissues appears as firm and blue violet mass.

Light Microscopy

- Capillary hemangioma is composed of closely packed aggregates of thin-walled capillaries usually filled with blood lined by single layer of bland endothelial cells. Each capillary is surrounded by scant connective tissue stroma. The lumen of capillaries may be partially or completely thrombosed and organized. Histology of capillary hemangioma is shown in Fig. 29.70.
- Juvenile capillary hemangioma in young children may be highly cellular and appearing solid with lumen formation due to protrusion of plump endothelial cells into the lumen and admixed with large number of pericytic cells. Mitoses may be demonstrated.
- Capillary hemangioma in adults, lumen of capillaries is more obvious due to flattening of endothelial cells. Each capillary is surrounded by scant connective tissue stroma. Old lesions are usually fibrotic.

Differential Diagnosis

Capillary hemangioma should be differentiated from kaposiform hemangioendothelioma (KHE) and pediatric round cell tumors.

Immunohistochemistry Technique

Capillary hemangioma shows positivity for CD31, CD34, FLI-1, vWF and GLUT-1 (glucose transporter protein 1).

Markers	Expression
▪ CD31	▪ Positive
▪ CD34	▪ Positive
▪ FLI-1	▪ Positive
▪ vWF	▪ Positive
▪ GLUT-1 (glucose transporter protein 1)	▪ Positive

Prognosis and Treatment

Treatment of capillary hemangioma depends on the age of patient, size of lesion and location. Large capillary hemangioma is treated by administration of interferon-α or glucocorticoids or both. Unresectable capillary hemangioma is treated by anti-angiogenesis agents.

KAPOSI SARCOMA

Kaposi sarcoma is a locally aggressive vascular neoplasm, which occurs in several distinct populations with a variety of presentations and courses. It usually occurs in patients with immunosuppression, such as those with acquired immunodeficiency syndrome (AIDS) or those undergoing immunosuppression due to an organ transplant.

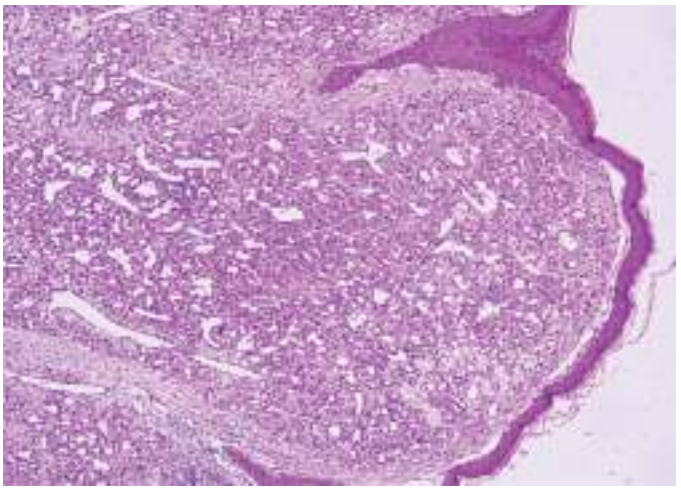

Fig. 29.70: Histology of capillary hemangioma. Capillary hemangioma is composed of closely packed aggregates of thin-walled capillaries usually filled with blood lined by single layer of bland endothelial cells. Each capillary is surrounded by scant connective tissue stroma. The lumen of capillaries may be partially or completely thrombosed and organized (400X).

- In AIDS-related Kaposi sarcoma, most common sites are mucosal surfaces, skin, face, lower extremities, visceral and cutaneous lesions in HIV-infected homosexual or bisexual persons. Patient with organ transplantation develops cutaneous or visceral lesions of the disease with unpredictable clinical course. Lesions resolve on withdrawal of immunosuppressive therapy.
- In classic Kaposi sarcoma, East European and Mediterranean elderly men present with tumor in the lower extremities in the subcutaneous region, that has indolent course.
- In endemic (African) Kaposi sarcoma, young male patient presents with bulky lymphadenopathy and soft tissue tumor. Disease has indolent clinical course in adults; and aggressive clinical course in African children with bulky lymphadenopathy. Clinicopathologic types of Kaposi sarcoma are given in Table 29.34.

Clinical Features

Patient presents with cutaneous violaceous patch, plaque, papule, macule or tumor mass usually on lower extremities. Lymphedema is demonstrated in an occasional patient. Involvement of viscera and lymph nodes presents with hemorrhagic mass. Clinical photograph of Kaposi sarcoma is shown in Fig. 29.71.

Table 29.34 Clinicopathologic types of Kaposi sarcoma

Kaposi Sarcoma Type	Clinical Groups	Location of Lesion	Clinical Course
Classic Kaposi sarcoma	Elderly males of East European and Mediterranean descent	Skin of lower extremities in the subcutaneous region	Indolent course
Endemic (African) Kaposi sarcoma	Children and middle-aged males from equatorial Africa	Skin of lower extremities; and possibly viscera (bulky lymph nodes in children) and soft tissue tumor	Indolent clinical course in adults; and aggressive clinical course in African children with bulky lymphadenopathy
Iatrogenic Kaposi sarcoma	Immunocompromised persons (e.g. post-renal transplantation patients)	Skin of lower legs; and possibly viscera	Unpredictable clinical course; lesions resolve on withdrawal of immunosuppressive therapy
Epidemic (AIDS-related) Kaposi sarcoma	Homosexual or bisexual males with HIV infection	Widespread involvement of skin, face, lower extremities, genitalia, and widespread involvement of viscera (e.g. lungs, lymph nodes, gastrointestinal tract, oral mucosa)	Aggressive clinical course

Fig. 29.71: Kaposi sarcoma of the lower extremity. Papule and ulcerated nodules are seen on foot.

Surgical Pathology: Kaposi Sarcoma

Gross Morphology

- Cutaneous lesions in Kaposi sarcoma are variable, i.e. violaceous patch, plaque, papule, macule or tumor mass.
- Visceral and lymph nodes involved in Kaposi sarcoma are large hemorrhagic mass.

Light Microscopy

Histologic features of Kaposi sarcoma are always identical regardless of clinical settings.

- **Patch stage in Kaposi sarcoma:** It is composed of small infiltrative blood vessels lined by endothelial cells surrounding large ectatic blood vessels; dissecting collagen bundles in the upper reticular dermis and infiltrated by lymphocytes and plasma cells.
- **Plaque stage in Kaposi sarcoma:** It is composed of proliferation of relatively bland, vaguely myxoid spindled cells producing slit-like vascular channels showing jagged outlines. There is presence of extravasated red blood cells and extracellular hyaline globule.
- **Papule (nodule) stage in Kaposi sarcoma:** It is well circumscribed cellular nodular polypoidal mass simulating pyogenic granuloma. It is composed of intersecting fascicles of spindle cells with little or without cytologic atypia. Numerous slit spaces contain red blood cells.

Differential Diagnosis

Kaposi sarcoma should be differentiated from acroangiodermatitis, spindle cell hemangioma and spindle cell sarcomas.

Immunohistochemistry Technique

Kaposi sarcoma shows positivity for immunomarkers CD31, CD34, D2–40, VEGFR3, HHV8 LANA protein (most sensitive marker), factor VIII-related antigen (demonstrated by immunoperoxidase method), Ulex europaeus 1, Fli-1 and Flt-4 (vascular endothelial growth factor receptor 3—VEGFR3).

Markers	Expression
▪ CD31 (PECAM1)	▪ Positive
▪ CD34	▪ Positive
▪ D2–40	▪ Positive
▪ VEGFR3	▪ Positive
▪ HHV8 LANA protein (most sensitive marker)	▪ Positive
▪ Factor VIII-related antigen (demonstrated by immunoperoxidase method)	▪ Positive
▪ Ulex europaeus 1	▪ Positive
▪ Fli-1	▪ Positive
▪ Flt-4 (vascular endothelial growth factor receptor 3—VEGFR3)	▪ Positive

Prognosis and Treatment

Kaposi sarcoma is treated by cryotherapy and radiotherapy. Prognosis is good in immunocompetent patients with cutaneous lesions. Prognosis is poor

in immunocompromised patients without highly active antiretroviral therapy (HAART). Prognosis can be improved by administration of HAART and chemotherapy.

CUTANEOUS ANGIOSARCOMA

Angiosarcoma is highly malignant tumor showing endothelial differentiation, which affects elderly persons without sex predominance. Characteristics and clinical behavior of angiosarcoma depend on the clinical presentation.

- Primary angiosarcoma is related to prolonged sun exposure and therapeutic radiation. Elderly patient presents with single or multiple lesions in the superficial region of head and neck.
- Angiosarcoma associated long-standing lymphedema may arise in the long-standing lymphedema due to Stewart-Treves syndrome, secondary to lymph node dissection and mastectomy performed for breast cancer.
- Stewart-Treves syndrome is a rare deadly cutaneous angiosarcoma that develops in long-standing chronic lymphedema.
- Post-irradiation angiosarcoma arises from soft tissue of patient treated by radiation as adjuvant treatment for breast cancer. It may arise in the settings of use of radiocontrast media thorostat, vascular grafts and arteriovenous fistulae.

Clinical Features

Patient presents with violaceous, erythematous plaque and nodule. Angiosarcoma in deep soft tissue is a hemorrhagic lump. Mammary angiosarcoma presents with rapidly growing mass in the women.

Surgical Pathology: Angiosarcoma

Gross Morphology

Gross morphology of angiosarcoma in cutaneous region is variable ranging from erythematous or violaceous plaque or nodule. Angiosarcoma in the deep tissue is large hemorrhagic mass.

Light Microscopy

Histologic features of angiosarcoma are variable ranging from well differentiated lesion simulating hemangioma; spindled lesion resembling fibrosarcoma; or epithelioid lesion simulating carcinoma.

- **High-grade angiosarcoma:** Tumor is composed of epithelioid like endothelial cells with high nuclear grade and sieve-like to solid architectural pattern. Mitoses and necrosis are frequently demonstrated.
- **Well differentiated angiosarcoma:** Tumor is composed of cells with low nuclear grade lacking mitotic activity and dissecting the adjacent connective tissue.
- **Epithelioid angiosarcoma:** Tumor is composed of epithelioid-like endothelial cells with abundant cytoplasm and uniform high nuclear grade and arranged in sheets. Such lesion is mistaken for carcinoma.

Differential Diagnosis

Angiosarcoma should be differentiated from hemangioma, diffuse angiomatosis, atypical vascular proliferation after radiation, carcinoma, spindle cell carcinoma, melanoma and other spindle cell sarcomas.

Immunohistochemistry Technique

Angiosarcoma shows positivity for CD31, CD34, Fli-1, vWF, D2–40, VEGFR3 and cytokeratins.

Markers	Expression
CD31	Positive (100%)
CD34	Positive (100%)
Fli-1	Positive (100%)
vWF	Positive (100%)
D2–40	Positive (some cases)
VEGFR3	Positive (some cases)
Cytokeratins (low molecular weight) in epithelioid tumors	Positive (25%)

Prognosis and Treatment

Patient with angiosarcoma has poor prognosis. Taxanes chemotherapeutic agent administration may be of value in cutaneous angiosarcoma related to sun exposed skin.

NEURAL TUMORS OF SKIN

PLEXIFORM NEUROFIBROMA

Plexiform neurofibromas can occur anywhere in the body outside the brain and spinal cord. These can occur on the face, around eye, neck, arms, legs, back, chest, abdomen and internal organs.

- Large plexiform neurofibroma can cause thickening of nerve that may affect nearby structures such as skin, muscle and bone.
- Patient presents with severe pain, restricted mobility, vision loss, hearing loss, high blood pressure and other medical problems.
- Most plexiform neurofibromas are benign in nature, but some may undergo malignant transformation. These tumors may be solitary.
- Multiple plexiform neurofibromas affect children as a part of genetic disorder of von Recklinghausen's disease (neurofibromatosis type 1), in which patients can develop multiple café au lait spots (six or more pale brown pigmented macules each >1.5 cm in size).

Surgical Pathology: Plexiform Neurofibroma

Gross Morphology

On gross examination, plexiform neurofibroma may be seen as a fusiform tumor originating from a nerve. Gross morphology of plexiform neurofibroma is shown in Fig. 29.72.

Light Microscopy

- Tumor shows well defined but non-encapsulated masses.
- Tumor is composed of wavy spindle cells with a lot of intervening collagen. Histology of plexiform neurofibroma is shown in Fig. 29.73.

TRAUMATIC NEUROMA

Traumatic neuroma is a firm small painful nodule present in the subcutis and deep soft tissue as a result of injury. The lesion develops most commonly in the soft tissue of the mental foramen area, lower lip and tongue.

Fig. 29.72: Gross morphology of plexiform neurofibroma. Plexiform neurofibroma (WHO grade I) is pathognomonic of neurofibromatosis type 1 (NF-1) involving single or multiple nerve fascicles of major nerve branches. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

Surgical Pathology: Traumatic Neuroma

Light Microscopy

- Traumatic neuroma is composed of irregularly arranged nerve fascicles embedded in fibrous scar tissue.
- Each fascicle is surrounded by fibrous tissue and perineural cells. There is presence of scattered mast cells.

CUTANEOUS METASTASES

In adults, cutaneous metastases are seen in cancers of bronchus, large bowel, melanoma, oral cavity, breast, and rhabdomyosarcoma. Cutaneous metastases occur in children with neuroblastoma. Panel of immunohistochemical markers is employed on histologic sections to find out primary cancers metastasizing to skin.

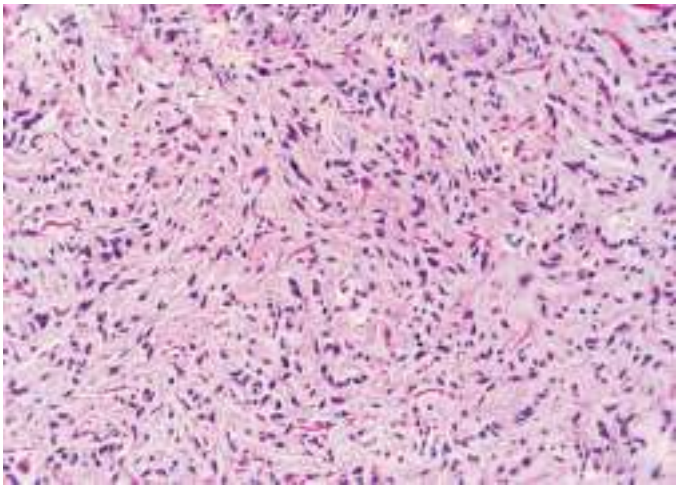

Fig. 29.73: Histology of plexiform neurofibroma. Tumor is composed of elongated wavy cells with small dark oblong nuclei. This lesion is benign. However, persons with neurofibromatosis have a long-term risk for development of malignant neoplasms: neurofibrosarcomas, malignant schwannomas, gliomas.

MISCELLANEOUS SKIN DISORDERS

ACNE VULGARIS

Acne vulgaris is an inflammatory disorder of the pilosebaceous unit, that runs a self-limited clinical course.

- During puberty, under the influence of dehydroepiandrosterone (DHEA), sebaceous glands synthesize excessive sebum. The sebum stimulates excessive proliferation of follicles resulting in retention of sebum. Distended follicles rupture and release proinflammatory chemical mediators in the dermis and induce inflammation. Schematic representation demonstrates stages of open comedone (blackhead) and closed comedone is shown in Figs 29.74 and 29.75.
- Disease is triggered by *Cutibacterium acnes*, *Staphylococcus epidermidis*, and *Malassezia furfur*, which induce inflammation and excessive proliferation of follicles. Acne vulgaris is aggravated by excessive ultraviolet radiation, drugs (steroids, anticonvulsants, lithium), use of occlusive wear, endocrine disorder (polycystic ovary), pregnancy and genetic factors affecting percentage of branched fatty acids in the sebum.
- Acne vulgaris is most often seen in adolescents and young adults involves hair follicles in areas of face,

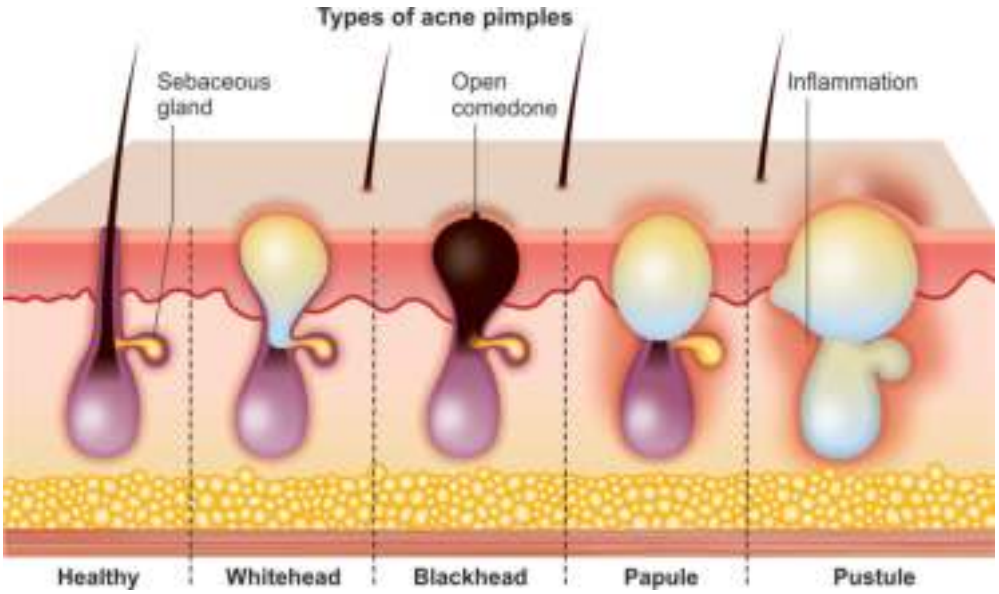

Fig. 29.74: Schematic representation demonstrates stages of open comedone (blackhead) and closed comedone (whitehead) transforming to papule and pustule in acne.

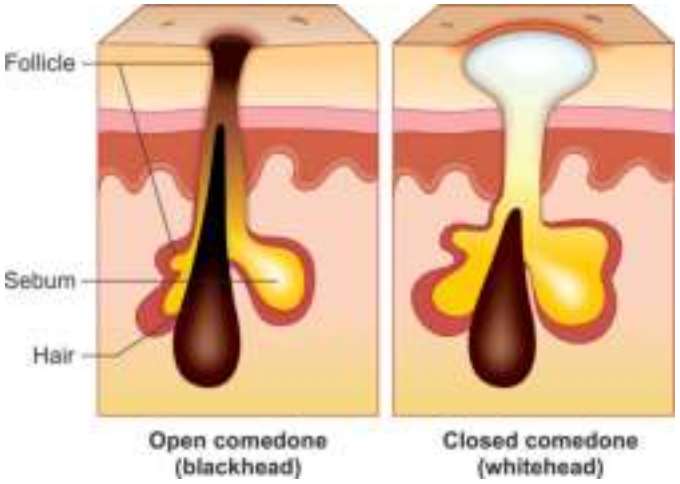

Fig. 29.75: Schematic representation demonstrates open and closed comedones in acne.

Fig. 29.76: Clinical photograph of open comedones in acne. Multiple blackheads or open comedones on the face (lower side), the skin lesions called milia are grouped together (arrows).

upper extremities, chest, and upper back. Lesions may be open or closed comedones.

- Open comedone consists of a distended hair follicle, that contains a central black keratin plug due to oxidation of melanin pigment (not dirt).
- Closed comedone is plugged follicles without a visible central opening, that most often ruptures into the dermis resulting in inflammation. Inflammatory acne is characterized by erythematous papules, nodules, and pustules. The most common lesion is the comedo that involves hair follicles.
- Clinical photograph of open comedones in acne is shown in Fig. 29.76. Clinical photograph of closed comedones in acne is shown in Fig. 29.77.

Fig. 29.77: Clinical photograph of closed comedones in acne. Closed comedone multiple whiteheads are observed on the forehead.

Fig. 29.78: Clinical photograph of fibroepithelial polyp. Fibroepithelial polyp, known as skin tag or acrochordon or papilloma, is benign tumor associated with obesity (arrows).

FIBROEPITHELIAL POLYP

Fibroepithelial polyp, known as skin tag or acrochordon or papilloma, is benign tumor associated with obesity, which most often occurs on the face near eyelids, neck, axilla, trunk and intertriginous regions. Patient presents with itching pain, soft, fleshy-colored and bag-like lesion attached to the skin by a small tender stalk.

- There may be a familial predisposition for developing the lesion, as well as the established association with obesity and insulin resistance. Skin tag is strongly associated with obesity and insulin resistance.
- On histologic examination, fibroepithelial polyp consists of papillary dermis composed of loosely arranged collagen fibers and dilated capillaries and lymphatic vessels, without appendageal structures (hair follicles, sweat glands).

Clinical photograph of fibroepithelial polyp is shown in Fig. 29.78.

EPIDERMAL KERATINOUS CYST

Epidermal keratinous cysts also called epidermal inclusion cysts are the most common cutaneous cysts in men than women during 20–40 years of age. Epidermal keratinous cysts can be primary or secondary occurring anywhere on the body especially on face, scalp, neck, back, and scrotum. Primary epidermal keratinous cysts arise directly from the infundibulum of the hair follicle.

- Plugging of the follicular orifice allows for cyst formation. The cyst often communicates with the surface of the skin through a small orifice or visible central punctum. The size of these cysts can range from a few millimeters to several centimeters in diameter.
- Lesions may remain stable or progressively enlarge over time. The center of epidermoid cysts almost always contains keratin and not sebum.
- Patient presents with well circumscribed, firm, often freely movable, fluctuant nodule with a visible central punctum. Large epidermal keratinous cyst often becomes painful upon traumatic rupture resulting in release of soft gray-white material.

Surgical Pathology: Epidermal Keratinous Cyst

Light Microscopy

- Histologic examination reveals an epidermal kerationus cyst lined by stratified squamous epithelium and is filled with laminated strands of keratinous material.
- A clinically similar lesion seen on the scalp is called a pilar cyst. The pilar cyst lacks a granular layer and is filled with more amorphous material.
- Rupture of epidermal keratinous cyst induce intense acute and chronic inflammatory reaction including formation of giant cells. Histology of unruptured epidermal keratinous cyst is shown in Fig. 29.79. Histology of ruptured epidermal keratinous cyst is shown in Fig. 29.80.

ACANTHOSIS NIGRICANS

Acanthosis nigricans is localized hyperpigmentation of the skin with poorly defined borders. It most common involves intertriginous areas such as skin folds of neck, forehead, armpits (axillae), antecubital and popliteal fossae, groin region and umbilicus in the settings of obesity and/or hyperinsulinemia, other

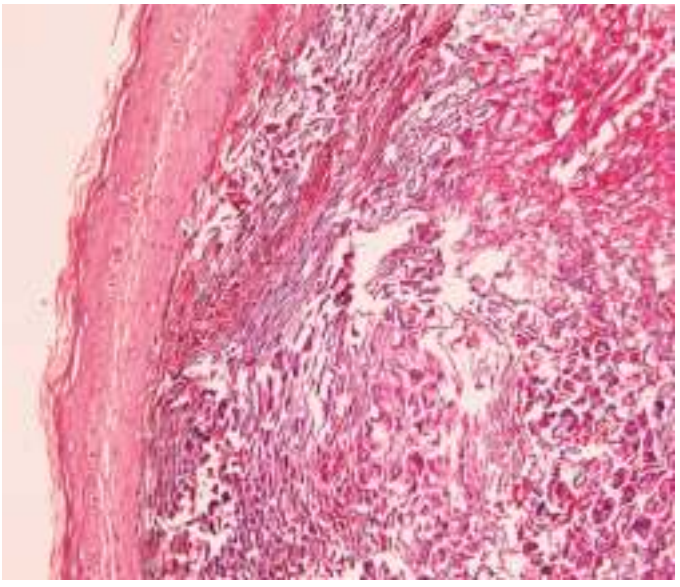

Fig. 29.79: Histology of unruptured epidermal keratinous cyst. The inclusion cyst lined by stratified squamous epithelium and is filled with laminated strands of keratinous material (400X).

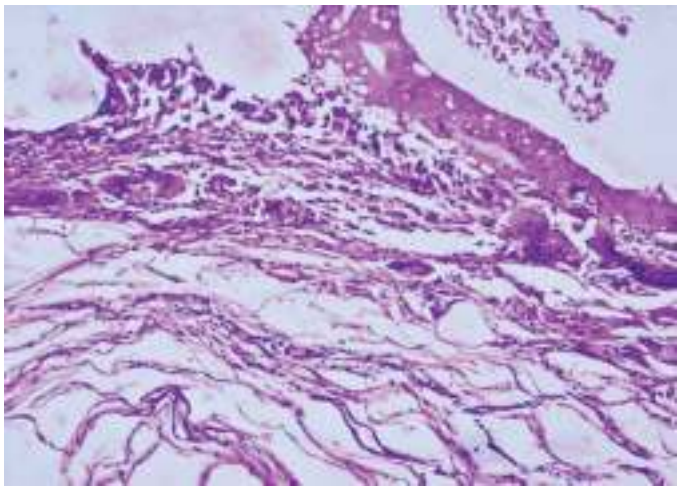

Fig. 29.80: Histology of ruptured epidermal keratinous cyst. The ruptured epidermal keratinous cyst is lined by stratified squamous epithelium and is filled with laminated strands of keratinous material. There is intense acute and chronic inflammatory reaction including formation of giant cells (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

endocrinopathies, administration of glucocorticoids and oral contraceptives; and visceral malignancy (stomach, colon, prostate, breast, ovary, uterus, lung). Etiology and features of acanthosis nigricans are given in Table 29.35.

- **Pathogenesis:** Multiple factors are involved in the pathogenesis of acanthosis nigricans. Increased concentration of insulin activates IGF-1 and keratinocyte insulin-like growth factor (ILGF) receptors. At higher concentration, insulin may displace IGF-1 from IGF-binding protein. Elevated circulating IGF causes proliferation of keratinocyte and dermal fibroblasts. Hereditary acanthosis nigricans variant is linked to malignancy due to synthesis of aberrant fibroblast growth factor (FGF), that acts via the epidermal growth factor receptor.
- **Clinical features:** Patient presents with pruritic, velvety, poorly defined hyperpigmented macules and patches and progress to palpable plaques in skin folds of neck, forehead, armpits (axillae), antecubital and popliteal fossae, groin region and umbilicus. In approximately one-third of cases, malignant acanthosis nigricans presents with skin changes before any signs of cancer.

Surgical Pathology: Acanthosis Nigricans

Light Microscopy

- Histologic examination of the skin lesion in acanthosis nigricans shows papillomatosis, hyperkeratosis with minimal hyperpigmentation.
- The dermal papillae usually have an upward projection with thinning of the epidermis. There is usually no dermal inflammatory infiltrate.

Table 29.35 Etiology and features of acanthosis nigricans

Acanthosis Nigricans	Comments
Familial acanthosis nigricans	Autosomal dominant trait presents at birth or during childhood due to mutation of fibroblast growth factor receptor 3 (FGFR3)
Obesity associated acanthosis nigricans	Associated with obesity and resistance to insulin
Medications associated acanthosis nigricans	Administration of nicotinic acid, systemic glucocorticoids, diethylstilbestrol, combined oral contraceptive pill, growth hormone therapy, estrogen, protease inhibitors, niacin, injected insulin
Acanthosis nigricans associated with endocrine dysfunction	▪ **Insulin resistance syndromes type A:** Hyperandrogenemia, insulin resistance and acanthosis nigricans ▪ **Insulin resistance syndromes type B in females:** Uncontrolled diabetes mellitus, ovarian hyperandrogenism, systemic lupus erythematosus, scleroderma, Sjögren's syndrome and acanthosis nigricans
Malignant acanthosis nigricans syndromes	▪ Most common cancers include gastrointestinal tract, adenocarcinoma, prostatic adenocarcinoma, breast carcinoma, ovarian carcinoma ▪ Rare cancers include lung carcinoma and lymphoma
Autoimmune disorders associated acanthosis nigricans	Systemic lupus erythematosus, scleroderma, Sjögren's syndrome and Hashimoto's thyroiditis
Unilateral acanthosis nigricans	Autosomal dominant disorder associated with unilateral lesions in infancy, childhood and adulthood

XANTHOMAS

Xanthomas are lesions characterized by accumulation of lipid-laden macrophages. These lesions can develop in the settings of altered systemic lipid metabolism or as a result of local cell dysfunction, e.g. hyperlipidemia, diabetes mellitus, hypothyroidism, primary biliary cirrhosis, cholestasis, nephrotic syndrome, monoclonal gammopathy, metabolic lipid disorders and drugs (prednisone, cyclosporine, tamoxifen).

- **Clinical features:** Patient presents with well circumscribed most often multiple plain or nodules in cutaneous regions, eyelids (xanthelasma), over tendon sheath or synovium, elbows, knees, feet and buttock regions associated with familial dysbetalipoproteinemia. Well controlled diabetes mellitus and cholesterol normal levels are less likely to cause xanthoma. Xanthomas resolve by treating underlying cause of hyperlipidemia.
- **Treatment:** Surgical excision of xanthoma is indicated in case of compromised joint function. Hyperlipidemia should be treated. Xanthomas are treated by surgical excision, laser surgery, or chemical treatment with trichloroacetic acid. Recurrence of xanthomas may occur unless hyperlipidemia is treated.

Surgical Pathology: Xanthoma
Gross Morphology
Xanthoma is well circumscribed white or yellow to brown masses.
Light Microscopy
Histologic examination of xanthoma shows focal dermal collections of lipid-laden histiocytes. Histology of xanthoma is shown in Fig. 29.81.

GRANULOMA PYOGENICUM

Granuloma pyogenicum is also known as lobular capillary hemangioma in the skin or mucous membranes and occasionally it can be found subcutaneously or intravascularly. It most often occurs following trauma in all age groups. Lesion is composed of numerous capillaries, venules with plump endothelial cells and fibromyxoid stroma. Hands, lower lips and gingiva are most frequently affected.

- **Pathogenesis:** Risk factors for granuloma pyogenicum include trauma, BRAF mutations, herpesvirus or human papillomavirus 2 (HPV-2); and certain medications such as oral contraceptives, retinoids, gefitinib, cabecitabine, and afatinib. Development of granuloma pyogenicum occurs three phases: (a) cellular phase, (b) vascular phase or capillary phase, and (c) involutionary phase.
- **Clinical features:** Patient presents with small or large, smooth or lobulated, reddish exophytic vascular nodule on hands, lower lips and gingiva; that can grow rapidly. Larger lesion becomes lobulated and sometimes develop into mushroom-like, pedunculated tumor. Profuse bleeding is the most common symptom. Depending on the area, size and patient wishes, granuloma pyogenicum is treated by surgical excision, curettage, electrocautery, radiosurgery, cryosurgery, sclerotherapy, or laser surgery. Clinical photograph of granuloma pyogenicum is shown in Fig. 29.82.

KELOID

Keloid is an exaggerated response to injury to skin, that extends outside the original wound due to ear piercing

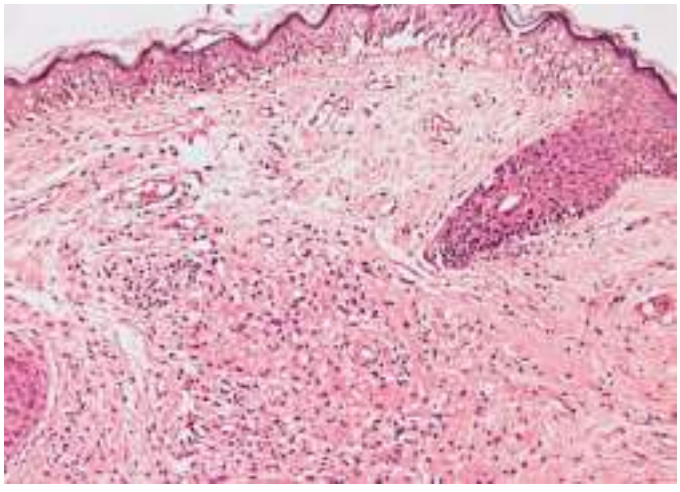

Fig. 29.81: Histology of xanthoma. Xanthoma is composed of focal dermal collections of lipid-laden histiocytes (100X).

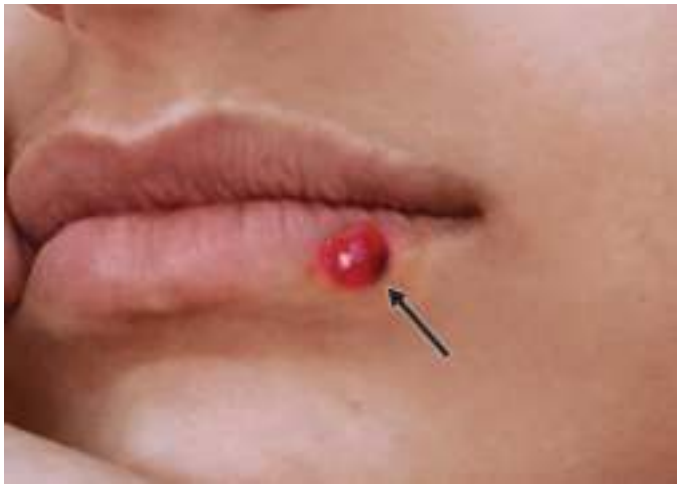

Fig. 29.82: Clinical photograph of granuloma pyogenicum (arrow).

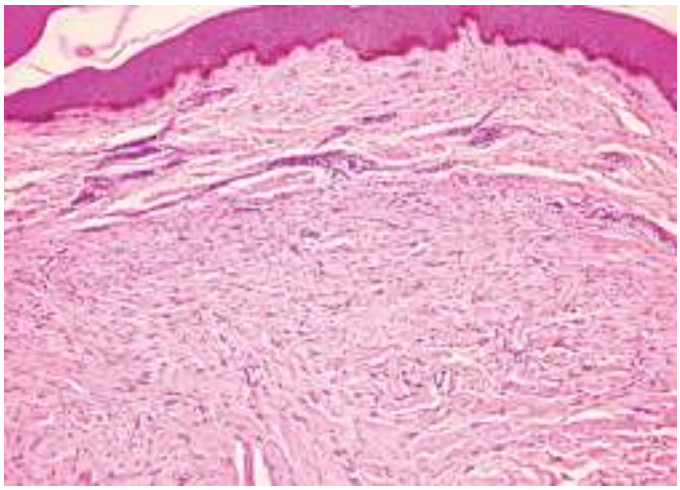

Fig. 29.83: Histology of keloid. Skin consists of thin top layer of epidermis and deeper layer of skin dermis. The pathology of the keloid resides in the dermis, where there is an excessive amount of tightly packed haphazard fascicles of dense and hyalinized collagen fibers randomly oriented in multiple directions, keloid tissue fibroblasts and lymphocytic infiltrate. Overlying epidermis is most often thinned out (400X).

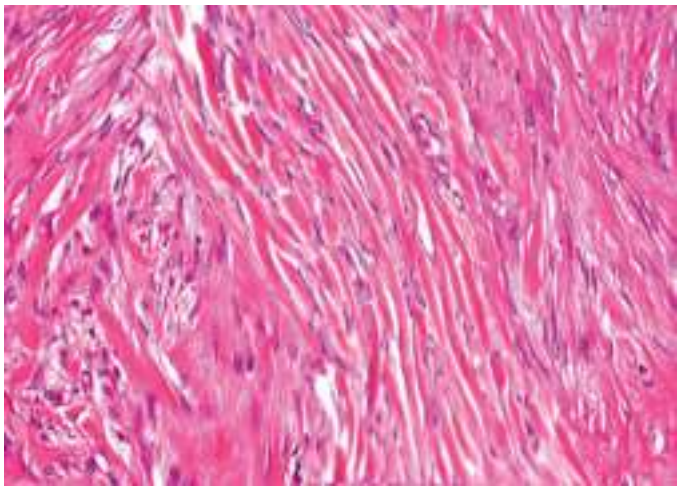

Fig. 29.84: Histology of keloid. Keloid scar is composed of homogenous, broad, eosinophilic fibrillary collagen bundles arranged in haphazardly array. Increased number of fibroblasts are found arrayed with an orientation that parallel the accompanying collagen bundles. Vascularity is diminished within the lesion. It is worth mentioning that overlying epidermis is most often thinned out.

or surgical wounds especially in dark persons. It is characterized by exuberant proliferation of fibroblasts and synthesis of abundant collagen bundles which caused by overexpression of cytokines and growth factors resulting in formation of large nodular scar. Keloid may recur after surgical excision.

- Most common sites of keloid are hands, ear lobe, neck, sternum, chest and shoulder. It most often in females on the earlobe secondary to ear piercing during 10–30 years of age.
- Patient presents with large nodular scar on the upper back, shoulder, presternal region and earlobe. Lesion is most often asymptomatic. Sometimes, lesion may be tender, pruritic or painful. On examination, lesion is elevated and protruding surrounding skin.

Surgical Pathology: Keloid

Gross Morphology

Keloid is polypoidal lesion and covered by thin and hairless skin.

Light Microscopy

- Hematoxylin and eosin-stained section examination of keloid reveals nonencapsulated haphazard fascicles of dense, hyalinized collagen that appears edematous due to dermal mucosubstances in dermis, scattered fibroblasts and myofibroblasts are present.
- Keloid blends with adjacent tissue, overlying epithelium is thin and lacks adnexal structures.
- There is presence of widely scattered dilated blood vessels. Histology of keloid is shown in Figs 29.83 and 29.84.

CHAPTER 30

Nervous System

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

CENTRAL NERVOUS SYSTEM

- Anatomy of nervous system
- Histology of nervous system
- Intracranial compartments
- Intraventricular space

CENTRAL NERVOUS SYSTEM INFECTIONS

- Meningitis
  - Pyogenic meningitis
  - Tuberculous meningitis
  - Viral meningitis
  - Fungal meningitis
  - Iatrogenic meningitis
  - Metastatic cancer-induced meningitis
- Encephalitis
  - Parasitic encephalitis
  - Viral encephalitis
- Cerebral abscess
- Tabes dorsalis in tertiary syphilis

CENTRAL NERVOUS SYSTEM TUMORS

- Nervous system tumors: overview
  - Primary nervous system tumors
  - Metastases to nervous system
- Astrocytic tumors
  - Diffuse astrocytoma, IDH-mutant
  - Diffuse midline glioma, histone H3K27M-mutant
  - Anaplastic astrocytoma, IDH-mutant
  - Primary glioblastoma multiforme, IDH-wildtype
  - Secondary glioblastoma multiforme, IDH-mutant
  - Pilocytic astrocytoma
  - Epithelioid glioblastoma
  - Glioblastoma multiforme with a primitive neuroectodermal tumor component
- Oligodendroglial tumors
- Ependymal tumors
  - Ependymoma
  - Ependymoma with RELA fusion positive
- Choroid plexus tumors
  - Choroid plexus papilloma
- Embryonal tumors
  - Medulloblastoma
  - Embryonal tumor with multilayered rosettes
- Meningeal tumors
  - Meningioma
  - Diffuse leptomeningeal glioneuronal tumor
- Tumors of the cranial and paraspinal nerves
  - Schwannoma (neurilemmoma)
  - Neurofibroma, neurofibromatosis type 1 and malignant change in neurofibroma
  - Malignant peripheral nerve sheath tumor
- Tumors of the sellar region
- Mesenchymal nonmeningeal tumors
- Primary CNS lymphoma
- Germ cell tumors of nervous system
- Primitive neuroectodermal tumors

HYPOXIA-INDUCED BRAIN INJURY

- Cerebral hypoxia
  - Clinical features
  - Pathophysiology
  - Laboratory diagnosis

CEREBROVASCULAR DISORDERS

- Cerebral infarction
- Cerebral hemorrhage
- Subarachnoid hemorrhage
  - Berry aneurysm
  - Mycotic aneurysm
  - Arteriovenous fistula
  - Cavernous hemangiomas
- Transient ischemic attacks
- Fat embolism syndrome

HEAD INJURY

- Epidural hematoma
- Subdural hematoma
- Intracerebral hemorrhage

DEMYELINATING DISORDERS OF NERVOUS SYSTEM

- Multiple sclerosis
- Acute disseminated encephalomyelitis
- Guillain-Barré syndrome
- Hydrocephalus
- Arnold-Chiari malformation

CONGENITAL DISORDERS OF NERVOUS SYSTEM

- Neural tube defects
- Agenesis of corpus callosum
- TORCH complex
- Fetal alcohol syndrome
- Tuberous sclerosis syndrome

CENTRAL NERVOUS SYSTEM

ANATOMY OF NERVOUS SYSTEM

Central nervous system consists of cerebrum, cerebellum, brainstem, spinal cord, 12 cranial nerves and blood vessels supplying these structures.

