We dedicate this book…
To our families.
To Gordana-Dana, to David and Sue; to Melissa, Joanne, and Kay for their love, understanding, and encouragement.
To Niko; to Alex and Matthew, Julie, Steven, Chris, Linda, Keisha, William, and Andrew; and to Jack, Leo, and Benjamin for helping us believe the best is yet to come.
To our colleagues everywhere, past and present for working hard each day to make a difference.
To our patients for constantly inspiring us.
In memory of our dear colleague Dr. Gabor
Petar, Judith, Andrew, Bob, and Jon

Foreword

Pediatric inflammatory bowel diseases (IBD) are the most common and most significant chronic disorders in pediatric gastroenterology. The onset of Crohn disease and ulcerative colitis in the first two decades of life presents a number of diagnostic and therapeutic challenges that are unique to pediatric patients. Although the studies available for pediatric diagnosis have improved dramatically in the past three decades, the improvement in technology alone cannot account for the increased frequency of IBD recognized in early childhood. While therapy for older patients has improved dramatically with the development of exciting biologic and small molecule strategies, rarely if ever have comprehensive studies of the pharmacokinetics, safety, and efficacy of any of the IBD medications been performed in pediatric patients. A number of excellent medications are not available in liquid preparations that can be swallowed by children, and others, such as timed-release formulations, are developed for delivery to an adult gastrointestinal tract. It is unfortunate that the care we provide to children is often an extrapolation of what is known about and available for adults with IBD.

Pediatric patients with IBD face a number of unique challenges. The onset of disease before puberty can be devastating. Growth failure is a particularly difficult problem with potentially permanent consequences. Much of the pediatric-specific research has focused on the role of nutritional therapy to treat growth failure and induce remission. Strategies such as nocturnal nasogastric administration of supplements are widespread in most pediatric centers and are surprisingly well tolerated even by the youngest patients, particularly when the value of nutritional therapy is presented in advance to both the family and the child. Nutrition must be strongly advocated for pediatric patients, as it has great therapeutic value and it is the only therapy for which there are no serious potential complications.

The long-term consequences of medical and surgical therapy are particularly troubling for pediatric patients. While most of the cosmetic side effects are reversible, the psychological trauma to an adolescent can be overwhelming. We are only beginning to understand and address the long-term consequences of therapy given at an early age. Bone mass accumulation and linear growth are critical processes that are age dependent, with peaks in early adolescence. Failure of therapy at this stage will have permanent and possibly debilitating consequences. However, the advances in biologic and small molecule therapies have resulted in a dramatic shift in the therapeutic armamentarium. In adults, the "therapeutic pyramid" has been turned on all of its sides, leading to improvement in quality of life and a decrease in overall corticosteroid exposure, but with a potential new set of adverse events from therapy. While pediatric patients undoubtedly benefit from the adult data supporting the "top-down" strategies, the data in adults does not necessarily predict the optimal strategies for children. The effects of more "aggressive" therapy are being recognized for their positives and negatives, and the risks and benefits are undoubtedly different in children and adolescents. Whether it is the

state of the immature immune system, the effect of rapid growth, or the background susceptibility to different malignancies at different ages, the incidence of profound problems such as hepatosplenic T-cell lymphomas reminds all practitioners that we do not understand the unique aspects of the younger patient that may confer increased susceptibility.

The incredible scientific advances have generated exciting insight into IBD with subsequent newer therapies and fully warrant a fourth edition of this book. In the decades since the first IBD gene association was discovered, another 200 loci have been identified, and the individual characteristics and functions of these sites are increasingly understood. This is only the beginning of the synergy that can be achieved from the combination of the human genome project results and the availability of genome-wide arrays. The increased focus on the unique aspects and causes of very early onset IBD (VEO-IBD) has led to an exciting and new group of diseases that are more likely to be monogenic. Sequencing technology, including targeted panels, whole exome and whole genome sequencing have moved the field forward with the identification of causative monogenic defects and new therapeutic targets. This has translated into a precision medicine approach for children with VEO-IBD, resulting in remission and in some cases even cure of the disease. Identification of monogenic defects has also led to the prevention of catastrophic sequelae of the disease, such as malignancy, as in the case of allogenic stem cell transplant in *IL10R* deficiency. To complement these advances, there is incredible progress in the technology available to study the microbiome, its role in immunomodulation, and the effects of prebiotic, probiotic, antibiotic, and nutritional therapy for gastrointestinal diseases. This work has given insight into the complex relationship between the human immune system and the enteric inhabitants that reside within us. This work will likely identify one important group of environmental triggers that comprise part of the cause of IBD, and through that understanding, we may have one more route for the prevention of IBD in genetically susceptible individuals. A better understanding of the resident microbiota will undoubtedly inform better enteric therapy for IBD.

There is no better care than that given by a well-educated and experienced practitioner who considers all aspects of a patient's problems. This book is designed for those practitioners who care for children. IBD therapy must be customized for each individual patient. There is no more ultimate "individual" patient than a child or adolescent with IBD. The many challenges of growth, nutrition, psychology, and adaptation weigh heavily upon the profound challenges of pediatric Crohn disease and ulcerative colitis. In addition to the need for induction and maintenance of remission, the pediatric gastroenterologist must be obsessed not only with the benefits of early achievement of mucosal healing but also with the long-term consequences of therapy, not just a decade away, but hopefully a half century or more hence. Although these patients will move on to adult gastroenterologists, the problems may only accumulate and multiply. "Above all else, do no harm" is a wise admonition for pediatric IBD, where therapies are rapidly improving, and there is a great potential for a cure of these devastating illnesses. These therapies and ultimate cures for Crohn disease and ulcerative colitis will come from the extraordinary advances in immunology and immunogenetics that are well detailed in this book. Until that time, we must rely on the conventional approaches developed in adults, but with the conviction to verify their efficacy for children with IBD.

This book is a landmark step toward better understanding of pediatric IBD and the challenges of IBD therapy in children. The editors are highly respected clinical scientists who have each contributed substantially to the knowledge about pediatric IBD. In addition, the knowledge gained from their extensive clinical experience is reflected in this book. They have assembled a truly extraordinary group of authoritative leaders whose contributions to this volume will guarantee that this will be a reference for all who care for pediatric IBD. The book is a tribute to those authors but is dedicated to the children and adolescents with Crohn disease and

ulcerative colitis. It is remarkable how far we have come since the first edition yet sobering how far the journey is yet to go. It is a sign of the times that increased focus at every level is directed toward children, and this book is one significant step along that road toward improving care for the hundreds of thousands of children and adolescents with inflammatory bowel diseases. It should be a required reading for all those who care for these children.

Preface

We are pleased to present the fourth edition of *Pediatric Inflammatory Bowel Disease.* Since the publication of the last edition, there has continued to be an explosion of discoveries and advances in the areas of genetics, immunology, pharmacogenomics, microbiome, optimization of therapeutic delivery, and epidemiologic knowledge, particularly regarding our youngest pediatric patients afflicted with inflammatory bowel disease. These advances have resulted in improved understanding of the etiology and pathogenesis of inflammatory bowel disease and have provided mechanisms to optimize therapeutic management of our patients.

The focus of the textbook remains unchanged. We hope to provide a reference that assists clinicians from multiple disciplines, including primary care, pediatric, internal medicine, and gastroenterology—all healthcare providers who care for children with inflammatory bowel disease. This textbook will augment other utilized references, focusing on pediatrics while also incorporating the adult evidence and experience that has informed and influenced the care of children.

The format of the textbook is similar to the last edition, with sections dedicated to etiology and pathogenesis, epidemiology and clinical features, diagnosis, medical and nutritional therapy, surgical therapy, research, and special considerations—a section that includes topics which have become increasingly important and challenging for the experienced clinician, including addressing the psychological aspects of pediatric inflammatory bowel disease, legislative advocacy, transition from pediatric to adult care, and quality improvement. We are pleased to offer topical new chapters regarding immune dysregulation in very early onset pediatric inflammatory bowel disease, fecal markers of disease activity, therapeutic drug monitoring, dietary therapies, complementary and alternative therapies, management of intra-abdominal complications, postoperative surveillance, and fostering self-management and patient activation, coauthored by two parents of patients with pediatric inflammatory bowel disease.

As with the previous three editions, we are indebted to the internationally recognized experts who contributed to this book, inculcating the latest research- and evidence-based clinical opinion to the updated chapters. This edition would not have been possible if not for their generous contributions and dedication.

Part I

Etiology and Pathogenesis

Genetics of Inflammatory Bowel Diseases

1

Christopher J. Cardinale and Hakon Hakonarson

Introduction

The inflammatory bowel diseases (IBD), Crohn disease and ulcerative colitis, are immune-mediated disorders resulting in chronic, relapsing inflammation of the gastrointestinal tract. The etiology of IBD is multifactorial, influenced by both genes and environment. It has been hypothesized that environmental factors and maladaptive immune responses to gastrointestinal flora generate a dysregulated inflammatory cascade, creating mucosal injury in genetically susceptible individuals. The identification of genetic linkage between Crohn disease and the pericentromeric region of chromosome 16 by Hugot et al. in 1996 spawned a series of genome scans and linkage analyses in search of susceptibility and phenotypic modifier genes [1]. In 2001, the discovery that specific polymorphisms in the *NOD2* were the underlying variants on chromosome 16 introduced a new era of genotype-phenotype investigations [2, 3]. The advent of genome-wide association studies has resulted in the successful identification of new, well-replicated disease associations, now encompassing 240 independent regions of the genome (loci) [4].

The field of IBD genetics is of special interest to pediatric gastroenterologists for both practical and investigational reasons. From a clinical practice standpoint, pediatric gastroenterologists are often faced with questions from concerned parents regarding the risk of IBD among current or future siblings, as well as the eventual offspring of the affected child. Understanding genetic associations of IBD can provide patients and their families with useful information that may help them cope with the disease. Furthermore, as our knowledge of genotype-phenotype associations grows, it is anticipated that genotyping at the onset of disease may enable physicians to predict disease course and tailor medical therapies specific for each patient. Studies of pediatric IBD lead to a better understanding of the disease because children have been exposed to fewer environmental confounders, which can provide insights into intrinsic genetic mechanisms that may not be detected in adult studies. This may be especially important in children with very early onset IBD (<5 years), whose disease course and phenotypes are the most discordant with those of adult-onset IBD.

Genetic Epidemiology

Ethnic and Racial Variations of Disease

The genetic underpinnings of IBD are supported by ethnic and racial variations in disease prevalence. The highest rates of IBD are found in Caucasian individuals, especially those of Jewish heritage. Among Jewish subgroups, Ashkenazi Jews have a two- to ninefold greater prevalence of IBD over non-Jewish counterparts [5, 6]. While the vast majority of genetic investigations in IBD have been conducted in Caucasians, it is apparent that it can occur in all racial and ethnic groups. African Americans and Asians have a lower risk of IBD, although there appears to be a trend toward growing prevalence in these populations [7].

Evidence is mixed on the question of phenotypic differences in IBD presentation between races. Basu et al. reported that African Americans and whites were more likely to have Crohn disease, whereas ulcerative colitis predominated among Mexican Americans [8]. While intestinal manifestations did not appear to vary based upon race or ethnicity, there were differences in extraintestinal manifestations between groups. Among Crohn's patients, African Americans were more likely to develop arthritis and uveitis than whites, whereas joint symptoms and osteoporosis were more com-

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_1

mon among whites with UC than Mexican Americans. On the other hand, other researchers have reported no major differences in disease location, behavior, upper gastrointestinal tract involvement, perianal involvement, and extraintestinal manifestations among races and ethnic groups [7, 9, 10].

Family Studies

Family studies have demonstrated that 5–30% of probands with Crohn disease and ulcerative colitis identify the presence of IBD in a family member [5]. This association appears to be stronger for Crohn disease than ulcerative colitis. Phenotypically, relatives of probands with IBD are more likely to develop the same form of disease as the affected family member, with a concordance between family members in the localization of disease but not disease severity. With regard to age of disease onset, patients with a family history of IBD are more likely to develop disease at an earlier age than affected individuals lacking a family history [11]. Among family members, the risk of developing IBD is the greatest among first-degree relatives, especially siblings. The relative risk (RR) for a sibling of a Crohn's patient developing disease is 13–26; for ulcerative colitis patients, the RR for a sibling is 7–17 [12]. Orholm et al. reported that 6.2% of children born to a parent with ulcerative colitis developed IBD and 9.2% of children born to a parent with Crohn disease developed IBD [13]. In the rare instance that both parents have IBD, studies estimate that their children have a 33% chance of developing IBD by age 28 [12]. While second- and third-degree relatives of IBD probands have a lower likelihood of disease, their risk is still elevated compared to the background population.

In all but rare individual patients and in VEO-IBD, the incidence of IBD is multifactorial and highly polygenic. This complex genetic architecture was illustrated by a study of two large Ashkenazi Jewish families, one with over 800 members and one with over 200 members containing 54 cases of Crohn disease and 26 cases of ulcerative colitis [14]. No monogenic, Mendelian locus was identified, but there was an enrichment in these families of risk alleles that are common in the human population.

Twin Studies

Twin studies are based upon the premise that, in the setting of a similar environmental milieu, rates of disease concordance between twins correlate with the influence of genetic factors. To date, three large studies of twin pairs with IBD from Scandinavia and the United Kingdom have consistently identified higher concordance rates among monozygotic twins with Crohn disease and ulcerative colitis than dizygotic twins [15–17]. The influence of genetics appears to be greater in Crohn disease than ulcerative colitis with reported cumulative monozygotic concordance rates of 30% and 15%, respectively [18]. Concordance rates for dizygotic twins are approximately 4% in both Crohn disease and ulcerative colitis. Co-twins with IBD are more likely to develop the same disease type, although mixed pairs of dizygotic twins with ulcerative colitis and Crohn disease have been reported. With regard to disease-specific characteristics, Scandinavian twin registries demonstrated concordance of 40–77% for disease location; however, there appeared to be no association of disease behavior or extent among co-twins [15, 17]. A trend toward concordance for age at diagnosis was identified with 40–67% receiving a diagnosis of IBD within 2 years of one another. The fact that monozygotic concordance is not 100%, and the low concordance between dizygotes demonstrates that genotype alone is not sufficient for disease evolution.

NOD2 Gene and Crohn Disease

The *NOD2* gene (formerly *CARD15*) located on the *IBD1* locus of chromosome 16 is associated with an increased susceptibility to Crohn disease, but minimally with ulcerative colitis. It is the highest risk gene for Crohn disease, and its share of the heritability is several times greater than other loci. Among the more than 30 known amino acid polymorphisms identified in the *NOD2* gene [19], the most common variants are two missense mutations, p.Arg702Trp and p.Gly908Arg, and one frameshift mutation p.Leu1007fsinsC. NOD proteins are mammalian pattern recognition receptors which serve the innate immune system as bacterial sensing molecules. NOD2 is a cytosolic protein found in a variety of cells including monocytes, macrophages, B and T lymphocytes, dendritic cells, and intestinal epithelial cells. Stimulation of NOD2 by its ligand, the bacterial cell wall component muramyl dipeptide (MDP), propagates signal transduction pathways leading to nuclear factor κB (NF-κB) and mitogen-activated protein kinase (MAPK) activation [20]. These three polymorphisms impair activation of NF-κB [21]. Studies of NOD2's role in mucosal immune homeostasis remain controversial in explaining how a loss-of-function mutation can paradoxically lead to increased inflammation. Some evidence suggests that deficient bacterial sensing by NOD2 leads to excessive activation of parallel pathogen-sensing pathways such as IL-1β/NRLP3 [22, 23].

Epidemiology of *NOD2* Mutations

A *NOD2* risk allele confers a two-to-three-fold relative risk of developing Crohn disease; this risk is increased to 17-fold if two alleles are present [24]. Ten to thirty percent of patients with Crohn disease are heterozygous for one of the three mutations, while 3–15% are homozygous or compound heterozygotes [25]. Although these variants are associated with an increased risk of Crohn disease, 8–15% of the healthy population possesses at least one of these mutations and 1% of healthy individuals are homozygous or compound heterozygotes. The widespread prevalence of risk alleles in the healthy population is explainable by polygenic factors, variable penetrance, and other environmental mediators.

Studies worldwide have revealed that the association of *NOD2* polymorphisms with Crohn disease varies between different ethnic populations. North American adult Caucasian cohorts report carriage rates of 10–30% for the three common *NOD2* variants, while minority groups were found to have lower allele frequencies. A North American, multicenter study of pediatric patients with Crohn disease identified *NOD2* polymorphisms among 25% White, 1.6% African American, and 1.6% Hispanic participants [26]. Significant diversity in allele carriage has been described among Crohn's patients in European countries and background control populations [27]. *NOD2* variants are virtually absent in Japanese, Korean, Chinese, and sub-Saharan African individuals. High rates of *NOD2* mutations have been seen in the Jewish Ashkenazim with one Israeli group reporting the presence of variants in 51% of pediatric and 37.5% of adult Crohn's patients studied [28].

Human Leukocyte Antigens in Ulcerative Colitis

The major histocompatibility complex (MHC) locus on chromosome 6p encodes genes in the human leukocyte antigen (HLA) family, which present peptide antigens to T-cells. Associated polymorphisms between HLA types and IBD have included the Class I type HLA-B and the Class II types HLA-DRB1, HLA-DQB1, and HLA-DP [29]. The polymorphism-rich nature of the HLA region as well as its complex linkage disequilibrium has resulted in heterogeneous findings among investigators across over a hundred studies. It is consistently shown, however, that the amount of trait heritability for Crohn disease conferred by the HLA locus is modest, but for ulcerative colitis it is the greatest genetic risk factor [30].

Class II alleles DRB1*0103, DRB*1502, and DRB*401 have been consistently associated with ulcerative colitis [31]. Phenotypic analyses have identified DRB1*0103 to be predictive of a more aggressive form of ulcerative colitis with shorter time to colectomy than those without the allele. In Crohn's patients, a particular link between DRB1*0103 and isolated colonic disease has been reported [32]. The correlation of DRB1*0103 with both colonic Crohn disease and ulcerative colitis has been postulated to provide a unifying molecular mechanism for colonic involvement in IBD. HLA associations with extraintestinal manifestations of IBD have also been evaluated. HLA-B*27, HLA-B*35, and HLA-DRB*103 have been associated with type I peripheral arthropathy, whereas HLA-B*44 is associated with type II peripheral arthropathy [33, 34]. Symptoms of uveitis have been linked with HLA-B27 and DRB*0103.

High-density genotyping using microarrays in the MHC region has reinforced the importance of HLA-DRB1*0103 in both Crohn disease and ulcerative colitis in a study by Goyette, et al. Their study genotyped 7,406 single nucleotide polymorphisms in 32,000 IBD cases and an equal number of controls [35], finding that DRB1*0103 gave by far the strongest association. The fine resolution of mapping allowed localization to specific amino acid substitutions in the MHC molecule which revealed that the causal variants are located within the peptide-binding groove and thereby influence antigen presentation directly [35].

Genome-Wide Association Studies in IBD

The use of linkage studies was prevalent during the 1990s and early 2000s because of the cost and labor associated with producing genotypes. The family-based design allows the genome to be scanned for associations using a few hundred markers, since closely related individuals will share large segments of chromosome. A major development in the field of human complex-trait genetics occurred in the mid-2000s with the introduction of genotyping millions of single nucleotide polymorphisms (SNPs) using microarrays. This technology has made possible the performance of genome-wide association studies (GWAS). These studies survey a large fraction of the common human genetic variation, testing each of millions of SNPs for direct association with the trait of interest by comparing the population allele frequency between IBD cases and healthy controls [36]. This direct association testing approach has the advantage of greater power to detect small effects. Risch and Merikangas estimated that 17,997 affected sibling pairs would be necessary to detect a risk allele with 50% frequency and odds ratio of 1.5 by linkage analysis [37]. By contrast, direct association analysis would require only 484 cases and controls.

IL23R Polymorphisms in Crohn Disease and Ulcerative Colitis

One of the first GWAS, in a North American Crohn disease cohort, identified new gene associations including multiple polymorphisms within the *IL23R* gene on chromosome 1p31 [38]. In particular, an amino acid polymorphism, p. Arg381Gln, located in the cytoplasmic domain of the *IL23R* protein, demonstrated highly significant evidence for association. The low-frequency allele conferred significant protection against developing IBD in non-Jewish and Jewish Crohn disease cohorts, as well as in non-Jewish ulcerative colitis cohorts. Additional independent association signals were observed indicating the presence of multiple associations within the *IL23R* gene [38]. As the second-strongest signal, after *NOD2*, this association has been extensively replicated by subsequent GWAS.

The functional IL-23 heterodimeric receptor is comprised of the IL23R and IL12RB2 [39] subunits, with the latter subunit being shared with the functional IL-12 receptor. Similarly, the IL-23 cytokine is comprised of a unique subunit, p19, as well as a p40 subunit which is common to the IL-12 functional cytokine. Additional support for the role of the IL-12/IL-23 pathway in mediating end-organ inflammation has been generated in mouse models demonstrating requirement for IL-23 in murine colitis [40–43] and experimental autoimmune encephalitis [44]. The monoclonal antibody therapy ustekinumab inhibits the p40 common subunit of IL-12 and IL-23 and was approved for the treatment of Crohn disease in 2016 [45] and is promising in the treatment of ulcerative colitis [46].

Association of the *ATG16L1* Autophagy Gene with Crohn Disease

A GWAS focusing on amino acid-altering polymorphisms identified the p.Thr300Ala substitution in *ATG16L1* in Crohn disease. The *ATG16L1* gene is part of the autophagosome pathway and is involved in the processing of intracellular bacteria [47]. *ATG16L1* is expressed in intestinal epithelial cells, as well as in $CD4^+$, $CD8^+$, and $CD19^+$ primary human lymphocytes [48]. Of interest is that no association was observed to ulcerative colitis suggesting that *ATG16L1*, like the *NOD2* polymorphisms, represent Crohn's-specific risk alleles. The *ATG16L1* association demonstrated that autophagy and host cell responses to intracellular microbes are involved in the pathogenesis of CD. Before the discovery of this genetic association, the role of autophagy in IBD was not as well appreciated, and this example demonstrates how genetic investigation can advance new treatment approaches and understanding of disease pathophysiology.

Non-Coding Variation

The IBD risk variants described to this point have been coding mutations which alter the amino acid sequence of a protein such as NOD2, HLA-DRB1, IL23R, or ATG16L1. These signals were the first to appear in the early days of GWAS is an indication of how impactful coding variants can be consistent with their overwhelming role in Mendelian genetics. However, at least 95% of the known loci associated with IBD are SNPs located in introns or intergenic regions. It is widely presumed that these non-coding variants alter transcription factor-binding sites, chromatin structure, or other regulatory processes to influence the expression of protein- and RNA-coding genes. A major focus of the post-GWAS era has been to identify the target genes and the mechanism of the non-coding variants [49].

SNPs located in close proximity on the same strand of DNA tend to be inherited together because they are unlikely to be separated by meiotic recombination. This DNA linkage results in the phenomenon of linkage disequilibrium (LD), where the population's history of meiotic recombination's demarcates stretches of chromosome—blocks—with an unbroken haplotype of variants shared among the individuals in the population. LD allows the geneticist to genotype a sampling of SNPs representing each of the haplotypes in each of the blocks, thereby capturing a sizeable fraction of all the common genetic variations in the population [50]. Consequently, it is usually not possible to identify the causal SNP distinctly from other SNPs that are in LD. The LD blocks tend to be small enough, around 30,000 base pairs, that the locus will contain a small number of potentially causal protein-coding genes near the associated LD block (Fig. 1.1). The examples discussed below highlight some instances where strong associations were found in proximity to genes with a functional role consistent with IBD risk.

Meta-Analysis

The associated common variants identified by single GWAS usually have modest individual effects, often with odds ratios of smaller than 1.2 for binary traits, or with explained variance of less than 1% for quantitative traits [51]. To discover common variants with even smaller effects, a sample size larger than that of single studies is required. Meta-analysis combines large datasets and is an economical way to improve sample size. An early meta-analysis of three genome-wide scans in Crohn disease identified 21 new Crohn susceptibility loci. It increased the number of independent loci conclusively associated with Crohn to 32, explaining approximately 20% of Crohn disease heritability [52]. Including three additional GWAS scans, a subsequent meta-analysis added 39 new confirmed Crohn disease

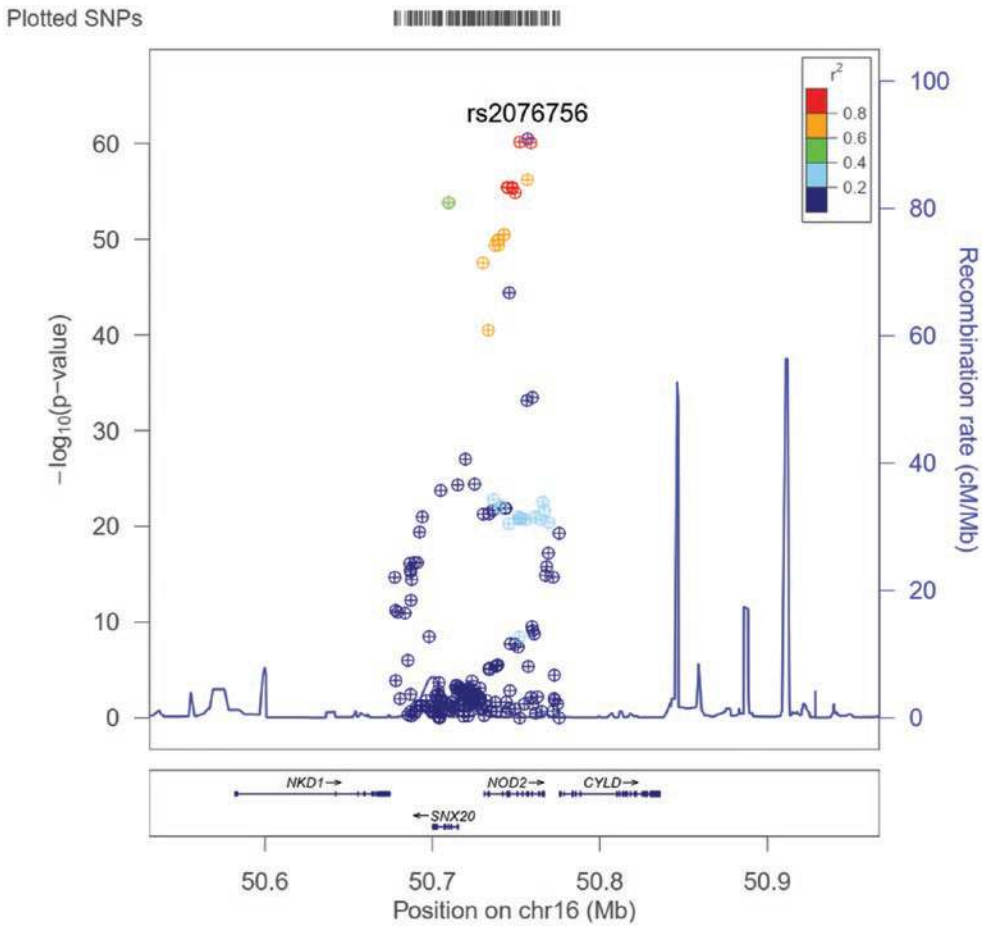

Fig. 1.1 The *NOD2* gene is an example of "synthetic association" in a GWAS locus. The regional association plot displays the sequence coordinates of the chromosome 16 locus (*x*-axis) *versus* the inverse logarithm of the association *p*-value for the Crohn disease trait (*y*-axis) in a published GWAS [4]. Genes situated in this locus include *NKD1*, *SNX20*, *NOD2*, and *CYLD*. The color coding of the SNPs in the plot reflects the strength of linkage disequilibrium (LD) with the lead variant. The lead SNP shown is a non-coding intronic SNP, and is non-causal. It is associated with the Crohn disease trait through its LD to the ensemble of amino acid mutations in the *NOD2* gene which sit disproportionately on this haplotype

susceptibility loci [53]. These 39 new loci increase the proportion of explained heritability to only 23.2% indicating their rather modest effects. While some of these newly identified loci contain a single gene, others contain multiple genes or none at all. Some functionally interesting candidate genes in the implicated regions include *STAT3*, *JAK2*, *ICOSLG*, *ITLN1*, and *SMAD3*.

Signal transducer and activator of transcription 3 (STAT3) and Janus kinase 2 (JAK2) are members of the JAK-STAT signaling pathway. This major signaling pathway transmits information from cell surface receptors stimulated by cytokines and growth factors to the nucleus to regulate transcription of genes involved in immune cell division, survival, activation, and recruitment [54].

Inducible T-cell co-stimulator ligand (ICOSLG) is a co-stimulatory molecule homologous to B-7 which is expressed on intestinal epithelial cells. Signaling through its receptor, ICOS, may have a key role in controlling the effector functions of regulatory T-cells [55]. Maturing plasmacytoid dendritic cells express ICOSLG to modulate the activity of IL-10-producing regulatory (Treg) T-cells [56].

Intelectin-1 (ITLN1) is a secreted protein expressed in human small bowel and colon, hence its name as an intestinal lectin, a carbohydrate-binding protein. ITLN1 binds to the surface carbohydrate chains of numerous bacterial species, implicating it in immune defense [57]. More recently, it has been identified as a circulating anti-inflammatory adipokine expressed in visceral fat and is associated with obesity, diabetes, and cardiovascular disease [58].

Mothers against decapentaplegic homolog 3 (SMAD3) is a transcription factor which binds to specific DNA sequences in the promoter region of many genes that are regulated by transforming growth factor beta (TGF-β), and on formation of the SMAD3/SMAD4 complex, activates transcription. SMAD3 deficiency will enhance Th17 differentiation during the TGF-β-mediated induction of Foxp3+ regulatory T-cells [59].

GWAS Meta-Analysis in Ulcerative Colitis

A meta-analysis combining data from six GWAS identified 47 risk loci in ulcerative colitis [60]. Some noteworthy candidate genes identified by this effort include *PRDM1*, *TNFRSF14*, *TNFRSF9*, *IL1R2*, *IL8RA*, and *IL8RB*.

PR domain containing 1 (PRDM1) is the master transcriptional regulator of plasma cells and drives the matu-

ration of B-lymphocytes into immunoglobulin-secreting cells [61].

Tumor necrosis factor receptor superfamily 14 (TNFRSF14), also known as herpes virus entry mediator (HVEM), transduces signals from the cytokine LIGHT and has an important role in preventing intestinal inflammation in a murine colitis model [62].

Tumor necrosis factor receptor superfamily 9, (TNFRSF9) encoding receptor 4-1BB, is a co-stimulator in the regulation of peripheral T-cell activation. This receptor is expressed by T-cells, dendritic cells, granulocytes, and endothelial cells at inflammation sites and enhances their proliferation and activation [63].

Interleukin 1 receptor 2 (IL1R2) is a non-signaling decoy receptor that reduces IL-1β activity by competing with the high-affinity receptor IL1R1. IL-1β is a pro-inflammatory cytokine produced by lamina propria macrophages and is increased in patients with ulcerative colitis [64].

Receptors for IL-8 (IL8RA and IL8RB) mediate the chemokines' role as a neutrophil chemotactic and activation signal. IL8RA may play a role beyond neutrophil recruitment in mediating the immune response in UC [65].

Association of *TNFRSF6B* and *IL27* with Pediatric Age of Onset IBD

Pediatric age of onset IBD is an attractive target for GWAS for several reasons. Early-onset IBD is characterized by unique phenotypes and increased severity, suggesting the possibility of loci specific to early-onset disease. Early-onset IBD also has a stronger association with family history of IBD, and the childhood population may also be less affected by exogenous factors implicated in adult-onset IBD, such as diet, smoking, and medication [66]. Therefore, GWAS in children provides additional power to reveal genetic risk variants with only modest effects in pediatric- and adult-onset IBD.

GWAS have been performed focusing on pediatric cases. One of these involved 3426 affected individuals and 11,963 genetically matched controls [67]. The study nominally replicated 29 of 32 loci previously associated with adult-onset Crohn disease, as well as 13 of 17 adult-onset ulcerative colitis loci. Further, it identified seven new regions associated with childhood IBD susceptibility.

Kugathasan et al. found an association located on chromosome 20q13 containing tumor necrosis factor superfamily receptor 6B (*TNFRSF6B*) [68]. The protein product of *TNFRSF6B*, decoy receptor 3 (DcR3), binds to and neutralizes signaling by pro-inflammatory cytokines LIGHT, TL1A, and Fas ligand [69–72]. Serum DcR3 levels were elevated in pediatric cases of IBD relative to controls, particularly in patients harboring the 20q13 minor allelic variants [68]. Follow-up studies by our group led to the launch of a clinical trial with an anti-LIGHT monoclonal antibody to treat Crohn's patients who have failed other therapies beginning in 2020.

The second locus of interest is the in 16p11 region, in a LD block containing several genes including *IL27*. The IL-27 cytokine regulates T-cell differentiation in adaptive immune responses, influencing the balance between pathogenic Th17 cells and inflammation-suppressing T-cell subsets [73]. Identification of *IL27* as a candidate gene is consistent with the involvement of the Th17 pathway in the pathogenesis of Crohn disease, corroborating findings from other genome-wide scans (*IL23R*, *STAT3*, *JAK2*, and *IL12B*).

Genome-wide significant association results throughout the IL12/IL23 and IL27/Th17 pathway genes support the relevance of these T-cell subsets in the pathogenesis of IBD (Fig. 1.2).

Impact of the Immunochip

Common immune disorders such as ankylosing spondylitis, celiac disease, multiple sclerosis, psoriasis, rheumatoid arthritis, systemic lupus erythematosus, and type 1 diabetes often share overlapping susceptibility loci in GWAS studies [74]. Motivated by this observation, the Immunochip Consortium was formed to produce an inexpensive genotyping array that could be used to analyze hundreds of thousands of samples in autoimmune disease. The chip interrogates approximately 200,000 SNPs at 186 loci to enable dense genotyping so that SNPs located close together in the loci of interest including those at low allele frequencies can be included in analyses [75]. The results gained from this effort played a large role in the meta-analysis of Jostins et al. which raised the tally of IBD-associated loci to 163 [76]. The Jostins study revealed that 113 of the 163 loci are shared with other complex diseases including 66 loci shared with other autoimmune diseases [74]. The economic cost of the Immunochip allowed many samples to be genotyped so that loci could be identified at a genome-wide significance level, where in the previous meta-analyses they showed only marginal significance.

A further goal of the Immunochip effort is to fine-map variants so that, by using Bayesian statistical analyses, the individual causal variant can be identified rather than a large ensemble of variants that are in linkage disequilibrium with each other [77]. For instance, this fine mapping was used to show that there are additional amino acid substitutions in *NOD2* and *IL23R* which are the causal SNPs that drive the genetic association signal.

Huang et al. applied Bayesian conditional analysis to the Immunochip data to identify credible sets, that is, a defined

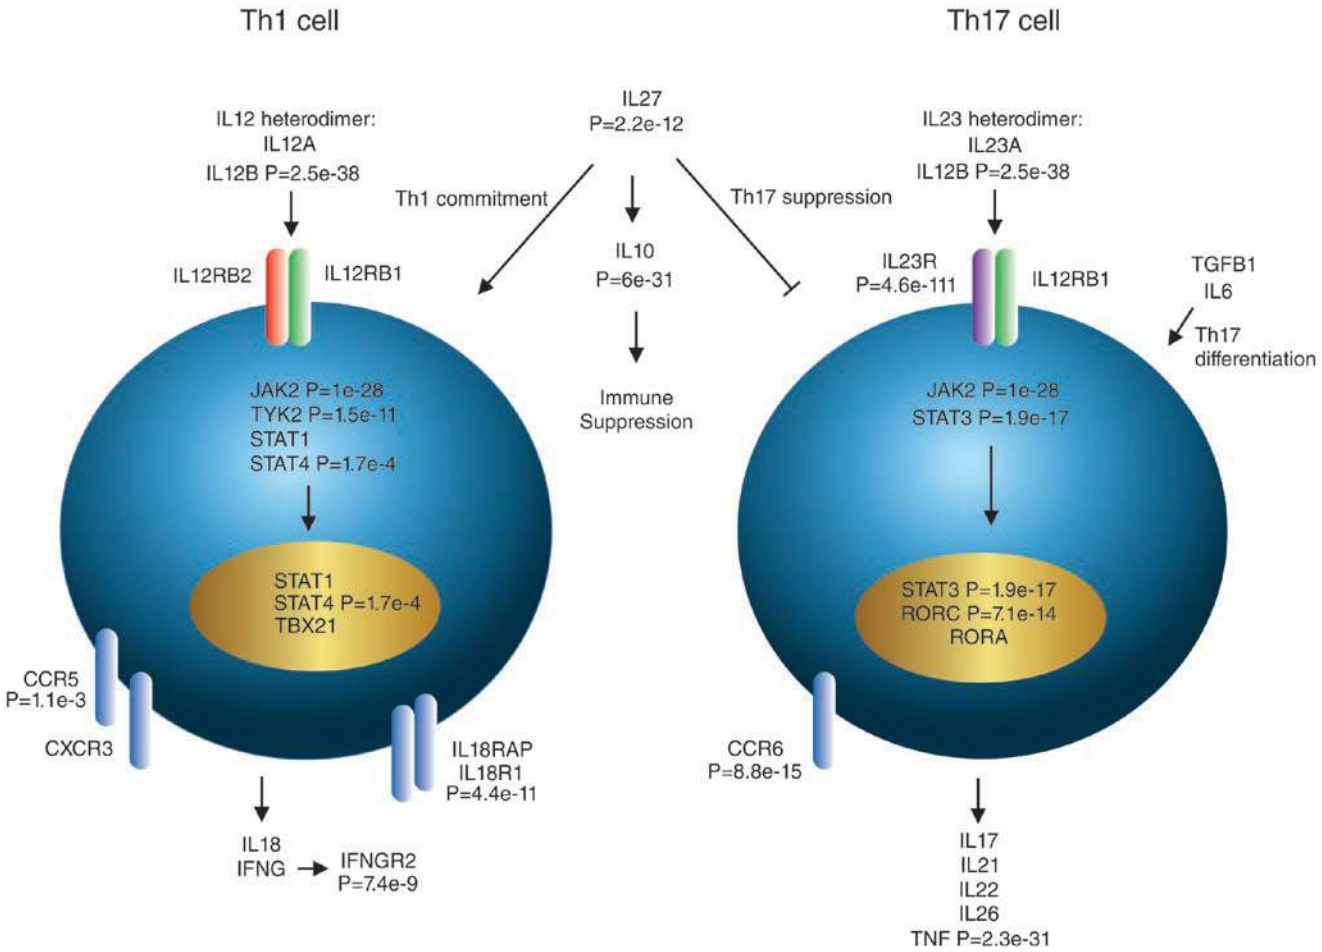

Fig. 1.2 Genes involved in cytokine signaling and T-cell differentiation are highly enriched in IBD GWAS. The competing pathways of Th1-type versus Th17-type helper T-cell differentiation are influenced by cytokines and their signaling cascades. The *p*-values for the genes shown are from a recent GWAS meta-analysis [93]

number of SNPs accounting for at least 95% of the posterior probability of causality at the locus of interest [78]. Eighteen loci were identified in which the 95% credible set consisted of a single variant, i.e., the causal variant was identified specifically. A revealing outcome of this analysis is that the causal SNPs frequently do not have functional annotations that would ordinarily implicate them in disease, such as an expression quantitative trait locus (eQTL) association, transcription factor-binding motif, or epigenetic modification.

Trans-ancestry Association Studies

A majority of genetic studies in IBD have been conducted in European ancestry populations. However, the expansion of these studies into Asian populations has yielded some insights. In the Japanese population, the well-known *NOD2* polymorphisms are virtually absent [79]. GWAS in Japan has shown that the single largest association signal is located in the *TNFSF15* gene encoding the pro-inflammatory cytokine TL1A [80].

Liu et al. conducted a trans-ethnic meta-analysis including 86,640 individuals of European ancestry and 9,846 individuals from East Asia, India, or Iran [4]. This study implicated 38 new loci, raising the tally to 200 total loci, and determined that there were significant differences in the frequency of risk alleles in the different populations. Nevertheless, the direction and magnitude of the effect at the shared loci were very similar between ancestries, suggesting that the casual variants are likely to be common (minor allele frequency greater than 5%). In addition to the large impact of TL1A in the Asian population, the HLA locus was also found to have a greater influence in ulcerative colitis [4].

A GWAS focusing on the African-American population not only replicated many of the known loci from the European population, but also yielded additional African-specific SNPs in *ZNF649*, *LSAMP*, and *USP25* [81]. These results demonstrate that different ancestries can have population-specific

variants and that predictive medicine based on genotypes will need to incorporate data from diverse backgrounds.

Next-Generation Sequencing

The traditional method of DNA sequencing was developed by Sanger et al. using dideoxy-nucleotides as chain terminators [82]. This technology has become quite efficient and can be run on an automated instrument to generate 700-bp sequence reads with fluorescently labeled terminators, but with very low throughput. In the last decade, a new generation of DNA sequencing technology has emerged which uses sequencing-by-synthesis on a massively parallel scale. The current generation of these instruments can generate up to 6 trillion raw bases in the form of 20 billion reads of sequence every two days, sufficient for 48 whole-human genomes (Illumina Inc., San Diego, CA). This technology has revolutionized the field of Mendelian genetics, that is, rare monogenic diseases, by enabling the identification of rare variants in a family setting. Interestingly, inflammatory bowel diseases can have Mendelian mimics that can be detected by next-generation sequencing, particularly in the very early onset (VEO) patients [83]. More attention will be given to the diagnosis of these genetic phenocopies and well as the management of the very young patients in the chapter of this textbook on very early onset IBD.

Sequencing in High-Risk Individuals and Families

Currently, the most cost-effective approach to massively parallel sequencing in IBD patients is to target the exome, that is, the 1% of the genome that encodes the amino acids of proteins. Congenital deficiency of the receptor for the immunomodulatory cytokine IL-10 was the first monogenic defect identified as causative of VEO-IBD in 2009. While refractory to medical therapy, these patients responded to bone marrow transplant [84]. Exome sequencing has revealed additional patients with IL-10 receptor deficiency [85], Since that time, multiple monogenic defects have been identified through exome sequencing. An early example of the success of this approach was seen in a 15-month-old child who presented with perianal fistulae and failure to thrive unresponsive to standard treatments which progressed to pancolitis. The patient underwent many surgical procedures and genetic tests that did not resolve his disease. Exome sequencing revealed that this patient carried an exceedingly rare mutation on the X chromosome in the *XIAP* gene, a potent regulator of the inflammatory response [86]. Since this protein acts in cells of the hematopoietic lineage, he was treated by a bone marrow transplant resulting in resolution of his disease. Other monogenic cases of VEO IBD have been identified and have resulted in life-saving therapy [87].

Features that suggest a patient may be a candidate for exome sequencing include early onset of disease, unusual severity, familial pattern of transmission, and refractory response to standard therapies. It is recommended to obtain DNA samples from the parents in addition to the proband because some probands may be compound heterozygotes, that is, inheriting a different defective allele of the gene from each parent. The trio of exomes is useful in identifying de novo mutations in either the parental germ line or in the child which may be pathogenic.

Next-Generation Sequencing in Research

It is hypothesized that some fraction of the heritability of complex genetic disorders, such as IBD and particularly VEO-IBD, is due to rare or low-frequency variants [88]. Due to their rarity, these variants are not in strong linkage disequilibrium with proxy SNPs, which is required to make the GWAS approach feasible. Therefore, discovery of additional genes and low-frequency variants will require direct sequencing of hundreds of thousands of genomes [89].

Initially, the approach to finding rare or coding variation has been to sequence-specific genes in a large cohort based on the gene's status as a GWAS candidates. Rivas et al. identified additional coding mutations in *NOD2* and *IL23R* as well as novel coding variants in *CARD9*, *IL18RAP*, *CUL2*, *C1orf106*, *PTPN22*, and *MUC19* [90]. Beaudoin et al. performed amplicon sequencing on 55 genes in 200 cases and 150 controls for ulcerative colitis. They confirmed the previous associations with *CARD9*, *IL23R*, as well as a novel association in *RNF186* [91].

Efforts are currently underway to extend sequencing to thousands of exomes to search for pathogenic coding variants. A difficulty to this approach is that any individual variant is so rare that there is insufficient statistical power to identify the variant at genome-wide significance. As a result, many statistical methods have been developed which aggregate all the discovered variants in a gene into a single supervariant to test the burden of rare mutations or to test the variance in allele frequencies between cases and controls [92].

As sequencing technology improves, it has become feasible to obtain a whole-genome sequence (WGS), including the 99% of the genome that is non-coding, for less than $1000. WGS has been used to expand the catalog of variation that can be assessed and thereby has led to GWAS studies on an increasing scale. The largest GWAS meta-analysis to date contained 59,957 IBD cases and yielded 240 genome-wide significant loci [93]. A companion study sequenced whole genomes at low depth in 4280 cases and found an additional rare variants in *ADCY7*, but essentially replicated

the known loci, suggesting that rare or low-frequency variants explain little heritability in IBD [94].

Risk Prediction

Encouraged by the notable success of GWAS in Crohn disease and ulcerative colitis, it is logical to ask if these advances can deliver sufficiently accurate predictions to make targeted intervention realistic. Several efforts have been made, but most results are modest [95]. As in meta-analysis, it is possible to compile a large sample size by combining as many cohorts as possible, yielding a boost in prediction performance. Using the large sample size and wide variant spectrum of the Immunochip dataset in combination with advanced machine learning methods, Wei et al. were able to achieve an area under the receiver–operator curve (AUC) of 0.86 for Crohn disease and 0.83 for ulcerative colitis [96]. Genotypes from the Immunochip were useful in predicting durable responders *versus* primary non-responders to anti-TNF therapy in ulcerative colitis [97]. The efficacy of these models depends on the status of the limited number of high-risk variants, with little contribution from the low frequency or rare variants present on the Immunochip [98]. Machine learning methods such as the study by Wei et al. run the risk of being "over-fit" to the training dataset, and encounter difficulty generalizing to other cohorts. A comprehensive catalog of variation from WGS combined with a massive number of subjects may be the way to overcome these challenges.

Genotype-Phenotype Correlations in Pediatric IBD

Cleynen et al. analyzed subphenotypes of IBD in 34,819 patients who were genotyped on the Immunochip [99]. For Crohn disease, the phenotypes examined were age at diagnosis, disease location, disease behavior (penetrating, stricturing, inflammatory), and requirement for surgery. For ulcerative colitis, the phenotypes examined were age of onset, disease extent, and colectomy. Across all 186 loci on the Immunochip, only SNPs in *NOD2*, the HLA locus, and 3p21 (*MST1*) were found to have genome-wide significance, influencing all subphenotypes [99]. The disease location was essentially fixed over time and was the main independent determinant of the patient's disease process, while disease behavior and requirement for surgery were largely markers of disease progression. A composite polygenic genetic risk score based on the 163 known loci was associated with all disease subphenotypes but only the three loci named above were individually significant. The authors concluded that the binary classification of IBD into Crohn disease and ulcerative colitis is not supported by genetic data and that a ternary classification should be used: ulcerative colitis, colonic Crohn disease, and ileal Crohn disease [99].

Genetic Sharing Between Pediatric Age of Onset IBD and Other Autoimmune Diseases

As the Immunochip genotyping effort amply demonstrated, there is a shared genetic architecture for a wide variety of autoimmune diseases. Li et al. performed GWAS in 6,035 cases of 10 different pediatric autoimmune diseases and 10,718 shared controls. This effort identified 27 genome-wide significant loci which had shared risk among multiple pediatric autoimmune diseases, for instance, a novel role for *CD40LG* in Crohn disease, ulcerative colitis, and celiac disease [100]. The main pathways identified as responsible for this shared risk were cytokine signaling (JAK/STAT and helper T-cell), antigen presentation, and T-cell activation [100]. A study of SNP-h^2, also called narrow-sense heritability, across these 10 pediatric autoimmune diseases showed that the heritability explained by common SNPs was 45.4% for Crohn disease and 38.6% for ulcerative colitis [101]. In pairwise analysis, Crohn disease and ulcerative colitis showed the strongest similarity to each other of all pairwise combinations of the 10 autoimmune diseases [101].

Summary

Family-based, twin, and ethnicity-based studies lend strong support for a genetic basis of IBD as a model complex mode-of-inheritance trait. The recent advent of GWAS has markedly advanced the identification of well-replicated IBD associations, leading to an abundance of genomic regions with individually modest amounts of heritability. As whole-genome sequencing, polygenic scores, and machine learning progresses, it will be possible to identify rarer variants, gene interactions, and networks that contribute to the pathogenesis of IBD allowing for stratification of IBD patients into different therapeutic pathways and interventions.

Immunologic Regulation of Health and Inflammation in the Intestine

2

Anees Ahmed and Gregory F. Sonnenberg

Introduction

The major functions of the gastrointestinal (GI) tract is digestion and nutrient absorption. To conduct these functions, this organ system has an enormous surface area to facilitate absorption and is also colonized with trillions of normally beneficial microbes, termed the microbiota, which are important in aiding in digestion and other important functions [1, 2]. This poses unique challenges of how to protect this large barrier from infectious microbes, while simultaneously establishing tolerance to the microbiota and preventing detrimental responses to these non-harmful stimuli. The immune system plays a central role in coordinating these diverse responses and maintaining a state of health in the GI tract.

For that reason, the GI tract contains a substantial portion of the entire human immune system [3]. Complex and dynamic interactions occur in this organ system between immune cells that are of hematopoietic origin (such as macrophages, dendritic cells, B-cells, or T-cells), as well as numerous other non-immune and tissue-resident cell types (such as epithelial cells, stromal cells, or neuronal cells) that are integral to the immune response and will be discussed in this chapter. It is also a niche for trillions of microbes ($\sim 10^{12}$ viable bacteria per gram of colonic content), consisting of roughly 500–1000 microbial species that are collectively known as the gut microbiota [4]. The microbiota comprises bacteria, as well as bacteriophages, viruses, fungi, and occasionally protists, which form a complex ecosystem thought to have co-evolved with mammalian hosts over time [5]. The co-existence of microbiota and host immune system is mutually beneficial, but a careful balance must be maintained to establish a state of health or homeostasis. Intestinal homeostasis is mediated in part by physical separation of microbiota from the immune system through various biochemical and biophysical barriers, such as the epithelial layer, mucus, and the production of antimicrobial factors by different cell types [6–8]. A breakdown in these protective barriers results in chronic activation of the immune system by intestinal microbiota and is a hallmark of IBD as well as various bacterial infections and cancer [9–11].

Despite this physical separation in the healthy intestine, there is a complex, dynamic, and bidirectional crosstalk between the microbiota and immune system, which is essential for normal development of the immune response, intestinal physiology, and regulation of intestinal health [12–15]. The impact of the microbiota in shaping the proper development of the immune system can be studied in the context of germ-free mice. Germ-free animals are born and raised in a completely sterile environment that is free from live microbial stimuli. Mice in these settings exhibit impaired development of the mucosal immune system and gut-associated lymphoid tissues [16]. In addition to altered cytokine secretion and numerous defects in antibody production, germ-free mice have relatively fewer and smaller lymphoid tissues, including Peyer's patches (PPs) and mesenteric lymph nodes (MLNs) as compared to specific pathogen-free (SPF) mice that are typically utilized in the laboratory. Germ-free mice also have reduced total numbers of peripheral $CD4^+$ T-cells, including both T helper (Th)17 [17] cells and regulatory T (Treg) cells [18, 19], two cellular subsets discussed below that critically impact intestinal health and inflammation. These developmental defects can be partially reversed following the introduction of live gut bacteria, demonstrating the existence of a dynamic relationship between mucosal immunity and the microbiota. Conversely, the intestinal immune system also actively shapes the composition and anatomically restricts microbiota through various mechanisms [20]. For example, the mammalian immune system

recognizes and responds to the members of the intestinal microbiota by promoting protective immune responses that reinforce barrier integrity, prime protective immunity to invading pathogens, and prevent over-reaction to beneficial microbes or food antigens, thus establishing a state of tolerance [21, 22]. Defects in these responses or microbial composition (termed dysbiosis) can rewire immune cell populations and their functionality, resulting in chronic inflammation or increased risk of infection.

IBD is a multifactorial disease caused by dysregulated immune responses to microbiota resulting in chronic intestinal inflammation [9, 11, 12, 23, 24]. This disease also impacts a growing number of children worldwide, and in addition, can manifest in a unique form of the disease in children younger than 5 years of age. The latter is termed very early onset IBD (VEO-IBD), which is phenotypically and genetically distinct from traditional-onset IBD [25]. The risk for developing VEO-IBD is strongly correlated with host genetics, displays aggressive progression with increased disease severity, and unfortunately these patients are often associated with poor responsiveness to conventional therapies [26, 27]. Studies with these patients, as well as numerous mouse models, have defined specific components of the immune system that are essential to establish and maintain a state of health in the GI tract. Here, we focus on these specific immune pathways that are essential to regulate intestinal health and homeostasis, as well as examine how these findings have shaped our understanding of host–microbiota interactions and created a foundation to develop future therapeutic strategies for treating chronic inflammatory diseases. Further, we discuss several unique features of the mucosal immune response in children that will be important in our understanding of IBD.

The Anatomy of the Intestinal Immune System

The intestine should not be perceived as a single homogeneous organ but rather as a combination of several anatomically distinct and functionally specialized compartments with different environmental pressures [28, 29]. Each compartment is divided into four major layers: the innermost mucosa, the submucosa, the muscularis, and the serosa. The mucosa is the most proximal part to the lumen of the intestine or outside environment and is composed of a single layer of columnar epithelial cells along with an underlying lamina propria (LP) region which contains the vast majority of intestinal immune cells. Immune cells within the intestine are primarily located within the organized lymphoid structures known as gut-associated lymphoid tissues (GALTs). GALTs collectively include the MLNs, PPs in the small intestine, colonic patches, caecal patches, and comparatively smaller structures which include cryptopatches (CPs) and isolated lymphoid follicles (ILFs). To maintain local tissue homeostasis, different intestinal segments (such as the small intestine that includes the duodenum, jejunum and ileum; and the large intestine that includes the cecum and colon) have developed physical barriers and unique defense strategies of appropriately responding to the complex variety of foreign substances in the GI tract, including the commensal microbiota, potential pathogens, and dietary antigens, while simultaneously facilitating the major functions of the GI tract that are necessary at each segment.

The Intestinal Epithelium: Structure and Functional Subsets

The intestinal epithelium is a large single layer of columnar cells that differs enormously in architectural structure and cellular composition between the small and large intestine (Fig. 2.1). In the small intestine, the epithelium protrudes into the lumen with brush border-like structures called villi, which increases the mucosal surface area for nutrient absorption. Villi are absent in the colon, limiting the potential damage that can be caused by transition of semi-solid stool through the large intestine. This may have important consequences in the context of IBD, where different forms of the disease impact distinct anatomical locations, such as Crohn disease (CD) that impacts the entire GI tract, while ulcerative colitis (UC) primarily impacts the large intestine. The epithelium layer itself has many invaginations termed “crypts of Lieberkühn” that contain specialized types of intestinal epithelial cells (IECs) [30]. The intestinal stem cells at the base of the crypts give rise to transient proliferative epithelial cells [31]. Under homeostatic conditions, these intestinal crypts undergo constant cycles of IEC replenishment and renewal every 4–5 days [32]. Various differentiated cell types are present in the epithelium, and each is attributed to specialized and unique functions. The number and distribution of these cell types differ markedly between the small and large intestine. These cell types are as follows: (a) Enterocytes, the most prominent cells specialized for water and nutrient absorption [33]. (b) Goblet cells, the most dominant secretory cells responsible for mucin secretion [34]. (c) Enteroendocrine cells, responsible for secreting different hormones [35]. (d) Paneth cells that release antimicrobial peptides to protect nearby cells [36, 37]. (e) M cells, that are integral to the luminal antigen uptake and presentation to the immune system [38, 39]. Finally, the different intestinal enteroendocrine cells are responsible for the production of hormones in the gut such as 5-HT/serotonin by enterochromaffin cells, somatostatin by D cells, and gastrin by G cells [35]. Enterocytes, the absorptive epithelial cells, have microvilli at their apical surface to enhance digestion and nutrient

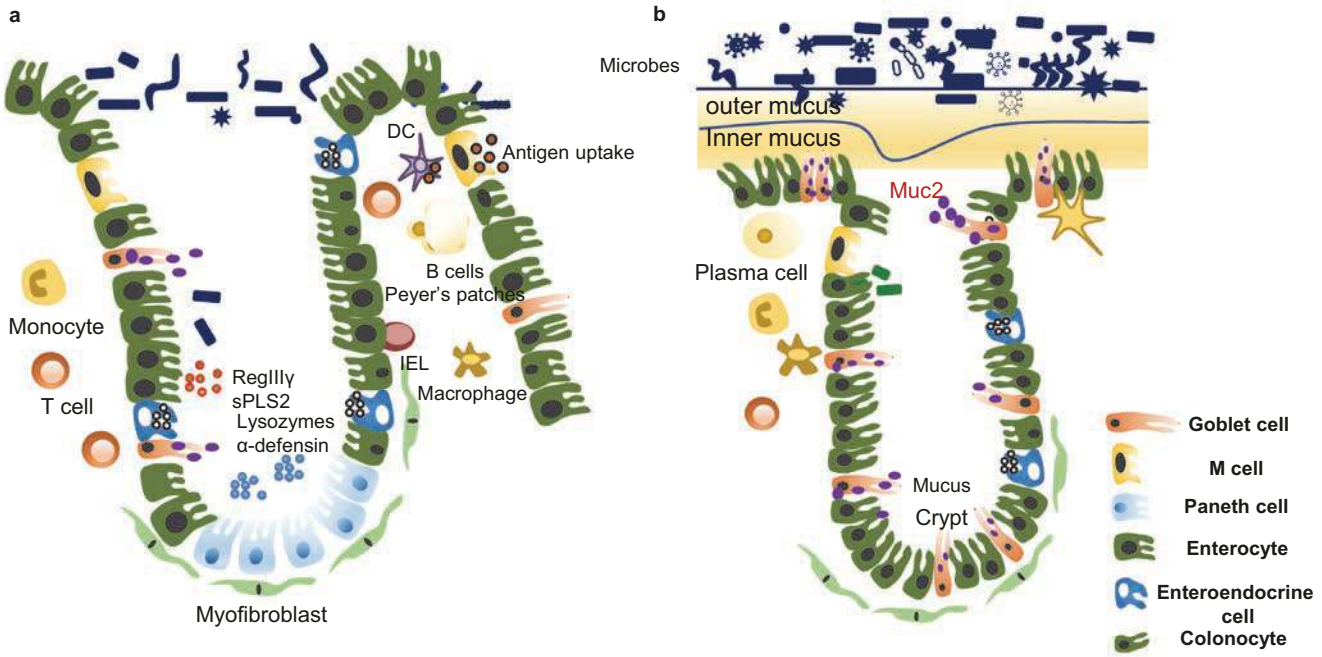

Fig. 2.1 Anatomy of the small and large intestinal mucosa. The small intestine (**a**) and large intestine (**b**) exhibit distinct anatomical features that have important consequences on host-microbiota interactions. These include structural differences, changes in abundance of epithelial cell types, and distinct mucus layers that control the physical separation of microbiota. The small intestine contains fewer microbes but is more permeable, while the large intestine is microbial-dense and has more physical separation between the microbiota and intestinal tissues

absorption. Mono-, di-, and tri-saccharides, amino acids-, fat- and water-soluble vitamins (A, D, E, K, B, and C) are primarily absorbed in the duodenum and jejunum, whereas vitamin B12 and bile salts are absorbed in the ileum of the small intestine. Mucus-producing goblet cells make up around 10% and 25% of epithelial cells in the small and large intestines, respectively [40]. As a result of that, the mucous layer (glycocalyx) is diffused and permeable to bacteria in the small intestine, whereas it forms a thick bilayered structure in the colon, creating a more robust barrier to the microbiota [41].

Epithelial Cell Function: Interlinked Connection with Microbiome and Dysfunction in IBD

Located in between the luminal microbiota and the underlying immune cells, the intestinal epithelium plays a pivotal role in detecting and differentiating beneficial microbiota from external pathologic microbial insult during infection. IECs express innate receptors, including the Toll-like receptors (TLRs) and Nod-like receptors (NLRs), including TLR2, TLR3, TLR4, TLR5, and TLR9 with different anatomical distributions and developmental expression patterns [42, 43]. A majority of these receptors are present at the basolateral membrane, while TLR2 and TLR9 are also expressed at the apical surface [44–46]. TLR activation by cognate ligands initiate a signaling cascade that drives nuclear translocation of nuclear factor kappa B (NF-kB) and expression and secretion of various cytokines and chemokines, including tumor necrosis factor (TNF), interleukin- (IL-)6, IL-8, IL-18, the chemokine CCL20, antimicrobial peptides including RegIIIβ, RegIIIγ, and α-defensins which signal and prime nearby immune cells [47–49].

Studies in germ-free mice has made it clear that microbes play an essential role in shaping normal intestinal architecture and function. The intestinal mucosa of germ-free mice is thin with reduced IEC proliferation and has compromised production of protective IEC-derived mediators including mucins and antimicrobial peptides [50, 51]. In 2004, groundbreaking studies showed that in the absence of innate recognition receptors that sense the microbiota (including TLR2, TLR4, or the signaling adaptor MyD88), mice become highly susceptible to the direct toxic effects of the colitogenic chemical agent dextran sodium sulfate (DSS), which could be attributed in part to reduced IEC proliferation and repair [52]. Additionally, IECs express all of the molecular machinery required to process and present luminal antigens to intraepithelial lymphocytes via either major histocompatibility complex (MHC) class I or class II. It is widely accepted that the host intestinal commensal microbiota

works in concert with IECs to maintain tissue homeostasis. For example, butyrate, produced by Clostridia species of the microbiota, is transported through the apical membrane of IECs by short-chain fatty acid transporters (SMCT1 and MCT1), and is subsequently metabolized through beta-oxidation and the tricarboxylic acid pathway [53]. This results in a positive feedback loop by which IECs limit the oxygen availability and thus favor butyrate-producing obligate anaerobes over facultative anaerobes such as *Escherichia coli*, a hallmark microbe of intestinal dysbiosis and tissue inflammation [54]. Mechanistically, the activation of the nuclear sensor, peroxisome proliferator-activated receptor (PPAR-γ), during β-oxidation mediates nuclear export of the NF-kB subunit RelA thereby limiting pro-inflammatory responses to non-commensal bacterial infection [55]. Butyrate is also known to increase the peripheral differentiation of Treg cells [19, 56]. Naïve $CD4^+$ T-cells treated with butyrate had increased histone H3 acetylation of the critical transcription factor FoxP3 at its promoter and intrinsic enhancers CNS1 and CNS3 DNA sequence [57]. Overall, microbiota-derived butyrate critically regulates pro- and anti-inflammatory responses in the intestine. During antibiotic treatment or IBD, this communication between host and microbiota is perturbed, which substantially impacts gut homeostasis [58, 59]. Together, these observations paint a picture of a dynamic and functional epithelium that is essential for maintaining barrier integrity, promoting tolerance, and providing active defense against pathogenic organisms.

Several lines of evidence suggest that the normal functions of the intestinal epithelium are disrupted during chronic intestinal inflammation such as IBD. Firstly, some of the IBD-susceptibility genetic loci have been linked to various aspects of epithelial function including hepatocyte nuclear factor 4α *(HNF4α)* and E-cadherin [60], which regulates epithelial tight junction formation; meprin 1A (*MEP1A*) [61], a brush border enzyme; and NOD2 (*CARD15*) which recognizes bacterial muramyl dipeptide [62, 63]. There are additional lines of evidence suggesting that patients with IBD have compromised epithelial barrier integrity, including reduced goblet cell numbers and mucus secretion as compared to healthy individuals. Abnormal intestinal permeability has been established among patients with CD, which can promote excessive antigen uptake, continuous immune stimulation, and eventually chronic mucosal inflammation [64]. Finally, epithelial cell death, particularly loss of Paneth cells, contributes to intestinal inflammation in mice and is associated with CD in humans [65–67]. Interestingly, increased cell shedding with gap formation and local barrier dysfunction is observed in intestinal biopsies of patients with IBD, and this dysfunction is predictive of disease relapse. In addition to the genetic factors discussed above, environmental insults may predispose to impaired intestinal barrier function in IBD. The view that IECs are a dynamic cell types that are central to the maintenance of intestinal homeostasis is consistent with IEC dysfunction contributing to IBD pathogenesis.

Gut-Associated Lymphoid Tissues

Immune cells within the GI tract are primarily located within organized lymphoid structures known as GALTs that can be found diffusely localized within the LP, the sub-mucosa, or throughout the epithelium. GALTs, together with intestinal draining MLNs, serve as the primary sites for the priming and initiation of adaptive immune responses, and collectively include the PPs in the small intestine, colonic patches, caecal patches, and comparatively smaller structures which include CPs and ILFs. Each of these sites plays an important role in recognizing luminal antigens and facilitating innate and adaptive immune responses. Conversely, effector immune cells are also diffusely present throughout the lamina propria and upper epithelium.

The GALT constitutes subepithelial lymphoid structures in the mucosa and submucosa with signature overlying follicle-associated epithelial cells. These are primarily microfold cells (M cells), specialized for the luminal antigens uptake and subsequent delivery to underlying dendritic cells (DCs) for presentation to adaptive immune cells [68, 69]. M cells also serve as a major entry site for multiple intestinal pathogens [70]. Macroscopically visible PPs located in the small intestine are the most well-characterized GALT tissue. The size and density of PPs vary along the intestine, increasing from the jejunum to the ileum. They are highly concentrated in the distal ileum and are fewer in the duodenum. PPs contain numerous B-cell lymphoid follicles (~10 in mice and ~100 hundred in humans), surrounded by smaller T-cell-rich areas [71]. In contrast to MLNs, PPs have constitutively active germinal centers indicative of continuous immune surveillance and stimulation by luminal antigen. Comparable to PPs in small intestine, the large intestine has cecal patches at the appendix and colonic patches throughout the colon serving as important sites for T-cell priming and immunoglobulin A (IgA) production [72, 73]. The development of PPs and colonic patches is initiated during the early embryonic life and is completed shortly after the birth. The GALT also includes microscopically visible small lymphoid structures including small cryptopatches that mature to ILFs and are collectively known as solitary isolated lymphoid tissues (SILTs). In contrast to PPs, ILFs primarily contain B-cells with no distinct T-cell zone. ILFs serves as important sites for T-cell-independent IgA class-switched antibody response due to the activity of the cytokines BAFF (B-cell-activating factor) and APRIL (a proliferation-inducing ligand) [74]. Mice and humans are estimated to have 1000–1500 and 30,000 SILTs, respectively [75, 76]. In mice, most

of the cryptopatches are developed within the first 2 weeks of postnatal life [77, 78]. DCs within the small intestinal SILTs express CXC-chemokine ligand 13 (CXCL13) which acts on B-cells through CXC-chemokine receptor 5 (CXCR5) to maintain cellular localization in SILTs [79, 80]. Also, mice deficient in RANK ligand (RANKL; also known as TNFSF11) have fewer small intestinal SILTs with very few B-cells [81]. Finally, the microbiota plays a major and dynamic role in the presence and maturation of SILTs, as studied in germ-free mice and discussed above.

Compartmentalized Gut Lymph Node Drainage

MLNs are the largest lymph nodes in the body and develop independently from the other GALT structures. The lymphatic drainage in the intestine is essential for appropriate immune cell trafficking and the development of adaptive immunity to luminal perturbation. Lymphocytes circulate to the MLNs as a result of expression of both L-selectin and $\alpha_4\beta_7$ integrin. L-selectin mediates lymphocyte migration into peripheral tissues, whereas $\alpha_4\beta_7$ mediates migration of lymphocytes into the intestinal mucosa. Separate segments of MLNs are attributed to drain the different sections of intestines [82, 83]. Seminal studies experimentally demonstrated that duodenum primarily drains to a small lymph node embedded in the pancreatic tissue; jejunum drains to the middle section of the MLNs, whereas the distal ileum, ascending colon and caecum drain to the distal segments of the MLNs [82]. Similar regional differences in lymph drainage are also observed in humans, and these differences in compartments have substantial consequences for how the immune response may react. For example, it has been shown that an identical luminal antigen in mice will give rise to distinct tolerogenic or inflammatory immune responses depending on delivery to distinct compartments of the MLN. Those delivered to the proximal small intestine-draining LNs give rise to tolerogenic responses, whereas delivery to distal LNs are more likely to elicit pro-inflammatory T-cell responses [84].

Innate Immune Cell-Dependent Regulation of Intestinal Health

The innate immune response comprises our first line of defense against the invading pathogens. Relative to the adaptive immune response discussed below, innate immune responses are generally rapid, non-specific, and lack long-lasting immunological memory. Innate immune cells, such as macrophages and DCs, have a unique ability to sense and respond to the intestinal microbiota and external pathogenic insults through the recognition of conserved structural motifs known as pathogen-associated molecular patterns (PAMPs) by pattern-recognition receptors (PRRs). These receptors include the membrane-bound TLRs and intracellular NLRs. This recognition allows the generation of effective inflammatory responses against microbial invasion. Furthermore, antigen presentation by professional antigen-presenting cells (APCs) such as DCs and other mono-nuclear phagocytes mediates T-cell activation and induction of adaptive immune responses. Neutrophils (or polymorphonuclear leukocytes) are the most common granulocytes in our circulation. They are highly capable of phagocytosing and killing invading microbes and play a major role in protecting the intestine, while also having the ability to be a major driver of intestinal inflammation.

Dendritic Cells

DCs are the most efficient APC of the immune system. DCs express a wide array of surface TLRs and intracellular NLRs that can detect environmental stimuli and modulate antigen-specific adaptive immune responses [85]. DCs in the gut samples luminal antigen through extended dendrites [69], encounter antigen via M cells [86], or through goblet cell-associated antigen passages [87]. Upon antigenic stimulation, activated DCs migrate toward the T-cell areas in lymphoid structures and present MHC-peptide complexes and co-stimulatory signals to naïve T-cells. DCs also dictate the effector T-cell function and polarization through secreting immunomodulatory cytokines or chemokines. In homeostatic conditions, intestinal DCs express low levels of co-stimulatory molecules and promote the induction of Tregs. In contrast, during pathogen encounter, DCs secrete inflammatory cytokines and promote effector T-cell polarization (Th1, Th2, and Th17 cells, discussed below) [88]. $CD103^+$ $Sirp\alpha^+$ DCs in humans and $CD103^+$ $CD11b^+$ DCs in mice play a prominent role in inducing Treg differentiation [89, 90]. Human studies have also indicated that $CD103^+$ DC subsets play a significant role in Th17 cell differentiation, while $CD103^-$ $Sirp\alpha^+$ DCs promote Th1 cell responses [91]. Gut-tropic migratory DC precursors through retinoic acid-dependent upregulation of α4β7 integrins and CCR9 induce their homing back into the intestine after priming in the MLN [92].

Abnormal DC functions have been attributed to the pathogenesis of several diseases including IBD [93]. Based on a series of studies in different clinical settings and experimental models, a novel paradigm has been proposed for DC functions. Depending upon the stage of inflammation DCs can promote regulatory or inflammatory responses. During the early inflammatory state, intestinal DCs play a protective role as their depletion in the intestinal mucosa leads to exac-

erbation of DSS-induced colitis, partly caused by the increased neutrophil influx [94]. In chronic immune dysregulation due to the absence of TGF-β signaling, DCs fail to gain a regulatory phenotype and promote inflammatory T-cell responses [95]. During IBD in humans, intestinal DCs can drive pathogenic phenotypes. DCs have higher expression of TLR2, TLR4 and the activation marker CD40 in patients with CD or UC relative to healthy individuals [96]. Furthermore, colonic DCs from IBD patients have higher expression of inflammatory cytokines such as IL-12 and IL-6 at steady state, suggesting DCs from patients with IBD exhibit a hyperactive phenotype [96]. Together, these observations highlight the importance of DCs in maintaining intestinal health and its contribution in IBD pathogenesis.

Macrophages

Macrophages are described as "the phagocytic cell of the immune system." Macrophages are fundamentally important for the phagocytosis of microbial pathogens, the degradation of apoptotic cells, and the production of inflammatory chemokines and cytokines [97]. However, macrophages also constantly surveil the residing tissue and actively participate in maintaining homeostasis [98, 99]. Due to these key functions, abnormal macrophage responses have been implicated in the pathophysiology of numerous human clinical conditions, including IBD [100]. It is estimated that an average human body contains approximately 200 billion macrophages throughout the body and they can be found in every tissue compartment. Macrophages can originate from their embryonic precursors or can be replenished from the bone marrow-derived monocytes at the site of infection during tissue inflammation [101]. Under the steady state, macrophages are primarily tissue resident and specialized to function specific tasks. Tissue-resident macrophages in the GI tract and GALT promote tolerance to commensal microbiota and food antigens. This unique ability is partly due to their relative hypo-responsiveness to TLR stimulation and reduced ability to prime adaptive immune responses (relative to DCs) [102]. It has been observed that during IBD, the number of macrophages is dramatically and significantly increased in the intestinal mucosa. These macrophages also exhibit enhanced expression for a large number of T-cell co-stimulatory molecules such as CD80 and CD86 [103]. It has been also observed that macrophages recruited during intestinal inflammation have upregulated expression for triggering receptor expressed on myeloid cells-1 (TREM-1) and further blocking TREM-1 leads to dampening in pro-inflammatory mediators such as TNF, IL-6, IL-8, IL-1 beta, and MCP-1 [104]. These results indicate that macrophages play a critical role both in intestinal health and in mediating the pathogenesis of IBD.

Granulocytes: Neutrophils, Eosinophils, Basophils, and Mast Cells

Granulocytes are a group of leukocytes that differentiate from myeloblasts in the bone marrow and are characterized by the presence of lobulated nucleus and granular cytoplasm. It includes mast cells, neutrophils, eosinophils, and basophils. Neutrophils (or polymorphonuclear leukocytes) are the most abundant form of all granulocytes and circulatory immune cells in humans [105]. PMNs are primarily phagocytes which actively engulf and degrade invading microbes, or dead cells in the body [106]. As a result, PMNs play an important role in early antimicrobial immunity. Unlike PMNs, eosinophils, basophils, and mast cells can mediate allergic inflammation. Both eosinophils and basophils are predominantly circulatory cells, whereas mast cells are primarily tissue-resident. Eosinophils and basophils along with mast cells are recruited at the site of inflammation and exert their effector functions through release of cytoplasmic granules containing enzymes, cytokines, chemokines, and growth factors [106]. There is a substantial body of evidence indicating that PMNs play an important role during the effector stages of IBD pathogenesis. In line with the importance of neutrophils in clearing invading microbes, mice lacking neutrophils have higher intestinal microbial burden during colitis [107]. Higher neutrophil infiltration is observed in inflamed colonic tissue in UC patients along with elevated fecal calprotectin (a neutrophilic inflammation marker) [108]. In an adoptive $CD4^+$ T-cell transfer mouse model of colitis, neutrophils are reported to have enhanced expression of major histocompatibility complex-II and CD86, which is indicative of immune activation [109]. Such neutrophils can induce $CD4^+$ T-cell activation in MHCII- and antigen-dependent manner. It has also been observed that inhibiting PMN recruitment at the sites of tissue inflammation, using CXCR2 antagonists or anti-CXCR2 monoclonal antibodies, is associated with reduced intestinal inflammation in animal models [110]. In contrast, additional evidence supports a role for neutrophil dysfunction in IBD pathogenesis. For example, evidence suggests that there is impaired neutrophilic infiltration and IL-8 production in CD patients [111]. Furthermore, treatment of CD patients with growth factor GM-CSF that mediates neutrophil development and function has been explored as a therapeutic approach and currently is under further investigation [112, 113].

Adaptive Immunity and Their Contribution to Intestinal Health and Inflammation

The lamina propria contains different populations of adaptive immune cells (particularly T-cells and B-cells) that interact and are regulated by numerous innate immune cell

populations including macrophages, DCs, granulocytes, and innate lymphoid cells (ILCs). Collectively, the intestinal epithelium and lamina propria account for the largest population of antibody-secreting plasma cells and T-cells in the body. However, the presence and distribution of different immune cell populations vary along the length of the intestine and this facilitates distinct functions.

T-cells

In the lamina propria, $CD4^+$ T-cells and $CD8^+$ T-cells are derived from conventional T-cells that undergo priming in secondary lymphoid organs and display an effector-memory phenotype. $CD4^+$ T-cells are highly diversified and instructed by the innate immune system to differentiate into distinct effector states including T-bet^+ Th1 cells that produce IFN-γ, RORγt $^+$ Th17 cells that produce IL-17 and IL-22, $GATA3^+$ Th2 cells that produce IL-4, IL-5, and IL-13, as well as FoxP3-expressing Treg cells that produce IL-10 and TGF-β (Fig. 2.2).

T-cells mediate a wide range of functions including cell-mediated killing of virus-infected cells, providing help in antibody class switching, differentiating into effector cell types to provide immunity against pathogens, and restraining inflammatory responses. Dysregulated adaptive immune response leading to breakdown of tolerance toward the commensal microbiota has been proposed as a major driver of IBD pathogenesis [114, 115]. For example, effector $CD4^+$ T-cells such as Th1, Th2, and Th17 cells provide defense against pathogens, but if left unchecked, can mediate distinct forms of intestinal inflammation [116]. On the other hand, regulatory states such as Tregs and T regulatory type 1 (Tr1) cells are critical for limiting the differentiation of effector $CD4^+$ T-cells and controlling inflammation. Therefore, a tight balance between effector and regulatory T-cells holds an important key for maintaining intestinal homeostasis. Homing of T lymphocytes from the lymph nodes is also dependent on $\alpha_4\beta_7$ integrin and their expression is regulated by all-trans retinoic acid synthesized by gut-associated DCs [117].

IBD can be a result of hyperactivation of effector T-cells and/or defects in the immunosuppressive function of Treg cells. IBD has been associated with altered T-cell responses including Th1 (IFN-γ), Tregs (IL-10), and more recently Th17 (IL-17A, IL-17F, IL-22 and GM-CSF) cells [114, 118]. In human IBD, Th17 and Th1 cells have been associated with CD pathogenesis, while UC can include an atypical Th2 cell response, as well as other mixed effector T-cell responses [119]. Microbiota drives the differentiation of RORγt expressing Th17 cells and in part through induction of the upstream cytokine IL-23 that supports Th17 cell responses and a population of IL-$17A^+$IFNγ^+ T-cells in the inflamed mucosa [120]. Th17 cells also combat bacterial infection by promoting the neutrophilic inflammatory response [114]. Therefore, Th17 cell effector responses can be both protective and pathogenic in the intestine [121, 122]. In this similar line, treatment with anti-IL-17A blocking antibody (secukinumab) worsened the symptoms of active CD in some patients, while it has provided therapeutic benefits in

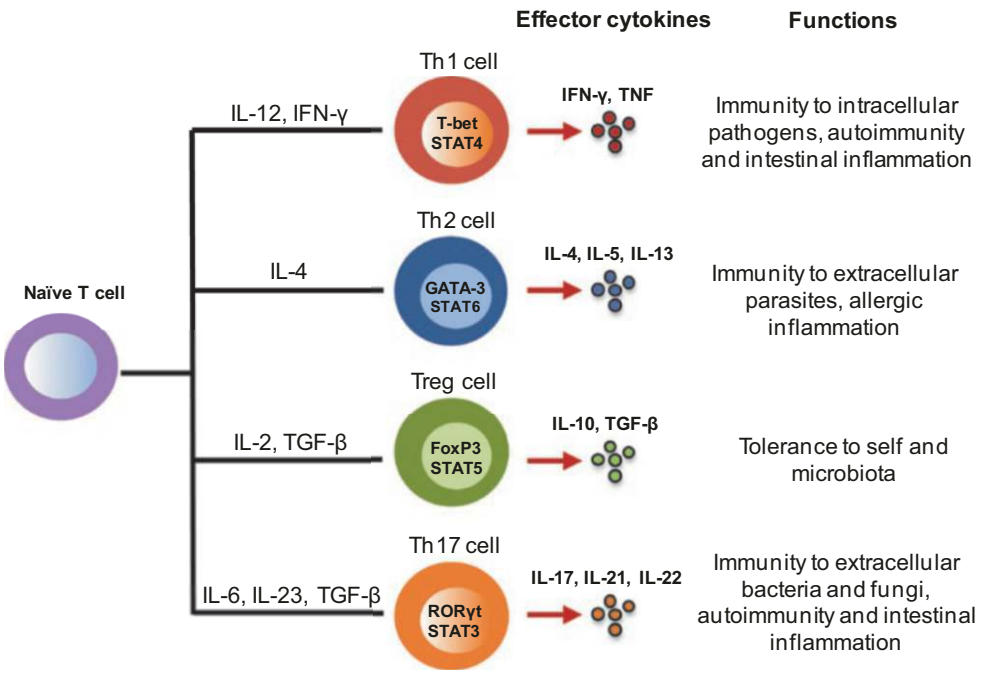

Fig. 2.2 Activation pathways, transcription factors, and effector cytokine profiles of the major T helper cell subsets. Activated $CD4^+$ T-cells differentiate into different lineages of T helper cells depending on the cytokine milieu of the microenvironment. For each lineage, a distinct transcription factor has been identified. Furthermore, each T helper subset produces a different set of effector cytokines, mediate distinct beneficial functions, or if dysregulated, can cause distinct types of diseases

other pathophysiological-related diseases [123]. Therefore, Th17 cells provide many beneficial and inflammatory functions in the intestine that must be tightly regulated.

Treg cells play an essential role in restraining effector T-cell responses and innate inflammatory mechanisms [9]. This restraining function is regulated in part by IL-10 and TGF-β produced by these cells, as well as through direct cellular contact that include pathways like CTLA-4 [124, 125]. Treg cells can adopt specialized fates and employ transcriptional or homing receptors that are utilized by effector T-cells, such as RORγt, to mediate their suppressive functions. In this context, Treg and Th17 cell differentiation are reciprocally regulated in the intestine. In an inflammatory milieu (such as by enhanced IL-6 and IL-23), Th17 cells expand at the expense of Treg cells and promote effector T-cell function [126]. There is also substantial evidence that Treg cells become fundamentally altered in the context of IBD. For example, T-cells from IBD patients have shown to be refractory to TGF-β [127]. Loss-of-function mutations in *FOXP3* (a key Treg cell transcription factor) is strongly correlated with intestinal inflammation [128]. Furthermore, Treg cells expand in the intestine of IBD patients, but exhibit a pro-inflammatory phenotype including expression of the inflammatory cytokine IL-17A [129, 130]. The pathways accounting for these phenotypic and functional changes in Tregs remain poorly understood and additional research in this area will be important for defining novel mechanisms coordinating intestinal tolerance.

B-cells

B-cells are an important constituent of mucosal immune responses in both healthy and diseased states. B-cells are primarily developed in the bone marrow but it can also originate via extramedullary hematopoiesis. During early embryonic development, pluripotent hematopoietic stem cells migrate to the fetal liver where mature B-cells develop and migrate to the intestine. Studies in experimental models of IBD have suggested that B-cells suppress mucosal inflammation either by secreting cytokines, antibodies or by directly dampening effector T-cell functions [131, 132]. During inflammation, an inducible regulatory B-cell subset (Breg cells) develops in GALT which restrains T-cell expansion through the production of IL-10 [133]. Antibody-mediated immunity is the most important arm of the mucosal immune system in mediating microbial exclusion and tolerance. However, the relationship between secretory antibodies and microbiota is not unidirectional. Studies from germ-free mice have shown that IgA production is acutely dependent on the presence of intestinal microbes [134]. This humoral defense mechanism also relies on cooperative interaction between secretory epithelial cells and local plasma B-cells. Plasma cells in the intestine primarily secrete dimers and larger polymers of IgA (pIgA) [135]. This induction of mucosal IgA responses can occur either in a T-cell-dependent or T-cell-independent manner (via the cytokines BAFF and APRIL) and these antibodies can bind through their J chains to the epithelial secretory component (pIg receptor) to get transported into the intestinal lumen [136]. This transmembrane glycoprotein receptor (pIgR) also mediates the translocation of pentameric IgM antibodies. Secretory antibodies mediate immune exclusion during microbial colonization and restrict mucosal recognition of soluble antigens. During IBD, local production of pIgA is significantly downregulated and has strikingly decreased J chain expression [137]. Individuals with IgA deficiency may have an increased risk of developing IBD [138]. However, the total deficit in pIgA level can be compensated by increased populations of plasma B-cells secreting other types of antibodies in IBD lesions (such as IgG and IgA1) [139].

During IBD, activation of mucosal APCs and a dramatic increase of IgG-producing B-cells may result in altered immunological homeostasis and can jeopardize the mucosal integrity. Luminal cytotoxic complement (C3b) deposition and complement activation are observed in relation to epithelium-bound IgG1 in UC [140]. This C3b deposition can be a sign of persistent immune activation. The early events that trigger B-cell driven immunopathology in IBD remains unknown. However, abrogation of oral tolerance to commensal microbial antigens has been presumed as an early mechanism, and GALT neogenesis and hyperplasia in the inflamed lesions enhance aberrant microbial stimulation of the local B-cell population. Under homeostasis, the production of IgA is primarily restricted to the mucosal surfaces and does not occur at systemic secondary lymphoid structures. However, breakdown of this normal compartmentalization can result inappropriate B-cell responses contributing to intestinal inflammation [141]. Indeed, systemic humoral responses to bacterial membrane and flagellar proteins have been detected in children with IBD [142].

Essential Immunologic Pathways that Regulate Intestinal Health

A balanced communication between populations of immune cells is necessary to maintain intestinal health, and impairment of the immune response or altered T-cell populations can directly promote intestinal inflammation. In 1993, seminal studies unequivocally established three pathways that are essential to regulate this balance and mediate intestinal health. These include the cytokines IL-2 and IL-10, as well as MHC class II and subunits of the T-cell receptor (TCR), which coordinate how T-cells receive signals from other immune and non-immune cell types [143–145]. Loss of any

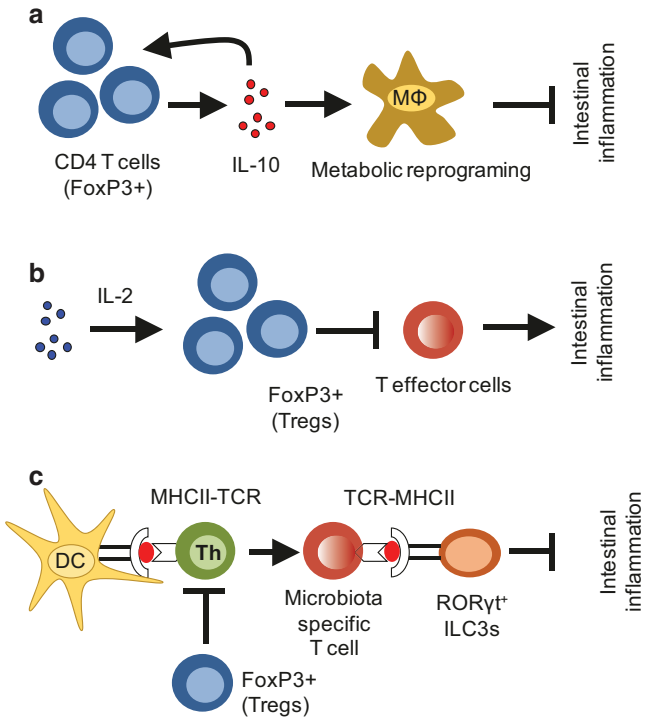

Fig. 2.3 Essential immunologic pathways that regulate intestinal health. Preclinical models and translational studies have revealed a number of immune pathways that are necessary to maintain a state of healthy in the mammalian intestine. (**a**) FoxP3⁺ T-cells (Treg cell) are the major cellular source of IL-10 in the mammalian intestine. Treg cell-derived IL-10 is essential to promote intestinal health by imprint tolerogenic phenotype in macrophages other T-cells. (**b**) Under homeostasis, IL-2 produced by activated CD4⁺ T-cells, DCs, and other unknown cells and it is essential for IL-2 to bind to the IL-2R on Treg cells, which subsequently limit T effector cell responses to coordinate intestinal health. (**c**) MHC class II on conventional DCs activate naïve CD4⁺ T-cells by presenting commensal bacterial antigens in MLNs. This supports the generation of Tregs cells. Further, MHCII⁺ ILC3s limit microbiota-specific T effector cells via apoptosis, a process termed intestinal selection

one of these pathways in mice is sufficient to results in spontaneous and chronic intestinal inflammation, and substantial investigation since this discovery has delineated the cellular and molecular mechanisms by which these pathways coordinate intestinal health (Fig. 2.3).

Previously, IL-10 was perceived as a critical immunoinhibitory cytokine that restricts effector function of Th1 cells, Th17 cells, NK cells, and macrophages [146]. In humans, polymorphisms in IL-10 and IL-10R are strongly correlated with IBD disease pathogenesis. Kühn et al. developed a genetically engineered model by targeted mutation in the IL-10 gene disrupting its function, which continues to be widely used to dissect IBD etiology in preclinical models [143]. IL-10 knockout mice develop spontaneous colitis after weaning and have impaired gut mucosal barrier function characterized by discontinuous and transmural inflammatory lesions and display extensive mucosal hyperplasia accompanied by increased immune cell infiltration [143]. Colitis in IL-10- and IL-10 receptor (IL-10R)-deficient mice is primarily driven by increased CD4⁺ T-cell Th1 responses and IFN-γ production. IL-10 is also known to directly inhibit IL-12 production from the myeloid cells and therefore restricts Th1 cell differentiation [147, 148]. In addition to IL-12, IL-10 suppresses IL-23 production from mononuclear phagocytes through transcriptional inhibition of the shared IL-12 p40 subunit, which is critical for driving pathologic Th17 cell responses during mucosal inflammation [148]. Critically, intestinal inflammation in IL-10-deficient mice can be completely prevented by treatment with antibiotics or deriving the mice in germ-free conditions, highlighting that a major function of this pathway is to promote immunologic tolerance to the microbiota.

Despite these advances, the exact cellular source and molecular pathways by which IL-10 maintains intestinal health remained unclear from these initial studies. Several hematopoietic cells such as T-cells, B-cells, macrophages, and DCs, as well as several non-hematopoietic cells are all capable of producing IL-10 in the mammalian intestine. The use of selective genetic models to specifically delete the IL-10 gene revealed that CD4⁺ T-cells are a crucial non-redundant source of IL-10, and many of the phenotypes in IL-10-deficient mice could be recapitulated in mice having a selective lineage-specific deletion of IL-10 only in Foxp3⁺ Treg cells [149]. In addition, expression of IL-10R and signal transducers and activators of transcription 3 (STAT3) are critical in Foxp3⁺ Treg cells to limit Th17 cell response [150, 151]. Ablation of the IL-10R or STAT3 in Treg cells resulted in selective dysregulation of Th17 cell responses and colitis. Treg cell-derived IL-10 also drives macrophages toward a tolerogenic phenotype through metabolic reprogramming to maintain mucosal homeostasis [152]. This is critically important to maintain intestinal health, as selective deletion of IL-10R on myeloid cells revealed this population as a critical target of IL-10. During inflammation, IL-10 suppresses mammalian target of rapamycin (mTOR) activity in myeloid cells through the induction of its inhibitor, DDIT4 (DNA damage–inducible transcript 4 protein) and preventing glucose uptake while promoting oxidative phosphorylation of essential signaling molecules [152]. In IL-10-deficient mice, dysfunctional mitochondria get accumulated in the macrophages, resulting in production of IL-1β through overactivation of the NLRP3 inflammasome [152]. Consistent with this, inhibiting caspase-1 activity or deficiency could partially protect IL-10-deficient mice from developing spontaneous intestinal inflammation.

IL-2 was discovered more than 30 years ago and studies with IL-2 or IL-2 receptor (IL-2Rα) deficient mice have highlighted the crucial role of IL-2 in maintaining Treg cell homeostasis and peripheral immune tolerance. Under steady-state conditions, IL-2 is mainly produced by activated CD4⁺

T-cells in secondary lymphoid organs and gets consumed by cells expressing the high-affinity IL-2R subunit CD25 (also known as IL-2Rα), which is robustly expressed by Treg cells. IL-2-deficient mice develop spontaneous colitis with striking clinical and histological similarity to IBD in humans [145]. Colitis in IL-2-deficient mice is also associated with higher infiltration of activated T- and B-cells, elevated immunoglobulin secretion, and aberrant expression of MHC class II molecules [153]. Similar findings were also observed with mice lacking IL-2Rα and IL-2Rβ. IL-2-deficient mice crossed with Rag2-deficient mice or raised in germ-free conditions were disease free, demonstrating an essential requirement of adaptive immune cells and the microbiota in disease progression [153, 154]. The importance of IL-2 in regulating $CD4^+$ T-cells was later refined with the identification of additional heterogeneity in this T-cell subset. It is now well appreciated that IL-2 promotes Th1, Th2, and Treg cells, while inhibiting Th17 cells function [155]. IL-2 plays a crucial role in the maintenance of $Foxp3^+$ Treg cells [126, 156]. Treg cells subsequently suppress $CD8^+$ T-cell and other $CD4^+$ effector T-cell responses via IL-2 sequestration. IL-2-, IL-2Rα-, and IL-2Rβ-deficient mice have a significantly low proportion of Tregs with impaired suppressive function [156]. Consistent with this, lineage-specific deletion of the IL-2R on only $Foxp3^+$ Treg cells was sufficient to result in spontaneous intestinal inflammation with enhanced activation and proliferation of $CD8^+$ T-cells [157]. The relevant cellular sources of IL-2 are yet to be fully defined, but expression has been observed in various immune cells such as T-cells, DCs, NK cells, and ILCs. Recently, ILC3s are shown to be the dominant source of IL-2 uniquely in the small intestine and ILC3-intrinsic IL-2 expression is essential to promote intestinal Tregs differentiation and function selectively in this anatomical compartment [158].

Beyond IL-10 and IL-2, chronic intestinal inflammation was also observed in mice lacking different components of the TCR, such as TCRα-deficient, TCRβ-deficient, TCRβ- and TCRδ-double deficient, as well as MHC class II-deficient mice [144]. The intestinal disease in these mice exhibits similarities to ulcerative colitis in humans. However, athymic or mice lacking T-cell and B-cells (*Rag1*$^{-/-}$) mice did not exhibit disease onset, suggesting that dysfunction of αβ T-cells, especially MHC class II-restricted $CD4^+$ T-cells contributes to the pathogenesis of intestinal inflammation in these models [144]. A recent study found that lineage-specific deletion of MHC class II on DCs and not on epithelial cells is sufficient for development of robust intestinal inflammation, but mice used in this study also target ILC3s. [159, 160]. Collectively, these seminal findings highlight the importance of different immunoregulatory molecules, cytokines, T-cell subsets, and innate immune populations in maintaining intestinal immunity and health.

A common theme among these findings is that a fine tuning of communication between the innate immune system, adaptive immune system, and intestinal microbiota is essential to coordinate intestinal health. Disruption of these pathways can manifest in overactivation of the immune response and spontaneous intestinal inflammation. These studies have critically informed our understanding of IBD, as it is now known that there are patients with loss-of-function mutations in many similar pathways (including IL-10, IL-10R, IL-2, and IL-2R) that also manifest in VEO-IBD [161, 162]. Furthermore, the appreciation that this can be an entirely hematopoietic phenotype (such as in the case of IL-10 or IL-10R) has allowed the development of hematopoietic stem cell transplantation as one viable therapeutic approach to stop intestinal inflammation in VEO-IBD patients with specific mutations [163]. A more advanced understanding and refinement of these pathways, as well as other novel pathways by which the immune system orchestrates intestinal health, will likely yield novel preventative, therapeutic, and curative treatment strategies to IBD.

Innate Lymphoid Cell-Dependent Regulation of Intestinal Health

ILCs are recently appreciated cell types of the innate immune system in mice and humans. They were first identified at barrier surfaces by their ability to secrete IL-22 and drive antimicrobial responses in the gut, but it is now well accepted that ILCs populate almost every tissue and are critical regulators of immunity, inflammation, and homeostasis [164–166]. ILCs are predominantly tissue-resident and highly enriched in mucosal barrier tissues. Therefore, they are well poised to be the first immune cells to react to colonizing microbiota or invading pathogens by the induction of inflammatory responses to infection, orchestrating the ensuing adaptive immune response and the resolution of inflammation after infection [165]. Critically, ILCs also play a major role in lymphoid organogenesis and maintenance of barrier integrity [20, 167].

Despite the resemblance to T-cells, ILCs lack somatically recombined antigen-specific receptors and are innate counterparts to different T-cell subsets [168]. They are also predominantly tissue resident and colonize tissues, such as the GI tract, early during developmental life [169]. ILCs are subdivided into three subgroups on the basis of their transcription factor expression and cytokine secretion profile: group 1 ILCs (ILC1s) express T-bet, are responsive to IL-12, and produce IFN-γ in response to intracellular pathogens; group 2 ILCs (ILC2s) express GATA-3, are responsive to IL-33, IL-25, and TSLP and secrete IL-5, IL-13, and amphiregulin in response to helminth infection; while ILC3s express RORγt, are responsive to IL-23, TL1A, IL-1α, and IL-1β and produce IL-17 and IL-22 in response to extracellular bacteria or fungi [168]. ILC3s are the most heterogeneous ILC popu-

lation in mice and humans, and encompass a subset of CCR6$^+$ lymphoid tissue-inducer (LTi)-like cells and a subset of T-bet$^+$ ILC3s that express the natural cytotoxicity receptors NKp46 or NKp44. Further, ILC3s have been the most closely studied in context to human IBD since they play a major role in intestinal homeostasis, repair, and immunity in various animal models of acute injury, and also their numbers are reduced in intestinal biopsies of IBD patients relative to healthy controls [170, 171]. The latter may be the result of substantial plasticity among these ILC subsets in which under inflammatory conditions, ILC3s can transition to an ILC1 or ex-ILC3 phenotype [171].

ILC3s regulate intestinal homeostasis, innate immunity and tissue inflammation through several distinct pathways, that occur at distinct developmental timepoints. During embryogenesis, a subset of CCR6$^+$ ILC3s known as LTi cells are considered as the initiators of lymphoid organ formation. RORγt-deficient mutant mice lacking LTi cells fail to develop lymph nodes, PPs or CPs [167]. RORγt$^+$ LTi cells secrete lymphotoxin (LT)-$\alpha_1\beta_2$ which engages LTβR on mesenchymal cells and bring about release of the chemokines CXCL13, CCL19, and CCL21. These chemokines recruit adaptive immune cells and enhance expression of the adhesion molecules VCAM-1, MadCAM-1, and ICAM-1, resulting in proper development of lymphoid tissues [167]. Indeed, ILC3s can represent up to 30% of the total hematopoietic cells within the developing human intestine [169]. This sets the stage for these cells to coordinate multiple developmental pathways and control the early immune response to colonizing microbiota. However, there is evidence that ILC3s are then replaced by other adaptive immune cells and greatly reduced in numbers over time, with even greater depletions occurring during intestinal infection or inflammation as noted above.

After birth, ILC3s maintain a bidirectional communication with the microbiota. For example, the proper development, activation, and effector functions of ILC3s are dependent on the signals derived from microbiota. ILC3s then produce IL-17, IL-22, IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF) in response to IL-23 and IL-1β secreted by myeloid cells after recognition of microbial PAMPs or microbial metabolites (such as aryl hydrocarbon receptor ligands) [172, 173]. Among these, IL-22 has been most well studied and is dominantly produced by ILC3s. IL-22 mediates resistance to intestinal infection by directly acting on non-hematopoietic cells in the intestine. IL-22 binding on epithelial cells through the IL-22Rα1–IL-10Rβ receptors induce fucosylation of epithelial cells and secretion of antimicrobial peptides such as RegIIIβ and RegIIIγ [174]. Fucosylation of the epithelial cells has been shown to be important for resistance against *Salmonella typhimurium* infection [174]. IL-22 is also shown to be critically important for protection against intestinal inflammation elicited by *Citrobacter rodentium* infection or DSS administration, in part by promoting mucus production, protecting intestinal epithelial stem cells, and promoting the above antimicrobial responses [175, 176].

ILC3s also regulate intestinal immunity through direct and indirect interactions with adaptive immune cells. Activation of stromal cells by LTi cells derived lymphotoxin-α3 mediates the recruitment of B-cells and stimulates the production of T-cell-dependent or -independent IgA which in turn shapes the composition of the intestinal microflora [74, 177]. Engagement of IL-1R on ILC3s brings about release of GM-CSF. ILC3-derived GM-CSF triggers retinoic acid and IL-10 production from the myeloid cell, which promotes the induction and expansion of Treg cells [173]. These GM-CSF-primed APCs promote Treg cell responses to food antigens and help maintain oral tolerance. ILC3s also contribute to Treg maintenance since IL-2 production by ILC3s is critical to support Treg homeostasis selectively in the small intestine [158], while MHC class II expression by a subset of ILC3s is an essential tolerogenic signal that limits exacerbated microbiota-specific T-cell responses in the large intestine of mice and promote microbiota-specific RORγt$^+$ Tregs [166, 178, 179]. Critically, both of these pathways were found to be reduced in the inflamed intestine of children with IBD and associated with changes in the adaptive immune response, indicating that disruption of this pathway contributes to disease pathogenesis. Although we are still in the early stages of investigating ILCs, their importance to intestinal health is apparent and may hold important keys for better understanding mucosal immunity.

Causes and Immunologic Drivers of Intestinal Inflammation in Humans

The cause of IBD in most individuals remains incompletely understood, but it is considered to be the result of dysregulated immune responses to environmental factors including luminal and microbial antigens. Human IBD is an outcome of a complex interplay between host genetic risk factors and extrinsic environmental stimuli. Over the past decade, genome-wide association studies (GWAS) have identified about 215 susceptibility genes loci associated with the pathogenesis of IBD, which are important for regulating intestinal barrier integrity, pro-inflammatory signaling pathways, modulation of immune cell responses and host–microbiota interactions [27]. These analyses have revolutionized our current understanding of IBD. For example, polymorphisms in IL-10 and IL-10R were reported early on as a human IBD risk allele through GWAS [180]. Further these studies also identified variations in IL-2, IL-2R signaling and HLA, a molecule critical for antigen presentation, that increases susceptibility to IBD [27, 181]. Homozygous, loss-of-

function mutations in *IL10*, *IL10RA*, *and IL10RB* are associated with a unique and rare form of IBD that develops at younger than 5 years of age, termed VEO-IBD [161, 182]. GWAS in adult IBD and studies of VEO-IBD have elucidated many novel pathways that are reviewed more in depth by others [183–185].

Various therapeutic interventions using broadly immunosuppressive glucocorticoids, antibiotics, and biologics have been applied to clinically manage and treat IBD patients. Beyond the frontline use of glucocorticoids, TNF blockade remains the most important therapeutic approach and is shown to exert its effect through increased IL-10 production from the macrophages [186]. However, a subset of patients become refractory to this blockade over time and these immunosuppressive therapies are often associated with an increased risk of opportunistic infections, malignancies, or autoimmunity. Thus, there is an urgent need to develop safer and more efficient approaches. Antibodies targeting IL-23-Th17 cell pathways or delivery of exogenous regulatory cytokines (IL-2) show promising initial clinical results, but several failed to achieve desired therapeutic benefits [123, 187]. Recently, Ustekinumab, an antagonist of the p40 subunit of both IL-12 and IL-23, was approved by the FDA for the treatment of Crohn disease and ulcerative colitis [188]. Recent clinical trials have also demonstrated success of selective blockade of IL-23 [188, 189]. Other promising therapies that can have potential therapeutic benefits, include using the small molecule inhibitors targeting transcription factors or kinases employed by various cytokine receptors and cells, are currently in the pipeline for clinical testing. Finally, clinical trials with idea to specifically increase and activate Treg cells using low-dose IL-2 therapy have provided a promising strategy and is under investigation [190]. Other groups are also harnessing the beneficial effect of the microbiota or microbial metabolites, and efficacy of probiotic or healthy human fecal microbiota in transplantation strategies is under clinical stages of investigation for treating IBD.

Understanding Intestinal Immunity and IBD in Children

IBD is most often diagnosed in adolescence and young adulthood, but there are rising number of incidences in pediatric populations. Pediatric IBD affects approximately 10 per 100,000 children in the US. Among children with IBD, 4% are below the age 5 years and 18% are under 10 years of age with the peak onset in adolescence [25]. Normally, children diagnosed with IBD have classic symptoms such as weight loss, abdominal pain, and bloody diarrhea but many children can present with overall poor growth, compromised bone health, and anemia [25]. In GWAS studies, no difference exists in the commonly known risk genetic loci between pediatric and adult IBD. However, early onset of IBD in children may be associated with a higher burden of common risk alleles and the presence of rarer variants with high penetrance [26]. Host genetics plays an important role in onset of VEO-IBD. Using advanced sequencing technology, monogenic defects have been identified in a variety of primary immunodeficiency genes such as CARD8, IL-10, IL10R, XIAP, and FoxP3 in some children with VEO-IBD [180, 191], and active investigations could further identify primary immunodeficiencies associated with VEO-IBD [192].

There are several unique considerations for host–microbiota interactions that exist in early life. The composition of microbiota that are the first to colonize the mammalian intestine promotes proper development of GALT and function of immune cells. Similarly, intestinal microbiota composition is also shaped by early dietary and introduction of solid-food antigens during weaning. Immune responses during this critical time point are vigorous and termed a "weaning reaction." Further, microbial metabolites, such as short-chain fatty acids and retinoic acid, critically promote the differentiation of RORγt$^+$ Treg cells during the early stages of life and imprint long-term tolerance to dietary antigens and microbiota [56, 193]. Alterations in this critical developmental window, "weaning reaction" and immunological imprinting can lead to enhanced susceptibility to immune pathologies later on in life, including IBD [194]. This can occur through a number of different ways, and as an example, limited evidence indicates that early-life exposure to antibiotics may increase the likelihood of developing pediatric IBD [195].

Finally, the clinical care of pediatric IBD is being advanced by development of new drug and collaborative research networks. Vedolizumab, a monoclonal antibody against α4β7 integrin, inhibiting lymphocyte trafficking back to the intestine can provide therapeutic benefits [196]. Using advanced scRNA-seq technology and whole-genome sequencing technologies, investigators are obtaining a more robust understanding of the cellular and genetic diversity to cell types involved in the healthy and inflamed pediatric intestine [26].

Summary

Deciphering the complexities of the mucosal immune system has revealed how defects in specific pathways can directly cause intestinal inflammation, as well as the critical mediators that drive this outcome. This has informed our understanding of IBD and provoked the development of novel therapeutic strategies. However, we remain at the early stages of understanding the full spectrum of cross-talk between the mucosal immune system, other resident non-immune cells, and the intestinal microbiota. It will also be important to continue to define the unique immunologic,

microbial, and developmental differences in the pediatric GI tract relative to the adult GI tract. Research of these pathways in pre-clinical mouse models and translational patient-based studies will not only advance our understanding of intestinal health and inflammation, but also provoke the development of novel preventative, diagnostic, therapeutic, and potentially curative treatment strategies in IBD.

Cytokines and Inflammatory Bowel Disease

3

Edwin F. de Zoeten and Ivan J. Fuss

Introduction

The etiology of inflammatory bowel diseases (IBD) is generally described as multifactorial including genetic predisposition, dysbiosis, and a dysregulated immune response. The immune response is the only one of these which is currently amenable to therapy. Understanding the factors that go into the activation of inflammation, and those that perpetuate this effect is improving greatly. With this mastery, we are able to define the cytokines that are important in the etiology of IBD. Over the past 20 years, many of the newest and arguably the most successful therapies for Crohn disease (CD) and ulcerative colitis (UC) have been due to an increased understanding of the immune response and specifically the cytokines essential to this response.

As stated above, IBD is in part due to a dysregulated or an inappropriate immune reaction, which has been thought in part to be against the microflora of the gut. Upon activation of the immune system, cytokines and chemokines, which are proteins produced by the cells involved in the immune response, are produced and trigger a cascade of downstream reactions. These cytokines are increasingly being defined as important molecules in the pathogenesis of IBD as well as putative and known targets for the therapy of IBD.

With the advent of murine models of mucosal inflammation, a great deal of knowledge has been acquired which has advanced our understanding of inflammation in IBD. In these models, it has been initially noted that the inflammation is due either to an excessive Th1 T-cell response or an excessive Th2 T-cell response, with the former characterized by increased IL-1, IL-2, IL-6, IL-12, IL-18, IFN-γ, and TNF-α production and the latter by increased IL-4, IL-5, IL-10, and/or IL-13 production. An example of a murine Th1 colitis is that induced by the haptenating agent TNBS [1], colitis in which the predominant immune response is dominated by IL-12, IFN-γ, and TNF-α. This correlates with human studies, which have shown increased levels of TNF-α, IFN-γ, IL-1, and IL-6 in the intestinal tissues and the peripheral blood of CD [2]. Similar to what has been observed in UC patients [3, 4] the oxazolone model of colitis in mice, which has similar histologic features as those seen in UC, is associated with a Th2 response that is dominated by IL-13. Thus, murine models have given important insights into the IBD entities; however, questions of whether CD and UC are "true," Th1- or Th2-mediated disease processes remain. These will be discussed later in this chapter.

In the immune cascade, cytokines help to determine the nature of the immune response; they can act in a dual nature as either pro- (IL-1, IL-6, TNF-α) or anti-inflammatory (IL-4, IL-5, IL-10, TGF-β) molecules. They can affect the synthesis or secretion of reactive oxygen species, nitric oxide, leukotrienes, platelet-activating factor, and prostaglandins. In addition, they can have differing qualities depending on when they are present in the inflammatory cascade. Finally, it is important to understand that pro- and anti-inflammatory responses are required to maintain the integrity of the intestinal mucosa due to the environment in which it exists. The intestinal mucosa is constantly bombarded with antigens from food, commensal bacteria and pathogenic bacteria and therefore it is important to be able to mount an inflammatory response to rid itself of harmful bacteria yet, at the same time, the mucosal immune system must be able to regulate itself either by the action of specific regulatory cells or by the action of cytokines such as IL-4, IL-5, IL-10, TGF-β, IL-1ra, and TNF-α.

Pro-Inflammatory Cytokines

Tumor Necrosis Factor-Alpha

For most gastroenterologists, TNF-α is the most recognized cytokine due to the increasing use of the monoclonal anti-TNF-α antibodies, infliximab, adalimumab, certolizumab, and golimumab, for the treatment of CD and UC. TNF-α is secreted by macrophages, monocytes, neutrophils, T-cells, and NK cells following their stimulation by bacterial lipopolysaccharides. $CD4^+$ T-lymphocytes secrete TNF-α, while $CD8^+$ T-cells do not. The synthesis of TNF-α is induced by many different stimuli including interferons, IL-2, and GM-CSF. The production of TNF-α is inhibited by IL-6 and TGF-β.

TNF-α can signal through two different cellular receptors (TNFR1 and TNFR2), both of which are an agonist of the NFKB, p38, and c-jun N terminal kinase (NK) cascades, important signaling pathways involved in the generation of the inflammatory responses [5]. An additional effect of TNF-α signaling is the induction of intermediate molecular complexes, via signaling through the TNFR1, that lead to the downstream activation of necroptosis and apoptosis pathways; mechanisms which are dependent on MLKL and caspase 8 [6, 7]. Of note, these processes both lead to effects on epithelial cell survival, therefore, epithelial barrier function.

It is a potent pro-inflammatory cytokine that exerts its stimulatory effect on cells that produce IFN-γ. Indeed, TNF-α in synergy with factors from non-lymphocyte lamina propria mononuclear cells can act with prostaglandin E2 to stimulate IL-12-mediated T-cell production of IFN-γ. In resting macrophages, TNF-α induces the synthesis of IL-1 and prostaglandin E_2, which can act in concert to potentiate the inflammatory cascade. TNF-α can also enhance the proliferation of T-cells induced by various stimuli in the absence of IL-2; in fact some subpopulations of T-cells only respond to IL-2 in the presence of TNF-α. Beyond its effect on the immune response, TNF-α activates osteoclasts and thus induces bone resorption and this effect may be associated with decreased bone mineral density in patients with CD.

Although TNF-α is required for normal host immune responses, the over expression can have severe pathologic consequences as exemplified by mice in which the over expression of TNF by a transgene is associated with a severe colitis [8].

In animal models, TNF-α knockout mice do not develop significant colitis [9], and as proof of principle that TNF-α is important for the pathogenesis of IBD, TNF-α neutralizing antibodies have been shown to be effective in ameliorating intestinal inflammation. Associated human studies have reported elevated levels of TNF-α in serum, stool, and mucosal tissue [10, 11] correlating with clinical and laboratory indices of intestinal activity. Furthermore, dramatic effects have been noted in clinical studies in patients with Crohn disease treated with infliximab [12, 13]. These effects have been observed in both disease amelioration and induction of clinical remission. Important for the understanding of some of the critical side effects of infliximab, TNF-α mediates a part of the cell-mediated immunity against obligate and facultative bacteria and parasites by stimulating phagocytosis and the synthesis of superoxide dismutase in macrophages. It confers protection against *Listeria monocytogenes* infections and tuberculosis. Anti-TNF-α antibodies have been shown to weaken the ability of mice to cope with these infections. Infection with these organisms is a possible risk of using anti-TNF-α monoclonal antibody therapy in the treatment of IBD and a reason that patients are screened for tuberculosis prior to initiation of therapy with infliximab.

Interferon-gamma

IFN-γ is produced mainly by $CD4^+$, $CD8^+$ T-lymphocytes and natural killer cells activated by antigens and mitogens. IFN-γ synergizes with TNF-α in inhibiting the proliferation of various cell types; however, the main biological activity of IFN-γ appears to be immunomodulatory in contrast to the other interferons (IFN-α or β), which are mainly antiviral. IL-2 and IFN-γ appear to be intricately interwoven in their functions. In T-helper cells, IL-2 induces the synthesis of IFN-γ and other cytokines. IFN-γ acts synergistically with IL-1 and IL-2 and appears to be required for the expression of IL-2 receptors (CD25) on the cell surface of T-lymphocytes. Blocking of the IL-2 receptor by specific antibodies inhibits the synthesis of IFN-γ. IFN-γ is a modulator of T-cell growth and functional differentiation, a growth-promoting factor for T-lymphocytes, and it potentiates the response of these cells to growth factors. Most importantly, IFN-γ can increase the expression of MHC class molecules allowing greater antigenic recognition. Furthermore, it can increase permeability at epithelial tight junction barriers, thereby allowing further antigenic exposure [14]. Finally, in concert with TNF-α, IFN-γ can cause direct tissue destruction as it increases local inflammation [14, 15].

IFN-γ secretion is one of the few cytokines that correlates with severity of disease in patients with CD. As a known pro-inflammatory cytokine, it would appear to be an obvious choice to target for treatment of IBD. IFN-γ has been targeted in CD using fontolizumab, a humanized monoclonal antibody against IFN-γ [16, 17]. In studies using these antibodies, positive results were found in patients with moderate to severe CD when compared to placebo. Although the studies did not reach statistical significance, the results did indicate a trend toward effect. This suggests a potential benefit of blocking IFN-γ in patients with CD.

Interleukin-1

This cytokine consists of IL-1α and IL-1β subunits, both are produced predominately by antigen-presenting cells such as monocytes and macrophages. In addition to these pro-inflammatory cytokines, there is an IL-1 receptor antagonist (IL-1ra) produced by intestinal epithelial cells, which is capable of inhibiting the pro-inflammatory actions of IL-1 by binding the IL-1 receptor and competitively blocking the interaction with IL-1. IL-1rα is considered to be one intestinal mechanism for downregulation of the immune response and has been shown to be elevated in the serum of patients with CD. Stimulation of IL-1rα secretion is activated by IL-1, forming a negative feedback loop.

Furthermore, in combination with TNF-α, IL-1 appears to be involved in the generation of lytic bone lesions. IL-1 activates osteoclasts thereby suppressing the formation of new bone, suggesting another etiology for decreased bone density in CD. Low concentrations of IL-1, however, can promote new bone growth.

IL-1 was one of the first cytokines targeted for therapy in animal colitis models. In these studies, administration of IL-RA led to amelioration of colitis, in a rabbit model. Thus, it was also one of the first demonstrations that blockade of a single cytokine could be effective in therapy of colitis [18]. In patients with IBD, increased serum levels of IL-1 are seldom detected. However, in intestinal lesions in patients with both CD and UC, IL-1 levels are elevated [19]. IL-1Ra is a possible intestinal mechanism for downregulation of the immune response and is elevated in the serum of patients with CD. IL-1Rα determines the biological effects of IL-1, as increased concentrations of this mediator will decrease IL-1 activity. In the inflammatory lesions of IBD patients, levels of this mediator are increased, although not as much as IL-1, leading to a disproportionate increase in IL-1 activity [20] overcoming competitive inhibition.

IL1-α and -β are essentially biologically equivalent pleiotropic factors that act locally and systemically. IL-1 has a multitude of effector functions, some of which are mediated indirectly by the induction of the synthesis of other mediators including ACTH, PGE_2, IL-6, and IL-8 (a chemotactic cytokine in the chemokine family). The main biological activity of IL-1 is the stimulation of T-helper cells, which are induced to secrete IL-2 and to express IL-2 receptors. IL-1 can also act on B-cells, promoting their proliferation and the synthesis of immunoglobulins. IL-1 stimulates the proliferation and activation of other immune cells such as NK-cells and fibroblasts, thymocytes. The IL-1-mediated proliferative effects can be inhibited by the suppressive cytokine, TGF-β.

The synthesis of IL-1 can be induced by other cytokines including TNF-α IFN-α, β or γ, and also by bacterial endotoxins and viruses. Furthermore, IL-1 activity is not only limited to stimulation of T-cells but it also promotes the adhesion of neutrophils, monocytes, T-cells, and B-cells by enhancing the expression of adhesion molecules such as ICAM-1 (intercellular adhesion molecule) and ELAM (endothelial leukocyte adhesion). All of which can contribute to the pathogenesis of CD. IL-1 is also a strong chemoattractant for leukocytes, as demonstrated by the local accumulation of neutrophils at the site of injection of tissue with IL-1. Beyond activation of other inflammatory factors, IL-1β can have direct inflammatory effects. It can be secreted in response to select microbial components (i.e., LPS or ATP derived from bacterial breakdown) via stimulation and activation of the NLR inflammasomes [21]. The importance of the inflammasome pathway previously has been overlooked as prototypic Crohn disease patients have not responded to blockade with anti-IL-1β therapy. In examination of IL-1β role in intestinal inflammation, murine models of colitis have demonstrated that inhibition of inflammasome function through use of knockout animals carrying deletions of NLRP3 has had mixed effects on colitis with both amelioration and increased colitis reported. However, overactivation of the NLRP3 inflammasome function has led to enhanced colitis induction [22]. Finally, several monogenic mutations leading to increased NLRP3 inflammasome activation are accompanied by severe Crohn disease that appears amenable to treatment with IL-1β inhibition therapy [23]. Therefore, IL-1β may play a central role in a subset of Crohn disease patients if the predominate dysregulated cytokine, the latter due to genetic influence of inflammasome activation.

Interleukin-2

IL-2 is a major T-cell growth factor, secreted by activated T-cells and acts via the high-affinity IL-2 receptor (CD25) on T-cells. This binding to CD25 promotes cell proliferation. Under physiological conditions, IL-2 is produced mainly by CD4+ T-lymphocytes following cell activation. Resting cells do not produce IL-2. In T-helper cells, IL-2 induces the synthesis of IFN-γ and other cytokines. IFN-γ acts synergistically with IL-1 and IL-2 and appears to be required for the expression of IL-2 receptors on the cell surface of T-lymphocytes. Blocking of the IL-2 receptor by specific antibodies also inhibits the synthesis of IFN-γ. IFN-γ in return is a modulator of T-cell growth and functional differentiation. It is a growth-promoting factor for T-lymphocytes and potentiates the response of these cells to growth factors.

IL-2 is a growth factor for all subpopulations of T-lymphocytes including importantly suppressive T regulatory cells. It is an antigen-unspecific proliferation factor for T-cells that induces cell cycle progression in resting cells and thus allows clonal expansion of activated T-lymphocytes.