- Brain and spinal cord are covered by meninges. Meninges are composed of outer dense fibrous dura mater and delicate leptomeninges (pia and arachnoid mater).
- Falx cerebri divides cerebrum into left and right hemispheres. Supratentorial compartment consists of cerebral cortex (frontal, temporal, parietal and occipital lobes), white matter and deep gray nuclei such as basal ganglion, thalamus, and hypothalamus.

- Neuroaxis term denotes brain and spinal cord. Tumors that involve brain parenchyma are said to be 'intra-axial' (e.g. astrocytoma, central neurocytoma or ependymoma).
- Tumors located outside the parenchyma are referred to as 'extra-axial' (meningiomas, hemangiopericytoma, schwannoma). Similar terms used for spinal lesions are intramedullary or extramedullary.

HISTOLOGY OF NERVOUS SYSTEM

Central nervous system (CNS) is composed of gray and white matter that differ quantitatively on gross and histopathologic examination. Nervous system is composed of neurons, glial supporting cells (e.g. astrocytes, oligodendrocytes, ependymal cells), microglial cells, connective tissue in meninges and blood vessels.

NEURONS

Central nervous system consists of 100 billion polarized neurons. Neurons cannot divide and hence have limited regeneration. Neurons respond to physical and chemical stimuli; conduct electrical impulses and release chemical regulators.

- A neuron is a microscopic structure composed of three major parts, namely neuronal cell body (perikaryon), dendrites and axons.
- Neuronal cell bodies and dendrites reside in the gray matter (cortex and deep gray matter). Axons create the framework of the white matter. Neuroglial cells (astrocytes, oligodendrocytes and microglia) are present in different proportions in these tissues.
- Oligodendrocytes are present in abundance in the white matter; and their processes form myelin sheath that insulin CNS axons. Neuropil is a fibrillary material between neuronal cell bodies and formed by the processes of neurons (axons and dendrites) and glial cells.

NEUROGLIAL TISSUE

Neuroglial Cells in CNS

- **Astrocytes:** Astrocytes are present in white matter of cerebral cortex, which participate in metabolism of neurotransmitters. Astrocytes form blood–brain barrier by providing a link between neuron and blood vessels.
- **Microglia cells:** Microglia cells participate in phagocytosis of microbes and cellular debris.
- **Ependymal cells:** Ependymal cells form links between the ventricles of the brain and the central canal of spinal cord. These cells participate in synthesis of cerebrospinal fluid in choroid plexus and its circulation.
- **Oligodendrocytes:** Oligodendrocytes form a supporting network by forming myelin sheath around neurons in CNS.

Neuroglial Cells in Peripheral Nervous System

- **Neurilemmocytes or Schwann cells:** Each Schwann cell produces part of myelin sheath around a single axon of peripheral nervous system neuron. Schwann cell is a type of glial cell wrapping axon forming insulating myelin sheath, which does not insulate node of Ranvier.
- **Satellite neuroglial cells:** These cells support neurons in ganglia of peripheral nervous system.

MENINGES

The meninges are the connective tissue coverings of the brain and spinal cord. The outermost layer is the dura mater, a dense and tough tissue, that forms the periosteum of the inner skull. Beneath the dura is the arachnoid, a network of loose connective tissue that lacks blood vessels.

BLOOD VESSELS OF BRAIN

The brain receives the blood through two internal carotid arteries and two vertebral arteries, which fuse to form the basilar artery. The basilar artery bifurcates into two posterior cerebral arteries, which interconnect with branches of the carotid arteries to form the 'circle of Willis' at the base of the brain. The blood vessels are non-fenestrated and tight junctions with adjacent cells.

Clinical Pearls: Blood–Brain Barrier

- Blood vessels are critical to deliver oxygen and nutrients to all of the tissues and organs throughout the body.
- The blood vessels that vascularize the CNS possess unique properties, termed the blood–brain barrier, which allow these vessels to tightly regulate the movement of ions, molecules, and cells between the blood and the brain.
- Blood–brain barrier protects the neural tissue from toxins and pathogens.
- The physiologic barrier is coordinated by a series of physical and metabolic properties possessed by the vascular endothelial cells (ECs) that form the walls of the blood vessels.
- These properties are regulated by interactions with different vascular, immune, and neural cells.
- Understanding how these different cell populations interact to regulate the blood–brain barrier, which is essential for understanding how the brain functions during health and disease (Fig. 30.1).

INTRACRANIAL COMPARTMENTS

Intracranial lesions or processes can be described according to which intracranial compartment they occur within. The simplest division is into three intracranial

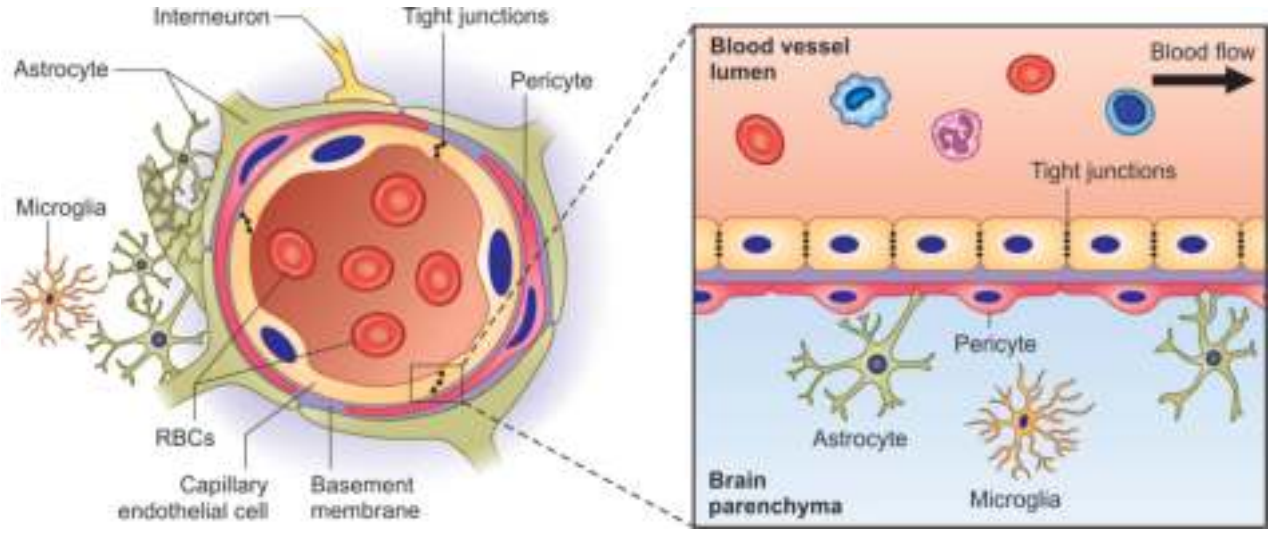

Fig. 30.1: Blood–brain barrier. Astrocytes form blood–brain barrier by providing a link between neuron and blood vessels.

compartments: extra-axial is external to the brain parenchyma; intra-axial is present within the brain parenchyma.

- **Epidural space:** This is a virtual space between the inner aspect of the cranial bones and the dura mater. The epidural space contains the middle meningeal arteries and three main branches, which are 'grooved' into the inner surface of the temporal–parietal bones.
- **Subdural space:** Subdural space is located between the arachnoid and pia mater and is filled with cerebrospinal fluid (CSF). It is contiguous with the perivascular 'Virchow-Robin spaces' surrounding the blood vessels penetrating from the meninges into the brain.
- **Cerebral parenchymal compartment:** Cerebral parenchymal compartment is occupied by the neural, glial, and vascular cells.

INTRAVENTRICULAR SPACE

Intraventricular space includes the lateral ventricles, the third and fourth ventricles, and the '**aqueduct of Sylvius**'. This compartment is filled with cerebrospinal fluid (CSF). CSF circulation in ventricles in central nervous system are shown in Figs 30.2 and 30.3.

- **Cerebrospinal fluid synthesis:** Most of the CSF is produced by choroid plexuses in the lateral cerebral ventricles at a rate of approximately 500 ml per day. The choroid plexus stretches along the roof of the third ventricle and then angles posteriorly to span the lateral ventricles.
- **Cerebrospinal fluid flow/circulation:** Cerebrospinal fluid flows from its intraventricular origin to sites of reabsorption, principally through the arachnoid villi,

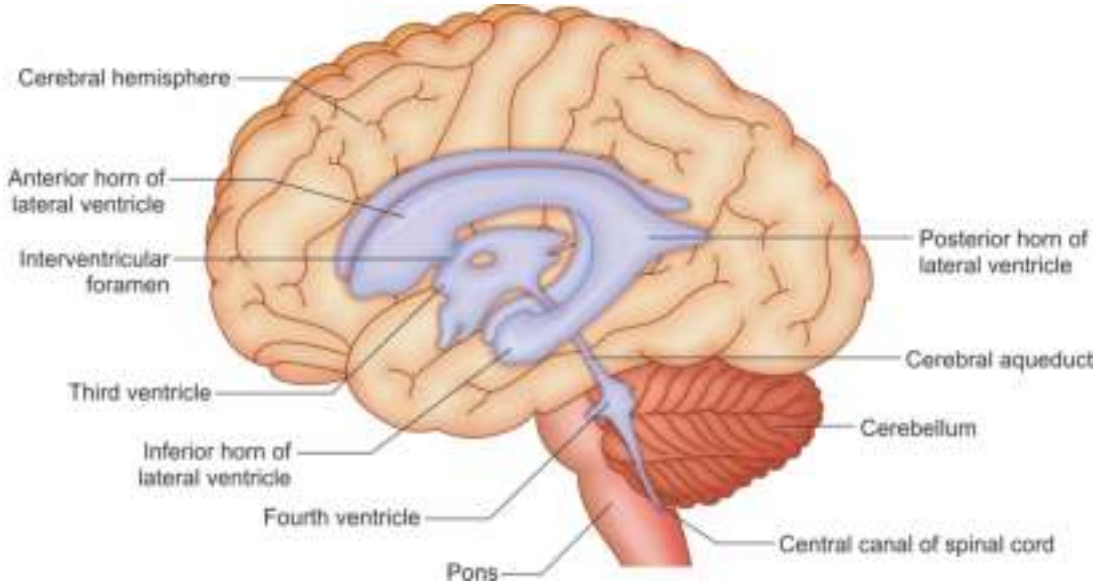

Fig. 30.2: Cerebrospinal fluid (CSF) circulation in ventricles in central nervous system.

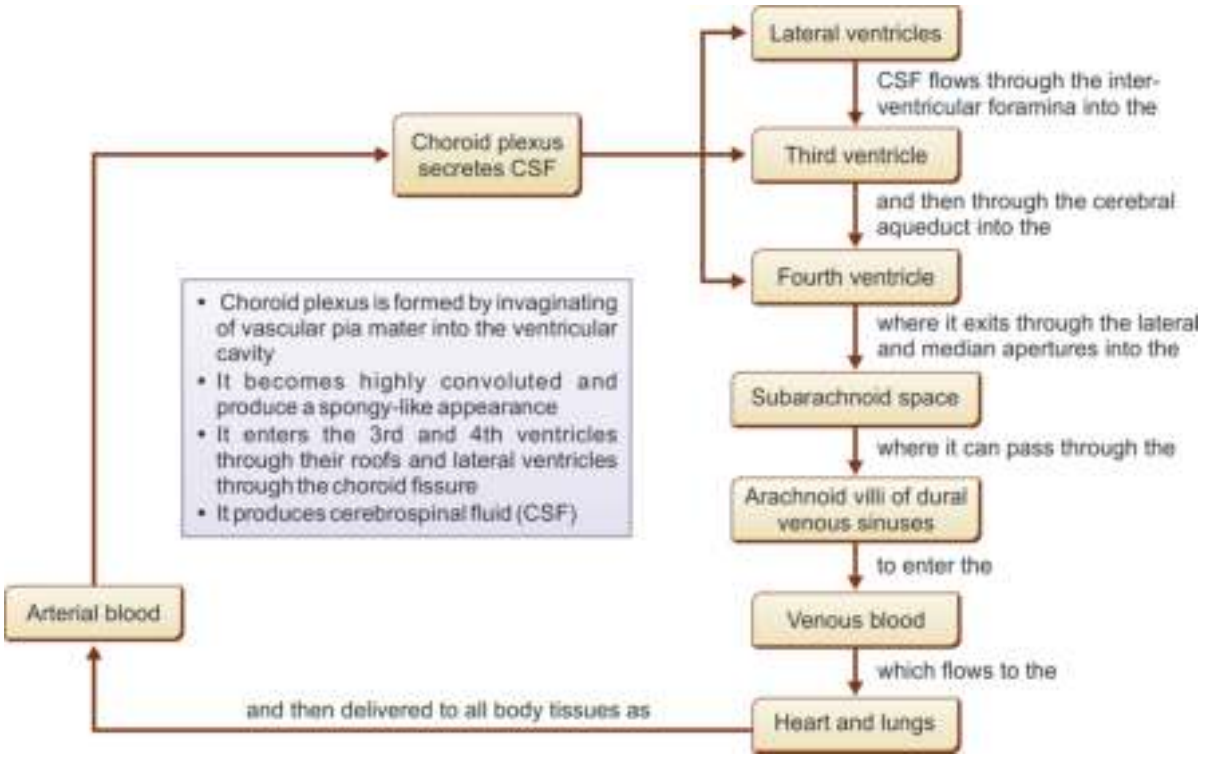

Fig. 30.3: Cerebrospinal fluid (CSF) circulation in central nervous system.

into the dural sinuses. From the ventricles, the CSF flows via the cerebral aqueduct and enters the space through the foramina of Luschka and Magendie. CSF is absorbed by the arachnoid villi, which provide the 'outlet' for CSF to flow into the major dural spaces. Normal values of CSF are given in Table 30.1.

- **Cerebrospinal fluid functions:** Cerebrospinal fluid supports and protects the brain and spinal cord. CSF acts as a cushion and shock absorber and reservoir to regulate the contents of the cranium. CSF keeps the brain and spinal cord moist. Cerebrospinal fluid may act as a medium for the interchange of metabolic substances between nerve cells. Cerebrospinal fluid clears metabolic waste of central nervous system. CSF is poor in colloids. Bilirubin is absent in CSF.

Table 30.1 CSF normal values

CSF Parameters	Normal Values
Volume	90–150 ml
Pressure	80–180 cm of water (20 drops/minute)
Specific gravity	1.006–1.008
pH	7.30–7.40
Colloids	Poor
Total solids	0.85–1.70 g/dl
Bilirubin	Absent
Proteins	▪ Total proteins (20–40 mg%) ▪ Albumin (50–70%) ▪ α_1-Globulin (3–9%) ▪ α_2-Globulin (4–10%) ▪ β-Globulin (4–10%) ▪ γ-Globulin (3–9%) ▪ Fibrinogen: Nil

CSF Parameters	Normal Values
Sugar	40–80 mg%
Chloride	118–132 mEq/L
Sodium	144–154 mEq/L
Potassium	2.0–3.5 mEq/L
Thyroxine	0.1–0.2 mg/dl
Iron	1.0–2.0 mg/dl
Glutamine	6–16 mg/dl
Urea	6–16 mg/dl
Uric acid	0.5–4.5 mg/dl
Creatinine	0.5–1.2 mg/dl
Cholesterol	0.2–0.5 mg/dl
Light microscopy	0–4 lymphocytes/mm^3
Culture and sensitivity	Sterile

Contd...

CENTRAL NERVOUS SYSTEM INFECTIONS

Infections of central nervous system may be classified into meningitis, encephalitis, myelitis and brain abscess. Meningitis refers to infection of meninges.

- Encephalitis is characterized by infection of brain parenchyma.
- Myelitis refers to infection of spinal cord.
- Encephalomyelitis is characterized by infection of brain parenchyma and spinal cord.
- CNS infections are caused by potentially life-threatening bacteria and viruses. Rarely fungi or *Entamoeba histolytica* and therapeutic drugs procaine or methotrexate in neurosurgical may cause meningitis. Prompt diagnosis and treatment of CNS infection is essential for patient survival, these infections to prevent morbidity and mortality.

MENINGITIS

Meningitis is inflammation of the meninges that surround the brain and spinal cord, which involves pia mater, the arachnoid and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation occurs around the brain and spinal cord.

- Patchy meningitis denotes an inflammatory process restricted to dura mater.
- Leptomeningitis denotes an inflammatory process localized to arachnoid and pia mater. The infection may be limited to subarachnoid space or may spread to the brain (meningoencephalitis).
- Meningitis is most often caused by bacteria and viruses. Rarely, fungi or *Entamoeba histolytica* or therapeutic chemical may also cause meningitis.
  - **Bacteria:** *Escherichia coli*, Salmonella, *Haemophilus influenzae*, Neisseria, streptococci, pneumococci-3 and Mycobacterium bacilli cause bacterial meningitis.
  - **Viruses:** Viral meningitis is caused by viruses, which include enteroviruses (echoviruses 3, 7, 9, 11, 21, 30), Epstein-Barr virus (EB virus), coxsackie-viruses (B1-5 and A-9), herpes II virus and mumps virus. Viruses are most often transmitted by fecal–oral route. Viral meningitis is less severe than bacterial meningitis.
  - **Fungi:** *Cryptococcus neoformans* causes meningitis in immunocompromised persons, which is demonstrated by India ink preparation of CSF in a black background. Capsule of *Cryptococcus neoformans* is also demonstrated by mucicarmine stain (magenta colored) and silver stain (black color).
  - **Iatrogenic agents:** Therapeutic administration of procaine or methotrexate in neurosurgical procedures may produce sterile chemical meningitis.
  - **Metastatic cancers:** Lymphoma, breast cancer, melanoma, and lung cancer (especially small cell lung cancer) are associated with the greatest predilection to metastasize to the subarachnoid space resulting in carcinomatous meningitis.
- Most CNS infections occur in children less than 5 years of age, young adults and elderly persons. Otitis media is most important risk factor for meningitis in children. Such infection can be acute or chronic. The pia mater is the layer most commonly affected. CNS infection increases the permeability of blood–brain barrier, which leads to cerebral edema and influx of toxic waste products resulting in increased intracranial pressure and damage to cranial nerves (especially VIII cranial nerve). Patient develops hydrocephalus that limits the normal circulation of cerebrospinal fluid within brain and spinal cord.
- The presence of neutrophils in the CSF is the most definitive index of bacterial meningitis.
- Lymphocytes are the hallmark of tuberculosis and the viral meningitis, as well as some chronic infections.
- In untreated cases, delirium gives way to coma and death. CSF findings in normal persons are given in Table 30.2. Color changes in CSF suggestive of disease states are given in Table 30.3. Differentiation between blood CSF caused by subarachnoid hemorrhage versus traumatic lumbar puncture is given in Table 30.4. Major cells demonstrated on microscopic examination of cerebrospinal fluid are given in Table 30.5. Laboratory analysis of cerebrospinal fluid (CSF) for infectious meningitis is given in Table 30.6.

Pathology Pearls: Lumbar Puncture—Clinical Alert

- Before lumbar puncture, fundus examination with ophthalmoscope should be performed for evidence of papilledema (swelling of optic disc generally due to an increased intracranial pressure).
- Because presence of papilledema may signal potential problems or complications of lumbar. However, if increased CSF pressure is found while performing lumbar puncture, it should not be essential to stop the procedure unless neurologic signs are present.
- Blood levels for specific substances should always be measured simultaneously with CSF determinations for meaningful interpretations of the results.

PYOGENIC MENINGITIS

Most cases of pyogenic meningitis are caused by *Streptococcus pneumoniae* (pneumococcus 3) or *Neisseria meningitidis* (meningococcus) in adults. *Escherichia*

Table 30.2 CSF findings in normal persons

Features	Normal CSF Findings
Causative organisms	No organisms
CSF pressure	60–150 cm of H_2O (20 drops/minute)
Color	Clear, colorless
CSF proteins	Normal 15–40 mg%
CSF sugar	50–80 mg% (CSF sugar : blood sugar ratio is 0.6)
CSF white blood cells	0–4 lymphocytes /mm^3
Gram staining	Organisms absent, hence insignificant
CSF culture	Sterile

coli, Salmonella, *Haemophilus influenzae* may also cause meningitis. Neonates develop meningitis by *Escherichia coli*, Salmonella and group B streptococci. Risk factors associated with contracting pyogenic meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromised persons.

Pyogenic Meningitis and Age Group Predilection

In pyogenic meningitis, majority of the organisms originate in nasopharynx. Causative organisms and age group predilection for pyogenic meningitis are given in Table 30.7.

Table 30.3 Color changes in CSF suggestive of disease states

Appearance of CSF	Cause	Clinical Significance
Clear CSF	Normal persons	Normal findings
Hazy, cloudy, opalescent, purulent slight yellow to frank pus	▪ WBCs ▪ Microorganisms ▪ Protein	▪ Pyogenic meningitis ▪ Blood–brain barrier disorders ▪ IgG production in the central nervous system
Slightly yellow with delicate clot (cobweb turbid)	Fibrinogen converted to fibrin	Tubercular meningitis
Viscous appearance	▪ Neoplastic cells ▪ Meningococci	▪ Metastatic colon carcinoma ▪ Severe meningococcal infection
Bloody	Red blood cells	▪ Traumatic lumbar puncture tap ▪ Subarachnoid hemorrhage ▪ Primary amebic meningoencephalitis
Xanthochromia	▪ Hemoglobin ▪ Microorganism ▪ Bilirubin ▪ Protein ▪ Carotene	▪ Old hemorrhage ▪ *Toxoplasma gondii* ▪ Elevated serum bilirubin ▪ Blood–brain barrier disorders ▪ Elevated carotene levels
Generally clear or slightly xanthochromia	Neoplastic cells	Tumors of brain and spinal cord
Pellicle	Clotting factors	Refrigerated tuberculous meningitis by CSF specimens

Table 30.4 Differentiation between blood CSF caused by subarachnoid hemorrhage versus traumatic lumbar puncture

CSF Findings	Subarachnoid Hemorrhage	Traumatic Lumbar Puncture
CSF pressure	CSF pressure most often increased	CSF pressure normal
Blood in test tubes for collecting CSF	Mixture of CSF with blood is uniform in all test tubes	Test tubes 1 and 2 more bloody than test tubes 3 and 4
CSF clotting	CSF does not clot	CSF often clots
Xanthochromia	Present if >8–12 hours since cerebral hemorrhage	Absent unless patient is jaundiced
Immediate repeat of lumbar puncture at higher level of intervertebral space	CSF same as initial procedure	CSF clear (if traumatic)

CSF with red blood cells >6000 per mm^2 appears grossly bloody.

Table 30.5 Major cells demonstrated on microscopic examination of cerebrospinal fluid

Cell Types	Disorders	Light Microscopy Findings
Blast forms	Acute myelogenous or lymphoblastic leukemia	Myeloblasts or lymphoblasts
Malignant cells	Metastatic carcinomas	Clusters of neoplastic cells with fused cell borders and nuclei
Neutrophils	▪ Bacterial meningitis ▪ Viral meningitis (early case) ▪ Fungal meningitis (early case)	Neutrophil containing granules
Lymphocytes	▪ Normal CSF ▪ Viral meningitis ▪ Fungal meningitis ▪ Multiple sclerosis	All stages of development of lymphocytes possible
Macrophages	▪ Viral meningitis ▪ Tubercular meningitis ▪ Red blood cells in CSF ▪ Contrast media administration	Macrophages may contain phagocytized red blood cells (appearing as empty vacuoles or ghost cells) and hemosiderin granules
Monocytes	▪ Chronic bacterial meningitis ▪ Viral meningitis ▪ Tubercular meningitis ▪ Fungal meningitis ▪ Multiple sclerosis	Monocytes are mixed with lymphocytes and neutrophils
Plasma cells	▪ Multiple sclerosis ▪ Tubercular meningitis ▪ Sarcoidosis	Classic plasma cells
Ependymal and choroid cells	Traumatic lumbar puncture	Clusters with distinctive cellular outlines and nuclei
Pia arachnoid mesothelial cells	Normal mixed reactions including neutrophils, lymphocytes, monocytes and plasma cells	Pia arachnoid mesothelial cells resemble young monocytes with a round, not indented, nucleus

Table 30.6 Laboratory analysis of cerebrospinal fluid (CSF) for infectious meningitis

Features	Pyogenic Meningitis	Tubercular Meningitis	Viral Meningitis	Normal Range
Causative organisms	*E. coli*, Salmonella, *Haemophilus influenzae. Neisseria meningitidis,* streptococci or pneumococci	Mycobacterium tubercle bacillus	Enteroviruses (echoviruses 3, 7, 9, 11, 21, 30), including coxsackievirus (B1–5 and A-9), poliovirus, and echovirus. Epstein-Barr virus, mumps virus, HSV, and West Nile virus	No pathogens in normal CSF
CSF pressure	Increased	Increased	Increased	60–150 cm H_2O (20 drops/minute)
Color	Opaque and turbid to frank pus	Straw colored	Clear or colorless	Clear, colorless
CSF proteins	Increased	Increased rich in fibrinogen. When allowed to stand forms 'cobweb turbidity' (fibrinogen → fibrin)	Increased	15–40 mg%
CSF sugar	▪ CSF sugar low or absent due to consumption by pyogenic bacteria ▪ CSF glucose: Serum glucose = <0.4; lactate >35 mg/dl	CSF sugar low and it starts rising on ATT therapy; lactate >25 mg/dl	CSF sugar normal except in mumps and herpes; lactate <25 mg/dl	50–80 mg%
CSF WBC count	Elevated WBCs and neutrophils	Elevated WBCs, lymphocytes and monocytes	Elevated WBCs and lymphocytes	0–4 lymphocytes/mm^3
Staining technique	Gram staining positivity sensitivity (75–80%)	ZN staining for AFB	Not stained by Gram stain or ZN stain	Insignificant
CSF culture	Positive in 70–80%	Detection of AFB antigens by CSF chromatography, ELISA and PCR	▪ Amplification of viral DNA or RNA from CSF by PCR amplification ▪ CSF IgG/serum IgG antibody titer >1.5	Insignificant

Table 30.7 Causative organisms and age group predilection for pyogenic meningitis

Age Group	Organisms
Neonates	*Escherichia coli*, Salmonella, Group B streptococci, *Listeria monocytogenes*
Infants and young children	*Streptococcus pneumoniae*, *Neisseria meningitidis*
Adults <30 years	*Haemophilus influenzae*, *Neisseria meningitidis*
Adults >30 years	*Streptococcus pneumoniae*, Mycobacterium tubercle bacilli
Epidemics in young adults in overcrowded living conditions (e.g. college dormitories and military barracks)	*Neisseria meningitidis*

Clinical alert: CSF should be cultured for bacteria, tuberculosis and fungi. In children, Haemophilus influenzae type B is the most cause of bacterial meningitis. In adults, meningococci and pneumococci are most common pathogens for meningitis. CSF with any degree of cloudiness should be treated with extreme care because it could be an indication of contagious disease.

- **Neonates:** *Escherichia coli* is the prime cause of meningitis in the newborn, whose resistance to gram-negative bacteria has not fully developed. The transplacental transfer of maternal IgG imparts protection to the newborn against many bacteria. Salmonella also causes meningitis in neonates.
- **Infants and young children:** *Streptococcus pneumoniae* or *Neisseria meningitidis* causes pyogenic meningitis in this age group. Pyogenic meningitis caused by *Neisseria meningitidis* may develop 'Waterhouse-Friderichsen syndrome', which is characterized by hemorrhagic destruction of the adrenal cortex, acute hypocorticism with circulatory collapse, and disseminated intravascular coagulation.
- **Adults <30 years:** *Haemophilus influenzae* and *Neisseria meningitidis* cause pyogenic meningitis at a later age.
- **Adults >30 years:** Adults more than 30 years of age develop pyogenic meningitis caused by *Streptococcus pneumoniae*. Mycobacterium tubercle bacilli may affect any age group.

Portal of Entry of Pyogenic Bacteria in Nervous System

Bacteria enter central nervous system via hematogenous route, direct inoculation route due to trauma, local spread from regional infective focus, ascending infection in surgical procedures and iatrogenic route.

- **Hematogenous spread:** Hematogenous spread is most common portal of entry of organisms to brain and meninges. Venous blood may serve as a carrier of infectious agents from the infected periocular and perinasal tissues (e.g. bacterial endocarditis and bronchiectasis) to brain and meninges. It is worth mentioning that CNS has no lymphatic channels.
- **Trauma:** Bacteria may be inoculated directly into the brain by bullets and sharp objects, such as a knife, or by direct entry of bacteria through an open or surgical wound or skull fracture.
- **Local spread:** Pyogenic meningitis occurs from spread of infection from paranasal sinuses, middle ear (drum perforation) and dental infections.
- **Ascent of infection:** Infection may ascend by various procedures like cystoscopy to brain and meninges.
- **Iatrogenic infection:** *Staphylococcus epidermidis* is most common organism to cause pyogenic meningitis.

Pathology

- **Organism's entry:** In the pathophysiologic process of bacterial meningitis, the bacteria replicate and undergo lysis in the cerebrospinal fluid, releasing endotoxins or cell wall fragments.
- **Release of chemical mediators:** Pyogenic bacteria products lead to release of inflammatory chemical mediators resulting in movement of glucose and neutrophils across the capillary wall into CSF.
- **Purulent exudate in the subarachnoid space:** Entry of pathogens into the subarachnoid space leads to formation of cloudy purulent exudate. Purulent exudate in the subarachnoid space is characteristic. CSF findings of diagnostic significance include numerous neutrophils, decreased glucose (<2/3 of the serum glucose concentration) and increased protein.
- **Leptomeningeal venulitis:** Thrombophlebitis occurs in dural sinuses and bridging leptomeningeal veins. Obliteration of arterioles by inflammation leads to vascular congestion, hemorrhagic infarction and cerebral abscess in the surrounding tissues. Net result is thickening of the meninges and formation of adhesions in patient with pyogenic meningitis.
- **Reactive fibroblastic arachnoiditis with scarring:** Formation of adhesions may impinge on the cranial nerves resulting in cranial nerve palsy. Adhesions may impair the outflow of cerebrospinal fluid resulting in hydrocephalus.

Surgical Pathology: Pyogenic Meningitis

Gross Morphology

- In pyogenic meningitis, the brain is edematous and congested. The subarachnoid space is filled with purulent exudates.
- The pus is most obvious in the sulci and subarachnoid cisterns at the base of the brain (Fig. 30.4).

Light Microscopy

The exudate in meninges consists predominantly of live and dead neutrophils (pus).

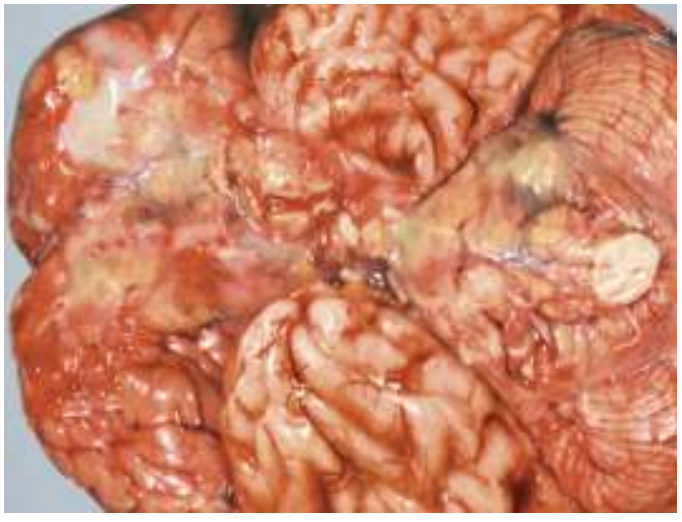

Fig. 30.4: Pyogenic meningitis. One cause for acute swelling is infection. The yellow-tan exudate of acute bacterial meningitis seen here obscures the sulci.

Clinical Features

The most common symptoms in patient with pyogenic meningitis are fever (>40°C) and chills; severe headache localized to the forehead; stiff neck; back, abdominal, mental confusion, somnolence, photophobia, seizures, neurologic symptoms and extremity pains; nausea and vomiting. Patient experiences knee pain on flexion of hip joint is called Kernig sign. Upon flexion of the neck, there is spontaneous similar movement of the hips and knees are known as Brudzinski's sign. Clinical manifestations of pyogenic meningitis are shown in Fig. 30.5. Complications of pyogenic meningitis are given in Table 30.8.

Laboratory Diagnosis

Diagnosis of pyogenic meningitis is based on the history and physical examination, along with laboratory data. Lumbar puncture findings are necessary for accurate diagnosis. These include a cloudy and purulent CSF under increased pressure. CSF findings in pyogenic meningitis are given in Table 30.9.

- CSF typically contains large numbers of polymorphonuclear neutrophils (≤90,000/mm^3), increased protein content, and reduced sugar content. Bacteria can be seen on smears and can easily be cultured with appropriate media.
- Occasionally, previous antibiotic use limits culture sensitivities, in which case latex agglutination can be used, or polymerase chain reaction (PCR) testing for *Neisseria meningitidis*, *Haemophilus influenzae*, and *Listeria* species.

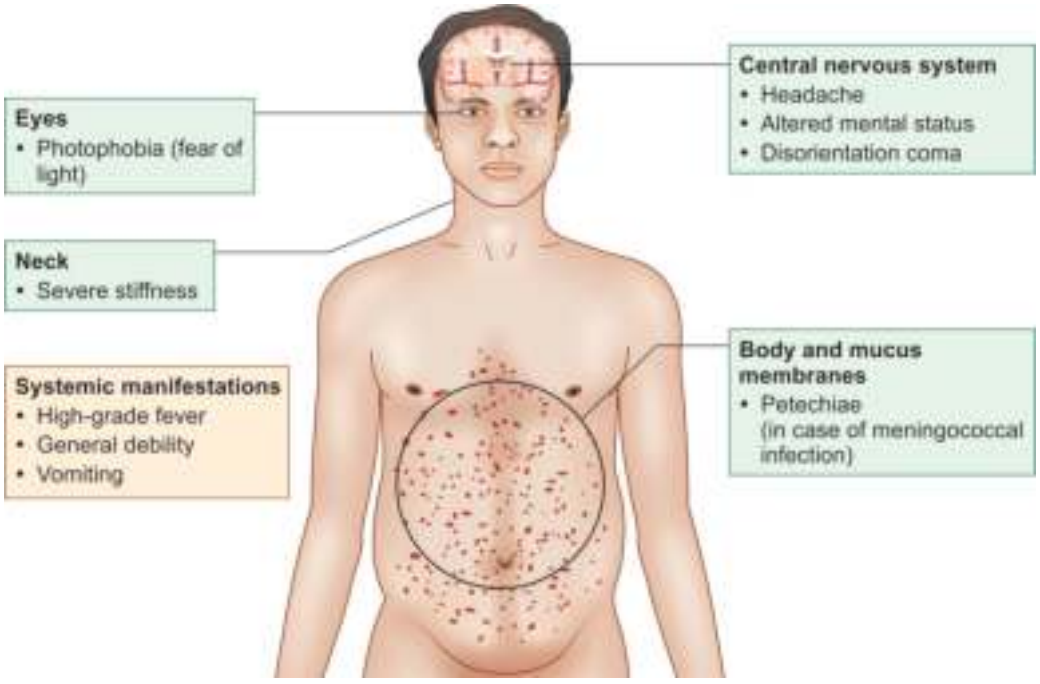

Fig. 30.5: Clinical manifestations of pyogenic meningitis.

Table 30.8 Complications of pyogenic meningitis

Cerebral infarction
Obstructive hydrocephalus
Cerebral abscess
Subdural empyema
Epilepsy (seizures) focal neurologic deficits
Cranial nerve palsies
Sensorineural hearing loss
Communicating and non-communicating hydrocephalus

Vaccination

Effective polysaccharide vaccines are available to protect against meningococcal groups A, C, Y, and W-135. These vaccines are now recommended for military recruits and college students, who are at increased risk for invasive meningococcal disease.

TUBERCULOUS MENINGITIS

Tuberculous meningitis has insidious onset and may last for weeks or months, which is secondary to tuberculous infection occurring elsewhere in the body. It has a predilection for the base of the brain. Basal cisterns and the lateral sulci contain gelatinous whitish gray material. Inadequately treated tuberculous meningitis results in meningeal fibrosis, communicating hydrocephalus and vasculitis. Inflammation of striate arteries results in cerebral infarcts.

Pathology

Tuberculous meningitis develops in two steps: (a) *Mycobacterium tuberculosis* bacilli, that enter the host by droplet inhalation and escalate within the lungs, and then disseminate to the regional lymph nodes and via hematogenous route to meninges or brain parenchyma resulting in the formation of small subpial or subependymal foci of disseminated caseous necrosis lesion, termed **Rich foci**. (b) Second step in the development of tuberculous meningitis is an increase in the size of Rich focus until it ruptures in the subarachnoid space of brain and spinal cord. Expansion of the tubercle 'Rich focus' determines the type of central nervous system involvement.

Clinical Pearls: Diagnostic Approach of Tuberculoma of the Brain

- Tuberculoma of the brain is an important clinical entity. It is main challenge in the management to diagnose it.
- CT scan of brain demonstrates solitary or multiple ring-enhancing lesion with moderate perilesional edema, but these findings are not specific for brain tuberculoma.
- Neurocysticercosis (NCC), coccidioidomycosis, toxoplasmosis, metastasis and few other diseases have identical appearance on CT scan of brain.
- Cerebrospinal fluid examination is most often normal.
- Magnetic resonance imaging (MRI) of brain with magnetic resonance spectroscopy (MRS) have advantage over CT scan in diagnosis of brain tuberculoma.
- Magnetic resonance spectroscopy (MRS) demonstrates a specific lipid peak in cases of brain tuberculoma, which is not seen in any other differential diagnosis of brain tuberculoma.
- Histologic examination of biopsy and tissue culture from the lesion can establish the diagnosis of tuberculoma.
- The tuberculoma consists of epithelioid cell granulomas, caseous necrosis and Langhans' giant cells (Fig. 30.6).

Clinical Features

Patient with tuberculous meningitis presents with headache, fever and stiff neck. Although the meningeal signs may be absent in the early stage of disease. The duration of symptoms before clinical presentation persist from several days to several weeks.