In patients with CD, it has been demonstrated in many studies that IL-2 secretion from lamina propria cells is

decreased as compared to normal patient samples. Daclizumab, a humanized monoclonal antibody to CD25, produced in an effort to block the binding of IL-2 to the IL-2R was tested in patients with UC and initially appeared promising in a small open label study [24] but upon testing in a placebo controlled study the therapy did not show efficacy [25]. This effect could be related to the fact that IL-2R (CD25) is also present on T regulatory cells. The inhibition of binding of IL-2 to its receptor present on Treg cells thereby inhibits the proliferation of these cells, which are important in down regulation of the immune response. This highlights a common problem in the targeting of the cytokine pathway for treatment of inflammatory diseases, in that, cytokines frequently have multiple effects and can function in both a pro-inflammatory as well as an anti-inflammatory capacity.

Interleukin-6

IL-6 is a pleiotropic cytokine considered to be a major player in inflammation, regulation of T-cell responses and apoptosis. Many different cell types produce IL-6. The main sources in vivo are stimulated monocytes, fibroblasts, endothelial cells, macrophages, T-cells, and B-lymphocytes. IL-6 is a B-cell differentiation factor in vivo and in vitro and an activation factor for T-cells. In the presence of IL-2, IL-6 induces the differentiation of mature and immature T-cells into cytotoxic T-cells. IL-6 also induces the proliferation of thymocytes and likely plays a role in the development of thymic T-cells. Most significantly, IL-6 and TGF-β together can induce the development of the inflammatory Th17 cell lineage. Finally, in opposition, if IL-6 is present, there is decreased propensity to development of FOXP3-positive Treg cells.

IL-6 activity as a pro-inflammatory cytokine lies in its ability to affect NF-κB signaling [26]. Furthermore, IL-6 can signal via its receptor directly or by binding to soluble IL-6R to form a IL-6/sIL-6R complex that binds membrane-bound signal transducer (gp130), by-passing membrane-bound receptor (trans-signaling). IL-6 trans-signaling of hematopoietic cells is the predominate manner IL-6 relates its pro-inflammatory effects [27].

Interestingly, IL-6 levels are increased in the serum of patients with active CD and UC compared to normal controls. A study looking at a known functional polymorphism of the IL-6 gene and the site of disease in CD patients did not demonstrate an association of IL-6 functional polymorphisms with CD or protection from CD. It did demonstrate that patients with the high producer genotype were more likely to have ileocolonic disease, while those with the low producer genotype had primarily colonic type disease, whereas those with intermediate producer genotype were more likely to have isolated ileal disease. These studies indicated an association of IL-6 production and site of disease [28]. The activity of IL-6 has made it an obvious target for clinical trials not only due to its pro-inflammatory effects but also due to its involvement in T-cell apoptosis [29]. A pilot study was performed [30] to investigate safety and efficacy of a humanized anti-IL-6R monoclonal antibody in patients with CD. This target appeared to be promising in these studies with 80% of the patients treated for 12 weeks demonstrating clinical improvement as compared to 31% treated with placebo.

Interleukin-12

IL-12 is a heterodimeric molecule composed of IL-12 p40 and IL-12 p35 subunits. IL-12 is secreted by antigen-presenting cells such as monocytes, macrophages, and dendritic cells, and to a lesser extent by NK cells. The most powerful inducers of IL-12 are bacteria, bacterial products, and parasites.

IL-12 is a pro-inflammatory cytokine that is important in the differentiation of naïve T-cells into IFN-γ producing pathogenic $CD4^+$ Th1 cells [15, 31]. In peripheral lymphocytes of the Th1 T-helper cell type, IL-12 induces the synthesis of IFN-γ, IL-2, and TNF-α. TNF-α also appears to be involved in mediating the effects of IL-12 on natural killer cells since an antibody directed against TNF-α inhibits the effects of IL-12. IL-12 and TNF-α are co-stimulators for IFN-γ production with IL-12 maximizing the IFN-γ response; the production of IL-12, TNF-α, and IFN-γ is inhibited by IL-10. In Th2 T-helper cells IL-12 reduces the synthesis of IL-4, IL-5, and IL-10.

This cytokine is considered a driving force behind chronic intestinal inflammation. Evidence for this comes forth from murine models of colitis by demonstrating that disease development could be inhibited by treatment with anti-IL-12p40 monoclonal antibodies [31]. In human studies, this master T-cell differentiating cytokine has been shown to be produced in large amounts in the intestines of patients with CD [32]. In addition, this cytokine has been targeted in human CD using various anti-IL-12p40 monoclonal antibodies and found to be effective in Phase 2 and Phase 3 multicenter trials [33, 34]. In the latter, significant clinical response and remission could be achieved in patients with moderate-to-severe active Crohn disease. Furthermore, the phase III UNITI trial also included a cohort of patients which failed TNF-α mAb, with significant response and remission rates demonstrated in this patient population. The long-lasting clinical effect observed may be due in part to the induction of apoptosis of the inflammatory effector cells. These studies suggest that in addition to IL-2, IL-12 is a necessary growth and survival factor for T-cells [35]. It also brings forth the point that the mechanism of action of the various anti-

biologic therapies lies not only in their capability to neutralize their respective cytokines but due to their ability to induce cell death of the inciting inflammatory effector cells. Interestingly, the p40 subunit is also found to be a portion of another significant pro-inflammatory master cytokine, IL-23. The positive effects observed in the anti-IL-12 p40 antibody may indeed be due to both the effects on IL-12 and IL-23 [32]. Further studies in models of colitis indicate that IL-23 is important in the inflammatory response in IBD in that it plays a significant role in the maintenance of Th-17 effective inflammatory cells [36].

Interleukin-17

The discovery of the Th17 cell lineage revolutionized our understanding of IBD pathogenesis. The Th17 type secretes IL-17 and IL-22. IL-17 has been associated with multiple immune regulatory functions. Most notably, IL-17 is involved in inducing and mediating pro-inflammatory responses. IL-17 induces the production of many other cytokines, such as IL-6, G-CSF, GM-CSF, IL-1β, TGF-β, TNF-α, chemokines including IL-8, GRO-α and MCP-1 and prostaglandins (e.g., PGE_2) from many cell types (fibroblasts, endothelial cells, epithelial cells, and macrophages). IL-17 expression is stimulated and/or maintained by IL-23 expression. These IL-17 expressing cells appear to be derived by a subset of CD4+ T-cells called T-helper-17 (Th17) cells, which are distinct from Th1 and Th2 cell lineage and need to be derived in the presence of IL-23; in addition, IL-17 may be derived to a lesser degree from monocytes and neutrophils [37]. Increased expression of IL-17 has been reported in the intestinal mucosa of IBD patients [38]. Some reports suggest that IL-17 alone is capable of inducing autoimmune tissue reactivity, whereas other groups suggest that IL-17 and IFN-γ synergize to stimulate this autoimmune reactivity [39, 40]. In these studies, it was indicated that T-cells and monocytes in the intestinal mucosa produce IL-17. IL-17 binds to the IL-17 receptor on endothelial cells and epithelial cells to promote secretion of pro-inflammatory substances that recruit inflammatory cells to the site [41]. In studies where the genes for either IL-17A or IL-17F were deleted, mice continued to develop severe colitis but when RORγτ (the transcription factor important for expression of all IL-17) genes was deleted minimal inflammation occurred in colitis models which suggests that the different forms of IL-17 are redundant but IL-17 together are important for the development of colitis. In addition, if both IL-17A and IL-17F were deleted, the colitis was ameliorated. Interestingly, as noted with other cytokines, it appears that IL-17 is not just simply an inflammatory cytokine. Recent murine studies in both chemically induced colitis as well as adoptive transfer colitis indicate that IL-17 plays a complex role in the inflammatory response. These studies showed that transfer of IL-17 deficient T-cells into an immunodeficient mouse led to more rapid onset of colitis that transfer of cells from WT mice. One explanation of this could be that Th1 cells bear IL-17 receptors and signaling through these receptors inhibits Th1 differentiation by suppressing the transcription factor T-bet. Thus, IL-17 may have pro- and anti-inflammatory properties. As a result of these roles, the IL-17 family has been linked to many immune/autoimmune-related diseases including rheumatoid arthritis, asthma, and lupus. IL-17 expression is increased in patients with a variety of allergic and autoimmune diseases, such as RA, MS, inflammatory bowel disease (IBD), and asthma, suggesting the contribution of IL-17 to the induction and/or development of such diseases. It must be stated that IL-17 may not appear to be the main cytokine important for inflammation in IBD, in those studies evaluating the effect of anti-IL-17A antibody, secukinumab for the treatment of Crohn disease have been disappointing and do not appear to have a therapeutic effect and may have worsened outcomes in CD, similarly in the use of the IL-17 receptor inhibitor, brodalumab, worsening of CD was noted compared to placebo. In a realm that is of interest in the development and progression of IBD, IL-17 has been identified as a key mediator of fibrosis in multiple organs including the intestine. As fibrosis is an important issue in IBD this makes understanding of IL-17 even more critical. Recently, Biancheri et al. demonstrated that IL-17 is upregulated in strictured tissue and that myofibroblasts express receptors for IL-17A [42]. An understudied area is the role of another IL-17 family member, IL-17C, which unlike its more studied relative IL-17A and F, does not appear to be produced by leukocytes but by epithelial cells. This cytokine shows increased concentrations in the tissues and serum of patients with UC and CD [43] and appears to activate the expression of multiple antimicrobial peptides [44]. While not a potent activator of the expression of pro-inflammatory cytokines, it has been shown to induce expression of IL-1β, TNFα, and IL-6 and likely enhance inflammation. It remains the current hypothesis that while IL-17 plays a role in inflammation in Crohn disease, the role is complex, and it appears that Th1 cytokines such as IFNγ may play a greater role.

Interleukin-23

IL-23 and IL-17 changed our view of the cytokines important in the development of IBD. Multiple murine colitis studies demonstrated that development of colitis appeared to be more dependent on IL-23 than on IL-12. IL-23 is a pro-inflammatory cytokine secreted by activated dendritic cells and macrophages that share structural homology with IL-12; specifically, it is composed of the p40 subunit and a unique p19 chain. Initial studies indicating an ameliorating effect of

an anti-p40 antibody in murine models of inflammation was felt to be due to its effect on IL-12. However, this effect was reevaluated and studies suggest that this ameliorating effect may be due to a decrease in IL-23 mediating effect. In these studies, mice deficient in the p19 subunit of IL-23 displayed attenuated inflammation in colitis models, whereas mice deficient in the p35 chain of IL-12 (therefore deficient in IL-12 but not IL-23) had no effect on colitis. These studies together suggest that the initial effects observed with anti-p40 in a variety of animal models may have been due to a decrease in IL-23. IL-23 promotes and stabilizes a novel subset of $CD4^+$ T-cells (TH17 cells) that is characterized by the production of IL-17, IL-6, and TNF-α and has been associated with autoimmune tissue inflammation [39]. Without IL-23, it has been noted that Th17 cells produce the cytokine IL-10. The exact mechanism by which IL-23 promotes The TH17 response has not been defined but it appears that TGF-β and IL-6 are important for the commitment into a TH17 cell and IL-23 is important for the proliferation of this cell type [45, 46]. Furthermore, recent studies may indicate a separate role for IL-23 in the occurrence of IL-17 expressing cells [47] whereby IL-23 may have a direct effect on regulatory T-cell development. Thus, in these animal studies mice that lack IL-23 fail to develop colitis, however this may not be secondary to the inability to produce IL-17 but rather because of the development of a dominant regulatory T-cell response. Moreover, Sunjino et al. demonstrated a dominant role for T regulatory cells in the suppression of colitis by blocking differentiation of TH17 into alternative TH1 type cells, therefore, establishing a significant role for this suppressive pathway [48].

IL-23 effect is not limited to TH17 cells but appears to have an effect of the innate immune system inducing monocytes and macrophages to produce pro-inflammatory cytokines such as IL-1, IL-6, and TNF-α as well. In murine colitis studies where either IL-23 or the IL-23 receptor were deleted, it was shown that IL-23 plays a major role in the development of colitis. These studies also have shown an increase in the number of anti-inflammatory Treg cells suggesting that IL-23 may play a role in suppressing this cell type.

In addition, in a genome-wide association study in adults [49] as well as in a pediatric population [50], the IL-23 receptor (IL-23R) gene on Chromosome 1p31 has been shown to have a highly significant association with CD, specifically, an uncommon coding variant of the IL-23R gene was shown to confer protection. These data indicate that the IL-23 pathway may have a causal link to CD.

Interleukin-18

This cytokine initially identified as Interferon-gamma-inducing factor (IGIF), is like the IL-1 family in structure, processing, receptor and pro-inflammatory properties. It is produced by intestinal epithelial cells and induces other pro-inflammatory cytokines and Th1 polarization. IL-12 and IL-18 have a synergistic relationship. Their production by activated macrophages appears to drive the development of Th1 CD4+ T-cell predominance in the intestinal mucosa. Recombinant IL-18 alone is able to induce a proliferative response in vitro in freshly isolated mucosal lymphocytes from patients with CD. The synergistic effect is likely due to the up regulation of the IL-18 receptor by IL-12.

Intestinal mucosa from patients with CD have been evaluated and found to have increased expression of IL-18 [51] and this was also noted in experimental murine colitis [52]. Tissues from CD patients have been shown in vitro to decrease suppressive cytokine IL-10 expression after treatment with IL-18 indicating one possible effector mechanism. IL-12 and IL-18 together appear to synergize to drive the lamina propria lymphocytes into a Th1 type response. IL-12 appears to induce increased IL-18 expression thus the synergistic effect [53, 54]. Using models of colitis multiple laboratories have tried to block IL-18 and the results indicate that IL-18 may have a role in the initiation of intestinal inflammation, while others have shown that IL-18 acts to reduce inflammation.

An additional source for IL-18 production is the inflammasome pathway. The role, however, of the inflammasome to induce secretion of cytokines such as IL-1β and IL-18 is complex. While IL-1β appears to function as a pro-inflammatory cytokine in murine models of colitis [55–58], the function of IL-18 remains a duality. Thus, whereas studies have demonstrated that IL-18 is necessary for the induction of DSS colitis [55, 59, 60], further studies have shown that a deficiency in IL-18 secretion affords mice more susceptibility rather than more resistance to DSS colitis [61–63]. This correlated to studies which show that a deficiency in NLRP3 inflammasome pathway leads to increased susceptibility to DSS colitis, which appears to be secondary to decreased IL-18 expression [61, 62]. Alternatively, the NLRC4 inflammasome assembles in response to detection of bacterial invasion, and NLRC4 activation leads to the production of IL-18 and IL-1β which have been implicated in inflammation [64]. In fact, hyper inflammation found in patients with NLRC4 mutations can be treated with inhibition of IL-18 [65, 66], suggesting a pro-inflammatory function of IL-18. identifying a dichotomous effect of IL-18 including pro-inflammatory properties as well as an important role in epithelial cell restitution and repair after injury [63, 67].

In a separate but similar role IL-6, a cytokine that can also affect epithelial cells acts as a tumor promoter by affecting the carcinogenicity of these intestinal epithelial cells [68]. IL-18 can have effects on these cell types since $IL18^{-/-}$ and $Il18r1^{-/-}$ mice display increased susceptibility to DSS colitis-

associated cancer [63]. This effect of IL-18 may be through the cytokine IL-22 and its IL-binding-protein (22 bp), the latter a decoy protein that neutralizes IL-22. The interplay between these various cytokine pathways is shown by the fact that IL-22 and IL-22 bp can regulate epithelial cell growth/repair and control tumorigenesis while these aforementioned factors can be regulated by IL-18 and the NLRP3, NLRC4 or NLRP6 inflammasomes [67].

Interleukin-13

IL-13 can have a dual functional role in that it can downmodulate macrophage activity, reducing the production of pro-inflammatory cytokines (IL-1, IL-6, IL-8, IL-10, IL-12) and chemokines (MIP-1, MCP) in response to IFN-γ or bacterial lipopolysaccharides. IL-13 can also enhance the production of the IL-1 receptor antagonist and decrease the production of nitric oxide by activated macrophages, leading to a decrease in parasiticidal activity. Yet, it appears that IL-13 is important in the development of Th2 type colitis such as the murine model of colitis oxazolone and its human component, UC [69]. In these studies, it was found that IL-13 produced by Natural Killer (NK) T-cells, when neutralized, led to decreased inflammation in the oxazolone model of colitis. Furthermore and most importantly, in human studies, these IL-13 secreting type II NK T-cells, (NK T-cells with non-invariant TCRs) recognize lyso-sulfatide glycolipid antigen; these cells bore IL-13Rα2 receptors and exhibited an increased cytolytic function against epithelial cell lines. Moreover, IL-13 itself has been shown to be directly toxic to epithelial cells as well as to cause increased permeability barrier functional defects [70]. Most recently, a correlative study of UC patients demonstrated that there were two divergent groups: a predominate group with high tissue IL-13 mRNA levels and a smaller group containing normal tissue IL-13 mRNA levels [71]. Of significance, the cohort group with high IL-13 expression exhibited more severe intestinal inflammation and extension of disease than their lower IL-13 counterparts.

Thus, in the oxazolone model of colitis and its human counterpart ulcerative colitis, it is believed that IL-13 secreting NK T cells play a role in the etiology of this disease entity. This is in contrast to the Th1/Th17 disease process discussed in the pathogenesis of CD. Although IL-13 can function as a pro-inflammatory molecule in UC it may also play a role in innate tumor surveillance pathways. In studies by Schiechl et al., tumor formation was accompanied by the co-appearance of F4/80 + CD11bhigh Gr1low macrophages, cells that undergo differentiation and activation by IL-13 and subsequently produce a source of tumor-promoting factor such as IL-6 after such activation [72]. In a similar vein, F4/80 + CD11bhigh Gr1intermediate macrophages after activation through IL-13 produced increased amounts of TGF-beta, a cytokine that inhibits tumor immunosurveillance.

Finally, clinical trials aimed at the IL-13 pathway have been performed. Although these trials did not meet their primary endpoints, they did reveal interesting findings concerning the IL-13 signaling pathway. In an initial trial, Anrukinzumab, an agent that binds to the IL-4/IL-13Rα1 complex and blocks signaling of IL-13 via the IL-13Rα1 pathway, was utilized [73]. As noted by the authors, these complexes consist of study drug and IL-13, which may be subsequently cleared through another IL-13 receptor pathway, IL-13Rα2. More recent findings demonstrate that the latter IL-13 receptor pathway, IL-13Rα2 and not the IL-13Rα1 pathway appear to be involved in the activation and secretion of IL-13 in ulcerative colitis [74]. Thus, the decreased efficacy of this trap molecule antibody directed against the IL-13Rα1 pathway may be expected based upon the former findings. The dose–response curves demonstrate some efficacy at low doses but not at higher levels. This might be explained by clearance of IL-13 initially but subsequently binding and activation of the aforementioned IL-13Rα2 pathway leading to decreased responses at higher doses. Finally, another monoclonal antibody, Tralokinumab directed at IL-13 itself had a significant remission rate as compared to placebo but did not achieve significance for response rate [75]. These results may demonstrate that a subgroup of patients may achieve a remission response; however, additional screening markers are necessary to evaluate these responder patients.

Interleukin-33

IL-33 is part of the IL-1 family and is expressed in various non-hematopoietic cells as well as in inflammatory cells (e.g., macrophages and dendritic cells) [76]. Similar to other IL-1 family members such as IL-1 and IL-18, IL-33 was originally thought to be synthesized as a 30-kDa-precursor molecule and then subsequently cleaved by caspase-1 upon inflammasome activation to its mature/bioactive 18-kDa form [77]. However, more recent studies have suggested that the full-length 30 kDa IL-33 (f-IL-33) is the bioactive form with decreased active forms (20–22 kDa) resulting from caspase cleavage [78, 79]. In addition, further reports indicate that the bioactive form may not depend upon any caspase cleavage [80]. Thus, IL-33 bioactive form can be regulated by cleavage through proteases, in particular, neutrophil serine proteases cathepsin G or elastase C, both released from neutrophils. Therefore, the inflammatory milieu may play a role in the generation of highly active mature forms of IL-33. This cytokine has both intracellular effects, as a transcrip-

tional repressor [81], and more classical cytokine-like extracellular effects.

The IL-1 receptor-related protein, ST2, is the IL-33 receptor and exists in two different splice variants. ST2L is a transmembrane receptor that confers IL-33's biologic effects, and sST2 is a soluble molecule that serves as a decoy receptor [77]. Signaling through ST2 receptor can drive cytokine production in a host of cell populations, which include type 2 innate lymphoid cells (ILCs) (natural helper cells, nuocytes), T-helper lymphocytes, mast cells, basophils, eosinophils, natural killer (NK), and invariant natural killer T (iNK T) cells [82, 83]. Thus, the IL-33/ST2 axis appears to play an important role in several chronic inflammatory disorders through the regulation of Th2 and/or Th17 cytokines responses such as IL-5, IL-9, IL-13, and IL-17 [76, 77, 84, 85]. Interestingly, studies on the effects of IL-33 have identified a regulatory effect on NFκB-induced pro-inflammatory signals, identifying an anti-inflammatory effect of overexpression of IL-33. Yet even more recent studies have demonstrated that IL-33 from intestinal epithelial cells in the setting of inflammation plays an active role in downregulating the Th17 cells and their secretion of IL-17 [86] and upregulation of Tregs and expression of IL-10 [87, 88].

Increased IL-33 production has been noted in murine models of colitis (i.e., oxazolone colitis, SAMP1-yit) as well as in ulcerative colitis [89, 90] when compared to healthy controls. Further studies of active UC patients reveal IL-33 production was localized to intestinal epithelial cells (IEC) and cells in colonic inflammatory infiltrates [84, 85, 89, 90]. This increase appears to be regulated in part by TNF-α as the latter can upregulate both IL-33 and sST2 and treatment of patients with anti-TNF-α monoclonal antibody decreases circulating levels of these molecules [84]. Of note, when assessing severity of ulcerative colitis, it has been shown that there is decreased expression of IL-33 noted in more severe ulcerative colitis [91] compared to less effected individuals suggesting an anti-inflammatory effect in UC. Further understanding of the dichotomous effects of IL-33 is critical to our understanding of how to target this cytokine in therapeutic studies.

Interleukin-37

IL-37 is an IL-1 family-related cytokine; however, in contrast to IL-1 related pro-inflammatory action of this gene family, it is anti-inflammatory in function. IL-37 is predominantly expressed by antigen-presenting cells such as macrophages or dendritic cells and can suppress a variety of inflammatory cytokine pathway signaling; IL-1β, IL-18, TNF, and IL-6 [92]. The IL-37 is a heterodimeric receptor which consists of the IL-1R8 (SIGIRR) and IL-18R1, both highly expressed within the gastrointestinal tract [93]. In prior studies, it has been demonstrated that although mice do not normally express IL-37, mice which carry a transgene to overexpress human IL-37 are protected from experimental dextran sodium sulfate (DSS) intestinal colitis [92, 94]. Furthermore, knockout mice that carry mutations in the IL-1R and IL-18R1/IL-18BP are more susceptible to the development of increased intestinal inflammation [95].

In related studies, silencing interleukin-37 (IL-37) in human $CD4^+CD25^+$ Tregs reduced the suppressive function of $CD4^+CD25^+$ Tregs. In addition, supplementation of rhIL-37 enhanced the suppressive function of $CD4^+CD25^+$ Tregs in naïve mice T-cells. Treatment with rhIL-37 was associated with increased expression of cytotoxic T-lymphocyte-associated antigen (CTLA)-4 and forkhead winged helix transcription factor p3 (FOXP3) on $CD4^+CD25^+$ Tregs. Finally, rhIL-37 increased the secretion of transforming growth factor-β1 (TGF-β1) but no other suppressive cytokines such as IL-10 in the $CD4^+CD25^+$ Tregs [96].

In human-related studies, patients with heterozygous IL-37 variants may have increased joint inflammation [97]. In addition, expression levels of IL-37 may be associated with a more modified IBD disease course [98]. In a more recent report, an initial case of a homozygous loss of function human IL-37 mutation was observed in a two-year-old child from a consanguineous family [99]. He presented at four-month old with recurrent bloody diarrhea with mucous eight to nine times per day and significant cachexia. As an infant, he was maintained on a hypoallergenic diet but continued to demonstrate inflammatory changes which encompassed on colonoscopy findings of diffuse ulcers with wide-based crater formation throughout the colon and rectum, but a normal appearance to the ileum, supported a diagnosis of infantile onset inflammatory bowel disease. In addition, significant lymphocytic infiltration with cryptitis and apoptotic crypt abscesses were also observed throughout the colon and rectum.

No abnormalities were found on immunophenotyping profile studies. Given the familial consanguinity and infantile onset IBD findings, a whole-exome sequencing analysis was performed which a *IL37* chr2: g.113676259 T > C (p.Ile177Thr) missense variant, thought to be pathogenic by Combined Annotation Dependent Depletion (CADD) scoring. This mutation destabilizes the protein structure to promote accessibility of the mutated amino acid change. IL-37 protein expression and stability studies demonstrated higher levels of IL-37 protein within cells albeit less stable in structure and therefore targeted for degradation. In functional analysis studies, as mutant IL-37 cannot be stably expressed, it was found that it did not properly inhibit pro-inflammatory cytokines generation.

These studies gives additional insight into monogenic VEO-IBD and in the long-term further studies may shed light on the significance of IL-37 effects on T regulatory sup-

pressive function and role of the IL-1, IL-18 and IL-37 axis in colonic homeostasis.

Interleukin-9

IL-9 is another Th2-related cytokine that appears to be involved in IBD pathogenesis. Production of IL-9, by Th9 cells, is induced in naïve T-cells by TGF-β and IL-4 in concert with additional cytokines (i.e., IL-1β and IL-25). This cytokine was initially identified as a Th2-type cytokine by its ability to induce Th2 inflammation in disease states such as parasitic infection, allergy, or autoimmune states [100–102]. Recent studies have elucidated the role of IL-9 in IBD, which demonstrated increased levels of this cytokine in UC and in CD [103, 104] both in the serum of affected patients as well as in intestinal biopsies. Studies of the murine colitis model, oxazolone colitis, revealed that mice lacking IL-9 develop no or reduced disease. However, mice deficient in IL-9 also manifest amelioration of several Th1/Th17murine colitis models, including cell-transfer colitis; thus, IL-9 contributes to inflammation in a variety of Th1/Th2/Th17 intestinal inflammatory conditions [105]. The mechanism by which IL-9 may have broad effects on intestinal inflammation is the ability to alter epithelial barrier function via effects on tight junction proteins. The junction complex protein Claudin 8 (CLDN8) was identified as a critical downstream component of the IL-9 inflammatory cascade [104].

Tumor Necrosis Factor-Like Ligand (Tl1a)

TL1A is a cytokine that appears to contribute to intestinal inflammation; however, it does not appear to be uniquely associated with TH1/TH2 or TH17 cells and appears to be within the category of cytokines that can bridge the T-cell spectrum. This cytokine is secreted by T-cells, antigen-presenting cells, and endothelial cells [106]. Studies involved in elucidating the exact function of TL1A indicate that TL1A enhances baseline T- and B-cell activation by T-cell receptor activation.

The significance of TL1A to intestinal inflammation is demonstrated in the studies where exogenous administration of TL1A to mice with Dextran sodium sulfate (DSS)-colitis increased both TH1 and TH17 responses. Furthermore, the administration of antibodies to TL1A led to the amelioration of colitis in the DSS and TNBS model of intestinal inflammation [107, 108]. While effects on TH1 and TH17 production have been associated with TL1A, in recent studies of mice carrying a transgene for TL1A, intestinal inflammation of the small intestine was developed, which appeared dependent on IL-13 [108]. In separate studies, TL1A was found to inhibit the induction of new $FOXP3^+$ regulatory cells and or the expansion of existing subsets [109]. Thus, these studies suggest that TL1A is a cytokine that optimizes both TH1/TH2 and TH17 responses either through direct effects on these cell lineages or through effects on suppressor T regulatory cell pathway.

The costimulatory activities of TL1A induces cytokines associated with inflammation, such as IL-2, IFNγ, IL-13, and IL-5 from T-cells, while the latter (IL-5/IL-13) can also be generated from innate lymphoid cells (ILC type 2) [110–114]. TL1A can also costimulate additional intestinal innate lymphoid cell groups (ILC3), with divergent effects. In combination with the ILC stimulatory cytokine IL-23, TL1A can enhance the secretion of the regulatory cytokine IL-22 [114, 115]. IL-22, as noted above, can induce antimicrobial peptides, which can affect intestinal barrier homeostasis [113–115]. Therefore, TL1A can play a role in both pro-inflammatory and regulatory function through costimulation of ILC populations.

Turning to human studies, elevated TL1A has been noted in both CD and UC indicating again that TL1A is not associated with a unique T-cell differentiation cell lineage [106]. Furthermore, lamina propria CD14+ macrophages in CD patients produced increased amounts of TL1A and the latter increased T-cell production of IFN-gamma and IL-17 from allo-antigen-stimulated T-cells (but had no significant effect as a lone stimulus reiterating the mouse model data demonstrating a co-stimulatory effect of TL1A) [116]. Finally, polymorphisms in the TL1A gene have been observed in CD patients indicating a possible significant clinical function to this cytokine [117].

Anti-Inflammatory Cytokines

As the host requires a pro-inflammatory response in the presence of a stimulating antigen, so too, the host requires a balancing anti-inflammatory response once the antigen has been dealt with or the offending infection has been cleared. Without the ability to turn off or downregulate the immune response the inflammation becomes overwhelming and can be detrimental to the host. This issue is exemplified in patients with the disease known as IPEX (immune dysregulation, polyendocrinopathy, and enteropathy, X-linked). This syndrome is characterized by the development of overwhelming systemic autoimmunity in the first year of life. It is associated with mutations identified in the *FOXP3* gene. FOXP3 is a member of the forkhead/winged-helix family of transcriptional regulators known to be specific to regulatory T-cells and important for their function. Without functional Treg cells, the activated immune system has little or no halt to the inflammatory process. Tolerance, in normal hosts, is mediated by these regulatory T-cells, as well as B lymphocytes, natural killer T-cells and dendritic cells that secrete

transforming growth factor (TGF-β), interleukin (IL)-10, interferon (IFN)-α/β, and prostaglandin J2. Another mechanism for regulation is the secretion of anti-inflammatory cytokines. As these cytokines are defined, they are being evaluated for methods to increase their secretion or for systemic therapy with the cytokine itself to treat IBD.

Transforming Growth Factor-Beta

TGF-β belongs to a family of multifunctional polypeptides produced by a wide variety of lymphoid and non-lymphoid cells. They exist in five different isoforms, three of which are expressed in mammals and designated as TGF-β1, TGF-β2, and TGF-β3 [1].

TGF-β can act in both autocrine and paracrine modes to control the differentiation, proliferation, and state of activation of immune cells. TGF-β can inhibit the production of and response to cytokines associated with CD4+ Th1 T-cells and CD4+ Th2 T-cells [118]. TGF-β inhibits the proliferation of T-lymphocytes by downregulating predominantly IL-2 mediated proliferative signals. It also inhibits the growth of natural killer cells in vivo and deactivates macrophages. Of significance, TGF-β has been shown to be important in stimulating the development of FOXP3$^+$ T regulatory cells from naïve CD4+ T-cells.

These activities have been verified by animal models of IBD [119]. These studies indicate that TGF-β production is relevant in the pathogenesis of experimental colitis. In two different models of Th1-mediated murine experimental colitis, it has been shown that protection from colitis development is strictly associated with the presence of increased numbers and/or upregulation of TGF-β1-producing cells. In these studies, T-regulatory cells were first characterized by the surface marker CD25 and that transfer of CD4$^+$ T-cells depleted of CD4$^+$CD25$^+$ cells into recipient mice recovered their ability to induce intestinal inflammation in a murine cell transfer colitis model [120]. Recently, further studies revealed that these CD25+ T-cells are indeed the same T regulatory cells which bear the more familiar marker FOXP3. In addition, it has also been shown that TGF-β can be expressed on the surface of CD4$^+$CD25$^+$ T regulatory cells in association with latency-associated peptide (LAP), and it is LAP molecule, which mediates CD4$^+$CD25$^+$ T cell suppression in in vitro suppression assays, and furthermore, that CD4$^+$LAP$^+$, but not CD4$^+$LAP$^-$, T-cells can convey protection against the development of colitis in murine intestinal inflammatory models [121]. Recently, a novel therapy targeting TGFβ expressing cells has been evaluated [122]. The target of this therapy is the expression of Smad7; Smad7 has been shown to inhibit the signaling of TGFβ in the setting of inflammation [123, 124]. The pharmaceutical Mongersen (GED0301) has been developed as an anti-sense RNA to inhibit the expression of Smad7. By inhibiting the expression of Smad7, there is an increase in TGFβ expression and concurrent decrease in inflammation. Unfortunately, treatment with Mongersen did not meet the Phase III study endpoints.

The Th17 T-cell pathway or specifically a major component of this pathway, IL-23, has been demonstrated to negatively influence regulatory T-cell development and/or responses. It has been demonstrated that IL-23p19-deficient mice exhibit an increased number of T regulatory cells in the colon [125]. Furthermore, the numbers of FOXP3$^+$ T regulatory cells in the colon of Rag$^{-/-}$-recipient mice (mice lacking T- and B-cells) reconstituted with IL-23 receptor-deficient T-cells are increased [47]. Thus, these findings show that IL-23 skews the development of inflammation by mediating Th17 effector cell responses and by inhibiting FOXP3$^+$ regulatory T cell differentiation. Recent studies, however, have demonstrated that a cytokine constitutively expressed by epithelial cells, in the response to tissue damage, namely IL-33, enhances regulatory T cell stability and function in murine transfer cell colitis [80]; moreover, T regulatory cells, which lacked the IL-33 receptor (ST2) were shown to be unable to protect mice from development of colitis in the aforementioned transfer colitis model [126]. Of note, an important role for the transcription factor GATA-3 was found in regulatory T-cell function [127, 128] as ST2 expression in T regulatory cells was significantly dependent on GATA-3 [126]. Importantly, as noted above, IL-33 is found in inflamed tissues of IBD patients and may function to bring inflammation under control via T regulatory cell differentiation.

In humans, the data pertaining to regulatory cells remain sparse. Maul et al. [129] have shown that there exists a decrease in FOXP3-expressing cells in the periphery of IBD patients. However, examination of mucosal tissue reveals that as compared to controls, IBD patients had a relative increase in these cells albeit this increase was less than that seen in other inflammatory disorders such as diverticulitis. The authors postulated that there is a relative lack of counter-regulation in IBD patients at the mucosal level and therefore an inability to increase the number of local resident regulatory cells in the face of inflammation. Similarly, in studies conducted in children naïve to treatment, it was demonstrated that the percentage of CD4+ T regulatory of the inflamed CD or UC intestine is increased as compared to that from control individuals [130]. Furthermore, in CD, an increase in Treg numbers could be secondary to affects from local dendritic cell subpopulation, which expresses increased amounts of the integrin αVβ8, an integrin that activates TGF-β [131].

More recently, transcriptional gene network analysis revealed a close association of FOXP3 with EZH2 [132]. EZH2 is a gene that participates in DNA methylation and

therefore transcriptional repression. Mutation or overexpression of EZH2 has been associated with many forms of cancer as EZH2 inhibits genes responsible for suppressing tumor development. In studies pertaining to regulatory cell generation and function, potential coordinated functions between FOXP3 and EZH2 were identified. Genetic ablation of EZH2 resulted in T regulatory instability and conversion to Th1/Th17 effector cells in a murine model. Furthermore, these T regulatory cells failed to ameliorate DSS or T-cell-mediated colitis. Thus, it was suggested given the above information that the defect in IBD may not be due to a failure in regulatory cells enumeration but suppressive function. In follow-up studies, however, FOXP3+ Tregs from IBD patients have been demonstrated to have normal capacity to suppress effector cells [133].

This, however, led to further studies to elucidate whether a deficiency in other suppressor TGF-β associated cells might cause disease. This appears not to be the case, as Butera et al. demonstrated that FOXP3-negative suppressor cells occur that bear surface TGF-β in association with latency-associated peptide (LAP) and that these cells regulate the extension of disease in UC [134].

Interleukin-4

IL-4 is produced mainly by a subpopulation of activated T-cells (Th2), which are the biologically most active helper cells for B-cells and which also secrete IL-5 and IL-6. Another subpopulation, Th1 also produces IL-4 albeit to a lesser extent. IL-4 is a stimulatory molecule for both B and T cells that has known immunosuppressive effects in the intestine and it promotes the proliferation and differentiation of activated B-cells and the expression of MHC class 2 antigens.

IL-4 enhances the expression of MHC class 2 antigens on B-cells. It can promote their capacity to respond to other B-cell stimuli and to present antigens for T-cells. While IL-4 is frequently described as an anti-inflammatory cytokine, recent studies have shown its capacity to perpetuate inflammatory diseases. Specifically, in a murine model of ileitis, a monoclonal antibody against IL-4 was shown to suppress disease severity [135]. Interestingly, IL-4-mediated disease in certain animal models appears to be most important in inflammation limited to the ileum and small intestine [136]. In the aforementioned oxazolone model of colitis, IL-4 is the predominant initial cytokine to appear in the mucosal lesions; however, this is subsequently superseded by an IL-13 response. This coincided with what one sees in the IBD disease entities as no significant measurable secreted levels of IL-4 have been found in either UC or CD patients to suggest a pathogenic role. Thus, IL-4, as with IL-13, displays both anti-inflammatory and inflammatory cytokine properties. Its targeting it for therapy in animal studies has had some beneficial effects. Its targeting in human disease is not as clear.

Interleukin-10

IL-10 is a critical regulator of intestinal homeostasis and has been shown to inhibit pro-inflammatory cytokines and activate regulatory T-cell function and gene expression. IL-10 is produced by activated $CD8^+$ peripheral blood T-cells, by T-helper $CD4^+$ T-cell clones after both antigen-specific and polyclonal activation. IL-10 is also produced by macrophages, dendritic cells, and B-cells. IL-10 affects both innate and adaptive immune cells modulating multiple functions of pro-inflammatory cells. IL-10 inhibits the synthesis of a number of cytokines such as IFN-γ, IL-2, and TNF-α in Th1 T-helper subpopulations of T-cells but not of Th2 T-helper cells. This activity is antagonized by IL-4. The inhibitory effect on IFN-γ production is indirect and appears to be the result of a suppression of IL-12 synthesis by accessory cells. In the human system, IL-10 is produced by, and downregulates the function of, Th1 and Th2 cells. In macrophages stimulated by bacterial lipopolysaccharides, it inhibits the synthesis of IL-1, IL-6, and TNF-α by promoting, among other things, the degradation of cytokine mRNA. It also leads to an inhibition of antigen presentation. The activation of macrophages can be prevented by IL-10. In human monocytes, IFN-γ and IL-10 antagonize each other's production and function. IL-10 has been shown also to be a physiologic antagonist of IL-12. In macrophages stimulated with bacterial lipopolysaccharides, IFN-gamma increases the synthesis of IL-6 by inhibiting the production of IL-10.

In B-cells activated via their antigen receptors or via CD40, IL-10 induces the secretion of IgG, IgA, and IgM. This effect is synergized by IL-4, while the synthesis of immunoglobulins induced by IL-10 is antagonized by TGF-β. It has been shown that human IL-10 is a potent and specific chemoattractant for human T-lymphocytes. Finally, IL-10 also inhibits the chemotactic response of CD4(+) cells, but not of CD8(+) cells, toward IL-8. In support of its role in IBD, mice deficient in IL-10 (IL-10−/−) gene spontaneously develop chronic colitis. In humans, patients with mutations in IL-10 or the IL-10 receptor (IL-10R) develop a severe form of IBD presenting in the first year of life demonstrating a critical anti-inflammatory pathway in IBD [137, 138]. Identifying one of the first known etiologies for Very Early Onset Inflammatory Bowel Disease (VEOIBD). Understanding of the etiology of this monogenic IBD identified a therapy for patients with defects in IL-10 or IL-10R using allogeneic hematopoietic stem cell transplant [139]. With this information, recombinant IL-10 has been used as therapy in patients

with CD. While initial studies appeared positive, upon further evaluation in larger clinical trials, results were not noted to be significant. Due to the concern that IL-10 was not delivered in significant quantities to the local mucosal level, another approach was attempted using "Turbo Probiotics." This was done by engineering *Lactobacillus lactis* to secrete IL-10 specifically at the intestinal level. A similar construct has been tried in patients with IBD, but results are lacking.

Interleukin-22

Interleukin-22 (IL-22) is a member of the IL-10 cytokine family [140]. IL-22 has been shown to induce proliferative, anti-apoptotic pathways as well as assist in tissue repair [141] and production of antimicrobial peptides [142]. IL-22 is secreted by both innate immune cells (NK cells and dendritic cell) as well as adaptive immune cells such as $CD4^+$ and $CD8^+$ cells. However, because its receptor is predominantly found on innate cell populations, it appears to regulate these cells and not adaptive immune cells [143]. IL-22 has been identified as an antimicrobial and pro-regenerative cytokine in IBD. This cytokine activates its function via the JAK/STAT pathways, specifically the STAT3 activation [144] appears to be quite strong similar to other IL-10 family members.

IL-22 is produced by a wide variety of cells, in innate lymphoid cells [145] in an IL-23-dependent manner, while it is produced by $CD4^+$ T-cells in an IL-6-dependent manner. Specifically, Th1 and Th17 cells [146] have been shown to secrete IL-22 after exposure to IL-6 and this secretion is somewhat inhibited by TGF-β. In addition, there is another Th cell type identified in human peripheral blood, which is defined by IL-22 secretion without IL-17 or IFNγ secretion now termed the Th22 cell [147], although their role is not well understood in the intestinal immune response.

Recent studies have identified a protective effect of IL-22 in IBD. In multiple models of colitis including epithelial cell disruption models as well as T-cell-mediated models of colitis, lack of IL-22 expression worsened the colitis or delayed recovery [148] and injection of IL-22 could ameliorate severe colitis. IL-22 also affects the production of antimicrobial proteins, which can protect against pathogenic bacteria and other infectious agents [149]. Although increased levels of IL-22 have been observed in patients with IBD, its effect may be altered in that it is accompanied by increased production of antagonistic IL-22 Binding Protein (BP) [150]. In humans, IL-22 has been associated by GWAS with multiple susceptibility genes including IL-23, IL-23R [151], as well as the IL-22 gene location within the ulcerative colitis risk locus at 12q15 [152]. No human studies to affect IL-22 expression or function are ongoing at this time in IBD, but studies in other diseases such as psoriasis are ongoing [153].

Summary

As evidenced above, there are a multitude of cytokines that are involved in the inflammatory response of the mucosa in inflammatory bowel disease. These cytokines can have pleiotropic effects including pro- and/or anti-inflammatory effects and are important in the pathogenesis of IBD as well as other autoimmune diseases. The above described cytokines are those that were deemed most significant to inflammatory bowel disease, but there are multiple other cytokines that are currently being evaluated or are as yet unknown that may in the future be targets for therapy of IBD.

The Gut Microbiota and Inflammatory Bowel Disease

4

Máire A. Conrad, Gary D. Wu, and Judith R. Kelsen

Abbreviations

AIEC	Adherent and invasive *E. coli*
AMP	Antimicrobial peptide
CD	Crohn disease
CDI	*C. difficile* infection
EN	Enteral nutrition therapy
FMT	Fecal microbiota transplantation
GWAS	Genome-wide array studies
IBD	Inflammatory bowel disease
ILC	Innate lymphoid cells
MAP	*Mycobacterium avium* subspecies *paratuberculosis*
NLR	Nucleotide-binding domain and leucine-rich repeat-containing receptor
NOD1	Nucleotide-binding oligomerization domain protein 1
PAMP	Pathogen-associated molecular pattern
PRR	Pattern recognition receptor
SCFA	Short-chain fatty acids
TLR	Toll-like receptor
TNF	Tumor necrosis factor
UC	Ulcerative colitis

Introduction

Inflammatory bowel disease (IBD), comprised of Crohn disease, ulcerative colitis, and indeterminate colitis, is a chronic inflammatory disease of the gastrointestinal tract. It is due to an aberrant immune response to environmental factors in a genetically susceptible host. The gut microbiota and its metabolites are thought to be critical environmental factors in the development of IBD. As a result of these different disease drivers, within the IBD subtypes, the phenotype and disease course are quite heterogeneous [1].

There is significant evidence to support the role of gut microbes in the development of IBD. Animal studies of IBD have demonstrated that germ-free animals show little sign of inflammation [2]; however, inflammation develops with exposure to microbes [3]. Adaptive immune responses to bacterial antigens have been shown to lead to the spontaneous development of colitis through immune activation and/or the loss of immune tolerance in various models [4]. From a clinical standpoint, inflammation in CD and UC occurs predominantly in the terminal ileum (in CD) and colon (both UC and CD) where the greatest concentrations of bacteria are found. Antibiotics can have efficacy in the treatment of IBD [5–7], and recently, therapy using a combination of antibiotics has been shown to be effective in patients with severe colonic disease [8, 9]. Furthermore, the fecal flow exacerbates IBD, and surgical diversion of the flow ameliorates the disease [10, 11]. From a more descriptive standpoint, studies have found that there are increased amounts of bacteria in the mucus layer in biopsy specimens of patients with IBD as compared to controls [12]. However, genetic studies have provided some of the strongest support for the role of microbiota in the development of IBD. Genome-wide association studies (GWAS) have identified >200 genetic risk loci, with 28 shared between CD and UC [13, 14]. Many of the genes and genetic loci identified involve pathways which are critical for the protection of the host against the gut microbiota, such as regulation of the epithelial barrier, microbial defense, and autophagy, as well as pathways involving regulation of the innate and adaptive immune systems [13]. Together, these aberrations support the notion that IBD is due to the inability of the host to protect against microbial invasion combined with an unrestrained immune activation.

Characteristics of the Gut Microbiome

The human gut microbiome is one of the most densely populated bacterial communities on Earth with up to 10^{11} organisms per gram of fecal weight composed of over 1000 species, most of which are obligate anaerobes [15, 16]. The bacterial concentration, as well as complexity, increases proximally from the stomach and duodenum, where there are approximately 10^2–10^3 aerobic organisms/gram luminal contents, to 10^{11}–10^{12} distally where anaerobic organisms predominate in the cecum and colon [4]. Throughout, the collective genome of the bacteria is 100-fold greater than that of its human host [17]. Indeed, humans should be viewed as a biologic "supraorganism" that is dynamic and carries out functions in parallel or cooperatively. Roles of the microbiota include immune education and metabolism. Although there are over 50 bacterial phyla on Earth, a majority of the bacteria in the human adult gut largely belong to one of four phyla, *Actinobacteria*, *Firmicutes*, *Proteobacteria*, and *Bacteroidetes* [18, 19].

Most gut microbes are obligate anaerobes, many of which are fastidious and difficult to grow in vitro making traditional culture techniques of limited value in characterizing the composition of the gut microbiota. The development of culture-independent methods, mainly through the use of high-throughput DNA sequencing, has provided new means to evaluate the gut microbiome and its relationship to IBD. There are two primary methods that utilize deep-sequencing technologies to characterize the microbiome. The first approach uses small-subunit ribosomal RNA (16S rRNA gene sequences (for Archaea and Bacteria) or 18S rRNA gene sequences (for eukaryotes)) as stable phylogenetic markers to define the lineages present in a sample [20]. Another approach uses shotgun metagenomic sequencing. This sequences the total community DNA, thereby allowing for the microbial community structure and genomic representation of the community to be evaluated. The genomic community evaluation provides an understanding of the functions encoded by the genomes of the gut microbiota [17]. Metatranscriptomics and metaproteomics provide a deeper understanding of microbial function through direct evaluation of gene expression [21].

These advances in sequencing technologies have allowed investigators to characterize the bacterial composition of the gut throughout different stages of life, a critical step in the study of health and disease. Colonization of the gut begins at birth, and individual characteristics of the gut microbiome begin to arise during infancy and throughout the first year of life. This process is dependent on several factors including the mode of delivery and form of infant feeding. During the first year of life, the human gut microbiome becomes more stable and adult-like [22] concurrent with the introduction of solid foods into the diet [23]. Interindividual differences in the characteristics of the bacterial microbiota observed early in life, within months, persist at 1 year of life [22]. Indeed, interindividual differences in the gut microbiome are the largest source of variance among healthy individuals that appear to be relatively stable over time, at least in the short term [18].

Characteristics of the Gut Metabolome

With ongoing characterization of the composition of the gut microbiota community structure, further studies have interrogated how it actively impacts host function through their produced metabolites. These are central to the mutualistic relationship that can ultimately result in a state of health or disease.

The metabolic products of the microbes are likely even more diverse than the microbiome, and they function as regulators of the immune system, neuronal signaling molecules, and even maintain homeostasis in the microbial community structure of the gut through their antimicrobial properties. These functions are carried out in part through fermentation of indigestible carbohydrates to produce short-chain fatty acids (SCFA) that are utilized by the host, biotransformation of conjugated bile acids, synthesis of certain vitamins, degradation of dietary oxalates, and education of the mucosal immune system [24]. Butyrate, along with other SCFA, is a primary energy source of enterocytes that can be transported intracellularly and activate anti-inflammatory signaling to maintain homeostasis. Bile acids, on the other hand, require bacteria for deconjugation. Bile acids have direct antibiotic effects on microbes in the intestine and indirect effects through FXR-induced antimicrobial peptides. Generated insight into the dynamic microbial environment in the gut has shown that the mutualistic relationship is mediated through the host microbe cross-talk at the mucosal interface.

Targeted and untargeted metabolic profiles can be obtained with various chromatographic techniques, including mass spectrometry systems and high-performance liquid chromatography. Targeted metabolomics allows for absolute quantification of a specific set of metabolites, such as bile acids, short chain fatty acids, or amino acids. Untargeted evaluation of the low-molecular weight molecules uses biochemical features such as retention time and mass to charge ratio for annotation and to determine the relative abundances. However, there remains a lack of standard reference material for many metabolites and identification cannot be inferred from fragments of the metabolites [25].

Diet and the Gut Microbiome

Together with increase in incidence of certain diseases, many environmental changes have occurred over the last several decades. These changes in modern lifestyle have been implicated in the alteration of the gut microbiome, including improved sanitation, increase in antibiotic use, less crowded living conditions, decline in *H. pylori*, smaller family size, vaccinations, refrigeration, decline in parasite infections, sedentary lifestyle, cesarean section, food processing, and diet changes [26].

The development of agriculture and domestication of animals have been major factors in recent human evolution [27] with the resultant changes in diet perhaps altering the host–gut microbiome relationship [28]. Over time in industrialized nations, there has been a reduction in fiber consumption with an increase in simple sugars, fats, and proteins. It has been hypothesized that this change in diet may have altered the interaction of the host and the microbiota in a manner that has played a role in the increasing incidence of metabolic disorders [28]. Furthermore, fluctuations in diet may have consequences for the bacteria and the host, allowing for predisposition to invasion or inflammation [29].

There has been recent evidence demonstrating the relationship between the gut microbiota and diet. An analysis of fecal 16S rRNA sequences from 60 mammalian species indicated clustering according to host phylogeny as well as clustering according to diet (herbivore, carnivore, and omnivore) [30]. Cross-sectional studies using shotgun metagenomic sequencing have suggested that there has been a functional evolution of the gut microbiome in relation to diet [31]. Microbial genes encoding for enzymes involved in carbohydrate and amino acid metabolism are dissimilar between herbivores and carnivores [31].

A study by Wu et al. focusing on the effect of diet on the gut microbiome revealed differences in the impact of habitual long-term versus short-term diet [32]. Long-term diet, similar to a "Westernized" diet (high in meats and fats, low in carbohydrates), was associated with high levels of *Bacteroides* and low levels of *Prevotella* genera. Diets high in carbohydrates but low in animal protein and fat had higher levels of the *Prevotella* and lower levels of *Bacteroides*. These results provide an explanation for previously described clustering of individuals into "enterotypes" dominated by *Bacteroides* and *Prevotella* based on the composition of the gut microbiota and not correlated to host properties such as age, gender, ethnicity, or body mass index [33]. These observations are also consistent with a study comparing the gut microbiome of children from a village in the West African country of Burkina Faso to those in Europe [34] where the inverse relationship between *Bacteroides* and *Prevotella* genera was also noted. These three studies suggest that long-term diet helps to distinguish a gut microbiota community or enterotype that is associated with a "Westernized" diet rich in *Bacteroides* from an enterotype associated with an agrarian diet where the bacteria of the *Prevotella* genus predominate. In addition, studies of monozygotic twins to assess host genotype influences on enterotypes showed most twin pairs had similar enterotypes longitudinally, although many of these subjects likely share similar diets and environments [35]. Enterotypes may function as a marker of disease; however, further studies are needed.

Gut Microbiota–Host Interactions at the Mucosal Interface

The alteration of the gut microbiota has a direct effect on the host's immune system. Mammalian hosts have coevolved to exist with our gut microbiota through a mutualistic relationship, where the host provides a uniquely suited environment in return for physiological benefits provided to the host by its gut microbiota [24]. Indeed, when viewed as a whole, the "supraorganism" of the gut can carry out enzymatic reactions distinct from those of the human genome and harvest energy that would otherwise be lost to the host. The consequences of these enzymatic reactions suggest that over the millennia, mammalian metabolism, physiology, and disease have shaped and have been shaped by the gut microbiota. Commensal bacteria may also directly inhibit the growth of specific pathogens, such as *Clostridium difficile*, by competitive inhibition thus preventing an adequate niche for expansion.

Relevant to pediatric IBD, the gut microbiota develops between birth and the first few years of life and each exposure during this time impacts the microbial structure. This may be particularly germane to very early onset IBD, as this dynamic period is the time that the disease develops. Further evidence supporting the role of the microbiome in VEO-IBD is the drastic increase in incidence of this population, which cannot be explained alone by the strong genetic drivers identified in this population. The relationship between host genetics and developing microbiome has been shown through germ-free (GF) murine models. GF mice have underdeveloped gut-associated lymphoid tissue. In an environment with specific defined flora, the gut microbiota elicits host-specific T-cell response and differentiation [36]. Concurrently, the aberrant T-cell development of GF mice shapes the gut microbiome, as seen by the different phylogenetic compositions of the microbiota in Rag1-deficient mice [37]. Zebrafish models show similar findings, in which Rag1-deficient zebrafish had overgrowth of *Vibrio* species [38].

In general, the interaction between the gut microbiota and the mammalian host is complex but can be roughly divided into

three major categories: the innate immune system, the adaptive immune system, and the intestinal epithelial interface.

The Innate Immune System

The innate immune system rapidly responds as the first line of defense against invading microbes. It encompasses receptors that recognize the microbial patterns, pattern recognition receptors (PRRs), serve as sensors of pathogen-associated molecular patterns (PAMPS) and reside in the lumen of the intestine [39]. The most studied PRRs are the Toll-like receptors (TLRs). PRRs are expressed on many cell types and activate an inflammatory response via NF-κβ activation, cytokine production, and recruitment of acute inflammatory cells [40]. TLR signaling in the intestine is important in homeostasis of the intestine through a variety of functions including epithelial cell proliferation [41], IgA production [42], antimicrobial cytokine production and peptide expression, and maintenance of tight junctions [43]. Nucleotide-binding domain and leucine-rich repeat-containing receptors (NLRs), another class of innate immune receptors, have the ability to respond to different stimuli with an inflammatory response. Examples of NLRs include nucleotide-binding oligomerization domain protein 1 (NOD1) and NOD2. NOD2 is highly expressed in monocytes and Paneth cells, and its ligand is common to both Gram-positive and Gram-negative bacteria. Rehman demonstrated via murine models that NOD2 is integral in the interaction between the host and the microbiota and for the development of the intestinal flora [44]. Disruptions in TLR and NLR expression have also been associated with intestinal dysbiosis [45, 46]. Notably, *NOD2* was the first gene associated with the susceptibility for Crohn disease.

The Adaptive Immune System

Innate immune signaling through the activation of PRRs or NLRs cannot distinguish between commensal and pathogenic bacteria. The adaptive immune system, involved in both humoral and cell-mediated immunity, has evolved to regulate immune responsiveness by selectively responding to or ignoring individual antigens based on previous encounters [47]. A lack of this immune tolerance results in unrestrained immune activation and subsequent inflammation in the absence of a microbial pathogen, the hallmark of immune-mediated diseases such as IBD. Studies in germ-free mice demonstrate that the gut microbiota plays a critical role in helping to shape adaptive immune function through the production of IgA [48], development of Th17-producing lymphocytes [49], as well as T regulatory cells [50], which play a critical role in the maintenance of immune tolerance [51].

In addition, innate lymphoid cells (ILCs) are innate immune cells without antigen-specific responses. There are three types, and they are functionally associated with T-cells with lymphoid lineage that also regulate effector T-cell response against commensal organisms. Group 3 ILCs are RORγt+ and produce IL-22 and/or IL-17 with stimulation by IL-23 and IL-1ß. ILCs are regulated by commensal organisms as the production of IL-22 is reduced in the absence of the microbiota [52]. Similar to the innate immune system, multiple gene variants associated with IBD involve components of the adaptive immune response including T- and B-cell regulation and the IL-23/Th17/T regulatory cell axis [13].

The Intestinal Epithelium

The intestinal epithelium functions as a physical and chemical barrier to separate the luminal gut microbiota from the host, by example through mucus secretion, and functions as an immune response. It produces antimicrobial peptides (AMPs) such as defensins, lysozyme, C-type lectins, and cathelicidin, some of which are produced by Paneth cells located at the base of small intestinal crypts [53]. Human genetic variants associated with IBD have been identified in a number of these pathways demonstrating that alterations in host innate immune protection from the gut microbiota play a role in the development of IBD. Among these include genes involved in epithelial barrier function, restitution, and solute transport as well as genes known to have an effect on the biology of Paneth cells [13, 54]. With respect to the latter, genetic polymorphisms in ATG16L1, associated with Crohn disease, lead to alterations in Paneth cells in both mice and humans that have functional consequences predisposing mice to the development of intestinal inflammation in response to bacteria and viruses [54, 55]. Paneth cell products, such as defensins, not only protect the host mucosal surface but can also help to shape the composition of the gut microbiome [56].

IBD and the Human Gut Microbiome

Epidemiological evidence provides strong evidence for the role of the environment in the pathogenesis of IBD. Over the last several decades, there has been an increase in the incidence of inflammatory bowel disease that is too rapid to be attributed solely to genetic factors. The association with residence in or immigration to industrialized nations [57], the consumption of a "Westernized" diet rich in fat and red meat [58], and the use of antibiotics at a young age [59] all implicate an alteration in the gut microbiota as a possible etiologic factor that may be playing a role in the increased incidence of IBD. Further support of this notion is the "hygiene hypothesis" suggesting that humans living in more

industrialized societies are exposed to fewer microbes or less complex microbial communities at an early age leading to the development of an immune system less able to "tolerate" exposure to the microbial-laden environment in later life resulting in inappropriate immune activation [60].

Several theories have been suggested to explain the role of the gut microbiota in the pathogenesis of IBD: (1) specific microbial pathogens that induce intestinal inflammation, (2) host genetic defects in containing commensal microbiota in combination with defects in host mucosal immunoregulation, and (3) dysbiosis of commensal microbiota (4). Multiple studies have been performed evaluating the role of specific bacteria in the development of IBD, such as *E. coli* and *Mycobacterium avium* subspecies *paratuberculosis* (MAP). In CD, there have been consistent findings of increased mucosa-associated *E. coli* in both the ileum and colon. The *E. coli* isolated in CD is often an adherent invasive *E. coli* (AIEC) phenotype, which is characterized by the invasion of epithelial cells and replication within macrophages [61] without causing cell death and induces the secretion of the tumor necrosis factor (TNF)-α [61, 62]. CD-associated AIEC strains are also capable of adhering to ileal enterocytes in patients with CD, however, not from control enterocytes [63].

MAP has also been implicated as a causal organism in the development of IBD. It is the known cause of Johne's disease in cattle which, similar to the histologic appearance of human CD, leads to chronic granulomatous enteritis. Multiple studies have explored the role of MAP in CD; however, controversy remains whether this organism indeed has a causal role. Some studies have shown remission in patients who have been treated with anti-MAP therapy; however, many argue that this has not proven causality. A large randomized controlled trial using combination antibiotics which have proven efficacy against MAP was performed by the Australian Antibiotic in Crohn Disease Study Group, but there was no significant effect on long-term maintenance of remission [64]. The recent Phase 3 clinical trial of RHB-104 for the treatment of Crohn disease in the United States also showed an increase in clinical remission as compared to those on placebo and mildly increased durable clinical remission through 52 weeks (RHB104 18.7% vs. placebo 8.5% $p = 0.0077$). Criticism of these studies remain that patients were not assessed for the presence of MAP prior to initiation of therapy. Thus far, the use of cutting edge sequencing technology has not yet identified improved our ability to detect MAP in patients with Crohn disease. As further studies are performed in MAP and IBD, perhaps a better understanding of this relationship will come to light [61].

The intestinal microbiome in patients with IBD is characterized by decreased microbial diversity and increased abundance of pro-inflammatory organisms. Multiple studies in patients with CD have demonstrated a reduction in the abundance of the phylum *Firmicutes* [62, 65–69]. Specifically, *Faecalibacterium prausnitzii*, a *Firmicutes*, has been found to be decreased in IBD, including pediatric Crohn disease [70–72]. Furthermore, a decrease in *F. prausnitzii* was predictive of recurrence of disease in patients with CD undergoing ileal resection. There have also been studies that have shown a decrease In the presence of *Faecalibacterium prausnitzii* in fecal samples and biopsy specimens [70, 73]. In animal studies, *F. prausnitzii* can induce an anti-inflammatory response by increasing IL-10 as well as produce short-chain fatty acids, both of which may protect against the development of intestinal inflammation [62]. Concurrent with a reduction in *Firmicutes*, multiple studies have reported a concomitant increase in the abundance of *Proteobacteria* (including *E. coli*) [69, 74, 75] and *Enterobacteriaceae* [76, 77].

To control for the influence of genetics on the microbiome, there have been several studies performed comparing the microbiota of twin pairs. Dicksved and colleagues compared the intestinal microbiome of identical twins concordant or discordant for CD. Total bacterial diversity was decreased among patients with CD. Within twin sets, both healthy twins and twins concordant for CD had closely matched bacterial community profiles. In comparing the twin pairs discordant for CD, however, there was a difference between the fecal microbiome of those with CD and the healthy twin. This suggests that the structure of the bacterial communities is more closely associated with the disease activity rather than the genetics of the host [78]. In another study focusing on twins, Willing and colleagues characterized gut microbial communities in 40 twin pairs who were concordant or discordant for CD or UC. There were differences in the bacterial communities of patients with CD, and there were phenotypic differences as well among ileal and colonic disease as compared to the healthy subjects. There was a decrease in two genera of core commensals in patients with ileal CD, *Ruminococcaceae* family (including *Faecalibacterium*) and *Roseburia* (a member of the *Firmicutes* phylum) [79]. Consistent with prior studies, there was an increase in *Enterobacteriaceae*, including *E. coli* in some of the patients with ileal CD [80].

The alterations in the gut microbiome that are associated with IBD are often described as being "dysbiotic," implying that there is a functional imbalance between enteric bacteria with potentially pathogenic influences and bacteria who have a benign or beneficial effect on the host [81]. There is currently no clear evidence to confirm this notion in humans. An alternative explanation is that the observed alteration in the gut microbiome of patients with IBD is simply a consequence of the intestinal inflammatory response without consequence to the host. Additionally, in a human study of pediatric ulcerative colitis, evaluation of normal terminal ileum biopsies revealed a loss of goblet cells, depletion of

the mucous layer, and loss of bacterial diversity despite a lack of inflammation in the sampled location, which may be due to a systemic effect to the gut epithelial lining independent of local inflammation [82].

There is, however, evidence for a functional effect of a "dysbiotic" intestinal microbiota in animal models. Investigators studying mice deficient in the immune regulatory transcription factor T-bet observed alterations in the intestinal microbiome that occurred simultaneously with the development of spontaneous colitis. Transfer of this bacterial community induced colitis in wild-type mice [83]. In a follow-up study, the investigators identified the presence of *Klebsiella pneumoniae* and *Proteus mirabilis* correlated with colitis in these mice [84]. Mice deficient in another immune regulator, the NLRP inflammasome, also develop spontaneous colitis, the susceptibility to which can also be transferred to wild-type mice [45]. Together, these studies suggest a causal role for the microbiota in IBD.

Beyond understanding the microbial contribution to the onset of IBD, longitudinal observational studies have begun to elucidate how the gut microbiome of children with inflammatory bowel disease changes over time. These changes may be able to be used as biomarkers in conjunction with clinical, genomic, and immunologic profiles for monitoring disease progression and stratifying risk of disease complications. Multiple studies have identified dysbiosis patterns in fecal microbial communities in a subset of treatment naïve pediatric IBD subjects [85–87]. Predictors of response to treatment, disease severity, and remission or progression of disease would greatly improve clinicians' ability to personalize therapy for this complex disease. The RISK study, a large multicenter inception cohort of pediatric Crohn disease, followed newly diagnosed patients for 3 years in order to create a risk stratification model using clinical, genomic, and serologic markers for complicated Crohn disease phenotype. In addition, they identified ileal microbiota signatures associated with these complicated disease phenotypes, but integration of microbiota data into the risk stratification model requires future studies [88, 89]. The PROTECT study of treatment naive children with ulcerative colitis collected stool samples for 52 weeks after diagnosis and identified microbial changes at baseline and shifts during follow-up that were associated with achieving remission as well as progression to colectomy within the first year [90]. There was expansion of *Veillonella dispar* and other organisms typically detected in the oral microbiome along with the previously described pro-inflammatory microbes, including *Enterobacteriaceae*, with more severe disease, more extensive disease, and higher risk of colectomy within the first year after diagnosis.

Diet, IBD, and the Gut Microbiome

Several investigators have examined the association of dietary patterns and the incidence of IBD [58, 91]. A systematic review of this subject found consistent results showing that high dietary intake of total fats, polyunsaturated fatty acids, Omega-6 fatty acids, and meat was associated with an increased risk of CD and UC; high fiber and fruit intakes were associated with a decreased CD risk; and high vegetable intake was associated with a decreased UC risk [91]. These studies support a potential role for dietary patterns in the pathogenesis of IBD. Together with the recent data characterizing the impact of diet on the gut microbiome and its association with enterotypes [32], it is tempting to speculate that the alteration of gut microbiota community structure through the consumption of agrarian versus a "Westernized" diet may play a role in either reducing or increasing, respectively, the risk for the development of IBD. This notion would be consistent with the increased incidence of IBD localized globally in more industrialized societies.

The Gut Microbiota as a Therapeutic Strategy

Probiotics and Prebiotics

Possible beneficial strategies for the treatment of IBD include probiotics, prebiotics, or a combination of both, synbiotics. Probiotics are defined as living microorganisms that, when administered in adequate concentration, confer a health benefit on the host [92]. Probiotics have been shown to be effective in the treatment of pouchitis and possibly in other forms of UC, but the benefits are often not sustained for the long term [93–96]. Although evidence for the efficacy of probiotics, mainly *Lactobacillus* and *Bifidobacterium*, in the treatment of IBD is currently equivocal, their beneficial effect in animal models is more consistent [97]. Possible mechanisms of action include the production of bacteriocins [98], the alteration of luminal pH of the intestine thereby altering the growth characteristics of some bacteria [99], the enhancement of epithelial barrier function through the production of SCFA, a primary source of energy for colonocytes [100], and mucosal and systemic immunomodulation by inducing anti-inflammatory cytokines, T and B regulatory cells, and reducing inflammatory cytokines [51, 101]. Numerous other proposed mechanisms of action have recently been reviewed [93, 100]. Prebiotics have also been investigated in the use of treatment of inflammatory bowel disease. Prebiotics are nondigestible food substances that stimulate the growth and/or activity of bacteria as well as the production of SCFA

[100]. Prebiotics have been used with probiotics; this combination is called synbiotics. Several prebiotics that have been studied extensively and accepted in the European Union include fructooligosaccharides, galactooligosaccharides, and lactulose. The difficulty with these substances is ensuring the bacteria selectivity, i.e., only bacteria beneficial to the host will ferment the oligosaccharide and that the products of fermentation will promote the growth and activity of nonpathogenic organisms [102]. There have been several clinical trials using prebiotics, including inulin and curcumin, as therapy [103–106], and some have shown promising results.

Enteral Nutrition Therapy

Enteral nutrition (EN) therapy, which has shown efficacy in the induction and maintenance of remission in patients with CD [107, 108], may ultimately provide additional support for the role of diet and the gut microbiota in the pathogenesis of IBD. As discussed in a separate chapter, EN is an attractive therapeutic option compared to pharmacological agents, as there are no serious associated side effects. While proven to be effective as therapy in CD, the mechanism of action of nutritional therapy has not been fully characterized. A recent study of pediatric CD patients on exclusive EN (at least 90% of total caloric intake by dietary formula) compared to partial EN (53% by formula) was superior at improving symptoms and quality of life as well as inducing mucosal healing, suggesting that the elimination of solid table foods may be the key to why EN is therapeutic [109]. In addition, the alteration of the gut microbiota may be another possible mechanism of action. In the same study of pediatric CD patients, effective EN therapy changed the microbiota within 1 week and reduced the dysbiosis seen initially [86]. Further investigation into the metabolic profiles of these patients' stool implicated the role of nitrogen metabolism in the disease-associated dysbiosis and its correlation with the presence of Proteobacteria species [110]. Leach and colleagues evaluated the fecal microbiome of patients with CD who were treated with EN and compared them to healthy control subjects on a regular diet [89]. Prior to initiation of EN, the two cohorts had similar diversity of bacteria present. At the 8-week follow-up, there was a significant reduction in diversity in the stool of the patients treated with EN that was sustained for several months following completion of therapy. Small studies have demonstrated shifts in the microbiota coincident with trends toward remission but larger controlled studies of dietary therapeutic interventions, such as the Crohn disease exclusion diet, specific carbohydrate diet, or anti-inflammatory diet are still needed [111, 112]. The success of nutritional therapy highlights the importance of characterizing the interactions among diet, the gut microbiota, and the mucosal immune system.

Bacterial Engineering

Another treatment in IBD utilizing the microbiome is bacterial engineering. In 2000, *Lactococcus lactis* was genetically engineered to secrete hIL-10 into the intestinal tissue in murine models. Colitis was prevented in IL-10 knockout mice, and there was a 50% reduction in inflammation in DSS-induced chronic colitis [113]. Additionally, *L. lactis* expressing IL-27 has been more effective than the IL-10 producing bacteria or systemic administration of IL-27 in mouse models of colitis by increasing production of IL-10 in the intestinal epithelium [114]. Similarly, *Bacteroides ovatus* has been engineered to deliver TGF-β with good results in murine models [115]. Other bacteria have been modified to counteract TNF-alpha and reactive oxygen species [116, 117]. There are ongoing trials of several live biotherapeutics in humans for the treatment of IBD.

Fecal Transplantation

Fecal microbiota transplantation (FMT) is another microbiota-based therapy that involves collecting stool from a healthy donor, preparing it in one of several ways, and transferring it to a patient with a disease or dysbiotic condition. The goal of FMT is to restore bacterial diversity through the microbiota of a healthy person. This healthy flora outcompetes *C. difficile* and produces secondary bile acids and antimicrobials that inhibit its growth. There remains no clear consensus regarding the mode of administration of fecal material. Possible delivery methods include upper endoscopy, nasogastric tube, nasointestinal tube, pill ingestion, colonoscopy to deliver to proximal colon, sigmoidoscopy, rectal tube, retention enema, or a combined approach. Patient comfort, safety, and cost-effectiveness should be considered when choosing how to deliver the material.

FMT was first safely described in humans in 1958 in the treatment of fulminant pseudomembranous enterocolitis [118]. Since then, there have been many published cases of *C. difficile* infection (CDI) and FMT, specifically for the treatment of recurrent or refractory CDI, which have been successful [119–121]. Multiple systemic reviews of fecal transplantation for CDI have demonstrated it to be well tolerated, and effective with a mean cure rate of 87–90% and as high as 100% worldwide [122–124]. Moreover, the new healthy microbiota environment appears to be durable [121, 125]. While there have been few serious adverse events associated with FMT especially in children, there are risks related to infections and the still unknown risks associated with changing the recipients' microbiota in the long term. In June 2019, the FDA issued a safety alert regarding the transmission of extended-spectrum-beta-lactamase-producing *E. coli* to two adult patients, one whom died, which prompted more

stringent screening requirements from the FDA. In addition, further screening has been recommended for SARS-CoV-2 due to concern for transmission as well. These developments have highlighted the importance of careful consideration of the indication for FMT and screening before proceeding. In pediatric cases of recurrent CDI, there is limited data regarding safety and efficacy, but an 86–92% cure rate has been reported without serious adverse events [126–128].

The effect seen in CDI may be possible in other dysbiotic conditions, particularly IBD. In 1989, Bennet and Brinkman published the first report of successfully treating UC with FMT, when Bennet successfully treated his own colitis [129]. In 2003, Borody and colleagues treated six patients with moderate to severe UC with FMT. All patients responded and remained in remission from 6 months to 13 years and had mucosal healing on endoscopy [130]. A review of several small studies of FMT as therapy for IBD showed mixed results, although the majority achieved clinical remission at least in the short term, none had serious adverse events, but there were several accounts of fever, chills, and gastrointestinal symptoms after, and one study reported worsening UC after FMT [131]. The largest studies of FMT for UC were randomized, placebo-controlled trials using FMT to induce remission in patients with mild to moderate UC which had mixed results regarding efficacy [132, 133].

A recent study showed that adult patients with IBD and parents of children with IBD were willing to consider fecal transplantation as therapy and felt that this was a safer option than many of the standard therapies [133]. In pediatric IBD, the use of FMT has shown clinical benefit for a small cohort of 7/9 subjects with CD via nasogastric administration but not for UC subjects [134]. As with most pediatric therapies, the long-term consequences of FMT are unknown and should be better understood before implementing in conventional practice. There are currently no standard protocols, and further larger controlled studies are necessary; however, this therapy, perhaps with a more targeted microbiota, may hold promise for IBD as we learn more about the role of the gut microbiota and IBD pathogenesis.

Conclusions

Inflammatory bowel disease has been associated with both genetic and environmental factors. It has shown a dramatic increase in incidence over the past several decades. Effects of environmental changes in modern lifestyle, such as diet, sanitation, vaccinations, and antibiotics, have contributed to an alteration in the gut microbiome. While gut microbes very likely play a large role in the pathogenesis and propagation of the disease, their exact role requires further elucidation. The challenge remains to identify genetic, immunologic, environmental, and microbial triggers of disease development. As technologies such as DNA sequencing, metagenomics, transcriptomics, proteomics, and metabolomics continue to advance, along with the development of more sophisticated biocomputational tools, mechanisms by which the gut microbiota plays a role in the pathogenesis IBD will be better elucidated. In turn, this may provide novel insights into microbial-based methodologies that can be used to effectively prevent or treat IBD.

5 Immune Dysregulation Associated with Very Early-Onset Inflammatory Bowel Disease

Judith R. Kelsen, Trusha Patel, and Kathleen Sullivan

Introduction

The immunologic component to IBD has been recognized for many years. The strong association with specific MHC haplotypes underlies the presumption that T cells are involved in the pathogenesis [1, 2]. Additionally, the serologic biomarkers also acknowledge that B cell responses are aberrent [3–5]. Nevertheless, the exact pathogenesis of IBD remains elusive and even more so for VEO-IBD. Two lines of recent evidence support the hypothesis that immunologic dysfunction is fundamental to both the development and perpetuation of IBD. Genome-wide association studies have identified over 160 variants in teenage and adult cohorts and the majority of those variants map to immunologically relevant genes [6–8]. These common variants are thought to synergistically interact with the microbiome to induce a state of susceptibility to IBD [9]. Some of these variants have independently been demonstrated to be associated with either impaired epithelial function or activation of immunologically competent cells [10, 11]. The effect size of each variant is rather small, however, and it has been difficult to define the precise pathophysiologic contribution related to each independent variant. On the other side of the spectrum, monogenic disorders occur in which the penetrance of IBD is high. Understanding the mechanisms driving these rarer monogenic disorders has dramatically enhanced our understanding of IBD. A critical aspect of VEO-IBD is the hypothesis that genetic variants with a high penetrance for IBD dominate the susceptibility in young children, while adult-onset IBD is dominated by common variants with much lower relative risks for disease (Fig. 5.1).

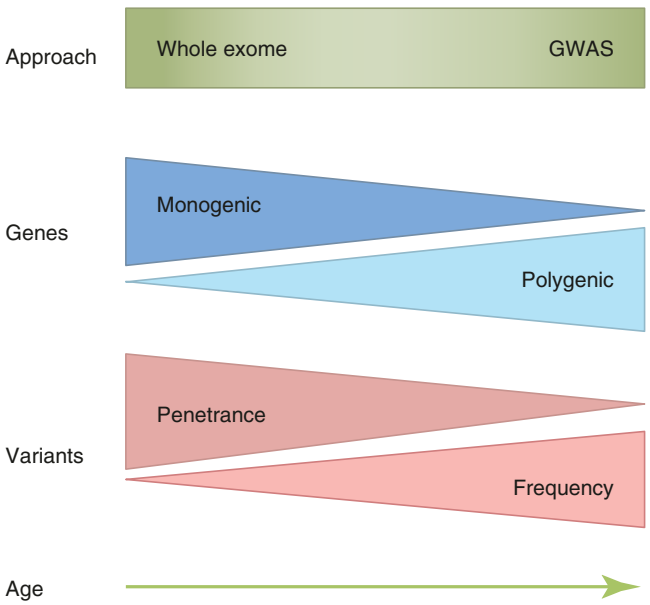

Fig. 5.1 Inheritance and penetrance of variants related to IBD. VEO-IBD is thought to be enriched for monogenic disorders, whereas adult-onset IBD has a polygenic inheritance with contributions from multiple variants, each of which may confer only a small increase in risk

Genomics and VEO-IBD

Inflammatory bowel disease (IBD), comprised of Crohn disease, ulcerative colitis, and indeterminate colitis, is a multigenetic and environmentally triggered disease resulting in a dysregulated immune response to commensal or pathogenic microbes that reside in the gastrointestinal tract [6, 12–17]. Patients with IBD exhibit local and systemic immune reactivity to various microbes, and as a result or inherently, have significant alterations in the composition of intestinal commensal bacteria, and can become colonized with pathogenic or opportunistic bacteria [18–25]. The multifactorial nature and environmental contribution to IBD are largely responsible for the increased incidence over the last several decades [26]. It is not surprising, therefore, that the genetic contribution to the disease largely involves host defense with recognition and response to microbes. Genome-wide association studies (GWAS) have supported this host–microbe relationship, and most of the identified >230 IBD-associated risk loci [8] are involved in host defense. Several genes located within the IBD-associated loci are critical in regulation of host defense, involving both the innate and adaptive immune response toward microbes [8]. However, GWAS studies were primarily performed in adult-onset IBD and children 10 years of age and greater, whose disease, as noted above, is most frequently a polygenic complex disease. Furthermore, GWAS often do not capture rare variants, specifically those with minor allele frequency (MAF) less than 5%. Therefore, these studies do not account for the subset of children with VEO-IBD who underlying rare or novel monogenic defects [6, 27–29].

While VEO-IBD is a heterogeneous population, including children with mild disease, some patients with VEO-IBD can present with distinctive disease phenotypes, including extensive and more severe disease than older children and adults [30, 31], as well as systemic disease manifestations. In addition, due to poor response to conventional therapies, severity of inflammation, and greater duration of disease, there are higher rates of morbidity in this population [29, 30, 32]. The aggressive disease phenotype, early age of onset and strong family history of disease, led to the identification of causal monogenic defects, often involving genes associated with primary immunodeficiencies and epithelial barrier in a proportion of children with VEO-IBD [33, 34]. Monogenic VEO-IBD was first recognized in 2009 with the discovery that mutations in IL-10R, and subsequently several *IL-10* [35], *IL-10RA, and IL-10RB* [29] variants, led to the specific phenotype of neonatal onset IBD with severe perianal disease, extraintestinal disease, and colitis. Since that time, numerous additional underlying immunodeficiencies or genetic disorders have been identified in children with VEO-IBD [30, 34]. Some examples include variants in genes that cause common variable immunodeficiency (CVID), Wiskott–Aldrich syndrome (WAS), Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX), X-linked inhibitor of apoptosis (XIAP), and chronic granulomatous disease (CGD) [30, 32, 36].

Studying consanguinity and targeted genetic sequencing has been an extremely valuable approach to allow the identification and characterization of genetic variants associated with VEO-IBD. However, these approaches alone may not identify novel and rare gene variants. Increasingly, whole-exome sequencing (WES) has led to the discovery of additional genes and pathways associated with the disease [36–40], and expanded our understanding of the pathogenesis of VEO-IBD. In recent years, whole-genome sequencing (WGS) has been incorporated into the pipeline for genetic discovery in VEO-IBD to further investigate variants in non-coding, regulatory regions of the genome that may be pathogenic as well.

While WES and WGS have revolutionized our ability to study rare variants and determine the genetic basis of disease, understanding the relevance of identified variants has remained challenging. The individual patient's phenotype may be shaped by mode of inheritance, epigenetics and gene–gene interaction. Environmental modifiers, such as the intestinal microbiota, antibiotic exposure, infection or diet, also significantly impact disease phenotype [27, 37]. Due to the clinical presentation, often of severe disease, together with the challenge of identifying the unique pathogenesis of the disease, the appropriate evaluation is critical patients with VEO-IBD. Indeed, in the setting of increasing recognition of the challenges of evaluation and treatment for this unique group of patients, a recent position paper from North American Society for Pediatric Gastroenterology Hepatology and Nutrition reviews factors that should trigger concern for underlying immunodeficiency in VEO-IBD, suggests immunological assays and genetic studies that can facilitate identification of underlying diagnosis and emphasizes the importance of targeted treatment approaches in the right context. [41].

Clinical Presentation of Very Early-Onset (VEO) IBD

Pediatric IBD has increased in incidence and prevalence and this phenomenon has included very young children [26, 42, 43]. VEO-IBD remains relatively uncommon, approximately 6–15% of the pediatric IBD population is less than 6 years old, and disease in the first year of life is rare [26, 43]. A subset of patients with VEO-IBD present with a phenotype that is distinct from older children and adults, including extensive colonic disease (pancolitis) that it is frequently difficult to differentiate ulcerative colitis (UC) from Crohn disease (CD). Due to the frequent extension of disease, to involve small bowel and perianal disease, (Table 5.1) [30, 43], indeterminate colitis is diagnosed more often in patients with VEO (11–31%) [44] as compared to older onset IBD (4–10%) [45–48]. In comparison, in older onset IBD (older children >6 and adults), CD is more prevalent (55–60%), while approximately 30–35% of VEO-IBD patients are diagnosed with CD [44].

Table 5.1 Differences between VEO-IBD and older-onset IBD

VEO-IBD	Older-onset IBD
Disease presentation Predominately colonic Ileal involvement <20% Extensive at presentation	Disease presentation Ileocolonic Less extensive at presentation
Disease classification CD: 30–35% UC: 35–39% IC: 11–22%	Disease classification CD: 55–60% UC: 40–45% IC: 4–10%
Histology Villous blunting Apoptosis	Histology Villous blunting/apoptosis rarely seen
Positive family history 40–50%	Positive family history 10–20%
Therapeutic response to conventional therapy Decreased	
Surgical intervention 70%	Surgical intervention 55%

The work-up in this population, similar to older patients, includes laboratory, radiologic, and endoscopic evaluation (Table 5.2). The laboratory studies should include not only routine screening utilized for IBD diagnosis, but also an immunological evaluation as well. This includes vaccine titers, immunoglobulin profiles, analyses of B and T cell function, and a dihydrorhodamine (DHR) flow cytometry assay for chronic granulomatous disease. Potential further targeted phenotyping and functional profiling of the systemic and mucosal immune system will be guided by the individual patient presentation. Diagnosis at a very young age should trigger concern for a monogenic-driven disease, particularly in IBD diagnosed less than 2 years of age. Marked growth failure and poor response to conventional therapies are more commonly seen in children with VEO-IBD than in older children with IBD as well [44, 49]. Furthermore, extensive family history, including history of disease in male family members (such as in X-linked disease), history of infection, skin disease, or autoimmunity can help guide appropriate laboratory screening. As shown below and in Table 5.2, initial screening laboratory studies such as inflammatory markers and complete blood count may point to the underlying defect, such as elevated inflammatory markers or neutropenia, which may represent a monogenic disorder causing functional defects in neutrophils, such as glycogen storage disease type 1b, leukocyte adhesion deficiency, or congenital neutropenia.

Table 5.2 Primary immune deficiencies associated with IBD

Category	Gene name	Name of immune deficiency	Prevalence of IBD	Characteristics of IBD in this syndrome	Other features of the disorder	Other autoimmune manifestations
Central tolerance	AIRE	APECED	≈10%	Enteropathy with villous blunting	Candida, malabsorption	Autoimmune polyendocrinopathies
	RAG1/2	SCID, Leaky SCID	≈50%	Not reported	Low CD4/CD45RA cells, infections	Autoimmune cytopenias, skin disease, vasculitis, neuropathy, interstitial lung disease
Peripheral tolerance	FOXP3	IPEX	≈90%	Villous atrophy		Diabetes, autoimmune polyendocrinopathies
	STAT5b	STAT5b deficiency	Unknown	Villous atrophy	Post-natal growth retardation, lymphocytic interstitial pneumonitis, severe varicella	Arthritis, thyroiditis
	CD25	IL-2RA deficiency	≈90%	Villous atrophy	Viral infections	Various autoimmune manifestations
	CTLA4	CTLA4 haplosufficiency	≈80%	Villous blunting	Hypogammaglobulinemia, infections	Cytopenias, arthritis, thyroiditis, dermatologic manifestations, granulomatous lung disease
	LRBA	LRBA deficiency	≈60%	Typical IBD and small bowel disease	Hypogammaglobulinemia, infections	
Apoptosis defects	FAS (TNFRSF6), FASLG (TNFSF6), somatic mutations of FAS in 30%	ALPS	≈1%	Not reported	Adenopathy, hepatosplenomegaly	Autoimmune cytopenias
	CYBA, CYBB, NCF1 < NCF2, NCF4	CGD	≈10–50%	Villous blunting with acute inflammation common, pigmented macrophages in half, granulomas in half, eosinophils prominent in 25%	Fungal infections, abscesses	ITP rarely
	XIAP	XLP2	≈20%	Granulomas	HLH, hypogammaglobulinemia	None
Lymphocyte signaling defects	PLCG2	PLAID	≈5%	Not reported	Skin granulomas, cold urticaria, infections, hypogammaglobulinemia	Autoantibodies, thyroiditis, vitiligo
	AID	AR Hyper IgM syndrome	≈5–10%	Not reported	Adenopathy, high IgM, low IgG	Autoimmune cytopenias, arthritis, hypothyroidism, kidney disease
	DOCK8	DOCK8 deficiency	≈5–10%	Not reported, may be secondary to infection	Severe infections	Vasculitis, autoimmune hemolytic anemia

Category	Gene name	Name of immune deficiency	Prevalence of IBD	Characteristics of IBD in this syndrome	Other features of the disorder	Other autoimmune manifestations
	WAS	Wiskott–Aldrich syndrome	≈5–10%	Not reported	Small platelets with thrombocytopenia, infections, eczema	Hemolytic anemia, vasculitis, arthritis, neutropenia
	NEMO (IKBKG), NFKB1A	Ectodermal dysplasia with immune deficiency	≈25%	Paucity of lymphocytes and relatively superficial neutrophil infiltrate	Infections are severe	Limited
	BTK	XLA	≈5–10%	Not reported	No B cells, hypogammaglobulinemia	Arthritis
Interferon hyper-production by lymphocytes	STAT1 GOF	STAT1 GOF	≈50%	Villous atrophy	Candida and other fungal infections	Diabetes common but other autoimmunity seen frequently
	STAT3 GOF	STAT3 GOF	60%	Villous atrophy	Short stature	Diabetes and other autoimmunity
	STAT3 LOF	Hyper IgE syndrome	≈1-5%	Can be due to infection	Infections, eczema	Rare
Unknown mechanism		CVID	10-20%	Villous atrophy, collagenous colitis, typical IBD all seen	Usually adult-onset, sinopulmonary infections	Autoimmune cytopenias, lymphoproliferation, granulomas
	DNMT3b, ZBTB24	ICF	50% have diarrhea	Not reported	Mild developmental delay, IgA deficiency	Rare

APECED autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia, *SCID* severe combined immune deficiency, *IPEX* immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome, *ALPS* autoimmune lymphoproliferative syndrome, *CGD* chronic granulomatous disease, *XLP2* X-linked lymphoproliferative syndrome 2, *PLAID*, phospholipase C-γ2–associated antibody deficiency and immune dysregulation, *XLA* X-linked agammaglobulinemia, *ICF* immunodeficiency, centromeric instability, facial anomalies syndrome

Genetic Variants Associated with VEO-IBD and Their Immunologic Consequences

Monogenic diseases that can present with the phenotype of intestinal inflammation include those that cause defects of intestinal epithelial barrier function, phagocyte bacterial killing, development and function of the adaptive immune system, and hyper or autoimmune inflammatory disorders [28]. These genetic alterations may differentially influence the development and progression of intestinal inflammation, and therefore these patients will likely exhibit significant heterogeneity in their responsiveness to therapeutic interventions. Below we discuss what we have learned from mouse models and translational patient-based studies, which should be considered when developing therapeutic strategies for these unique patient populations. Increasingly, there is a recognition that treatment strategies for children with VEO-IBD, particularly in those with immunologic alteration, should be personalized based on the individual patient's clinical and immunophenotype, as well as genetic data when available, and management may include therapies not standardly used for the treatment of IBD.

Genetic Variants Influencing Intestinal Epithelial Barrier Function

Mutations in genes associated with maintaining integrity of the intestinal epithelial barrier can present with intestinal inflammation in patients with VEO-IBD. These include loss-of-function mutations in *ADAM17* resulting in ADAM17 deficiency [50, 51], *IKBKG* (encoding NEMO) resulting in X-linked ectodermal dysplasia and immunodeficiency [52], *COL7A1* resulting in dystrophic epidermolysis bullosa [53], *FERMT1 resulting in* Kindler syndrome [54–56], *TTC7A resulting in multiple intestinal atresia* [39], and *EGFR* leading to neonatal skin and inflammatory bowel disease [57]. Gain-of-function mutations may also lead to similar epithelial barrier defects, as seen in the case of *GUCY2* resulting in familial diarrhea [27, 58] and *TGFBR1* and *TGFBR2* leading to Loeys–Dietz syndrome, type 1 and 2, respectively [59, 60]. Mutations in these genes may all lead to an impairment of the intestinal epithelial barrier through distinct pathways, such as limiting epithelial regeneration (*ADAM17*) [61], loss of signaling pathways involved in gene expression (*IKBKG, EGFR, and TGFBR1/2*) [57, 60, 62, 63] altered cell adhesion, barrier formation and apoptosis (*COL7A1*, *FERMT1,* and *TTC7A)* [39, 53–56], or impaired bacterial sensing and ion homeostasis (*GUCY2*) [27, 58]. The intestinal histology of patients with epithelial defects can be helpful in distinguishing the disease from other etiologies of intestinal inflammation. Patients with *IKBKG* (NEMO) defects may have villous atrophy or epithelial cell shedding on pathology [64]. Histology in patients with *ADAM17* mutations may demonstrate hypoplastic crypts in small bowel secondary to a low rate of epithelial production as *ADAM17* is necessary for TGF-α to be cleaved from the cell membrane [65, 66].

The intestinal barrier is necessary to maintain a physical separation between commensal bacteria and the mammalian immune system, and a breakdown in this barrier through multiple distinct pathways can directly promote chronic intestinal inflammation [12, 14]. In addition to genes listed above, intestinal barrier function is maintained through a number of physical and biochemical structures, including mucus production, intestinal epithelial cell tight junction proteins, Immunoglobulin A (IgA), and antimicrobial peptides. In mice, chemical disruption of the intestinal barrier, through administration of dextran sodium sulfate (DSS) in the drinking water, results in dissemination of commensal bacteria and activation of the innate immune system [67]. Chronic exposure to DSS can lead to activation of the adaptive immune response and the development pro-inflammatory, commensal bacteria-specific, B and T cell responses [18, 68], which are similar to those observed in IBD patients [18, 69]. Intestinal epithelial cells play a significant role in directly regulating immunologic homeostasis in the intestine, as mice with intestinal epithelial cell lineage-specific deletion of factors regulating the NFκB pathway, including NEMO and IKKβ, result in susceptibility to chronic intestinal inflammation [62, 63]. Although we know that loss of intestinal barrier function can directly cause intestinal inflammation, additional mouse models and translational patient-based approaches are required to further define how mutations in the above genes specifically lead to a break down in the barrier, and whether we can develop more targeted therapies to restore barrier integrity and limit chronic inflammation.

Genetic Variants Impairing Development of the Adaptive Immune System

Several genetic variants can alter the development or function of adaptive immune cells in a cell-intrinsic or -extrinsic manner. Defects that affect development or function of B cells and T cells occur with loss-of-function mutations in recombination activating genes (*RAG1* or *RAG2*) or the IL-7R (*IL7R*) causing Omenn syndrome, or the *PTEN* gene causing PTEN syndrome. Defects in *RAG1*, *RAG2,* or *IL-7R* can cause cell-intrinsic defects in the development of both T cells and B cells, by blocking either early lymphocyte survival or recombination of the B cell receptor (BCR) or T cell receptor (TCR) [70–72]. Defects in B cell development lead to an absence of circulating mature B cells and antibody production, which have been linked to an IBD phenotype [73]. This includes agammaglobulinemia, which can also occur in

X-linked agammaglobulinemia (XLA) [74] and common variable immune deficiency (CVID), a complex and heterogeneous disease, with the responsible mutations known for only a minority of cases [75]. Loss-of-function mutation in *LRBA* may lead to multiple defects in immune cell populations (including lymphoproliferation, autoimmune cytopenias, and immune deficiency), along with enteropathy and endocrine dysfunction [76]. Related to CVID, antibody deficiency associated with IBD manifestations include IgA deficiency and severe combined immunodeficiency (SCID), which can be secondary to multiple variants that influence the development or function of the adaptive immune system (including *RAG1, RAG2, JAK3, CD45, CD3G, ZAP70, ADA, DCLRE1C, DOCK8*) [28, 73, 77]. Omenn syndrome, a recessive form of SCID, involves abnormal development of B cells and T cells, and can also be associated with intestinal disease as well as severe eczematous rash [77, 78]. In these patients, laboratory studies are significant for increased oligoclonal T cells and reduced B cells, and histology can show an intestinal graft versus host appearance [79, 80]. Aberrant function of immunoglobulins, such as in hyper IgM and Hyper IgE syndromes, can also result in intestinal inflammation and an IBD phenotype [81]. It is currently unclear exactly how these selective impairments of the adaptive immune system can manifest in intestinal inflammation. There is a potential involvement of altered regulatory pathways, or chronic infections with pathogenic and opportunistic microbes. Therefore, additional lines of study are required to further interrogate the link of these mutations to intestinal inflammation.

Wiskott–Aldrich syndrome (WAS) results from a loss of function mutation in Wiskott–Aldrich syndrome protein (*WASP*), and patients can exhibit thrombocytopenia, eczema, immune deficiencies, and intestinal inflammation [82]. The clinical manifestation of patients with VEO-IBD with this genetic defect can be pancolitis in addition to other autoimmune processes. *WASP* is a critical cytoskeleton protein expressed in hematopoietic cells that are required for the normal development and function of multiple cell types [83, 84]. WASP is also requited for peripheral B cell development and function, with subsequent ability to respond to antigens [85, 86]. Laboratory studies of these patients may show thrombocytopenia, low IgM levels, low marginal B cells, and lymphopenia [87]. Snapper and colleagues identified that intestinal inflammation in WASP-deficient mice was critically dependent on inflammatory T cells [88], and may result from an impaired development of regulatory T cells (Tregs) in the thymus and periphery [89]. Surprisingly, these defects are likely occurring in a cell extrinsic manner, as the absence of WASP in cells of the innate immune system directly contributed to the development of inflammatory T cell responses in mice [90]. The causes of intestinal inflammation in other similar patient populations are less well understood, but defects in regulatory T cells, IgA, and abnormal selection of T cell and B cell specificities likely contribute. The clinical manifestations of Wiskott–Aldrich syndrome, including bowel inflammation, have successfully been managed with HCT and, more recently, with gene therapy [91, 92]. Similarly, HCT is an effective management strategy for the systemic manifestations of SCID, hyper-IgM syndrome, and other defects of adaptive immunity [93, 94]. Additional immunological analyses and mouse models, such as those described above, are required to further define the causes of disease and potential therapeutic options in these patient populations.

Genetic Variants Impairing Regulatory T cells

Defects in regulatory T cells can clinically present as colonic disease and well as an enteropathy. The prominence of villous atrophy is a clue to these disorders. Immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) is most often secondary to mutations of Forkhead box protein 3 (*FOXP3*) gene, a transcription factor that is essential for the development and immunosuppressive activity of CD4 FOXP3$^+$ Tregs [78, 95–97]. There are over 20 mutations in *FOXP3* that have been identified in patients with IPEX [96], and patients frequently present with neonatal severe secretory diarrhea, failure to thrive, infection (due to defects in immunoregulation), skin rash, insulin-dependent diabetes, thyroiditis, cytopenias, and other autoimmune disorders [78]. Tregs are absent or dysfunctional in these patients, and in the intestine, histologic analyses may reveal infiltration of inflammatory cells in the lamina propria and submucosa of the small bowel and colon as well as changes in the mucosa of the small bowel [98]. Other genetic defects have been found to cause IPEX-like disease, including loss of function mutations impacting IL-2–IL-2R interactions, STAT5b, and ITCH, or gain-of-function mutations in STAT1, all of which critically influence the development and function of Tregs [78]. Further, Blumberg and colleagues have identified in a novel loss of function mutation in *CTLA4,* a surface molecule of regulatory T cells that directly suppresses effector T cell populations, in VEO-IBD [99].

The mechanisms by which regulatory T cells limit intestinal inflammation are well characterized in mice. Regulatory T cells can develop in the thymus as "natural Tregs" and directly contribute to limiting pro-inflammatory T cells in the intestine [100]. The composition of commensal bacteria influences the repertoire of Tregs [100] and commensal bacteria-specific "induced Tregs" can also be generated in the periphery following sampling of commensal bacteria by dendritic cells in the intestine and migration to the mesenteric lymph node [12, 16, 97, 101]. Once generated, Tregs can then promote intestinal homeostasis through direct regu-

lation of innate and adaptive immune cell responses to commensal bacteria, a process which involves cytokine production, direct cell–cell contact (in part through CTLA4) and sequestering of growth factors [12, 16, 97]. Consistent with a major role for regulatory T cells in limiting pro-inflammatory immune cell responses to commensal bacteria, mice deficient in IL-2 or FoxP3 develop significantly less intestinal inflammation when maintained in germ-free versus conventional housing conditions, but exhibit comparable levels of systemic autoimmunity [102, 103]. Evidence also suggests that the balance of tissue-specific IL-23 and IL-33 expression in mice is critical in regulating the function of regulatory T cells in the intestine and ability to limit chronic inflammation [104], although the role of these pathways in human VEO-IBD has not been extensively examined.

Genetic Variants in the IL-10-IL-10R Pathway and Related Cytokine Family Members

Homozygous loss of function mutations in *IL-10* ligand and receptors *IL-10RA* and *IL-10RB* are associated with significant intestinal inflammation, particularly in neonatal or infantile VEO-IBD, with a phenotype of severe enterocolitis and perianal disease [29, 35]. In addition, compound heterozygote loss of function mutations of *IL-10RA* have been reported with neonatal Crohn disease and enterocolitis [105]. IL-10 is an anti-inflammatory cytokine secreted by a variety of cells, including dendritic cells, natural killer (NK) cells, eosinophils, mast cells, macrophages, B cells, and $CD4^+$ T cell subsets (including Th2 cells, Th1 cells, Th17 cells, and Treg) [106, 107]. IL-10 maintains homeostasis through suppression of an excessive pro-inflammatory response and exerts its effect through binding to the IL-10 receptor, IL-10R, which is a tetrameric complex [108]. It is composed of 2 distinct chains, 2 molecules of IL-10R1 (α chain) and 2 molecules of IL-10R2 (β chain) [109]. IL-10 binding to IL-10R activates the JAK1/STAT3 cascade, which subsequently limits pro-inflammatory gene expression [109]. In addition to intestinal inflammation, IL-10 defects are associated with arthritis, folliculitis, and predisposition to large B cell lymphoma [105, 110]. Given that the defects in IL-10–IL-10R interactions predominantly influence the immune system, a potential treatment for these patients is successful hematopoietic stem cell transplantation [111]. Although this can be challenging and typically requires an HLA-identical donor, there has been recent success reported with haploidentical stem cell transplantation; however, non-engraftment complications can occur [112].

An essential role for IL-10 in limiting intestinal inflammation was demonstrated by the spontaneous development of severe colitis in IL-10-deficient mice [113], and studies by Sartor and colleagues identified that the intestinal inflammation in IL-10-deficient mice was entirely dependent on the presence of commensal bacteria [114]. Therefore, IL-10 plays a critical role in limiting dysregulated immune cell responses to intestinal commensal bacteria. The exact cellular sources and targets of IL-10 that contribute to the maintenance of intestinal homeostasis have been less well defined until the recent development of mice that permit conditional deletion of IL-10 and IL-10R. These critical studies have revealed an essential role of regulatory T cell-intrinsic IL-10 expression in preventing intestinal inflammation in mice [115, 116]. Furthermore, IL-10R expression on myeloid cells in mice is critical to elicit anti-inflammatory responses and limit T cell-dependent intestinal inflammation [117, 118]. Critically, patients with loss-of-function mutations in *IL-10RA* or *IL-10RB* also exhibited an impaired ability to differentiate anti-inflammatory myeloid cells in vitro, and rather exhibited increased pro-inflammatory properties, such as elevated expression of IL-6, IL-12, TNFα, MHCII, and co-stimulatory molecules [117]. Although mouse models have provided invaluable insight into human health and disease, it should be noted that mice deficient in *IL-10* do not completely replicate the phenotypes of humans with loss-of-function mutations in *IL-10*, likely due to many confounding factors.

IL-22 is a cytokine that is related to IL-10, shares the IL-10R2 chain with a unique IL-22R1, signals through predominantly STAT3, and also plays a critical role in mediating intestinal homeostasis [119]. However, unlike IL-10, the complete IL-22R is restricted to non-hematopoietic cells, and in the intestine, IL-22 acts almost exclusively on intestinal epithelial cells to mediate innate immunity and intestinal barrier function [119]. IL-22 can be produced by Th17 cells, and more recently has been identified to be predominantly expressed by a previously unrecognized cell type of the innate immune system, termed group 3 innate lymphoid cells (ILC3) [119, 120]. This breakthrough in immunology has led to the identification of other members of the innate lymphoid cell (ILC) family, including group 1 ILCs (ILC1) that express T-bet and pro-inflammatory cytokines TNFα and IFNγ, and group 2 ILCs that express GATA3 and type 2 cytokines IL-4, IL-5, IL-9, and IL-13 [120, 121]. The ILC family exhibits a heterogeneity comparable to that of differentiated CD4 T cell subsets, and plays a profound role in regulating intestinal health and disease in mouse models [119–121]. Critically, recent reports suggest that ILC3 is a dominant source of IL-22 in the intestine of healthy humans, and that dysregulated ILC responses are observed in adult patients with IBD [122–128]. ILC3 expresses MHCII, and that selective deletion of MHCII on ILC3 results in dysregulated CD4 T cell responses and spontaneous intestinal inflammation, suggesting that these cells are essential for regulation of T cell-mediated inflammation in the gut [123]. $MHCII^+$ ILC3 selectively induces cell death of pro-inflammatory, commen-

sal bacteria-specific, CD4 T cells in the intestine. MHCII was reduced on ILC3 from intestinal biopsies of pediatric IBD patients versus non-IBD controls and inversely correlated with levels of pro-inflammatory Th17 cells [129]. In recent years, there is increasing understanding about the role of IL-22 in inflammatory bowel disease [130, 131]. However, much remains to be learned about ILC and IL-22 responses in VEO-IBD, and given the importance of these pathways in mediating intestinal health and disease, it is likely the genetic variations associated with VEO-IBD may differentially influence ILC responses.

Genetic Variants Influencing Bacterial Recognition and Clearance

Chronic granulomatous disease (CGD) is a result of defective intestinal phagocytes, specifically the granulocytes responsible for bacterial killing and clearance [132]. The NADPH oxidase complex is responsible for killing of ingested microbes through its production of the respiratory burst. Mutations in any part of the complex molecules (CYBB, CYBA, NCF1, NCF2, NCF4) can result in intestinal inflammation as well as autoimmune disease [133, 134]. Intestinal inflammation can be observed in as high as 40% of patients with CGD [135–138]. Several variants have been associated with VEO-IBD, in particular, defective NCF2 results in altered binding to RAC2 [139]. These patients can present in the neonatal or first year of life with colitis, severe fistulizing perianal disease, and tructuring [139]. Histology frequently demonstrates multiple granulomas that may not have associated inflammatory change [37]. Critically, a recent study by Muise and colleagues identified that heterozygous loss of function mutations in components of the NADPH oxidase complex can determine susceptibility to VEO-IBD, without directly causing overt immunodeficiency [140]. Other neutrophil defects that are associated with VEO-IBD include Leukocyte Adhesion Deficiency Type I and II caused by mutations in *ITGB2* and *SLC35C1,* respectively [141, 142]. These patients can present with an IBD phenotype, history of bacterial infection, and laboratory studies remarkable for increased peripheral granulocytes [143]. Glycogen storage disease Type 1b, with hallmark features of neutropenia and neutrophil granulocyte dysfunction, can present with intestinal inflammation [144]. The reasons for why CGD and other bacterial processing defects may manifest in intestinal inflammation are poorly understood and warrant additional research. It is possible that the causes include bacterial overgrowth or dysbiosis in the intestine, dysregulated activation of the innate and adaptive immune system, or both. Further, the therapies used to treat such patients need to be carefully considered. For example, anti-TNFα therapy is contraindicated in CGD. Though effective for intestinal disease can increase the risk of severe infections in these patients [145]. Other therapies include leukine, antibiotics, and allogenic hematopoietic stem cell transplantation, which have demonstrated some success [146]. In addition, IL-1R antagonists may be particularly attractive approach to limit disease in mouse models and patients with CGD by restoring autophagy and directly limiting inflammation [147].

Autoimmune and Autoinflammatory Disorders

Several autoimmune/autoinflammatory diseases have been linked with intestinal inflammation in children with VEO-IBD. (Fig. 5.2) These include mevalonate-kinase deficiency [148], familial Mediterranean fever (FMF) [149, 150], Hermansky–Pudlak syndrome [151] X-linked lymphoproliferative syndrome (type 1 and 2) [36, 152, 153], and mutations in *NLRC4*. [154, 155] These diseases occur due to loss of function mutations in an enzyme critical for metabolism (mevalonate-kinase deficiency), cytoskeletal proteins (FMF), proteins involved in organelle fusion or biogenesis (Hermansky—Pudlak syndrome), or proteins involved in

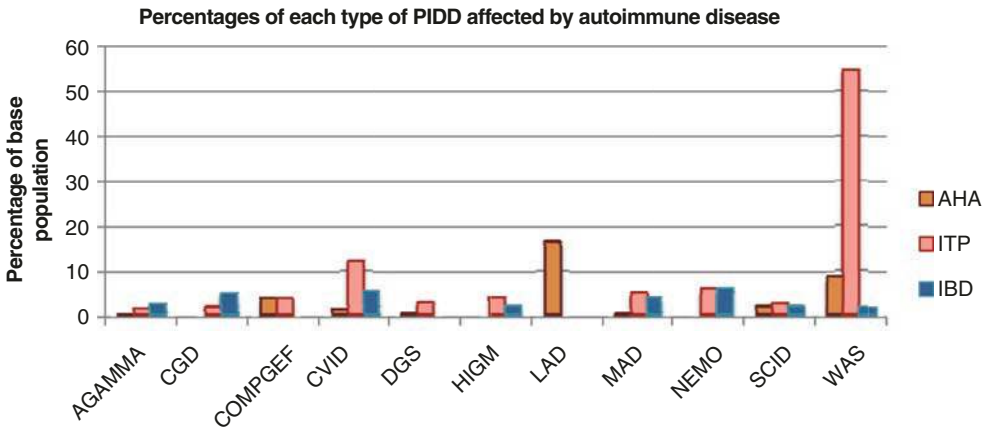

Fig. 5.2 Primary immune deficiencies have an increased frequency of autoimmune disease. The USIDNET registry was used to identify three types of autoimmune manifestations among different types of immune deficiencies. IBD occurs at a low frequency in many of the primary immune deficiencies. There is no strong relationship among the three types of autoimmune disease, suggesting distinct mechanisms of disease

cell signaling or apoptosis (X-linked lymphoproliferative syndrome) or from gain-of-function mutation in *NLRC4* leading to constitutive interleukin-1 family cytokine production and macrophage cell death. While there are many additional clinical manifestations in these patients, twenty percent of patients with X-linked lymphoproliferative syndrome with loss of function defect in the gene X-linked inhibitor of apoptosis protein (*XIAP*), present with VEO-IBD [156]. *XIAP* is involved in NOD2-mediated NFKB signaling, and therefore these children may have an impaired ability to sense bacteria. In addition, as an inhibitor of apoptosis, it prevents apoptosis of activated T cells, thus allowing for expansion and survival of T cells in response to pathogens [157, 158]. Therefore, in XIAP deficiency, due to the inability to clear pathogens, there is a hyperinflammatory state, with increased production of cytokines resulting in an IBD phenotype [156, 158]. Children with these mutations can present with severe colonic and perianal fistulizing disease [36, 159], and of great concern, EBV infection can result in fatal hemophagocytic lymphohistiocytosis [159].

While this is not an exhaustive description of the rare genomic drivers of VEO-IBD, it highlights the different components of the immune system, including innate and adaptive response, involved in this disease. Treatments guided toward the specific defect, such as IL-1 antagonists, colchicine, HSCT, or leukine can be used if the defect is determined. Additionally, monitoring for potential complications associated with a genetic defect is essential, such as in XIAP, IL-10 gene variants, and CGD. In addition to these monogenic diseases, VEO-IBD has been shown to have a high degree of genetic heterogeneity. It is therefore likely that there are more pathways involved in VEO-IBD, and the outcome of therapeutic intervention can be improved through further study and identification of the associated variants. Utilizing next-generation sequencing (NGS) such as WES can improve detection of variants and diagnosis of disease. Further, there is an urgent need to also directly translate genes-to-function and functionally profile the immunological significance of known genetic variations in intestinal inflammation.

Immunologic Considerations

Autoimmune disease in general is strongly associated with variants related to immune deficiency. In a meta-analysis of rheumatoid arthritis, 377 candidate genes were identified as risk loci for rheumatoid arthritis. Among 98 genes with a relative risk greater than 2, 15 of those genes were related to primary immune deficiencies [160]. Therefore, it should come as no surprise that VEO-IBD is similarly enriched with gene defects related to primary immune deficiencies. The study of primary immune deficiencies and their association with VEO-IBD has illuminated the critical and delicate interaction of the immune system with the luminal contents of the gastrointestinal tract. Primary immune deficiencies undoubtedly increase the susceptibility to IBD through multiple mechanisms. Even a mild immune deficiency such as IgA deficiency has a significantly higher rate of IBD than the general population [161]. This may reflect changes to the microbiome due to the lack of selective pressure [162] increased microbial translocation, compromised signaling within the gastrointestinal tract, or stimulation of an aberrant response due to active infection. There are two compelling reasons to further understand defects in genes related to immunologic function in cohorts of patients with IBD. From a purely clinical perspective, identification of patients with monogenic disorders is critical to deliver optimal care. Whether it be through the use of targeted biologic therapy or hematopoietic stem cell transplantation, these patients clearly require a precise, targeted approach to their specific disease state. The second reason for the focus on monogenic disorders is the critical perspective that they provide for the population overall. As was shown above, many of the common variants as well as the monogenic disorders can be categorized according to pathologic pathways that drive the development of VEO-IBD. Even in those patients for which a monogenic cause is not found, these pathways contribute to greater insights and allow better selection of therapeutic approaches.

While defects in epithelial barrier function, lymphocyte signaling defects, regulatory T cell defects, innate responses to infection, and autoinflammatory disorders may seem to represent highly diverse types of defects leading to VEO-IBD, they come together at the epithelial surface where immune responses must be perfectly tuned to prevent inappropriate responses. Increased translocation of bacteria or translocation of inappropriate bacteria, as is the case in dysbiosis, drives an inflammatory loop. An important component of the integrity of the epithelial surface is the contribution of innate lymphoid cells. There are no known monogenic disorders that affect innate lymphoid cells; however, in murine models, their role is now firmly established. These cells contribute to the maintenance of the epithelial layer as well as secretion of antimicrobial peptides and mucins. When this carefully constructed epithelial barrier is penetrated, cells of the innate immune system are activated and recruit additional cells to the inflammatory process. It may be that some of the signaling defects that have been described for conventional T cells also impact the function of innate lymphoid cells and contribute to the susceptibility of IBD through their roles in innate lymphoid cells more substantially than is currently appreciated. Within the lamina propria, T cells and innate lymphoid cells perform an intricate

choreography mediated by the secretion of cytokines. Many of the recognized cytokines are already being targeted through biologic therapies. From this framework, the high impact of the monogenic disorders may be appreciated.

One of the initial strategies to identify patients with primary immune deficiencies is to simply survey their immunologic function, as described above. While many of the defects may not have demonstrable effects on cells within the peripheral blood, many of the monogenic disorders will have an impact that can be appreciated through simple screening studies. Obtaining lymphocyte subsets, testing neutrophil oxidative burst, and evaluating immunoglobulin levels and function represent a reasonable first step. In patients with phenotypic features of specific monogenic conditions, additional functional studies may also be indicated. When suspicion for monogenic disease is high, targeted sequencing panels or whole-exome sequencing (and in some cases whole-genome sequencing) may be pursued. This strategy is now sufficiently available and the consequences of identification of a primary immune deficiency are sufficiently large, that it is appropriate to expend the energy and effort to obtain this type of sequencing.

Perspective and Future Directions in Genetic and Immunologic Analyses of VEO-IBD

In order to advance our understanding of VEO-IBD, sequencing technology must be utilized to completely understand the genetic landscape of this disease, and immunologic studies spanning basic mouse models and translational patient-based approaches are required to determine the contribution of those genetic variations to human disease. Given that dysregulated interactions between the immune system and commensal bacteria underlie the pathogenesis of intestinal inflammation, it is also important to include analyses of composition and function of the microbiome. As these patient populations are studied worldwide, and sometimes in small numbers, international collaborations are needed to integrate genetic, immunologic, and environmental results pertaining to VEO-IBD patients to better understand the effects of different variants within known genes, and identify new gene defects causing IBD through the study of mutations that arise in the same genes of multiple unrelated individuals. With increased understanding of the disease processes operating in VEO-IBD, we can begin to individualize therapies to the specific patient as well as employ unconventional therapies that are not routinely part of the IBD therapeutic arsenal. These approaches could provide a roadmap to establishing a standard of care for this disease and improving patient quality of life.

Part II

Epidemiology and Clinical Features

The Epidemiology of Pediatric Inflammatory Bowel Disease

6

M. Ellen Kuenzig and Eric I. Benchimol

Introduction

The global epidemiology of pediatric-onset inflammatory bowel disease (IBD) is rapidly evolving. Based on studies of adult-onset IBD, a four-stage model has been proposed to describe this evolution: (1) emergence of IBD; (2) acceleration in incidence; (3) compounding prevalence; and (4) prevalence equilibrium (Fig. 6.1) [1]. Compounding prevalence occurs when the incidence of IBD is relatively stable over time, while prevalence continues to grow because the incidence of IBD exceeds mortality rates among IBD patients [2]. If the incidence of IBD were to sufficiently decline in a region such that it approaches the mortality rate, prevalence equilibrium would be reached. Much of the developing world has evolving incidence rates of adult-onset IBD consistent with either the first or second stage of this epidemiologic model; the developed world is in the third stage [1]. Thus far, no world region has reached prevalence equilibrium.

The evolution of IBD in children has lagged the evolution in adults. Specifically, many developed, high-income regions in the Western world remain in a stage of accelerating incidence, with many countries describing a rapidly rising incidence of childhood-onset IBD. Further, a lack of data on the epidemiology of childhood IBD in other regions of the world suggests that the emergence of IBD in children may be anticipated in low- and middle-income countries. This chapter will describe our current knowledge of the epidemiology of IBD, including changing age demographics of IBD within children and ethnocultural (including racial) differences and summarize the importance of studying children to understand how environmental exposures influence the pathogenesis of IBD.

Incidence and Prevalence

There are two metrics that describe the epidemiology of a disease: incidence and prevalence. Incidence is defined as the number of newly diagnosed people in a given time period, most frequently reported as annual incidence per population. Prevalence is defined as the number of people living with a disease at one point in time. A frequently used analogy to describe incidence and prevalence is water filling and draining from a sink. Incidence is analogous to the water flowing from the tap into the sink—higher incidence is analogous to faster flow of water from the faucet resulting in the sink filling more quickly with cases. Prevalence is analogous to the total volume of water in the sink. For a lifelong chronic disease, like IBD, the only mechanism for cases to "drain away" is death or migration out of the population under study. In pediatric studies where prevalence is often defined as number of children living with IBD in the population, aging out of the population (i.e., becoming an adult) will also remove cases from the sink. Because mortality from IBD is low and is far exceeded by the number of new cases, the number of cases accumulating in the sink continues to grow—resulting in a growing total burden of disease.

Regional incidence and prevalence estimates of pediatric-onset IBD are summarized in Table 6.1 and Fig. 6.2. There is wide geographic variation in the incidence and prevalence rates of pediatric IBD internationally. Systematic reviews indicate that the highest incidence rates of pediatric IBD occur in Canada, Northern Europe, the Northern United States, and Israel, but there remains a paucity of data on the epidemiology of pediatric IBD in the developing world [3, 4]. In general, Crohn disease (CD) is more common among children than ulcerative colitis (UC). More recent studies confirm this geographic distribution of IBD with North America, Northern Europe, and Israel continuing to have the highest rates of IBD and the number of countries reporting rates continues to grow. A longitudinal gradient can be observed, with prevalence being much higher in northern regions of Europe than southern regions. Australia and New Zealand have intermediate rates of IBD. Where data are available, countries in Asia and the Middle East indicate lower rates of IBD in children. Pediatric IBD is rapidly emerging in these regions where it was previously unreported or underreported. Despite our growing knowledge of the epidemiology of pediatric IBD, gaps in knowledge remain for many parts of the world.