Laboratory Diagnosis

Tuberculous meningitis is difficult to diagnose. It is essential to enquire patient's history, including recent

Table 30.9 CSF findings in pyogenic meningitis

Features	Pyogenic Meningitis	Normal CSF
Causative organisms	*Escherichia coli*, Salmonella, *Haemophilus influenzae*, *Neisseria meningitidis*, streptococci or pneumococci	No organisms
CSF pressure	Increased	60–150 cm of H_2O (20 drops/minute)
Color	Opaque and turbid to frank pus	Clear, colorless
CSF proteins	Due to increased vascular permeability	Normal 15–40 mg%
CSF sugar	▪ ↓ or absent due to consumption by pyogenic bacteria ▪ CSF sugar:blood sugar ratio is <0.4	▪ 50–80 mg% ▪ CSF sugar:blood sugar ratio is 0.6
CSF white blood cells	Polymorphonuclear cells ≤90,000/mm^3	0–4 lymphocytes /mm^3
CSF culture	Positive in 70–80% of cases	Sterile
Gram staining	Sensitivity in 75–80% of cases	Organisms absent, hence insignificant

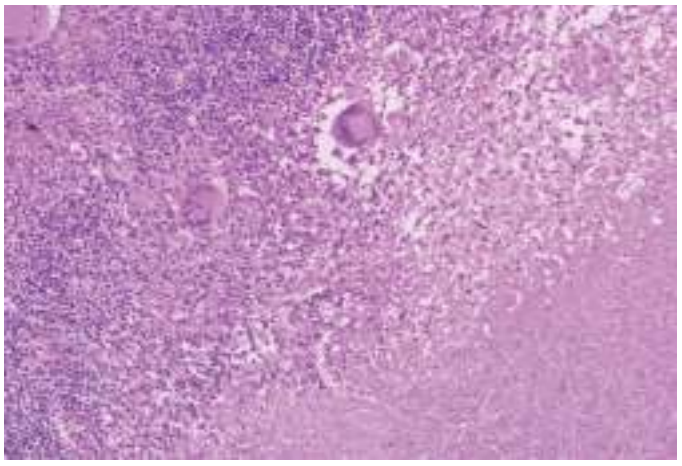

Fig. 30.6: Tuberculosis of brain. It shows epithelioid granulomas, Langhans giant cells and caseous necrosis (100X).

contact with patient suffering from tuberculosis. Lumbar puncture reveals increased cerebrospinal pressure yielding straw-colored cerebrospinal fluid (CSF). Proteins content is markedly increased. Light microscopy of CSF shows numerous lymphocytes. Acid-fast bacteria may be grown on culture media. CSF findings in tuberculous meningitis are given in Table 30.10.

VIRAL MENINGITIS

Viral meningitis may be caused by many different viruses, most often enteroviruses (echoviruses 3, 7, 9, 11, 21, 30), including coxsackieviruses (B1-5 and A-9), poliovirus, and echovirus. Others include Epstein-Barr virus, mumps virus, HSV, and West Nile virus.

- Viruses are most often transmitted by fecal–oral route. It is worth mentioning that herpesviruses especially HHV6 residing in the trigeminal ganglion of infected persons can also infect brain. Rabies virus ascends into brain along with the axons of peripheral nerves.
- The clinical manifestations of viral infections of CNS parenchyma are heterogeneous, owing to viral tropism to specific regions of the brain.
- The classic hallmark of most CNS viral infections is the presence of perivascular lymphocytes around arteries and arterioles.
- Viral meningitis is less severe than bacterial meningitis. Viral infections are limited to the meninges. It seldom involves the brain or spinal cord.
- The acute viral meningitis is self-limited and usually require only symptomatic treatment, except for herpes simplex virus (HSV) type 2, which responds to intravenous acyclovir.

Laboratory Diagnosis

Cerebrospinal fluid examination demonstrates moderately increase in CSF pressure and proteins with normal sugar. Light microscopy shows increase in lymphocytes in the cerebrospinal fluid rather than polymorphonuclear cells. Although often the virus cannot be identified, newer assays are emerging that allow in some circumstances for rapid identification of viral ribonucleic acid (RNA) in CSF. Cerebrospinal fluid findings in viral meningitis are given in Table 30.11.

FUNGAL MENINGITIS

Meningitis caused by fungi has insidious onset and may last for weeks or months. *Cryptococcus neoformans*, *Coccidioides immitis*, Aspergillus, or *Histoplasma capsulatum* involve the brain substance or the meninges in immunocompromised persons.

- *Cryptococcus neoformans* is the most common virulent fungi causing fungal meningitis in immunocompromised persons especially in AIDS patients. *Cryptococcus neoformans* is demonstrated by mixing a drop of infected CSF with India ink. Histopathologic examination shows a clear halo about the encapsulated organism.
- Histologic identification of *Cryptococcus neoformans* can be performed by methenamine silver stain for yeast forms and mucicarmine stain for yeast and capsule forms and Fontana-Masson stain for the melanin in the yeast.

Table 30.10 Cerebrospinal fluid (CSF) findings in tuberculous meningitis

Features	Tubercular Meningitis	Normal CSF
Causative organism	Mycobacterium tubercle bacillus	No organisms
CSF pressure	Increased	60–150 cm of H_2O (20 drops/minute)
Color	Straw colored	Clear and colorless
CSF proteins	Increased due to increased vascular permeability	Normal 15–40 mg%
CSF sugar	Within normal range	50–80 mg%
CSF white blood cells	Lymphocytes increased	0–4 lymphocytes/mm^3
ZN staining	Acid-fast bacteria demonstration	Organisms absent, hence insignificant
CSF culture	Bacterial growth on LJ medium	Sterile

Table 30.11 Cerebrospinal fluid (CSF) findings in viral meningitis

Features	Viral Meningitis	Normal CSF
Causative organism	Enteroviruses (echoviruses 3, 7, 9, 11, 21, 30), including coxsackieviruses (B1–5 and A-9), poliovirus, and echovirus. Others include Epstein-Barr virus, mumps virus, HSV, and West Nile virus	No organisms
CSF pressure	Increased	80–180 cm of H_2O (20 drops/min)
Color	Clear colorless	Clear, colorless
CSF proteins	↑ due to increased vascular permeability	Normal 15–40 mg%
CSF sugar	Normal range	50–80 mg%
CSF white blood cells	Lymphocytes increased	0–4 lymphocytes/mm^3

IATROGENIC MENINGITIS

Iatrogenic meningitis is a rare, but potentially fatal complication of diagnostic and therapeutic lumbar puncture (LP).

- Therapeutic administration of procaine or methotrexate in neurosurgical procedures may produce sterile chemical meningitis, iatrogenic bacterial meningitis (IBM) is a rare but serious complication of neuraxial procedures such as spinal and epidural anesthesia or lumbar puncture.
- The cerebrospinal fluid (CSF) culture is positive for *Pseudomonas aeruginosa* and *Staphylococcus aureus*.

METASTATIC CANCER-INDUCED MENINGITIS

Metastatic cancer-induced meningitis results from metastatic spread of cancer to the leptomeninges of central nervous system.

- Lymphoma, breast carcinoma, melanoma, and lung carcinoma (especially small cell lung carcinoma) are associated with the greatest predilection to metastasize to the subarachnoid space. Patient has overall median survival of 2–4 months.
- There are many new approaches to the diagnosis and treatment of metastatic cancer-induced meningitis that promise to extend life and prevent disability. Leptomeningeal metastatic cancer-induced meningitis is diagnosed by molecular techniques.
- Patients are treated by drugs available for intrathecal administration, using systemic chemotherapy; and applying strategies such as gene therapy and immunotoxins to the management of leptomeningeal metastases.
- Leptomeningeal metastases consist of atypical tumor cells growing either attached to the pia mater of brain and spinal cord or floating in the cerebrospinal fluid (CSF) in the subarachnoid space, that provides hospitable environment for the growth of metastatic tumor cells.
- Rich vascular supply of meninges provides hematogenous metastatic tumor cells access to the subarachnoid space.
- Cerebrospinal fluid has high content of glucose and oxygen to support metastatic tumor cells with high metabolic activity.
- Leptomeningeal metastases can therefore, escape from the need for angiogenesis, which limits the growth of parenchymal metastases.

ENCEPHALITIS

PARASITIC ENCEPHALITIS

Parasitic encephalitis occurs due to neurocysticercosis, cerebral malaria, amoebic encephalitis and toxoplasmosis.

Neurocysticercosis

Neurocysticercosis is a common CNS parasitic infection and seizures worldwide caused by *Taenia solium*. Death of the parasite triggers granulomatous inflammatory response. Inflammation subsides over months to years and cyst becomes small fibrotic calcified nodule.

Cerebral Malaria

Cerebral malaria is caused by lodging of parasitized RBCs within the microvasculature of the brain and accompanied by petechial hemorrhages in the white matter around necrotic blood vessels. Prompt treatment with corticosteroids and antimalarial drugs reduces mortality.

Amoebic Encephalitis

Amoebic encephalitis is caused by highly lethal CNS infection caused by free-living amoebae found in

rivers such as *Naegleria fowleri*, *Balamuthia mandrillaris* and *Acanthamoeba* species. *Naegleria fowleri* enters CNS through cribriform plates during swimming. Patient develops acute meningitis progressing to coma and death. Organisms are demonstrated in subarachnoid space. It is worth mentioning that *Entamoeba histolytica* causes brain abscess.

Toxoplasma Gondii Encephalitis

Toxoplasma gondii is a parasite causing brain infection. It is one of the TORCH infections. It is transmitted via transplacental route in neonates, and ingestion of contaminated food due to urine or feces of household cats and pets. Newborn manifests with hydrocephalus, mental retardation, neurologic abnormalities of cerebral cortex, basal ganglia, retinae, and involvement of heart, lungs, and liver. Calcification in periventricular is demonstrated on radiograph. Immunocompromised adults present with lymphadenitis and CNS involvement.

VIRAL ENCEPHALITIS

Inflammation of the brain parenchyma is most often caused by viruses. It may be diffuse/localized inflammation of brain. The nervous system is subject to invasion by many viruses such as arbovirus, poliovirus, and rabies virus.

- Person contracts arbovirus infection from reservoirs such as horses, birds and mosquitoes.
- Herpes simplex encephalitis is most common in teenagers and young adults. Herpes simplex targets the temporal lobes by binding on the plasma membranes of CNS cells. The virus has ability to remain latent or selective replication in distinct intracellular microenvironments.

Mode of Transmission

The mode of transmission of arbovirus may be due to bite of mosquito, rabid animal such as dog, fox and bat (rabies virus in saliva), or ingestion (poliovirus). Common causes of encephalitis in the United States are HSV and West Nile virus. Patient develops severe encephalitis with increased excitability of the CNS.

Clinical Features

Patient suffering from rabies presents with hydrophobia (fear from water) characterized by violent muscle contractions and convulsions. It is usually fatal once clinical signs develop.

Surgical Pathology: Viral Encephalitis

Light Microscopy

- Light microscopy of affected brain shows eosinophilic intracytoplasmic inclusions (Negri bodies) in the hippocampus and Purkinje cells of the cerebellum.
- Brainstem and spinal cord show neuronal degeneration, perivascular accumulations of mononuclear cells.

CEREBRAL ABSCESS

Cerebral abscess is a focal area necrosis with surrounding membrane within the brain parenchyma usually resulting from infectious process by bacteria, *Entamoeba histolytica* and fungi.

- Cerebral abscess can result from penetrating skull injuries, which may be solitary or multiple.
- Cerebral abscess can originate directly from otitis media, mastoiditis secondarily cause inferior temporal lobe and cerebellar abscesses, paranasal sinuses infections, dental infection and facial trauma. Metal fragments or other foreign bodies left in the brain parenchyma can also serve as a nidus for infection.
- Bacteria may gain entry via hematogenous route from bronchopulmonary infections (bronchiectasis, lung abscess, emphysema), pulmonary arteriovenous malformation, and bronchopleural fistula, cyanotic congenital heart diseases, bacterial endocarditis, ventricular aneurysms, skin infection, pelvi infection and intra-abdominal infection.
- Cerebral abscesses associated with bacteremia usually cause multiple abscesses mostly in the distribution of the middle cerebral artery and usually at the gray and white matter junction. Most important bacteria isolated from cerebral abscess are *Staphylococcus aureus* and *Streptococcus viridans*.

Pathophysiology

Damaged brain tissue and immunosuppression contribute to cerebral abscess in some cases. Cerebral abscess matures over two weeks' period. Initially vascular endothelial swelling occurs within 1–2 days followed by neutrophilic infiltration over 3–4 days. Chronic inflammatory cells composed of macrophages, lymphocytes and plasma cells are present over 5–7 days. Granulation tissue is formed over 8–14 days, which is followed by fibrosis (gliosis).

Clinical Features

The triad of fever, headache, and the focal neurologic deficit is observed in 50% of cerebral abscess patients.

Patient presents with headache, lethargy, focal neurological deficits, seizures (frontal lobe abscess), nausea, vomiting, nuchal rigidity (occipital lobe abscess), third and sixth cranial deficits. Rupture of cerebral abscess presents with sudden worsening headache and followed by emerging signs of meningismus.

Laboratory Diagnosis

Routine tests carried out include total and differential leukocyte count, erythrocyte sedimentation rate, platelet count, C-reactive protein, blood culture at least twice preferably before antibiotic therapy. CT scan and MRI scan are done to rule out increased intracranial pressure. Lumbar puncture is rarely required. Stereotactic CT-guided surgical aspiration is performed to obtain a sample for culture, Gram stain, serology, histopathology and polymerase chain reaction.

Treatment

Cerebral abscess is treated by medical and surgical approaches. Patient is treated with specific medicines targeting the etiological pathogens. Steroids can be considered in selected patients specially to reduce the brain abscess mass effect and improve antibiotic penetration and cerebral edema. The surgical approach has important role in the management of brain abscess. CT-guided needle aspiration is performed via stereotactic procedure, burr hole and craniotomy for loculated multiple abscess. Intravenous or intrathecal agents are administered against specific microorganism along with surgical procedure.

TABES DORSALIS IN TERTIARY SYPHILIS

Tabes dorsalis is a manifestation of tertiary syphilis involving the lumbar spinal cord. Patient develops chronic fibrosing syphilitic meningitis, and compression of the posterior nerve roots (carrying sensory nerves) associated with lancinating pain in extremities. It also damages the transmission of proprioceptive impulses, causing gait disturbances (ataxia). Joint deformities are common and known as Charcot joints.

Surgical Pathology: Tabes Dorsalis
Gross Morphology
Focal irregular thickening is seen around spinal cord but may be seen over the convexity of the brain or over the cerebellum.
Light Microscopy
▪ Tertiary syphilis may also present in the form of granulomatous inflammation (gumma syphilis). ▪ Meninges contain infiltrates of lymphocytes and plasma cells, typically arranged around the meningeal blood vessels.

CENTRAL NERVOUS SYSTEM TUMORS

Primary brain tumors account for 2% of all cancer deaths. Brain tumors can arise from neuroepithelial tissue, non-neuroepithelial tissue and metastases. Intracranial brain tumors are more frequent than spinal cord neoplasms. All brain tumors are malignant except meningioma and schwannoma.

- Primary malignant of CNS tumors rarely metastasize. Most often, metastatic brain tumors occur secondary to breast carcinoma, lung carcinoma, colorectal carcinoma, renal cell carcinoma, and malignant melanoma.
- Astrocytoma, glioblastoma multiforme, ependymoma and oligodendroglioma arising from neuroglial tissue occur in the temporoparietal regions. Astrocytoma is the most common tumor in adults. Neuron-specific enolase and synaptophysin are markers for neurons.
- World Health Organization (WHO) system updated in 2021 is the most widely used classification system for CNS tumors based on histopathologic characteristics with addition of genetic basis of tumorigenesis and molecular markers. This classification provides prognostic or predictive data analysis within diagnostic categories established by conventional histology which help effective targeted therapy.
- Revised 2021 WHO classification of tumors of central nervous system is given in Table 30.12. Anatomic predilection of primary central nervous system tumors is given in Table 30.13 and Figs 30.7 to 30.9.

NERVOUS SYSTEM TUMORS: OVERVIEW

PRIMARY NERVOUS SYSTEM TUMORS

Most primary brain tumors are derived from neuroglial cells. These tumors are characterized by an extensive infiltration of growth into the surrounding brain parenchyma and confined to the central nervous system, and the tumor metastasis to other organs is rare. Because leptomeningeal tissue is barrier against tumor invasion. However, other tumors of non-neural origin may frequently metastasize to the central nervous system.

- In adults, the majority of intracranial tumors (70%) originate in the supratentorial region, which include glioblastoma multiforme, meningioma, ependymoma and acoustic neuroma in order of frequency.

Table 30.12 Revised 2021 WHO classification of tumors of central nervous system

Astrocytic Tumors	
▪ Adult-type diffuse gliomas	▪ Diffuse pediatric-type high-grade glioma, H3-wildtype and IHD-wildtype
▪ Astrocytoma, IHD-mutant (grade II)	▪ Infant-type hemispheric glioma
▪ Oligodendroglioma, IHD-mutant and 1p/19q-codeleted	▪ Circumscribed astrocytic glioma
▪ Glioblastoma, IHD-wildtype (grade IV)	▪ Pilocytic astrocytoma
▪ Pediatric-type diffuse low-grade gliomas	▪ High-grade astrocytoma with piloid features
▪ Diffuse astrocytoma, MYB- or MYBL1-altered	▪ Pleomorphic xanthoastrocytoma
▪ Angiocentric glioma	▪ Subependymal giant cell astrocytoma
▪ Polymorphous low-grade neuroepithelial tumor of the young	▪ Choroid glioma
▪ Diffuse low-grade glioma, MAPK pathway-altered	▪ Astroblastoma, MN1-altered
▪ Pediatric-type diffuse high-grade gliomas	▪ Glioneuronal and neuronal tumors
▪ Diffuse midline glioma, H3K27M-altered (grade IV)	
▪ Diffuse hemispheric glioma, H3G34-mutant	
Glioneuronal and Neuronal Tumors	
▪ Ganglioglioma	▪ Myxoid glioneuronal tumor
▪ Desmoplastic infantile ganglioglioma/desmoplastic infantile astrocytoma	▪ Diffuse leptomeningeal glioneuronal tumor
▪ Dysembryoplastic neuroepithelial tumor	▪ Gangliocytoma
▪ Diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters	▪ Multinodular and vacuolating neuronal tumor
▪ Papillary glioneuronal tumor	▪ Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease)
▪ Rosette-forming glioneuronal tumor	▪ Central neurocytoma
	▪ Extraventricular liponeurocytoma
Ependymal Tumors	
▪ Supratentorial ependymoma	▪ Spinal ependymoma
▪ Supratentorial ependymoma, ZFTA fusion-positive	▪ Spinal ependymoma, MYCN-amplified
▪ Supratentorial ependymoma, YAP1 fusion-positive	▪ Myxopapillary ependymoma
▪ Posterior fossa ependymoma, group PFA	▪ Subependymoma
▪ Posterior fossa ependymoma, group PFB	
Choroid Plexus Tumors	
▪ Choroid plexus papilloma	▪ Choroid plexus carcinoma (grade III)
▪ Atypical choroid plexus papilloma	
Tumors of the Pineal Region	
▪ Pineocytoma	▪ Papillary tumor of the pineal region
▪ Pineal parenchymal tumor of intermediate differentiation	▪ Desmoplastic myxoid tumor of the pineal region, SMARCB1-mutant
▪ Pineoblastoma (grade IV)	
Embryonal Tumors	
▪ Medulloblastoma	▪ Medulloblastoma, SHH-activated and TP53-mutant
▪ Medulloblastoma, molecularly defined	▪ Medulloblastoma, non-Wnt/non-SSH
▪ Medulloblastoma, Wnt-activated	▪ Medulloblastoma, histologically defined (grade IV)
▪ Medulloblastoma, SHH-activated and TP53-wildtype	
Other Embryonal Tumors	
▪ Schwannoma	▪ CNS neuroblastoma, FOXR2-activated
▪ Atypical teratoid/rhabdoid tumor	▪ CNS tumor with BCOR internal tandem duplication
▪ Cribriform neuroepithelial tumor	▪ CNS embryonal tumor
▪ Embryonal tumor with multilayered rosettes	

Contd...

Table 30.12 Revised 2021 WHO classification of tumors of central nervous system (*Contd...*)

Cranial and Paraspinal Tumors	
▪ Schwannoma ▪ Neurofibroma ▪ Perineuroma ▪ Hybrid nerve sheath tumor	▪ Malignant melanocytic nerve sheath tumor ▪ Paraganglioma ▪ Meningiomas
Mesenchymal and Non-meningoepithelial Tumors	

▪ Soft tissue tumors
  • Fibroblastic and myoblastic tumors
  • Solitary fibrous tumor
▪ Vascular tumors
  • Hemangiomas and vascular malformations
  • Hemangioblastoma
▪ Skeletal muscle tumors
  • Rhabdomyosarcoma
	▪ Tumors of uncertain differentiation
	  • Intracranial mesenchymal tumor, FET-CREB fusion-positive
	  • Sarcoma with CIC-rearrangement
	  • Primary intracranial sarcoma, DICER1-mutant
	  • Ewing sarcoma
	▪ Chondro-osseous tumors
	  • Chondrogenic tumors
	  • Mesenchymal chondrosarcoma

Notochordal Tumors	
▪ Chordoma	▪ Poorly differentiated chordoma
Melanocytic Tumors	
▪ Diffuse meningeal melanocytic neoplasms ▪ Meningeal melanocytosis and meningeal melanomatosis	▪ Circumscribed meningeal melanocytic neoplasms ▪ Meningeal melanocytoma and meningeal melanoma
Hematolymphoid Tumors	
▪ CNS lymphoma ▪ Primary diffuse large B cell lymphoma of the CNS ▪ Immunodeficiency-associated CNS lymphomas ▪ Lymphomatoid granulomatosis ▪ Intravascular large B cell lymphoma	▪ Miscellaneous rare lymphomas in the CNS ▪ MALT lymphoma of the dura ▪ Low-grade B-cell lymphoma of CNS ▪ Anaplastic large cell lymphoma (ALK+/ALK–) ▪ T cell and NK/T cell (natural killer/T cell) lymphomas
Histiocytic Tumors	
▪ Erdheim-Chester disease ▪ Rosai-Dorfman disease ▪ Juvenile xanthogranuloma	▪ Langerhans cell histiocytosis ▪ Histiocytic sarcoma
Germ Cell Tumors	

▪ Germinoma
▪ Embryonal carcinoma
▪ Yolk sac tumor (endodermal sinus tumor)
▪ Choriocarcinoma
	▪ Teratoma
	  • Mature teratoma
	  • Immature teratoma
	  • Teratoma with somatic type malignancy
	▪ Mixed germ cell tumor

Tumors of the Sellar Region	
▪ Adamantinomatous craniopharyngioma ▪ Papillary craniopharyngioma ▪ Pituicytoma, granular cell tumor of the sellar region, and the spinal cell oncocytoma	▪ Pituitary adenoma/pituitary neuroendocrine tumor (PitNET) ▪ Pituitary blastoma
Metastatic Tumors	
▪ Metastases to the brain and spinal cord parenchyma	▪ Metastases to meninges

Adapted from 2021 WHO classification of tumors of the central nervous system (5th edition)
SSH (sonic Hedgehog)
Histologic variants of meningiomas under cranial and spinal tumors include: meningoepithelial, fibrous, transitional, psammomatous, angiomatous, microcytic, secretory, lymphoplasmacytic-rich, metaplastic, choroid, clear cell, atypical, papillary, rhabdoid anaplastic types.

Table 30.13 Anatomic predilection of primary central nervous system tumors

Anatomic Predilection	Primary Central Nervous System Tumors	
Cerebral hemispheres	▪ Glioblastoma multiforme ▪ Astrocytoma	▪ Oligodendroglioma
Meninges	Meningioma	
Ventricles	▪ Ependymoma (children)	▪ Choroid plexus papilloma
Cerebellum	▪ Astrocytoma (children) ▪ Hemangioblastoma	▪ Medulloblastoma
Medulla and spinal cord	▪ Glioblastoma multiforme ▪ Astrocytoma (adults)	▪ Ependymoma of cauda equina (adults)
Cranial nerve	Schwannoma	

All brain tumors are malignant except for meningioma and schwannoma.

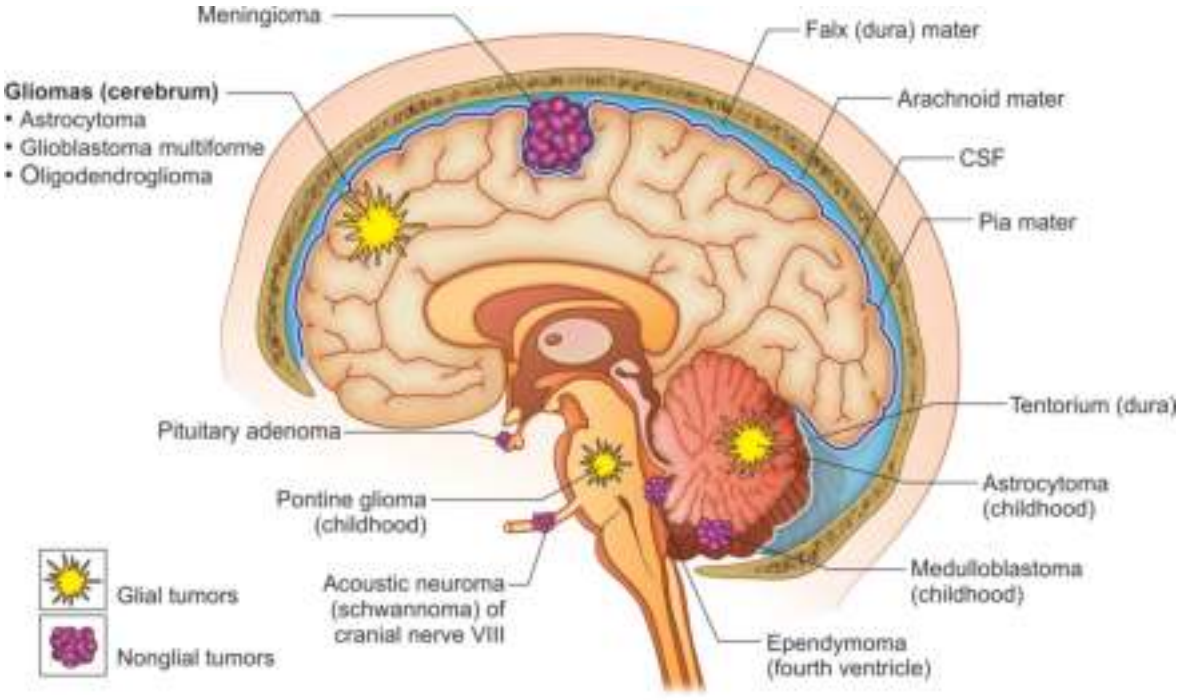

Fig. 30.7: Most common intracranial primary central nervous system tumors.

- In children, the majority of intracranial tumors originate in the infratentorial region, which include cerebellar astrocytoma, medulloblastoma, glioma in brainstem, and ependymoma in the fourth ventricle in order of frequency.

Predisposing Factors

Exposure to environmental (tobacco smoke) and occupational agents (vinyl chloride and EB virus); immunosuppression (organ transplant and HIV) and familial tumor syndromes and related chromosomal abnormalities increase the risk for primary brain tumors (Tables 30.14 and 30.15).

Molecular Genetic Alterations

Several molecular genetic alterations have emerged in recent years as powerful prognostic factors in diffuse glioma (astrocytoma, oligodendroglioma, mixed glioma, and glioblastoma). These molecular genetic alterations may guide patient management.

- Specific molecular genetic alterations include: (a) DNA methylation of the 6-methylguanine-DNA methyltransferase (MGMT) gene promoter, (b) mutation of isocitrate dehydrogenase (IDH), i.e. IDH1 or IDH2 genes, and (c) codeletion of chromosomes 1p and 19q.

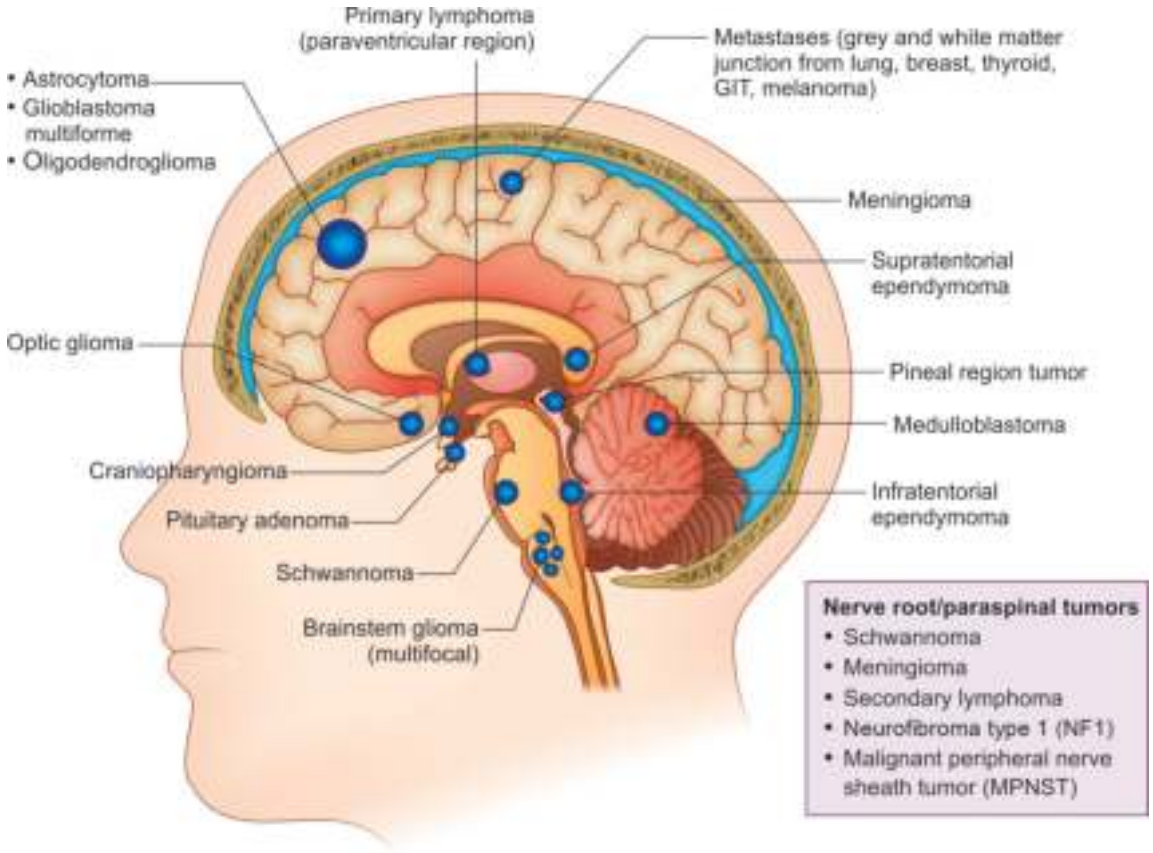

Fig. 30.8: Common primary CNS tumors in adults.

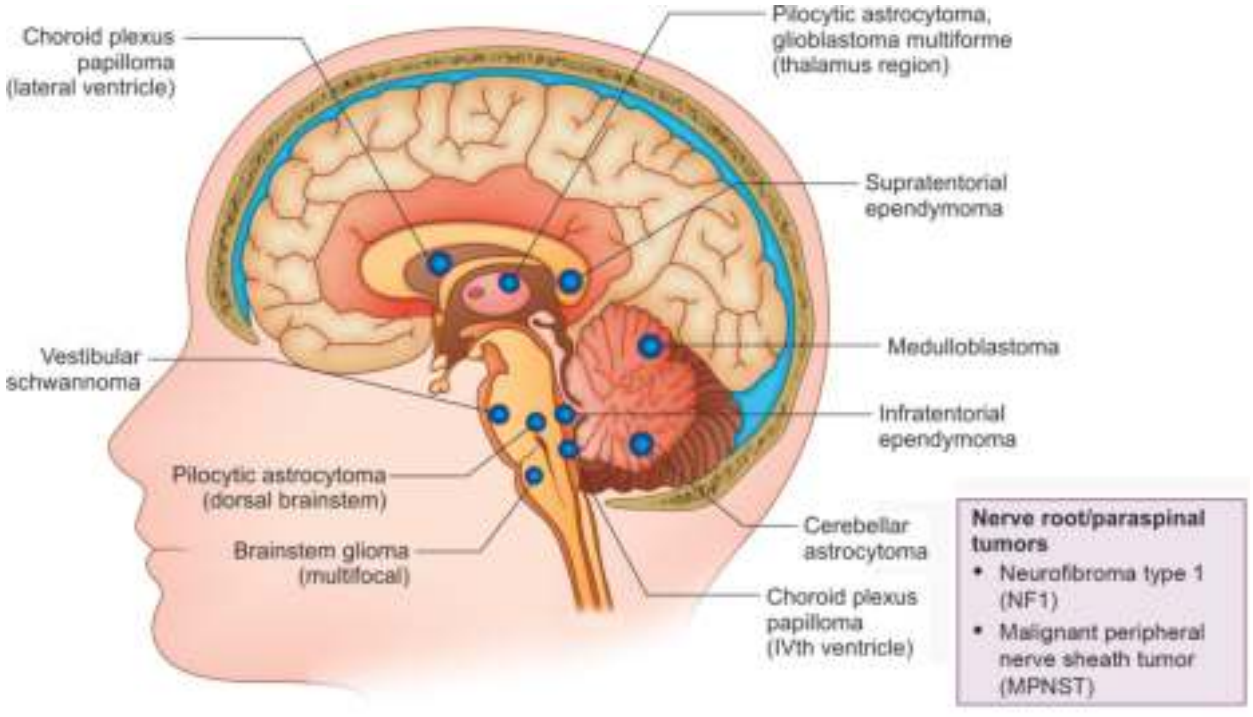

Fig. 30.9: Common primary CNS tumors in children.

Table 30.14 Environmental and occupational predisposing factors for primary CNS tumors

Predisposing Risk Factors	Primary CNS Tumors
Tobacco smoking	Brain tumors
Exposure to vinylchloride	Glioma
Epstein-Barr virus infection	CNS lymphoma
Transplant recipients and patients with AIDS	CNS lymphoma

- Main molecular markers used in diagnosis of gliomas include isocitrate dehydrogenase (IDH), i.e. IDH1 and IDH2, 1p19q codeletion, MGMT, TERT, ATRX and TP53 genes, which are of diagnostic significance. Molecular genetic markers for diagnosis of brain tumors are given in Table 30.16. Oncogenes and tumor suppressor genes (inactivated/biallelic loss) associated with primary CNS tumors are given in Tables 30.17 and 30.18.

Table 30.15 The familial tumor syndromes and related chromosomal abnormalities that are associated with CNS neoplasms

Syndrome	Chromosome
Neurofibromatosis type 1	17q11
Neurofibromatosis type 2	22q12
von Hippel-Lindau disease	3p25–26
Tuberous sclerosis	9q34, 16p13
Li-Fraumeni syndrome	17p13
Turcot syndrome type 1	3p21, 7p22
Turcot syndrome type 2	5q21
Nevoid basal cell carcinoma syndrome	9q22.3

Table 30.16 Molecular genetic markers for diagnosis of brain tumors

Tumor	Molecular Genetic Markers
Astrocytoma	IDH1, IDH2, TP53, ATRX
Oligodendroglioma	IDH1, TERT, 1p/19q codeletion
Glioblastoma	IDH1, TERT, MGMT methylation
Diffuse midline glioma, H3K27M-mutant	H3K27M-mutant, TP53, ATRX

IDH: Isocitrate dehydrogenase, TP53: Tumor protein 53, ATRX: Alpha-thalassemia/mental retardation syndrome X-linked, MGMT: O-6-methylguanine-DNA methyltransferase.

Table 30.17 Oncogenes associated with primary CNS tumors

Category	Proto-oncogene	Mode of Activation	Associated Malignancies
Growth factors			
PDGFB chain	PDGFB (*sis*-Simian sarcoma)	Overexpression	▪ Astrocytoma ▪ Osteosarcoma
TGFA	TGFA	Overexpression	Astrocytoma
Growth factor receptors			
PDGF receptor	PDGFRB	▪ Overexpression ▪ Translocation	▪ Glioma ▪ Leukemia
Cyclin-dependent kinases (cell cycle regulators)			
Cyclin-dependent kinase	CDK4	Amplification or point mutation	▪ Glioblastoma multiforme ▪ Melanoma ▪ Sarcoma

Table 30.18 Tumor suppressor genes (inactivated/biallelic loss) associated with primary CNS tumors

Gene	Protein	Function	Familial Tumors	Sporadic Cancers
Mitogenic signaling pathway inhibitors				
NF1	▪ Neurofibromin 1 (locus 17p11) ▪ Mutation occurs by deletion	NF1 inhibits RAS/MAP-kinase signaling activator pathway	Neurofibromatosis type 1 (neurofibroma and malignant peripheral nerve tumors)	▪ Schwannoma ▪ Neuroblastoma ▪ Juvenile myeloid leukemia

Contd...

Table 30.18 Tumor suppressor genes (inactivated/biallelic loss) associated with primary CNS tumors (*Contd...*)

Gene	Protein	Function	Familial Tumors	Sporadic Cancers
NF2	▪ Merlin (locus 22q) ▪ NF2 stabilizes cytoskeleton membrane linkage	Mutation by deletion or nonsense mutation	Neurofibromatosis type 2 (acoustic schwannoma and meningioma)	▪ Schwannoma ▪ Meningioma
PTCH	Patched	Inhibits Hedgehog signaling pathway	Gorlin's syndrome (basal cell carcinoma, medulloblastoma, other benign tumors)	▪ Medulloblastoma ▪ Basal cell carcinoma
Cell cycle progression inhibitors				
RB gene	▪ Retinoblastoma protein (locus 13p14) ▪ Mutation by deletion and nonsense	RB gene codes for pRB protein, master brake on cell cycle. It inhibits G1 to S transition during cell cycle. It inhibits nuclear transcription factor	▪ Retinoblastoma ▪ Osteosarcoma	▪ Retinoblastoma ▪ Osteosarcoma ▪ Breast carcinoma ▪ Colon carcinoma ▪ Prostatic carcinoma ▪ Urinary bladder carcinoma ▪ Lung carcinoma

Molecular Genetic Alterations in Primary Brain Tumors

- **IDH mutations:** Both IDH1 and IDH2 are enzymes in Krebs' cycle which catalyzes the conversion of isocitrate to α-ketoglutarate.
  - IDH1 involves an amino acid substitution (glycine to arginine) in the active site of the enzyme in codon 132 (R132H) resulting in the abnormal production of 2-hydroxyglutarate, which causes histone and DNA methylation, hence promoting tumorigenesis.
  - IDH2 mutation involves codon 172 results in seizures, weak muscle tone (hypotonia), and progressive damage to the cerebrum. IDH is most important diagnostic marker, that can differentiate glioma from gliosis.
  - IDH is positive in astrocytoma, oligodendroglioma, and secondary glioblastoma (10%).
  - IDH1 or IDH2 mutation can be demonstrated by immunohistochemistry using gene mutation-specific antibody against R132H mutant IDH1. If immunohistochemical analysis is negative, then it should be followed by IDH1/IDH2, DNA genotyping.
  - Mutation in both IDH1 and IDH2 entity is known as IDH mutant and if both are negative then it is known as IDH wildtype. If IDH testing is not available or cannot be fully performed or is inconclusive, then it is labeled as IDH glioma, NOS.
- **1p/19q codeletion:** In 1p/19q codeletion, there is complete deletion of both the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q).
  - 1p/19q codeletion can be demonstrated by fluorescent *in situ* hybridization (FISH), polymerase chain reaction (PCR), chromogenic in situ hybridization (CISH), or molecular genetic testing for diagnosis of grade II and grade III (anaplastic) oligodendroglioma.
  - 1p/19q codeletion is a strong prognostic factor associated with improved survival and also a predictive factor for response to chemotherapy as well as radiotherapy.
- **O-6-Methylguanine-DNA methyltransferase (MGMT) methylation mutations:** O-6-Methylguanine-DNA methyltransferase (MGMT) methylation gene encodes a DNA repair enzyme that can nullify the effects of alkylating chemotherapy such as temozolomide. Alkylating chemotherapeutic drugs cause damage to DNA by adding methyl group. Therefore, a brain tumor with a high degree of MGMT activity will become resistant to chemotherapies which target DNA at this location.
  - Addition of methyl group to the promoter region of MGMT results in silencing of the gene. Removal of methyl group to the promoter region of MGMT gene results in activation of the gene.
  - If the MGMT gene is active, the DNA is rapidly repaired. Methylation of the MGMT gene promoter is a favorable prognostic and predictive factor in glioblastoma patients, but it is not a diagnostic marker for the same.
- **Telomerase reverse transcriptase (TERT) promoter mutations:** TERT mutations involve C228T and C250T mutations of the promoter region. TERT promoter mutations and long telomere length predict radiotherapy resistance in gliomas and poor survival. TERT gene mutations most often occur in glioblastoma and oligodendroglioma.
- **α-Thalassemia/mental retardation syndrome X-linked (ATRX):** ATRX is a chromatin remodeling protein essential in DNA replication, gene transcription, chromosome congression (assembly), and cohesion between cell division.
  - ATRX mutation leads to lengthening of telomerase, that helps in chromatic maintenance and remodeling. Immunohistochemical analysis demonstrates positive staining of cells with normal ATRX.
  - If ATRX mutation is present, then there will be a loss of staining in the cells.
  - ATRX mutations are almost always accompanied by other mutations such as IDH, TP53, and H33K27M in the histone regulation.