Changes in Incidence and Prevalence Over Time

Incidence rates of childhood IBD are increasing globally. These increases have been long established in North America and Europe [3, 4]. As more data on the global incidence of IBD come to light, these rates are continuing to increase in North America [5, 6] and Europe [7–11] and being mirrored

Table 6.1 Summary of the most recently reported incidence and prevalence of pediatric inflammatory bowel disease summarized by world region

Region	Countries reporting incidence and/or prevalence	Incidence per 100,000 person-years	Prevalence per 100,000 people
Africa			
Northern Africa	Libya [16]	**IBD:** 0.9	**IBD:** 3.6
Americas			
Caribbean	French West Indies (Guadeloupe, Martinique) [91], Puerto Rico [92]	**IBD:** • <10 years at diagnosis: 0.3 (French West Indies) • 10–19 years at diagnosis: 3.1 (French West Indies)	**IBD:** 24 (Puerto Rico) **CD:** 7 (Puerto Rico) **UC:** 11 (Puerto Rico)
Central America	Costa Rica [93]	**IBD:** 2.96	
North America	Canada [5, 20], United States of America [94] (California [95], Minnesota [96], Texas [27], Wisconsin [19])	**IBD:** 2.4 (Texas) to 10 (Canada) **CD:** 1.3 (Texas) to 6.5 (Canada, Minnesota) **UC:** 0.5 (Texas) to 4 (Minnesota)	**IBD:** 38 (Canada) to 62 (Canada) **CD:** 25 (Canada) to 43 (United States) **UC:** 11 (Canada) to 28 (United States)
South America	Colombia [97]		**CD:** 0.4 **UC:** 0.9
Asia			
Eastern Asia	China [12], Japan [23], South Korea [98], Taiwan [99]	**IBD:** 0.6 (China) to 3.3 (South Korea) **CD:** 0.25 (Taiwan) to 2.8 (South Korea) **UC:** 0.6 (South Korea)	**CD:** 7.2 (Japan) **UC:** 1.5 (Japan)
South-Eastern Asia	Singapore [17]	**IBD:** 4.3 **CD:** 2.1 **UC:** 1.0	
Southern Asia	Sri Lanka [100, 101]		**CD:** • <10 years: 0 to 0.2 • 10–19 years: 0.44 to 3.9 **UC:** • <10 years: 0 to 0.93 • 10–19 years: 1.8 to 2.73
Western Asia	Bahrain [13, 14], Israel [15, 22], Kuwait [102], Saudi Arabia [18]	**IBD:** 0.49 (Saudi Arabia) to 21.6 (Kuwait) **CD:** 0.34 (Saudi Arabia) to 15.3 (Kuwait) **UC:** 0.15 (Saudi Arabia) to 6.0 (Kuwait)	**IBD:** 373 (Israel) **CD:** 9.32 (Bahrain) to 245 (Israel) **UC:** 128 (Israel)
Europe			
Eastern Europe	Czech Republic [103, 104], Hungary [105], Poland [106]	**IBD:** 2.7 (Poland) to 12.5 (Czech Republic) **CD:** 0.6 (Poland) to 6.8 (Hungary) **UC:** 1.3 (Poland) to 4.0 (Hungary)	
Northern Europe	Denmark [107, 108], Faroe Islands [109], Finland [110, 111], Iceland [11], Ireland [112], Norway [113], Sweden [114–117], United Kingdom (England [9], Scotland [118, 119])	**IBD:** 5.0 (Iceland) to 41.5 (Faroe Islands) **CD:** 2.2 (Faroe Islands) to 10.0 (Sweden) **UC:** 2.4 (Iceland) to 12.5 (Finland)	**IBD:** 46.3 (Scotland) to 75.0 (Sweden) **CD:** 29.0 (Sweden) to 39.5 (Scotland) **UC:** 12.5 (Scotland) to 30.0 (Sweden)
Southern Europe	Croatia [120], Italy [121], Malta [122], San Marino [123], Slovenia [124], Spain [10]	**IBD:** 1.4 (Italy) to 9.4 (Slovenia) **CD:** 0.62 (Malta) to 8.69 (Croatia) **UC:** 0.9 (Croatia, Spain) to 9.1 (San Marino)	**IBD:** 31.0 (San Marino) **CD:** 15.5 (San Marino) **UC:** 15.5 (San Marino)
Western Europe	Austria [125], France [7], Germany [126], Netherlands [127]	**IBD:** 5.2 (Netherlands) to 17.4 (Germany) **CD:** 2.1 (Netherlands) to 10.6 (Germany) **UC:** 1.6 (Netherlands) to 6.2 (Germany)	**IBD:** 66.3 (Germany) **CD:** 37.7 (Germany) **UC:** 23.7 (Germany)
Oceania			
	Australia [29, 128–130], New Zealand (NZ) [131, 132]	**IBD:** 5.2 (NZ) to 6.8 (Australia) **CD:** 3.5 (NZ) to 5.9 (Australia) **UC:** 1.0 (NZ) to 1.6 (Australia)	**IBD:** 21.7 (NZ) to 46.0 (Australia) **CD:** 16.5 (NZ) **UC:** 3.3 (NZ)

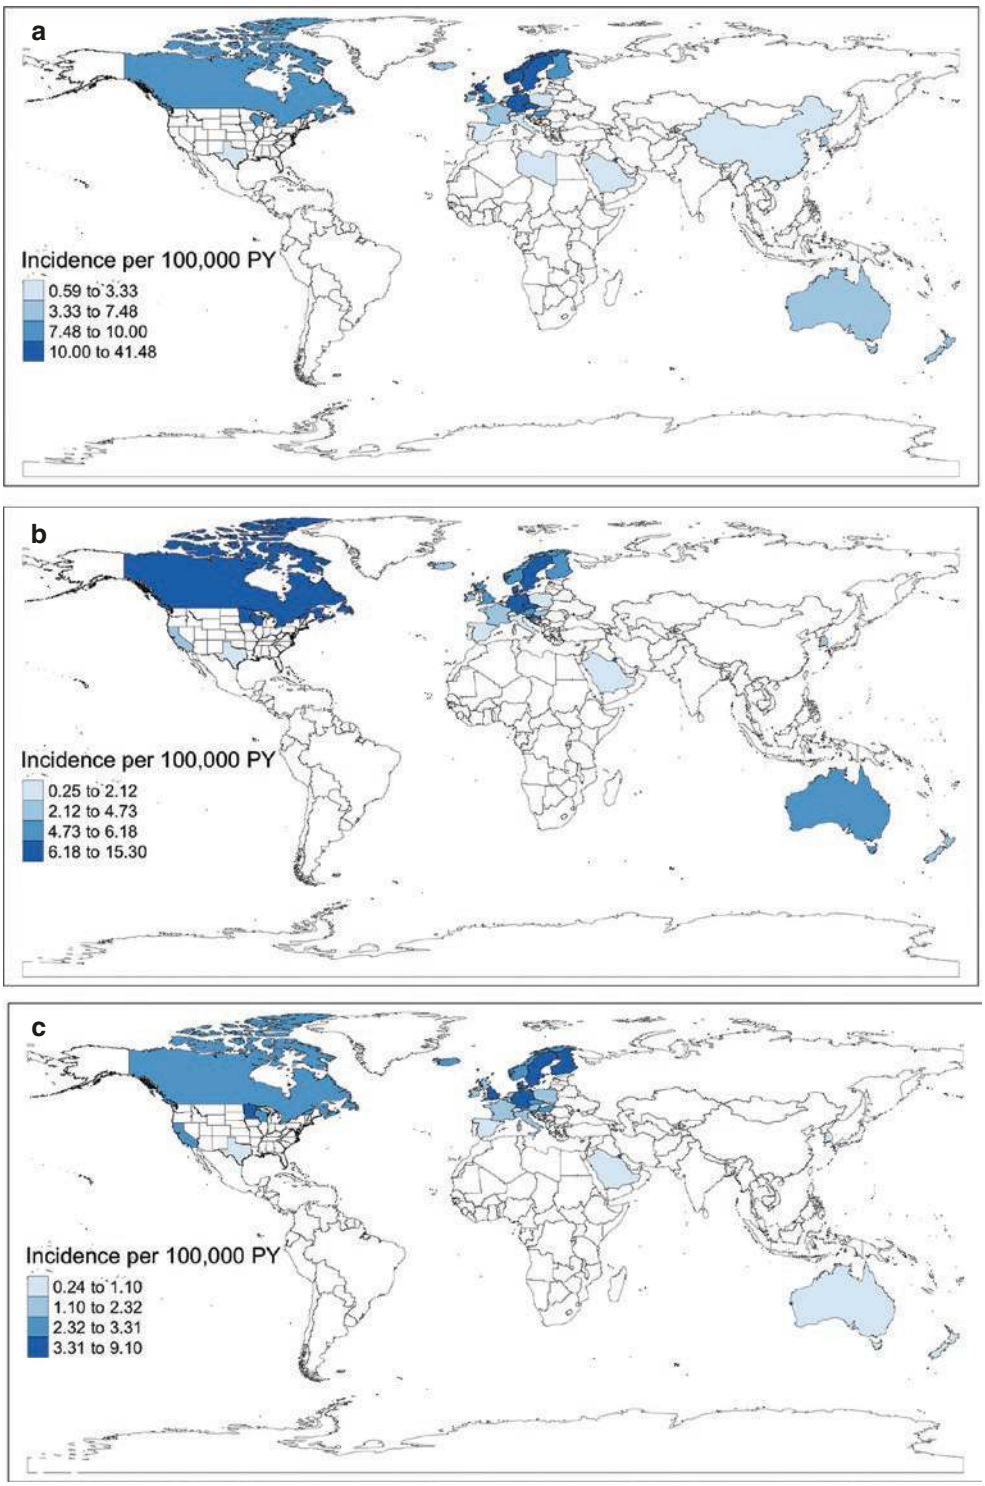

Fig. 6.2 Maps describing global patterns in the incidence of pediatric-onset (**a**) inflammatory bowel disease (IBD); (**b**) Crohn disease (CD); and (**c**) ulcerative colitis (UC)

in other parts of the world, including in China [12], Bahrain [13, 14], Israel [15], Libya [16], Singapore [17], and Saudi Arabia [18]. Incidence rates in Wisconsin, USA remained stable between 2000 and 2007 [19].

Changes in incidence vary by age. For example, incidence of IBD is increasing among Canadian children of all ages [6]; however, this is largely driven by increases in Very Early-Onset IBD (VEO-IBD), defined by IBD diagnosed in children <6 years of age [5]. In Saudi Arabia, incidence of VEO-IBD and VEO-CD have declined over time, but incidence of IBD, CD, and UC have increased among all those diagnosed before their 15th birthday; the incidence of

VEO-UC was stable over this period [18]. France has reported stable rates of VEO-IBD but increasing rates of IBD diagnosed between the ages of 6 and 16, before age 10, and among children of any age [7, 8].

Canada [5, 6, 20, 21], Israel [15, 22], Libya [16], and Japan [23] have reported significant increases in the overall prevalence of childhood IBD over time. Japan reported an increase of 71.4% in the prevalence of CD (4.2 to 7.2 per 100,000) and 36.4% increase in the prevalence of UC (from 11 to 15 per 100,000) between 2004 and 2013 [23]. The prevalence of IBD in Libya increased from 1.2 per 100,000 to 3.6 per 100,000 between 2002 and 2006 [16]. Israel similarly reported increases in the prevalence of CD and UC, with prevalence increasing faster among Arabs than Jews [15]. In Canada, increases in prevalence differ by age group. The most notable increases in prevalence were reported for those <5 years of age and was specific to overall IBD (average annual percentage change [AAPC] +10.7%, 95% CI +3.32 to +18.09) and CD (AAPC +13.14, 95% CI +7.24 to +19.04) [5]. Changes in the prevalence of VEO-UC were not statistically significant (AAPC +5.48, 95% CI −5.01 to +15.98). Increases in the prevalence of CD and UC were similar among Canadian children 5 to 9 years of age (CD: AAPC +9.11, 95% CI +4.38 to +13.84; UC: AAPC +9.98, 95% CI +5.91 to +14.05). The prevalence of overall IBD and CD significantly increased among those 10 to 13 years of age, though the annual increases in this age group were much smaller in magnitude relative to the other age groups (IBD: +3.14%, 95% CI +1.61 to +4.67; CD: +2.99, 95% CI +0.79 to +5.20). There were no significant changes in the prevalence of IBD, CD, or UC among those 14 to 15 years of age.

Projecting the Future Epidemiology of Pediatric Inflammatory Bowel Disease

The availability of large population-based cohorts of IBD patients derived from routinely collected health data has enabled investigators to predict the future burden of IBD. In Canada, the overall prevalence of IBD in children (<18 years) will rise from 62 per 100,000 in 2008 to 159 per 100,000 (prediction interval [PI] 133 to 185) in 2030 [20]. This same degree of projected increase in the prevalence of pediatric IBD (<17 years) was not replicated in Scotland, where the 2018 prevalence was reported to be 106 per 100,000 and the 2028 prevalence is predicted to be 124 (95% CI 80 to 169) per 100,000 [24]. The prevalence of IBD in Portugal is expected to be 4–6-times higher in 2030 than in 2003; however, this study did not forecast pediatric-specific prevalence estimates [25]. These studies predicting future trends in epidemiology are important to understand the future global burden of IBD, as well as to plan for health system changes required to meet the needs of children with IBD. The rising prevalence in some regions will be accompanied by increasing health services utilization and use of biologic medications, resulting in alarming increases in direct health care costs and other resource needs.

Changing Age at Inflammatory Bowel Disease Diagnosis

The differing trends in incidence rates across age groups begs the question: Is the age at which children are being diagnosed with IBD changing? The data needed to answer this question are not clear. An Israeli study reported that the mean age at IBD diagnosis among Jewish children significantly decreased from 15.0 ± 2.8 years for those diagnosed between 2002 and 2008 to 14.3 ± 3.1 years for those diagnosed between 2009 and 2016 [22]. A second study from Israel conducted between 2005 and 2017, including both Jews and Arabs, reported significant increases in the incidence of both CD and UC in children diagnosed between 10 and <18 years but no change in the incidence of CD and UC diagnosed <10 years [15]. In France, an increasing proportion of children were diagnosed with an inflammatory phenotype (64% in 1988–1990 to 87% in 2009–2011) with notable declines in fibrostenotic disease behavior at diagnosis (33% in 1988–1990 to 11% in 2009–2011) [7]. These changes in phenotype over time implies earlier identification of disease, prior to progression from inflammatory to fibrostenotic disease. However, this was not reflected in the analysis assessing age demographics: the proportion of children diagnosed before 10 years of age did not significantly change between 1988–1990 (17.0%) and 2009–2011 (18.7%) [7]. Changes in the age at IBD diagnosis likely resulted from a combination of factors including early disease onset and earlier diagnosis resulting from increasing awareness of IBD in young children and improved access to specialist pediatric gastroenterologist care, endoscopy, and imaging [26].

Ethnocultural Differences in the Epidemiology of Inflammatory Bowel Disease

There are notable differences in the epidemiology of IBD among children of different ethnocultural backgrounds living in the same geographic regions. A study from Texas reported incidence of 4.15 (95% CI 3.48 to 4.82), 1.83 (95% CI 1.14 to 2.51), and 0.61 (95% CI 0.33 to 0.89) per 100,000 person years in White, African American, and Hispanic children, respectively [27]. These rates increased in all groups over the course of the study but the relative increase in incidence was the greatest for Hispanic children. This same study reported a higher incidence of CD relative to UC in all

groups; however, this difference was most pronounced in African-American children. A Wisconsin study reported a similar ethnic distribution among children with IBD to the general population of the state [19].

In Israel, both the incidence and prevalence of pediatric IBD are substantially higher in Jews than in Arabs. However, one study found that the gap has decreased between 2005 and 2018. The prevalence of both CD and UC increased much faster among Arab children (CD: AAPC +6.0%, 95% CI +3.8 to +8.3; UC: AAPC +7.0%, 95% CI +5.0 to +9.2) than among Jewish children (CD: AAPC +1.4%, 95% CI +0.9 to +1.9; UC: +2.9%, 95% CI +2.5 to +3.4) [15].

A study from British Columbia, Canada, described significantly higher incidence of IBD in South Asian children relative to non-South Asian children [28]. In South Asian children, the incidence of IBD increased from 5.95 per 100,000 person-years in 1996 to 18.01 per 100,000 person-years. In non-South Asian children, the incidence increased from 4.44 to 7.73 per 100,000 person-years over the same period. Although the incidence of all IBD types was higher among South Asian children, this difference was highest for UC (South Asians: CD 6.41 per 100,000 person-years, UC 6.70 per 100,000 person-years; non-South Asians: CD 3.69 per 100,000 person-years, UC 0.96 per 100,000 person-years). The majority of IBD cases presenting in South Asian children occurred in second-generation residents (the children of immigrants).

There is a paucity of data on the incidence and prevalence of IBD in indigenous populations, such as Native Americans, Canadian First Nations, and Australian Aboriginal people, although it has been suggested that the risk remains lower in these populations. In Australia, 0.56% of children with IBD have at least one parent of Aboriginal or Torres Strait Islander origin; 4.13% of Australian children are of Aboriginal or Torres Strait Islander origin [29]. Regions of Manitoba, Canada with the lowest per capita rates of First Nations peoples have the highest rates of IBD [30, 31]. The penetrance of IBD susceptibility genes differs in Canadian First Nations peoples and individuals of European ancestry. For example, mutations in *ATG16L1* and *NOD2*—two genes important for bacterial recognition and autophagy—are less common in healthy Manitoba First Nations peoples than Caucasians [32].

Studies of migrants from low to high prevalence countries can also provide valuable information about the risk of IBD in individuals of differing ethnocultural backgrounds. Individuals migrating from low prevalence regions to Western countries remain at lower risk of IBD compared with other residents of those Western countries [33–35]. However, age at immigration may mediate this effect, with those immigrating during childhood or adolescence having an increased risk of IBD relative to those immigrating at older ages [33]. This implies that earlier life exposure to environmental factors in high-prevalence countries increases the risk of IBD. However, even Canadian-born children of immigrant mothers were less likely to develop IBD than children born to non-immigrant mothers [33]. Being an immigrant or child of an immigrant was associated with significantly lower risk of CD, but was less protective for UC. This implies that even in-utero and early-life exposure to the Canadian environment are insufficient to convey risk, despite the high prevalence of IBD in Canada. However, this risk modulation is associated with ethnic background, and therefore genetic risk or protective factors. In the Canadian study, the decreased risk of IBD was most pronounced for those born to parents migrating from East Asia. Children born to parents from the Middle East, South Asia, Sub-Saharan Africa, and Western countries had the same risk of developing IBD as children born to non-immigrant parents [33]. Second-generation immigrants to Sweden were at similar risk to non-immigrants notwithstanding their region of origin [35]. However, there were regional differences in the risk of IBD subtypes, such as in second-generation immigrants from Eastern Europe (increased risk of CD, but decreased risk of UC), Southern Europe (increased risk of UC), and Latin America (decreased risk of CD). No significant associations were identified among second-generation immigrants from other regions, including Asia (although migrants from South and East Asia were not distinguished) [35]. The findings of differential risk of IBD in migrants from different regions indicate important differences in host susceptibility to Western environmental factors and may aid in our understanding of the complex pathogenesis of IBD.

Environmental Risk Factors

IBD results from a complex interaction between an individual's genetic background, environmental exposures, microbiome, the epithelial lining of their intestine, and their immune response to commensal bacteria [36]. This is further complicated by the number of lifestyle and other environmental exposures associated with IBD. A recent umbrella review of meta-analyses identified 43 lifestyle and environmental exposures that were either associated with an increased or decreased risk of IBD [37]. Therefore, the contributing factors in one individual may not have the same impact to another individual's risk of IBD. As a result, identifying environmental risk factors that predispose to the development of IBD remains a challenge. The evolving epidemiology of pediatric IBD will provide extraordinary opportunities to study how shifts in environmental exposures in developing and newly developed regions contribute to IBD pathogenesis.

The Asia-Pacific Crohn's and Colitis Epidemiology Study (ACCESS) was designed to describe the emergence of IBD across Asia and identify environmental risk factors associated with IBD in regions where the prevalence of IBD was

previously low [38–40]. Australia was included in ACCESS to allow for comparisons between risk factors in Asians and those in a Westernized country primarily composed of people of European origin. Although the data generated from this cohort are not specific to IBD in children, they enhance our understanding of how the same environmental risk factors may play differing roles in individuals across ethnocultural backgrounds.

Many environmental exposures that have been hypothesized to be associated with the development of IBD likely modify the intestinal microbiome and these factors may act in concert to influence the microbiome. For example, the development of the intestinal microbiome is jointly influenced by mode of delivery (vaginal or cesarean section), breastfeeding, early-life antibiotic exposure, and other environmental exposures [41]. Because the microbiome is established early in life [42], and children have been exposed to fewer environmental risk factors than adults, we may be able to more clearly identify environmental risk factors contributing to IBD pathogenesis in those diagnosed with IBD in childhood.

The Hygiene Hypothesis

The "Hygiene Hypothesis" has long been postulated to be an explanation for the emergence of IBD and other immune-mediated inflammatory diseases (IMIDs) in developed countries in the twentieth century, and the ongoing emergence of IBD in low- and middle-income countries more recently. This hypothesis posits that early exposure to unhygienic circumstances early in life is important for proper immune system development, with a focus on the role of various environmental microscopic organisms in priming the immune system. Without these exposures, aberrant immune responses develop. In IBD, this is exemplified by excessive immune responses to the commensal intestinal bacteria resulting in intestinal inflammation.

The impact of environmental hygiene on the risk of IBD is often studied by evaluating exposures such as availability of indoor plumbing (e.g., tap water, flush toilets), household crowding (e.g., family size, bed sharing, number of siblings), and household pets. However, studies describing associations between these environmental factors have reached inconsistent conclusions and have not always been congruent with the Hygiene Hypothesis.

The availability of tap water has been associated with a reduced risk of developing IBD in some studies but not others [43, 44]. Among Asian participants of the ACCESS cohort, having a hot water tap and a flush toilet were associated with an increased risk of developing CD in unadjusted analyses (hot water tap: OR 1.48, 95% CI 1.03 to 2.13; flush toilet: OR 1.72, 95% CI 1.15 to 2.57) but neither association persisted when adjusting for sex, age, and country-level gross national income [39]. In contrast, having an in-home water tap, hot water tap, and flush toilet were associated with a decreased risk of UC (in-home water tap: OR 0.60, 95% CI 0.44 to 0.81; hot water tap: OR 0.58, 95% CI 0.43 to 0.78; flush toilet: 0.62, 95% CI 0.46 to 0.83); these associations persisted when adjusting for age, sex, and country-level income [39].

Exposure to animals at a young age may protect against later development of IBD. Growing up on a farm in Manitoba, Canada, was associated with a decreased risk of developing CD but not UC, with no differences noted by type of farm (cattle, pig, or poultry) [45]. This is consistent with another Canadian study demonstrating a strongly protective effect of early-life rural household (compared to growing up in a city) [46]. Having a household pet or exposures to other animals has generally been associated with a decreased risk of IBD [39, 45, 47–49]. Some differences have been noted across studies, with some describing an association that was specific to having a pet before age 5 [45] and the type of pet (e.g., pet dogs decreased the risk of CD but not UC, aquarium fish decreased the risk of UC but not CD) [39]. The association between household pets and risk of IBD appears to be consistent across geographic regions and ethnocultural groups.

Studies describing the associations between household crowding, family size, and birth order have been less conclusive. Inconsistent with the Hygiene Hypothesis, some studies have described an increased risk of IBD with bed sharing, while others have the described protective effects for bed sharing and other measures of household crowding congruent with the Hygiene Hypothesis [43, 47, 50, 51]. Large households, having older siblings, and having younger siblings have been shown to protect against the development of IBD, but this association has not been consistently reported in all studies [44, 45, 47, 49, 50, 52, 53].

Breastfeeding

Systematic reviews have consistently demonstrated a protective association between breastfeeding and pediatric-onset IBD [54, 55]. This decreased risk of IBD among those who are breastfed appears consistent across ethnicities and may exhibit a dose–response effect whereby longer durations of breastfeeding are associated with decreased risk [39]. The impact of breastfeeding is thought to influence IBD risk through modification of the intestinal microbiome. There are marked differences in the microbiome between children who are exclusively breastfed and those who are exclusively formula-fed; smaller differences have also been noted among infants who are exclusively and partially breastfed [56]. Perhaps the most remarkable difference between breastfed

and formula-fed infants is the time to maturity of the intestinal microbiome: the microbiome appears to reach maturity at three months of age among infants who are not breastfed, while maturity is not reached until 12 months of age in those who are continuously breastfed [56].

Cesarean Section

Babies delivered vaginally are exposed to their mother's microbiome at birth. Without this earliest exposure, babies born via cesarean section have an altered trajectory for the development of their microbiome from the time they are born. Consequently, it has been hypothesized that babies born via cesarean section may be at higher risk of developing IMIDs such as IBD. Studies on the association between mode of delivery and the risk of IBD have been inconclusive. Meta-analyses have failed to detect a significant association between cesarean delivery and the risk of IBD [57, 58]. However, the included studies were heterogenous in both study design and conclusions: Cesarean section delivery was associated with an increased risk of IBD in case–control studies relying on self-reported mode of delivery but not in population-based cohort studies relying on routinely collected health data [57]. A second meta-analysis described an increased risk of CD, but not UC, among individuals born via cesarean section delivery [58].

Infectious Diseases and Antibiotic Use

Antibiotic exposure alters the intestinal microbiome. While the microbiome of adults tends to revert to its pre-antibiotic state, the impact of early-life antibiotic exposure may have a long-lasting impact on the microbiome [59]. Accordingly, antibiotic exposure during childhood has been associated with an increased risk of IBD, with antibiotics during the first of life conferring the greatest risk on later development of IBD [39, 60–64]. In British Columbia, Canada, antibiotic usage and the incidence of childhood asthma have declined in parallel and the association between antibiotic use and asthma is mediated by the impact of antibiotics on the intestinal microbiome [65]. This same decline in IBD incidence in the era of declining antibiotic use has not been observed.

The impact of infections themselves on the subsequent risk of IBD is less clear. Infectious gastroenteritis and other infections (e.g., otitis media) have been associated with an increased risk of developing IBD in most studies evaluating the association [50, 51]. Other studies have reported that early-life infection protects against the development of IBD [47, 48, 66]. However, the relative contributions of the sequalae following infection and any antibiotics used to treat the infection in influencing this increased risk are not clear. In addition, the association between infections and IBD may be confounded by the presence of genetic polymorphisms conferring the risk of relative immunodeficiency, which may be more frequent in children with IBD [67].

Exposure to Cigarette Smoke

Cigarette smoking is the most consistently replicated environmental risk factor in IBD. Cigarette smoking is associated with an increased risk of developing CD; current smoking is associated with a decreased risk of developing UC, while former smoking is associated with an increased risk of developing UC [68]. Smoking is believed to impact the risk of IBD through several mechanisms, including alterations to the following: (1) mucus production, altering the physical barrier between the body and intestinal lumen; (2) innate immune response though altered macrophage functioning; (3) adaptive immune response through increased production of pro-inflammatory cytokines; (4) alterations to the gut microbiome; and (5) microvasculature of the intestines [69, 70]. The impact of cigarette smoking likely only occurs in someone who is genetically susceptible to developing IBD. Evidence from areas where IBD is emerging (e.g., Asia) suggests that the impact of smoking on the risk of developing IBD varies across ethnicities. For example, the ACCESS cohort demonstrated an increased risk of CD among smokers in Australia but not in Asia; former smoking still increased the risk of UC in this cohort [39]. It has been suggested that there is an interaction between *NOD2* and cigarette smoking, such that smokers who also carry a mutation in this gene are unexpectedly less likely to develop CD [71]. However, this interaction was likely driven by the differing penetrance of *NOD2* and cigarette smoking across the age spectrum [72]. Specifically, *NOD2* mutations are common in those diagnosed with CD as children but rare in those diagnosed as adults, while a history of cigarette smoking is very rare in children but common in adults. The impact of cigarette smoke on the risk of CD may be more pronounced in individuals with genetic variants involved in how the body metabolizes tobacco smoke [73], suggesting important differences in the causes of IBD across individuals.

The impact of smoking on the risk of childhood-onset IBD would most likely result from passive exposure to cigarette smoke—either through maternal smoking during pregnancy or exposure to second-hand smoke during childhood. However, a meta-analysis of 13 studies failed to identify an association between IBD and exposure to cigarette smoke, either in-utero or during early childhood [74].

Urban Environments, Air Pollution, and Residential Greenspace

A systematic review and meta-analysis described an increased risk of developing IBD among individuals living in urban areas but with a high degree of variability across studies [75]. Further study suggests the association between living in a urban area and the risk of IBD is highest for those diagnosed during childhood [46] and has been replicated in Asian countries with data from the ACCESS cohort [40]. One hypothesized mechanism for this association is through environmental exposures that are more common in urban environments: increased air pollution and reduced residential greenspace.

The association between air pollution and IBD has been inconsistently reported in the literature. In a study using a UK primary care database, high levels of exposure to NO_2 (a traffic-related pollutant) increased the risk of developing CD in those diagnosed ≤23 years of age (OR 2.31, 95% CI 1.25 to 4.28); there was a dose–response whereby the risk increased with increasing levels of NO_2 [76]. This same study found that SO_2 (a pollutant often found in industrial areas) exposure increased the risk of UC among those diagnosed ≤20 years (OR 2.62, 95% CI 1.15 to 6.00). These associations were specific to those who were young at diagnosis and there was either no significant association or a protective association between air pollution and IBD in those diagnosed later in life. A second study evaluating the association between NO_2 and childhood IBD reported no association [77]. Instead, this study reported a significant increased risk of pediatric IBD associated with the redox-weighted oxidant capacity of air pollutants (calculated using a combination of NO_2 and O_3 levels): HR 1.08 (95% CI 1.01 to 1.16). In a third study, high levels of traffic intensity on major roads (within a 100-m buffer) were associated with an increased risk of adult-onset IBD (adjusting for smoking, education, and NO_2 concentration OR 1.60, 95% CI 1.04–2.46) [78]. Higher exposure to particulate matter ($PM_{2.5}$ and PM_{10}) was associated with a decreased risk of adult-onset IBD in one study but not in the other two [76–78].

In Canada, children living in areas with more greenspace were less likely to develop IBD (HR 0.77, 95% CI 0.74 to 0.81) [79]. The association was consistent in both CD and UC and persisted after adjusting for air pollution (NO_2, $PM_{2.5}$, and O_3). The magnitude of the associations between childhood exposure to residential greenness was more pronounced when restricting to IBD diagnosed at ≤10 years of age (fully adjusted models for IBD: HR 0.70, 95% CI 0.69 to 0.72; CD: HR 0.70, 95% CI 0.68 to 0.72; UC: 0.71, 95% CI 0.69 to 0.73). This study also reported a dose–response relationship of residential greenspace and pediatric IBD. In-utero exposure to residential greenspace during pregnancy was not significantly associated with childhood-onset IBD after adjusting for NO_2, $PM_{2.5}$, and O_3 (HR 0.92, 95% CI 0.83 to 1.01).

Diet

The association between diet and the risk of IBD is challenging to study—and is likely to be influenced not only by individual food items (fats, proteins, processed food, fiber, micronutrients, preservatives, etc.) but also by the interaction between these food items, the intestinal microbiome, and the immune system [80]. Systematic reviews have summarized the literature between dietary factors and the risk of IBD. In general, these reviews have reported increased risk of IBD with diets high in animal protein/meat and fat (total fat, polyunsaturated fatty acids, and omega-6 fatty acids), and low in fiber [50, 80–82]. The mechanism through which this occurs involves the breakdown of dietary fiber by bacteria in the intestine into short-chain fatty acids which then play a role in the production of anti-inflammatory signaling molecules (e.g., butyrate) ultimately resulting in intestinal inflammation. Short-chain fatty acids also play a role in the maintenance of the mucosal barrier and tight junctions between intestinal epithelial cells—also important in the pathogenesis of IBD. When the diet is high in processed food (high fat, high sugar, high preservatives), there is decreased microbial diversity and decreased production of short-chain fatty acids which, in turn, decreases the body's natural defenses. This results in a breakdown of the mucosal barrier and a "leaky gut" allowing bacteria to cross the epithelial lining of the intestinal tract, triggering an inflammatory response. With increasing "Westernization," processed food diets become increasingly common. These dietary changes and subsequent impact on the microbiome, immune system, and the intestinal barrier function may be contributing to the emergence of IBD in regions where it was previously unknown [83].

Association vs. Causation

Solely studying the environmental risk factors described above using an epidemiologic lens does not allow us to conclude that these factors "cause" IBD. Instead, as with all non-interventional research studies, we are limited to interpreting these findings as associations. Sir Austin Bradford Hill proposed nine criteria for determining if environmental exposures truly cause disease (Table 6.2). [84] These criteria are not universally agreed upon as necessary or sufficient for determining causality. The most important criteria for establishing causality are arguably temporality and lack of confounding. Establishing a biological mechanism through which an exposure causes disease is also important in establishing a causal association.

Table 6.2 Hill criteria [84] for determining if an environmental exposure causes disease, including explanations and examples from the IBD literature to evaluate the application of the causal criteria

Criterion	Explanation	Example application from the IBD literature
Strength	Associations that are larger in magnitude are more likely to be causal. However, many causal relationships may be small in magnitude while many non-causal relationships may be large.	Many of the >200 IBD susceptibility genes confer a very small increase in the risk of IBD (i.e., ORs ranging from 1.05 to 1.4, with most less than 1.2) [133, 134].
Consistency	Repeated studies of a causal association reach the same conclusions, across populations, time, and study methodology. Since many environmental risk factors interact with an individual's genetics, microbiome, and other environmental exposures, a cause may not be replicable in all scenarios [135, 136].	Cigarette smoking is a well-established risk factor for CD. Yet, this association could not be replicated in Asia [39].
Specificity	A particular cause is only responsible for a single outcome or, alternatively, a particular outcome can only have one cause. However, it is unlikely for a single environmental exposure to cause a single disease [84].	The specificity criterion could imply that (1) cigarette smoking causes only CD or (2) the only cause of CD is cigarette smoking. Both are false: cigarette smoking causes many diseases and multiple factors play a role in CD pathogenesis.
Temporality *This is the only causal criterion that is necessary for causation, but it is not sufficient.*	An event (e.g., IBD diagnosis) must occur after the exposure that caused it.	Because subclinical inflammation can exist long before a formal IBD diagnosis is made, ensuring temporality can be challenging. In studies of early-life environmental factors (e.g., antibiotic use in the first year of life), exposure likely occurred prior to preclinical disease.
Biologic gradient	The greater the exposure, the greater the risk of the outcome (i.e., there is a dose response). However, the observed gradient may result from another exposure that increases in parallel with the exposure of interest.	Increasing levels of residential greenspace early in a child's life is associated with a decreasing risk of developing IBD [79] but this association may have resulted from another unknown factor that increases in parallel with greenspace.
Plausibility	There is a biological mechanism that explains how A causes B. This criterion is speculative, at best, and is subject to change as advances in knowledge contradict mechanisms that were previously hypothesized.	Evidence from basic and translational science suggests many ways through which cigarette smoke may cause CD, including altering: (1) mucus production; (2) innate and adaptive immune responses; (3) the gut microbiome; and (4) microvasculature of the intestines [69, 70].
Coherence	All evidence of a causal relationship is consistent, including from basic and translational science and epidemiology. Inconsistent findings may not mean that an association is not causal due to unmeasured confounding as the true cause (for example).	The relationship between cigarette smoking and CD is not coherent. The lack of association between smoking and CD in Asia does not mean this relationship is not causa. Instead, it likely results from underlying differences across populations.
Experiment	Hill's original explanation refers to the removal of an exposure (e.g., what happens after someone stops smoking?) [84]. Recent interpretations include evidence from randomized controlled trials and basic and translational experiments. However, experiments in humans are often unethical and findings from lab-based experiments may not extrapolate well to humans.	In addition to being an important risk factor for developing CD, cigarette smoking also worsens its prognosis [137]. The risk of negative outcomes in CD (e.g., the need for intestinal resection, disease flare) diminishes over time in people who quit smoking [138, 139].
Analogy	If X causes Y, then it is also possible for A to cause B (if X is similar to A and Y is similar to B). Criticisms often cite investigators' creativity as analogy's greatest limitation: creative individuals are often better at identifying analogous situations [135, 136].	If cigarette smoking causes CD, then it could be analogous for smoking to cause UC—as both diseases involve intestinal inflammation. However, the paradoxical impact of cigarette smoking on CD and UC contradicts this analogy.

Abbreviations: *CD* Crohn disease, *IBD* inflammatory bowel disease, *OR* odds ratio, *UC* ulcerative colitis.

Temporality requires that the proposed cause of disease occurs prior to the onset of disease. In studies of early-life environmental factors, temporality is less concerning than if studying long-term environmental factors where pre-symptomatic disease may have developed prior to exposure.

Confounding occurs when the described association between an environmental exposure and disease is due to a third variable that is associated with both the environmental exposure and the disease. An often-cited example is the association between birth order and Down syndrome. Having more older siblings is associated with an increased risk of Down syndrome; however, this association is confounded by maternal age. Determining the relative contribution of studied environmental factors and other, as of yet unknown, environmental factors is challenging without knowing the impact of confounding on these associations. For example, both childhood infections and early-life antibiotic exposure may be causally associated with IBD; however, understanding how each alters risk, independently and in combination, is not easy.

Lastly, the plausibility of an epidemiologic associations is substantially strengthened when there is a biological mechanism through which the environmental exposure results in disease. Many of the environmental factors described above are believed to influence the risk of IBD, in part, through their interaction with the intestinal microbiome. Causation can more convincingly be demonstrated by combining epidemiological associations with scientific experimentation, such as that using animal models of disease. The inclusion of particulate matter (PM_{10}) in mouse chow resulted in higher expression of inflammatory cytokines, pro-inflammatory changes to the intestinal microbiome, increased intestinal permeability, and changes in the immune response to microbes in mouse models of IBD [85, 86]. The impact of particulate matter in chow was most pronounced in young mice providing support for the epidemiologic evidence that the impact of air pollution on IBD may be more pronounced in children [85]. Using evidence from basic and translational science, air pollution is hypothesized to result in intestinal inflammation by altering the microbiome, then impacting the gut epithelial cells, resulting in increased intestinal permeability, and ultimately resulting in a dysregulated immune response [87]. This experimental evidence is an example of how epidemiology research findings can be used to shape scientific experiments to better understand the pathophysiology behind epidemiologic research.

Gaps in Knowledge and Challenges in Determining the Global Epidemiology of Pediatric Inflammatory Bowel Disease

Our knowledge of the global epidemiology of pediatric IBD has evolved greatly over the past decade. However, there remains a paucity of data on rates of IBD in children from many regions of the world. Our ability to understand global patterns, as well as to identify risk factors driving increases in pediatric IBD, shifts to younger ages at diagnosis, and ethnocultural differences depends on our ability to generate and study high-quality data. Studying the epidemiology of a disease can be even more challenging than studying factors that confer risk. Population-based estimates of incidence and prevalence require identification of all cases of disease within a specified geographic region. Without systematic strategies for population-based data generation, rates of disease are almost impossible to determine.

We are currently seeing exponential growth in research using routinely collected health data (e.g., electronic medical records and health administrative data)—including in regions where the current epidemiology of pediatric IBD remains unknown. As these systems are increasingly integrated into clinical practice and health system planning, the data they capture will facilitate research. As with all research, ensuring these data are of high quality—capturing all IBD cases in the region and confirming the accuracy of IBD diagnosis (e.g., through validation)—will be paramount [88–90]. Combining the increase in data availability with the continuing emergence of IBD in areas where the epidemiology has not previously been reported, we expect that our knowledge of the global epidemiology of pediatric-onset IBD will evolve rapidly. Initiatives are currently underway through the International Organization for the Study of Inflammatory Bowel Diseases (IOIBD) to enhance our understanding of the global epidemiology of adult-onset IBD, with future expansion planned for pediatric IBD. The emergence of these data will provide further opportunity to understanding the environmental exposures resulting in the rapid emergence of these diseases.

Conclusions

IBD is common in children in many parts of the world and becoming increasingly common in regions where it was previously unreported. Despite our growing knowledge of the global epidemiology of pediatric IBD, significant gaps in knowledge persist. As IBD continues to emerge and rates continue to rise, we are poised to be able to further understand environmental risk factors, including those specifically increasing the risk of IBD in children, and how these factors may differ across ethnocultural groups.

SIR	Standardized Incidence Ratio

Introduction

Determining the natural history of Crohn disease (CD) involves the consideration of a number of different factors: the disease activity over time, the frequency of complications, the need for surgery, and the risk of disease recurrence following both medically induced and surgically induced remission. In children, evaluation of the natural history also must include the effects of CD on growth and development and on quality of life.

The true natural history of CD remains largely unknown, however, primarily because there are virtually no data describing the long-term course of untreated children or adults with this illness. The data that do exist arise from early clinical experience treating patients with corticosteroids and 5-aminosalicylate medications and from a small number of placebo-controlled treatment trials. These data document that the natural history of CD is associated with significant morbidity. As a consequence, one of the primary goals of current therapy includes improving the natural history of the disease. In the past decade, there has been a rapidly growing understanding of the roles that gene expression, proteomic, microbiome, and metabolomic factors play in the pathogenesis of disease and risk for complications over time. Capitalizing on this novel information is critical to understanding how to identify children at risk for complications and when to use therapies that may be able to alter these factors toward a more sustainable disease remission.

Disease Activity

The definitions of disease activity and remission are changing over time. The more historical body of literature defined remission clinically as the absence of symptoms. Today, we use clinical, biochemical, endoscopic, and histologic remission benchmarks to define treatment targets and successes. Scientific discovery may one day allow us to consider a patient in "genetic remission" via normalization of the gut microbiota and reversal of aberrant gene expression.

Spontaneous clinical remission in the absence of specific treatment can occur in Crohn disease. Two early adult trials, the National Cooperative Crohn Disease Study (NCCDS) [1] and the European Cooperative Crohn Disease Study (ECCDS) [2], included placebo treatment arms enrolling a total of less than 300 adult subjects. Among the 135 subjects with active symptoms at entry into the two trials, 26–42% achieved clinical remission after 3–4 months of placebo treatment, and 18% in both studies remained in clinical remission at 1 year [1, 2]. Prolonged spontaneous clinical remission, therefore, appears to occur in only a small number of adults with CD. However, in the NCCDS, among the subgroup of 20 subjects with active disease who achieved clinical remission by 17 weeks, 75% remained asymptomatic at 1 year, and 63% at 2 years [1]. Similarly, among the 153 subjects in the NCCDS and ECCDS who had the inactive disease when randomized into the placebo arms of a maintenance

study, 52–64% remained asymptomatic at about 1 year and 35–40% at about 2 years [1, 2].

No comparable data from untreated or exclusively placebo-treated children exist. However, in children with moderate–severe disease activity who achieve remission after a course of prednisone, the likelihood of prolonged remission without ongoing therapy appears lower than in adults. Newly diagnosed children randomized to the control arm of a multicenter trial received prednisone for induction of remission and were then maintained only on a placebo [3]. One year following the course of corticosteroids, only 43% remained continuously asymptomatic. Similarly, 95% of a cohort of Italian children maintained on mesalamine following an 8-week course of corticosteroids relapsed by 1 year [4].

Whether specific genetic variants impact the likelihood of disease recurrence is only beginning to be investigated. In a study of 80 children with CD, the patients with homozygous ATG16L1 mutations had frequent relapses in the first year, while those with homozygous IRGM1 mutations had significantly fewer relapses in the first year [5].

Periods of active CD continue to be a problem beyond the first year after diagnosis. Disease activity over time has been described in a report derived from a large population-based inception cohort of patients with inflammatory bowel disease diagnosed and treated in Copenhagen County, Denmark, between 1962 and 1987 [6]. While useful, the data describing the course of pediatric CD in this study are based on observations of only 23 children. At diagnosis, 82.6% had disease activity characterized as moderate to severe. In each of the succeeding 9 years, only about 50% of the cohort was characterized as inactive during any given year, while roughly 20–35% had periods of high disease activity despite treatment [7] (Fig. 7.1).

Observations in the larger, primarily adult-onset cohort from the same geographic area revealed that individual patients had different patterns of clinical activity over time: some experienced frequent relapses, some only occasional relapses, and others had prolonged periods of disease quiescence [7]. In this cohort, relapse in any given year after diagnosis increased the risk of relapse in the following year. The relapse rate in the first year after diagnosis is also correlated with the relapse rate in the next 5–7 years. A review of North American experience revealed similar patterns of disease in adult CD patients treated prior to the widespread introduction of biologic therapy. Most experienced a chronic intermittent disease course, but 13% of patients had an unremitting disease course and only 10% experienced a prolonged clinical remission [8].

Increased disease activity is often seen in those with earlier disease-onset. In a study comparing the disease activity of 206 pediatric-onset patients with 412 adult-onset patients living in France between 1995 and 2007, a higher proportion of patient-years was marked by active disease in those with pediatric-onset (37%) compared to those with adult-onset CD (31%), ($p < 0.001$) [9]. In the study years 1999–2007, antitumor necrosis factor (anti-TNF) alpha therapy was required in 10.5% vs. 3.5% patient-years ($p < 0.001$), respectively. While many children have moderate to severe disease activity at diagnosis, a smaller subset of poorly studied children will have a quite mild disease activity. In a single-center retrospective study from Boston, MA, 29 of 1205 (2.4%) children with CD did not require any immunosuppressive therapy in the first 2 years after diagnosis. More of these children had isolated colonic disease, most had persistent colonic histologic disease activity on follow-up colonoscopy, and only 8/29 required escalation to immunosuppressive therapy in the follow-up period [10]. The long-term outcomes for children with the most mild inflammatory disease at diagnosis remain unclear.

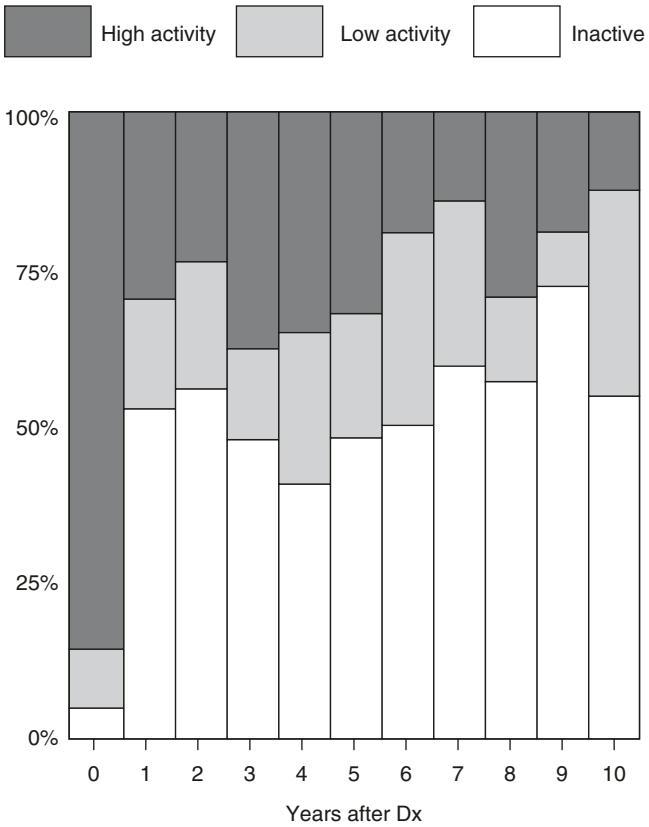

Fig. 7.1 Yearly Crohn disease activity over the first 10 years after diagnosis in a Danish population of children diagnosed prior to 15 years of age (Data from Langholz et al. [6])

Evolution of Disease Phenotype

Disease location is highly variable at diagnosis and is not fixed over time. Data from a large multicenter European registry found the initial disease location of 582 children with Crohn disease to be widely distributed according to the Paris classification [11], with disease location L1 in 16%, L2 in 28%, L3 in 53%, and isolated L4a + L4b in 4% [12]. In a report from Scotland, at diagnosis, extensive disease including the ileum, colon, and upper GI tract (disease location characterized as L3 + L4 by the Montreal classification [13]) was found in 31% of children [14]. However, among a subgroup of 149 children with a less extensive disease at diagnosis who were followed at least 2 years after diagnosis, the extension of CD was noted in 39% [14].

Disease behavior also evolves over time. At initial diagnosis, the vast majority of children have an inflammatory disease phenotype. However, as time goes on, an increasing proportion expresses a changing phenotype, characterized as either stricturing or penetrating. In a systematic review of the literature from years 1966 to 2010 evaluating 3505 pediatric-onset CD patients with at least 5 years of follow-up, development of stricture occurred in 24–43%, fistulae in 14–27%, and perianal disease in 25–30% of patients [15]. Similar disease behavior has also been documented clearly in data derived from the pooled observations from three multicenter North American pediatric IBD registries [16]. Among 796 children followed prospectively from diagnosis, 96 (12%) presented with a stricturing and/or penetrating CD phenotype. Among the 700 who had an inflammatory phenotype at presentation, 140 (20%) developed stricturing or penetrating disease after a mean of 32 months of follow-up [16], a finding strikingly similar to the 24% rate of complicated CD behavior described after 4 years in a pediatric study from Scotland [14]. Similar observations over extended periods of time have been reported in population-based studies in adults from both France [17] and New Zealand [18] (Fig. 7.2). In the latter study, a comparison of 630 subjects with adult-onset disease and 85 children diagnosed before age 17 years revealed no difference in the rate of progression from inflammatory to either stricturing or penetrating disease phenotype [18].

Racial differences may affect the frequency of complicated CD, as a study from Baltimore has demonstrated more frequent stricturing and penetrating disease in black children compared to white children seen in the same university-based practice [19]. The risk for phenotypic change may also be associated with the presence of specific genetic allelic variants. Earlier reports suggested an increased risk of fibrostenosis complications for patients with NOD2/CARD15 variants [20, 21], while those with abnormalities in the IBD5 gene may be more likely to develop perianal fistulae [22]. However, more recent studies only implicate NOD2/CARD15 mutation in risk of ileal disease location (which may be more likely to stricture compared to colonic disease) and not independently with increased risk of stricture [23, 24]. CD in children who are homozygous carriers of ATG16L1 mutation may have significantly increased stricturing behavior and have lower risk of perianal disease compared to wild-type patients [5]. In a small study of children and adults in Taiwan, a homozygous mutation in the risk candidate gene SLCO3A1 was significantly associated with perforating disease compared to those with wild type

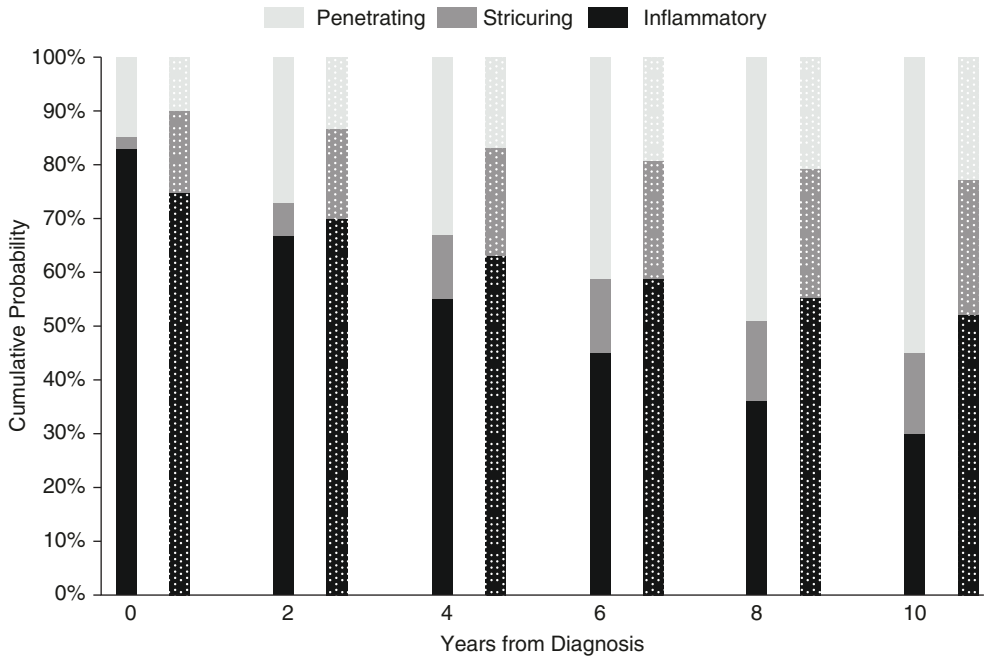

Fig. 7.2 Change in Crohn disease behavior over time (Adapted from Cosnes et al. [17] (*solid bars*) and Tarrant et al. [18] (*dotted bars*))

who had more inflammatory disease [25]. Children at risk for stricturing or internal penetrating complications have also been shown to be more likely to have increased immune responses to microbial antigens, characterized by the presence of high-titer antibodies such as anti-ompC, CBir1, and anti-I2 [16, 26].

The pediatric RISK trial [27]—a prospective multicenter inception cohort study of newly diagnosed children with CD—has provided a wealth of new information on factors that impact the evolution of CD over time. In 913 children from this cohort presenting with an inflammatory (B1) phenotype, the investigators found several genes from ileal tissue samples associated with the subsequent development of stricturing (B2) or penetrating (B3) complications, including a pronounced extracellular matrix gene signature in many who went on to develop fibrostenotic disease [27]. In a subset of these subjects with B1 disease at diagnosis, those with higher circulating levels of serum Extracellular Matrix Protein 1 at diagnosis were more likely to subsequently develop B2 behavior [28]. In the entire RISK cohort, early use of anti-TNF therapy markedly reduced the risk of progressing to fistulizing disease, but this same therapy did not appear to lessen the risk of developing a stricturing phenotype.

Microbial factors associated with progression to a complicated CD phenotype were also identified in the RISK cohort. Compared to children who remained B1 over 3 years of observation, baseline fecal and mucosal samples revealed increases in *Ruminococcus* and decreases in *Rothia* species in children developing stricturing disease, while those developing fistulizing disease were characterized by an increase in *Collinsella* and decrease in *Veillonella* species [27].

The RISK cohort has also been studied for environmental factors that may impact disease evolution. In one such study of early life environmental exposures, of 1119 pediatric CD patients, 15% developed B2 or B3 disease within 3 years of diagnosis. Infant breastfeeding was inversely related to the development of these complicated phenotypes, while maternal smoking was associated with an increased rate of CD-related hospitalization [29].

Growth

For a significant subgroup of children with CD, growth impairment is an important characteristic of the disease's natural history. While acute weight loss commonly is present in children with both ulcerative colitis and CD, impairment in linear growth is primarily a problem in the latter condition. Data derived from clinical observations in the 1970s and 1980s document that at the time of initial diagnosis, about a third of children with CD had already dropped two or more major growth channels from their pre-illness growth percentiles [30, 31]. More dramatically, 88% had delayed height velocity at diagnosis [32]. Over time, periods of significantly impaired growth can be seen in about 60% of children and adolescents [31]. While catch-up growth is often possible, 7–35% of children diagnosed during the 1970s and 1980s had final adult heights that were significantly shorter than expected [31]. As a group, young adults who develop CD as children have adult heights skewed toward the lowest percentiles. In reports from both Chicago and New York, ~50% of young adults with childhood-onset CD have final adult heights less than the 10% for the general population, and ~25% have adult heights less than the 5% [30, 31]. Therapies including enteral nutrition [33], methotrexate [34], and infliximab [35, 36] may improve growth parameters. Children diagnosed with CD at earlier pubertal Tanner stages (I-III) who achieve disease remission with anti-TNF therapy have improved linear velocity compared to those diagnosed in later puberty [37]. In the analysis of children with baseline growth impairment from the IMAgINE 1 trial, adalimumab therapy led to linear growth improvement or normalization at weeks 26 and 52 of treatment, with greater improvement in those who achieved remission after 4 weeks of induction [38].

Corticosteroid Dependence

An important characteristic of CD in children as well as adults is the tendency to develop corticosteroid (CS) dependence. Population-based studies in adults from both Olmstead County, Minnesota [39], and Copenhagen County, Denmark [40], demonstrate similar findings; acute response to CS therapy in adults with CD is reasonably good (complete remission in 48–58%, partial remission in 26–32%, and no response in 12–20%). However, long-term response is less optimal, with rates of CS dependence of 28–36% at 1 year reported from observations arising during the years before biologic therapies. [39, 40]

A similar risk for CS dependence is evident in children. As in adults, acute response to a course of corticosteroids is good. In data derived from a multicenter North American observational registry, among 109 newly diagnosed children with moderate–severe CD activity treated with corticosteroids, 60% had a complete and 24% a partial clinical response by 3 months after initiation of treatment [41]. However, despite the concomitant use of immunomodulators in many of these children, 31% were CS dependent at 1 year. In fact, without infliximab, only 46% of the children in this study maintained a CS-free remission to 1 year following an initial course of corticosteroids [41]. In a French population-based

cohort study of 535 CD patients diagnosed under the age of 17 years between 1988 and 2004 and followed for a median of 11.1 years, 42% were CS dependent and 15% were CS resistant at 1 year [42]. In an assessment of the impact of systemic corticosteroids on pediatric CD, Jakobsen and colleagues found ileal and ileocolonic disease location is a risk factor for CS dependency [43]. It is now evident that early anti-TNF therapy reduces CS dependency at 1 year from diagnosis. In 552 pediatric CD subjects in the RISK cohort, CS-free remission was achieved in 85% of those treated with early anti-TNF therapy, 61% treated with immunomodulators (IM), and 55% treated with neither anti-TNF nor IM [44]. When subjects were divided into propensity score-matched cohorts based on a variety of baseline characteristics, anti-TNF therapy remained significantly more likely to achieve CS-free remission.

Surgery

The need for surgery represents another important aspect of the natural history of CD in children. Table 7.1 summarizes published rates for surgery in children from a variety of different countries that were observed in the prebiological era. Data from Denmark estimate a mean yearly operation rate of approximately 13%. The cumulative probability of surgery in this Danish cohort at 20 years was estimated to be 47% [6]. A multicenter pediatric experience from the USA estimates the cumulative incidence of surgery to be 6% at 1 year, 17% at 5 years, and 28% at 10 years after diagnosis [49]. Similarly, a pediatric study from Scotland noted resection rates of 20% at 5 years and 34% at 10 years [14]. More recent data does not appear substantially different. In a more contemporary cohort of 852 children followed in a multicenter North American study between 2002 and 2008, the 1-year and 5-year risk of CD-related surgery was 4.8% and 17.7%, respectively [50]. Older age at diagnosis, increased disease severity, or complicated (stricturing or penetrating) disease behavior increased risk.

Table 7.1 Surgical frequency in Crohn disease

Author	No. of children observed (period studied)	% Operated	% Permanent stomas
Farmer [45] (USA)	522 (1955–1974)	67	??
Ferguson [46] (UK)	50 (1968–1983)	78	30
Griffiths [47] (Canada)	275 (1970–1987)	32	2
Besnard [48] (France)	119 (1975–1994)	30	2
Langholz [6] (Denmark)	23 (1962–1987)	43	??

The presence of variant NOD2/CARD15 [20, 21] and ATG16L1 [5] alleles appears to increase the risk for surgery, presumably due to the known association of these genetic polymorphisms with the development of fibrostenotic ileal disease. Beyond these well-described genes, our knowledge of genetic and serologic factors impacting surgical risk is expanding through genome-wide studies. For example, in a study performing a whole-genome analysis of 1115 adult and pediatric CD patients, the IL12B gene was independently associated with a need for surgery and early surgery [51]. The presence of anti-Saccharomyces cerevisiae antibodies and other serologic markers also appears to be associated with an increased risk for surgery [16, 49].

The effect of immunomodulatory therapy on the need for surgery remains an open question. An analysis from France evaluated a series of successive 5-year adult CD cohorts [52]. Although there was a significant increase in the use of immunomodulatory therapy over time, there was no associated change in the rate of surgery [52]. By contrast, multivariate analysis from a similar series of 5-year adult CD cohorts from the UK identified the early use of thiopurines (within 3 months of diagnosis) to be associated with a marked reduction in the rate of surgery [53, 54].

The studies evaluating infliximab therapy in decreasing surgical rates are also mixed. In a Spanish retrospective assessment of infliximab therapy used in a "step-up" fashion, no significant decrease in surgical rates could be identified in patients receiving infliximab compared to those not receiving the treatment [55]. However, other studies reach the opposite conclusion. For instance, in a study utilizing data from a combined Danish and Czech collaboration, surgical rates in adults 40 months after starting infliximab were 20–23% in infliximab responders compared to 76% in non-responders [56]. In the ACCENT I [57] and ACCENT II [58] trials of adults with moderate to severe CD, and fistulizing CD, respectively, response to maintenance infliximab was associated with decreased surgery. Similar findings in children have been reported, with surgical rates 50 months after starting infliximab of 10% in patients maintained on the biologic compared to 70% in infliximab failures [59]. Further, in children with a favorable initial response, development of antibodies to infliximab led to loss of response and increased risk of surgical resections [60]. In the data from the RISK inception cohort, 1 year post-diagnosis surgical risk in those treated with early anti-TNF was not different from those treated with immunomodulators [44]. A longer term analysis from the RISK cohort identified a significant reduction of penetrating disease but not fibrostenotic disease with early anti-TNF use [27], raising a possibility that early anti-TNF reduces surgical risk related to internal fistulas but not strictures.