- Loss of ATRX expression is demonstrated in anaplastic astrocytomas (45%), anaplastic oligoastrocytomas (27%), and anaplastic oligodendrogliomas (10%) and also in pediatric and adult high-grade astrocytoma.

- **TP53 mutation:** The TP53 is a tumor suppressor gene located on the short arm of chromosome 17. Loss of TP53 results in DNA damage, hypoxia, oxidative damage, oncogene activation, microtubule disruption, which in turn contributes to the tumorigenesis of CNS tumors mainly medulloblastoma, glioblastoma, and in IDH-mutant astrocytomas (56–58%). Astrocytomas demonstrate mutations of both TP53 and IHD1.

Clinical Features

The clinical presentation of various primary brain tumors is best appreciated by considering the relationship of signs and symptoms to anatomy.

- General signs and symptoms include headache, seizures, visual disturbances, anorexia, nausea, vomiting and changes in personality, mood, mental capacity, and concentration.
- Seizures are the presenting symptom in about 20% of patients with supratentorial slow-growing brain tumors in the supratentorial region over months to years before the clinical diagnosis. All patients with either primary brain tumors or metastatic brain tumors can present with seizures.

Imaging Techniques

Contrast-enhanced computed tomography (CT) scan and magnetic resonance imaging (MRI) have complementary roles in the diagnosis of CNS neoplasms. CT scan is superior to detect calcifications, skull lesion and bleeding of <24 hours, and thus helps diagnosis and immediate management.

- High-quality MRI is the diagnostic tool of choice in the evaluation of intramedullary and extramedullary spinal cord lesions.
- When a glioma spreads across the corpus callosum into both hemispheres of the brain, the tumor often has the appearance of a butterfly on a CT scan or MRI scan. Hence, it is given the general term 'butterfly glioma'.

Surgical Pathology: Primary Brain Tumors

Gross Morphology

- Fast growing primary brain tumors may have apparent pseudocapsule.
- Primary large size brain tumors are poorly delineated. When a glioma spreads across the corpus callosum into both hemispheres of the brain, the tumor often has the appearance of a butterfly, hence it is known as butterfly glioma.
- Peritumoral edema is most commonly demonstrated.
- Cut section of brain tumor gives variegated appearance, i.e. yellowish necrotic central area, grayish peripheral rim, recent and old hemorrhage, cysts due to liquefaction of the necrotic tissue.

Light Microscopy

Salient features of selected primary central nervous system tumors including metastatic tumors are given in Table 30.19.

Immunohistochemistry Technique

Immunohistochemistry (IHC) is a powerful microscopy-based diagnostic technique, which involves the process of selectively identification of target antigen (protein) in the cells of a tissue section by exploiting the principle of antibodies binding specifically to antigens in biological tissues (Tables 30.20 to 30.22).

Table 30.19 Salient features of selected primary central nervous system tumors including metastatic tumors

Histologic Variants	Age Predilection	Most Frequent Site	Characteristics
Glioblastoma multiforme	Older persons (40–70 years)	Cerebral hemispheres frontal lobe, crossing corpus callosum involving opposite cerebral hemisphere	▪ Most common highly malignant intracranial tumor ▪ Butterfly shaped tumor on MRI ▪ Increased intracranial pressure and seizures ▪ Dual loss of 1p,19q associated with good prognosis ▪ Mutations of EGFR, MDM2, PTEN ▪ Seeding CSF ▪ Surgical resection impossible, but treated by radiotherapy and chemotherapy
Astrocytoma	Children	Cerebellum, optic nerve, brainstem	▪ Low-grade tumor associated with good prognosis ▪ Immunohistochemistry (GFAP positive)
Pilocytic astrocytoma	Any age, common in children	Any location, common in cerebellum and third ventricle	▪ Hair-like processes ▪ Rosenthal fibers
Oligodendroglioma	4th–5th decades	Cerebral hemispheres frontal lobe white matter	▪ Prone to spontaneous hemorrhage owing to delicate vasculature ▪ Round cells with perinuclear halos; satellitosis

Contd...

Table 30.19 Salient features of selected primary central nervous system tumors including metastatic tumors (*Contd...*)

Histologic Variants	Age Predilection	Most Frequent Site	Characteristics
			▪ Calcification seen on radiograph ▪ IDH1/IDH2, mutation in FUBP1 due to 1p/19q codeletion ▪ Chemosensitive tumor
Medulloblastoma	Most often during 15–35 years, may occur in children (<15 years), peak at 7 years	Cerebellum (close to 4th ventricle) in adults, cerebellar vermis in children	▪ Highly malignant intracranial tumor ▪ Small round tumor cells ▪ Homer Wright rosettes ▪ Chromosome 17 inversion ▪ Seeding CSF ▪ Resection difficult, highly radiosensitive associated with poor prognosis ▪ Immunohistochemistry (synaptophysin or nestin, neuron-specific enolase and GFAP positive)
Ependymoma	Most common during first two decades	4th ventricle of brain, spinal cord	▪ Histologic variants (well differentiated, myxopapillary and anaplastic) ▪ Immunohistochemistry (GFAP, S-100, vimentin positive) ▪ Increased intracranial pressure, hydrocephalus
Choroid plexus	Children	Lateral ventricle, 4th ventricle of brain	▪ Uncommon neuroectodermal tumor but seeding CSF ▪ Hydrocephalus
Meningioma	20–40 years (more common in women)	Convexity of cerebral hemispheres, falx cerebri, olfactory groove beneath frontal lobe, lesser wing of sphenoid, sella turcica, foramen magnum, thoracic region of spinal cord	▪ Second most common primary intracranial neoplasm (WHO grade I) ▪ Aggressive meningiomas (clear cell and chondroid variant—WHO grade II, papillary and rhabdoid variant—WHO grade III) ▪ Benign tumor presents external to the brain hence easy resection ▪ Associated with type 2 neurofibromatosis
Schwannoma (neurilemmoma)	Middle to later life	8th cranial nerve (when schwannoma is intracranial)	Acoustic schwannoma, common intracranial tumor, ranking third after glioblastoma multiforme and meningioma, most often benign tumor is usually respectable
Retinoblastoma	Young children (<3 years)	Retina, bilateral and multifocal in familial form; unilateral and unifocal in sporadic forms	Most common eye tumor of young children; linked to Rb gene deletion or inactivation
Metastatic tumors	Variable age	Metastases from lung, breast, kidney, colon, thyroid, skin melanoma	Metastatic tumors are more common than primary intracranial tumors

Table 30.20 Panel of immunohistochemical markers applied in central nervous system tumors showing neuroglial differentiation

Immunohistochemical Marker	Expression in Tumors
CNS tumor with neuroendocrine (NE) differentiation	
▪ Synaptophysin	▪ Pheochromocytoma, carcinoid tumor, medulloblastoma, PNET/Ewing sarcoma, paraganglioma, thyroid medullary carcinoma
▪ Chromogranin A	▪ Pheochromocytoma, carcinoid tumor, medulloblastoma, PNET/Ewing sarcoma, paraganglioma, thyroid medullary carcinoma
▪ NSE (neuron-specific enolase)	▪ Pheochromocytoma, carcinoid tumor, medulloblastoma, PNET/Ewing sarcoma, paraganglioma, thyroid medullary carcinoma
▪ CD56 (neuronal cell adhesion molecule—NCAM)	▪ Pheochromocytoma, carcinoid tumor, medulloblastoma, PNET/Ewing sarcoma, paraganglioma, thyroid medullary carcinoma

Contd...

Table 30.20 Panel of immunohistochemical markers applied in central nervous system tumors showing neuroglial differentiation (*Contd...*)

Immunohistochemical Marker	Expression in Tumors
CNS tumor with glial differentiation	
GFAP (glial fibrillary acidic protein)	Astrocytes, astrocytoma, oligodendrocytes, oligodendroglioma, ependymal cells, ependymoma, GFAP may be used to differentiate a glioma from non-glial neoplasm (lymphoma, carcinoma, melanoma, and multiple sclerosis), GFAP also reacts variably with Schwann cells
CNS tumor with neuronal/ganglion differentiation	
▪ Sm311 (pan-NF)	▪ Sm31 (axon) may be used to highlight axon
▪ Sm32 (cell body)	▪ Sm32 (cell body) may be used to highlight normal axons and identify permeation of normal brain parenchyma by a glioma or meningioma
▪ NeuN (neuronal nuclei)	▪ NeuN (neuronal nuclei) to highlight neuronal nucleoli
▪ Synaptophysin	▪ Gangliocytoma, neuroblastoma, medulloblastoma
▪ Chromogranin A	▪ Gangliocytoma, neuroblastoma, medulloblastoma
▪ NSE (neuron-specific enolase)	▪ Gangliocytoma, neuroblastoma, medulloblastoma
CNS tumor with Schwann cells	
▪ S-100 protein	▪ Schwannoma, neurofibroma, glioma, melanoma, ependymoma, melanocytes, myoepithelial cells, histiocytes
▪ CD57 (Leu7) lymphoid marker	▪ CD57 cross-reacts with myelin-associated protein and second-tier marker for Schwann cells

All glial/neuronal/ nerve sheath are CAM 5.2 negative and AE1/AE3. However, AE1/AE3 staining is observed in normal and neoplastic brain and reactive astrocytes.

Table 30.21 Panel of immunohistochemical markers applied in central nervous system tumors with neuroglial differentiation

Immunohistochemical Marker	Expression
Astrocytoma	GFAP (glial fibrillary acidic protein) (++), p53 (+30%), (1p/19q deletion absent)
Oligodendroglioma	GFAP (glial fibrillary acidic protein variable staining), p53 (–), (1p/19q deletion present), reticulin (–)
Ependymoma	GFAP (glial fibrillary acidic protein) (+), vimentin (+), EMA (epithelial membrane antigen) (+)
Meningioma (grade I variants include angiomatous, fibroblastic, lymphocyte-rich, meningothelial, metaplastic, psammomatous, secretory, transitional types; grade II variants include atypical, choroid and clear cell types, and grade III variants include anaplastic, papillary and rhabdoid types)	Vimentin (+++), EMA (epithelial membrane antigen) (+), PR (50%), S-100 protein (80%); Note: secretory meningioma shows positivity for cytokeratin (CK), CEA (carcinoembryonic antigen), PAS (periodic acid–Schiff); and atypical meningioma shows positivity for Ki-67 proliferative marker
Primitive neuroectodermal neoplasms (medulloblastoma)	Synaptophysin (+), chromogranin A (+), nestin (+), NSE (neuron-specific enolase) (+)
Primitive neuroendocrine tumor (PNET)	Synaptophysin (+), GFAP (glial fibrillary acidic protein) (+), CD99 (–)
Retinoblastoma	GFAP (glial fibrillary acidic protein) (+), S-100 protein (+), synaptophysin (+), NSE (neuron-specific enolase) (+), MBP (myelin basic protein) (+)
Hemangioblastoma	CD31 (+), CD34 (+), CD56, S-100 protein (+), vimentin (+), NSE (neuron-specific enolase) (+), inhibin A (+)
Atypical teratoid/rhabdoid tumor (AT/RT)	EMA (epithelial membrane antigen) (+), GFAP (glial fibrillary acidic protein) (+), cytokeratin (CK) (+), vimentin (+), SMA (smooth muscle actin) (+), IN11 (HSNF/BAF47) loss of expression due to 22q11 deletion, synaptophysin (variable staining), chromogranin A (variable staining)
Dysembryoplastic neuroepithelial tumor (DNT)	S-100 protein (+), NeuN (+), synaptophysin (–)
Pituitary neoplasms	Synaptophysin (+), chromogranin A (+), growth hormone (+), ACTH (+), prolactin
Choroid plexus tumors	Cytokeratin (CK) (+), transthyretin (+), S-100 protein (+), GFAP (glial fibrillary acidic protein) (+), EMA (epithelial membrane antigen) (+)

Table 30.22 Panel of immunohistochemical markers applied in nerve and nerve sheath tumors

Immunohistochemical Marker	Expression
Traumatic neuroma	S-100 protein (stains Schwann cell), neurofilament (stains axons), EMA (epithelial membrane antigen stains perineural cells), collagen IV
Schwannoma (cellular variant)	S-100 protein (strong uniform staining), GFAP (glial fibrillary acidic protein variable staining), CD57 (Leu7) lymphoid marker (variable staining), laminin (pericellular staining), collagen IV (pericellular staining)
Schwannoma (ancient variant)	S-100 protein (strong uniform staining), GFAP (glial fibrillary acidic protein positive in minority of cases), CD57 (Leu7) lymphoid marker (positive in minority of cases)
Ganglioneuroma	Synaptophysin (+), neurofilament (+), tubulin (+), NSE (neuron-specific enolase) (+), S-100 protein (+), GFAP (glial fibrillary acidic protein) (+); all markers are positive for ganglion cells
Neurothekeoma	NKIC3 (+), S-100 protein (+), PGP9.5 (+), MITF (microphthalmia transcription factor) (+), SMA (smooth muscle actin) (+)
Cellular schwannoma	NKIC3 (+), S-100 protein (+), GFAP (glial fibrillary acidic protein variable staining), CD57 (Leu7) lymphoid marker (variable staining), PGP9.5 (–)
Neurofibroma	S-100 protein (+), CD57 (Leu7) lymphoid marker (variable staining), CD34 (variable staining), factor XIIIa (variable staining), EMA (epithelial membrane antigen variable staining)
Plexiform neurofibroma	S-100 protein (+), CD57 (Leu7) lymphoid marker (variable staining), CD34 (variable staining), factor XIIIa (variable staining), EMA (epithelial membrane antigen) (–)
Perineuroma	EMA (epithelial membrane antigen) (+), S-100 protein (+), GLUT1 (glucose transporter 1 protein isoform) (+), claudin (+), laminin (outlines the basal lamina around individual cells or small group of cells), type 4 collagen (outlines the basal lamina around individual cells or small group of cells)
Malignant peripheral nerve sheath tumor with spindle cell variant	HMB-45 (human melanoma black 45) (+), S-100 protein (+), CD57 (Leu7) lymphoid marker (+)
Malignant peripheral nerve sheath tumor with epithelioid variant	HMB-45 (human melanoma black 45) (+), S-100 protein (+), CD57 (Leu7) lymphoid marker (+)
Malignant peripheral nerve sheath tumor with rhabdoblastic differentiation	Desmin (+), myogenin (+), MyoD1 (+), HMB-45 (human melanoma black 45) (+), CD57 (Leu7) lymphoid marker (+)
Malignant-Triton tumor	S-100 protein (++++ in 50%), CD57 (Leu7) lymphoid marker (+ in 30–40%), cytokeratin (CK) (+), desmin (+)
Granular cell tumor (benign tumor)	CD68 (++++), SMA (smooth muscle actin), inhibin (+), NSE (neuron-specific enolase) (+), laminin (+), myelin P0 (+), myelin P2 (+)
Granular cell tumor (malignant tumor)	S-100 protein (+), NSE (neuron-specific enolase) (+), vimentin (+), PAS-D CD68 (–)
Neuroglial heterotopia	S-100 protein (stains glial tissue), GFAP (glial fibrillary acidic protein stains glial tissue)
Neuroblastoma	Synaptophysin (+), chromogranin A (+), NSE (neuron-specific enolase) (+), neurofilament (+), N-myc amplification (+ demonstrated by FISH), deletion of chromosome 1p (demonstrated by cytogenetic analysis), CD99 (–)
Esthesioneuroblastoma	Synaptophysin (+), chromogranin A (+), CD56 (+), neurofilament (+), NSE (neuron-specific enolase) (+), S-100 (+ around periphery of tumor), cytokeratin (CK) (–), desmin (–), myogenin (–)
Paraganglioma	NSE (neuron-specific enolase) (+), synaptophysin (+), chromogranin (+), neurofilament (+), peptide hormones, e.g. calcitonin, somatostatin (+), S-100 protein (+), GFAP (glial fibrillary acidic protein) (+)
Melanocytic neuroectodermal tumor of infancy	Cytokeratin (CK) (+), HMB-45 (human melanoma black 45) (+), NSE (neuron-specific enolase) (+), synaptophysin (+)

Prognostic Factors

Prognostic factors for primary brain tumors are age of the patient >40 years, progressive disease attaining >5 cm, tumor crossing the midline, contrast enhancement of tumor on MRI, WHO performance status 1, neurological symptoms and less than a gross total resection. Poor prognostic factors for primary brain tumors are given in Table 30.23.

Table 30.23 Poor prognostic factors for primary brain tumors

Age of the patient >40 years
Progressive disease
Tumor size >5 cm
Tumor crossing the midline
Contrast enhancement of tumor on MRI
World Health Organization performance status (≥1)
Neurological symptoms
Less than a gross total resection

METASTASES TO NERVOUS SYSTEM

Metastatic brain tumors, also called secondary brain tumors, are caused by malignant tumors metastasizing to the brain from a different part of the body. These tumors are more common than primary intracranial tumors of the CNS in adults (30%) and children (6–10%).

- Common sources of metastases in adults include lung carcinoma, breast carcinoma, skin melanoma, renal cell carcinoma, colorectal carcinoma, thyroid carcinoma and NHL.
- In children, sources of metastases include acute lymphoblastic lymphoma, osteosarcoma, Ewing sarcoma and rhabdomyosarcoma.
- The cancer stem cells break away from the primary tumor and travel through the bloodstream, break down blood–brain barrier and then invades cerebral hemisphere or cerebellum.
- Metastatic brain tumors can grow rapidly, crowding or destroying nearby brain tissue, inflammation, and edema. Sometimes, a patient may have multiple metastatic tumors in several different areas of the brain.
- Distribution throughout the central nervous system is more common in areas of high blood flow; however, different histologic subtypes tend to have different distributions of location within the brain.

Locations of Metastases in Nervous System

Most metastatic tumors seed to the gray-white junction, reflecting the rich capillary bed in this region. The borders of a metastasis deposit tend to be more discrete than those of a primary glioma. These metastatic tumors involve subarachnoid space and cause meningitis (Figs 30.10 and 30.11).

Basic Laboratory Assessment of Metastases to Brain

Basic laboratory assessment including complete blood count, metabolic panel, and liver function test should be performed.

Imaging Techniques

- A head CT allows for a quick examination, although fine-slice MRI of the brain with contrast is the gold standard for neuroimaging in cases of suspected brain metastases.
- MRI allows for a determination of the number and anatomical location of tumors and degree of associated edema. Metastasis in brain appears as discrete, globoid shape lesion, and prominent halo of edema in contrast to primary glioma or medulloblastoma.
- Spinal cord involvement is uncommon, but if present, then metastases deposits are seen in extradural space.

Surgical Pathology: Metastases to Brain

Gross Morphology

Metastatic tumor deposits are usually multiple and well circumscribed in nervous system. Pigmented secondaries indicate secondary melanoma (Fig. 30.12).

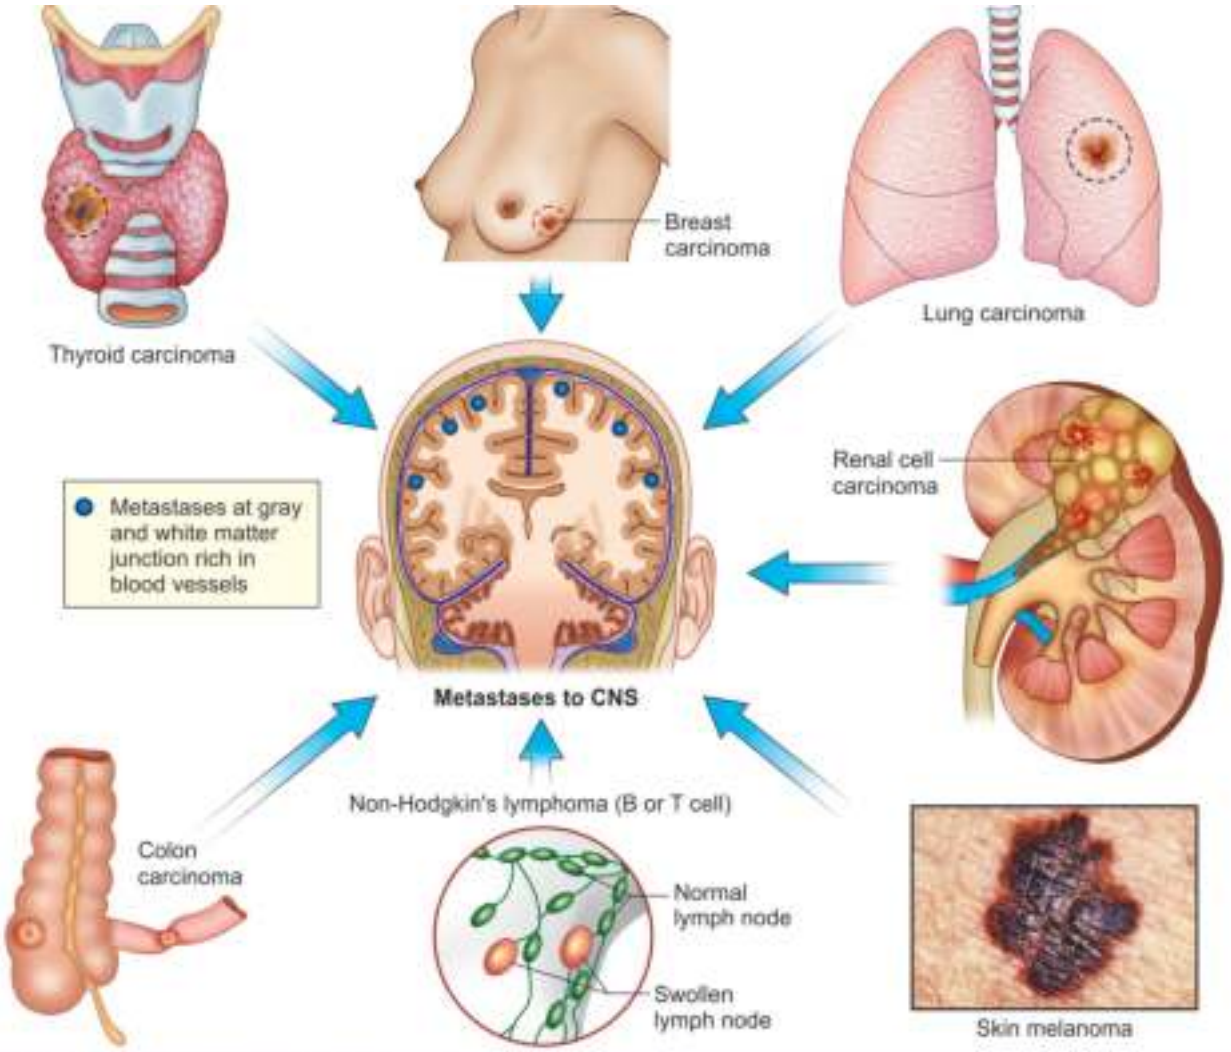
Light Microscopy

- A biopsy is required to differentiate metastatic tumors. A solitary brain mass in an adult can be primary or metastatic.
- In some cases, the metastases become clinically apparent before primary site is observed (Fig. 30.13).

Immunohistochemistry Technique

Immunohistochemistry is useful to confirm source of primary cancers metastasizing to central nervous system in adults and children (Tables 30.24 and 30.25).

Management

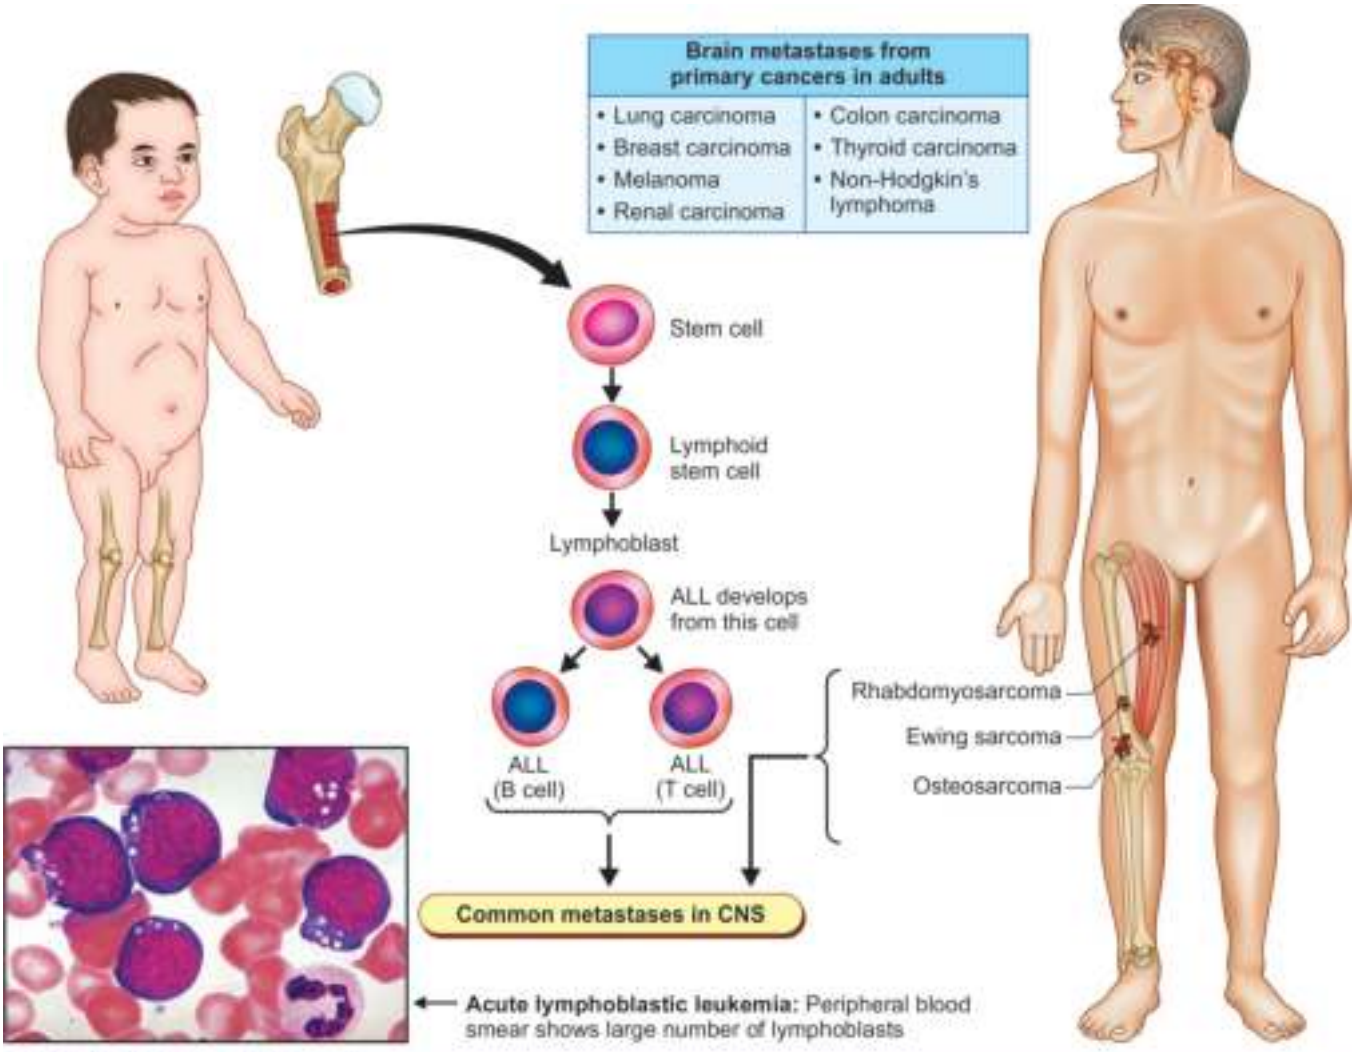


The first step in the management of newly diagnosed brain metastases is the treatment of intracranial edema.

- A loading dose of dexamethasone (10 mg) should be administered by oral or intravenous route and followed by 4 mg IV every six hours is one dosing regimen.
- Following initiation of steroids, definitive management may be initiated.
- Treatment options include surgical resection (for limited brain metastases in patients with good performance status and surgically accessible lesions), whole brain radiotherapy, and stereotactic radiosurgery.

ASTROCYTIC TUMORS

Astrocytic tumors are neuroepithelial tumors arising from neuroglial cells.



- Astrocytomas account for 20% of primary brain tumors, which originate from astrocytes in the cerebral hemisphere (most common), cerebellum, optic nerve, brainstem and spinal cord.

Primary cancer metastases to central nervous system	Immunohistochemistry
• Thyroid carcinoma	Thyroglobulin, CA 125 cell surface glycoprotein demonstrated by monoclonal antibody OC-125 and TTF1
• Breast carcinoma	ER, PR, HER2/neu, CK7, GCDFP-15 and mammoglobulin
• Lung carcinoma (squamous cell carcinoma)	EMA, CK7, TTF1, p63
• Renal cell carcinoma	Cytokeratin, vimentin
• Skin melanoma	HMB-45, melan-A (MART-1), CAM 5.2, S-100
• NHL (B cell type)	CD10, CD19, CD20
• NHL (T cell type)	CD3
• Colon carcinoma	CK20, CDX2 and β-catenin

Fig. 30.10: Common brain metastases in adults from thyroid, breast, lung, kidney, colon, skin melanoma and NHL.

- Cystic astrocytomas occur in cerebellar region in children.
- Peak occurrence of astrocytomas is in the late middle age group. Most patients die within 5–7 years.
- Diffuse astrocytoma usually occurs in the cerebral hemispheres (most common), cerebellum, optic nerve, brainstem and spinal cord.
- Histologic classification and grading: Astrocytic tumors in the cerebral hemispheres can be further categorized according to their histologic differentiation and clinical course.
  - Histologic grading of astrocytic tumors is based rapid progression and increasing pathologic anaplasia of tumors such as nuclear atypia, mitotic activity, endothelial cells or microvascular proliferation and necrosis in tumor.
  - These astocytic tumors are termed: (a) grade I: low-pilocytic astrocytomas, (b) grade II: diffuse

Primary cancer metastases to central nervous system	Immunohistochemistry
• Acute lymphoblastic leukemia	B cell lineage: cCD79a/cCD22 T cell lineage: cCD3, CD2, CD3, CD4, CD5, CD7 and TdT
• Osteosarcoma	Vimentin
• Ewing sarcoma	CD99 (MIC2 specific marker) Vimentin, neuron-specific enolase (NSE) and neurofilament Cytokeratin: Sometimes tumor cells are reactive to low molecular weight keratins
• Rhabdomyosarcoma	Desmin, vimentin, myoglobin and MyoD1

Fig. 30.11: Common brain metastases in children and young adults from acute lymphoblastic leukemia, Ewing sarcoma, osteosarcoma and rhabdomyosarcoma.

astrocytomas, (c) grade III: anaplastic astrocytomas, and (d) grade IV: astrocytomas, glioblastoma multiforme.

- Astrocytomas may be classified based on their invasion into surrounding brain parenchyma.
  - Noninvasive astrocytomas include pilocytic astrocytomas, pleomorphic xanthoastrocytoma, and subependymal giant cell astrocytomas. Many low-grade astrocytomas eventually transform to anaplastic (grade III) and highly malignant glioblastoma multiforme (grade IV).
  - Invasive (diffuse) astrocytomas include low-grade fibrillary astrocytoma, anaplastic astrocytomas and glioblastoma multiforme (grade IV). Fibrillary astrocytomas account for 80% of adult primary brain tumors. These are most common in middle age. Anaplastic astrocytoma has a peak incidence in the sixth decade. Although they usually are found in the cerebral hemispheres, they also can occur in the **cerebellum, brainstem**, or spinal cord. Clinically, infiltrating astrocytic tumors present with symptoms of increased intracranial pressure

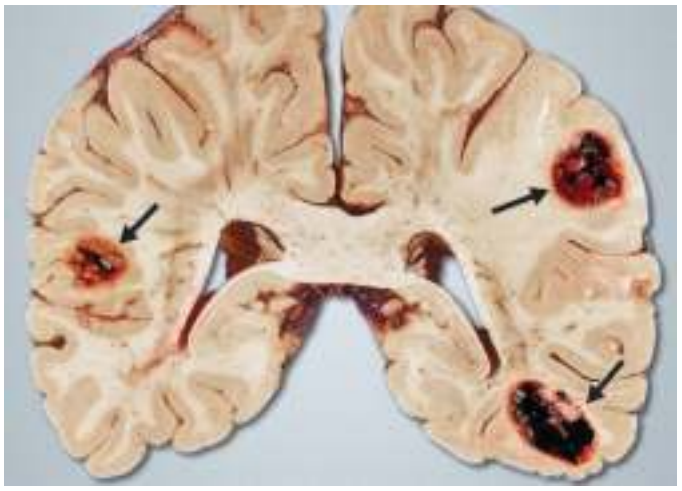


Fig. 30.12: Secondary tumor in the brain. Secondary tumor deposits are usually multiple and well circumscribed. Pigmented secondaries indicate secondary melanoma (arrows).

Table 30.24 Primary tumors metastasizing to central nervous system in adults

Primary cancers	Immunohistochemistry
Lung carcinoma	CK7+, CAM 5.2+, TTF-1+, EMA+, CK20–
Breast carcinoma	CK7+, CAM 5.2+, CK20–, TTF-1–
Melanoma	HMB-45, melan-A (MART-1), CAM 5.2, S-100
Renal cell carcinoma	CK+, CAM 5.2+, vimentin+
Colon carcinoma	CK20+, CK7–, TTF-1–
Thyroid carcinoma	TTF-1+
Non-Hodgkin's lymphoma	CD10, CD19 and CD20

Variable expression of ER, PR, HER2/neu is demonstrated in different histologic variants of breast carcinoma.

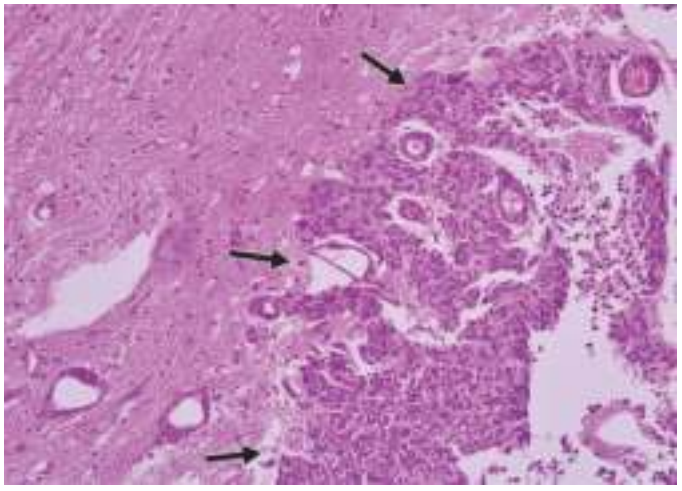

Fig. 30.13: Metastases to brain from carcinoma (arrows) (100X).

Table 30.25 Primary tumors metastasizing to central nervous system in children

Primary Cancers	Immunohistochemical Markers Expression
Acute lymphoblastic leukemia	▪ B cell lineage: cCD79a/cCD22+ ▪ T cell lineage: cCD3+, CD2+, CD3, CD4+, CD5+, CD7+ and TdT+
Osteosarcoma	Vimentin
Ewing sarcoma	MIC2+ (specific marker), vimentin+, neuron-specific enolase+ (NSE), CD99+, neurofilament+, cytokeratin+ (LMW sometimes)
Rhabdomyosarcoma	Desmin+, vimentin+, myoglobin+, MyoD1+

(e.g. headache) or focal abnormalities related to their position (e.g. seizures).

- Low-grade astrocytomas arising from cerebellum, optic nerve and brainstem in children have good prognosis. Glioblastoma multiforme arising in cerebrum is highly malignant tumor in adults associated with fatal outcome, which has ill-defined margins and grow irregularly into the surrounding brain tissue and therefore it is difficult to eradicate the tumor. These increase intracranial pressure.

DIFFUSE ASTROCYTOMA, IDH-MUTANT

Diffuse astrocytoma with a mutation in either IDH1 or IDH2 gene corresponds histologically to WHO grade II neoplasm.

- Tumor is composed of moderately pleomorphic cells and characterized by a high degree of cellular differentiation and slow growth. The diagnosis is supported by the presence of ARTX and TP53 gene mutations.
- The tumor most often affects young adults with peak in mid-30s and occurs throughout the central nervous system especially in the frontal lobes of brain.
- Diffuse astrocytoma can progress to IDH-mutant anaplastic astrocytoma and eventually to IDH-mutant glioblastoma. The median ages of patients with IDH-mutant diffuse astrocytoma are in the mid-30s.
  - Tumor can be located in any region of central nervous system, but most common site is frontal lobe in the supratentorial region.
  - It is worth mentioning that astrocytoma and oligodendroglioma with codeletion of 1p/19q arise in the supratentorial region. It supports the hypothesis that these gliomas arise from a distinct population of precursor cells.

- Gemistocytic astrocytoma, IDH-mutant is a variant of IDH-mutant diffuse astrocytoma characterized by the presence of variable proportion of gemistocytic neoplastic astrocytes in adults. Diffuse astrocytoma, NOS has morphologic features without IDH mutations.

Genetic Susceptibility

Diffuse astrocytoma especially anaplastic astrocytoma and glioblastoma multiforme can occur in patients with inherited TP53 germline mutations/Li-Fraumeni syndrome. There is increased risk for development of low-grade astrocytoma in patients with inherited Ollier-type multiple enchondromatosis.

Clinical Features

Patient presents with seizures (most common), speech difficulty, sensation and vision disturbances. Patient with frontal lobe tumor develops behavioral or personality changes.

Radiologic Findings

CT scan demonstrates poorly defined, homogenous mass without contrast enhancement. However, calcification and cystic change may be demonstrated early in the evolution of the astrocytoma.

- MRI studies usually demonstrates T1-hypodensity and T2-hyperintensity.
- Gadolinium enhancement is uncommon in low-grade astrocytoma, but tends to demonstrate during tumor progression.

Surgical Pathology: Diffuse Astrocytoma, IDH-mutant

Gross Morphology

- Because of infiltrative nature, astrocytoma usually exhibits blurring of the gross anatomical boundaries.
- Enlargement of the tumor distorts invaded anatomical structures without causing destruction of cortex.
- Tumor is gray or white with indistinct boundaries, cysts formation and spongy, soft to firm in consistency.
- Extensive microcyst formation can cause gelatinous appearance. Focal calcification may be demonstrated.
- Extension of tumor into contralateral structures, particularly frontal lobes are rarely observed (Figs 30.14 and 30.15).