Postoperative Recurrence

Following surgery, the natural history of CD is to recur both endoscopically and symptomatically. The natural progression of CD following ileocolonic resection has been previously described by Rutgeerts and colleagues, with five levels of disease severity (i0–i4) found endoscopically. Postoperatively, disease appears to evolve from normal mucosa (i0) to the initial appearance of a few aphthous ulcers (i1–i2), followed by progressively more and/or deeper ulcerations until an area of confluent inflammation, large ulcers, or stricturing develop (i3–i4) [61]. CD recurrence is defined by an endoscopic score of i2, i3, or i4, while postoperative remission is defined by a score of i0 or i1.

In retrospective adult studies, symptomatic recurrence of CD following the so-called curative resection (complete resection of all visibly evident disease) is reported to be 20–30% within the first year after surgery, with the increasing likelihood in each subsequent year [62]. One or more additional surgeries are required in 15–45% of adults within 3 years, 26–65% in 10 years, and 33–82% in 15 years [63]. Controlled trials document severe endoscopic recurrence after placebo treatment in 43–79% of adult subjects by 1 year after surgery and in 42–85% of subjects after 2 years [63–68].

In children, the overall rate of clinical recurrence is estimated to be 50% at 5 years after initial resection [47]. However, the site and extent of preoperative CD can affect the recurrence-free interval such that it is estimated that 50% of children with extensive ileocolitis recur within 1 year, compared to a 50% recurrence rate after 5 years in children with ileocecal disease and a 50% recurrence rate after 6 years if preoperative disease is confined to the small bowel [47]. In a more recent retrospective review of 81 children in the UK with a median age of 14.5 years and 7.7 years of follow-up, 52% had disease recurrence by end of follow-up, with younger age at first resection being a risk factor for clinical recurrence. The authors additionally identified colonic disease, as compared to more localized ileocecal disease, and post-operative complications as risk factors for requiring future intestinal resection [69]. Conversely, in a multicenter review of 122 children in the Netherlands undergoing ileocecectomy between 1990 and 2014, ileocecal disease location, along with positive histologic resection margins, was the risk factor for surgical recurrence [70]. Altering the natural history of postoperative CD and preventing recurrence has become an integral part of CD management. Use of mesalamine or thiopurines appears to have limited benefit [68, 71], while anti-TNF therapy may be effective in preventing CD recurrence [72–74].

Cancer Risk

Whether children with CD are at increased risk for malignancy over their lifetime is unknown. Limited but growing population data exists, and it can be difficult to isolate effects of CD from medications, or comorbid diseases, toward cancer risk from these reports. In a recent report from a Manitoba, Canada registry reviewing 947 people diagnosed with pediatric IBD followed for 14,938 person years, 17 post-IBD diagnosis cancers were identified. A diagnosis of CD had an increased risk of cancer with a hazard ratio of 2.47; the median age of cancer diagnosis was 37 years. Of note, there was no difference in exposure to thiopurine or anti-TNF medications between those who developed a cancer and those who did not [75]. Similarly, a large combined Finnish and Danish cohort that included 2921 cases of CD diagnosed in children between 1992 and 2014 found this group of people with CD had a 2.5-fold increase risk of cancer compared to the general population, a standardized incidence ratio (SIR) of 3.2 for lymphoproliferative diseases, and an SIR of 6.7 for skin cancer. The authors highlight that thiopurines are standard of care in these countries and the data could not determine the degree of risk related to this medication exposure [76].

One of the more comprehensive pediatric IBD malignancy risk studies to date comes from the DEVELOP registry—a multicenter, prospective, long-term registry of safety and outcomes data in pediatric IBD patients. The DEVELOP registry evaluated 5766 children including 4047 with CD, identifying 15 cancers and 5 cases of lymphoproliferative disease in >24,000 patient-years of follow-up from 2007 to 2016. Twelve of the 15 cancers occurred in patients with CD. Thiopurine exposure was found in all but 2 of these cancers. Malignancy incidence rates in this population were compared to the Surveillance, Epidemiology, and End Results (SEER) database to calculate the SIR to report differences in risk compared to the general population. The authors found SIRs of 2.88 for thiopurine exposed, and 1.3 for nonexposed individuals, suggesting in this cohort the risk of cancer is very low in those with pediatric IBD, particularly those not treated with thiopurine [77].

Studies in adults, however, suggest that patients with CD do have an excess of malignancies compared to the general population. In a population-based cohort from the Uppsala region of Sweden, there was an increased relative risk of colorectal cancer of 2.5 (95% confidence interval (CI) 1.3–4.3) in patients with CD [78]. Duration of illness and gender did not affect risk, but those subjects with colonic disease had a greater risk of colorectal cancer than those with only small bowel involvement. Of note, however,

among those subjects with any colonic involvement diagnosed with CD before the age of 30 years, the relative risk of colorectal cancer increased to 20.9 (95% CI 6.8–48.7) [78]. By contrast, a similar population-based study from Denmark identified a relative risk of colorectal cancer of only 1.1 (95% CI 0.6–1.9), and no risk differences were noted in different subgroups of patients [79]. A similar modest increase in colorectal cancer risk (1.9; 95% CI 0.7–4.1) was found in a population-based study from Olmstead County, Minnesota [80].

By contrast, the risk of small bowel cancer consistently appears to increase in patients with CD. In part, because the rate of small bowel cancer in the general population is very low (estimated to be 0.005% at 5 years and 0.03% at 25 years), there is a significantly elevated relative risk for small bowel cancers in patients with CD [80]. In the Danish study cited above, the relative increased risk for small bowel cancer was 17.9 (95% CI 4.8–42) [79]. In Olmstead County, the relative risk was found to be 40.6 (95% CI 4.4–118) [80]. Duration of CD did not appear to influence risk of developing small bowel cancer. Adenocarcinoma, carcinoid, leiomyosarcoma, and primary intestinal lymphoma have all been reported. The effect of age at CD onset on the risk of developing small bowel cancer has not been reported.

There may also be a slight increase in the risk of developing lymphoma, although data are mixed and not always controlled for risk associated with therapeutic agents. In a single-center, retrospective study between 1979 and 2008 that included 791 children with CD followed in Boston, MA, one non-Hodgkin's lymphoma occurred in a patient receiving thiopurines; the overall cohort lymphoma risk did not meet statistical significance [81]. In a large population-based retrospective study of adults living in the UK between 1988 and 1997, seven patients with lymphoma were reported among 6605 patients with CD, and 0/7 were exposed to thiopurines. The risk of lymphoma in this cohort was not increased compared to the control population (relative risk 1.39; 95% CI 0.50–3.40) [82]. The published data from the DEVELOP registry described above offers a stratified view of different patient cohorts based on medication exposure. Of cancer type described, 8/15 were leukemia or lymphomas. Importantly, the 763 non-biologic, non-thiopurine exposed patients, and 1146 biologic exposed, non-thiopurine exposed patients did not have a statistically increased cancer risk compared to the healthy matched SEER database reference population. This suggests cancer risk in the early years after CD diagnosis is based more on therapy than the intrinsic disease [77].

Quality of Life

In addition to imposing significant physical morbidity, CD in childhood imposes potentially dramatic psychosocial burdens as well. Health-related quality of life (HRQOL) scores, as measured by the IMPACT questionnaire (a validated, pediatric IBD health-related quality of life questionnaire) [83], correlate with physician's global assessment of disease severity, such that children with moderate–severe activity have the poorest HRQOL scores [84]. Pre-biologic era reports on quality of life have noted that children with CD frequently experience absences from school, require home tutoring, and express fears concerning everyday childhood activities, schooling, and ability to get a job [85–87]. Fifty-seven percent of a young–adult cohort was reported to have had an absence from school of at least 2 months duration and 8% were involuntarily unemployed. [88]

The past two decades have found improved quality of life measures correlating with greater ability to achieve disease remission [89, 90]. A recent study of 218 children in France found clinical remission status was the main independent factor determining IMPACT-III scores, with older age and the presence of comorbid psychological disorder associated with lower scores [91]. The psychological effect of IBD can also impact HRQOL separate from disease activity. De Carlo and colleagues found the degree of pain catastrophizing followed by generalized distress levels directly correlated with HRQOL in an Italian pediatric cohort [92].

One by-product of increased disease severity is increased parental stress. The effect of parental stress was found to partially contribute to lower HRQOL in children with active disease [93]. In a study of 100 children with IBD including 45 with CD, parental distress substantially correlated with patient HRQOL; in this study, parental distress was most affected by flares and disease activity [94].

Natural History of Ulcerative Colitis in Children

8

Joelynn Dailey and Jeffrey S. Hyams

Introduction

We continue to strive to change the natural history of ulcerative colitis which is often marked by intermittent or continuous disease activity despite treatment with 5-aminosalicylates and corticosteroids. While the data presented in this chapter reflect the effect of our current therapies, we hope that management advances in the next decade will achieve greater disease control without increasing risk. This chapter will focus on natural history elements pertaining to clinical remission, endoscopic remission, and colectomy. Discussion of drugs will focus mainly on maintenance of remission. Lastly, new insights in predicting response to therapy and altering natural history will be addressed.

Overview

Clinical reports from the 1970s and 1980s describe a severe clinical course for children newly diagnosed with ulcerative colitis resulting in chronic activity, recurrent hospitalizations, frequent colectomy, and rare deaths [1, 2]. Subsequently, a report in 1996 of 171 subjects seen at two large pediatric inflammatory bowel disease centers in the Northeastern United States found that 43% of patients had mild disease and 57% moderate to severe disease at presentation. Forty three percent had pancolitis [3]. Over 80% had resolution of symptoms within 6 months of diagnosis, and during subsequent yearly follow-up intervals, 55% were symptom free, 38% had chronic intermittent symptoms, and 7% had continuous symptoms. Corticosteroid therapy was used in 27% of those with initially mild disease and 70% of those with moderate/severe disease by 1 year. Eleven percent of those with moderate/severe disease received additional immunomodulatory therapy (azathioprine/6-mercaptopurine or cyclosporine) during the first year. The colectomy rate during this time period of widespread immunomodulator use ranged from 1% to 8% at 1 year and 9% to 26% at 5 years, with initial disease severity and progression of disease greatly affecting colectomy rates [3–6].

More recent cohorts have encompassed populations that were diagnosed in the era of biologic agents. Much of our recent understanding of ulcerative colitis in children has been informed by the PROTECT Study: Predicting Response to Standardized Pediatric Colitis Therapy which was a 29 center North American inception cohort of children newly diagnosed with ulcerative colitis who were treated with standardized treatment protocols based on initial disease severity [7]. In this cohort of 428 children newly diagnosed with UC, 7% had proctosigmoiditis, 10% had left-sided colitis, and 83% had extensive colitis or pancolitis. Of the 400 patients who remained evaluable at 52 weeks, 25 (6%) had colectomy within that first year. The majority of the patients going on to colectomy had moderate to severe disease at diagnosis. A retrospective study from 25 centers across Europe and North America between 2009 and 2011 found that 83% of patients admitted for acute severe colitis, defined as PUCAI $\geq$ 65, had extensive colitis or pancolitis at diagnosis, versus 16% with left-sided disease [8]. In total, 16/141 (11.3%) of patients underwent a colectomy during their initial admission for acute severe colitis. Of those who had a colectomy, 82% had extensive colitis or pancolitis at diagnosis, while 18% had left-sided disease. Long-term follow-up showed colectomy rates of 28.7%, 33.6%, and 36.4% at 1, 3, and 5 years after initial acute severe colitis admission, respectively. A retrospective chart review of 110 patients from a center in Italy reported 29% of patients initially presenting with proctitis, 22% left-sided colitis, 15% extensive colitis, and 34% pancolitis [9]. Disease extension at follow-up was noted in 29% of patients and cumulative

rates of colectomy were 9% and 14% at 2 and 5 years, respectively. A review of the published literature on population-based natural history studies of pediatric ulcerative colitis suggested an overall colectomy rate of between 4% and 17% at 1 year [7, 10, 11] and about 20% at 5 years follow-up [5]. All studies indicate that more severe disease at diagnosis correlates strongly with need for colectomy within the first several years after diagnosis.

Of course, the natural history of any disease is largely a function of the efficacy of medications used to treat it. Large-scale, blinded, placebo-controlled trials are generally lacking in the pediatric population, and much of what is done is extrapolated from adult studies.

Aminosalicylates

Data supporting the use of 5-aminosalicylate (5-ASA) compounds for the induction and maintenance therapy in adult ulcerative colitis (UC) are strong [12, 13]. Data in adults suggest that higher dose 5-ASA may be more effective in inducing remission (4.8 g mesalamine vs. 2.4 g mesalamine), but this added efficacy seemed limited to patients with moderate disease, and was not observed in those with mild disease [14].

One randomized, double-blind, controlled study of children with mild-to-moderately active ulcerative colitis compared the safety and efficacy of high-dose and low-dose oral, delayed-release mesalamine, and found that both doses were equally effective as short-term treatment, without a specific benefit or risk to using either dose [15]. Dosing was weight-dependent, with the low-dose group receiving 27–71 mg/kg/day and high-dose group receiving 53–118 mg/kg/day, within the constraints of using a 400 mg tablet. Twenty-three of 41 (56%) and 22 of 40 (55%) of patients achieved PUCAI-defined treatment success in the low- and high-dose groups, respectively ($P = 0.924$) after 6 weeks of treatment. No differences in efficacy, tolerability, or adverse reactions with either high- or low-dose mesalamine were noted but the large overlap in potential doses between the two groups makes interpretation of this study difficult.

In the PROTECT study mentioned previously, patient outcomes at one year from diagnosis were determined after the start of standardized treatment regimens based on initial disease severity. One-hundred fifty out of 400 (38%) patients achieved corticosteroid-free clinical remission (PUCAI<10) on mesalamine only at week 52 without the need for immunomodulators or biologics [7]. Of the initial cohort about two-thirds started therapy with corticosteroids (oral or intravenous) with an opportunity to transition to mesalamine maintenance if they responded to corticosteroids. Initial therapy used in this study was based on disease severity using Pediatric Ulcerative Colitis Activity Index (PUCAI) scores, as well as a joint decision by the prescribing physician, patient, and family. For patients with mild disease at diagnosis, mesalamine only was started with weight-based daily dosing given in two divided doses (range 50–75 mg/kg/day) to a maximum dose of 4 g/day. In this mild group, slightly less than half of all patients (48%) achieved PUCAI<10 with no other therapy at week 52. In PROTECT, about 5–7% of patients were intolerant of mesalamine and 1% developed pancreatitis.

The use of adjunctive rectal mesalamine therapy (suppositories, enemas) is often encouraged in those with limited distal disease or proctitis. However, many children and adolescents are unwilling to accept this type of therapy. When used, however, it is often quite helpful.

Corticosteroids

Corticosteroids remain the mainstay of induction therapy for moderate to severe ulcerative colitis, and therefore, understanding the course of disease following these medications is critical to understanding natural history. Corticosteroid use is more widespread in the treatment of pediatric ulcerative colitis compared with adults, with a rate of 79% reported in an observational registry [16]. Traditional corticosteroid therapy has usually meant prednisone for moderate to severe disease, though budesonide MMX has been used for mild to moderate disease [17]. There are minimal published data on budesonide for the treatment of pediatric UC.

In the PROTECT study, data are available on one-year outcomes in large groups of patients started on either oral prednisone or intravenous corticosteroids [7]. In this study, following standardized treatment guidelines, corticosteroids were used as initial therapy for moderate to severe disease (PUCAI score > 45), with goal of weaning steroid dosing and starting mesalamine based on response at 2 weeks. Prednisone was used at a dose of 1–1.5 mg/kg/day to a maximum dose of 40–60 mg in a single morning dose. For those hospitalized with severe disease at time of diagnosis, treatment with intravenous corticosteroids was started, with a suggested dose of 1–2 mg/kg/day of methylprednisolone to a maximum of 60 mg. Of the 400 patients who were followed to week 52, 140 (35%) were initially given oral corticosteroids and 135 (34%) initially received intravenous corticosteroids. If patients showed a response to corticosteroids at 2 weeks, defined by PUCAI decrease of at least 20 points with resulting PUCAI < 35, mesalamine was added, and the initial dose of oral corticosteroids was continued for one more week prior to tapering. Of the 275 patients initially treated with corticosteroids, at week 52 after diagnosis, 32% achieved corticosteroid-free remission on mesalamine only, 9% neither achieved corticosteroid-free remission nor required additional therapy, 22% required escalation to an immunomodulator only, and 37% required escalation to anti-TNFα therapy.

Optimal dosing regimens for corticosteroids have not been established though there appears to be little advantage to exceeding the equivalent of 40–60 mg/day in adults. An exhaustive description of the mechanisms underlying corticosteroid resistance is beyond the scope of this discussion and has been reviewed elsewhere [18]. In a study of 128 children hospitalized with ulcerative colitis (OSCI) and treated with intravenous corticosteroids, non-response to therapy was associated with overexpression of several genes involved in inflammatory pathways [19]. In vitro studies have identified the expression of certain microRNAs as potential mediators of glucocorticoid (GC) resistance [20], but few clinical studies have been published that support this relationship. One clinical study investigated a possible correlation between microRNA expression and variability in GC-resistant and GC-sensitive patients [21]. Assessing serum microRNA of patients with UC, it was noted that downregulated microRNAs had a significant correlation with several signal transduction pathways, including the PI3K-Akt and MAPK signal pathways, and to target genes, including HSP90B1, MAPK13, MAPK9, PIK3AP1, and TLR4, related to GC resistance. This study also found six specific microRNAs (miR-16-2-3p, miR-30e-3p, miR-32-5p, miR642a-5p, miR150-5p, and miR-224-5p) that were significantly downregulated in GC-resistant patients.

Immunomodulators

The use of immunomodulators, such as thiopurines, for the treatment of corticosteroid-dependent ulcerative colitis has greatly diminished with the emergence of more effective and perhaps safer biologic agents. A review of seven blinded, controlled trials of azathioprine in ulcerative colitis highlighted the methodological issues with many early studies of adults which left unanswered the question of whether this drug was useful in maintaining remission [22]. A review of the 30-year experience with azathioprine in a large cohort of adult patients in Oxford, England suggested significant utility of azathioprine in maintaining remission [23]. Almost two-thirds of patients maintained remission for up to 5 years, and median time to relapse upon stopping the drug was 18 months. The addition of the 5-aminosalicylate olsalazine to azathioprine did not improve the maintenance of remission rate compared to azathioprine alone in steroid-dependent adults with ulcerative colitis.

Pediatric data are more limited. One report detailed thiopurine use in 133 children from an inception registry cohort in North America [24]. Of these, 65 (49%) had CS-free inactive UC without rescue therapy at one year from thiopurine start. CS-free inactive disease at 1 year after initiating thiopurine was not affected by starting thiopurine $\leq$ 3 months versus >3 months from diagnosis, gender, age, or concomitant treatment with 5-aminosalicylates. Kaplan–Meier analysis showed that the likelihood of remaining free of rescue therapy (surgery, calcineurin inhibitors, or biologic therapy) in the thiopurine-treated patients was 73% at 1 year.

A more recent pediatric study looked to assess the efficacy of azathioprine comparing the outcomes of early (0–6 months) versus late (6–24 months) initiation of therapy from time of diagnosis with UC [25]. Of the 121 children, 76 (63%) started AZA between 0 and 6 months after diagnosis and 45 (37%) started between 6 and 24 months. By 6 months, 21 patients withdrew due to either lack of efficacy, adverse events, or lost to follow-up. Seventy-five percent of the early group received CS at diagnosis, with 30 (50%) achieving CS-free remission at one year. Fifty-three percent of the late group received CS at diagnosis, with 23 (57%) achieving CS-free remission at one year. Mucosal healing was also assessed at one and two years, with either endoscopy (49%) or fecal calprotectin (51%). Mucosal healing only occurred in 37% of patients at one year and 40% of patients at 2 years, with no difference between the early and late groups.

Overall, the use of thiopurines has increasingly fallen into disfavor among many pediatric gastroenterologists in North America because of concerns for malignancy, particularly hepatosplenic T-cell lymphoma, and hemophagocytic lymphohistiocytosis (HLH). Although quite rare, these devastating conditions have been linked to thiopurine therapy [26]. The reluctance to use thiopurines in UC is generally not shared in Europe as they remain part of standard treatment options [27].

The use of methotrexate as an immunomodulator for the treatment of ulcerative colitis remains controversial. A recently published study was the first randomized, placebo-controlled study comparing the efficacy of 25 mg parenteral methotrexate weekly compared to placebo in adults with UC who had previously responded to open-label methotrexate [28]. One hundred and seventy-nine patients with active UC based on Mayo score were first given open-label methotrexate for a 16-week induction period with a 12-week steroid taper. At week 16, 91 (51%) patients achieved steroid-free clinical response and 84 of these patients were randomly assigned to 32-week maintenance period with either 25 mg/week subcutaneous methotrexate (n = 44) versus placebo (n = 40) until week 48. Of the 84 patients, 25/40 (63%) and 27/44 (61%) were in steroid-free remission and 15/40 (37%) an 17/44 (39%) were in steroid-free response in the placebo and methotrexate groups, respectively. Sixty percent (24/40) and 66% (29/44) of patients in the placebo and methotrexate groups, respectively, discontinued their therapy before week 32 of the maintenance period, with lack of efficacy or relapse of UC being the main reason for discontinuation in 22 patients in each group. At week 48, 30% (12/40) of patients in the placebo group and 27% (12/44) of patients in the methotrexate group were in steroid-free clinical remission

without the need for additional therapies ($p = 0.91$). This study provided similar findings to the METEOR trial, with a large proportion of patients achieving steroid-free response and remission during open-label induction phase [29]. However, parenteral methotrexate monotherapy was not superior to placebo in maintaining steroid-free clinical response or remission and preventing relapse in patients with UC.

Although calcineurin inhibitors are widely accepted as effective therapy for inducing remission in severe ulcerative colitis [30–32], their use as maintenance therapy is uncommon. In children, there are limited data on the use of these agents and while short-term response averages about 80% the majority of treated children still require colectomy within 2–3 years of their use [33]. Additionally, because of their nephrotoxicity, increased susceptibility to infection, and other side-effects, the use of calcineurin inhibitors is generally limited to several months as a bridge to other immunomodulators, infliximab, vedolizumab, or surgery.

Biologics

There are ample data supporting the use of anti-TNF therapy in children with ulcerative colitis. In a formal clinical trial of 60 children and adolescents with active ulcerative colitis despite treatment with corticosteroids, immunomodulators, and 5-aminosalicylates, a response as defined by a decrease in Mayo score by ≥30% and ≥3 points was seen at 8 weeks in 73% of patients following a 3-dose induction of 5 mg/kg at 0, 2, and 6 weeks [34]. Clinical remission by Mayo score, as defined by a score ≤ 2 with no individual subscore > 1, was seen in 40% at 8 weeks. At 54 weeks, in those patients treated with this induction regimen followed by maintenance therapy every 8 weeks, remission was noted in 38% of subjects. Similar to the experience in adults, a direct relationship was found between serum infliximab levels and a positive therapeutic response [35].

It has been demonstrated that low-serum trough levels of infliximab as well as the development of antibodies to infliximab negatively affect response and durability [36]. One such retrospective chart review of 129 children with IBD treated at a tertiary care pediatric IBD center included 278 samples of infliximab levels and antibodies to infliximab, determined that for those who were treated with a dose of 5 mg/kg, 6 week dosing had significantly higher infliximab levels compared to 8 week dosing ($p = 0.009$) [37]. Out of the 129 patients, 48 (37.2%) demonstrated low infliximab levels (<3 μg/ml) and 24 of those 48 (50%) demonstrated antibodies to infliximab. Twenty-nine (22.5%) developed antibodies to infliximab, and low or undetectable serum infliximab levels were associated with the development of antibodies. This review was in line with prior studies [38, 39] showing the association that low infliximab levels have to the development of immunogenicity to infliximab as measured by antibodies to infliximab.

Therapeutic drug monitoring for IBD patients on anti-tumor necrosis factor (anti-TNF) therapy has become more common, though reactive versus proactive monitoring has not yet been standardized. A 2017 multicenter, retrospective study of 167 adults with Crohn disease and 97 with UC on infliximab maintenance therapy received either proactive ($n = 130$) or reactive ($n = 134$) monitoring and was followed to assess long-term outcomes including treatment failure, first IBD-related surgery or hospitalization, serious infusion reactions, and detection of antibodies to infliximab [40]. This study found that proactive drug monitoring was independently associated with reduced risk of treatment failure ($p < 0.001$), IBD-related surgery ($p = 0.017$), IBD-related hospitalization ($p < 0.001$), antibodies to infliximab ($p = 0.025$), and serious infusion reaction ($p = 0.023$) when compared to reactive monitoring. Rapid clearance of anti-TNF medications has been noted in patients with extensive disease and high C-reactive protein levels, likely through multiple mechanisms including the concept of a "large antigen-sink" of TNF, hypoalbuminemia, and loss in the stool [36, 41–43]. As rapid clearance can lead to loss of response or drug-related adverse events, the results of this study suggest that it is better to optimize infliximab therapy with use of proactive therapeutic drug monitoring rather than wait for these undesirable outcomes to occur before testing.

There are limited data on the use of adalimumab to treat pediatric ulcerative colitis. In a retrospective study assessing the effectiveness and safety of adalimumab in children with UC, all of whom were previously treated with infliximab, 32 patients received adalimumab, and at week 52, 13 (41%) were in corticosteroid-free remission, of whom 9 (28%) had mucosal healing [44]. 17 (53%), 15 (47%), and 13 (41%) were in steroid-free remission at 12, 30, and 52 weeks, respectively. Ten patients (31%) had a primary failure and 5 (15%) a loss of response to adalimumab. And, 12.5% of this study population required colectomy at 1-year follow-up, a rate that is consistent with previous data on disease course in UC. No serious side effects, including deaths or malignancies, were reported. Overall, adalimumab seemed to be effective in inducing clinical and endoscopic remission in children with UC who previously failed or were intolerant to infliximab therapy.

Golimumab is another humanized IgG1 antibody to TNFα, used in adults for the treatment of UC, as well as select other diseases. Although few pediatric studies have been performed, one multicenter, prospective, open-label study evaluated the safety, outcomes, and pharmacokinetics of golimumab in anti-TNF naïve children with moderate to severe active UC [45]. Thirty-five patients were enrolled in the study and received golimumab induction at weeks 0 and

2. Of the 35 participants, a total of 15 (43%) discontinued the medication prior to week 14; 3 after the 2 induction doses, 11 were not in Mayo clinical response at week 6 and medication was discontinued per study protocol, and 1 discontinued the medication prior to week 14 due to a disease flare. At week 6 following induction, Mayo clinical response was induced in 21 (60%) patients, Mayo clinical remission in 15 (43%), PUCAI clinical remission in 12 (34%), and mucosal healing (Mayo subscore 0/1) in 19 (54%), with 8 (23%) achieving complete mucosal healing (Mayo subscore 0). No malignancies, deaths, or serious infections were reported in this small cohort. Overall, the outcome data at week 6 of this study suggest that in pediatric patients with UC, golimumab offers generally comparable clinical benefits to the adult UC population.

Anti-integrin therapy has shown efficacy in the treatment of adults with ulcerative colitis [46], and published data in children are available. Vedolizumab is an α4β7 anti-integrin monoclonal antibody with gut specificity. A retrospective, multicenter review of 52 pediatric IBD patients (58% Crohn disease and 42% ulcerative colitis) receiving vedolizumab was performed to examine efficacy in pediatric IBD. Ninety percent of (47/52) patients had previously failed ≥ 1 anti-TNF agent. All patients received vedolizumab at 0, 2, and 6 weeks, then approximately every 8 weeks thereafter. At week six and week 14, 14/22 (63%) and 13/17 (76%) of UC patients were in clinical remission based on PUCAI score ≤ 10, respectively. Patients with UC were more likely to be in remission at week 14 compared to those with Crohn disease (76% vs. 42%, $P < 0.05$). Week 6 corticosteroid-free remission was associated with week 14 corticosteroid-free remission among both groups ($P < 0.0001$). At week 33, anti-TNF-naïve patients had a higher remission rate compared to TNF-exposed patients (100% vs. 45%, $P = 0.04$). This study also found that both pediatric Crohn disease and UC patients with colonic-only disease had higher rates of remission at multiple time points throughout the study. No infusion reactions or serious adverse events, including tuberculosis, meningitis, or progressive multifocal leukoencephalopathy were observed at last follow-up.

Ustekinumab is a monoclonal antibody to the p40 subunit of interleukin-12 and interleukin-23 that is approved for use in the treatment of psoriasis, psoriatic arthritis, Crohn disease, and most recently ulcerative colitis in adults. The phase 3 UNITI trial recently evaluated 961 adults with moderate-to-severe ulcerative colitis in a randomized, double-blind, placebo-controlled study, with the primary end point being clinical remission at week 8 after induction and week 44 for the maintenance trial [47]. Nine-hundred and twelve (94.9%) patients completed the induction trial, either receiving approximately 6 mg/kg dose, 130 mg dose, or placebo intravenously, with 783 (81.5%) entering into the maintenance trial. Of these 783 patients, 523 underwent randomization into the maintenance population (primary population) receiving 90mg every 8 weeks, every 12 weeks, or placebo every 8 weeks subcutaneously; and 260 were placed in a nonrandomized maintenance population (157 receiving 90 mg every 8 weeks and 103 placebo). Histo-endoscopic mucosal healing, improvements in partial Mayo scores, and reductions in serum and fecal concentrations of inflammatory biomarkers were observed in inductions and sustained in maintenance by both doses of ustekinumab. Ustekinumab was found to be more effective in achieving induction of clinical remission at 8 weeks when compared to placebo, and for those who achieved response to induction and underwent second randomization into the maintenance population, the patients receiving ustekinumab were more likely to be in clinical remission at week 44 compared to those assigned to placebo.

Off-label use in the pediatric IBD population has been increasing, though no controlled clinical trials in this population have been performed. One observational cohort study followed 52 pediatric IBD (42 Crohn disease, 4 ulcerative colitis, and 6 IBD-unspecified) patients receiving ustekinumab for steroid-free remission at 52 weeks [48]. For this patient population, 81% had failed >1 anti-TNF, 37% failed anti-TNF and vedolizumab, and 10 patients were biologic-naïve. At week 52, 39 patients (75%) were still receiving ustekinumab (31 CD, 8 UC/IBDU), with 30 patients in steroid-free remission (25 CD, 5 UC/IBDU). No significant associations were round in respect to disease type or location and remission outcomes. At week 52, biologic-naïve patients (90%, $n = 9$) were significantly more likely to achieve steroid-free remission compared to biologic-exposed patients (50%, $n = 21$) ($P = 0.03$). With regard to safety, no serious infections or other serious adverse events were reported in this cohort.

Small Molecules

Due to a lack of universal response, risks of infections and neoplasia, parenteral administration, and risk of developing antidrug antibodies with use of immunomodulators and biologics, oral non-biologic small molecule therapies are now being investigated for the treatment of ulcerative colitis. The OCTAVE trials [49, 50] investigated tofacitinib, an oral small-molecule Janus kinase (JAK) inhibitor that inhibits all JAKs, but preferentially JAK1 and JAK3, for use of induction and maintenance therapy for adults with moderate to severely active ulcerative colitis. In the OCTAVE Induction 1 trial, remission at 8 weeks occurred in 18.5% (88 of 476) of patients receiving 10 mg tofacitinib twice daily versus 8.2% (10 of 122) in the placebo group ($P = 0.007$) and in OCTAVE Induction 2 trial, remission occurred at 16.6% (71 of 429) of the tofacitinib group versus 3.6% (4 of 112) in the placebo

group ($P < 0.001$). In the OCTAVE Sustain trial, 34.3% (68 of 198) of patients in the 5mg bid and 40.6% (80 of 197) of patients in the 10 mg tofacitinib bid groups achieved remission at 52 weeks compared to 11.1% (22 of 198) in the placebo group ($P < 0.001$ for both comparisons with placebo). In the OCTAVE Sustain trial, the rate of herpes zoster infections was higher among those treated with tofacitinib ($n = 13$; 3 receiving 5 mg and 10 receiving 10 mg) compared to placebo ($n = 1$). Across all three trials, non-melanoma skin cancer and cardiovascular events occurred in more patients who received tofacitinib ($n = 5$) compared to placebo ($n = 0$). Although no formal trials have yet been performed in the pediatric ulcerative colitis population, tofacitinib has started to be used off-label by some centers for children who have been refractory to biologics.

Ozanimod is the newest small molecule oral therapy showing promising outcomes for the treatment of ulcerative colitis in adults. Ozanimod is an oral agonist of the sphingosine-1-phosphate receptor subtypes 1 and 5, which induces peripheral lymphocyte sequestration, leading to potential decrease in the number of activated lymphocytes in the gastrointestinal tract. Preliminary data from phase 2 of the TOUCHSTONE trial [51], a double-blind, placebo-controlled trial of 197 adults with moderate-to-severe active ulcerative colitis, showed that daily use of 1 mg ozanimod resulted in a slightly higher rate of clinical remission, based on Mayo clinic scores (Mayo score ≤2, with no subscore >1) at week 8, compared to placebo. At week 8, clinical remission occurred in 16% who received 1mg dosing ($P = 0.048$) and 14% who received 0.5 mg dosing ($P = 0.14$), when compared to the placebo group, of which 6% achieved clinical remission. At week 32, exploratory outcome measures showed that those receiving 1mg of ozanimod daily continued to have higher rates of clinical remission, clinical response, mucosal healing, histologic remission, and lower Mayo scores compared to those with placebo. One limitation of this study was the use of 8 weeks at the timepoint for the primary outcome analysis, as this might not have been sufficiently long enough for ozanimod to target lymphocyte tracking.

Antibiotics

In recent years, there has been an increase in use of broad-spectrum antibiotics as salvage therapy in refractory colitis. In one small pediatric cohort of 15 children with moderate to severe refractory UC, almost half (7/15) entered complete clinical remission defined as PUCAI < 10 when treated with a 2–3 week oral broad-spectrum antibiotic regimen consisting of metronidazole, amoxicillin, doxycycline, or ciprofloxacin, and, in hospitalized patients only, the addition of vancomycin [52].

In a single-center retrospective study of 63 children with refractory UC, Crohn's colitis, or IBD-U given the same 3 or 4 antibiotic regimen, 40/63 (63.5%) experienced a clinical response, defined as PUCAI change ≥20 points, and 25/63 (39.7%) achieved clinical remission, defined as PUCAI < 10 [53]. The combination antibiotics led to a significant decrease in median PUCAI score from 55 (40–65) to 10 (0–40; $p < 0.0001$) over 3 ± 1 weeks after initiation of antibiotics. In a subset analysis of only patients with acute severe colitis ($n = 26$), the median PUCAI decreased from 65 (60–70) at baseline to 35 (10–65) at 3 ± 1 weeks after initiation of antibiotics ($p < 0.0001$).

In the first randomized controlled trial conducted in pediatric acute severe colitis (ASC), 28 hospitalized children with ASC were randomized to receive the quadruple oral antibiotic cocktail (amoxicillin, vancomycin, metronidazole, and doxycycline or ciprofloxacin) and intravenous corticosteroids ($n = 16$), or intravenous corticosteroids only for 14 days ($n = 12$). There was a significant difference in the mean day 5 PUCAI score, 25 ± 17 vs 40 ± 20, respectively ($p = 0.037$) [54]. Secondary endpoints of remission rate and calprotectin values were numerically better in the antibiotic + intravenous corticosteroid group, but did not reach statistical significance in this small study.

Can We Predict the Course of Disease?

The wide range in phenotypic expression of pediatric ulcerative colitis and its response to therapy has heretofore made prediction of disease course difficult. Clinical factors examined have included features such as severity of disease (i.e., fulminant features requiring hospitalization), endoscopic appearance, laboratory markers, and early response to therapy [55–57]. Specific laboratory markers present at diagnosis, including hypoalbuminemia [7], elevated CRP [58], and anemia [11, 59], have shown to be predictive of eventual colectomy. Clinical severity at diagnosis, the need for hospitalization at diagnosis, and the need for rapid rescue with immunomodulators or biologics remain the greatest risk factors for early colectomy.

Pediatric data of early outcomes following standardized therapy after initial diagnosis suggest that baseline PUCAI < 35, higher baseline albumin, and week 4 clinical remission are predictors of week 12 corticosteroid-free remission (PUCAI < 10) [60]. Following this same cohort of patients, predictors for achieving week 52 corticosteroid-free remission for all patients included PUCAI < 35 at diagnosis, higher baseline hemoglobin and albumin, and week 4 clinical remission [7]. Assessing for biological predictors of disease course, this study showed that patients with rectal eosinophil count < 32 per high power field before treatment and those with Vitamin D-25(OH) level <20 ng/mL were

more likely to escalate to anti-TNFα therapy during the first year. Using RNA sequencing to assess the pattern of rectal gene expression and fecal microbiota profiles, it was also found that lower levels of an antimicrobial peptide gene signature and *Sutterella* organisms, and a higher relative abundance of Ruminococcaceae were independently associated with week 52 corticosteroid-free remission. Specifically, it was found that the α-defensin antimicrobial peptide pathway showed a stronger negative association with week 52 corticosteroid-free remission, and that a greater number of α-defensin 5 positive cells were present in rectal biopsy samples from patients who did not achieve week 52 corticosteroid-fee remission, compared to those who did and healthy controls. Those with more severe disease in this same cohort of patients were found to have a significant increase in bacteria typically found in the oral cavity within their gut mucosa at both baseline and in follow-up [61].

Attempts have also been made to try to correlate disease course with genetic profiles. An association between severe and extensive disease and the major histocompatibility complex (MHC) genes DRB1*0103 and DRB1*15 has been identified in adults [62–64]. Human leukocyte antigen (HLA) DRB1*0103 has shown an association with both UC and colonic Crohn disease, strongly suggesting that this allele is critically involved in determining the colonic immune response to local flora [65, 66]. A genome-wide association study (GWAS) compared 324 adults with ulcerative colitis who required colectomy for refractory disease with 537 ulcerative colitis patients who did not [67]. A risk score determined from a combination of 46 single nucleotide polymorphisms (SNPs) associated with the medically refractory group accounted for a little less than 50% of the variance for the colectomy risk. Specifically, the known IBD susceptibility gene *TNFSF15 (TL1A)* on chromosome 9q32 was implicated in UC severity. The sensitivity and specificity of the risk score were over 90%.

Microarray of RNA isolated from colonic biopsy tissue has identified genes that may predict the response to infliximab in adults [68]. This panel of five genes (osteoprotegerin (OPG), stanniocalcin-1, prostaglandin-endoperoxide synthase 2 (COX2), interleukin 13 receptor alpha2 and interleukin 11) discriminated responders from non-responders with 95% sensitivity and 85% specificity. Another study of mucosal gene expression found a positive correlation between high IL-17 and IFN-γ expression and response to infliximab [69]. Variants of the IL-23R gene that increase susceptibility to UC seem to improve response to infliximab [70]. One study used a pharmacogenetics GWAS to evaluate infliximab non-response in a combined pediatric ulcerative colitis and Crohn disease group, finding BRWD1, TACR1, FAM19A4, and PHACTR3 to predict non-response [71].

In pediatric patients, elevated fecal levels of osteoprotegerin (OPG) are associated with failure to respond to intravenous corticosteroids in children with severe ulcerative colitis [72]. One study found that 41 genes, with statistical significance, were differentially expressed between IV corticosteroid responders and non-responders in children with severe ulcerative colitis [73]. Two of the genes, CEACAM1 and MMP8, are possibly inhibited by methylprednisolone through IL-8, and found to be over-expressed in corticosteroid non-responsive patients. The expression pattern of 10 out of the 41 genes were able to classify the treated patients with 80% sensitivity and specificity. Emerging areas of research into biologic molecules (e.g., metabolomics, proteomics, and epigenomics) have the potential to clarify disease phenotypes, behavior, and responsiveness to medications [74–76].

Summary

The optimal therapy for ulcerative colitis quickly induces and then effectively maintains remission with healing of the colonic mucosa and presents minimal toxicity to the patient. While 5-aminosalicylates are effective in inducing and maintaining remission in some patients, their efficacy in both aspects of therapy is limited for those with more severe disease. Nonetheless, 5-aminosalicylates should be the cornerstone of therapy if possible. Immunomodulators and anti-TNFα therapy are effective in many patients not maintained in remission on 5-aminosalicylates, but remission at one year is noted in less than half of patients treated with these agents, and disease flares are still common. Evidence suggests that the short-term impact of biological agents on disease course is positive, though it is still not clear that disease course is altered for those who present with fulminant disease. This group continues to exhibit a greater degree of treatment unresponsiveness and has an unacceptably high rate of colectomy. Long-term observations will be required to better understand the changing natural history of ulcerative colitis in children with the emergence of new therapies. Current research holds the promise of development of risk assessment (e.g., gene expression, microbiome, and genetics) promptly following diagnosis that will facilitate treatment design, decreasing the likelihood of treatment failure, and complications of ineffective treatments.

Pediatric Inflammatory Bowel Disease: Unclassified

9

Brooke Boyer and Elana B. Mitchel

Abbreviations

CD	Crohn Disease
UC	Ulcerative Colitis
IBD	Inflammatory Bowel Disease
IBD-U	Inflammatory Bowel Disease-Unclassified

Introduction

A diagnosis of inflammatory bowel disease is made following a detailed clinical history in combination with biochemical, radiographic, endoscopic, and histologic evaluation. While for many pediatric patients, initial evaluation results in a clear diagnosis of either Crohn disease (CD) or ulcerative colitis (UC), the phenotype of IBD can be heterogeneous, existing across a spectrum. A subset of patients with colonic disease may present with atypical features that do not clearly fit the diagnostic criteria for UC or CD, resulting in a diagnosis of inflammatory bowel disease-unclassified (IBD-U).

A diagnosis of IBD-U can pose a challenge to providers as there have been varying definitions of this entity and less is known about the natural history, prognosis, or efficacy of treatment of the disease. Additionally, this diagnosis, even by its very name, can lead to confusion and a sense of uncertainty among patients and their caregivers. In this chapter, we will review the criteria used to establish a diagnosis of IBD-U, the epidemiology of IBD-U, diagnostic evaluation, as well as considerations for medical and surgical management.

Definition

The term indeterminate colitis was first introduced in the 1970s as a diagnosis in IBD patients whose pathology after colectomy showed features consistent with both UC and CD [1]. This diagnosis has since evolved overtime. The Montreal classification, published in 2006, replaced the term indeterminate colitis with IBD-U to define the pre-surgical patient who has clinical, endoscopic, and biochemical features of IBD but no definitive features of UC or CD [2]. Since this time, with advances in diagnostic tools and disease detection, the uncertainty of IBD subtype classifications has increased and in the pediatric setting, several groups have worked to further define IBD-U [3, 4].

In 2014, the revised Porto criteria by the European Society for Pediatric Gastroenterology and Nutrition (ESPGHAN) were published, providing clinicians with a more defined framework for establishing a diagnosis of IBD-U. Certain features of IBD were divided into three distinct classes to help differentiate subgroups of pediatric IBD. Class 1 features were considered features incompatible with UC, making CD the definitive diagnosis. Class 2 features were more commonly found in CD but rarely found in UC (<5% of UC cases). Class 3 were features suggestive of CD but also found in UC (5–10% of UC cases). With increasing features from class 2 or 3, the likelihood of CD increased. The criteria stated that a diagnosis of IBD-U should be considered if a patient had at least one Class 2 feature such as rectal sparing, significant growth delay, transmural inflammation in the absence of severe colitis, duodenal or esophageal ulcers not explained by other causes, multiple aphthous ulcerations in the stomach not explained by other causes, or reverse gradient mucosal inflammation with more inflammation proximally rather than distally. IBD-U could also be diagnosed if a patient had at least 2 to 3 Class 3 features such as severe scalloping of the stomach or duodenum not explained by other etiologies, focal chronic duodenitis on multiple biopsies or marked scalloping of the duodenum not explained by other causes, focal active

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_9

Table 9.1 Updated revised Porto Group classification system [6]

Class	Feature	Determination of IBD-type
Class 1		**CD diagnosis** If any class-1 features present If class-1 features absent, at least 1 class-2 feature and 4 or more class-3 features **UC diagnosis** If class-1 and class-2 features absent **Atypical UC** If class-1 and class-2 absent with 1-2 class-3 features **IBD-U** If class-1 features absent with at least 1 class-2 feature and up to 3 class-3 features
1	At least one well-formed granuloma anywhere in the GI tract, remote from ruptured crypt	
2	At least one of: deep ulcerations; cobblestoning; or stenosis anywhere in the small bowel or upper GI tract (excluding stomach)	
3	Fistulizing disease (internal or perianal)	
4	Large inflamed perianal skin tags	
5	Thickened jejunal or ileal bowel loops on radiology or other evidence of significant small bowel inflammation on capsule endoscopy not compatible with backwash ileitis	
6	Any ileal inflammation in the presence of normal cecum (incompatible with backwash ileitis)	
Class 2		
7	Macroscopically and microscopically normal appearing skip lesions in untreated patient (excluding rectal sparing and cecal patch)	
8	Complete (macroscopic and microscopic) rectal sparing	
9	Macroscopically normal colon in between inflamed mucosa but with microscopic inflammation (relative patchiness)	
10	Significant growth delay (height velocity <−2 SD), not explained by other causes	
11	Transmural inflammation in the colon in the absence of severe colitis	
12	Small and not deep ulcers (including aphthous ulcerations) anywhere in the small bowel, duodenum and esophagus (excluding stomach and colon) not explained by other causes	
13	Multiple (≥5) small and not deep ulcers (including aphthous ulcerations), in the stomach or colon (on the background of normal mucosa), not explained by other causes	
14	Ileitis, otherwise compatible with backwash ileitis, but in the presence of only mild inflammation in the cecum	
15	Positive ASCA in the presence of negative pANCA	
16	Reverse gradient of mucosal inflammation (proximal > distal [except rectal sparing])	
17	Severe scalloping of the stomach or duodenum, not explained by other causes	
18	Deep ulcerations (at least one) or severe cobblestoning of stomach not explained by other causes	
Class 3		
19	Focal chronic duodenitis on histology	
20	Focal active colitis on histology in more than one biopsy	
21	Several [<5] aphthous ulcerations in the colon or in the stomach	
22	Non-bloody diarrhea	
23	Focal enhanced gastritis on histology	

colitis, non-bloody diarrhea, or aphthous ulcerations in the colon or upper gastrointestinal tract [5].

In 2017, the Porto Group of ESPGHAN performed a retrospective longitudinal multicenter study to validate the classification system described above. The algorithm was slightly revised to allow for maximal diagnostic accuracy in over 500 IBD patients. The final classification system is listed in Table 9.1. IBD-U was defined if a patient had at least one Class 2 feature and/or up to three Class 3 features. This updated algorithm differentiated UC from CD and IBD-U with 80% sensitivity and 84% specificity and CD from IBD-U and UC with 78% sensitivity and 94% specificity [6]. Thus, while considerable progress has been made in defining IBD-U, there is still a need for further study.

Epidemiology

Estimating the incidence and prevalence of IBD-U is challenging due to variability in the classification of this disease phenotype, potential for labeling of this diagnosis when the work-up is incomplete, and the high likelihood of reclassification of this subtype.

The overall incidence of pediatric IBD is increasing [7]. Based on recent studies, the incidence of IBD-U in the pediatric population is also increasing [7–10]. The incidence is widely varied but in most pediatric studies ranges from 0.3 to 1.2 per 100,000 person years [7–14]. The highest annual incidence reported is 2.1 per 100,000 persons in North America and 3.6 per 100,000 person years in Europe [15, 16].

The proportion of patients with IBD who receive the diagnosis of IBD-U varies widely across studies and is more likely to be changed to CD or UC overtime. In the RISK study, a multicenter inception cohort of pediatric IBD patients, 136 of 1411 (9.6%) patients were diagnosed with IBD-U at enrollment. Within 2 years after diagnosis, only 60% of patients remained with the diagnosis of IBD-U, 26% were reclassified as UC and 14% as CD. Of those requiring reclassification, the ratio of change to UC versus CD was 2:1 [17]. In another large inception cohort from Canada, 8% of pediatric patients were classified as IBD-U at diagnosis. Within the first year after diagnosis, 39 (44%) were reclassified to UC, 11 (12%) were switched to a diagnosis of CD and only 39 (44%) continued to hold a diagnosis of IBD-U [18]. In one tertiary care center registry of 250 children with IBD, retrospectively 74 (29.6%) were diagnosed with IBD-U and only 49 (66.2%) remained with the diagnosis of IBD-U after a mean follow-up time of 6 years. In another retrospective single-center study, 78 (22%) children and adolescents were diagnosed with IBD-U over a 25-year period with a significant proportion undergoing reclassification during follow-up [19]. These studies also illustrate that study design impacts the estimate of IBD-U, with higher estimated proportions found in retrospective as compared to prospective studies [20].

Age at diagnosis plays a major role in the diagnosis of IBD-U. IBD-U is more commonly diagnosed in pediatric patients as compared to adults. In one meta-analysis, 13% of children as compared to 6% of adults were given the diagnosis of IBD-U [20]. In a large cohort study, 18% of pediatric as compared to 11% of adult patients were diagnosed with IBD-U [21]. This difference is likely related to the fact that pediatric patients are more likely to present with colonic CD as compared to adults and adult UC is more likely to present with left-sided disease or proctitis [5, 22]. However, even within pediatric populations, IBD-U is more commonly applied to younger children, present in 13% of children <10 years old and 7% of children ≥10 years old ($p < 0.001$). In another study, early presentation before age 10 was seen in 31% patients with IBD-U as compared to 17% CD and 20% UC [14]. This finding may be related to the different phenotype that many very-early onset (VEO) IBD patients display and may be compounded by difficulty completing the diagnostic work-up in young children.

Finally, when considering the epidemiology of IBD-U, the importance of pursuing a complete diagnostic work-up in pediatric and adolescent patients is underlined by a study using the EuroKIDS Registry. IBD-U was made as the initial diagnosis in 7.7% of children (265 out of 3461). However, about half of these children had not undergone complete diagnostic work-up. Upon reinvestigation with endoscopy and imaging, 12% had a change in diagnosis from IBD-U to CD and 20% to UC over a median of 5.7 years of follow-up. After reinvestigation, IBD-U diagnosis was only in 5.6% of pediatric patients [23]. Furthermore, IBD-U epidemiology may be impacted by the subspecialist and the diagnostic capabilities of the pediatric center under which the patient is being cared for.

Diagnosis

A complete diagnostic work-up including endoscopy and small bowel imaging is essential in making the diagnosis of IBD-U or reclassifying patients to a diagnosis of CD or UC. Additionally, throughout the disease course and during periods of exacerbation, patients given a diagnosis of IBD-U should undergo complete endoscopic and radiographic evaluation in order to assess disease distribution and potential progression which may result in reclassification [4].

Clinical Features

There are no definitive clinical or histological features that are diagnostic of IBD-U. There have been few studies that have looked to further define clinical features suggestive of IBD-U. Patients with IBD-U typically display a more UC phenotype with the most common symptoms at presentation being diarrhea and rectal bleeding [24]. In one large pediatric study of 3991 children and adolescents with IBD, initial diagnostic symptoms were compared across IBD subtypes. Blood in the stool was reported most commonly in UC and IBD-U as compared to CD. In addition, diarrhea was less common in CD patients. Abdominal pain was present in all three subtypes (59.2% UC, 77.3% CD, and 57.9% IBD-U) [25].

Endoscopic Evaluation

Upper endoscopy and ileocolonoscopy are essential to the diagnostic evaluation of IBD-U. Studies have shown that IBD-U and UC share similar endoscopic findings [23, 24]. In one study evaluating 158 IBD-U patients, 58% presented with pancolitis, 17% with ulcerative proctitis, 7.6% with left-sided colitis, and 7.0% with extensive colitis [23]. In another recent pediatric study, 61% of patients with IBD-U had pancolitis on diagnostic endoscopy [6]. Interestingly, Rinawi et al., in a retrospective study of over 700 patients with pediatric IBD, found that patients with IBD-U had more extensive colonic involvement than those with pediatric-onset UC at diagnosis (70% vs. 45%, $p = 0.02$) suggesting that IBD-U may have more extensive and aggressive features at the time of presentation [26].

Studies have also shown the wide-spread and heterogenous endoscopic findings in IBD-U patients, including involvement of the esophagus, stomach, duodenum, and ileum [27]. In one study, 23% of pediatric patients with IBD-U were found to have visual inflammation in the stomach, duodenum, or both [23]. Therefore, it is important, even if a diagnosis of IBD-U or UC is suspected, that full endoscopic evaluation be performed to understand extent.

Small Bowel Imaging

Comprehensive evaluation of the gastrointestinal tract at the time of diagnosis must include small bowel evaluation to further differentiate IBD subtype and potentially confirm the diagnosis of IBD-U. Imaging in the pediatric population requires multiple considerations including the patient's ability to tolerate the study with attention to duration of the study, need for sedation, ingestion of contrast, and radiation exposure. Imaging studies and capsule endoscopy can provide important diagnostic information.

Radiologic Studies: Several imaging modalities exist to evaluate the gastrointestinal tract. Previous fluoroscopic barium studies including small bowel follow through and contrast enema have been largely replaced by cross-sectional imaging with either magnetic resonance enterography (MRE) or computed tomography enterography (CTE). Both MRE and CTE, through the use of intravenous and enteral contrast, are able to detect luminal, transmural, and extraintestinal inflammation [28]. Both studies are similar in their detection of active inflammation; however, MRE is more sensitive in identifying fibrosis [28, 29]. In many pediatric centers, MRE has become the preferred imaging modality of choice given its high specificity and sensitivity in detecting inflammatory changes in the intestinal wall as well as other disease complications. In addition, MRE has no associated ionizing radiation exposure [30, 31]. However, due to the long study duration, issues related to claustrophobia and tolerance of enteral contrast may pose a challenge, particularly in young children and those with developmental delay. This is important to consider especially in IBD-U, a subtype that favors the pediatric population, particularly a younger cohort. In cases where MRE is not feasible, CTE or alternatively ultrasound should be pursued. Contrast-enhanced ultrasound (CEUS), an emerging imaging modality in pediatric IBD, is a complementary or alternative means to assess for bowel inflammation in addition to extramural complications such as abscess or inflammatory mass [32, 33].

In general, IBD-U patients seem to be less likely to undergo a complete diagnostic study as compared to CD and UC, respectively (48% vs. 60% vs. 64%, $p < 0.001$) [23]. One pediatric study found that patients diagnosed with IBD-U were less likely to have small bowel imaging performed as compared to CD patients (73% vs. 62%, $p < 0.001$). A wide variety of small bowel imaging in IBD-U patients was also used in this study [34].

Video Capsule Endoscopy: Video capsule endoscopy (VCE) allows for complete visual examination of the small intestine. In pediatric patients, swallowing a capsule may be difficult, and in these instances, endoscopic placement should be pursued. Limitations to capsule endoscopy include capsule retention as well as poor bowel preparation which can obscure visualization. The greatest risk for capsule retention is a known diagnosis of IBD (5.2% risk) [35]. In patients with higher clinical suspicion of CD with small bowel involvement, patency capsule should be considered prior to capsule endoscopy.

VCE has been shown to be helpful in defining IBD subtype and may be particularly helpful in the IBD-U cohort. In one retrospective study, the impact of VCE on decision-making and diagnostic accuracy was evaluated in 66 pediatric IBD patients. Use of VCE allowed for clarification of the diagnosis where 50% of patients with a diagnosis of IBD-U or UC were changed to CD with this additional information [36]. In an adult study, 36 patients with IBD-U underwent VCE. After VCE, about 25% of patients had reclassification to a diagnosis of CD and in about 44%, a diagnosis change to UC. Twenty-eight percent maintained a diagnosis of IBD-U based on the VCE results [37].

Medical Management

Patients with IBD-U are often excluded from randomized clinical trials or, when included, are often grouped with UC. As such, there are no medications approved specifically for the treatment of IBD-U. This cohort of patients is heterogenous and therapy should be guided by clinical presentation in addition to disease phenotype. Patients with IBD-U are treated with the same classes of medications as children with CD or UC, including aminosalicylates, immunomodulators, and biologic agents.

In 2017, the Porto Group of ESPGHAN published results from a retrospective multicenter study reviewing therapeutic management of patients with a diagnosis of IBD-U. A total of 797 children were included in the study, 260 patients diagnosed with IBD-U, of which 23% had extensive colitis at the time of diagnosis. Patients with IBD-U had a statistically significant lower use of corticosteroids and higher use of exclusive enteral nutrition compared to those with UC. In comparison to patients with CD, patients with IBD-U received more aminosalicylates and were less likely to be treated with EEN or immunomodulators. Biologic therapy use was higher in patients with CD (34%) versus UC (17%) and IBD-U (12%) [6]. More work is needed to better understand this population and to better define therapeutic algorithms.

Surgical Management

Surgical intervention is taken very seriously in IBD-U patients due to the uncertainty of the diagnosis and the potential for later reclassification. IBD-U patients are less likely to undergo surgery as compared to patients with UC and CD [38]. In those with IBD-U who do undergo surgery, a diagnosis reclassification is more likely to occur [23].

One surgical option for this group of patients is ileal diversion. This procedure can be a helpful temporizing measure in patients with IBD-U who are ill but in whom the IBD phenotype is unclear. In one pediatric retrospective study at a single tertiary care center, patients who underwent surgical diversion had significant improvement in height and weight velocities, height velocity *z*-score, blood transfusion requirement, hemoglobin, and hospitalization rates. Fifty-four percent of the patients who underwent diversion had the diagnosis of IBD-U at the time of diversion. About half of these IBD-U patients had reclassification of their disease after diversion. Thus, in these patients, diversion allowed for the time needed to determine the diagnosis [39].

Ileal pouch-anal anastomosis (IPAA) is another common surgical approach in patients with IBD-U. Multiple studies have shown that patients with IBD-U have similar retention of the pouch, pouch function, and favorable quality of life scores after IPAA as compared to those with UC [35, 40–42]. Failure rates are also similar to patients with UC [42]. However, IBD-U patients have higher rate of pouch fistula, perianal fistulae, and pelvic abscesses; thus the risks and benefits of this procedure must be weighed [35, 40, 41].

Conclusion

The IBD phenotype can be heterogeneous and exists across a spectrum, not always distinctly categorized as UC or CD. The diagnosis of IBD-U is made in patients with colonic disease but with atypical features that do not fit clearly into a diagnosis of UC or CD. While there is less known about the natural history, prognosis, and efficacy of treatment in patients with IBD-U, there has been recent work to better define this entity. IBD-U is increasing in incidence and is more prevalent in the pediatric population, particularly in younger patients. A complete diagnostic work-up including endoscopy and small bowel imaging is essential to solidifying the diagnosis of IBD-U or reclassifying patients to a diagnosis of CD or UC. Additionally, throughout their disease course and during periods of exacerbation, patients given a diagnosis of IBD-U should undergo complete endoscopic and radiographic evaluation in order to assess disease distribution and potential progression which may result in reclassification. Once a diagnosis is made, medical management is similar to that in CD and UC; however, there is little evidence in efficacy of therapies as IBD-U patients are often excluded from drug trials. Medical management should be guided by the patient's clinical presentation in addition to their disease phenotype. Surgical intervention can be helpful in the treatment of IBD-U but must be approached with extreme caution given the uncertainty tied to the diagnosis of IBD-U and potential later reclassification. Future research in this patient population is extremely important to better define the pathogenesis, diagnostic accuracy, and medical and surgical management.

Extraintestinal Manifestations of Pediatric Inflammatory Bowel Disease

10

Shervin Rabizadeh and Maria Oliva-Hemker

Introduction

Inflammatory bowel disease (IBD) is not just a disorder of one organ system, but rather a multi-systemic disease. In addition to the more typical gastrointestinal involvement which can present with symptoms such as abdominal pain, chronic diarrhea, or bloody stools, several other organs can be involved as well, including the eyes, skin, joints, kidneys, and liver. In fact, these extraintestinal manifestations (EIMs) may be the presenting symptom and become the predominant source of morbidity for a given patient.