Light Microscopy

- Diffuse astrocytoma is composed of well-differentiated fibrillary astrocytes in the background of a loosely structured, often microcystic tumor matrix.
- Tumor is moderately cellular without cytologic atypia, necrosis and microvascular proliferation, when compared with normal brain.
- Presence of necrosis and/or microvascular proliferation is incompatible with the diagnosis of diffuse astrocytoma.
- The histologic patterns with respect of their size, cell processes and cytoplasmic glial filaments may vary in different regions of the tumor.
- Histological recognition of neoplastic astrocytes is studied by using hematoxylin and eosin stained sections. Tumor is composed of cells with vesicular nuclei, intermediate chromatin and distinct nucleoli.
- When compared, normal astrocytes contain oval or elongated nuclei and without stainable cytoplasm, that is distinct from the background neuropil (Fig. 30.16).

Immunohistochemistry Technique

Panel of immunohistochemical markers is applied on paraffin-embedded hematoxylin and eosin stained sections in diffuse astrocytoma with IDH mutation.

Markers	Expression
Glial fibrillary acidic protein (GFAP)	Positive
IDH1 R132H mutation	Positive
p53	Positive
Ki-67 proliferation index of <4%	Positive

Molecular Genetic Alterations

Molecular genetic alterations for diffuse astrocytoma are IDH1, IDH2, TP53 and ATRX.

DIFFUSE MIDLINE GLIOMA, HISTONE H3K27M-MUTANT

Diffuse midline glioma, histone H3K27M mutant is a new tumor entity defined by the recent 2021 WHO classification of tumors of the central nervous

Fig. 30.14: Astrocytoma. Brain slice examined from its posterior aspect. The tumor has arisen in the right hemisphere and extends through the genu of the corpus callosum into the left hemisphere. There is hemorrhage and necrosis in the tumor, indicating that it is a high-grade malignancy. It has extended into the third ventricle, obstructing the interventricular foramina and resulting in hydrocephalus, as shown by the dilatation of the anterior horns of both lateral ventricles (arrow).

Fig. 30.15: Astrocytoma in cerebellum. Cerebellum containing a large astrocytoma. The majority of the brain tumors in children occur below the tentorium cerebelli (arrow).

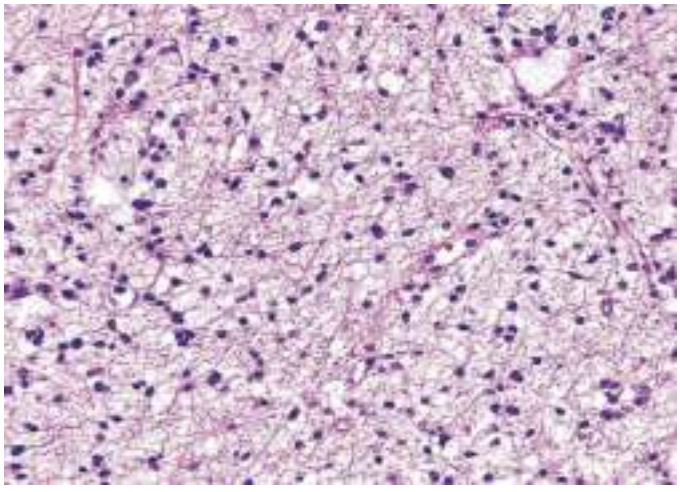

Fig. 30.16: Diffuse astrocytoma. Tumor is composed of well-differentiated fibrillary astrocytes with vesicular nuclei, intermediate chromatin and distinct nucleoli. in the background of a loosely structured, often microcystic tumor matrix. Tumor is moderately cellular without atypia, necrosis and microvascular proliferation, when compared with normal brain. There is no necrosis or microvascular proliferation. The histologic patterns with respect their size, cell processes and cytoplasmic glial filaments may vary in different region of the tumor (400X).

system corresponding to WHO grade IV. It affects adults and children in the region of brainstem, thalamus and spinal cord. It was previously known as glioma in brainstem tumor and diffuse intrinsic pontine glioma in spinal cord.

Radiologic Findings

Radiographic features of diffuse midline glioma histone H3K27M-mutant are diffuse growth with hypointense on T1 and hyperintense on contrast enhancement along with hemorrhage and necrosis. Tumor spreads by leptomeningeal dissemination associated with poor prognosis.

Surgical Pathology: Diffuse Midline Glioma, Histone H3K27M-mutant

Gross Morphology

Tumor distorts anatomic structures and demonstrates areas of hemorrhage and necrosis.

Light Microscopy

- Tumor is composed of primitive, poorly differentiated, small uniform cells with scant cytoplasm, nuclear molding, and brisk mitotic activity, exhibiting PNET-like appearance. In the hypocellular area, oligodendroglioma-like cells are demonstrated.
- Neuropil-like islands are observed in the cellular area.
- Microvascular proliferation and necrosis are also present.

Immunohistochemistry Technique

In diffuse midline glioma, histone H3K27M mutant panel of markers is applied on paraffin-embedded sections such as H3K27M, p53, neural adhesion molecule 1, S-100 protein, OLIG2, MAP2 and nuclear p53.

Markers	Expression
H3K27M	Positive (strong nuclear staining)
p53	Positive
Neural adhesion molecule 1	Positive
S-100 protein	Positive
OLIG2	Positive
MAP2	Positive
Nuclear p53	Positive
NeuN	Negative
Chromogranin A	Negative

ANAPLASTIC ASTROCYTOMA, IDH-MUTANT

Anaplastic astrocytoma, IDH-mutant is a diffuse infiltrating astrocytoma with focal or dispersed anaplasia and significant proliferative activity. The cell of origin is not known. The fact that diffuse astrocytoma grade II and astrocytoma grade III and glioblastoma IDH-mutant grade IV carry IDH mutations suggest these tumors may share a cell of origin different from other IDH-wildtype glioblastomas and pilocytic astrocytoma.

- Anaplastic astrocytoma, IDH mutant tumor can originate from low-grade diffuse astrocytoma, which corresponds histologically to WHO grade III. It is usually diagnosed without indication of low-grade diffuse astrocytoma.
  - Tumor resembles identical to oligodendroglioma in the absence of 1p/19q codeletion.
  - Anaplastic astrocytoma has tendency for malignant progression to IDH-mutant glioblastoma. It occurs in adults with mean age of 38 years. Tumor can

develop in any region of central nervous system, but cerebrum (especially in frontal lobe) is the most common site.

- Anaplastic astrocytoma, IDH wildtype corresponding to WHO grade III is a diffusely infiltrating astrocytoma with focal or dispersed anaplasia with significant proliferative activity but without mutations in the IDH genes, which can extensively involve cerebrum (three lobes involving deep gray mater), brainstem, cerebellum and spinal cord. Another histologic variant anaplastic astrocytoma, NOS corresponds to WHO grade III and has identical histopathologic features but lacks IDH mutation.

Clinical Features

Patient presents with a history of seizures and neurological deficits due to increased intracranial pressure depending on location of the tumor, degree of edema and tumor effect on the surrounding anatomical structures. Tumor is generally characterized by diffuse infiltrative growth in the brain. Occasionally, leptomeningeal spread of anaplastic astrocytoma, IDH mutant is evident.

Radiologic Findings

Anaplastic astrocytoma, IDH-mutant appears as a poorly defined mass of low density. Partial contrast enhancement is demonstrated unlike WHO grade II diffuse astrocytoma. Tumor lacks necrosis with ring enhancement. Rapidly growing tumor demonstrates peritumoral edema, that can lead to tumor mass shift and increased intracranial pressure.

Surgical Pathology: Anaplastic Astrocytoma, IDH-mutant

Gross Morphology

- Anaplastic astrocytoma, IDH-mutant tends to infiltrate the surrounding brain, with causing frank destruction.
- Invasion in surrounding brain parenchyma results in enlargement of adjacent gyri and basal ganglion.
- Cut section of tumor reveals discernible opaque tumor mass, soft in consistency with granular surface, which is distinguished from the surrounding brain structures. Macroscopic cysts are uncommon.
- It is most often difficult on gross examination to differentiate grade III anaplastic astrocytomas from grade II diffuse astrocytoma.

Light Microscopy

- Histologic features of anaplastic astrocytoma, IDH-mutant and diffuse astrocytoma are identical.
- Anaplastic astrocytoma, IDH-mutant is highly cellular and composed of cells with nuclear atypia and mitoses.
- Ki-67 labeling in the range of 5–10% may be helpful in analyzing significant proliferative activity of tumor.
- With progressive anaplasia, tumor is composed of cells with variation in size and shape of nuclei, dispersion of chromatin and prominent nucleoli.
- Multinucleated tumor giant cells and abnormal mitoses may be demonstrated (Fig. 30.17).

Immunohistochemistry Technique

Panel of immunohistochemical markers is applied on paraffin-embedded hematoxylin and eosin stained sections in anaplastic astrocytoma, IDH mutation.

Markers	Expression
GFAP	Positive
IDH1 R132H mutation	Positive
p53	Positive
Ki-67 proliferation index of 5–10%	Positive

Molecular Genetic Alterations

Molecular genetic markers for anaplastic astrocytoma, IDH mutant are IDH1, IDH2, TP53 and ATRX. There are higher frequencies of chromosome 9p and 19p losses.

Clinical Course

Patient with anaplastic astrocytoma, IDH mutant has median survival in the range of 3–5 years. The extent of surgical resection of tumor at diagnosis also has impact on outcome. EGFR amplification and genotype of 7q gain and 10q loss have been associated with fatal outcome.

PRIMARY GLIOBLASTOMA MULTIFORME, IDH-WILDTYPE

Primary glioblastoma multiforme, IDH-wildtype is a high grade glioma corresponding to WHO grade IV with predominantly astrocytic differentiation with features of

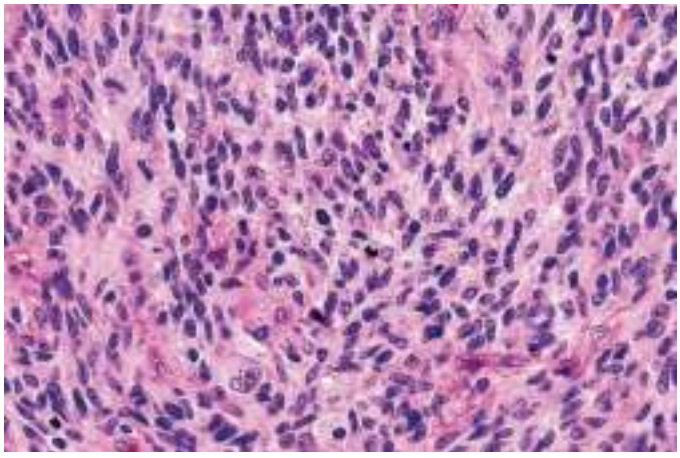

Fig. 30.17: IDH-multant. Histologic features of anaplastic astrocytoma, IHD-mutant is highly cellular and composed of pleomorphic cells with nuclear atypia, dispersion of chromatin, and prominant nucleoli. Ki-67 labeling in the range of 5–10% may be helpful in analyzing significant proliferative activity of tumor. Multinucleated tumor giant cells and atypical mitoses may be demonstrated (400X).

nuclear atypia, cellular pleomorphism, mitotic activity, diffuse growth pattern, microvascular proliferation and/or necrosis, which lacks mutations in IDH gene. It arises in *de novo* and usually affects adults of 40–60 years.

- Tumor has infiltrative growth that can affect bilateral cerebral hemispheres (temporal lobe, parietal lobe, occipital lobe). Tumor infiltration occurs along white mater tracts, but can also involve cortical and deep gray mater. Tumor extends into the adjacent cortex and through the corpus callosum into the contralateral cerebral hemisphere.
- Similarly, tumor spreads rapidly along white matter tracts of the internal capsule, fornix, and anterior commissure.
- Despite its rapid and infiltrative growth, primary glioblastoma multiforme, IDH-wildtype does not extend into the subarachnoid space or spread through cerebrospinal fluid. Although tumor spreads via cerebrospinal fluid in children. Extracranial metastasis of primary glioblastoma multiforme, IDH wildtype is uncommon.
- Tumor in basal ganglion and thalamus is common in children. It rarely occurs in brainstem, cerebellum and spinal cord.
- Tumor is invariably lethal within 8–12 months of diagnosis. It accounts for 15% of all intracranial neoplasms and 45–50% of all primary malignant brain tumors.
- Genetic susceptibility in primary glioblastoma multiforme, IDH-wildtype are given in Tables 30.26 and 30.27.

Clinical Features

Primary glioblastoma multiforme, IDH-wildtype develops rapidly. The symptoms depend on location of tumor. Patient presents with focal neurological deficits (aphasia, hemiparesis), seizures, nausea, vomiting, severe pulsating headache, behavioral changes and neurocognitive changes.

Radiologic Findings

Primary glioblastoma multiforme, IDH-wildtype tumors are irregularly shaped. These tumors demonstrate ring-shaped zone of contrast enhancement around a dark, central area of necrosis. These tumors may extend widely into the adjacent lobes of cerebral hemisphere.

Table 30.26 Genetic susceptibility in primary glioblastoma multiforme, IDH-wildtype

Syndrome	Gene	Chromosome
Li-Fraumeni syndrome	TP53	17p13.1
Turcot syndrome	MLH1, PMS2, MSH2, MSH6	3p21.3, 7p22, 2p22–p21, 2p16
Neurofibromatosis type 1	NF1	7p12
Ollier/Maffucci syndrome	PTHR1	3p21–22
L-2-hydroxyglutamic aciduria	L2HGDH	14q21.3

Table 30.27 Genetic alterations in primary glioblastoma multiforme, IDH-wildtype

Genetic Alterations	Expression (%)
IDH1 promoter	≤80%
CDKN2A/CDKN2B	≤60%
Loss of chromosome 10p	≤50%
Loss of chromosome 10q	≤70%
EGFR alterations (rearrangement, splicing or amplification)	≤55%
PTEN mutations/deletions	≤40%
TP53 mutations	≤30%
P13K mutations	≤25%
TERT	70–90%
NF1 mutation	15–18%
RB1 mutation	8–12%
MDM4 amplification	5–15%
MET amplification	4%
MGMT methylation	Gives information about response of tumor to alkylating chemotherapeutic agents

Surgical Pathology: Primary Glioblastoma Multiforme, IDH-wildtype

Gross Morphology

- Most glioblastomas, IDH-wildtype of cerebral hemisphere are large tumors either unilateral or bilateral within brain parenchyma. These are rarely found to involve leptomeninges.
- Tumor is poorly circumscribed. As the tumor invades and causes obliteration of blood vessels, the tumor features patchy (multifocal areas) yellow areas of necrosis and red zones of hemorrhage.
- Macroscopic cysts in the tumor, when present contain turbid fluid with liquefied necrotic material (Fig. 30.18).

Light Microscopy

- Glioblastoma multiforme, IDH-wildtype is a highly cellular tumor and composed of poorly differentiated, pleomorphic, round, or fusiform astroglial cells with nuclear atypia, brisk mitotic activity, multinucleated giant cells and marked proliferation of endothelial cells.
- Tumor cells are arranged in palisading pattern around prominent vessels. Areas of hemorrhage and necrosis are common.
- Pseudopalisading necrosis is prominent feature of glioblastoma multiforme, IDH-wildtype.
- The term multiforme derives from the variegated gross appearance of these tumors and the histologic pleomorphism of the tumor cells.

- Diagnosis of glioblastoma multiforme, IDH-wildtype is mainly based on the identification of the tissue pattern rather than of specific cell types (Figs 30.19 and 30.20).

Immunohistochemistry Technique

Panel of markers is applied to paraffin-embedded sections of primary glioblastoma multiforme, IDH-wildtype such as GFAP, α_1-antitrypsin, α_1-antichymotrypsin, actin, EMA, S-100 protein, OLIG2, nestin, TP53 mutation and cytokeratins with AE1/AE3.

Markers	Expression
GFAP	Positive
α_1-Antitrypsin	Positive
α_1-Antichymotrypsin	Positive
Actin	Positive
EMA	Positive
S-100 protein	Positive
OLIG2	Positive
Nestin	Positive
TP53 mutation	Positive
Cytokeratin with AE1/AE3	Positive

Treatment

Surgical resection of tumor is impossible, but radiation and chemotherapy may add months to patient's survival.

SECONDARY GLIOBLASTOMA MULTIFORME, IDH-MUTANT

Secondary glioblastoma, IDH-mutant develops through malignant progression from diffuse astrocytoma (WHO grade II) or anaplastic astrocytoma (WHO grade III) is almost associated with IDH mutation. It is a high-grade glioma corresponding to WHO grade IV with astrocytic differentiation; featuring cellular pleomorphism, mitotic activity, diffuse growth pattern and/or necrosis; with mutation in either IDH1 or IDH2 gene.

Fig. 30.18: Primary glioblastoma multiforme (GBM), IDH-wildtype. This is the worst possible form of glioma, a GBM. These neoplasms are quite vascular with prominent areas of necrosis and hemorrhage. Note how this one has crossed the midline to the opposite hemisphere (arrow).

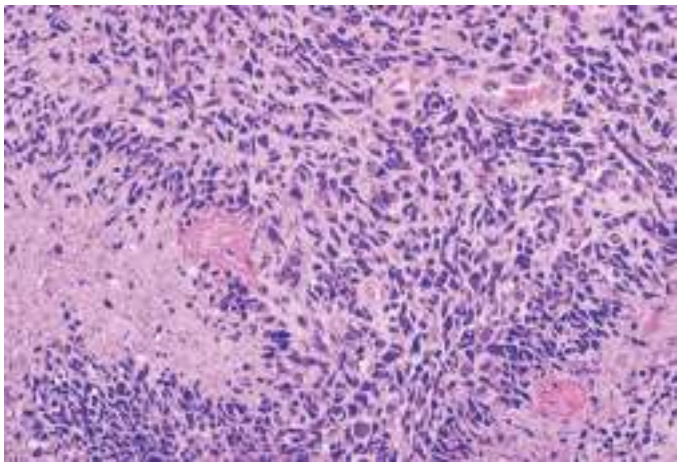

Fig. 30.19: Primary glioblastoma multiforme (GBM), IDH-wildtype. Tumor demonstrates marked cellularity with marked hyperchromatism and pleomorphism.Note the prominent vascularity as well as the area of necrosis at the left with neoplastic cells palisading around it (400X).

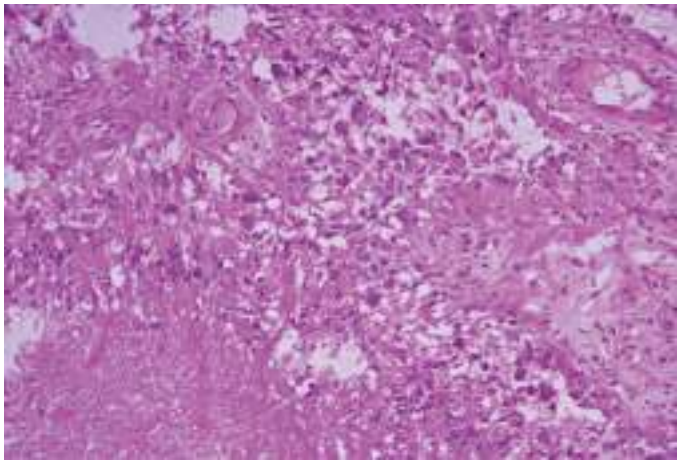

Fig. 30.20: Primary glioblastoma multiforme (GBM), IDH-wildtype. Tumor demonstrates marked cellularity with marked hyperchromatism and pleomorphism. Note the prominent vascularity as well as the area of necrosis with neoplastic cells palisading around it (400X).

- Tumor is morphologically indistinguishable from primary glioblastoma multiforme, IDH-wildtype except for a lesser extent of necrosis.
- Tumor affects young adults. It occurs in the frontal lobe of cerebral hemisphere and associated with better prognosis than primary glioblastoma multiforme, IDH-wildtype.

Molecular Genetic Alterations

Secondary glioblastoma multiforme, IDH-mutant arises from common precursor cells with IDH1/IDH2 mutation, in contrast to primary glioblastoma, IDH-wildtype that arises from glial progenitor cells. Development of secondary glioblastoma multiforme, IDH-mutant develops from common precursor cells with IDH1/IDH2 mutation through malignant progression from diffuse astrocytoma with TP53 and ATRX mutations

Table 30.28 Comparison of primary glioblastoma multiforme, IDH-wildtype, and secondary glioblastoma multiforme, IDH-mutant

Synonym	Primary Glioblastoma Multiforme, IDH-wildtype	Secondary Glioblastoma Multiforme, IDH-mutant
General features		
▪ Origin	▪ Glial progenitor cells	▪ Common precursor cells
▪ Precursor lesion	▪ Originates in *de novo* without identifiable lesion	▪ Diffuse astrocytoma (WHO grade II), anaplastic astrocytoma (WHO grade III)
▪ Frequency	▪ 90%	▪ 10%
▪ Median age at diagnosis	▪ 62 years	▪ 44 years
▪ Sex predilection	▪ Males > females	▪ Males < females
▪ Location of tumor	▪ Supratentorial region	▪ Frontal lobe of cerebral hemisphere
▪ Clinical history mean duration	▪ 4 months	▪ 15 months
Gene mutations		
▪ TERT promoter mutations	▪ 72%	▪ 26%
▪ TP53 mutation	▪ 27%	▪ 81%
▪ ATRX mutation	▪ Exceptional	▪ 71%
▪ EGFR amplification	▪ 35%	▪ Exceptional
▪ PTEN mutation	▪ 24%	▪ Exceptional
Gross morphology		
Necrosis	Extensive necrosis	Limited necrosis
Median survival		
▪ Surgery and radiotherapy	▪ 10 months	▪ 24 months
▪ Surgery, radiotherapy and chemotherapy	▪ 15 months	▪ 30 months

(WHO grade II) or anaplastic astrocytoma with loss of heterozygosity LOH 19p and 10q (WHO grade III). Comparison of primary glioblastoma multiforme, IDH-wildtype and secondary glioblastoma multiforme, IDH-mutant is given in Table 30.28.

Clinical Features

Patient with secondary glioblastoma multiforme, IDH-mutant located in frontal lobe, presents with behavioral and neurocognitive changes, focal neurological deficits such as hemiparesis and aphasia. Due to its slow evolution from diffuse astrocytoma and anaplastic astrocytoma, tumor is associated with cerebral edema due to increase in intracranial pressure.

Radiologic Findings

Unlike in primary glioblastoma multiforme, IDH-wildtype, large areas of central necrosis are absent in secondary glioblastoma multiforme and IDH-mutant.

Surgical Pathology: Secondary Glioblastoma Multiforme, IDH-mutant

Gross Morphology

- Secondary glioblastoma multiforme, IDH-mutant diffusely infiltrates in the brain parenchyma.
- Tumor is not delineated.
- Cut surface shows large yellowish areas of necrosis or hemorrhage.

Light Microscopy

- Histologic features of secondary glioblastoma multiforme, IDH-mutant are identical to primary glioblastoma multiforme, IDH-wildtype. However, morphologic studies revealed two significant differences.
- Secondary glioblastoma multiforme, IDH-mutant demonstrates areas of ischemic and/or palisading necrosis in 50% of cases; while 90% in primary glioblastoma multiforme, IDH-wildtype.
- Focal oligodendroglial components are more common in secondary glioblastoma multiforme, IDH-mutant than primary glioblastoma multiforme, IDH-wildtype.

Immunohistochemistry Technique

Panel of immunohistochemical markers is applied to paraffin-embedded sections of secondary glioblastoma multiforme, IDH-mutant such as TERT promoter, p53, ATRX and GFAP.

Markers	Expression
▪ IDH1/IDH2	▪ Positive (100%)
▪ TERT promoter	▪ Positive (26%)
▪ p53	▪ Positive (81%)
▪ ATRX	▪ Positive (71%)
▪ GFAP	▪ Positive (variable)

Treatment and Prognosis

Secondary glioblastoma multiforme, IDH-mutant is treated by surgery, radiotherapy and chemotherapy. Overall survival is 24–36 months.

PILOCYTIC ASTROCYTOMA

Pilocytic astrocytoma is the most common pediatric WHO low-grade I brain tumor in children and young adults. Tumor tends to occur in cerebellum and optic chiasma, and floor and wall of third ventricle in the hypothalamic region. However, it can occasionally occur in cerebral hemispheres.

- Child with neurofibromatosis 1 can predispose to pilocytic astrocytoma primarily within the optic pathway.
- Alterations in the RAS/RAF/mitogen-activating protein kinase (MAPK) pathway are exclusively found in almost all cases, indicating that pilocytic astrocytoma represents a one-pathway disease. Dissemination of tumor is uncommon.

Clinical Features

Patient with pilocytic tumor in cerebellum presents with ataxia, cranial nerve defects, and signs of increased intracranial pressure, i.e. headache, nausea and vomiting. When tumor is present in the optic pathway, the tumor may produce loss of visual acuity or field defects. Tumor localized in the hypothalamus, may result in endocrine syndromes, such as diabetes insipidus, precocious puberty, or electrolyte imbalance. Blocking of CSF pathways may result in hydrocephalus associated with rapid deterioration.

Surgical Pathology: Pilocytic Astrocytoma

Gross Morphology

Tumor is discrete. Cut surface shows macrocystic or microcystic areas.

Light Microscopy

- Pilocytic astrocytoma tumor is composed of bipolar neoplastic cells with long hair-like cells cytoplasmic processes, that are arranged in parallel bundles.
- Tumor has biphasic pattern with varying proportions of piloid areas alternating with spongy areas.
- Piloid areas are composed of compacted strongly GFAP+ bipolar cells (with hair-like bipolar processes) associated with Rosenthal fibers (tapered corkscrew shaped, brightly eosinophilic, hyaline masses).
- Spongy areas are composed of loosely textured and formed of weakly GFAP+ multipolar cells (protoplasmic astrocytes) associated with microcysts and eosinophilic granular bodies (brightly eosinophilic PAS+ globular aggregates).
- Vascular changes are commonly demonstrated, which include glomeruloid vascular proliferation and vascular hyalinization.
- Other findings in tumor demonstrated include hyalinized blood vessels, infarct-like necrosis, degenerative nuclear atypia, calcification, hemosiderin deposits and lymphocytic infiltrate.
- Leptomeningeal extension is not a sign of malignancy. Some tumors in cerebellum show a diffuse growth pattern.

Immunohistochemistry Technique

Glial fibrillary acidic protein (GFAP) is an intermediate filament protein expressed in variable proportions in tumor.

Treatment and Prognosis

When required, treatment of pilocytic astrocytoma consists of surgery, chemotherapy, and/or radiation, although new molecular agents targeting the RAS/RAF and related MAPK signaling pathways are promising new approaches. The 10-year survival rates are >90% in pediatric patients; however, they are poorer in adults.

- Tumors that are amenable to complete resection (i.e. cerebellum and cortex) have the best overall survival.
- The prognosis of people with pilocytic astrocytomas is influenced primarily by their location.
- The prognosis is usually better for patients with surgically respectable tumors located in the cerebellar cortex, than for patients with less accessible tumors, such as those involving the hypothalamus or brainstem.

EPITHELIOID GLIOBLASTOMA

Epithelioid glioblastoma has predilection for children and young adults. *De novo* tumor usually expresses SMARCB1. Tumor frequently has BRAF V600E mutations. Most common sites of tumor are temporal and frontal lobes of cerebral cortex and diencephalon. Tumor spreads by leptomeningeal dissemination. It is an aggressive tumor associated with fatal outcome with six months.

Radiologic Findings

Gadolinium enhanced magnetic resonance imaging demonstrates epithelioid glioblastoma as solid mass in the cerebral cortex (frontal or temporal region) or diencephalon with leptomeningeal seeding.

Surgical Pathology: Epithelioid Glioblastoma

Gross Morphology

Tumor is unifocal with prominent areas of hemorrhage and necrosis.

Light Microscopy

- Tumor is composed of monomorphic population of large epithelioid cells containing abundant eosinophilic cytoplasm, vesicular nucleus with prominent nucleoli.
- Tumor cells are reminiscent of melanoma cells.
- Rhabdoid cells are also sometimes demonstrated.

Immunohistochemistry Technique

Panel of immunomarkers is applied on paraffin-embedded sections of epithelioid glioblastoma such as vimentin, S-100 protein, GFAP, cytokeratin AE1/AE3, EMA. Tumor is negative for melan-A, desmin, myoglobin and smooth muscle actin.

Markers	Expression
▪ Vimentin	▪ Positive
▪ S-100 protein	▪ Positive
▪ GFAP	▪ Positive
▪ Cytokeratin AE1/AE3	▪ Positive
▪ EMA	▪ Positive
▪ Melan-A	▪ Negative
▪ Desmin	▪ Negative
▪ Myoglobin	▪ Negative
▪ Smooth muscle actin (SMA)	▪ Negative

GLIOBLASTOMA MULTIFORME WITH A PRIMITIVE NEUROECTODERMAL TUMOR COMPONENT

Glioblastoma multiforme with a primitive neuroectodermal tumor component (GBM-PNET) affects elderly persons. It has high rate of cerebrospinal fluid dissemination.

Surgical Pathology: Glioblastoma Multiforme with a Primitive Neuroectodermal Tumor Component

Light Microscopy

- Tumor is composed of two histologically distinct different components: astrocytic cells and fibrillary network, supports the glial nature of the tumor.
- Another component of the tumor demonstrates cellular areas of small tumor cells distributed in multifocal pattern.
- Tumor cells contain narrow cytoplasm and hyperchromatic nuclei, which can occasionally form pseudorosettes and numerous mitoses.

Immunohistochemistry Technique

GFAP is demonstrated in astrocytic cells and fibrillary network in glioblastoma with a primitive neuroectodermal tumor component.

Marker	Expression
GFAP	Positive

OLIGODENDROGLIAL TUMORS

Oligodendroglial tumors are neuroepithelial tumors arising from neuroglial cells, which include oligodendroglioma, IDH-mutant (WHO grade II) and anaplastic oligodendroglioma, IDH-mutant and 1p/19q codeleted (WHO grade III).

OLIGODENDROGLIOMA

Oligodendrogliomas account for <20% of all intracranial tumors and 25% of gliomas. Oligodendroglioma is slow growing and well circumscribed low-grade tumor (WHO grade I) affecting middle age group (30–50 years).

- Tumor arises from oligodendrocytes in the white matter of frontal lobe (most common).
- Molecular genetic analysis of oligodendroglioma demonstrates mutation in IDH1/IDH2, mutation in FUBP1 due to 1p/19q codeletion, and promoter hypermethylation of the MGMT gene.

Clinical Features

Patient presents with seizures, increased intracranial pressure, focal neurological deficits and cognitive changes.

Radiographic Findings

Radiograph most often shows intra-axial mass, occasionally well-circumscribed mass, and small foci of calcification (best seen on CT scan).

Surgical Pathology: Oligodendroglioma

Gross Morphology

- Oligodendroglioma is soft well-defined grayish-pink tumor.
- Cut surface is gritty due to calcification. Tumor has gelatinous appearance.

Light Microscopy

- Oligodendroglioma is diffusely growing highly cellular tumor and composed of cells with round uniform nuclei, distinct borders, eosinophilic to clear cytoplasm, moderate to marked nuclear atypia resembling 'fried egg' appearance.
- Acutely branched delicate capillary sized blood vessels with 'chicken wire' like appearance are present between group of neoplastic cells.
- Calcification (calcispherite) is an important feature throughout the tumor.
- Anaplastic oligodendroglioma (WHO grade III) shows brisk mitotic activity (>6 mitoses/10 high power fields), microvascular proliferation and necrosis (Fig. 30.21).

Immunohistochemistry Technique

Oligodendroglioma is positive for immunomarker GFAP.

Marker	Expression
GFAP	Positive

Molecular Genetic Alterations

A translocation between chromosomes 1p and 19q is the characteristic molecular finding in oligodendroglioma.

Prognosis

Prognosis of patient with oligodendroglioma depends on the histologic grade of the tumor, its location, and recognition of molecular genetic features that can be linked to chemosensitivity. The oligodendroglial tumors are prone to spontaneous hemorrhage owing to their delicate vasculature.

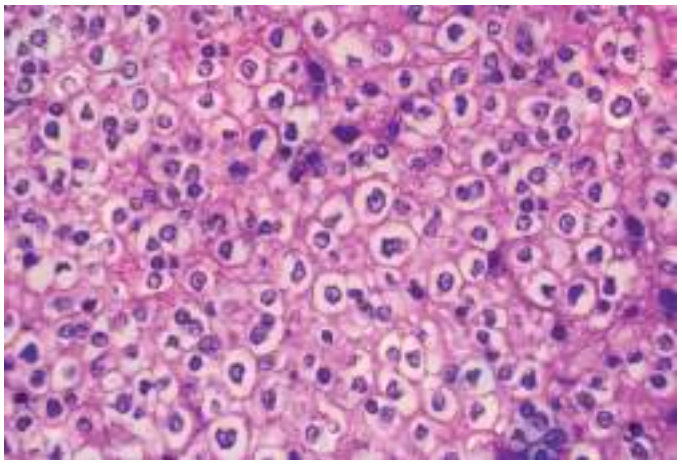

Fig. 30.21: Oligodendroglioma. The tumor cells show acute swelling of the perinuclear zones giving them a characteristic poached egg-like appearance (400X).

EPENDYMAL TUMORS

Ependymal tumors are neuroepithelial tumors arising from neuroglial cells, which include subependymoma (WHO grade I), myxopapillary ependymoma (WHO grade II), ependymoma, RELA fusion positive (WHO grade II or III) and anaplastic ependymoma (WHO grade III).

EPENDYMOMA

Ependymoma is a slow-growing malignant tumor derived from ependymal cells, which line the choroid plexus and ventricles and spinal cord. Ependymal cells participate in synthesis of cerebrospinal fluid.

- In children, tumor most often occurs in the 4th ventricle, where papillary growth produces obstruction and results in hydrocephalus.
- Whereas in middle-aged adults, tumor is most often located in the spinal cord and cauda equina. Although tumor can occur at any age, yet it most often occurs in the first two decades of life.

Clinical Features

The clinical features depend on the location of ependymal tumor. Intracranial tumor is often associated with hydrocephalus and evidence of increased intracranial pressure (ICP).

Surgical Pathology: Ependymoma

Gross Morphology

- Ependymoma is well-circumscribed, soft tan tumor with discrete margin from surrounding brain or spinal cord.
- Tumor grows exophytically into fourth ventricle and exit.
- Tumor can fill fourth ventricle and exit out through Luschka foramen or Magendie foramen.
- Gross morphology of ependymoma in right lateral ventricle is shown in Fig. 30.22.

Light Microscopy

- **Well-differentiated ependymoma:** Most ependymomas are well differentiated giving epithelial appearance similar to that of normal ependymal cells and glial differentiation. Tumor is composed of round to oval cells forming tubules with 'carrot-shaped nuclei' with abundant granular cytoplasm. A characteristic finding is the orientation of ependymal cells around vascular channels forming pseudorosettes.
- **Myxopapillary ependymoma:** A special variant, myxopapillary ependymoma may also originate from the lining of the central canal of the spinal cord and the filum terminale in lumbosacral portion region. Extensive invasion of adjacent CNS structures is uncommon. Light microscopy shows myxoid background (Fig. 30.23).
- **Anaplastic ependymoma:** Tumor is highly cellular and composed of numerous mitoses, blood vessels proliferation and necrosis with infiltrative vascularized cores lined by elongated cells forming papillary structures.

Immunohistochemistry Technique

Panel of markers is used to analyze expression in ependymoma on histopathologic sections.

Markers	Expression
GFAP	Positive
S-100 protein	Positive
Vimentin	Positive

Epithelial membrane antigen (EMA) is expressed on luminal surface of rosettes.

EPENDYMOMA WITH RELA FUSION POSITIVE

Ependymoma with RELA fusion positive tumor of central nervous system most often occurs in supratentorial region (mostly in lateral or third ventricle)

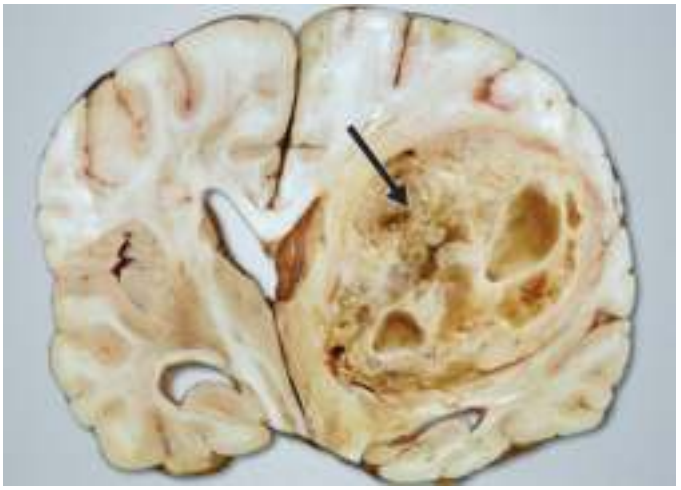

Fig. 30.22: Ependymoma in the right lateral ventricle. The tumor is well circumscribed and apparently confined to the ventricle. It has compressed the CSF pathways, causing dilatation of the third ventricle and the left lateral ventricle. The macroscopic appearance of this tumor suggests an ependymoma, but microscopic confirmation would be required (arrow).

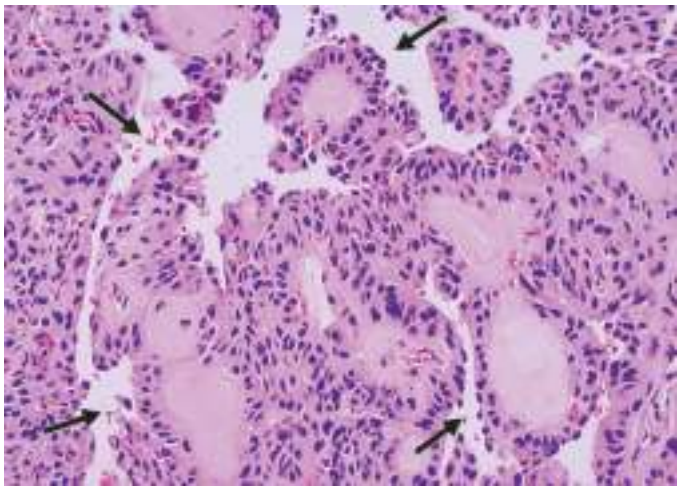

Fig. 30.23: Myxopapillary ependymoma. It is typically found arising in the filum terminale of the spinal cord. Note the cells around papillae structures that have a myxoid connective tissue core. Surgical removal is made easier if this tumor has not grown around nerve roots of the cauda equina (arrows) (400X).

in 70% of children and 30% of adults. It has not been reported in the infratentorial region. Detection of RELA fusion gene by fluorescence *in situ* hybridization (FISH) technique is diagnosis of ependymoma. It is worth mentioning that ependymoma in posterior fossa and spinal compartment do not harbor RELA fusion gene. Patient presents with headache, seizures or location-dependent focal neurological deficits. **Tumor spreads via cerebrospinal fluid** and is associated with poor prognosis.

Radiologic Features

Gadolinium enhanced magnetic resonance imaging demonstrates well circumscribed supratentorial mass (most in lateral or third ventricle but may not have obvious connection to a ventricle) with various degrees of contrast enhancement. Intratumoral hemorrhage, necrosis, calcification or cystic components may be present.

Surgical Pathology: Ependymoma with RELA Fusion Positive

Gross Morphology

- Tumor is well circumscribed arising in or near ventricular system.
- Cut surface is tan colored and spongy.
- Occasionally, gritty calcium deposit is demonstrated.

Light Microscopy

- Tumor is composed of well delineated glioma with monomorphic cells containing round to oval nuclei with speckled nuclear chromatin.
- Main features of the tumor are perivascular pseudorosettes and ependymal true rosettes, or anaplastic cells with high nucleocytoplasmic ratio with brisk mitotic activity, delicate network capillary blood vessels and focal clear cells.
- Uncommon variants of ependymoma such as tanycytic ependymoma are less likely to harbor RELA fusion.
- It should be differentiated from astrocytoma and medulloblastoma.