EIMs are frequently encountered in pediatric IBD. The incidence of developing any EIM is estimated to be as high as 40% in predominately adult studies and it can be the presenting symptom in one out of four patients with IBD [1, 2]. Pediatric studies have shown similar or even higher rates. In a retrospective study of over 1600 children with IBD, the incidence of EIMs was 29% at 15 years post-diagnosis [3]. These complications were more common in older patients and 6% of the patients had extraintestinal symptoms prior to diagnosis. In another prospective study of over 1000 pediatric IBD patients, the incidence of EIMs was 28% with the majority (87%) occurring in the first year after diagnosis [4]. More recent studies have shown higher rates of EIMs in pediatric patients than adult counterparts especially at disease onset. The Pediatric IBD Swiss Cohort reported EIM in 8.5% of children at disease onset compared to 5.0% of adults [5]. Prior to IBD onset, EIMs were present in over 27% of the patients in this study [5]. EIMs appear more common in Crohn disease than ulcerative colitis and have been reported as a surrogate maker of more severe disease as defined by increased need for biologics, surgery, or increased flares [6, 7]. Interestingly, patients with abnormal biomarkers and more severe disease had a higher likelihood of having an EIM [6, 8]. Further, the presence of one extraintestinal manifestation confers a risk to develop other manifestations [2].

EIMs have been classified into various ways such as their relationship with the presence or degree of inflammation of the underlying bowel disease or by the location of the bowel disease, for example, colonic versus small intestinal [9]. They can also be divided by whether or not they are a consequence of the IBD itself. EIMs effecting the joints, skin, hepatobiliary system, and eye can be differentiated from those that are complications of the disease such as malabsorption leading to osteoporosis, growth issues, kidney stones, etc.

The pathogenesis of the extraintestinal manifestations, like the etiology of IBD, is unknown. However, possible hypotheses include abnormal self-recognition, antibody production against specific extraintestinal organs that cross-react with gastrointestinal antigens, and/or genetic susceptibility. It is postulated that the inflammatory response in patients with IBD leads to the inability of the intestine to act as a selective barrier. Hence, the uptake of bacterial products or dietary antigens can induce circulating immune complexes or a systemic inflammatory response [10]. Another theory involves the cross-reaction with a bacterial epitope leading to autoimmunity directed against an antigen shared among the intestine, skin, synovium, eye, and biliary system [11]. An autoimmune reaction to an isoform of tropomyosin which is expressed in the eye (non-pigmented ciliary epithelium), skin (keratinocytes), joints (chondrocytes), biliary epithelium, and the gut is speculated as the focal point for this theory [12]. Similarly, extraintestinal manifestations may share a common pathway with the bowel disease in that recruitment of mucosal memory and/or effector T-cells to various tissues via the expression of endothelial adhesion molecules that are usually restricted to the gut may lead to destruction from the influx of inflammatory cells [13]. Table 10.1 Common extraintestinal manifestations of IBD in children and their relative prevalence

Extraintestinal manifestation	Prevalence
Growth failure	++++
Sacroiliitis	++++
Osteoporosis/Osteopenia	+++
Peripheral joint inflammation	+++
Aphthous ulcers	+++
Primary sclerosing cholangitis	++
Granulomatous skin lesion	++
Erythema nodosum	++
Pyoderma gangrenosum	+
Uveitis/Episcleritis	+
Ankylosing spondylitis	+

mechanism does not explain all of the different extraintestinal symptoms described in IBD patients. This is supported by the lack of uniform response to treatment. For example, half of patients with Crohn disease had complete resolution of their extraintestinal manifestations with adalimumab treatment. There was a significant reduction in arthralgias, arthritis, oral aphthous ulcers, and erythema nodosum but not ankylosing spondylitis, iritis, or uveitis [14].

There is a strong genetic influence on EIMs with reports of 70% concordance between parent–child pairs and 83% concordance between siblings [15]. The human leukocytes antigens (HLA) system is postulated as a link between IBD and certain extraintestinal manifestations, especially ocular and articular manifestations [15]. HLA-A2, -DR1, and -DQw5 are more commonly associated with extraintestinal co-morbidities in Crohn disease. On the other hand, genotypes HLA-DRB1, -B27, and -B58 are linked with EIMs of ulcerative colitis. Primary sclerosing cholangitis as well as other autoimmune disorders (e.g., celiac disease, autoimmune hepatitis, and myasthenia gravis) have been associated with IBD patients with haplotype HLA B8/DR3, while HLA B27 is reported in 50–80% of IBD patients with ankylosing spondylitis [12].

Many EIMs have been reported in the literature associated with IBD, and although fortunately most of these are rare, there are multiple excellent comprehensive reviews available on this topic [16–23]. This chapter will focus on the more common EIMs found in the pediatric population and present them by the affected system and descending order of prevalence (Table 10.1).

Growth Failure

A discussion of EIMs in pediatric IBD patients cannot be presented without first mentioning growth failure, which is estimated to occur in 30% of children with Crohn disease and in 5–10% with ulcerative colitis [1]. Children can present with an obvious lack of growth such as a height below the fifth percentile for age, or growth changes can be more subtle with a gradual flattening of the child's height velocity that is only evident upon plotting of multiple height measurements on a growth chart and comparing to mid-parental height. Some children can have delays in bone maturation and pubertal development. It is important to not merely assume that growth failure is a consequence of gastrointestinal manifestations as decreases in weight and height velocities can precede any clinical evidence of bowel disease [24]. Thus, the concept of viewing growth failure as an independent manifestation of IBD will help clinical providers develop a higher index of suspicion for the diagnosis of IBD in children presenting in this manner, even if they do not have gastrointestinal complaints.

IBD-associated growth failure could be secondary to deficient nutrient intake, poor digestion, and absorption as well as increased metabolic demands; however, the most likely etiology remains chronic caloric insufficiency [25]. Unfortunately, treatment for the IBD, especially with chronic corticosteroids, can have deleterious effects on overall growth and this needs to be weighed against the detrimental effects of the inflammatory process on growth. In addition to consideration of immunomodulator (such as 6-mercaptopurine/azathioprine or methotrexate) and tumor necrosis factor-alpha (TNF-α) antagonists earlier in the disease course of pediatric patients, administration of oral or enteral formula feedings should be considered to rehabilitate the growth-stunted patient. A more extensive review can be found in the chapter devoted to growth issues in pediatric IBD.

Joint Manifestations

Joint inflammation is a commonly seen EIM of IBD in both adults and children with arthritis or joint pain occurring in 16–33% of children with IBD [1, 26]. Similar to most other EIMs, symptoms of joint inflammation may occur before or after the development of bowel disease. Besides joint inflammation, one in five pediatric patients report enthesitis, inflammation at the bony insertion sites of ligaments, tendons, and fascia [27]. Joint manifestations can be divided into an axial form (involvement of the axial spine and sacroiliac joints) and a peripheral form (involvement of larger joints such as the knees, ankles, hips, wrists, and elbows).

The axial form of joint involvement which includes ankylosing spondylitis and sacroiliitis, is less common than peripheral arthropathies with reported incidence of 3–25% [23]. These axial forms of joint involvement are demonstrable on magnetic resonance imaging enterography (MRE), although further dedicated imaging may be necessary [28]. Ankylosing spondylitis, which is associated with the HLA-B27 antigen, occurs in less than 2% of IBD patients. Symptoms include back stiffness, pain, and eventually

stooped posture as well as peripheral arthralgias. Almost all of these patients will have involvement in their sacroiliac joints. On the other hand, asymptomatic sacroiliitis is more common with an estimated incidence of 10–52% [15]. Isolated sacroiliitis seems not to be associated with HLA-B27; however, there appears to be striking racial disparity in occurrence rates [12, 29]. African Americans have a fourfold adjusted odds of sacroiliitis compared to Caucasian cohorts [29]. Asymptomatic HLA-B27-negative patients with normal spinal mobility do not require specific treatment. Physical therapy and an exercise program to stop the progression of any disability and deformation in addition to nonsteroidal anti-inflammatory drugs (NSAIDs) remain a mainstay of treatment. However, there is concern of IBD relapse with the latter and hence some emerging literature supporting coxibs in IBD patients. Glucocorticoid injections are an option as well but there is a risk of long-term complications [29, 30]. Although ankylosing spondylitis has been shown to respond to sulfasalazine in multiple double-blind studies, none of the studies addressed ankylosing spondylitis in IBD patients [31]. Small studies have demonstrated a role of TNFα antagonist therapy in patients with IBD and ankylosing spondylitis [29, 30]. There are case reports of response to ustekinumab and vedolizumab, although these are best used primarily to control the intestinal disease [29, 30, 32].

Peripheral joint inflammation is most frequently reported with Crohn disease and is most typically associated with colonic inflammation although it can also be associated with small bowel disease [15]. The patient usually presents with erythema, swelling, and decrease range of motion in an asymmetric pauciarticular pattern. Fortunately, joint deformity is uncommon. The arthritis tends to worsen during times of increasing bowel disease and there is an association with other EIMs such as those of the skin, mouth, and ocular systems. In fact, patients with involvement of these systems can share serologic markers such as elevations in antibody levels against exocrine pancreas compared to other IBD and non-IBD patients [33].

Primary treatment of the bowel inflammation with 5-aminosalicylate medications, corticosteroids, immunomodulator, or biologic is the first course of action for peripheral joint inflammation [1]. Often resolution is achieved with this approach in less than 8 weeks [26]. Methotrexate and intraarticular corticosteroid injections should be considered in refractory cases. Studies have shown that TNF-alpha and Il12/23 antagonists are efficacious in the treatment of spondyloarthropathies such as the articular and musculoskeletal findings in IBD [15, 29, 30]. Similar to the treatment of the axial joint EIM, treatment with NSAIDs and cyclooxygenase-2-inhibitors may need to be limited due to the potential for gastrointestinal mucosal injury.

Bone Disease

There has been increasing interest in identifying osteopenia and osteoporosis in patients with IBD especially given that IBD commonly presents during adolescence and young adulthood when bone mass is being rapidly attained. In adult populations, the overall prevalence of osteoporosis in IBD is estimated between 4 and 40% with increasing prevalence in older patients [12]. A large population-based adult study reported an osteoporosis prevalence of 15% and relative risk of 1.4 for fractures in IBD patients compared to the general population [34]. Prevalence of osteopenia and osteoporosis in the pediatric population is estimated between 8 and 30% based on several smaller studies [35]. The increased risk of eventually developing osteoporosis in IBD patients, especially those with Crohn disease, is secondary to multiple factors including inadequate intake or malabsorption of calcium and vitamin D, corticosteroid use, low estrogen states in females, and negative effects of circulating proinflammatory cytokines [36]. This osteoporosis can make the patients prone to bone fracture, bone deformities, and chronic pain.

Diagnosis of osteopenia/osteoporosis is made with dual-energy X-ray absorptiometry (DEXA) which measures bone mineral density in the spine, femoral neck, or other bones rapidly and with low amounts of radiation. Treatment with calcium and vitamin D may prevent further deterioration of bone but not necessarily help in recovery of lost bone density. However, some pediatric studies have suggested bone recovery in children with IBD on treatments. Prevention has not been well studied in IBD patients, but it would be prudent to ensure intake of at least the recommended daily requirement for age of calcium and vitamin D, proper exercise, and minimization of corticosteroid usage to maximize the pediatric patient's potential in achieving an appropriate peak bone mass. The role of bone protecting agents in IBD, especially pediatrics, is unknown so far.

Other bone complications in IBD patients include osteonecrosis of the femoral head, hypertrophic osteoarthropathy, and chronic recurrent multifocal osteomyelitis (CRMO). Osteonecrosis of the femoral head is usually associated with patients who have received chronic steroids and have complaints of hip or knee pain. Clubbing or hypertrophic osteoarthropathy is another bone manifestation associated with IBD especially with small intestinal Crohn disease. The etiology, though unknown, is postulated to involve increased blood flow to the fingers and hence increased connective tissue growth secondary to circulating cytokine production [1]. Chronic recurrent multifocal osteomyelitis (CRMO), rarely described in children with IBD, is an aseptic inflammatory bone disease that typically affects the long bones and clavicles [37].

Oral Lesions

Oral lesions can arise at any time in patients with IBD and at any age. Although the incidence can vary, the highest report rate was 50% in a pediatric age group study [38, 39]. More common in males and Crohn disease patients, oral lesions can be asymptomatic and precede intestinal involvement in up to 20% of patients [38, 39]. Oral manifestation of IBD can be specific such as cobblestoning of the mucosa, granulomatous cheilitis (Fig. 10.1), pyostomatitis vegetans, or nonspecific such as ulcers (Fig. 10.2) including aphthous, lichen planus, and cheilitis angularis. Nonspecific lesions can be due to malnutrition or drug effect. Recurrent aphthous ulcers are the most common oral lesions associated with IBD with a reported incidence of approximately 8–14% in pediatric IBD patients with higher rates in Crohn disease compared to ulcerative colitis. Aphthous lesions, shallow round ulcers surrounded by an erythematous halo with a central fibrin membrane, tend to parallel intestinal disease though they often can predate intestinal symptoms and can correlate 40–70% of the time with active intestinal disease [38]. Other oral lesions can consist of lip swelling, fissures, and gingivitis which can demonstrate granulomas on histology [40]. Angular cheilitis, sores in the corner of the mouth, often occurs due to anemia or secondary to a fungal or bacterial infection [39]. Orofacial granulomatosis is a rare syndrome with chronic swelling of the lips and lower half of the face combined with oral ulcerations and hyperplastic gingivitis that has been reported in three dozen Crohn's cases [41]. Orofacial granulomatosis can be seen in other disorders such as foreign body reaction, tuberculosis, sarcoidosis, and idiopathic causes which share similar histopathologic features. Another rare disorder seen in association with ulcerative colitis patients is pyostomatitis vegetans which can present with oral and cutaneous findings in the axillae, genital areas, and scalp. The oral lesions consist of multiple neutrophil and eosinophil-filled pustules on erythematous bases which can erode and fuse to form shallow ulcers that have been described as being "snail track" configuration [42]. Lichen planus, a chronic inflammatory dermatosis, has also been seen as a suspected drug reaction to sulfasalazine and mesalamine [39]. Oral lesions in IBD patients could also be a result of nutritional deficiencies, specifically low levels of zinc, folic acid, niacin, and vitamin B12 [38, 39].

Treatment of oral lesions is usually reserved for those causing significant discomfort and may involve topical, intralesional or systemic corticosteroids, dapsone, or preparations directed at the bowel disease including immunomodulators, biologics, and thalidomide [39, 43].

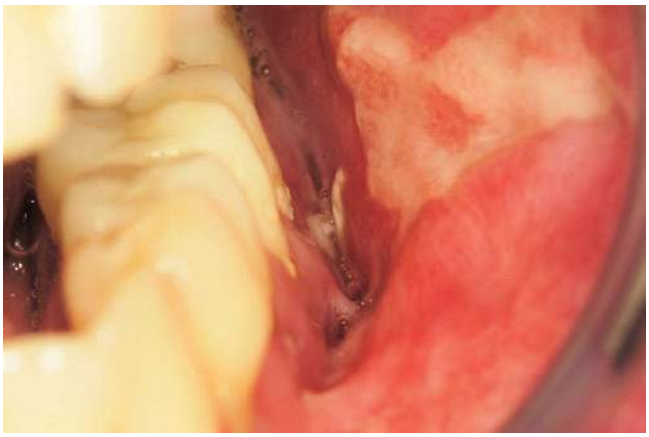

Fig. 10.2 Oral ulcer, Courtesy of Dr. James J. Sciubba, Johns Hopkins University

Skin Lesions

Cutaneous manifestations of IBD can be classified into three principal groups: granulomatous, reactive, and secondary to nutritional deficiency. Granulomatous skin manifestations have the same histological features as the bowel disease and can include perianal and peristomal ulcers and fistulas, oral granulomatous ulcers, epidermolysis bullosa acquisita, and metastatic Crohn disease. The latter is a rare complication that manifests as subcutaneous nodules or ulcers mainly in the lower extremities and on occasion can occur in the genital areas. The lesions have a heterogenous presentation including erythematous and violaceous plaques, nodules, ulcerations, crusts, and erosions including the knife-cut sign describing linear ones [44]. It appears unrelated to bowel activity and can be treated successfully with corticosteroids, antibiotics, azathioprine, methotrexate, and biologics [15]. Epidermolysis bullosa acquisita is seen mostly in Crohn's patients and secondary to antibodies against tyle VII colla-

Fig. 10.4 Pyoderma gangrenosum, Courtesy of Dr. Anna L. Grossberg, Johns Hopkins University

gen. Patients have skin fragility, blister formation, and scarring. The antibodies may be related to bowel inflammation and hence treatment involves improvement in the active intestinal disease [45].

Of all the skin manifestations associated with IBD, erythema nodosum (Fig. 10.3) and pyoderma gangrenosum (Fig. 10.4) are the most common. However, in the pediatric patient, erythema nodosum, which is more commonly associated with Crohn disease than with ulcerative colitis, is encountered more frequently [1]. Erythema nodosum presents as tender, subcutaneous, erythematous nodules, usually on the extremities, especially the lower legs and the majority of patients with this skin manifestation will have associated joint pain or develop arthritis. Children may appear systemically ill with fever. Over days to weeks, the nodules will flatten, turn brown, or gray and can be mistaken for bruises. Histologically, erythema nodosum is a septal panniculitis consisting of a lymphohistiocytic infiltrate. The prevalence in all IBD patients, adult and pediatric, is estimated between 3% and 15% [34]. Erythema nodosum appears more significantly in women and Hispanics who have an adjusted odds ratio of 3 and 3.3, respectively, compared to Caucasian counterparts [29]. Exacerbations of erythema nodosum correlate most often with increased intestinal inflammation; hence, treatment toward the bowels is considered a primary form of management. Recent reports in children have shown good response to infliximab [29].

Pyoderma gangrenosum is an ulcerating lesion often correlating with exacerbations of the bowel disease; however, it can persist for long periods, while the intestinal inflammation is clinically quiescent. Fortunately, it is relatively rarely associated with IBD with a reported incidence of 2% in UC patients and a smaller number in Crohn's patients [45]. The lesions are often painful and located on the lower extremities. Histopathology reveals endothelial injury with fibrinoid necrosis of blood vessels and marked neutrophilic and lymphocytic infiltrates. Treatment is difficult and patients may require large doses of systemic corticosteroids or immunomodulators as well as topical ulcer care. Infliximab and other TNF antagonists have been shown to be effective in refractory cases; however, some extreme cases might require grafting [30, 46]. There are scant reports of response to vedolizumab,

ustekinumab, and tofacitinib, the latter especially as there may be upregulation of the JAK-STAT pathway in both erythema nodosum and pyoderma gangrenosum [30, 32].

Sweet's syndrome is another very rare reactive cutaneous disorder associated with IBD. It is a neutrophilic dermatosis presenting with painful erythematous plaques or nodules often associated with fever and leukocytosis. Usually, there is a good response to corticosteroids and a study has demonstrated the benefit of cyclophosphamide in steroid refractory patients [47].

Psoriasis can be seen commonly (7–11%) in patients with IBD [45]. The link and therapeutic overlap suggests common inflammatory pathway, genetics, and pathogenesis. Therapy-related psoriasiform skin lesions have also been reported in patients undergoing TNFα antagonist therapy. Anti-IL-12/IL-23 therapy may have a role in treatment of these patients from an intestinal and skin standpoint [45].

Nutritional issues, such as trace mineral and vitamin deficiencies, can be common in children with IBD, especially Crohn disease; however, skin disorders secondary to these are unusual. There are rare reported cases of acrodermatitis enteropathica, pellagra, and scurvy secondary to zinc, niacin, and vitamin C deficiency, respectively.

Vulvar lesions have also been associated with IBD with patients presenting with vulvar ulcers, labial swelling, exophytic lesions, condylomatous lesions, and abnormalities on pap smear. Most often the histopathology demonstrates non-caseating vulvar granulomas, but dysplasia and carcinoma have also been reported [48].

Eye Lesions

Eye manifestations in IBD patients can be classified into inflammatory and vascular disorders [49]. Inflammatory conditions include uveitis, episcleritis, orbital myositis/pseudotumor, optic neuritis, and dacryoadenitis. Vascular disorders usually result from an inflammatory etiology, possibly retinal vasculitis leading to reported conditions of retinal artery or vein occlusion. There is a reported lower prevalence of ocular involvement in children (0.6–1.8%) with IBD than in adults with IBD [49]. The most common eye manifestation of IBD is episcleritis [15]. Episcleritis (Fig. 10.5), inflammation of the blood-rich episclera, may parallel bowel activity and is often confused with conjunctivitis as the patients present with eye redness and burning. It is the most common ocular manifestation. Episcleritis does not impair vision and usually responds clinically to cool compress, lubricant eye drops, topical non-steroidal anti-inflammatory medications, and topical corticosteroids. If visual impairment or pain is present, the possibility of scleritis, which can occur with protracted intestinal disease, needs to be considered and an emergent evaluation by an ophthalmologist is required to evaluate for retinal detachment or optic nerve swelling. Scleritis needs systemic treatment with steroids or immunosuppressants [50].

Fig. 10.5 Episcleritis, Courtesy of Dr. Rachel Nussbaum, Johns Hopkins University

Uveitis is defined as inflammation of the uveal tract or middle layer of the eye which includes the iris, ciliary body, and choroid. Its prevalence seems to increase with time post-IBD diagnosis and is unrelated to the patient's age of disease onset [49]. An evaluation of 147 children with IBD who had no ophthalmologic complaints revealed a prevalence of uveitis of 6.1% in those with Crohn disease [51]. African Americans have a 5.5-fold adjusted odds ratio compared to Caucasian counterparts [29]. Uveitis, is often associated with other EIMs, especially arthritis and erythema nodosum and likely does not correlate with intestinal disease activity [50]. Symptoms can include acute or subacute eye pain, headache, photophobia, and blurred vision or occasionally decreased vision; however, many patients may be asymptomatic. Recognition and appropriate treatment can help prevent complications which can be serious and include iris atrophy, synechiae, pigment deposits, glaucoma, cataracts, and permanent visual deficits. Attention must be paid for early signs of uveitis which can include a cellular or proteinaceous exudate of inflammatory cells in the anterior chamber of the eye. Like scleritis, acute anterior uveitis is an ophthalmologic emergency. Treatment involves covering the eye to reduce pain and photophobia, pupillary dilatation, and use of topical for milder cases. More aggressive disease can require systemic corticosteroids, as well as immunomodulator and biologic regimens, with more data for TNF antagonists [30].

Liver Disease

Liver pathology, including hepatitis, fatty liver, cholelithiasis, amyloidosis, and primary sclerosing cholangitis, is found in less than 5–10% of patients with IBD [1]. Screening with periodic checks of serum aminotransferases, alkaline phosphatase, gamma-glutamyl transferase, and direct bilirubin is necessary as many of the children with liver disease are asymptomatic. A more extensive review of this EIM can be found in another chapter devoted to liver disease in pediatric IBD.

Other Extraintestinal Manifestations

Many other systems, listed below, have had reported involvement in IBD but they have been reported to occur in less than 1% of pediatric IBD patients [1].

Hematologic Abnormalities

Anemia, thrombocytosis, and leukocytosis are common hematologic abnormalities in IBD patients and can be seen in up to half the patients with active disease [1]. Usually, the anemia is secondary to iron, vitamin B12, and folic acid deficiency as well as anemia of chronic disease. The thrombocytosis is postulated to result from circulating inflammatory cytokines that stimulate platelet production. Similarly, leukocytosis can occur as a result of generalized inflammation. On the other hand, patients should be monitored for leucopenia with certain therapies such as use of thiopurine immunomodulators (e.g., 6-mercatopurine or azathioprine).

Vascular

Patients with IBD have been reported to have a threefold increased risk of venous thrombosis compared to matched controls [52]. Interestingly, this increased risk is specific for IBD as it is not seen with other inflammatory conditions such as rheumatoid arthritis or other bowel disorders such as celiac disease. Deep venous thrombosis and pulmonary embolism are the most common complications resulting from an overall increased coagulation. Coagulation factors may be elevated as part of an acute phase response. Factor V Leiden, a genetic disorder characterized by an impaired anticoagulant response to protein C leading to a prothrombotic state, may be increased in Crohn's patients [53]. Furthermore, IBD patients might have higher levels of homocysteine, which can be a potential cause of thrombosis [53]. Awareness of the risk of thrombosis is even more important with the approval of tofacitinib for ulcerative colitis in adults given the recent link of this medication with certain vascular side effects. Another vascular complication, arteritis of small or large vessels, has been reported in children with IBD [54].

Pancreatitis

The incidence of pancreatic involvement in IBD varies but estimated to be 0.7–1.6% in children [55]. The most likely etiologies are medications, anatomic, immunologic, or gallstones secondary to ileal disease. Although patients with IBD appear to have a small increased risk for idiopathic pancreatitis, the most common cause of pancreatitis in IBD appears to be associated with medications such as 5-aminosalicylate preparations or 6-mercaptopurine. As this is presumed to be an idiosyncratic reaction, discontinuation of the medication is indicated. Although pancreatic autoantibodies have been found been found in up to 40% of Crohn's patients, their significance remains unclear. In one series, patients with Crohn disease who were pancreatic antibody positive had a higher rate of pancreatic exocrine insufficiency than those who were antibody negative [12]. Furthermore, chronic pancreatitis has also been reported in a series of six adult IBD patients, five of whom had changes on pancreatic pathology samples [56]. Autoimmune pancreatitis, some with elevations in IgG4, has been rarely reported in children and adults with IBD [57].

Renal

Children with IBD appear to be at risk for kidney abnormalities. A small study of pediatric IBD patients reported that 25% of patients had either previously reported kidney disease or ultrasound signs of chronic kidney disease [58]. IBD patients, especially those with extensive ileal disease or ileal resection with significant fat malabsorption or fluid losses, are at risk for developing calcium oxalate and uric acid stones. Although uncommon in children, nephrolithiasis is reported in 12–28% of adults with IBD compared to 5% of the general population [59]. Tubular injury and tubulointerstitial nephritis, unrelated to medications, can be seen as an EIM in IBD as well. Patients typically recover fully post-treatment of their IBD. Glomerulonephritis with immune complex deposition can also be seen which can progress to severe renal disease. The most common type is IgA nephropathy which is associated with HLA-DR1 [59]. Treatment is focused on controlling IBD inflammation though specific renal treatment may be needed in some patients. Other renal diseases, described in children with IBD, include renal artery stenosis, amyloidosis leading to renal failure, ureteral compression, and perinephritic abscesses secondary to abscesses or inflammation surrounding the terminal ileum [60]. Most IBD treatments have nephrotoxic adverse effects. Nephritis (tubulointerstitial or interstitial) has been reported with aminosalicylates, thiopurines, and vedolizumab. TNF antagonist medications, especially infliximab, have been linked to glomerulonephritis in a small subset of patients.

Pulmonary

Pulmonary manifestations associated with IBD are reported less frequently in children than adults, although the scope of disorders is similar. Nearly 10% of children with IBD reported respiratory related quality of life issues on a ques-

tionnaire [61]. Reactive airway disease, bronchitis, bronchiectasis, tracheal obstruction, granulomatous lung disease, interstitial or hypersensitivity pneumonitis, and bronchiolitis obliterans are being reported at an increasing frequency [12, 15, 62–64]. However, the latter two have been associated with 5-aminosalicylate products and methotrexate treatment [12, 64]. Similar to other extraintestinal manifestations, pulmonary disease can predate the bowel disease by months or years. Most pulmonary manifestations respond to corticosteroids via an inhaled, oral, or intravenous route.

Neurologic

Peripheral nerve disorders, cardiovascular disorders, myopathy, multiple sclerosis, optic neuritis, and epilepsy have been described in IBD patients [65]. Peripheral neuropathies are the most common neurologic disorder reported, while cardiovascular disorders with neurologic morbidities have been documented in up to 4% of patients [66]. A retrospective cross-sectional study of adult patients with IBD reported an odds ratio of 1.67 for developing multiple sclerosis, optic neuritis, or a demyelinating disorder [12]. An interesting future focus will center around the role of medication treatments for IBD and neurologic adverse events especially given the risk of progressive multifocal leukoencephalopathy related to anti-alpha 4 integrin antibody, natalizumab.

Cardiac

Rarely children with IBD can develop myopericarditis and pleuropericarditis with symptoms of chest pain and dyspnea. Cardiac manifestations are not necessarily associated with active bowel disease and respond to corticosteroids and nonsteroidal anti-inflammatory agents, which need to be used with caution in IBD patients. An active area of research is the risk of cardiovascular events in patients with IBD. A recent study showed an increase in incidence in coronary artery disease in adults with IBD [67]. Interestingly, the IBD patients had significantly lower rates of traditional coronary artery disease risk factors such as hypertension, diabetes, obesity, and dyslipidemia. Further work will help determine the effect of various treatments on decreasing risk of cardiac disease.

Summary

Given that Crohn disease and ulcerative colitis are associated with numerous EIMs, it is clearly evident that IBD is a multisystemic disease that stretches beyond the gastrointestinal tract. Knowledge about EIMs is critical as patients can present with these instead of more classic bowel symptoms. Furthermore, the EIMs associated with IBD can be a cause of major morbidity in patients and need to be considered and addressed at all points of care.

Liver Disease in Pediatric Inflammatory Bowel Disease

11

Rebecca Little, Binita M. Kamath, and Amanda Ricciuto

Introduction

Diseases involving the hepatobiliary system are among the most common extraintestinal manifestations of inflammatory bowel disease (IBD). They can be classified into a few broad categories: (1) liver diseases that may share a common pathogenic mechanism with IBD, such as primary sclerosing cholangitis (PSC), autoimmune hepatitis (AIH), and PSC/AIH overlap, also known as autoimmune sclerosing cholangitis (ASC); (2) liver diseases that reflect the pathophysiology of IBD, such as cholelithiasis and portal vein thrombosis; and (3) liver diseases that result from the adverse effects of IBD therapy, such as drug-induced hepatitis [1]. In addition, an association has been noted between a number of other less common hepatobiliary diseases and IBD, including IgG4-associated cholangitis (IAC). Some of the conditions listed above are observed more frequently in Crohn disease (CD) or ulcerative colitis (UC), while others occur at similar rates in both types of IBD (Table 11.1). Liver enzyme abnormalities are common in IBD and, while often transient and inconsequential, deranged hepatic biochemistry may herald serious underlying liver disease, such as PSC. The challenge lies in determining which patients merit further work-up versus observation. No standardized algorithm exists to guide clinicians in this decision-making process, particularly in children, in whom there is a relative paucity of data. This chapter strives to facilitate this task by providing an overview of liver disease occurring in association with pediatric IBD.

Table 11.1 Hepatobiliary diseases associated with pediatric IBD

Hepatobiliary disease	Ulcerative colitis	Crohn disease
Primary sclerosing cholangitis (PSC)	++	+
Autoimmune hepatitis (AIH)	++	++
Autoimmune sclerosing cholangitis (ASC)	++	+
IgG4-associated cholangitis (IAC)	++	+
Cholelithiasis	–	++
Portal vein thrombosis and hepatic abscess	+	++
Drug-induced hepatitis	++	++
Hepatitis B reactivation (anti-TNFα)	++	++
Hepatosplenic T-cell lymphoma	+/–	+
Fatty liver	++	++
Hepatic amyloidosis	–	++
Granulomatous hepatitis	–	++
Primary biliary cholangitis (PBC)	++	–

Abnormal Liver Chemistry

Abnormal liver chemistry is common in IBD. Liver enzyme abnormalities (any value exceeding the upper limit of normal (ULN)) have been reported in 15–40% of adults with IBD over 1–5 years of follow-up [2–4], with more marked elevations (>2× the ULN) occurring in 5% [2]. Abnormal liver biochemistry appears to be similarly frequent in pediatric IBD. Nemeth described "pathological liver function tests" in 52% of his 46-patient cohort in 1990 [5], and similar findings have since been reproduced by two large retrospective pediatric studies, in which at least one liver enzyme elevation was observed in 40–60% of children with IBD over 3 years [6, 7], even after excluding patients with PSC/ASC. No differences were observed between patients with CD and UC. Liver enzyme elevations >2× the ULN occur in a smaller proportion of children, roughly 15–30% [7, 8]. The pattern of biochemical injury is typically hepatocellular, but can be mixed or, less commonly, cholestatic [4, 6]. ALT is the most frequently abnormal test [7], with the caveat that ALT also

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_11

tends to be measured more often than other tests, like GGT. The majority of these biochemical abnormalities are mild, transient, and benign in nature [4, 6–8]. The degree of transaminase elevation appears to correlate with the likelihood of identifying underlying liver disease; in one study, 95% of children with peak ALT <2× ULN were found to have no specific liver disease [6], and conversely, in another study, 93% of children with PSC or ASC had liver enzymes 2× the ULN or greater, sustained for 30–90 days [7]. In this latter study, GGT was found to be particularly useful for identifying PSC/ASC, with a value of 252 U/L having a sensitivity of 99% and specificity of 77% for PSC or ASC [7].

Well-defined chronic liver disease (PSC/ASC and AIH) accounts for only 1.4–6% of elevated liver enzymes in pediatric IBD, whereas a majority of cases remain idiopathic [6, 7, 9]. The most common etiology, when one is identified, is drug toxicity [2, 6, 8]. In children, steroids, antibiotics, methotrexate, anti-tumor necrosis factor-α (anti-TNFα), as well as exclusive enteral nutrition, have been associated with liver enzyme abnormalities [7]. Conversely, liver enzyme abnormalities appear to be less frequent in children taking 5-ASA and sulfasalazine, although these agents may simply be surrogates for milder IBD [3, 7]. Other less common causes of deranged hepatic biochemistry in pediatric IBD include infection (particularly CMV and EBV), nonalcoholic fatty liver disease (NAFLD), cholelithiasis, and vascular abnormalities [6]. Active IBD has also been proposed as a cause of abnormal liver enzymes, but the evidence is conflicting; several studies lend support to this hypothesis [4, 8, 10], while others refute it. One such study in adults found a higher prevalence of liver enzyme abnormalities in patients in remission compared to those with active IBD [3]. In children, biochemical abnormalities do not appear to be associated with IBD duration or extent [5, 6, 9]. With regard to prognosis, death was found to be 4.8 times higher in adults with abnormal liver biochemistry, even after excluding those with any diagnosis of liver disease [3]. No equivalent pediatric data exist.

In summary, abnormal liver biochemistry is common in children with IBD. Most cases are mild and resolve spontaneously, and such cases tend to be associated with undefined etiologies. However, a small subset of patients with more severe, prolonged derangements have serious disease or medication adverse effects. Given this, it seems reasonable to adopt a period of watchful waiting in patients with mild elevations (<2× the ULN) unless there are overt signs of underlying liver disease. More marked or persistent (>1 month) abnormalities may warrant further investigation. We suggest obtaining a liver biochemical panel, including ALT and GGT, in all newly diagnosed IBD patients and repeating this at least every 6–12 months for surveillance.

Primary Sclerosing Cholangitis

Epidemiology and Pathogenesis

Primary sclerosing cholangitis (PSC) is a chronic, progressive, cholestatic liver disease characterized by inflammation and obliterative fibrosis of the intrahepatic and/or extrahepatic biliary tree, resulting in multifocal strictures and dilatation. It is a rare disease, with an incidence and prevalence of 0.1–0.2 and 1.5 per 100,000 children, respectively, which is substantially lower than in adults [11–13]. Pediatric PSC typically presents in the second decade of life and has a modest male predominance, as in adults [12, 14–16]. The link between PSC and IBD has been known for greater than five decades [17]. As many as 60–80% of adults with PSC in North America and Northern Europe have IBD, primarily ulcerative colitis (UC) [18, 19]. The prevalence of IBD in children with PSC is also very high, >50% in most series and up to 97% in a recent population-based study [12, 14, 16, 20, 21]. Conversely, only a minority of children with colitis, <10% in most series, have or develop concurrent PSC [7, 12, 21, 22]. A Norwegian study highlighted that screening MRCP performed in 322 patients with established IBD identified PSC-like lesions in 7.5% of patients, of whom only 2.2% were known to have PSC [23]. Adjusting for missed diagnoses and small duct disease, the overall incidence is 8.1%, around threefold higher than initially detected based on symptoms [23]. Subclinical PSC associated with IBD was detected on MRCP in sixty-five percent of patients in the absence of biochemical abnormalities and mild disease [23].

Most patients are found to have PSC within a year of their IBD diagnosis [12], but the two can occur years apart. PSC can manifest first, in which case a full colonoscopy is recommended at PSC diagnosis to screen for IBD [24].

The pathogenesis of PSC remains incompletely understood. Genome-wide association studies have identified a number of HLA and non-HLA risk loci [25, 26], some of which are shared with IBD, and a hallmark paper in 2004 reported an accumulation of gut-homing CCR9-positive T-cells in explanted human livers of patients with PSC [27], findings that point to both a genetic and immunological basis for PSC. In addition, there is growing evidence for the role of the "gut-liver" axis in the pathogenesis of PSC. Several animal models and human tissue-based translational studies support that enteric microbial products/dysbiosis can lead to PSC-like hepatobiliary inflammation [28]. Mucosal biopsy cultures have identified enriched taxa levels of several organisms including *Pseudomonas, Streptococcus,* and *Haemophilus* species as well as alterations in beta diversity in patients with PSC-IBD compared with healthy controls and conventional UC [29–33]. Similarly, enriched fecal microbiota levels of *Veillonella* and *Enterococcus* species

have been reported [34, 35]. *Klebsiella pneumoniae* strains derived from gnotobiotic mice transplanted with PSC-IBD microbiota were found to induce pore formation in human intestinal epithelial cells and enhanced Th17 response thus adding credence to the role of heightened immune response to enteric dysbiosis in PSC-IBD pathogenesis [36]. The gut microbiota in PSC/PSC-IBD patients may further exert a pathogenic influence through their role in bile acid synthesis. Deconjugation of the primary bile acids (BA), cholic acid (CA), and chenodeoxycholic acid (CDCA), by gut microbes produces secondary Bas, predominantly lithocholic acid (LCA) and deoxycholic acid (DCA). Secondary Bas function as signaling molecules via their interaction with the nuclear receptor Farnesoid X receptor (FXR) and the membrane-bound G protein-coupled bile acid receptor-1 TGR5 [37]. Agonism of these receptors exerts important cholangioprotective and anti-inflammatory effects. Two recent small studies of fecal BA profiles in patients with PSC-IBD compared to conventional IBD have identified a significant reduction in total BA pool, more conjugated Bas, lower DCA/CA ratio, and a lower relative abundance of bacteria known to be actively involved in BA synthesis (12% in PSC-IBD compared with 0.4% IBD) [38, 39]. A recent pilot study evaluating microbial metagenomic alterations in PSC-IBD versus UC and differentially expressed genes between these two groups implicated dysregulation of bile acid (BA) metabolism in PSC-IBD [30]. Multi-omics integration identified upregulated networks involved in bile acid homeostasis and cancer pathway regulation.

Primary Sclerosing Cholangitis and IBD

There is growing evidence that the intestinal inflammation in individuals with PSC and colitis constitutes a distinct IBD phenotype, termed PSC-IBD. This phenotype has been well characterized in adults as extensive colonic involvement, often worse on the right, and relatively frequent "backwash ileitis," rectal sparing, and an increased rate of pouchitis post colectomy [40, 41]. Figure 11.1 highlights the apparent disconnect between the extensive disease distribution and the mild clinical course of PSC-IBD. Crohn disease (CD) is uncommon in the setting of PSC, but, when it does occur, it too tends to have an extensive colonic distribution; isolated small bowel, perianal, and fistulizing disease are very uncommon [42]. Despite the extensive nature of the colonic inflammation, PSC-IBD tends to have a relatively mild clinical course with a paucity of overt clinical symptoms [43, 44].

Findings analogous to those in adults have been reported in a large retrospective pediatric series in which 74 children with PSC-UC/IBD-unclassified (IBD-U) were compared to colitis controls [45]. This study identified growth impair-

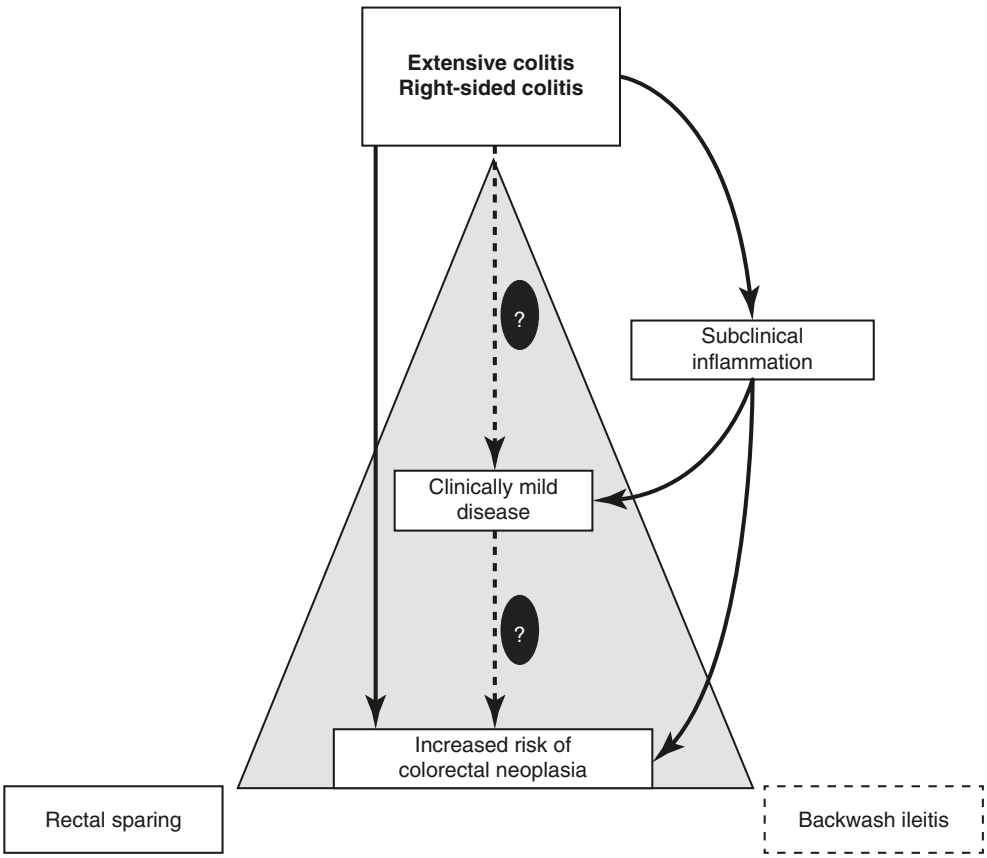

Fig. 11.1 The IBD phenotype of PSC-IBD, highlighting the apparent disconnect between the extensive disease distribution/increased risk of colorectal cancer and mild clinical course, and the way in which subclinical inflammation might bridge these inconsistencies [52]. Reprinted with permission from Springer Nature

ment as a novel pediatric-specific phenotypic feature of PSC-IBD compared to conventional UC. In a separate prospective study from the same center, subclinical inflammation (active endoscopic disease in the absence of significant symptoms) was found to be much more common in children with PSC-IBD compared to those with UC without PSC [46]. Unlike symptom report, fecal calprotectin, a stool biomarker of intestinal inflammation, was found to be highly accurate for endoscopic healing in this pediatric PSC-IBD cohort.

The interplay between IBD and PSC remains to be elucidated. Interestingly, adults with severe PSC requiring liver transplant (LT) have been found to have milder UC than patients with less severe liver disease [47]. Studies have also suggested that IBD activity may worsen following LT for PSC, despite heightened immunosuppression [48]. Furthermore, while it has long been maintained that PSC and IBD progress independently, as supported by older studies indicating that the natural history of PSC is unaffected by colectomy [49], more recent findings suggest that colectomy may reduce the risk of PSC recurrence post-LT [50]. In line with this, studies have suggested that moderate to severe active IBD post-LT constitutes a risk factor for recurrent PSC [51]. The interaction between PSC and IBD, including the effect of ongoing colonic inflammation on PSC progression, if any, requires further clarification.

Diagnosis

The diagnosis of PSC in a child is based on a compatible clinical presentation and biochemistry, with characteristic changes on cholangiography and/or liver biopsy, after excluding secondary causes of sclerosing cholangitis [53]. The most common presenting symptoms and signs are hepatomegaly and abdominal pain, followed by diarrhea, splenomegaly, fatigue, pruritus, weight loss, impaired growth, and jaundice. The presenting features may also, uncommonly, be those of advanced liver disease, such as gastrointestinal bleeding and cholangitis, or those of associated colitis, especially bloody diarrhea [53]. A substantial subset of children with PSC is asymptomatic at presentation and come to medical attention solely due to deranged liver biochemistry. Transaminases are often modestly elevated, with a predominantly cholestatic pattern. GGT is more reliable in children as ALP elevations may reflect bone growth. The odds of PSC are 660-fold greater in children with ALT and GGT elevations >50 U/L within 3 months of IBD diagnosis compared to children whose values remain <50 U/L [9]. INR, albumin, and conjugated bilirubin, which reflect synthetic function, are generally normal at presentation. Elevated conjugated bilirubin may signal a stricture, cholangitis, or a mass, and warrants further work-up. Serum immunoglobulin G (IgG) levels may be elevated, and a variety of autoantibodies may be present, the most common of which is antineutrophil cytoplasmic antibody (ANCA), usually with an atypical perinuclear ("p") pattern, which is found in up to 80% of patients. None of these are specific to PSC, however [12, 24]. Serum IgG4 should be measured at least once in children with PSC. An elevated IgG4 may denote IgG4-associated cholangitis (IAC), which has important implications, given its favorable response to corticosteroids [53].

Ultrasound is a reasonable initial imaging modality; it may reveal bile duct wall thickening, focal bile duct dilatation, and/or gallbladder changes, including wall thickening, enlargement, cholecystitis, and mass lesions. It is also useful for ruling out alternate etiologies. However, none of these findings are diagnostic, and ultrasound may be normal in the setting of PSC [24]. Cholangiography, preferably by magnetic resonance cholangiopancreatography (MRCP), which has supplanted endoscopic retrograde cholangiopancreatography (ERCP) as the first-line diagnostic imaging modality due its less invasive nature and lower cost, is a vital component of the PSC diagnostic work-up [23, 54, 55]. Characteristic cholangiographic findings include multifocal, short strictures alternating with normal or dilated segments, producing a "beaded" appearance (Fig. 11.2) [24]. The gallbladder, cystic duct, and pancreatic duct may also be abnormal [56]. Contrary to adult practice, a liver biopsy is often performed in a child with suspected PSC given the more frequent occurrence of autoimmune sclerosing cholangitis (ASC), which is typically treated with immunosuppressive therapy (although definitive evidence that this is associated with improved outcomes is lacking). A liver biopsy is also useful to diagnose small-duct PSC, a label applied to cases

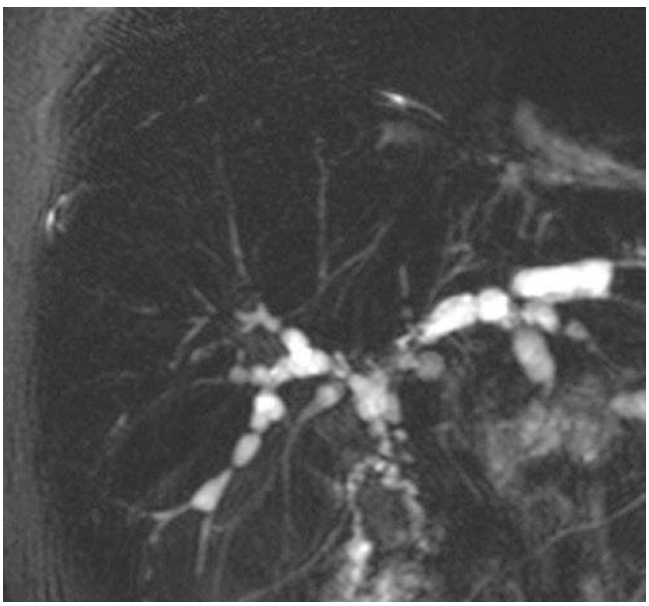

Fig. 11.2 Cholangiographic appearance of PSC with typical "beading"

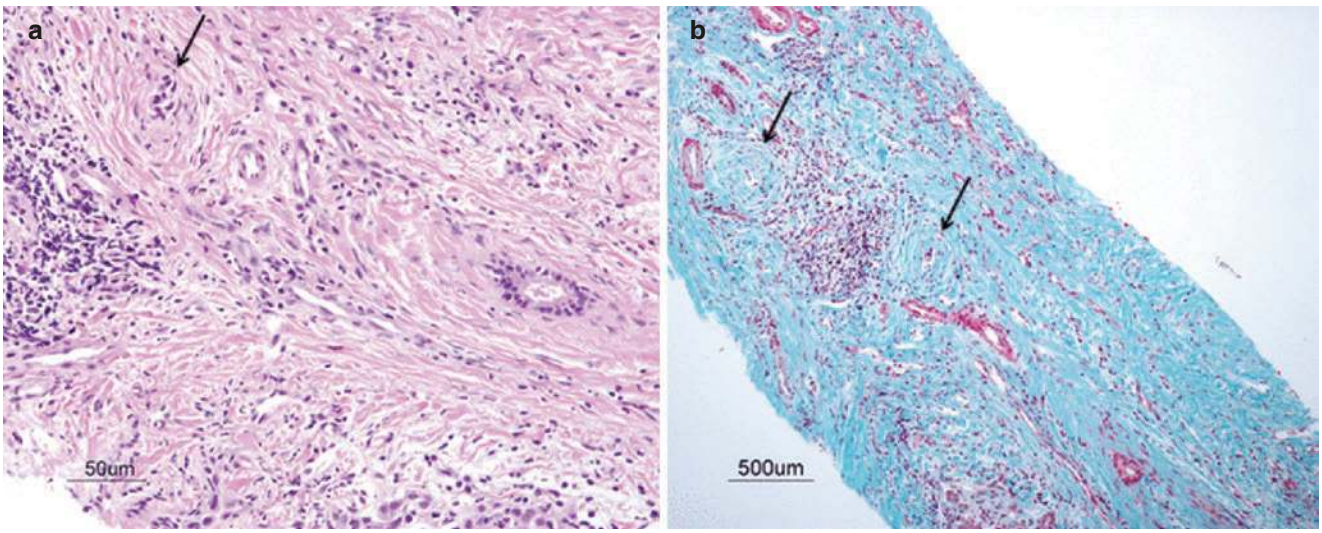

Fig. 11.3 Liver biopsy showing typical histological changes of PSC, including periductular concentric fibrosis denoted by the arrows with (**a**) H&E and (**b**) trichrome staining

with compatible histological changes but without cholangiographic abnormalities, and to stage the degree of fibrosis. Periductular concentric fibrosis, or "onion-skinning" (Fig. 11.3), is pathognomonic for PSC, but not always observed. Other, nonspecific findings may include ductular proliferation or periductular inflammation, with variable types of portal inflammation and fibrosis. Liver biopsy may also be normal in PSC given its patchy nature. The diagnostic work-up for suspected PSC in children is illustrated in Fig. 11.4.

Outcomes

PSC is one of the most important sources of morbidity and mortality in IBD, but few studies have examined its natural history in children. In 2017, the Pediatric PSC consortium published a large multi-center, retrospective international study of long-term outcomes in 781 children with PSC [57] with time to event analysis across key outcomes, including portal hypertension, biliary complications, cholangiocarcinoma, liver transplant, and death. In this study, the development of portal hypertension and biliary complications marked pivotal points in the natural history of pediatric PSC and occurred in 38% and 25% of patients, respectively, over 10 years of follow-up. The median survival with native liver (SNL), once portal hypertension and biliary complications occurred, was 2.8 and 3.5 years, respectively [57]. Overall event-free survival was 70% at 5 years and 53% at 10 years of follow-up [57]. Fourteen percent of children underwent LT at a median age of 15 years, a median of 4 years following PSC diagnosis. Long-term outcome data for pediatric-onset PSC into adulthood are lacking. Unfortunately, recurrence post-LT occurs in about 10–25% of cases [13, 58, 59]. Survival is significantly shorter in children with PSC compared to age- and sex-matched children, although absolute mortality rates are low during the pediatric period, 1.4% in the Pediatric PSC Consortium [57]. Lower platelet count, high bilirubin, higher GGT, splenomegaly, and older age at diagnosis are associated with shorter survival [57]. GGT nor-

malization at one year, on the other hand, has been associated with favorable outcomes, regardless of ursodeoxycholic acid use [60].

Adults with UC and PSC have an almost five times greater risk of colorectal neoplasia compared to adults with UC alone [61]. While data on the risk of colorectal neoplasia in PSC-IBD during the pediatric period are sparse, the absolute event rates appear to be low, particularly before puberty. In the Pediatric PSC Consortium, there were eight cases of colorectal dysplasia/carcinoma among 509 children (1.6%) with PSC-IBD, including three discovered incidentally on colectomy for medically refractory IBD [62]. Surveillance colonoscopies every 1–2 years from the time of diagnosis are recommended in adults [24]. No equivalent pediatric guidelines exist, but it seems reasonable for similar screening practices to be applied to older children and teenagers. There is a markedly increased risk of cholangiocarcinoma (7–9%) in adults with PSC [63–65], but this malignancy is exceedingly rare (1%) in children [57]. Nevertheless, a handful of cases have been reported in older teenagers [66]. While adult guidelines suggest consideration be given to screening for cholangiocarcinoma with regular cross-sectional imaging and CA 19–9, this is not routinely recommended in children [24, 54]. However, based on clinical experience and expert opinion, the authors suggest an ultrasound yearly, an MRI every 2 years, and CA 19–9 levels yearly in children with PSC to screen for cholangiocarcinoma.

Small-duct PSC may have a more favorable prognosis than classic PSC. It has been associated with a longer transplant-free survival in adults, and there have been no reports of cholangiocarcinoma occurring with small-duct PSC. However, small-duct PSC can progress to classic PSC with cholangiographic abnormalities over time, and it can recur post-LT [67]. It is unclear whether small-duct PSC represents an early stage of classic PSC or a distinct entity. The Pediatric PSC Consortium recently developed a clinical risk score, termed the SCOPE index (which includes total bilirubin, albumin, platelets, GGT and large duct involvement), for use specifically in pediatric PSC [68]. The tool demonstrates excellent predictive ability for adverse events at 1 and 5 years and correlates strongly with biopsy-proven liver fibrosis. It also outperforms other tools developed in adult populations, such as the Mayo Risk Score.

Treatment

Data pertaining to the medical management of PSC in children are scarce, and current practices largely derive from adult studies. No medical therapy currently exists to reverse or halt the progression of PSC liver disease. As such, treatment is mainly supportive. Although numerous aspects of PSC invoke an autoimmune basis for the disease, thus far, no single immunosuppressive or immune-modulating agent has been found to be efficacious [69].

Ursodeoxycholic acid (UDCA) is widely used in adults and children with cholestatic liver disease, including PSC. Although biochemical improvement has been demonstrated in children, a beneficial effect on the natural history of PSC, as reflected by a decrease in mortality and/or LT rates, has never been shown [14, 70, 71]. Similarly, adult studies have documented improvements in biochemistry, but not in hard outcomes [72]. Furthermore, the use of high-dose UDCA >28 mg/kg has been associated with a twofold increased risk of death/transplant [73] and a fourfold increased risk of colorectal cancer in adults [74, 75]. There is no consensus regarding the use of UDCA in adults with PSC, with one expert group advising against its use entirely [76] and another merely recommending against the use of high doses [54]. In light of this, it appears prudent to avoid high-dose UDCA in children with PSC, but continued use of low-to-moderate doses, not exceeding 20 mg/kg/day, is reasonable.

There has been substantial interest in the use of oral vancomycin therapy (OVT) for treating pediatric PSC [71, 77–82]. Oral vancomycin's therapeutic effect may occur through immunomodulation, by increasing transforming growth factor-β (TGF-β) and peripheral levels of regulatory T-cells [81, 83]. However, most studies (excluding small uncontrolled case reports/case series) have shown only biochemical benefit [82]. In an open label study of OVT, with a median treatment duration of 2.7 years, 96%, 81%, and 95% of patients experienced reduction of GGT, ALP, and ALT, respectively [82]. Yet, when OVT was compared to UDCA or observation alone in a propensity score-matched analysis from the Pediatric PSC Consortium, OVT was not associated with superior outcomes [71]. Limited data in the form of case series suggest possible benefit of OVT for the IBD in PSC-IBD [84]. Overall, more rigorous, clinical trial data are needed to ascertain the role of OVT in treating PSC and PSC-IBD. Metronidazole and minocycline, but not rifaximin, have also been associated with improved liver biochemistry in adults with PSC [85–87]. At the current time, the use of oral antibiotics for pediatric PSC remains experimental, as a benefit beyond biochemical improvements has yet to be confirmed. The role of fecal microbial transplant (FMT) to modulate the dysbiosis seen in PSC has garnered much interest recently following the publication of a pilot study of 10 PSC-IBD patients where 30% of FMT recipients displayed an ALP reduction of at least 50% [88]. FMT also resulted in an increase in bacterial diversity with no adverse safety events reported. Larger prospective studies are required.

BA-targeting therapies for PSC currently under study include FXR agonists such as obeticholic acid (OCA) [89] and cilofexor [90], and Apical Sodium Dependent Bile Acid Transport (ASBT) inhibitors [73]. A phase 2 trial of 5–10 mg OCA demonstrated significant reductions in serum ALP at week 24 of treatment compared to placebo with no

significant effect on total bilirubin [89]. The main limitation of OCA is tolerability, especially pruritus. Cilofexor has been shown to reduce serum ALP by 21%, GGT by 30%, and ALT by 49% compared to placebo after 12 weeks of therapy [90]. Significant pruritus also emerged as a predominant adverse event with cilofexor, but with much lower rates compared to OCA. ASBT inhibitors A4250 and LUM001 (lopixibat) which act to interrupt the enterohepatic circulation of bile acids are currently under investigation for PSC treatment [91].

Dominant strictures are less common in children than adults, but should, when identified in association with symptoms or signs such as cholangitis, jaundice, pruritus, right upper quadrant pain, or worsening biochemistry, be managed with ERCP and balloon dilatation, often with sphincterotomy, with or without stent placement [24]. This may prolong symptom-free intervals prior to LT [92]. Although cholangiocarcinoma is rare in pediatrics, brush cytology in the setting of a dominant stricture remains important. ERCP should be performed by a physician who is adequately experienced with the procedure, which often requires collaboration with an adult gastroenterologist.

Vedolizumab, an IBD therapy, is a selective monoclonal antibody directed against the $\alpha_4\beta_7$ integrin expressed on lymphocytes. It interferes with the interaction of $\alpha_4\beta_7$ with mucosal cellular adhesion molecule-1 (MAdCAM-1) expressed on gut endothelial cells, thereby preventing lymphocyte trafficking to the gut. Although MAdCAM-1 is not expressed in normal liver tissue, it is expressed on portal vein and sinusoidal endothelial in chronically inflamed human liver, including in PSC [93, 94]. As such, the introduction of vedolizumab stimulated excitement as a potential biological treatment for PSC. Disappointingly, this has not been upheld by clinical studies thus far, although these have all been retrospective [95, 96]. A multicenter cohort study by the French GETAID group reported that vedolizumab therapy failed to result in liver biochemical improvements even when followed out to 30 and 54 weeks [96]. These findings were echoed by two additional adult [95, 97], and one small pediatric study [98]. On the other hand, vedolizumab appears to display similar efficacy for treating IBD in PSC-IBD, as in non-PSC IBD populations [95].

LT remains the only definitive treatment for PSC and should be considered for children with decompensated cirrhosis, recurrent or chronic cholangitis refractory to ERCP, hilar cholangiocarcinoma, and intractable pruritus [24, 99]. PSC accounts for 2.6% of pediatric transplants [100]. The median age at transplant is 15 years [57]. Patient and graft survival after LT for PSC are comparable to that for non-PSC pediatric indications, with 1-year and 5-year patient and graft survival rates of 99% and 97%, and 93% and 76%, respectively. However, a diagnosis of IBD prior to LT is associated with an increased risk of death post-LT. Intrahepatic biliary strictures and cholangitis are more common in the first 6 months post-LT in children with PSC compared to other liver diseases [101]. Furthermore, PSC recurs in 10–25% of pediatric patients by 5 years post-LT [57]. A diagnosis of IBD and younger age have been linked with an increased risk of PSC recurrence [101, 102]. As mentioned above, colectomy prior to or during LT may decrease the risk of PSC recurrence [50].