Immunohistochemistry Technique

- Panel of immunomarkers is applied on paraffin-embedded sections of ependymoma with RELA fusion positive such as GFAP, EMA, S-100 protein, vimentin and L1CAM with C11 or 95 rearrangement.
- Presence of RELA fusion gene can be analyzed by fluorescence *in situ* hybridization (FISH).

Markers	Expression
GFAP	Positive
EMA	Positive
S-100 protein	Positive
Vimentin	Positive
L1CAM with C11 or 95 rearrangement	Positive

CHOROID PLEXUS TUMORS

Choroid plexus tumors are neuroepithelial tumors arising from neuroglial cells, which include choroid plexus papilloma (WHO grade I), atypical choroid plexus papilloma (WHO grade II) and choroid plexus carcinoma (WHO grade III).

CHOROID PLEXUS PAPILLOMA

Choroid plexus papilloma is an uncommon tumor, which originates from neuroectodermal cells adjacent to embryonic lateral ventricles and fourth ventricle. Tumor leads to increased intracranial pressure due to obstruction to CSF flow resulting in obstructive hydrocephalus. There is little tendency of local infiltration. It spreads via CSF. It commonly affects children.

Surgical Pathology: Choroid Plexus Papilloma

Gross Morphology

- Choroid plexus papilloma is well circumscribed tumor.
- Cut surface shows cystic areas, calcification and hemorrhage.

Light Microscopy

- Tumor is composed of benign cuboidal to columnar cells arranged in tubules and acini.
- Tumor cells exhibiting pleomorphism, numerous mitoses, invasion, and lack of papillary pattern indicates malignant behavior.

EMBRYONAL TUMORS

Embryonal tumors are neuroepithelial tumors arising from neuroglial cells, which include medulloblastoma (all subtypes, WHO grade IV), embryonal tumor with multilayered rosettes, C19MC-amplification (WHO grade IV), medulloepithelioma (WHO grade IV), CNS embryonal tumor, NOS (WHO grade IV), atypical teratoid/rhabdoid tumor (WHO grade IV) and CNS embryonal tumor with rhabdoid features (WHO grade IV).

MEDULLOBLASTOMA

Medulloblastoma, WHO grade IV is second most common and highly malignant brain tumor of cerebellum. It originates from primitive neuroectodermal cells (fetal external granular layer) within cerebellar vermis (midline) in children; and within cerebral hemispheres in adults.

- Tumor accounts for 10% of primary central nervous system tumors. However, it accounts for 60% primary central nervous system tumors in children <15 years of age. It can occur in adults between 15 and 35 years.
- Molecular genetic alterations involving chromosome 17 are common in this tumor.
- Tumor originating within cerebellar vermis most often spreads down the neuroaxis and occludes the fourth ventricle resulting in hydrocephalous. Tumor may metastasize to bone and lymph nodes. Tumor suppressor genes associated with medulloblastoma are given in Table 30.29.

Surgical Pathology: Medulloblastoma

Gross Morphology

- Medulloblastoma is soft, fleshy, gray-tan tumor with variable hemorrhage and sometimes necrosis.
- Extensive stromal reticulin deposition may impart a firm consistency to desmoplastic variant of medulloblastoma.
- Medulloblastoma of spinal cord is shown in Fig. 30.24.

Light Microscopy

- Tumor is composed of poorly differentiated small cells with round-to-oval hyperchromatic nuclei and scant cytoplasm.
- Mitotic figures are often present in abundance. These cells form 'Homer-Wright' rosettes, histologic feature of neuroblasts.
- Histologic variants include classic and desmoplastic/nodular medulloblastomas (Figs 30.25 and 30.26).

Immunohistochemistry Technique

Panel of markers is used to differentiate from metastatic epithelial tumors, lymphomas, or other neuroectodermal malignancies.

Markers	Expression
Synaptophysin	Positive
Neuron-specific enolase (NSE)	Positive

Molecular Genetic Alterations

In 2021 WHO classification update, medulloblastoma is classified according to molecular characteristics and histologic features. Molecular classification is based on transcriptome, micro-RNA (miRNA), and methylome profiling for clinical treatment and histologic classification has also been retained due to its clinical utility when molecular genetic analysis is not feasible.

- **Wnt and sonic Hedgehog activation:** Wnt-activated and some Hedgehog active groups demonstrate activation of cell signaling pathways resulting in tumorigenesis in medulloblastoma.
- **C19MC alterations:** Amplification of the C19MC region on chromosome 9 is observed in embryonal tumor with multilayered rosettes (ETMR). The presence of focal amplification at chromosome region 19q13.42 is associated with an upregulation of the oncogenic miRNA cluster.

Metastasis

Since medulloblastoma occurs close to the fourth ventricle, it commonly disseminates into the subarachnoid space and via CSF seeds into the spinal cord.

Treatment

The location of the medulloblastoma tumor often makes it difficult to excise completely. Although highly radiosensitive, yet patients have poor prognosis.

EMBRYONAL TUMOR WITH MULTILAYERED ROSETTES

Embryonal tumor with multilayered rosettes (ETMR) is new entity defined by recent 2021 WHO classification of tumors of the central nervous system.

- Tumor is WHO grade IV in infants also known as embryonal tumor with abundant neuropil and true rosettes. Tumor demonstrates combined histologic features of neuroblastoma and ependymoblastoma, which had predilection for children in first five years of life in the cerebrum, cerebellum and brainstem.
- Presence amplification of the C19MC on chromosome 19 in both central nervous system PNET and embryonal tumor with abundant neuropil and true rosettes suggesting that these are the one entity exhibiting variable growth patterns.
- Tumor is locally invasive and disseminates via leptomeningeal extraneural routes. Tumor is aggressive and associated with poor prognosis.

Clinical Features

Patient presents with symptoms due to increased intracranial pressure such as seizures, hemiparesis, cerebellar signs, nerve palsies and other neurological deficits.

Table 30.29 Tumor suppressor genes associated with medulloblastoma

Tumor Suppressor Gene	Protein	Function	Familial Tumors	Sporadic Cancers
Mitogenic signaling pathway inhibitors				
PTCH	Patch	Inhibits Hedgehog signaling pathway	Gorlin's syndrome (basal cell carcinoma, medulloblastoma, other benign tumors)	▪ Medulloblastoma ▪ Basal cell carcinoma

Fig. 30.24: Medulloblastoma. Transverse section of spinal cord shows tumor in the subarachnoid space around the cord. This mode of spread is characteristically seen in medulloblastoma (arrow).

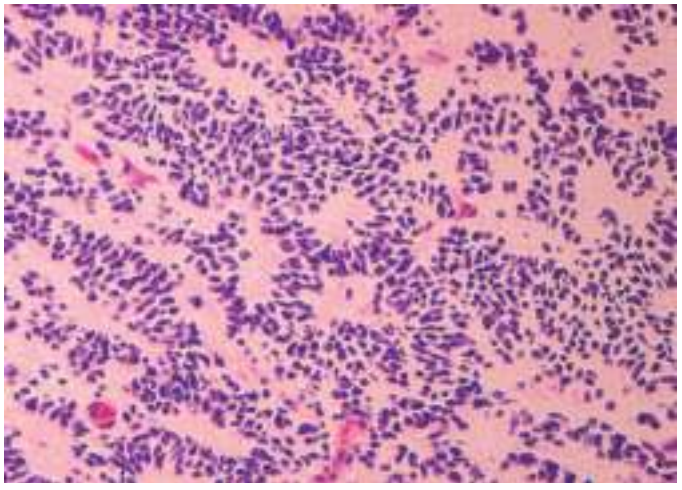

Fig. 30.25: Medulloblastoma. Tumor is composed of poorly differentiated small cells with round-to-oval hyperchromatic nuclei and scant cytoplasm. Mitotic figures are often present in abundance. These cells form 'Homer-Wright' rosettes, histologic feature of neuroblasts. Histologic variants include classic and desmoplastic/nodular medulloblastomas (400X).

Radiologic Findings

Magnetic resonance imaging (MRI) demonstrates a large, well demarcated and solid tumor with surrounding edema. There is no contrast enhancement. Macrocalcifications and cystic components may be demonstrated in some cases. Magnetic resonance spectroscopy demonstrates choline peak and high ratio of choline and aspartate suggesting hypercellularity of the tumor.

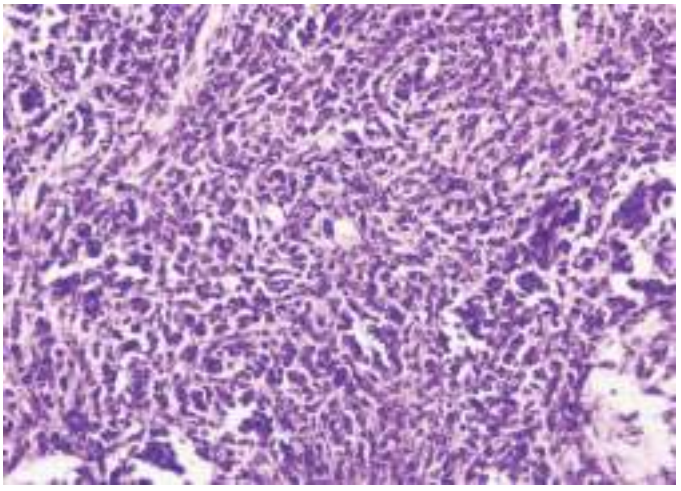

Fig. 30.26: Medulloblastoma. Tumor is composed of poorly differentiated small cells with round-to-oval hyperchromatic nuclei and scant cytoplasm. Mitotic figures are often present in abundance. These cells form 'Homer-Wright' rosettes, histologic feature of neuroblasts. Histologic variants include classic and desmoplastic/nodular medulloblastomas (400X).

Surgical Pathology: Embryonal Tumor with Multilayered Rosettes

Gross Morphology

- Large tumor involving multiple lobes can protrude to cerebellopontine cistern.
- Tumor is well circumscribed, grayish to pink with areas of hemorrhage, necrosis and calcification.

Light Microscopy

- Tumor is composed of highly cellular population of primitive cells alternating with hypocellular neuropil-rich regions containing multilayered pseudostratified neuroepithelium, true rosettes and cells with glial and neuronal differentiation.
- The lumen is either empty or filled with eosinophilic debris. Nucleus of cells is pushed away from the lumen.

Molecular Genetic Alterations Analysis

Amplification of 19q13.42 chromosomal region on fluorescence *in situ* hybridization analysis confirms the diagnosis.

Immunohistochemistry Technique

Panel of immunomarkers is applied on paraffin-embedded sections such as vimentin, EMA, cytokeratin, CD99, neuropil, synaptophysin and NFPs.

Markers	Expression
▪ Vimentin	▪ Positive
▪ EMA	▪ Positive
▪ Cytokeratin	▪ Positive
▪ CD99	▪ Positive
▪ Neuropil	▪ Positive
▪ Synaptophysin	▪ Positive
▪ NFPs	▪ Positive
▪ Glial marker	▪ Negative
▪ Neuronal marker	▪ Negative

MENINGEAL TUMORS

Meningeal tumors include meningoepithelial meningioma (WHO grade I), fibroblastic meningioma (WHO grade I), transitional meningioma (WHO grade I), psammomatous meningioma (WHO grade I), metaplastic meningioma (WHO grade II), chondroid meningioma (WHO grade II), clear cell meningioma (WHO grade II), atypical meningioma (WHO grade II), papillary meningioma (WHO grade III), rhabdoid meningioma (WHO grade III) and anaplastic meningioma (WHO grade III).

MENINGIOMA

Meningioma is the second most common primary intracranial benign neoplasm of adults, which arises from the meningoepithelial cells of the arachnoid mater. Tumor accounts for 20% of all primary intracranial neoplasms. Tumor may compress the brain or permeate the overlying bone. It most often occurs in women than men between 20 and 60 years of age with a peak incidence around 45. Spinal meningiomas are more common in females than males. Tumor is uncommon in children.

Locations

Common locations of meningiomas include convexities of the brain near venous sinuses, parasagittal region along the falx cerebri (most common site), along skull base, or tentorium, olfactory nerve sheath in the groove beneath the frontal lobe, lesser wing of sphenoid wing, sella turcica, and foramen magnum and within the spinal cord in thoracic segment. Occasionally, these tumors may arise in the ventricular system.

Clinical Features

Meningioma is slow-growing, well-circumscribed, and often highly vascular benign tumors. Complete removal is possible if the tumor does not involve vital structures especially present external to the brain.

Radiologic Findings

Meningiomas often infiltrate overlying bone and cause increased bone density (hyperostosis) seen on X-ray.

Surgical Pathology: Meningioma

Gross Morphology

- Meningiomas are popcorn shaped, firm, well circumscribed lobulated masses adherent to dura and invade dura or dural sinuses.
- Tumor may indent the surface of the brain without invading, which is common cause of new-onset focal seizures (Fig. 30.27).

Light Microscopy

Meningiomas are classified based on grade according to WHO classification. Grade I tumor has benign course. Grades II and III grow rapidly with great propensity to recur following resection. Fluorescence *in situ* hybridization (FISH) technique can detect genetic alterations and histologic grading of tumor. Histologic variants, grades, mitotic figures and survival rate in meningiomas are given in Table 30.30.

- **WHO grade I meningiomas:** Examples are meningoepithelial, fibroblastic, transitional and psammomatous meningiomas. Meningiomas exhibit many different microscopic patterns.
  - Tumor consists of swirling masses of fusiform meningothelial cells with oval nuclei containing dispersed chromatin in a composite solid and whorled pattern.
  - Small foci of calcification (psammoma bodies–calcified bodies) are common. These express estrogen receptors.
  - Meningoepithelial or transitional meningiomas should be differentiated from metastatic carcinoma and fibroblastic meningioma from schwannoma (Figs 30.28 to 30.31).
- **WHO grade II meningiomas (atypical meningiomas):** Examples are metaplastic, chondroid, clear cell and atypical meningiomas. These tumors have a higher mitotic index (≥4 mitoses/10 high power fields), increased cellularity, increased nucleocytoplasmic ratio, prominent nucleoli. Immunohistochemistry reveals increased Ki-67. These are associated with local invasion and increased risk for recurrence after resection.
- **WHO grade III meningiomas (anaplastic meningiomas):** Examples are papillary, rhabdoid and anaplastic meningiomas. These tumors must exhibit increased mitoses (≥20 mitotic figures/10 or 40 high power fields).

Immunohistochemistry Technique

Most meningiomas show weak positivity for epithelial membrane antigen (EMA) and progesterone receptors. Immunoreactivity for progesterone receptor is less in grades II and III meningiomas. S-100 protein immunoreactivity is patchy rather than diffuse in meningiomas. Atypical meningiomas exhibit increased Ki-67 (MIB-1 antibody).

Molecular Genetic Alterations

Meningioma is associated with neurofibromatosis type 2 due to mutation of NF2 gene located on long arm of chromosome 22 in person with previous history of irradiation. It is considered to be important for tumor development. Loss of the CDKN2A/p16 region on 9p/21 in anaplastic meningiomas is associated with

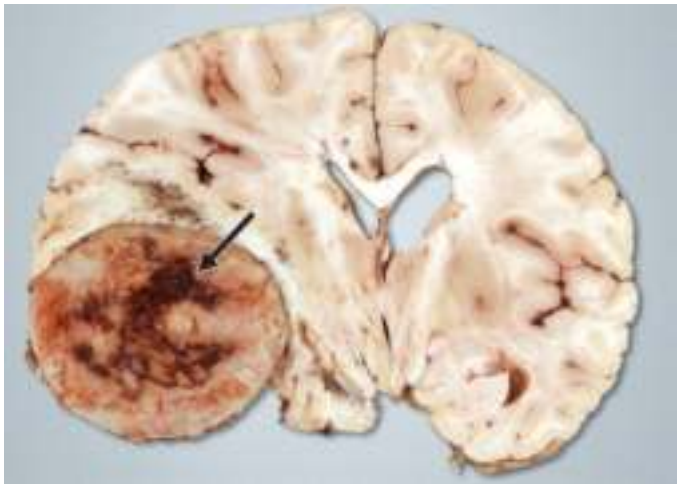

Fig. 30.27: Meningioma. Tumor arises from the dura is well encapsulated. It is cured by surgical excision (arrow).

poor prognosis. Lack of genetic 9p/21 alteration in meningiomas is associated with long survival. Tumor suppressor genes associated with meningiomas are given in Table 30.31.

DIFFUSE LEPTOMENINGEAL GLIONEURONAL TUMOR

Diffuse leptomeningeal glioneuronal tumor is a new entity defined by recent 2021 WHO classification of tumors of the central nervous system. It is also known as disseminated oligodendroglial-like leptomeningeal tumor of childhood, that presents as a plaque-like subarachnoid tumor, commonly involving the basal cisterns and interhemispheric fissure but lacking intraparenchymal tumor. It usually affects children and adolescents. Most common sites of tumor are posterior fossa, spinal region, intracranial leptomeninges.

Table 30.30 Histologic variants, grades, mitotic figures and survival rate in meningioma

Tumor and Histologic Grade	Histologic Features and Mitoses	Clinical Course and Survival
WHO grade I meningiomas		
▪ Meningothelial (syncytial) meningioma	▪ Cell borders are not easily demonstrated (syncytium-like histologic features) ▪ Mitoses nil ▪ Survival 5–20 years	▪ Slow-growing benign tumors ▪ Enlargement of tumor growth leads to clinical manifestations like headache, seizures, or focal neurologic deficits due to compression
▪ Fibroblastic (fibrous) meningioma	▪ Tumor is composed of spindle cells admixed with syncytium-like cells; and calcification in a linear fashion ▪ Mitoses nil	
▪ Transitional meningioma	▪ Tumor is composed of syncytial and fibroblastic elements; and psammoma bodies ▪ Mitoses nil	
▪ Psammomatous meningioma	▪ Tumor is composed of syncytial and fibroblastic elements; and numerous psammoma bodies ▪ Mitoses nil	
▪ Angiomatous meningioma	▪ Tumor is composed of neoplastic cells and dense vasculature ▪ Mitoses nil	
▪ Metaplastic meningioma	▪ Tumor is composed of neoplastic cells and areas of cartilage and/or bone ▪ Mitoses nil	
▪ Secretory meningioma	▪ Tumor is composed of neoplastic cells with brightly eosinophilic intracytoplasmic globular inclusions of proteinaceous secretions of varying size and shape termed 'pseudopsammomatous bodies', strongly positive for epithelial membrane antigen and cytokeratins ▪ Mitoses nil	
▪ Lymphoplasmacytic-rich meningioma	▪ Tumor is composed of bioplastic cells admired with chronic inflammatory cells, i.e. lymphocytes and plasma cells ▪ Mitoses nil	
▪ Microcystic meningioma	▪ Tumor is showing microcystic architecture throughout and often hyalinized, vasculature and angiomatous subtype ▪ Mitoses nil	
WHO grade II meningiomas		
▪ Choroid meningioma	▪ Tumor is composed of neoplastic cells, separated by myxoid matrix ▪ Mitoses ≥4 mitoses/10 high power fields	▪ Rapidly growing tumors ▪ Recurrence following excision

Contd...

Table 30.30 Histologic variants, grades, mitotic figures and survival rate in meningioma (*Contd...*)

Tumor and Histologic Grade	Histologic Features and Mitoses	Clinical Course and Survival
▪ Clear cell meningioma	▪ Tumor is composed of neoplastic cells with cytoplasmic clearing obscuring meningothelial nature; highlighted by immunostaining for vimentin or epithelial membrane antigen ▪ ≥4 mitoses/10 high power fields	▪ Survival rate of 5 years
WHO grade III meningiomas		
▪ Rhabdoid meningioma	▪ Tumor is composed of small epithelioid cells with globular eosinophilic cytoplasm and eccentric nuclei termed 'rhabdoid'; and increased mitotic activity ▪ Mitoses ≥20 mitotic figure/10 or 40 high power fields	▪ Rapidly growing tumors ▪ Recurrence following excision ▪ Survival rate of <2 years
▪ Papillary meningioma	▪ Tumor is composed of perivascular pseudorosettes giving papillary appearance; and increased mitotic activity ▪ Mitoses ≥20 mitotic figure/10 or 40 high power fields	

Genetic alterations: Grade I meningiomas demonstrate NF gene mutation (locus 22q); and grade III meningiomas exhibit loss of the CDKN2A/p16 region on 9p/21.

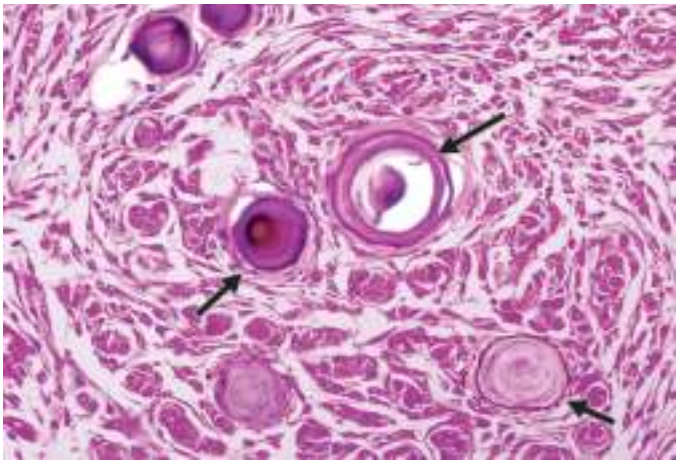

Fig. 30.28: Meningioma. Tumor consists of swirling masses of fusiform meningoepithelial cells with oval nuclei containing dispersed chromatin in a composite solid and whorled pattern. Small foci of calcification (psammoma bodies–calcified bodies) are common (arrows) (400X).

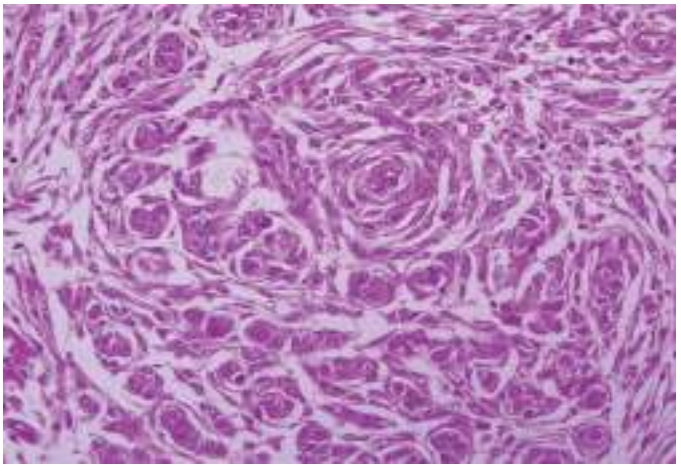

Fig. 30.30: Meningothelial meningioma. Tumor is composed of sheets, whorls, or syncytia of neoplastic cells with round to oval centrally located smooth nuclei with dispersed chromatin, small indistinct nucleoli, and absence of mitoses (400X).

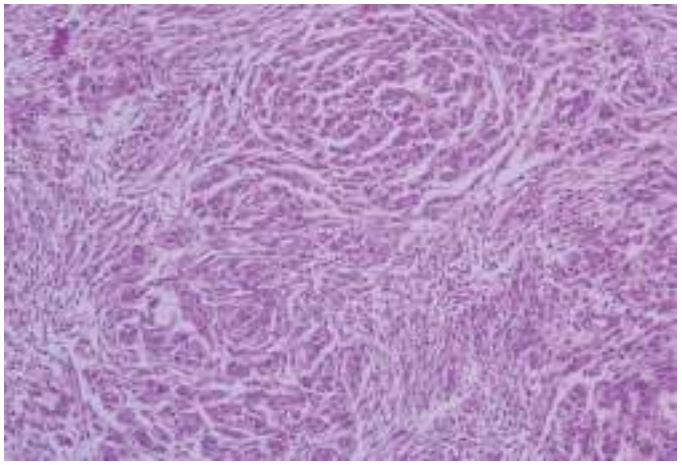

Fig. 30.29: Meningothelial (syncytial) meningioma. Cell borders are not easily demonstrated (syncytium-like histologic features) and absence of mitoses (400X).

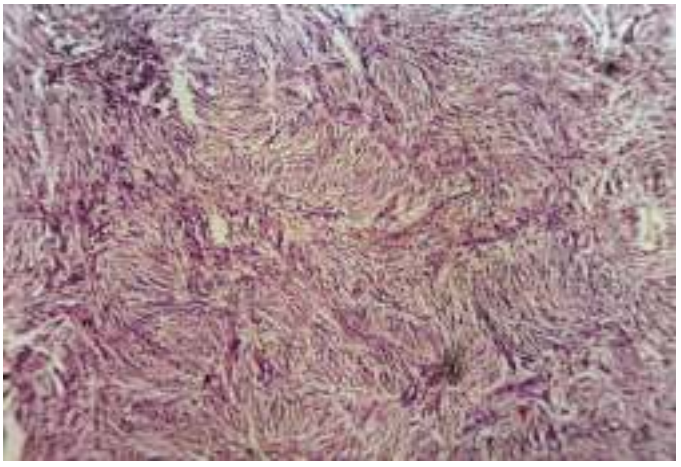

Fig. 30.31: Fibroblastic meningioma. Tumor composed of spindle cells admixed with syncytium-like cells; and calcification in a linear fashion. Mitoses are absent (400X).

Table 30.31 Tumor suppressor genes associated with meningiomas

Gene	Protein	Function	Familial Tumors	Sporadic Cancers
Mitogenic signaling pathway inhibitors				
NF2	▪ Merlin (locus 22q) ▪ Mutation by deletion or nonsense mutation	NF2 stabilizes cytoskeleton membrane linkage	Neurofibromatosis type 2 (acoustic schwannoma and meningioma)	▪ Meningiomas ▪ Schwannomas

Clinical Features

Patient presents with headache, nausea and vomiting due to increased intracranial pressure as a result of obstructive hydrocephalus; opisthotonos (spasm of skeletal muscles causing backward arching of the head and neck), and signs of meningeal or cranial nerve damage. Prognosis is moderate.

Radiologic Findings

Magnetic resonance imaging (MRI) demonstrates meningeal enhancement with thickening and hyperintense T2.

Mode of Spread

Tumor spreads via cerebrospinal fluid. Cerebrospinal fluid examination shows high protein and negative cytology.

Surgical Pathology: Diffuse Leptomeningeal Glioneuronal Tumor

Gross Morphology

- Intraparenchymal tumor is well circumscribed and solid/cystic nodules.
- Multifocal extension of the tumor occurs along Virchow-Robin space.

Light Microscopy

- Tumor demonstrates low-to-moderate cellularity. Tumor is composed of sheets of monotonous rounded cells with perinuclear halos identical to oligodendroglial cells.
- Tumor cells contain round-to-oval nuclei with finely granular dispersed chromatin and inconspicuous nucleoli and low mitotic index (<1%).
- Intense desmoplastic fibrous response is seen.

Immunohistochemistry Technique

Panel of immunomarkers is applied on paraffin-embedded sections such as BRAF fusion, synaptophysin, OLIG2, S-100 protein, glial fibrillary acidic protein (GFAP).

Markers	Expression
▪ BRAF fusion	▪ Positive (most common)
▪ Synaptophysin	▪ Positive (diffuse staining)
▪ OLIG2	▪ Positive (diffuse staining)
▪ S-100 protein	▪ Positive (patchy staining)
▪ GFAP	▪ Positive (patchy staining)
▪ Neurofilament	▪ Negative
▪ EMA	▪ Negative
▪ IDH mutation absent	▪ Negative

TUMORS OF THE CRANIAL AND PARASPINAL NERVES

Tumors of the cranial and paraspinal nerves include schwannoma (WHO grade I), neurofibroma (WHO grade II), perineuroma (WHO grade I) and malignant peripheral nerve sheath tumor (WHO grade III).

SCHWANNOMA (NEURILEMMOMA)

Schwannoma (also known as neurilemmoma) is a slowly growing benign encapsulated tumor (WHO grade I).

- The tumor originates from differentiated Schwann cell intimately surrounding axons of cranial nerves (e.g. vestibulocochlear cranial nerve), posterior spinal nerve roots or peripheral nerves. Tumor is eccentric to nerve.
- Essential features of schwannoma include: (a) biphasic tumor with highly ordered cellular component (Antoni A) that palisades (Verocay bodies) plus myxoid hypocellular component (Antoni B); (b) tumor usually associated with an identifiable nerve; and (c) strong immunoreactivity for S-100 calcium-binding protein.
- The tumor usually affects adults of 20–50 years of age with equal sex predilection. About 90% are sporadic and 3% associated with neurofibromatosis type 2.

Locations

Schwannomas are most often intracranial in cerebellopontine angle with involvement of the vestibulocochlear cranial nerve (acoustic neuroma). Expansion of the tumor results in tinnitus (most common) and sensorineural deafness. These tumors also originate frequently in posterior spinal nerve roots and peripheral nerves (upper limbs, head and neck, salivary glands, posterior mediastinum and retroperitoneum).

Pathophysiology

Schwannoma can occur sporadic in 90% and 3% with neurofibromatosis type 2 (NF2), schwannoma or Carney complex, which occurs due to direct genetic alteration involving the NF2 gene on chromosome 22 or secondarily to merlin inactivation. NF2 gene mutation can cause other neoplasms including meningioma, mesothelioma, glioma multiforme and carcinomas of breast, colorectum, kidney (clear cell type), liver, prostate and skin.

Table 30.32 Comparison of neurofibromatosis type 1 and neurofibromatosis type 2

Parameters	Neurofibromatosis Type 1 (NF1)	Neurofibromatosis Type 2 (NF2)
Mitogenic signaling pathway inhibitors		
Germline NF1 and NF2 gene mutation	NF1 gene mutation on chromosome 17p11 by deletion	NF2 gene mutation on chromosome 22q12.2 by deletion or nonsense mutation
Encoded defective protein by NF1 and NF2	Neurofibromin 1 inactivation	Merlin inactivation
Encoded protein function by NF1 and NF2 genes	Neurofibromin 1 homologous to GAP protein, that influences cell cycle by downregulating p21 ras gene (RAS/MAP-kinase signaling pathway)	Merlin stabilizes skeleton membrane linkage
Diagnostic criteria	Patient presents with two or more neurofibromas or one plexiform neurofibroma, six or more café au lait macules >5 mm (pubertal) or >15 mm (postpubertal), ocular iris hamartomas, sphenoid bone dysplasia and first degree relative with neurofibromatosis type 1	Diagnostic criteria of neurofibromatosis type 2 include bilateral vestibular schwannomas or family history of neurofibromatosis type 2 in first degree relative and unilateral vestibular schwannoma in below 30 years of age and any two of the lesions, i.e. meningioma, schwannoma, glioma, posterior subcapsular lenticular opacities/juvenile cortical cataract

Pathology Pearls: Neurofibromatosis Type 2

- Diagnostic criteria of neurofibromatosis type 2 include bilateral vestibular schwannomas or family history of neurofibromatosis type 2 in first degree relative and unilateral vestibular schwannoma in below 30 years of age and any two of the lesions, i.e. meningioma, schwannoma, glioma, posterior subcapsular lenticular opacities/juvenile cortical cataract.
- Comparison of neurofibromatosis type 1 and neurofibromatosis type 2 is given in Table 30.32.

Radiologic Findings

Schwannoma is well circumscribed mass eccentric to nerve, which displaces adjacent structures without direct invasion. Cystic degeneration or hemorrhage can be seen as areas of heterogeneity in large tumor. Hemorrhage and calcification are less frequent.

Surgical Pathology: Schwannoma (Neurilemmoma)

Gross Morphology

Classic schwannoma is encapsulated tan-yellow mass measuring 2–10 cm in diameter. Sinonasal and intracranial schwannomas are not encapsulated.

Light Microscopy

Classic schwannoma is encapsulated and composed of alternating Antoni A cellular component with Verocay bodies (cellular areas surrounded by nuclear palisading); and Antoni B hypocellular component with myxoid architecture (Fig. 30.32).

- **Antoni A cellular component of schwannoma:** It is cellular component composed of monomorphic spindle-shaped Schwann cells containing poorly defined cytoplasm, pointed basophilic nuclei set in a variably collagenous stroma showing nuclear palisading surrounding pink areas known as 'Verocay bodies'.
- **Antoni B cellular component of schwannoma:** It is composed of Schwann cells containing inconspicuous cytoplasm and nuclei suspended in abundant myxoid microcystic matrix (the pattern resembles the stripes of a zebra).

Differential Diagnosis

Schwannoma should be differentiated from neurofibroma, nevomelanocytic lesions, leiomyosarcoma, gastrointestinal stromal tumor and malignant peripheral nerve sheath tumor (MPNST).

Immunohistochemistry Technique

Schwannoma shows strong positivity for S-100 protein.

Marker	Expression
S-100 protein	Positive

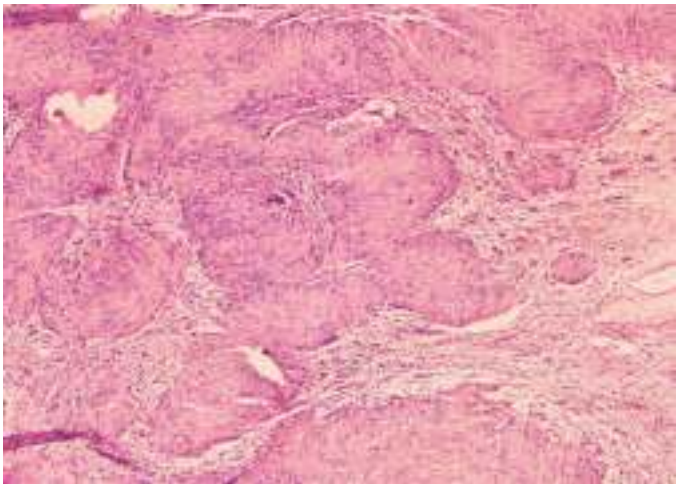

Fig. 30.32: Schwannoma (neurilemmoma). Tumor is composed of cells with palisading nuclei arranged in compact whorls and fascicles (Antoni type A), interspersed with less cellular loosely structured myxomatous appearing areas designated Antoni type B areas (100X).

Prognosis and Treatment

Schwannoma is a slow-growing tumor that very rarely undergoes malignant transformation. It is treated by surgical excision. Sudden progressive increase in size of tumor is a concerning feature. Schwannoma may transform to malignant peripheral nerve sheath tumor (MPNST), angiosarcoma and epithelioid malignant change. Neurofibromatosis type 2 caused due to germline NF2 gene mutation is difficult to treat.

NEUROFIBROMA, NEUROFIBROMATOSIS TYPE 1 AND MALIGNANT CHANGE IN NEUROFIBROMA

Neurofibroma is a benign tumor, which arises from within a peripheral nerve. Solitary neurofibroma is relatively common, which can be associated with neurofibromatosis type 1. Neurofibromatosis type 1 is characterized by multiple neurofibromas, café au lait spots, optic iris hamartoma, sphenoid bone dysplasia, macrocephaly, short stature and mental retardation.

Pathology Pearls: Diagnostic Criteria of Neurofibromatosis Type 1

- Patient presents with two or more neurofibromas or one plexiform neurofibroma, six or more café au lait macules >5 mm (pubertal) or >15 mm (postpubertal), ocular iris hamartomas, sphenoid bone dysplasia and first degree relative with neurofibromatosis type 1.
- Out of these clinical manifestations, patient must have at least two or more features.

Locations and Age Distribution

Solitary neurofibroma is relatively a common tumor. Plexiform neurofibroma associated with neurofibromatosis type 1 is relatively uncommon. Both tumors originate from peripheral nerve especially in the scalp region and lower extremities. Neurofibroma usually affects persons 20–40 years of age. Neurofibroma associated with neurofibromatosis type 1 affects children and adolescents with male predominance.

Clinical Features

Patient with neurofibromatosis type 1 presents with solitary or multiple neurofibromas, café au lait spots, optic iris hamartoma, sphenoid bone dysplasia, macrocephaly, short stature and mental retardation. Clinical photograph of patient with multiple neuromas in neurofibromatosis type 1 is shown in Fig. 30.33.

Surgical Pathology: Neurofibroma, Neurofibromatosis Type 1 and Malignant Change in Neurofibroma

Gross Morphology

- **Solitary neurofibroma:** Tumor is well delineated and fusiform-shaped mass measuring 1–2 cm in diameter.
- **Diffuse neurofibroma:** Tumor is gray plaque-like thickening of dermis with soft in consistency.
- **Plexiform neurofibroma:** Tumor is large soft tissue mass giving 'bag of worms' appearance (Fig. 30.34).

Light Microscopy

- **Neurofibromatosis type 1:** Cellular and stromal milieu in neurofibromatosis type 1 include Schwann cells, intraneural fibroblasts, collagen bundles, myxoid change and increased cellularity in the center of neurofibroma, when compared with edematous appearance in the peripheral region of neurofibroma.
- **Solitary neurofibroma:** Tumor is composed of spindle cells arranged in storiform pattern with abundant intervening collagen fibers. Intraneural growth is extending into the surrounding tissue (Fig. 30.35).
- **Diffuse neurofibroma:** Tumor is composed of small round to spindle cells associated with fibrillar and myxoid background. It infiltrates subcutaneous fat in a honeycomb pattern. Presence of 'Wagner-Meissner bodies' is the hallmark of diffuse neurofibroma.
- **Plexiform neurofibroma:** Tumor is tortuous distension of peripheral nerve showing plexiform architecture demonstrated on imaging technique, gross morphology and histologic features with multiple intraneural nodules of tumor separated by epineurium and stroma. It can involve the subcutis or skeletal structures or both. Clinicopathologic diagnosis is established due to its 'bag of worms' appearance.
- **Low-grade malignant peripheral nerve sheath tumor (low-grade MPNST):** Neurofibroma may undergo early malignant transformation. Low-grade malignant peripheral nerve sheath tumor resembles neurofibroma but with increased cellularity with pleomorphism and arranged in fascicular architecture and scattered mitotic activity in the deep area of tumor.

Differential Diagnosis

Neurofibroma should be differentiated from schwannoma, malignant peripheral nerve sheath tumor (MPNST), benign fibrous histiocytoma and desmoplastic malignant melanoma.

Immunohistochemistry Technique

Neurofibroma and neurofibromatosis type 1 may undergo early malignant transformation show positivity for immunomarkers S-100 protein (Schwann cells), epithelial membrane antigen (EMA), CD34 (intraneural fibroblasts), neurofilament protein (NFP) and glial fibrillary acidic protein (GFAP).

Markers	Expression
S-100 protein	Positive
EMA	Positive
CD34	Positive
NFP	Positive
GFAP	Positive (occasional)

Molecular Genetic Alterations

Neurofibromatosis type 1 occurs due to germline mutation of NF1 tumor suppressor gene located on chromosome 17.

Fig. 30.33: Multiple neurofibromas in neurofibromatosis type 1.

Fig. 30.34: Plexiform neurofibroma. Plexiform neurofibroma (WHO grade I) is pathognomonic of neurofibromatosis type 1 (NF1) involving single or multiple nerve fascicles of major nerve branches.

- NF1 gene encodes aberrant protein product known as 'neurofibromin', homologous that affects cell cycle by disrupting p21 and RAS gene.
- Malignant transformation of neurofibroma is common in these patients.
- Neurofibromatosis type 1 is characterized by multiple neurofibromas, café au lait spots, optic iris hamartoma, sphenoid bone dysplasia, macrocephaly, short stature and mental retardation.

Prognosis and Treatment

Solitary neurofibroma, diffuse neurofibroma and plexiform neurofibroma may be associated with neurofibromatosis type 1. These are treated by surgical excision. Recurrence is common in diffuse neurofibroma after surgical excision. Early malignant peripheral nerve sheath tumor in a case of neurofibromatosis type 1 is treated similar to low-grade sarcoma. High-grade malignant transformation in neurofibroma is treated similar to high-grade sarcoma.

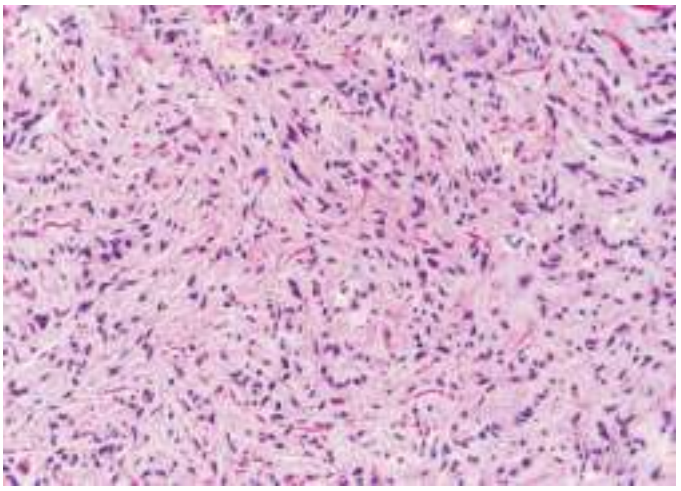

Fig. 30.35: Neurofibroma. Tumor is composed of elongated wavy cells with small dark oblong nuclei. This tumor is benign. However, persons with neurofibromatosis type 1 have a long-term risk for development of malignant neoplasms such as neurofibrosarcomas, malignant schwannomas, gliomas (400X).

MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

Malignant peripheral nerve sheath tumor (MPNST) can originate in *de novo* or in the setting of neurofibroma and neurofibromatosis type 1.

- Most common sites of MPNST buttock, thigh, brachial plexus, upper arm and paraspinal regions. Sporadic malignant nerve sheath tumor affects adults during second to fifth decades of life.
- On the other hand, malignant nerve sheath tumor originating in the setting of neurofibromatosis type 1 affects during third to sixth decades of life. Patient presents with signs and symptoms depending on location of malignant nerve sheath tumor.

Radiologic Findings

Malignant peripheral nerve sheath tumor (MPNST) poses diagnostic difficulty to differentiate from benign nerve sheath tumor on radiologic techniques. Tumor size >5 cm with irregular borders and presence of necrosis are suggestive of MPNST.

Surgical Pathology: Malignant Peripheral Nerve Sheath Tumor
Gross Morphology
▪ Malignant peripheral nerve sheath tumor is creamy gray and fusiform shaped measuring >5 cm in diameter. ▪ Cut surface shows areas of hemorrhage and necrosis.

Light Microscopy

- Malignant peripheral nerve sheath tumor exhibits diverse histologic patterns resembling marble-like appearance with alternating zones of hypercellularity and hypocellularity.
- Tumor is composed of neoplastic cells with waxy or buckled hyperchromatic nuclei and moderate amount of lightly eosinophilic cytoplasm.
- Neoplastic cells are arranged in long fascicles. In occasional area of the tumor, neoplastic cells may be arranged in storiform pattern.
- Hemangiopericytoma-like vascular pattern may also be demonstrated.
- Heterologous differentiation, e.g. skeletal muscle, cartilage, bone, blood vessels and glands, is demonstrated in few cases of neurofibromatosis type 1 related MPNST.

Differential Diagnosis

Malignant peripheral nerve sheath tumor should be differentiated from synovial sarcoma, fibrosarcoma, malignant solitary fibrous tumor and malignant melanoma.

Electron Microscopy

Malignant peripheral nerve sheath tumor shows melanosomes combined with schwannian features of well-developed basement membranes and complex processes.

Immunohistochemistry Technique

- Spindled malignant peripheral nerve sheath tumor accounts for 95% and shows positivity for HMB-45 and S-100 protein (weak and focal staining).
- Epithelioid malignant peripheral nerve sheath tumor shows positivity for HMB-45 and S-100 protein (strong staining).
- Malignant peripheral nerve sheath tumor with rhabdoblastic differentiation shows positivity for immunomarkers desmin, myogenin, MyoD1 and HMB-45.

Markers	Expression
Spindled malignant peripheral nerve sheath tumor	
▪ HMB-45 ▪ S-100 protein	▪ Positive ▪ Positive (weak and focal staining)
Epithelioid malignant peripheral nerve sheath tumor	
▪ HMB-45 ▪ S-100 protein	▪ Positive (strong staining) ▪ Positive
Malignant peripheral nerve sheath tumor with rhabdoblastic differentiation	
▪ Desmin ▪ Myogenin ▪ MyoD1 ▪ HMB-45	▪ Positive ▪ Positive ▪ Positive ▪ Positive

Prognosis and Treatment

Malignant peripheral nerve sheath tumor arising *de novo* and in the setting of neurofibromatosis type 1 has five-year survival rate in 85% of cases. Malignant nerve sheath tumor of head and neck region is a low-grade tumor with best prognosis.

TUMORS OF THE SELLAR REGION

Tumors of the sellar region include craniopharyngioma (WHO grade I), granular cell tumor of the neurohypophysis (WHO grade I), pituicytoma (WHO grade I), and spindle cell oncocytoma of the adenophysis (WHO grade I). Craniopharyngioma has been discussed in Chapter 26 (Endocrine System).

MESENCHYMAL NONMENINGEAL TUMORS

Mesenchymal nonmeningeal tumors include solitary fibrous tumor/hemangiopericytoma (WHO grade I, II or III) and hemangioblastoma (WHO grade I).

HEMANGIOBLASTOMA

Hemangioblastoma WHO grade I tumor occurs most frequently in the cerebellum, brainstem and spinal cord, which has cellular and reticular variants. Tumor sometimes produces erythropoietin, leading to secondary polycythemia. It is a slow-growing highly vascular tumor favoring cerebellum in adults.

Molecular Genetic Alterations

Hemangioblastoma occurs due to mutations of von Hippel-Lindau (vHL) disease gene located on 3p25–26. Mutation of vHL gene is associated with similar lesions in the retina, pheochromocytoma and renal cell carcinoma (clear cell variant) as part of vHL disease.

Radiologic Findings

Classic hemangioblastoma is well circumscribed tumor demonstrated by imaging techniques.

Surgical Pathology: Hemangioblastoma

Gross Morphology

- Hemangioblastoma is well circumscribed tumor.
- Cut surface shows cystic areas filled with fluid.

Light Microscopy

Tumor is composed of thin-walled vascular channels surrounded by large polygonal tumor cells with pale cytoplasm. There may be foci of hematopoietic tissue and mast cell infiltration (Fig. 30.36).

Immunohistochemistry Technique

Panel of immunomarkers is employed on histologic sections to highlight endothelial cells.

Markers	Expression
▪ CD31	▪ Positive
▪ CD34	▪ Positive
▪ CD56	▪ Positive
▪ S-100 protein	▪ Positive
▪ Vimentin	▪ Positive
▪ Neuron-specific enolase (NSE)	▪ Positive
▪ Inhibin-α	▪ Positive

PRIMARY CNS LYMPHOMA

Primary lymphoma occurs first in central nervous system (CNS) without evidence of system lymphoma, which usually occurs in cerebrum but also elsewhere. It accounts for <2% of brain tumors especially in AIDS, immunocompromised persons and even in immunocompetent elderly persons.

- Most primary CNS lymphomas are high-grade diffuse large B cell lymphoma. High incidence of T cell subtype of lymphoma is seen in Korea.
  - Patient presents with focal neurological deficits (50– 80%), neuropsychiatric symptoms (20–30%), increased intracranial pressure (10–30%), seizures (5–20%) and ocular symptoms (5–20%).
  - CSF cytology is helpful in diagnosing lymphoma of dura, leptomeningeal space or nerve roots.
  - CT and MRI scans demonstrate bilateral symmetric, subependymal, high signal foci are suggestive of primary CNS lymphoma on CT/MRI studies.
- In immunocompetent patients treated with radiotherapy and chemotherapy, 2-year overall survival is 40–75% and 5-year overall survival is 25–45%. AIDS patients have median survival of 2–6 months, increasing to 13 months with multimodal therapy.
- Poor prognostic factors for primary CNS lymphoma include multiple lesions, with periventricular or meningeal involvement, immunocompromised state, elderly person over 60 years, preoperative and Karnofsky performance scale index score (≤70).
- Karnofsky performance scale index is used to compare effectiveness of different therapies and to assess the prognosis in individual patient. In most serious illnesses, the lower the Karnofsky score, the worse the likelihood of survival. Expression of TP53, c-Myc or BCL-6 in immunocompetent patients is associated with poor prognosis in one study.

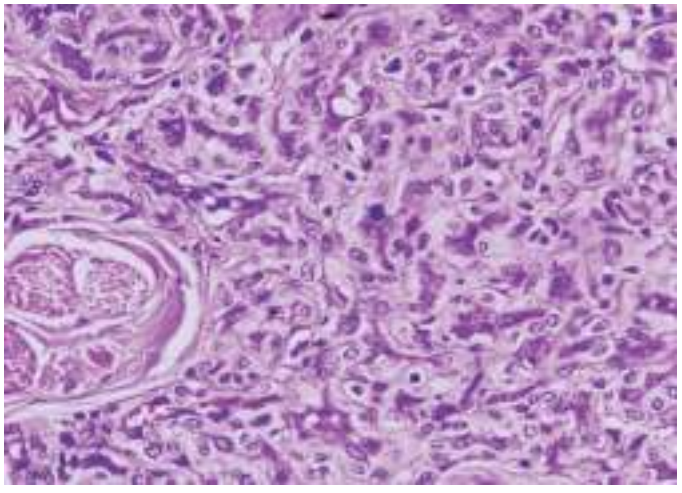

Fig. 30.36: Hemangioblastoma. Tumor is composed of thin-walled vascular channels surrounded by large polygonal tumor cells with pale cytoplasm (400X).

GERM CELL TUMORS OF NERVOUS SYSTEM

Germ cell tumors of central nervous system include germinoma, embryonal carcinoma, endodermal sinus tumor (yolk sac tumor) teratoma, and choriocarcinoma. These tumors usually occur in children, but may occur in adults especially in males than females.

- Patient with germ cell tumor located in pineal region presents with increased intracranial pressure. Tumor located in suprasellar region is associated with diabetes insipidus and hypopituitarism. Less common sites are basal ganglia and thalamus.
- Germ cell tumors exhibit heterogenous enhancement on MRI scan. Calcification is seen in teratomas. Hemorrhage is strongly suggestive of choriocarcinoma. Histologically, these tumors are homologous to their gonadal and mediastinal counterparts. Histologic examination and immunohistochemistry are diagnostic tools.
- Pure germinomas are radiosensitive tumors associated with excellent prognosis. Germinoma with syncytiotrophoblastic element has tendency to recur with less favorable prognosis. Mature teratomas are treated by surgical resection. Yolk sac tumor, embryonal carcinoma and choriocarcinoma have less favorable prognosis.

PRIMITIVE NEUROECTODERMAL TUMORS

Primitive neuroectodermal tumors (PNETs) are small blue tumors of the nervous system, which include medulloblastoma, neuroblastoma arising from autonomic ganglia in the abdomen, cerebral neuroblastoma, retinoblastoma, pineoblastoma and esthesioblastoma arising from nasal mucosa. These PNETs show similar morphology. Tumor cells possess high nucleocytoplasmic ratio and fibrillary processes demonstrated by silver staining technique. Nuclei are

small, oval and darkly stained. Mitoses are common. Many tumors show evidence of neuronal, glial or ependymal differentiation.

RETINOBLASTOMA

Retinoblastoma is a malignant retinal tumor of childhood. The tumor is sporadic (60%) and familial (40%). Sporadic retinoblastomas are unilateral and monocentric in origin. Familial retinoblastomas are more often bilateral and multicentric in origin. Some inherited cases also develop pinealoblastoma (so-called trilateral retinoblastoma). Retinoblastoma arises from the retina in children under 3 years. Around 40% of cases are inherited and the tumor may be bilateral. Remaining tumors arise sporadically and are usually unilateral.

Molecular Genetic Alterations

Retinoblastoma gene (RB gene) is a tumor suppressor gene situated on the short arm of chromosome 13(13q14), which encodes pRB. The normal RB protein prevents cell mitosis. The tumor is the prototype of the two-hit hypothesis of Knudson.

- In first hit, germline deletion inherited mutation of RB1 gene occurs in allele 1.
- In second hit, somatic deletion of RB gene occurs in remaining normal allele. Both deletions are required for tumor development of familial or sporadic retinoblastoma.
- Onset of familial retinoblastoma is earlier than sporadic form. Inherited and sporadic retinoblastoma is shown in Fig. 30.37A and B.

Surgical Pathology: Retinoblastoma

Gross Morphology

- Endophytic retinoblastoma growth protrudes into the vitreous cavity. Exophytic tumor grows between retina and pigment epithelium.
- Tumor may exhibit endophytic as well as exophytic growth patterns.
- Gross morphology of retinoblastoma is shown in Figs 30.38 and 30.39.

Light Microscopy

- Tumor is composed of small round cells with hyperchromatic nuclei and scant cytoplasm, numerous mitoses and formation of Flexner-Wintersteiner rosettes.
- These rosettes show central lumen lined by pink material with nuclei away from lumen (Fig. 30.40).

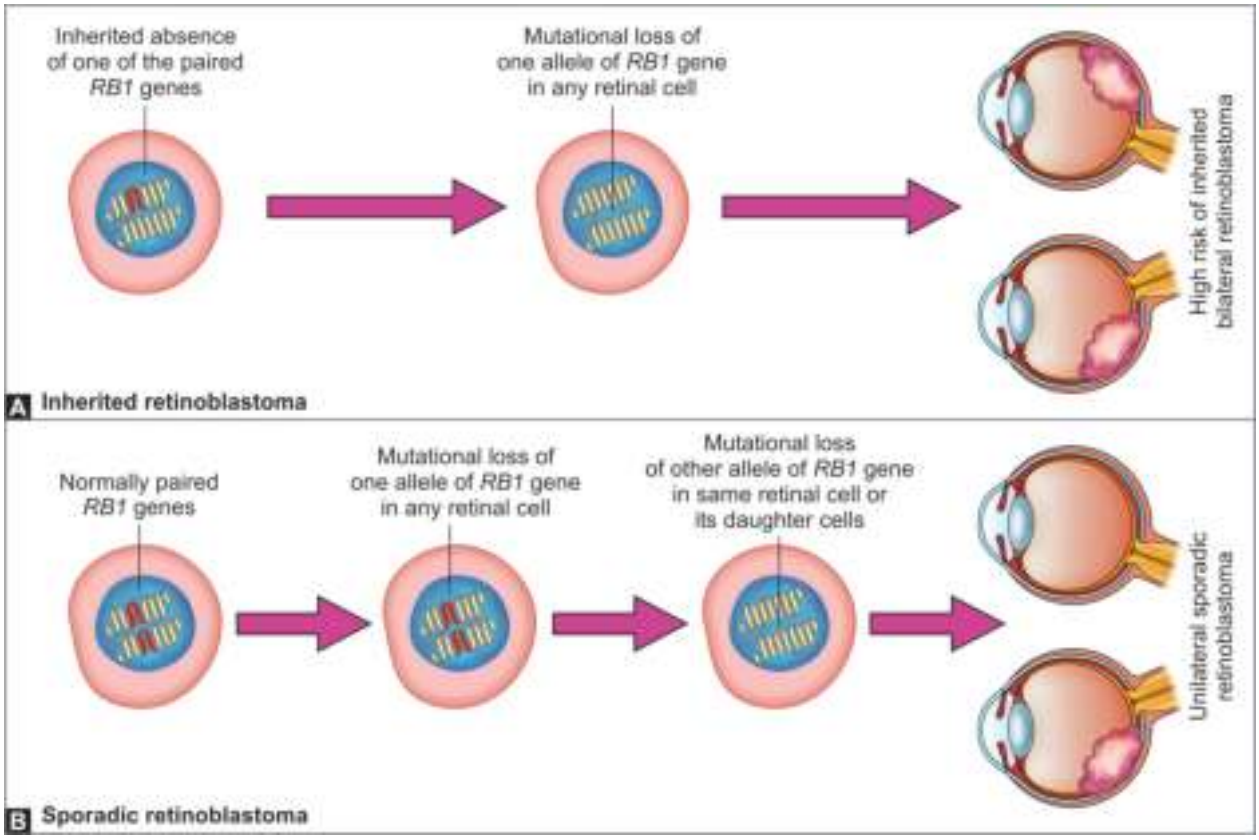

Fig. 30.37: Inherited and sporadic retinoblastoma. RB gene is a tumor suppressor gene located on long arm of chromosome 13. Mutation of RB1 gene predisposes to increased risk of development of retinoblastoma. (A) Germline mutation is one of the paired alleles of the RB1 gene is required to develop inherited bilateral retinoblastoma, (B) normal individuals without an inherited germline mutation of the RB1 gene have a low incidence of sporadic unilateral retinoblastoma.

Fig. 30.38: Retinoblastoma. The mother was alerted to the condition by the white color of the pupil. There was also some loss of vision.

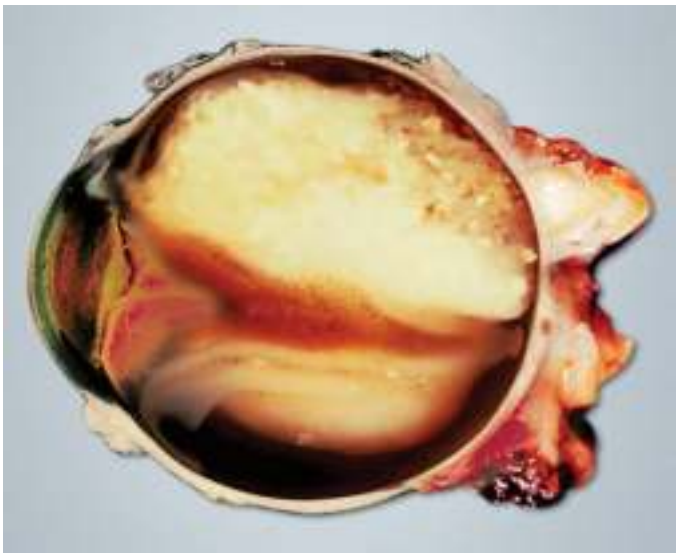

Fig. 30.39: Retinoblastoma. Tumor is filling the posterior chamber of the eye surgically excised. There was no spread along the subdural space around the optic nerve, no tumor in the other eye. There was no family history.

Immunohistochemistry Technique	
Panel of immunomarkers is used to analyze expression in retinoblastoma on histopathologic sections.	
Markers	**Expression**
▪ GFAP ▪ S-100 protein ▪ Neuron-specific enolase (NSE) ▪ Synaptophysin ▪ Myelin basic protein	▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Positive

Mode of Spread

The tumor may fill the eye and spread locally into the brain via the optic nerve or systemically after invasion of the choroid. Distant metastases are demonstrated in cranial vault and skeletal system.

Management

Modern therapy of retinoblastoma is curative in and around 90% of cases. Some inherited cases also develop pinealoblastoma, so-called trilateral retinoblastoma.

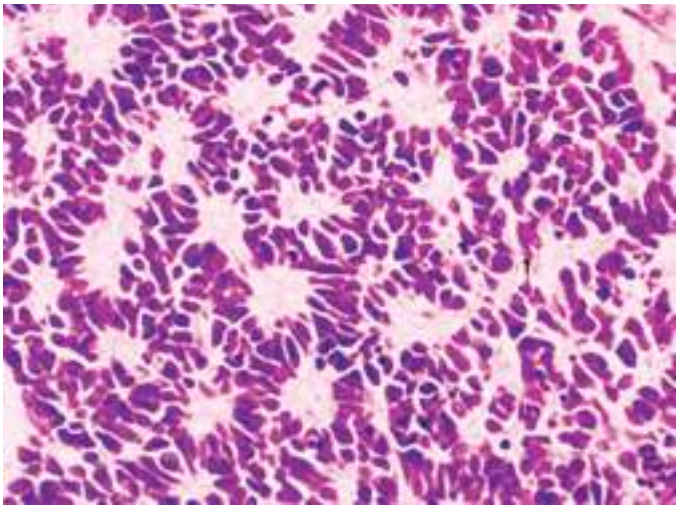

Fig. 30.40: Retinoblastoma shows small round cells with hyperchromatic nuclei and scant cytoplasm, numerous mitoses and formation of Flexner-Wintersteiner rosettes. These rosettes show central lumen lined by pink material with nuclei away from lumen (400X).

HYPOXIA-INDUCED BRAIN INJURY

CEREBRAL HYPOXIA

Neurons are most vulnerable cells of the central nervous system. Reactive gliosis is a normal response of the brain to injury and infection but is not visible on the cut surface of the brain at autopsy. The various cells of CNS are not equally sensitive to hypoxia and deficiency of nutrients. Cerebral hypoxia affects hippocampus neurons, cerebellar Purkinje cells, pyramidal neurons, and neurons within layers of III and V of neocortex (laminar necrosis).

CLINICAL FEATURES

Cerebral hypoxia causes loss of consciousness in less than a minute. Restoration of blood circulation and oxygenation in <1 minute leads to complete recovery.

- Interruption of blood circulation and oxygenation more than three minutes leads to brain damage and coma, with dilated pupils unresponsive to light, inert or rigid extremities, unresponsive to all stimuli, abolition of brain reflexes and ultimately no electrical activity on electroencephalogram (EEG).
- Causes of interruption to the blood flow and oxygen to the brain are hypotension, cardiac arrest, anesthesia complications during major surgical procedures, carbon monoxide poisoning, travelling high altitude, breathing in carbon monoxide and smoke, strangulation, head injury, and extreme bronchial asthma.

PATHOPHYSIOLOGY

Brain hypoxia symptoms range from mild to severe depending on the cause. Mild symptoms are temporary such as memory loss, difficulty in taking sound decisions and reduced ability to move body. Severe symptoms are seizures, coma and brain death. Cardiac arrest is a major cause of mortality and neurologic disability.

- During cardiac arrest, cessation of cerebral oxygen delivery O_2 occurs with resultant neuron ischemia and cell death within minutes. The cerebrum consumes 20–25% of cardiac output to maintain function. The brain is devoid of nutrient stores, and consequently neuroglycopenia and metabolic crisis occur within minutes after cardiac death leading to irreversible cell death. Reduced cerebral oxygen supply to brain manifests as reduced neuronal aerobic metabolism leading to decreased cellular adenosine triphosphate (ATP) production.
- Intracellular accumulation of calcium leads to mitochondrial toxicity, that further causes reduction of ATP production. Inability to sustain cellular respiration results in cell death and apoptosis. In addition, microvasculature endothelial dysfunction leads to a porous blood–brain barrier resulting in cerebral edema, formation of microthrombi and limitation of cerebral blood flow with exacerbation of cellular ischemia. Reduced cerebral oxygen delivery results in cessation of ATP production, causing cessation of energy-dependent ion channel function. Subsequent intracellular Na^+ accumulation leads to cytotoxic edema.
- Depletion of adenosine triphosphate leads to anaerobic metabolism, cerebral lactate accumulation, and intracellular acidosis. Additionally, cellular ischemia leads to intracellular Ca^{2+} influx through N-methyl-D-aspartate channels, which activates hydrolytic enzymes and mitochondrial dysfunction, thereby depleting adenosine triphosphate further. Finally, excitatory neurotransmitter release activates lipases and proteases, which leads to apoptosis. Brain structures especially susceptible to reduced cerebral oxygen supply include the hippocampi, thalami, cerebral cortex, corpus striatum, and cerebellar vermi, owing to highly metabolically active tissue.

Surgical Pathology: Cerebral Hypoxia

Light Microscopy

- Cerebral hypoxia of more than three minutes results in liquefactive necrosis in the brain. When the cells die, they are digested by lysosomes in the body. This digestion process results in the formation of pus-filled cysts.
- Affected neurons have pyknotic nuclei and an acidophilic cytoplasm, which stains intensely red with eosin (red is dead) in standard hematoxylin and eosin slides.

LABORATORY DIAGNOSIS

Brain hypoxia is diagnosed by blood oxygen concentration, skull, MRI scan, echocardiogram, electrocardiogram and electrocephalogram (electrical activity).

CEREBROVASCULAR DISORDERS

Cerebrovascular disorders are the most common group of CNS disorders; which include cerebral stroke, carotid stenosis, vertebral stenosis and intracranial stenosis, aneurysms, and vascular malformations. Restrictions in blood flow may occur from blood vessel narrowing, thrombus formation, embolus formation interrupting blood flow or blood vessel rupture. Cerebrovascular disorders rank after heart disease and cancer as the third major cause of death in the United States. Predisposing factors for cerebrovascular diseases are given in Table 30.33.

CEREBRAL INFARCTION

Cerebral infarction is more frequent than hemorrhage. Brain does not contain proteins; hence ischemia produces liquefactive necrosis and formation of cystic spaces containing creamy liquid necrotic cell debris by hydrolytic enzymes released by phagocytes.

- The cyst wall is formed by proliferating capillaries, neutrophils, macrophages and gliosis (proliferating neuroglial cells).

Table 30.33 Predisposing factors for cerebrovascular diseases

Type	Predisposing Factors	Common Sites
Cerebral infarction		
▪ Thrombus formation	▪ Atherosclerosis	▪ Arterial obstruction of internal and external carotid arteries at the origin in the neck, vertebral arteries, basilar arteries, middle cerebral arteries of circle of Willis
▪ Embolism	▪ Cardiac mural thrombi, valvular vegetation and fat emboli	▪ Middle cerebral is the most frequent site of embolic occlusion
Cerebral hemorrhage		
▪ Intracerebral hemorrhage	▪ Hypertension, coagulation disorders, hemorrhage within a malignant tumor	▪ Intracranial hemorrhage may result from rupture of Charcot-Bouchard aneurysms in a long-standing case of hypertension
▪ Subarachnoid hemorrhage	▪ Rupture of congenital berry aneurysm especially in hypertension	▪ Circle of Willis and bifurcation of the middle cerebral artery

- Arterial occlusion occurs either due to complicated atheromatous plaques in blood vessels supplying brain (bifurcation of carotid arteries), or emboli arising from cardiac mural thrombi, infected vegetations on cardiac valve, tumor emboli, bubbles of air, or droplets of fat into middle cerebral artery. Embolism is much less common than thrombosis.

PATHOPHYSIOLOGY

Liquefactive necrosis (colliquative necrosis) transforms the tissues into liquid viscous mass. It most often occurs as a result of ischemic necrosis of brain.

- Brain does not contain proteins; hence ischemia produces liquefactive necrosis.
- Hydrolytic enzymes liberated by neutrophils and macrophages digest the tissue resulting in transformation of the tissue into soft, circumscribed creamy liquid viscous.
- Later a cyst wall is formed. It is worth mentioning that ischemia causes coagulative necrosis in organs rich in proteins such as kidney, spleen and heart; except brain, that lacks proteins. Gross morphology and histologic features of cerebral infarct are given in Table 30.34.

CLINICAL FEATURES

Clinical features of cerebral infarction depend on the site of vascular obstruction and extent of collateral circulation. Arterial obstruction in this site causes contralateral paralysis, as well as motor and sensory defects and aphasias.

- **Carotid bifurcation and middle cerebral arteries occlusion:** These blood vessels are the most frequent sites of thrombotic occlusion as a result of complicated atherosclerotic plaques.

Table 30.34 Gross morphology and histologic features of cerebral infarct

Feature	Duration	Gross Morphology	Histologic Features
Acute cerebral infarct	Hours to few days	▪ Soft parenchyma with preservation of architecture and edematous infarct ▪ Poorly defined area of soft parenchyma; preservation of architecture and edematous infarct	▪ Red neurons and rarefaction of white mater within 12–24 hours ▪ Liquefactive necrosis of neurons. Mild neutrophilic infiltrate and extravasated blood cells as a result of reperfusion
Subacute (organizing) cerebral infarct	Hours to weeks	Partially liquefied infarcts with well-defined are of soft tissue, friable parenchyma; loss of architecture	Liquefactive necrosis of neurons and glial components drop out, marked macrophage infiltrate, reactive capillaries and gliosis at periphery
Chronic (remote) cerebral infarct	Months to years	Cystic cavity with collapse of surrounding tissue	▪ Cystic spaces lined by 'gliotic scar' without collagen, loss of parenchyma, sparing of subpial region as opposed to old contusion; with or without hemosiderin and macrophages ▪ Gliosis at the periphery

Hemorrhagic cerebral infarcts occur due to emboli or compression of the blood vessels. Nonhemorrhagic cerebral infarcts are caused by thrombi.

- **Middle cerebral arteries occlusion:** These blood vessels are the most frequent site of embolic occlusion. Emboli are arising from left side of heart. Patient presents with contralateral upper extremity weakness and ipsilateral facial weakness. Also, in right-handed individuals, the left side of the cerebral cortex is usually dominant, and verbal aphasias are caused by left-sided lesions in the great majority of cases.
- **Anterior cerebral artery occlusion:** Occlusion in anterior cerebral artery causes contralateral lower extremity weakness and altered mental status.
- **Posterior cerebral artery occlusion:** Occlusion in posterior cerebral artery causes contralateral visual loss.
- **Small cerebral arteries occlusion:** Obstruction of small cerebral arteries produce lacunar strokes involving motor or sensory areas. Pure motor lacunar stroke most often results from lesions affecting the internal capsule. Pure sensory lacunar stroke most often results from lesions affecting the thalamus.

Surgical Pathology: Cerebral Infarction

Gross Morphology

Brain tissue is creamy liquid viscous. It may show cyst formation (Fig. 30.41).

Light Microscopy

- Histologic examination of liquefactive necrotic tissue obtained from brain reveals cystic space contains necrotic cell debris.
- The cyst wall is formed by proliferation of capillaries, neutrophils, macrophages and gliosis (proliferating glial cells).

CEREBRAL HEMORRHAGE

Cerebral hemorrhage refers to hemorrhage into the tissue of cerebral hemispheres. It is most often complicated by long-standing hypertension, coagulation disorders, hemorrhage within a brain tumor and Charcot-Bouchard aneurysms. Hemorrhage most often occurs in the basal ganglia/thalamus; other favored sites include the pons, cerebellum, and frontal lobe white matter.

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage is commonly associated with rupture of a congenital berry aneurysm in the circle of Willis compounded by hypertension. Other causes are mycotic aneurysms, arteriovenous malformations and cavernous hemangiomas. A transient ischemic attack is a brief episode of impaired neurologic function caused by a brief disturbance in cerebral circulation. Mortality can occur in the first week in 30% of cases. Common sites of aneurysms formation in intracranial arteries linked to cardiovascular diseases are shown in Fig. 30.42.

Fig. 30.41: Cerebral infarct. This intermediate infarct of the frontal lobe shows liquefactive necrosis with formation of cystic spaces as resolution begins (arrow).

BERRY ANEURYSM

Berry aneurysm is rounded sac-like structure at the site of congenital defect in vessel wall involving only part of the circumference of a blood vessel. It throbs and pushes against surrounding structures. Mural thrombus is most often found within aneurysmal sac.

- The most common site of berry aneurysm formation is between the anterior communicating and the anterior cerebral arteries in the circle of Willis. It develops as saccular structure (1.0–1.5) at site of congenital defect in smooth muscle distribution at a branch point of the arterial wall.
- Risk factors for berry aneurysm are hemodynamic stress, hypertension and coarctation of aorta, autosomal dominant adult polycystic kidney disease, Marfan's syndrome and type 1 neurofibromatosis. Rupture of berry aneurysm is the most common cause of subarachnoid hemorrhage.

Clinical Features

Patient with berry aneurysm presents with history of severe headache, nuchal rigidity from irritation of the meninges. Aneurysm present on the anterior communicating artery may rupture into the third ventricle leading to massive intraventricular hemorrhage.

Complications

Cerebral infarction is the most common complication of berry aneurysm. Patient may develop hydrocephalus as a result of blockage by blood clot of the channels through

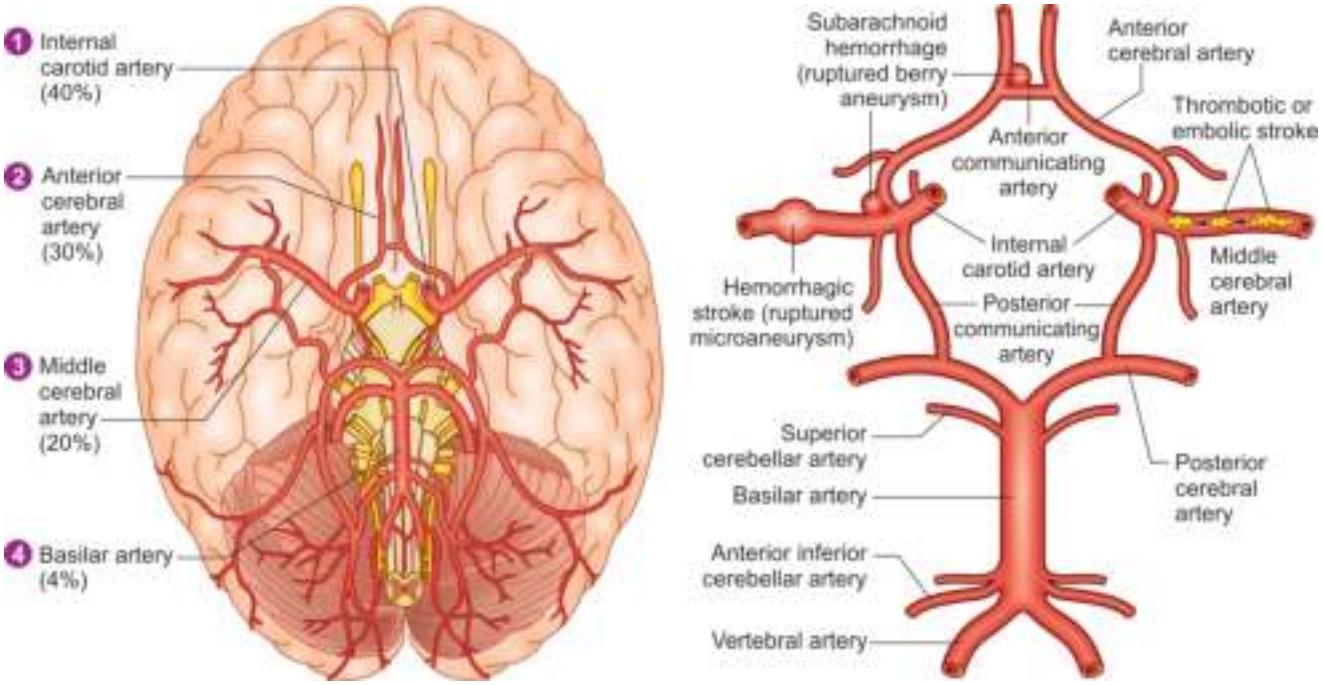

Fig. 30.42: Common sites of aneurysms formation in intracranial arteries linked to cardiovascular diseases.

Table 30.35 Sites for rupture of berry aneurysm in brain

Site of Aneurysm	Frequency
Junction of the internal carotid and the posterior communicating artery	40%
Junction of the anterior cerebral and anterior communicating artery	30%
Main bifurcation of the middle cerebral artery in the sylvian fissure	20%
Point where the basilar artery divides into the posterior cerebral artery	4%

which cerebrospinal fluid flows. Sites of rupture of berry aneurysm in brain are given in Table 30.35.

MYCOTIC ANEURYSM

Mycotic aneurysm is caused by infection of the artery wall. Most cases develop mycotic aneurysm due to impaction of infected emboli derived from cardiac vegetation occurring within first 5 weeks of development of infective endocarditis in 3–10% of patients.

- Causative organisms of infective endocarditis include pyogenic bacteria such as *Streptococcus pyogenes* and *Staphylococcus aureus*. True aneurysms result from fungal meningitis or fungal emboli from cardiac valves. Aspergillus is the species most commonly involved.
- Emboli from infective endocarditis may involve cerebral blood vessels, which result in hemorrhage in the basal ganglia, extending into the subarachnoid space.

ARTERIOVENOUS FISTULA

Arteriovenous (AV) fistulas are abnormal communications (direct shunt) between arteries and veins. Arteriography with thorostat dye establishes the diagnosis. It is often secondary to trauma.

- Penetrating knife injury is the most common cause of arteriovenous fistula.
- Most common sites are scalp, arm and leg vessels. Veins are arterialized.
- Patient develops increased circumference of the limbs. There is presence of bruits and thrills. Large arteriovenous fistulas reduce systemic resistance and bypass the microcirculation, hence increasing venous return to the heart and producing high output cardiac failure.

CAVERNOUS HEMANGIOMAS

Cavernous hemangiomas are located in the white matter of the brain. Patient presents in the 3rd to 5th decades with neurological symptoms such as epilepsy (38%), intracranial bleeding (23%), headache (28%) and focal neurological deficits.

TRANSIENT ISCHEMIC ATTACKS

Transient ischemic attacks are brief episodes of impaired neurologic function caused by a temporary disturbance of cerebral circulation due to breaking of small proportion of mural thrombus from underlying atheromatous plaque.

- Other causes of transient ischemic attacks are sudden decline in cardiac output and hypercoagulable states.
- Transient ischemic attacks are not associated with permanent damage, but are considered precursors to more serious occlusive events.

FAT EMBOLISM SYNDROME

Fat embolism is presence of emboli comprising of fat microglobules in the circulation. Fat embolism syndrome is most often a consequence of severe trauma with long bone fractures such as femur with abundant fatty marrow. It can also be seen with extensive trauma to fat laden tissues, burns, and very rarely with orthopedic procedures.

- On long bone fracture, bone marrow fatty fragments enter the circulation, lodge in small blood vessels of the lung, skin, kidneys, brain and other organs producing ischemia and hemorrhage. Fat embolic syndrome results in the clinical manifestations.
- Fat microglobules are converted into fatty acids, which damage vascular endothelium resulting in formation of platelet thrombi in areas of injury.
- Bronchoalveolar macrophages take up the fatty acids in fat embolism syndrome cases. Bronchoalveolar lavage should be done. Smears stained by fat stains demonstrate fat in the alveolar macrophages. Fat embolus in cerebral hemisphere is given in Fig. 30.43.

CLINICAL FEATURES

Patient develops potentially fatal fat embolism syndrome within 24–72 hours. Patient presents with pulmonary distress, cutaneous petechial hemorrhages, and various neurologic manifestations.

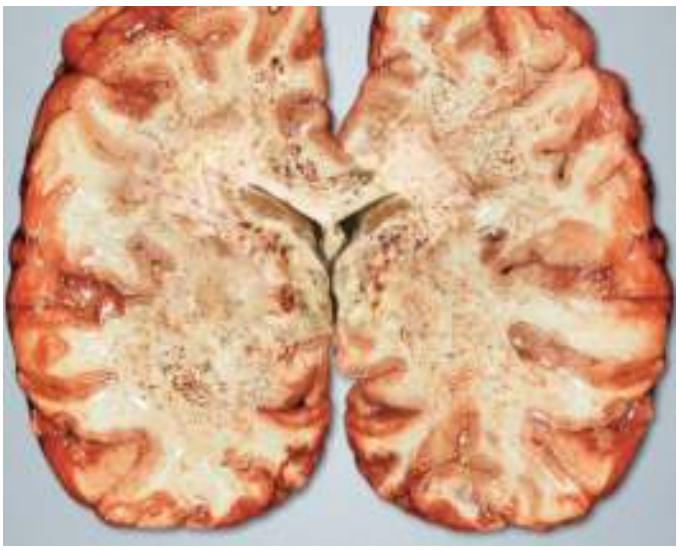

Fig. 30.43: Fat embolus in cerebral hemisphere. The patient was in a motorcycle accident and sustained multiple fractures of both legs. The fat emboli caused petechial hemorrhages in the white mater throughout the brain, resulting in coma and death. The macroscopic appearance of cerebral malaria is identical to this.

- **Pulmonary manifestations:** Patient develops dypnea and tachypnea is due to presence of fat microglobules in pulmonary capillaries causing hypoxemia.
- **Petechial hemorrhage:** Patient develops petechial hemorrhage over the chest and upper extremities due to thrombocytopenia from platelet adhesion to microglobules of fat.
- **Neurologic manifestations:** Numerous petechial hemorrhages are produced by fat emboli to the brain, particularly in white matter known as 'brain purpura'. Patient develops neurologic manifestations such as loss of consciousness, cerebral edema and herniation within a week in less than 10% of cases with fatal outcome.

HEAD INJURY

Head injuries are caused by penetrating wounds and nonpenetrating injuries. Penetrating wounds result in brain damage predisposing to infection of brain (meningitis, cerebral abscess). Brain injury caused by penetrating injuries producing impact at the site of injury is known as coup injury. Injury on the opposite side of the brain from the impact is known as contrecoup injury.

Contusions comprise both coup and cuntrecoup injuries. Location of epidural, subdural and intracerebral hematomas are shown in Fig. 30.44.

EPIDURAL HEMATOMA

An epidural hematoma is an arterial hemorrhage between the dura and the skull, which results from skull fracture of temporal bone and laceration of the middle meningeal artery. Patient presents with short period of consciousness (lucid interval), headache, vomiting, inability to move parts of the body followed by loss of consciousness and signs of cerebral compression. Complications of epidural hematoma may induce seizures. Epidural hematoma is shown in Fig. 30.45.

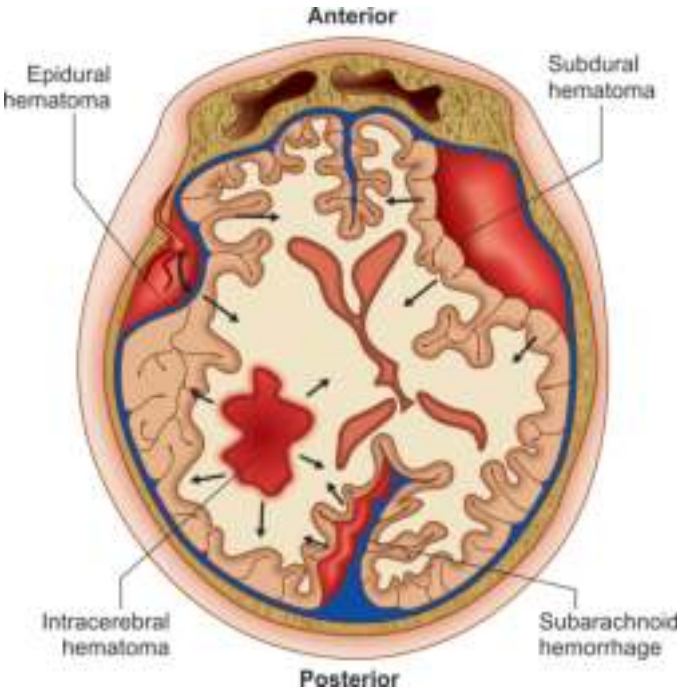

Fig. 30.44: Location of epidural, subdural and intracerebral hematomas.

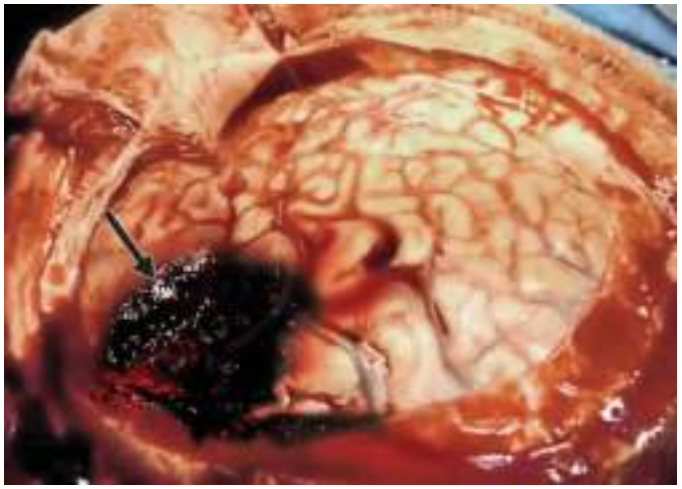

Fig. 30.45: Epidural hematoma. A blood clot is seen over the external surface of the dura. It occurs as a result of trauma to middle meningeal artery (arrow).

SUBDURAL HEMATOMA

A subdural hematoma is venous hemorrhage underneath the dura usually associated with traumatic brain injury. Bleeding in subdural space most often results from laceration of the bridging veins joining the cerebrum to venous sinuses within the dura. Patient presents with gradual signs of cerebral compression occurring hours, days, or weeks after injury. After cessation of bleeding, the resultant blood clot can slowly imbibe water, resulting in signs of increasing intracranial

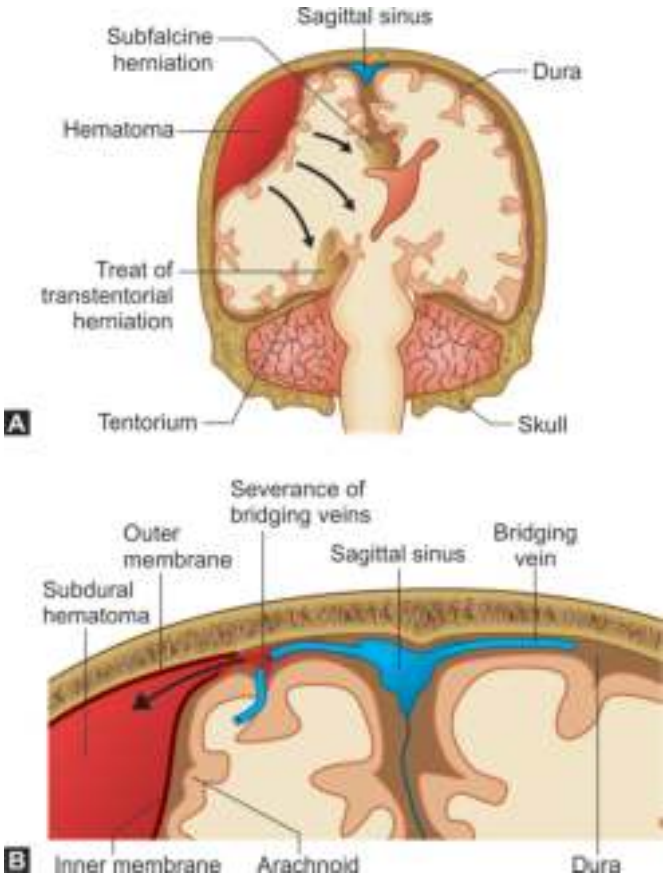

Fig. 30.46: Mechanism of bleeding in subdural hematoma.

pressure. Mechanism of bleeding in subdural hematoma is shown in Fig. 30.46A and B.

INTRACEREBRAL HEMORRHAGE

Intracerebral hemorrhage (ICH) is caused by bleeding within the brain tissue itself—a life-threatening type of cerebral stroke.

- Cerebral stroke occurs when the brain is deprived of oxygen and blood supply. Intracerebral hemorrhage is most commonly caused by hypertension, arteriovenous malformations, or head trauma (penetrating injury). Less common causes cerebral stroke are anticoagulant therapy, aneurysms, bleeding disorders (hemophilia, sickle cell anemia, disseminated intravascular coagulation, thrombocytopenia), highly vascular angiomas and metastatic tumors, amyloid angiopathy, alcohol and cocaine.
- Tiny arteries bring blood to areas deep inside the brain. Hypertension can cause thin-walled tiny arteries to rupture, and releasing blood into the brain tissue. Enclosed within the rigid skull, clotted blood and fluid buildup increases intracranial pressure that can crush the brain against the bone or cause it to shift

and herniate. Spillage of blood from the ruptured tiny blood vessel into the brain parenchyma is called cerebral stroke.

- **Laboratory diagnosis:** Patient is diagnosed by clinical history, family history, CT scan, MRI and angiography by administration of contrast medium into the blood-stream to view arteries of the brain. Diagnostic tests help to determine the source of bleeding.
- **Complications:** Cerebellar hemorrhage causing brain-stem compression and hydrocephalus are treated by surgical procedures (craniotomy, stereotactic clot aspiration) is to remove the intracerebral hematoma as soon as possible.
- **Management:** Patient with small hemorrhages and minimal neurological deficits are treated by medicines.

DEMYELINATING DISORDERS OF NERVOUS SYSTEM

MULTIPLE SCLEROSIS

Multiple sclerosis is the most common demyelinating disease of unknown etiology and characterized by destruction of myelin sheaths in the spinal cord and brain with relative preservation of axons. It is considered to be autoimmune disorder (probable viral etiology) due to increased incidence in HLA haplotypes (A3, B7, DR2, and DW2).

- Multiple sclerosis is associated with plaques scattered irregularly throughout the central nervous system.
- Common sites involved in multiple sclerosis are the optic nerve, brainstem, and paraventricular areas. CD4+ helper T cells, CD8+ cytotoxic T cells and macrophages infiltrate plaques; reactive gliosis occurs later. Peripheral nerves are not affected.
- Multiple sclerosis begins between 20 and 30 years of age, which most often affects men than women.
- Clinical course of multiple sclerosis is highly variable depending on the site of involvement. Patient may present with numbness, weakness of the lower extremities, visual disturbances and retrobulbar pain, sensory disturbances, and possible loss of bladder control. The classic Charcot triad (nystagmus, intention tremor, and scanning speech) is significant for diagnosis.
  - The classic CSF electrophoretic finding is that of multiple oligoclonal bands of immunoglobulin.
  - Clinical course of multiple sclerosis is characterized by exacerbations and remissions. Clinical course is progressive, leading to increasing disability.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis refers to wide-spread demyelination, which is preceded by viral illnesses such as measles, mumps, rubella, chickenpox, and is often known as post-infectious encephalitis. It may be due to delayed hypersensitivity reaction. The clinical course varies from a complete recovery to a fatal outcome.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an autoimmune disorder involving acute inflammation and destruction of myelin sheath of peripheral nerves by macrophages and lymphocytes. It is often preceded by viral infection, immunization, or allergic reactions. It most often occurs in young adults. Guillain-Barré syndrome has four variants. Acute inflammatory demyelinating polyradiculoneuropathy is the most common variant (90%).

- Acute motor axonal neuropathy occurs in children and has good prognosis. Acute motor sensory axonal neuropathy affects adults and has poor recovery rate. Miller Fisher syndrome is rare variant of Guillain-Barré syndrome involving only cranial nerves.
- Guillain-Barré syndrome usually starts in the extremities and moves toward the trunk, may result in respiratory failure. If cranial nerves are involved, patient has facial weakness, pain, and difficulty in speech's examination shows increased proteins concentration with only modest increase in cell count, which is an important diagnostic finding.
- Patients are administered immunomodulators to inhibit antibodies formation. Anticoagulants are given to reduce risk of deep vein thrombosis and pulmonary embolism. Nonsteroidal anti-inflammatory drugs are given to relieve pain.

HYDROCEPHALUS

Hydrocephalus denotes increased volume of cerebro-spinal fluid (CSF) within the cranial cavity. In infants, it is associated with (sometimes marked) enlargement of the skull. It is most often caused by obstruction to the CSF circulation by various mechanisms such as congenital malformations, inflammation, and tumors.

- Hydrocephalus can also result from overproduction of CSF by choroid plexus papilloma (rare). Intrauterine CMV infection is one of the agents

of TORCH syndrome, which crosses placenta to induce encephalitis in developing fetus during intrauterine life in proximity to the third ventricle and the aqueduct and the patient is prone to develop hydrocephalus. It can also occur as hydrocephalus *ex vacuo* without obstruction or increased CSF production in disorders characterized by decreased cerebral mass such as ischemic brain atrophy or advanced Alzheimer disease.

- Congenital hydrocephalus refers to an excessive amount of CSF and ventricular enlargement. It is caused by congenital atresia of the aqueduct of Sylvius.
- Histologic examination of the midbrain may disclose multiple atretic channels or an aqueduct narrowed by gliosis.

Clinical Pearls: Congenital Hydrocephalus

- **Internal hydrocephalus:** The increased volume of CSF is entirely within the ventricles.
- **External hydrocephalus:** The increased volume of CSF is confined to the subarachnoid space.
- **Communicating hydrocephalus:** Free flow of CSF occurs between the ventricles and the subarachnoid space.
- **Noncommunicating hydrocephalus:** Obstructed flow of CSF occurs from the ventricles to the subarachnoid space.

ARNOLD-CHIARI MALFORMATION

Arnold-Chiari malformation is characterized by downward displacement of the cerebellar tonsils and medulla through the foramen magnum. The cerebellar vermis is herniated below the level of the foramen magnum. Arnold-Chiari malformation results in pressure atrophy of displaced brain tissue. In addition, it causes hydrocephalus as a result of obstruction of the CSF outflow tract. Presence of a thoracolumbar meningomyelocele is almost always characteristic in this disorder.

CONGENITAL DISORDERS OF NERVOUS SYSTEM

NEURAL TUBE DEFECTS

Neural tube defects occur due to failure of closure of the neural tube linked with maternal folic acid deficiency. These neural defects can involve vertebrae or skull with or without involvement of the underlying meninges, spinal cord, or brain. In neural tube defects, an increase in fetoprotein in both the maternal serum and the amniotic fluid is noted. Maternal folic acid deficiency has been associated with an increased incidence of neural tube defects, and folic acid has, therefore, been approved for inclusion as a food supplement in commercial flour. Neural defects are shown in Fig. 30.47A to C.

SPINA BIFIDA

Spina bifida is neural tube defect, that occurs when the spine and spinal cord do not develop properly. Neural

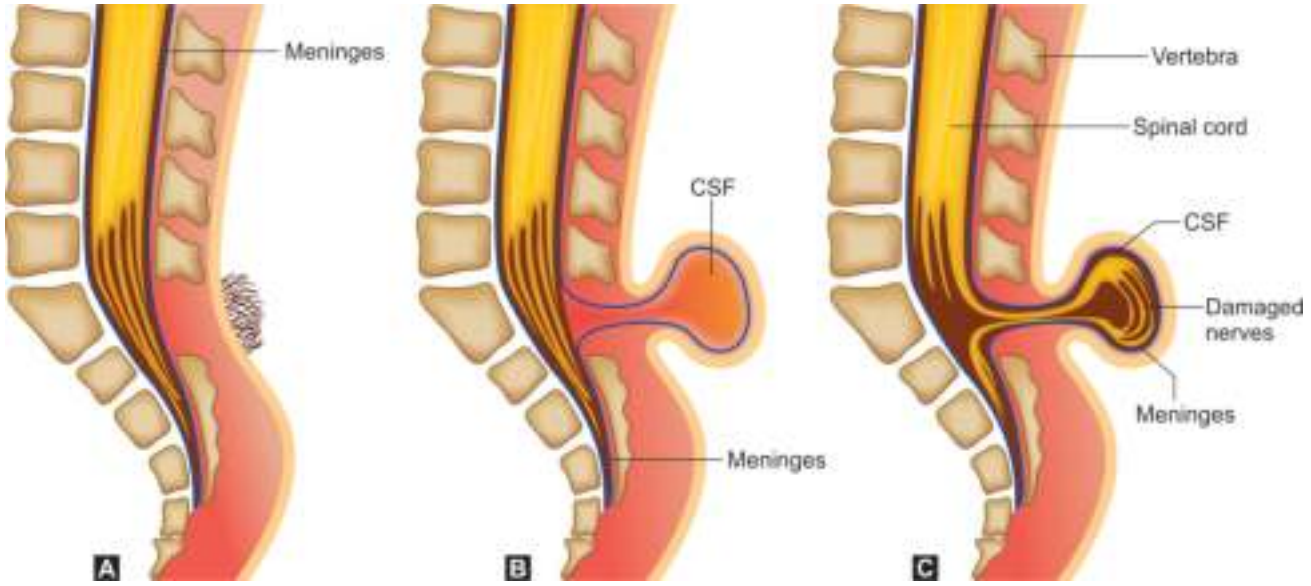

Fig. 30.47: Neural defects. (A) Spina bifida occulta, (B) meningocele, (C) myelomeningocele.

tube is the structure in a developing embryo that eventually becomes the baby's brain, spinal cord and the tissues that enclose them. Normally, the neural tube is formed during early pregnancy and closed by the 28th day after conception. In baby's spina bifida, a portion of the neural tube fails to close or develop properly causing defects in the spinal cord and in the bones of the spine. Spina bifida can range from mild to severe depending on the size of defects, location and complications. Surgery does not always resolve the defect.

- **Spina bifida occulta:** Spina bifida occulta is neural tube defect with no clinically apparent abnormalities. Vertebral arch defect is most often limited to one or two vertebrae.
- **Spina bifida cystica:** Spina bifida cystica is complicated by herniation of meninges through a defect.
- **Meningocele:** Meningocele is defect in which herniated membranes consist only of meninges, and spina bifida occulta does not manifest any apparent abnormalities.
- **Meningomyelocele:** Meningomyelocele is a neural tube defect in which portion of spinal cord along with meninges are protruded in the fluid filled herniated tissue. This neural tube defect exposes the spinal canal and causes the nerve roots to be entrapped.

ANENCEPHALY AND OTHER DEFECTS

Anencephaly is characterized by the absence of a major portion of the brain, skull and scalp, that occurs during embryonic development. It is a cephalic disorder, that results from neural tube defect. Anencephaly occurs when the rostral (head) end of the neural tube fails to close usually between the 23rd and 26th day following conception. It can also be caused by folic acid deficiency in pregnant women. Anencephaly can be diagnosed before birth through ultrasonography. The maternal serum α-fetoproteins screening and detailed fetal ultrasonography can be useful for screening to detect spina bifida.

- **Holoprosencephaly:** Holoprosencephaly is a microcephalic brain in which the interhemispheric fissure is absent. Infant rarely survives more than a day. Holoprosencephaly is characterized by microcephalic brain in which the interhemispheric fissure is absent. The horseshoe-shaped cerebral hemispheres have fused frontal poles, across, which the gyri show an irregular horizontal orientation.
- **Meroanencephaly:** Meroanencephaly is a rare form of anencephaly characterized by malformed cranial bones, a median cranial defect, and a cranial protrusion called area cerebrovasculosa, which denotes abnormal spongy, vascular tissue admixed with glial tissue ranging from thin membrane to large pseudocephalic tissue.
- **Hydromyelia:** Hydromyelia refers to an abnormal dilation of the central canal of the spinal cord, that creates a cavity in which cerebrospinal fluid can accumulate. As the cerebrospinal fluid builds up, and it can cause abnormal pressure on the spinal cord resulting in damage to nerve cells and their connections.
- **Syringomyelia:** Syringomyelia is a congenital malformation, in which a tubular cavitation (syrinx) extends for variable distances along the entire length of the spinal cord.
- **Rachischisis:** Rachischisis is a developmental birth defect involving the neural tube most often without a recognizable spinal cord. This anomaly occurs *in utero*, when the posterior neuropore of the neural tube fails to close by the 27th intrauterine day. As a consequence, the vertebrae overlying the open portion of the spinal cord do not develop properly and remain unfused and open, leaving the spinal cord exposed. Patient develops motor and sensory neurological deficits, recurrent infections and dysfunction of urinary bladder. Rachischisis usually occurs with anencephaly.
- **Polymicrogyria:** Polymicrogyria affects development of the human brain with formation of multiple small, irregular and randomly distributed gyri (microgyri) creating excessive folding of the brain leading to an abnormally thick cortex.
  - **Arrhinencephaly:** Arrhinencephaly is a congenital absence of rhinencephalon, the part of the brain that includes the olfactory bulbs and olfactory tracts.
  - **Lissencephaly:** Lissencephaly is a congenital disorder in which the cortical surface of the cerebral hemispheres is smooth or has imperfectly formed gyri. It occurs due to defective neuronal migration during the 12th to 24th weeks of gestation resulting in a lack of development of brain gyri and sulci.
  - **Pachygyria:** Pachygyria is a developmental disorder due to abnormal migration of neurons in the developing brain and nervous system. Brain has few broad and flat gyri.

AGENESIS OF CORPUS CALLOSUM

Agenesis of corpus callosum can be asymptomatic and is often found in association with other abnormalities.

TORCH COMPLEX

TORCH complex is a group of infections transmitted from the mother to the fetus.

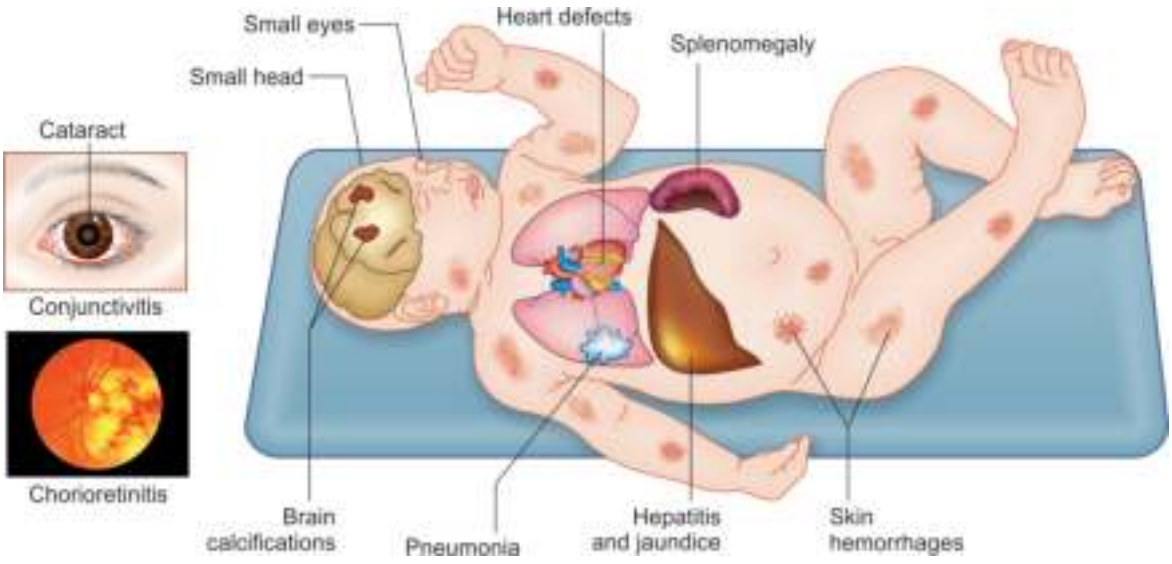

Fig. 30.48: TORCH complex infections. Fetuses infected in the first trimester by Toxoplasma, rubella, cytomegalovirus, herpesvirus or many other microbes have similar clinical findings as those illustrated in this figure.

- TORCH infections comprise *Toxoplasma gondii*, rubella, cytomegalovirus (CMV), and herpes simplex virus (HSV) infection including *Treponema pallidum*, human immunodeficiency virus, varicella, parvovirus B19 and enteroviruses. These infections can cause pregnancy wastage at any stage of gestation and TORCH complex syndrome is characterized by microcephaly, chorioretinitis, central nervous system (CNS) calcifications, petechial rash, hepatosplenomegaly, and thrombocytopenia.
- Intrauterine CMV infection is one of the agents of TORCH complex syndrome, which crosses placenta to induce encephalitis during intrauterine life in proximity to the third ventricle and the aqueduct. The patient is prone to develop hydrocephalus.
- Severe CMV infection can cause mental retardation, microcephaly, chorioretinitis, and hepatosplenomegaly; periventricular calcifications.
- For many of these pathogens of TORCH complex, treatment or prevention strategies are available. Early recognition, including prenatal screening, is key.
- Serological assays are important diagnostic tools. ELISA is highly specific and sensitive diagnostic technique of TORCH complex. Life-immunoassay is a new, cheaper and reliable diagnostic technique on the contrary on single panel strip. TORCH complex infections are shown in Fig. 30.48.

FETAL ALCOHOL SYNDROME

Fetal alcohol syndrome is the most common acquired cause of mental retardation in the United States associated with excessive maternal alcohol intake during pregnancy (Fig. 30.49). The common features

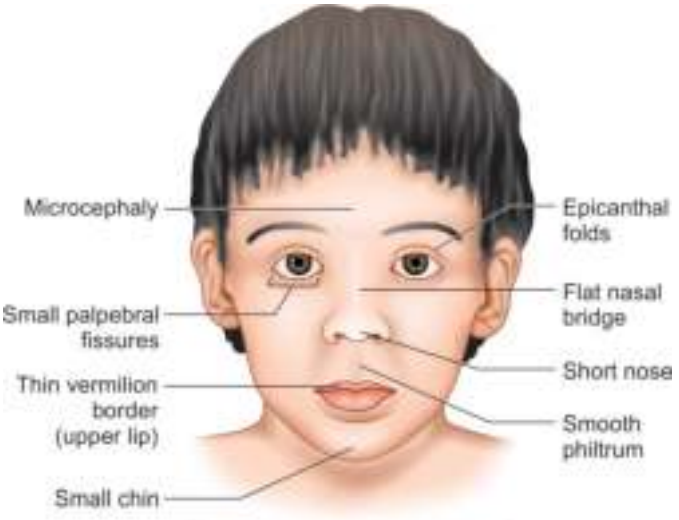

Fig. 30.49: Fetal alcohol syndrome.

of fetal alcohol syndrome include intrauterine growth retardation, mental retardation, neurologic impairment, microcephaly, and atrial septal defect. Children later suffer from mental retardation and minor facial dysmorphic features.

TUBEROUS SCLEROSIS SYNDROME

Tuberous sclerosis syndrome is an autosomal dominant disorder characterized by nodular proliferation of multinucleated atypical astrocytes forming tubers (small white nodules scattered in the cerebral cortex and periventricular areas), adenoma, sebaceoma of the skin, and angiomyolipoma of the kidney. Seizures and mental retardation beginning in infancy are characteristic.

choriocarcinoma of testis 2343
choroid plexus papilloma 2920
chromophobe renal cell carcinoma 2291
chronic atrophic gastritis type A 1926
chronic endometritis 2406
chronic lobular hepatitis 2039
chronic pyelonephritis 2250
chronic salpingitis 2427
chronic venous congestion of liver 2095
clear cell adenocarcinoma of vagina 2387
clear cell carcinoma of ovary 2449
clear cell renal cell carcinoma 2285
collecting duct carcinoma of Bellini 2294
colloid carcinoma of breast 2521
colorectal adenocarcinoma 1995
common warts (verrucous vulgaris) 2829
complete hydatidiform mole 2471
condyloma acuminatum 2365
conventional chordoma 2701
conventional chondrosarcoma 2677
conventional hepatocellular carcinoma 2107
conventional intramedullary osteosarcoma 2687
craniopharyngioma 2650
cribriform carcinoma of breast 2526
Crohn's disease 1974
cystitis glandularis 2310
dedifferentiated chondrosarcoma 2679
dedifferentiated liposarcoma 2747
deep fibromatosis 2754
dermatitis herpetiformis (herpes simplex virus II infection) 2830
dermatofibroma 2871
dermatofibrosarcoma protuberans 2756, 2872
dermatophytosis 2834
diffuse astrocytoma, IDH-mutant 2911
diffuse infiltrative type of gastric carcinoma (linitis plastica) 1939
diffuse large B cell lymphoma 1512
diffuse leptomeningeal glioneuronal tumor 2926
diffuse midline glioma, histone H3K27M-mutant 2912
drug-induced hepatocellular injury 2058
dysgerminoma of ovary 2451
dysplastic melanocytic nevus 2847
eccrine spiradenoma 2869
eczematous dermatitis 2818
embryonal carcinoma of ovary 2455
embryonal carcinoma of testis 2338
embryonal rhabdomyosarcoma 2769
emphysema 1808
endocervical polyp 2392
endometrial hyperplasia 2406
endometrial polyp 2411
endometrioid adenocarcinoma of ovary 2447
endometriosis 2409
ependymoma 2919
ependymoma with RELA fusion positive 2920
epidermal keratinous cyst 2879
epithelioid glioblastoma 2917
epithelioid hemangioendothelioma 2118
epithelioid sarcoma 2789
epithelioid trophoblastic tumor 2475
Erdheim-Chester disease 2715
esophageal adenocarcinoma 1920
esophageal squamous cell carcinoma 1919
Ewing sarcoma 2694
extrahepatic biliary atresia/stenosis 2031
extranodal marginal zone lymphoma of MALT 1520
extranodal NK cell/T cell lymphoma 1527
extraskeletal mesenchymal chondrosarcoma 2795
extraskeletal myxoid chondrosarcoma 2794
fat necrosis of breast 2489
fatty change in liver 2079
fibroadenoma of breast 2496
fibrocongestive splenomegaly 1532
fibrocystic disease of breast 2491
fibroma of ovary 2465
fibromatosis colli 2751
fibrous dysplasia of bone 2711
flat urothelial lesions with atypia 2314
follicular lymphoma 1516
follicular cyst in ovary 2429
follicular thyroid adenoma 2605
follicular thyroid carcinoma 2613
gallbladder adenocarcinoma 2135
gallbladder pigment stones 2131
gastric MALT lymphoma 1941
gastrointestinal stromal tumors 1943, 2773
genital herpes simplex virus 2 infection 2377
gestational choriocarcinoma 2473
giant cell tumor of bone 2698
Gilbert syndrome 2029
glioblastoma multiforme with a primitive neuroectodermal tumor component 2918
glomus tumor 2776
gouty arthritis 2727
granular cell tumor 2779
granuloma inguinale 2376
granulomatous mastitis 2489
granulosa cell tumors of ovary 2463
Graves' disease 2598
gynecomastia 2547
Hashimoto's thyroiditis 2590
hemangioblastoma 2930
hemangiopericytoma and solitary fibrous tumor 2775
hepatic angiosarcoma 2117
hereditary nonpolyposis colon cancer 1986
hibernoma 2745
high-grade surface osteosarcoma 2692
Hirschsprung's disease 1965
HPV-related epithelial changes in vulva 2376
hydatid cyst in liver 2056
hyperplastic polyps in colon and rectum 1981
hypertrophic cardiomyopathy 1728
idiopathic giant cell myocarditis 1725
immature teratoma of ovary 2460
impetigo 2819
Indian childhood cirrhosis 2091
infantile fibrosarcoma 2755
infantile polycystic kidney disease 2269
intestinal tuberculosis 1954
intestinal type of gastric adenocarcinoma 1938
intraductal papilloma of breast 2500
invasive ductal carcinoma (NOS) of breast 2517
invasive ductal carcinoma of male breast 2547
invasive hydatidiform mole 2473
invasive micropapillary carcinoma of breast 2523
invasive urothelial carcinoma 2317
ischemic bowel disease 1978
juvenile xanthogranuloma 2761
Kaposi sarcoma 2875
keloid 2751, 2882
keratoacanthoma 2862
Krukenberg tumor 2432
Langerhans cell histiocytosis 2714
leiomyoma 2422
leiomyosarcoma of vagina 2388
Leydig cell tumor of testis 2346
lichen planus 2842
lichen sclerosus 2378
lipoma 2744
liver biopsy in HBV infection 2048
liver cirrhosis 2064
liver in Gaucher's disease 2090
liver in Niemann-Pick disease 2090
liver metastases 2122
lobular carcinoma of breast 2516
low-grade central osteosarcoma 2689
lymph node biopsy in mantle cell lymphoma (MCL) 1312
lymphocyte-rich classic variant of Hodgkin's disease 1496
malignant fibrous histiocytoma of bone 2705
malignant nephrosclerosis 2265
malignant peripheral nerve sheath tumor 2785, 2929

mammary duct ectasia 2488
mantle cell lymphoma 1518
massive hepatic necrosis 2017
mature cystic teratoma of ovary 2458
mature solid teratoma of ovary 2459
medullary carcinoma of breast 2520
medullary sponge kidney 2271
medullary thyroid carcinoma 2617
medulloblastoma 2921
melanocytic nevus 2847
melanoma 2851
melanoma of vagina 2389
meningioma 2923
Merkel cell carcinoma 2867
mesenchymal chondrosarcoma 2679
metaplastic carcinoma of breast 2524
metastases to brain 2907
metastatic bone disease 2721
mixed cellularity classic variant of Hodgkin's disease 1498
mixed Müllerian tumor 2421
molluscum contagiosum 2828
mucinous cystadenocarcinoma of ovary 2445
mucinous cystadenoma of ovary 2443
mucocele of gallbladder 2133
mucoepidermoid carcinoma 1894
multicystic renal dysplasia 2272
multinodular goiter 2602
multiple myeloma 2707
myopericytoma family of tumors 2776
myositis ossificans 2792
myxofibrosarcoma 2758
myxoid liposarcoma 2748
nerve sheath myxoma 2784
neuroblastoma 2638
neuroendocrine tumor 1921
neurofibroma and neurofibromatosis type 2 2782
neurofibroma, neurofibromatosis type 1 and malignant change in neurofibroma 2928
nodal marginal zone lymphoma 1519
nodular fasciitis 2752
nodular hidradenoma 2869
nodular lymphocytic–histiocytic predominant variant of Hodgkin's disease 1499
nodular sclerosis classic variant of Hodgkin's disease 1497
nonalcoholic fatty liver disease 2083
ochronosis of joints 2728
oligodendroglioma 2918
oncocytoma of salivary glands 1893
osteoarthritis 2727
osteoblastoma 2683
osteochondroma 2674
osteofibrous dysplasia 2712
osteoid osteoma 2682
osteoma 2681
osteopetrosis 2717
Paget's disease of breast 2519
Paget's disease of vulva 2379
pancreatic adenocarcinoma 2149
papillary (chromophil) renal cell carcinoma 2288
papillary carcinoma of breast 2523
papillary hidradenoma of vulva 2378
papillary thyroid carcinoma 2607
paraovarian or paratubal cysts 2431
paraovarian or paratubal cysts in ovaries 2431
parathyroid adenoma 2631
parathyroid carcinoma 2631
parosteal osteosarcoma 2691
partial hydatidiform mole 2472
pemphigus vulgaris 2843
penile squamous cell carcinoma 2368
peptic ulcer disease 1929
periductal mastitis 2488
perineuroma 2783
periosteal osteosarcoma 2692
pheochromocytoma 2637
phyllodes tumor of breast 2497
pilocytic astrocytoma 2917
pilomatrixoma 2871
placental site trophoblastic tumor 2475
plasmablastic lymphoma 1520
pleomorphic adenoma 1890
pleomorphic liposarcoma 2749
pleomorphic rhabdomyosarcoma 2771
plexiform fibrohistiocytic tumor 2762
plexiform neurofibroma 2877
polycystic ovary syndrome (Stein-Leventhal syndrome) 2430
polyembryoma of ovary 2462
precursor B cell lymphoblastic leukemia/lymphoma 1504
primary adenocarcinoma of urinary bladder 2321
primary biliary cirrhosis 2093
primary bone marrow lymphoma 2708
primary glioblastoma multiforme, IDH-wildtype 2914
primary sclerosing cholangitis 2095
prostatic adenocarcinoma 2359
psammomatous melanotic schwannoma 2783
psoriasis 2841
pyogenic meningitis 2891
rapidly progressive glomerulonephritis (RPGN) 2228
rectal mucosal prolapse 2001
renal angiomyolipoma 2296
renal oncocytoma 2281
renal papillary necrosis 2253
retinoblastoma 2932
rheumatoid arthritis 2726
salpingitis isthmica nodosa 2427
Schwannoma (neurilemmoma) 2927
seborrheic keratosis 2866
secondary biliary cirrhosis 2094
secondary glioblastoma multiforme, IDH-mutant 2916
secretory carcinoma of breast 2526
seminoma of testis 2332
serous cystadenocarcinoma of ovary 2442
serous cystadenoma of ovary 2441
Sertoli cell tumor of testis 2345
simple bone cyst 2710
simple nontoxic goiter 2600
small cell osteosarcoma 2690
soft tissue chondroma 2794
soft tissue giant cell tumor with low malignant potential 2763
soft tissue leiomyoma 2765
soft tissue leiomyosarcoma 2766
solitary renal cyst 2271
spermatocytic seminoma of testis 2335
splenic marginal zone lymphoma 1535
squamous cell carcinoma in oral cavity 1883
squamous cell carcinoma of skin 2860
squamous cell carcinoma of urinary bladder 2320
squamous cell carcinoma of vagina 2385
struma ovarii 2461
superficial fibromatosis 2753
surface epithelial inclusion cysts in ovaries 2431
synovial sarcoma 2787
tabes dorsalis 2896
telangiectatic osteosarcoma 2690
teratoma of testis 2341
testicular diffuse large B cell lymphoma 2347
thymoma 1539
traumatic neuroma 2779, 2877
tubal endometriosis 2427
tubercular osteomyelitis 2656
tubercular pyelonephritis 2252
tubular adenomas 1983
tubular carcinoma of breast 2522
type 1 endometrioid carcinoma 2416
type 2 nonendometrioid carcinoma 2418
ulcerative colitis 1972
undifferentiated pleomorphic sarcoma 2764
uterine endometrium during menstrual cycle 2404
uterine leiomyosarcoma 2424
vaginal intraepithelial neoplasia 2384
viral encephalitis 2895
Warthin's tumor 1891
well-differentiated liposarcoma/atypical lipomatous tumor 2746
well-differentiated papillary mesothelioma 2003
Whipple disease (tropical sprue) 1953
Wilms' tumor (nephroblastoma) 2278
Wiskott-Aldrich syndrome 1537
xanthogranulomatous pyelonephritis 2252
xanthoma 2761
yolk sac tumor of testis 2339
yolk sac tumor of ovary 2453
Surgical

Textbook of Pathology

Systemic Pathology & Molecular Diagnostics

2nd Edition

Volume II

Second Edition of ***Textbook of Pathology*** has been designed for undergraduate and postgraduate medical students, and aspirants for postgraduate courses and related health sciences.

Textbook of Pathology has three sections: (a) general pathology, (b) hematology, (c) systemic pathology and molecular diagnostics. It provides comprehensive coverage of etiology, molecular pathogenesis of the disorders, clinical manifestations, clinicopathological correlation and diagnostic approach.

The chapters of this textbook have been rewritten and shared with the eminent teachers, and young promising postgraduate residents across nation. After taking their valuable suggestions, chapters have been finalized to meet the need of young generation of pathologists.

An unrivaled collection of high-resolution lavishly colored illustrations/photographs of surgical pathology and hematolymphoid disorders have complemented the clear concise text.

Salient Features

- Textbook has unrivaled collection of high-resolution lavishly 1901 colored figures and 1719 tables complementing the clear concise text.
- Textbook has clinical photographs, schematic illustrations, flow diagrams, gross morphologic and microscopic photographs of surgical specimens, and photographs of peripheral blood smear, bone marrow aspirate smear and bone marrow trephine biopsy section to understand clinicopathologic correlation of human disorders and diagnostic approach.
- Textbook has reader-friendly large font-size of the text for quick revision of chapters.
- Revised WHO classification of solid neoplasms and hematolymphoid malignancies is given in this textbook.
- Chapters on 'Cellular–Molecular Diagnostic Techniques in Clinical Practice' and 'Blood Banking and Transfusion Practices'.
- Recent concepts in cellular biology with key points of the disorders are given in boxes in the chapters.
- Immunohistochemistry of surgical specimens and immunophenotyping of hematolymphoid neoplasms have been given in tabulated forms.

Vinay Kamal has more than three-decade of teaching experience at India's premier institution, while serving as Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi. An alumnus of Post Graduate Institute of Medical Sciences (PGIMS), Rohtak, Haryana, he has also served in the premier institute. He has published articles in national and international journals. Budding medical professionals Dr Anubhav and Dr Vigyat have put sincere efforts in the completion of *Textbook of Pathology*.