Other Autoimmune Liver Diseases

Autoimmune Hepatitis

Epidemiology and Pathogenesis

Autoimmune hepatitis (AIH) is an idiopathic, progressive, inflammatory liver disease characterized by elevated transaminases, interface hepatitis on biopsy, hypergammaglobulinemia, and autoantibody positivity. It is the most common pediatric autoimmune liver disease, with an incidence and prevalence of 0.23–0.4 and 3 per 100,000 children, respectively [12, 103]. The prevalence of IBD in children with AIH, which approaches 20% [103–105], exceeds that in the general pediatric population, but the magnitude of the association between AIH and IBD is less than that between PSC and IBD as demonstrated in Fig. 11.5. Only 0.3–0.6% of children with IBD develop AIH and, unlike in PSC, this proportion does not differ substantially between children with UC and CD [12]. Two main types of AIH are recognized: AIH type 1 (AIH-1), which accounts for the majority (60–87%) of cases, is characterized by positive antinuclear (ANA) and/or

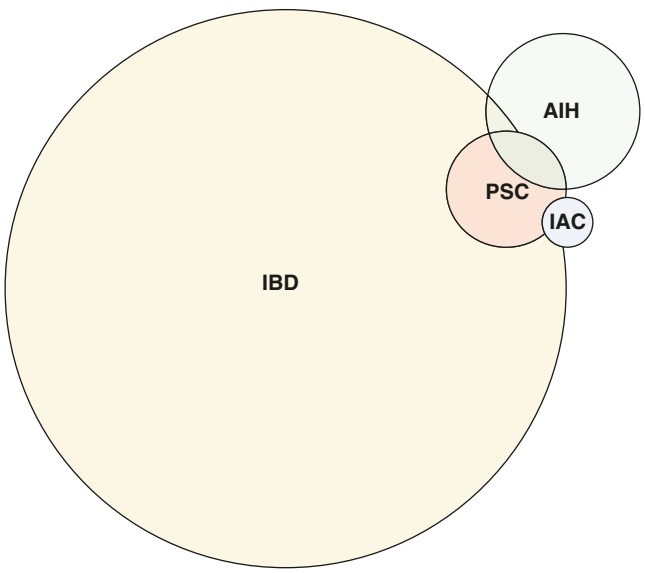

Fig. 11.5 The relationship between autoimmune liver disease and IBD. *AIH* autoimmune hepatitis, *IAC* IgG4-associated cholangitis, *IBD* inflammatory bowel disease, *PSC* primary sclerosing cholangitis

anti-smooth muscle (SMA) autoantibodies, whereas AIH-2 is distinguished by positive anti-liver kidney microsomal type 1 (LKM-1) and/or anti-liver cytosol type 1 (LC-1) autoantibodies. Of note, lower antibody titers are considered significant in children, namely, 1:20 for ANA and SMA, and 1:10 for LKM1 and LC-1, compared to a threshold of 1:40 in adults [106]. Both types of AIH have a female predominance [103], although it is not clear whether this is also true of cases associated with IBD [103, 104, 107]. The pathogenesis of AIH is unknown, but is likely multifactorial, involving genetic susceptibility and immune dysregulation, modified by environmental factors. An aberrant immune response targeting liver autoantigens has been implicated [108].

Diagnosis

Pediatric AIH can present in a highly variable manner, ranging from nonspecific insidious symptoms to fulminant liver failure. The most common presenting symptoms are fatigue, jaundice, and abdominal pain, which occur in about half of patients. Hepatomegaly and splenomegaly are the most frequently observed abnormalities on physical exam [103]. In the context of IBD, however, AIH typically comes to light as a result of elevated transaminases, which can fluctuate over time. The pattern of injury is predominantly hepatocellular, with AST and ALT values typically in the several hundred range which are comparatively higher than the levels seen in PSC and ASC [109]. Conjugated bilirubin may be normal or elevated, and GGT and ALP levels may be modestly elevated [109]. Serum IgG is elevated in 80% of cases, but a normal result does not rule out AIH. Although none of the autoantibodies listed above are entirely specific to AIH, the presence of high-titer autoantibodies, in combination with compatible clinical features and histological findings, strongly supports a diagnosis of AIH. A liver biopsy is typically performed to confirm a diagnosis of AIH and to establish the severity of liver damage. Characteristic findings include interface hepatitis, lymphoplasmacytic infiltrates, and rosetting of hepatocytes. Biliary changes, such as ductular proliferation, can be seen, as well as fibrosis. Cirrhosis is observed in 20–80% of children at presentation and is more common in AIH-1 [103, 110, 111]. Of note, the distinction between AIH and drug-induced liver injury, which is particularly relevant in children with IBD, can be very challenging. In addition to the AIH work-up presented above, it is recommended that all children with IBD with presumed AIH undergo cholangiography to investigate for ASC or PSC.

Outcomes and Treatment

Although a significant fraction of children with AIH present with cirrhosis, when treatment is instituted promptly, outcomes are usually favorable. Conventional treatment is with prednisone 1–2 mg/kg/day (maximum 60 mg/day) to induce remission, decreased over 4–8 weeks, and then continued at a lower dose (0.1–0.2 mg/kg/day, or 2.5–5 mg/day) as maintenance, often with azathioprine [112]. Azathioprine is generally started at a dose of 1–2 mg/kg/day and increased to a maximum of 2–2.5 mg/kg/day until remission is achieved [112–114]. Thiopurine methyltransferase (TMPT) activity may be verified prior to initiating azathioprine to identify patients at heightened risk of myelosuppression [108]. This treatment regimen is associated with biochemical remission (normalization of liver enzymes and IgG) rates >80% in children with AIH, although this can take several months, and relapses requiring temporary increases in immunosuppression are common [103, 107]. In patients who have had sustained biochemical remission for 2–3 years, a liver biopsy may be performed and, if resolution of histological inflammation has occurred, treatment withdrawal may be attempted [112, 114].

Children with AIH have an approximately 15% probability of developing liver cirrhosis and portal hypertension in the 5 years post diagnosis [12]. Transplant rates for AIH are variable but range from 5 to 10% in recent studies [12, 103, 115]. AIH can recur post-transplant with recurrence rates varying between 12 and 46% [115, 116]. It is therefore recommended that steroid-based immunosuppression be maintained at a higher dose than that used for non-AIH transplants [117]. At the current time, it is unclear whether the disease course of AIH occurring in association with IBD differs from that in children without IBD [57]. However, it has been recognized that flares of pre-existing UC can occur following liver transplantation for AIH with the resulting IBD activity taking a more aggressive course than previous and up to 9% of patients require colectomy post-transplant [118–120].

Autoimmune Sclerosing Cholangitis

Epidemiology and Pathogenesis

Autoimmune sclerosing cholangitis (ASC) is an overlap condition between AIH and PSC, characterized by the combination of autoimmune features, namely, positive autoantibodies (especially ANA and SMA), hypergammaglobulinemia and interface hepatitis on liver biopsy, and cholangiopathy, as demonstrated by an abnormal cholangiogram or histological evidence of ductal involvement [105]. However, there are no clear diagnostic criteria for ASC. The International Autoimmune Hepatitis Group (IAIHG) suggests that conditions with overlapping features between autoimmune liver diseases not be considered separate diagnostic entities [121]. Rather, ASC may exist along a continuum of pathological changes between AIH and PSC. Given the lack of established diagnostic criteria, the epidemiology of ASC is difficult to ascertain. However, a recent population-based study reported

an incidence and prevalence of 0.1 and 0.6 per 100,000 children, respectively [12]. ASC appears to occur predominantly in children and young adults: a quarter to a third of children with sclerosing cholangitis have autoimmune overlap features [14–16, 57], compared to only 1.4–17% of adults [24]. Similar to PSC, ASC is typically diagnosed in the first half of the second decade of life, but, unlike PSC, it tends to affect both sexes more equally [12, 15, 104]. A definite association exists between ASC and IBD, the magnitude of which appears to be intermediate between that of PSC and AIH. Up to 75% of children with ASC have IBD [122]. Conversely, 1.5–1.7% of children with IBD, mostly UC, have ASC [7, 12]. Given this, all children with ASC should undergo an evaluation for IBD, even if asymptomatic.

Diagnosis

The clinical presentation of ASC in children is similar to that described above. Biochemistry can provide some guidance in distinguishing ASC from AIH and PSC. Although ALP and GGT levels may be normal or only mildly elevated in the early stages of ASC [122], compared to AIH, ASC is typically associated with a higher ALP to AST ratio (around 4), and p-ANCA positivity is more common (74% compared to 36% of cases). Anti-LKM1, on the other hand, is more specific to AIH [105]. Clues of a possible diagnosis of ASC rather than PSC include higher transaminases, elevated serum IgG, and high-titer ANA and SMA autoantibodies. However, none of these biochemical parameters is sufficiently specific to make a diagnosis of ASC. The ability to firmly diagnose ASC and to differentiate it from AIH and PSC requires both cholangiography and liver biopsy. This is particularly relevant in children with IBD given the known association between ASC and IBD. It is noteworthy that despite having abnormal cholangiograms up to one quarter of children with ASC have no histological evidence of bile duct involvement and, conversely, 27% of patients with AIH have histological evidence of bile duct damage, chronic cholangitis, and biliary periportal hepatitis [104, 123].

Outcomes and Treatment

An accurate diagnosis of ASC is important as it may have prognostic and therapeutic implications. While the authors feel that a trial of corticosteroids with or without azathioprine is generally warranted in the setting of ASC [124, 125], whether this alters disease natural history (beyond improving biochemistry) remains unclear. There are data to support that the biliary disease in ASC typically progresses despite treatment [104]. UDCA is often used at doses of 15–20 mg/kg/day to address the biliary component of the disease, but, as with PSC, there is no evidence that biochemical improvement translates into a positive effect on natural history [112, 126]. Twenty-five percent of children with ASC develop liver cirrhosis and portal hypertension within 5 years of diagnosis, a rate that is intermediate between that for PSC and AIH [12]. Given the lack of well-defined diagnostic criteria, it is difficult to comment on precise LT and mortality outcomes in children with ASC and studies to date have yielded conflicting results. An older series reported a 65% 10-year survival with native liver, distinctly worse than the 100% survival in children with AIH [104], whereas a more recent study found a 90% 5-year survival with native liver, comparable to the rate observed in children with AIH. Overall, it is believed that transplant rates in ASC are similar to those in PSC, around 20% [105, 109]. As with PSC and AIH, ASC can recur post-LT [116]. Uncontrolled intestinal inflammation in patients with IBD may be a risk factor for ASC recurrence [105].

IgG4-Associated Cholangitis

IgG4-associated cholangitis (IAC) is a rare inflammatory disorder of the biliary tree, characterized by elevated serum IgG4 levels and infiltration of IgG4+ plasma cells in the bile duct walls, causing thickening and stenoses. IAC is often associated with type 1 autoimmune pancreatitis (AIP), the pancreatic manifestation of IgG4-related disease (IgG4-RD), a systemic multiorgan disorder only defined during the last decade [127]. The typical IAC/IgG4-RD patient profile is that of an elderly man with obstructive jaundice, weight loss, and abdominal discomfort. However, IAC occurring in association with UC has been reported, including in children [128]. The clinical and cholangiographic presentation of IAC is often indistinguishable from that of PSC. Furthermore, 9–36% of patients with PSC have elevated serum IgG4 levels (although usually lower than in IAC) [129, 130], and IgG4+ plasma cells have been documented on liver biopsy in PSC patients [131], further blurring the relationship between the two. However, PSC and IAC appear to be distinct entities, as evidenced by their vastly different response to corticosteroids; in contrast to PSC, IAC typically shows excellent response to immunosuppressive treatment, including resolution of strictures. However, relapse is common after tapering immunosuppression; long-term low-dose therapy with corticosteroids/azathioprine is often needed, analogous to the management of autoimmune hepatitis [132]. Diagnostic criteria have been proposed for IAC; these combine biochemical, radiographic, and histopathological characteristics with the multiorgan involvement of IgG4-RD and responsiveness to immunosuppressive treatment [133].

Figure 11.5 graphically depicts the relationship between autoimmune liver diseases and IBD.

Table 11.2 Differential diagnosis of clinical syndromes associated with IBD drugs causing liver injury

Syndrome	Drug
Acute hypersensitivity reaction	Sulfasalazine, mesalamine, thiopurines
Acute granulomatous hepatitis	Sulfasalazine, mesalamine
Autoimmune hepatitis-like	Anti-TNFα
Noncirrhotic portal hypertension	Thiopurines
Fibrosis/cirrhosis	Methotrexate
Cholestatic jaundice	Sulfasalazine, mesalamine, thiopurines, anti-TNFα
Sinusoidal obstruction syndrome	Thiopurines
Hepatic rupture	Thiopurines (peliosis)
Hepatic mass on imaging	Thiopurines (peliosis), anti-TNFα/ thiopurines (HSTCL)
Hepatitis B reactivation	Anti-TNFα

HSTCL hepatosplenic T-cell lymphoma

Drug Hepatotoxicity (Table 11.2)

Methotrexate

A recent systematic review and meta-analysis examining 32 randomized controlled trials, including a total of 13,177 adults primarily with rheumatological indications for treatment, demonstrated an increased risk of liver enzyme abnormalities in patients treated with methotrexate compared to a comparator agent, but no difference in the risk of liver failure, cirrhosis, or death [134]. The results of two adult IBD studies, in which fairly large numbers of liver biopsies were performed, also found very low rates of hepatic fibrosis in patients receiving methotrexate [135, 136], indicating that hepatic fibrosis is not as commonly observed in methotrexate users as suggested by older studies.

Pediatric IBD studies have found varying rates of biochemical liver abnormalities in children treated with methotrexate, ranging from 10% in a systematic review to 39% in a multicenter retrospective comparison of oral and subcutaneous methotrexate [137]. Most resolved spontaneously or with dosage adjustment; medication discontinuation was required in only a minority (<5%) [138–141]. These studies are limited, however, by their retrospective nature, the inability to correlate biochemistry with histopathology, and the inability to definitively ascribe the biochemical abnormalities to methotrexate given the absence of documented normal laboratories prior to medication initiation in most cases. Conflicting data exist regarding whether higher methotrexate doses and parenteral versus oral administration are associated with a greater risk of hepatotoxicity [135, 139, 142]. The risk of hepatotoxicity may be higher in the immediate period after starting methotrexate [143]. Importantly, abnormal liver biochemistry does not reliably identify methotrexate-associated fibrosis.

Based on the available evidence, when initiating methotrexate in children with IBD, the authors recommend obtaining liver biochemistry at baseline, weekly for the first month and every 2–3 months thereafter. In cases of persistent moderate enzyme elevations (up to 2–3× ULN), the dose of methotrexate can be adjusted, whereas, when faced with more marked elevations (>5× ULN), methotrexate should be entirely held, at least temporarily. A liver biopsy should be performed in cases in which liver enzymes remain abnormal despite medication cessation, or when methotrexate discontinuation would be deleterious to IBD management. The use of methotrexate in patients with underlying liver disease, such as PSC, should generally be avoided, if possible.

Thiopurines

Azathioprine (AZA) is a prodrug for 6-mercaptopurine (6-MP), which is, in turn, converted to 6-thioguanine (6-TG), the final effector metabolite. The enzyme thiopurine methyltransferase (TPMT) catalyzes the formation of 6-methylmercaptopurine (6-MMP) and 6-methylmercaptopurine ribonucleotides (6-MMPR) [144]. A systematic review, including 34 mostly adult IBD studies, found a mean prevalence of AZA/6-MP-induced "liver disorder" of 3.4% and a mean annual rate of abnormal liver tests (up to 2× ULN) per patient-year of 1.4%, suggesting that thiopurine-associated hepatotoxicity is relatively uncommon. However, most studies did not provide definitions for "liver disorder" and were retrospective in design [145]. Two large pediatric studies examining the use of thiopurines in IBD also found fairly low rates of hepatotoxicity, namely, 4.6% and < 3%, respectively [146, 147].

Thiopurine-induced hepatotoxicity can be grouped into four syndromes: [1] hypersensitivity reactions; [2] idiosyncratic cholestatic reactions; [3] endothelial cell injury including sinusoidal obstruction syndrome (SOS or veno-occlusive disease); and [4] nodular regenerative hyperplasia (NRH) [148]. Hypersensitivity reactions occur in 5–15% of patients and usually have their onset within 2–3 weeks. Non-allergic cholestatic injuries are characterized by increased serum bilirubin and ALP, with or without moderate aminotransferase elevations, and typically occur within 2–5 months of therapy initiation. Variable parenchymal cell necrosis is typically seen on liver biopsy. Jaundice regression is not universal upon medication cessation [145]. Peliosis hepatis, sinusoidal dilatation, SOS, and NRH are felt to be dose dependent. The inciting injury in this group of vascular pathology is at the level of the endothelial cells lining the sinusoids and terminal hepatic venules and tends to occur

between 3 months and 3 years of treatment [148, 149]. IBD patients treated with AZA have a cumulative incidence of NRH of approximately 0.6 and 1.3% at 5 and 10 years, respectively [150]. Patients with NRH may be asymptomatic with normal or only mild elevations in liver function tests or isolated thrombocytopenia, or may present with clinically evident portal hypertension (PH). NRH can be detected on liver biopsy, which demonstrates diffuse transformation of normal hepatic parenchyma into small, regenerative nodules with little or no fibrosis [151], and on MRI, which shows multiple fine, non-enhancing nodules [152]. The course is usually indolent, but, rarely, NRH may progress to end-stage liver disease requiring LT [153]. Thiopurine cessation in patients with NRH is generally followed by biochemical normalization, but patients with PH have a variable course, with resolution of PH in some, but persistence in others. Peliosis hepatis results in multiple cystic blood-filled spaces in the liver, spleen, lymph nodes, and other organs, which can lead to hepatic hematomas and, rarely, hepatic rupture [154]. SOS typically presents with a Budd-Chiari-like picture, with the triad of rapid-onset ascites, painful hepatomegaly, and jaundice.

A reasonable monitoring strategy when initiating thiopurine therapy might include liver biochemistry at baseline, weekly for the first month, biweekly for the second and third months, and monthly thereafter. 6-MMP levels >5700 pmol/8 × 10^8 red blood cells have been linked with liver toxicity in children [155], but this finding has not been consistent across all studies [156]. If available, metabolite levels may be used to complement liver enzyme monitoring, and TPMT genotype or activity may be determined prior to initiating therapy, but this remains controversial. Mild liver enzyme abnormalities in children on thiopurine therapy may be observed with repeat blood work, but the authors suggest that the dose of thiopurine be reduced by about 50% in patients with more marked derangements. If this does not result in biochemical normalization after several weeks to months, therapy should be withdrawn entirely. Immediate thiopurine discontinuation should be the approach in any patient with clinically overt jaundice. Liver biopsy should be considered if liver tests fail to normalize after medication withdrawal or if there is any suggestion of PH, even in patients with normal laboratory parameters.

Antitumor Necrosis Factor-α (Anti-TNFα)

Based on post-marketing surveillance, the Food and Drug Administration (FDA) has issued warnings about the potential risk of serious liver injury with the use of anti-TNFα antibodies [157]. TNFα plays an important role in many aspects of immune response regulation. The association between anti-TNFα use and the development of autoantibodies is well known, although the pathological role of these antibodies remains unclear [158]. Anti-TNFα-related hepatotoxicity does not appear to be dose-dependent, but instead idiosyncratic. The release and presentation of hepatic autoantigens by immune cells may be involved [159].

Infliximab (IFX) and adalimumab (ADA) have been implicated in drug-induced liver injury (DILI) in both rheumatology and IBD populations. The median latency period is 13–18 weeks, but is hugely variable; DILI may have its onset after a single infusion/injection, but 20% of cases occur more than 6 months into therapy [160, 161]. DILI seems to occur more frequently with IFX than ADA; the rate of DILI has been found to be 1/120 IFX-treated patients compared to 1/270 ADA-treated patients [162]. This is in keeping with the findings of a large retrospective review of adult IBD patients, in which IFX accounted for a disproportionate fraction of the 2.7% of patients who developed significant liver enzyme elevations felt to be secondary to anti-TNFα therapy [161]. The most common presentation is an autoimmune phenotype with primarily hepatocellular injury, high rates of autoantibody (especially ANA) positivity, and histological findings compatible with autoimmune hepatitis. However, mixed non-autoimmune and predominantly cholestatic patterns also occur. Cases with autoimmune features may have a longer latency and higher peak ALT [160]. Autoantibody positivity prior to anti-TNFα initiation does not appear to predict the risk of DILI [162]. Cases of DILI with AIH features should be managed with anti-TNFα discontinuation, in which case the prognosis is favorable. Some patients benefit from treatment with corticosteroids [160]. Anti-TNFα-associated DILI does not seem to be a class effect, and switching to a different anti-TNFα, with close observation, appears safe. Milder cases of hepatotoxicity without overt autoimmune features often resolve spontaneously without anti-TNFα discontinuation [161]. Pediatric data exploring abnormal liver enzymes in children receiving anti-TNFα therapy are scarcer. In a study of 195 pediatric IBD patients on infliximab, liver biochemical abnormalities were common; AST was elevated in 27% and ALT in 25% of patients [163]. A retrospective study of 659 children with IBD who initiated anti-TNFα therapy revealed that 7.7% experienced a hepatocellular pattern of liver injury with new ALT elevations at least 2x the ULN [164]. Ninety-three percent had normalization of ALT and only 8% required cessation of anti-TNFα therapy [164].

Another concern with anti-TNFα agents is the risk of viral reactivation, in patients with chronic hepatitis B (HBV) infection, particularly those who are HBsAg-positive. Approximately, one-third of HBsAg-positive IBD patients were observed to develop liver dysfunction while receiving immunosuppressive therapy, including anti-TNFα [165]. Treatment with anti-TNFα in IBD patients with hepatitis C (HCV) appears to be less of a concern and is generally well

tolerated, with most patients displaying either unchanged or even improved biochemistry while receiving anti-TNF therapy [166]. Notably, no pediatric data exist regarding the outcomes of children with IBD and HBV or HCV receiving anti-TNFα. Strong consideration should be given to treating chronic HBV infection in children who are to commence anti-TNF therapy, whereas this may not be necessary in children with HCV. Regardless, routine surveillance with liver enzymes and viral loads should be performed regularly in such children.

A child's immunization history should be carefully reviewed at the time of IBD diagnosis, and viral serologies, including HBsAb, HBsAg, anti-HBc, and anti-HCV, should be verified. Although it is preferable to vaccinate for hepatitis A (HAV) prior to anti-TNFα initiation, seroconversion is still likely once on therapy and should be attempted regardless [167]. Patients with IBD who have nonimmune HBsAb levels (<10 mI U/mL) should be revaccinated with the routine three-dose regimen.

Other Biologics and Small Molecules

Licensed non-anti-TNFα biologics (vedolizumab, ustekinumab) and small molecules (tofacitinib) have not consistently been linked to significant risk of hepatotoxicity.

Sulfasalazine and Mesalamine

Sulfasalazine causes two main forms of hepatic injury. First, acute hepatocellular damage may develop as part of a generalized hypersensitivity reaction. This reaction, sometimes referred to as DRESS (drug rash with eosinophilia and systemic symptoms), is characterized by fever, rash, hepatomegaly, lymphadenopathy, atypical lymphocytosis, and eosinophilia, and is thought to be due to the sulfapyridine moiety [168]. The injury typically manifests within 2 months of starting therapy, with a shorter latency upon re-exposure [169]. This reaction is uncommon with data from the UK suggesting an incidence of 0.4% [170]. Prompt sulfasalazine discontinuation is critical, and corticosteroids may be helpful. However, progression to acute liver failure and death has been reported [170, 171]. Second, acute granulomatous hepatitis, characterized by fever, malaise, right upper quadrant pain, variable transaminases, and ALP and non-caseating granulomas on biopsy, may also occur [172]. In addition, cholestatic injury has been described with sulfasalazine use [173]. Mesalamine-induced hepatotoxicity is rare. A UK audit reported an incidence of 3.2 cases per million prescriptions, which was not statistically different from the six cases per million for sulfasalazine [174]. Cholestatic injury, with or without granulomatous hepatitis, resolving upon mesalamine discontinuation, has been reported [175–177]. An apparent cross-reactive hypersensitivity reaction with mesalamine after a reaction to sulfasalazine [178] and a case of chronic hepatitis with autoimmune features have also been described [179].

Glucocorticoids

It is postulated that glucocorticoid-related alterations in hepatic lipid metabolism may lead to hepatic steatosis. Steroid use has been identified as an independent risk factor for nonalcoholic fatty liver disease (NAFLD) identified by abdominal imaging in IBD patients [180–182].

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) is a rare, aggressive, and almost uniformly fatal extranodal lymphoma. The usual presentation includes fever, fatigue, abnormal liver tests, hepatosplenomegaly, and pancytopenia. As of 2020, 62 cases of HSTCL have been identified in IBD patients with a median age of 28 years (range 12–81); 83.6% were male, 84.7% had Crohn disease [183]. At the time of HSTCL diagnosis, 57 of 62 patients had current or previous exposure to thiopurines, 38 had exposure to anti-TNFα therapy, 27 were on combination therapy and 3 patients had exposure to natalizumab, vedolizumab or ustekinumab (of which all 3 also had anti-TNF and azathioprine exposure) [183]. The absolute risk of HSTCL in all patients receiving thiopurines has been estimated to be 1:45,000 compared to 1:7404 in men <35 years old, whereas the absolute risk for all patients receiving concomitant thiopurine and anti-TNF has been estimated to be slightly less than 1:22,000 compared to approximately 1:3534 in men <35 years [184]. In keeping with this, in a case–control study, anti-TNF combined with thiopurine therapy was associated with a higher risk of HSTCL compared to infliximab alone [185]. At the current time, the role of anti-TNFα agents in the development of HSTCL is uncertain [186], but the risk appears to be greater with combination therapy [187, 188]. A high degree of suspicion must be maintained for this diagnosis, especially in young males.

Other Liver Diseases and IBD

Cholelithiasis

The incidence and prevalence of cholelithiasis in CD patients are 14.35 per 1000 person-years and 11–34%, respectively, compared to 7.75 per 1000 person-years and 5.5–15%,

respectively, in controls [189, 190]. Overall, the odds of gallstones are 2.1-fold higher in CD patients compared to the general population. In contrast, definite evidence of an association between UC and cholelithiasis is lacking [189]. Although gallstones are relatively unusual in pediatric populations, 2.3% of children with IBD in an American consortium developed cholelithiasis [22], which significantly exceeds the population prevalence of 0.88–0.99% in individuals <30 years [191]. Previous intestinal resection is the strongest risk factor for gallstone disease in patients with CD, with an ileal resection >30 cm increasing the odds of cholelithiasis sevenfold. Other risk factors include ileal location, disease duration, age, number of clinical recurrences and hospitalizations, total parenteral nutrition, prolonged hospitalization, and female sex. Symptomatic cholelithiasis should prompt a referral to a pediatric surgeon. Children may also present with cholecystitis, which should be managed with broad-spectrum antibiotics and a general surgery consultation to guide eventual cholecystectomy.

Liver Abscess

Liver abscess is a rare complication of IBD. The incidence of pyogenic liver abscess is higher in IBD patients (6.72 per 10,000 person-years) compared with healthy controls (4.06 per 10,000 person-years) [192]. It is more common in CD and in males and tends to occur in the setting of active disease. There is a tendency to develop multiple abscesses, which almost invariably involve the right lobe. The presentation is similar to that in non-IBD patients, but the diagnosis can be challenging and is often overlooked. Investigations, when suspected, should include an ultrasound and blood cultures, which are positive in 50% of cases. Compared to hepatic abscesses in the general population, which are usually polymicrobial, a single pathogen, often *Streptococcus milleri*, is frequently isolated in patients with IBD. Treatment is with prolonged parenteral antibiotics (commonly 4–8 weeks) with or without drainage, preferably percutaneously. An intra-abdominal source should be ruled out. Risk factors for liver abscess in IBD include intra-abdominal abscesses, fistulizing disease, intestinal perforation, abdominal surgery, and malnutrition [189, 193].

Portal Vein Thrombosis and Budd-Chiari Syndrome

Adult and pediatric patients with CD and UC are at increased risk of thromboembolism (TE). To date, the mechanism behind this prothrombotic state is not fully understood, but it is likely multifactorial and related to the inflammatory state. The potential etiologies for increased thrombosis in IBD include thrombocytosis/platelet activation, hyperhomocysteinemia, increased fibrinogen, impaired fibrinolysis, increased procoagulation factors, decreased anticoagulation factors, and procoagulation mutations. The extent of IBD has also been shown to correlate with the risk of TE, but TE can occur in patients with UC even after proctocolectomy [194].

Portal vein thrombosis (PVT) appears to occur at higher rates in the IBD population, particularly postoperatively. Most studies suggest it is a rare complication, with a prevalence of 0.1–1% in IBD [195]. The incidence specifically in pediatric IBD patients has been reported to be 9 per 10,000 hospitalizations, with sixfold increased odds compared to non-IBD controls [194]. Overall, the precise epidemiology of the condition is difficult to ascertain as most patients are asymptomatic. Intra-abdominal surgery, IBD flare, and intra-abdominal infection have been identified as key risk factors [196]. The diagnosis may be made at the chronic stage, at which time cavernomatous transformation of the portal vein may be evident on imaging. A variety of imaging modalities can be used to make the diagnosis, including ultrasound with Doppler, contrast-enhanced CT, and MR angiography. Treatment is generally with anticoagulation for 3–9 months depending on the particular anticoagulant agent chosen [196]. While older studies suggested high mortality rates with this complication, more recent publications indicate a more benign natural history [195].

Budd–Chiari syndrome is a rare complication of UC, mostly in adults, but has been reported in a small number of children as well, with an incidence of 2.1 per 10,000 hospitalized pediatric IBD patients [194, 197–199]. It typically presents with hepatomegaly, right upper quadrant pain, and rapid-onset ascites with abnormal liver tests, but 25% can be asymptomatic. Diagnosis is supported by imaging and/or liver biopsy. Therapy may include thrombolysis, anticoagulation, angioplasty, or vascular stents. More definitive treatment, such as porto−/mesocaval shunts, or even liver transplant, may be required in medically refractory cases. Symptomatic treatment of ascites is with diuretics and paracentesis. While outcomes have often been poor in adults, the pediatric cases reported to date have had a favorable evolution, with anticoagulation or even spontaneously.

Non-Alcoholic Fatty Liver Disease

The prevalence of nonalcoholic fatty liver disease (NAFLD) in IBD has varied widely across different studies, ranging from 13 to 100% [1], depending on the diagnostic modality employed and the indication for screening/testing. According to a systematic review, the mean prevalence of fatty liver disease in adults is 23% in UC and 1.5–39.5% in CD, in comparison to 20% in the general population [189]. The prevalence of NAFLD in pediatric IBD patients has never

been specifically examined. Overall, it would appear that fatty liver is common in the IBD population, but definitive evidence that the prevalence of NALFD in IBD exceeds that in the general population is lacking. Adult studies point to an increased risk of NAFLD in male patients with IBD [200] and those who develop IBD at a younger age, [201] but these risk factors have not been demonstrated in pediatric IBD cohorts. Patients with metabolic risk factors, such as obesity and hypertension, are at increased risk, but these risk factors are not universally present in IBD patients with NAFLD. Indeed, IBD patients with NAFLD have a significantly lower weight and BMI than patients with NAFLD alone, pointing to a unique NAFLD phenotype [202]. Coupled with the asymptomatic nature of NAFLD, a high degree of suspicion must be maintained, particularly in the setting of raised liver enzymes. Since IBD patients can have multiple possible etiologies for elevated liver enzymes (medications, obesity, immune-mediated liver disease), liver biopsy is often required.

Management includes attaining adequate IBD control, withdrawing therapies that may be associated with hepatic steatosis (such as steroids), if possible, and working toward a healthy BMI in patients who are overweight, in conjunction with a pediatric dietitian.

Granulomatous Hepatitis

Granulomatous hepatitis is estimated to occur in <1% of IBD patients, primarily those with CD. It tends to present as unexplained hepatic masses on routine imaging or asymptomatic elevations of cholestatic liver enzymes, especially ALP. The diagnosis is confirmed by visualizing granulomas on liver biopsy. The most common cause in the setting of IBD is medications, especially mesalamine and sulfasalazine, but granulomatous hepatitis can also be an extraintestinal manifestation of IBD and can be associated with malignancy or infections [172, 175, 203]. Corticosteroids and immunosuppressive agents have been used as treatment [1].

Hepatic Amyloidosis

Amyloidosis is a rare but serious complication of IBD, especially CD. It has a prevalence of 0.5% in IBD, more specifically 0.9–3% in CD, and 0–0.07% in UC [204–206]. The pathogenesis remains unclear. Patients are usually male with extensive, long-standing disease, although amyloidosis may be present at the time of, or even prior to, the diagnosis of IBD. Fistulae and/or abscesses, as well as other extraintestinal manifestations, are common. Amyloidosis is predominantly a disease of the kidneys, but hepatic involvement has been described in a small subset of patients, including in children [206]. Signs and symptoms of hepatic amyloidosis are few, and liver tests are generally normal. The diagnosis is established by biopsy, and, often, only comes to light at the time of autopsy. Management in hepatic amyloidosis focuses on achieving control of underlying IBD in an effort to modulate release of serum amyloid A, an acute phase reactant [182]. Mortality is closely tied to the renal disease, but hepatic involvement is associated with a reduced likelihood of survival [207].

A Clinical Approach to Children with IBD and Liver Abnormalities

Children with IBD who develop abnormal liver biochemistry or physical stigmata of liver disease may have a wide range of potential underlying diagnoses, as reviewed in this chapter. Based on the available but limited evidence presented, the authors suggest the following approach to liver disease in pediatric IBD (Fig. 11.6). All children with IBD should have routine liver biochemistry with ALT, AST, GGT, ALP, fractionated bilirubin, and albumin measured every 6–12 months when the child is well. The frequency of blood work can be increased if the child is unwell or receiving medications with known potential hepatotoxicity, as detailed above. If low-grade abnormalities are detected, liver tests should be repeated in 2 weeks to ensure they are not rising acutely and subsequently followed for the first few months. With more marked elevations, or clinically overt evidence of liver disease, such as hepatosplenomegaly or jaundice, further investigations should be considered, including autoantibodies (ANA, SMA, LKM1, ANCA), serum IgG, viral hepatitis serologies, celiac serology, ceruloplasmin, and alpha-1 antitrypsin level, along with abdominal ultrasound. Depending on the clinical context, MRCP and/or liver biopsy may also be indicated. If medications are felt to be a potential contributor, a trial of reducing the dose or holding the medication entirely (if this is not felt to be detrimental to the child's IBD care) should be performed. The distinction between "low" and "high-grade" elevations is controversial. The authors propose that elevations >2–3× ULN are significant and require further investigation. Additional studies in pediatric IBD populations are required to construct truly evidence-based algorithms to guide the work-up and management of abnormal liver biochemistry and liver disease in children with IBD.

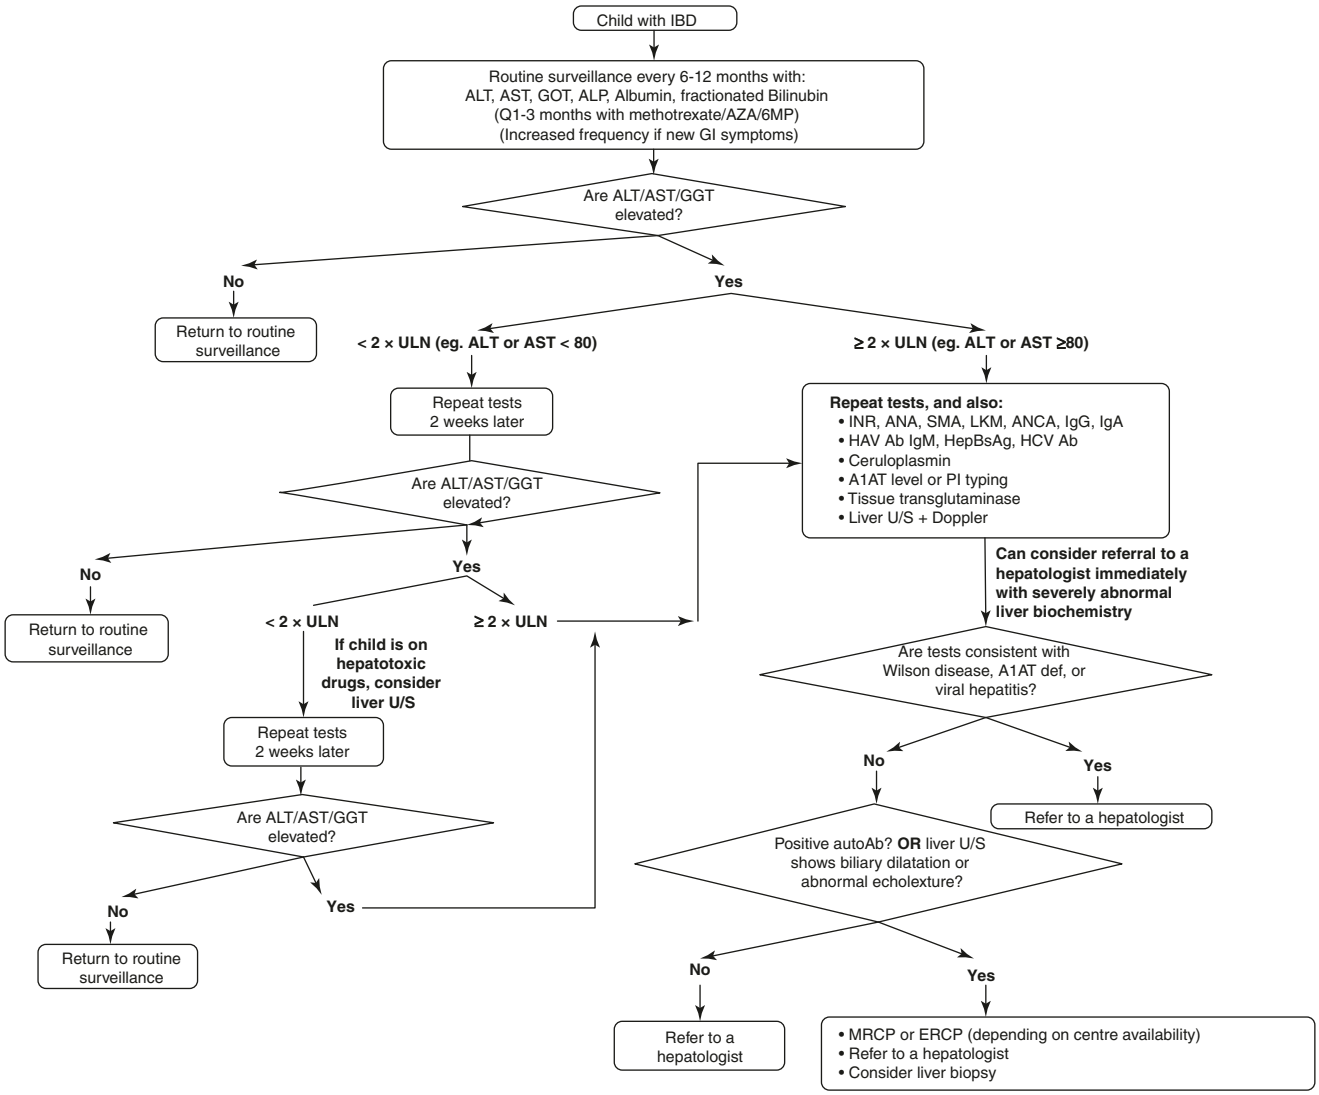

Fig. 11.6 Suggested approach to liver disease in pediatric IBD

Growth Impairment in Pediatric Inflammatory Bowel Disease

12

James Huang and Thomas D. Walters

Normal Growth and Pubertal Development

"Normal" children grow at very different rates. Patterns of growth and pubertal progression in young patients with IBD can only be accurately recognized as pathologic, if the variations in the normal development of healthy children and adolescents are first appreciated [1, 2]. A child's growth is the result of both genes and environment; it appears principally mediated by hormones and nutrition [3]. Linear growth can be represented by stature (attained height) or by the rate of growth (height velocity). A child's attained height represents the culmination of growth in all preceding years; height velocity reflects growth status at a particular point in time.

Normal Growth Patterns

Growth can be conceptualized as the product of three overlapping biological phases: infancy, childhood, and puberty. Final height represents the sum of each of the individual components.

Linear growth velocity decreases from birth onwards, punctuated by a short period of growth acceleration (the "adolescent growth spurt") just prior to the completion of growth. As the rapid growth of infancy tails off, the steady growth of childhood predominates. Healthy children grow at a consistent rate in the range of 4–6 cm annually from 6 years of age until the onset of puberty [4].

At puberty, there is a rapid alteration in body size, shape, and composition; for a year or more, height velocity approximately doubles. Puberty depends on a healthy hypothalamic-pituitary-gonadal (HPG) axis and is marked by the return of gonadotropin-releasing hormone (GnRH) secretion. GnRH stimulates the secretion of luteinizing and follicle-stimulating hormones, which then stimulate gonadal maturation and sex-steroid production [5]. Although much is known about the components of the HPG axis, the factors that trigger pubertal onset remain elusive [5]. The age of onset of puberty, and hence of the pubertal growth spurt, varies among normal individuals and between ethnic populations. Puberty begins earlier in girls than in boys; moreover, the pubertal growth spurt occurs in mid-puberty (prior to menarche) in girls but in late puberty (after Tanner stage 4) in boys [4]. There is hence quite consistently a two-year difference in the timing of peak height velocity (PHV) in girls compared to boys [4]. In North American females, PHV occurs at a mean age of 11.5 years, but in males not until 13.5 years (2SD = 1.8 years) [4]. The occurrence of menarche is an indication that linear growth is nearing completion; usually, girls gain only 5–8 cm more in height within the two subsequent years [4].

Normal Growth Physiology

To understand the mechanisms by which growth is inhibited in children with IBD, and to thoughtfully consider solutions by which it might be corrected, it is necessary to understand the normal physiology and regulation of growth. The growth hormone/insulin-like growth factor-1 (GH/IGF-1) axis plays a pivotal role in normal postnatal growth. Thyroxine, cortisol, and the sex steroids are also implicated in the maintenance of normal linear growth.

The GH/IGF-1 Axis

The Somatomedin Hypothesis

In 1956 Daughaday and Salmon proposed that an intermediate hormone they termed "Somatomedin C" mediated all the growth-promoting effects of Growth hormone (GH). This hormone was subsequently purified and named "Insulin-like Growth Factor-1" (IGF-1) [6–8] and found to act in both an "endocrine" fashion, via its hepatic generation and subsequent release into the circulation, as well as in an "autocrine/paracrine" fashion, through its local generation within target

organs [9, 10]. More recent work has determined that, by acting on different cell types, both hormones (GH and IGF-1) can directly stimulate longitudinal growth: GH induces differentiation of epiphyseal growth plate precursor cells toward chondrocytes, which in turn become responsive to IGF-1, while IGF-1 stimulates the clonal expansion of differentiated chondrocytes [10, 11] (Fig. 12.1).

Growth Hormone and IGF-1

The precise mechanism by which GH is released and subsequently stimulates the release of IGF-1 is now well established [12–16] (Fig. 12.2). In humans, the majority of circulating IGF-1 is synthesized in the liver, although a low level of GH-dependent and GH-independent IGF-1 expression does occur in extrahepatic tissues.

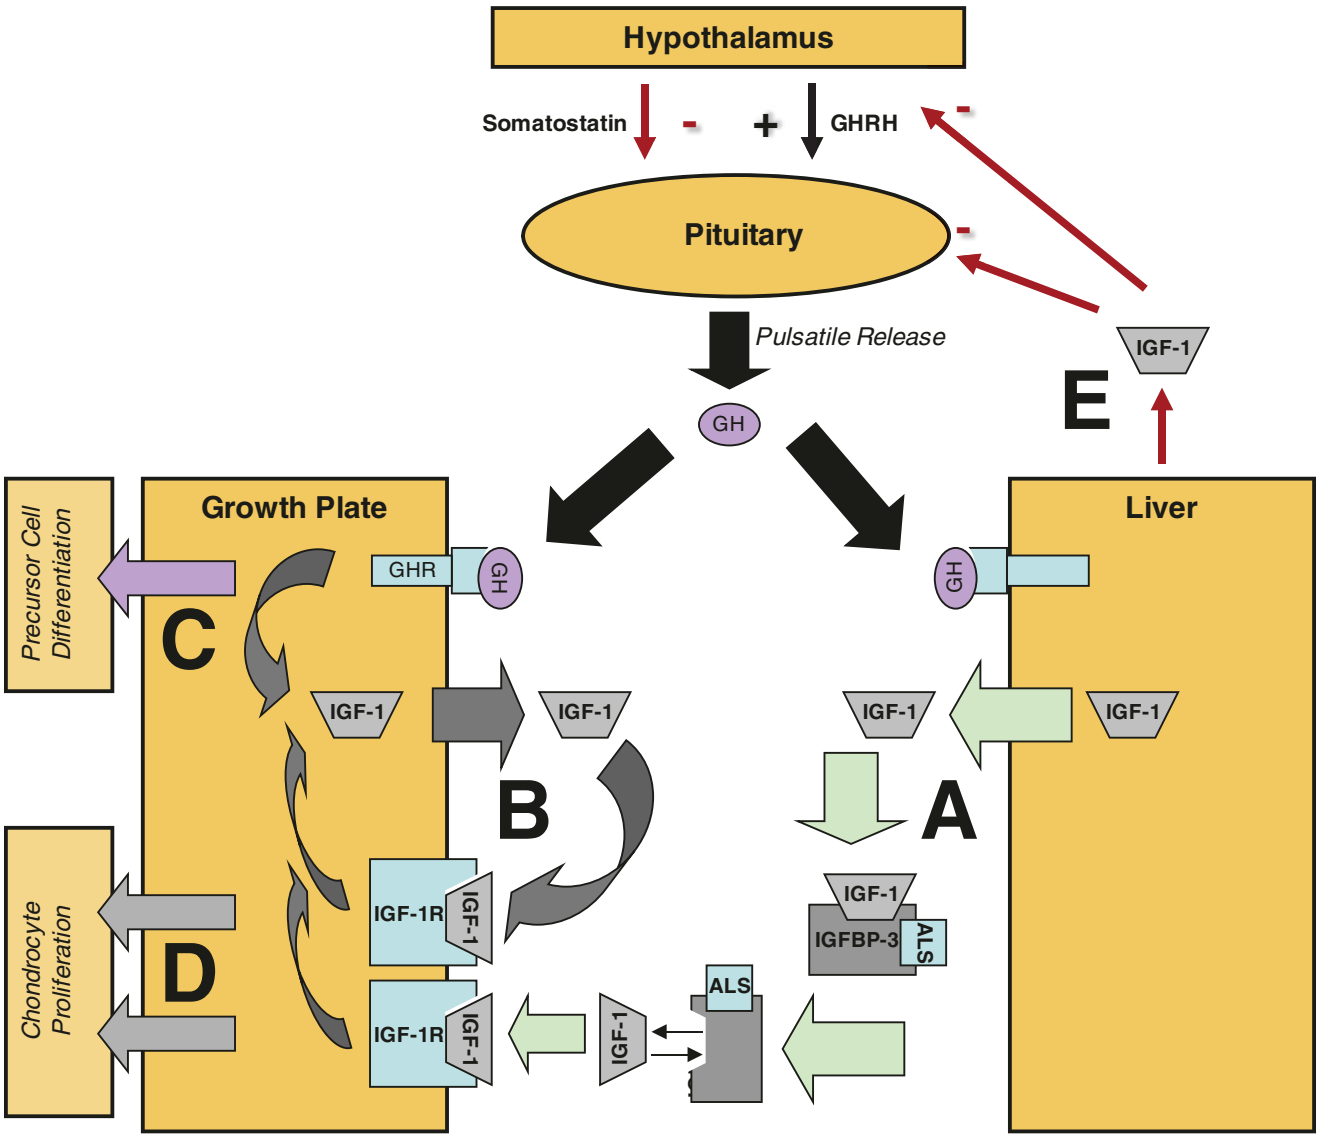

Fig. 12.1 The GH/IGF-1 Axis and its role in linear growth. The hypothalamic release of Growth Hormone-Releasing Hormone (GHRH) stimulates the pulsatile release of Growth Hormone (GH) from the pituitary. The GH cell surface receptor (GHR) is widely expressed throughout the body. GH binds to the extracellular domain of GHR, inducing the upregulation of various anabolic target genes including Insulin-like Growth Factor 1 (IGF-1). The majority of circulating IGF-1 forms a ternary complex with acid-labile subunit (ALS) and Insulin-like Growth Factor Binding Protein-3 (IGFBP-3). IGF-1 acts in both an "endocrine fashion" (process **a**) and "autocrine/paracrine" fashion (process **b**). In addition to up-regulating IGF-1 production, GH contributes directly to linear growth by inducing differentiation of the precursor cells within the growth plate toward chondrocytes (**c**). IGF-1 stimulates mitosis of epiphyseal chondrocytes (**d**) and also mediates the negative feedback of GH (**e**)

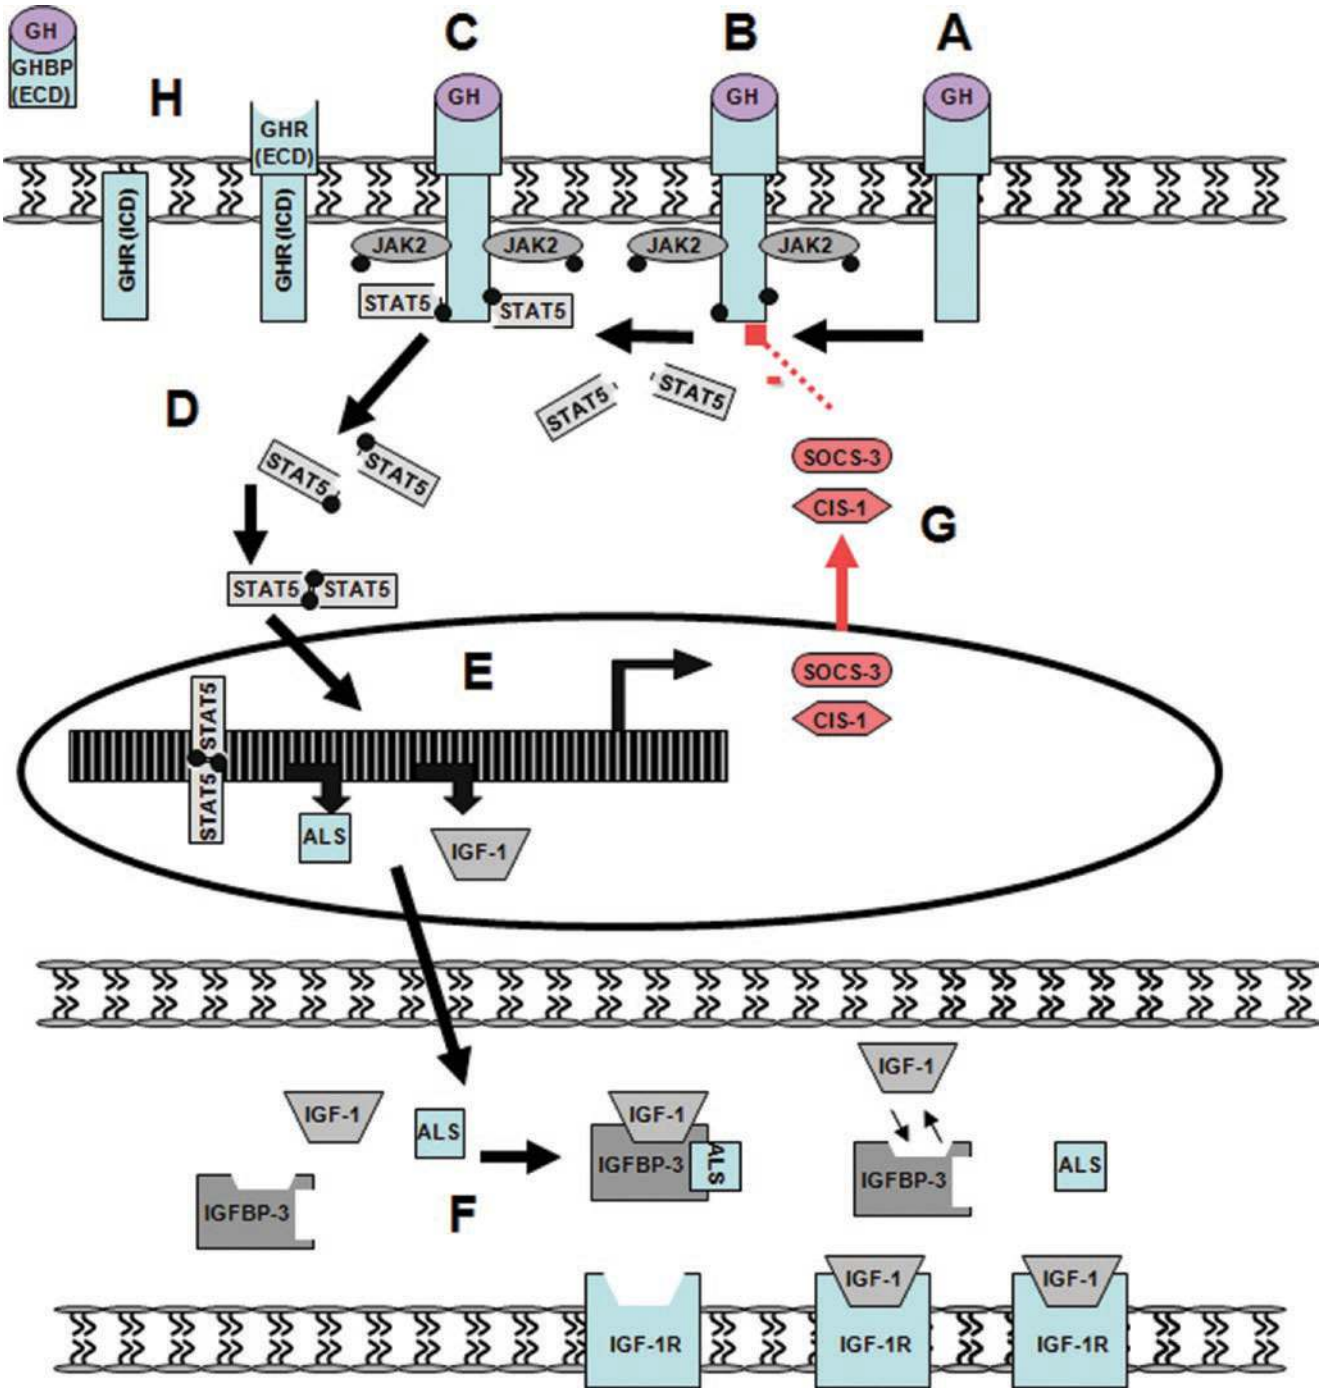

Fig. 12.2 The Growth Hormone Receptor and JAK2/STAT5 signaling pathway. (**a**) Within its various target tissues, GH binds to the extracellular domain of the Growth Hormone Receptor (GHR), (**b**) inducing the intracellular auto-phosphorylation of Janus kinase 2 (JAK2). (**c**) In turn, phosphorylated JAK2, in association with activated GHR, leads to the phosphorylation of signal transducer and activator of transcription protein 5 (STAT5). (**d**) Activated STAT5 dimerizes and then (**e**) translocates to the nucleus, resulting in the upregulation of various anabolic target genes including IGF-1 and acid labile subunit (ALS) [13–15]. (**f**) IGF-1 and ALS pass to the circulation and form ternary complexes with Insulin-like Growth Factor-Binding Protein (IGFBP), about 75% as a 150 kDa complex with IGFBP-3. (**g**) Suppressors of cytokine signaling (SOCS) proteins are post-receptor inhibitors of cell signaling that mediate their effect via the JAK/STAT pathway [16]. GH rapidly and prominently induces expression of SOCS-3 and cytokine-inducible SH2-containing protein-1 (CIS-1) within the liver as part of a negative feedback loop that functions by blocking the phosphorylation of STAT5. SOCS-3 inhibits JAK2 by a mechanism requiring GHR. (**h**) The GHR has both an intra- and extracellular domain (ICD and ECD). Growth Hormone Receptor-Binding Protein (GHBP), present within the circulation, is produced by the inducible metalloproteolytic cleavage of the GHR's extracellular domain. Serum concentrations of this protein are thought to reflect GHR density [215]

Gender Differences in the GH/IGF-1 Pathway

GH is released in a pulsatile pattern that is gender-specific, with males experiencing higher peaks and deeper troughs compared to females [17]. Interestingly, STAT5 exists in two genetically distinct, although highly homologous, forms (STAT5A and STAT5B) [18] which are known to differ somewhat in their tissue distribution [19]. Of note, while STAT5A and STAT5B are both required for normal GH-dependent growth, STAT5B is responsive to pulsatile GH, whereas STAT5A is not. Indeed, STAT5B-deficient male mice have pronounced growth impairment, and tend to grow at a rate similar to normal females. Thus, the complex regulation of sexually dimorphic growth appears to be mediated, at least in part, by STAT5B "interpreting" the differing GH pulsatile secretion patterns of males versus females [18]. Given this, it seems plausible that any interference within the GH/STAT5B/IGF-1 pathway is likely to have a more pronounced effect on growth patterns in males than in females.

Insulin-Like Growth Factor Binding Proteins (IGFBPs)

The bioavailability of IGF-1 depends on its unbound or "free" fraction. Six specific high-affinity IGF-1-binding proteins (IGFBP-1 to IGFBP-6) are present within the circulation and can each bind IGF-1 with an affinity at least equal to the binding of IGF-1 to the IGF receptor [20]. The IGFBPs are each regulated by specific proteases that dramatically reduce their IGF-1-binding affinity. The specific function and structure of the six IGFBPs differ significantly [21]. IGFBP-1,-2,-4, and -6 primarily inhibit IGF-1 by tightly binding to it and preventing it from binding to its receptor [20, 22, 23]. Conversely, IGFBP-3 potentiates the action of IGF-1 by "loosely" binding to it, thus prolonging the time it is available within the circulation to interact with its receptor. About 75% of IGF-1 circulates as a 150 kDa ternary complex composed of IGF-1, acid-labile subunit (ALS), and IGFBP- 3 [20]. This large complex, which cannot cross the endothelial barrier [24] significantly increases the half-life of IGF-1 from less than 10 min to greater than 16 h [20]. Caloric and protein restriction can cause a reduction in the levels of IGFBP-3 [25, 26].

Growth Plate Proliferation, Senescence, and Fusion

The normal age-dependent decline in growth rate is due primarily to a senescent decline in the rate of growth plate chondrocyte proliferation[27, 28] referred to as "growth plate senescence" [29–31]. The proliferative capacity of the "stem-like" cells within the resting zone of the growth plate is finite. Thus, "senescence" is not a function of time per se, but of proliferative cycle number. Given this, it becomes apparent that interventions that slow the proliferation rate of growth plate chondrocytes, such as glucocorticoid exposure, will also slow the rate of growth plate senescence [30, 32]. That is to say, following transient growth inhibition, growth plates are "less senescent," retaining a greater proliferative capacity than expected for age. Thus, in the "post inhibitory period," the growth plate will show a greater growth rate than expected for age, resulting in "catch-up growth," the apparently "accelerated" linear growth that occurs after resolution of a growth-inhibiting condition [31, 33].

The pubertal growth spurt is primarily induced by estrogen, which acts to increase the activity of the GH/IGF-1 axis [34, 35]. In addition, the sex steroids, especially the androgens, appear to stimulate growth by a direct effect on growth plate chondrocytes [36–38]. Estrogen is also known to be the key hormone that promotes epiphyseal fusion [29].

Monitoring and Assessment of Growth

Standardized charts are available for graphically recording height, weight and height velocity such that an individual child's growth can be compared to normative values [39–41]. Wherever possible, reference data most appropriate to the child being monitored should be utilized. An individual child's growth measurement can be represented as a percentile or as a standard deviation score, a quantitative expression of distance from the reference population mean (50th percentile) for the same age and gender [42]. Healthy children grow steadily along the same height percentile and hence maintain the same standard deviation score for height from early childhood through until adulthood. Combined parental heights can be used to estimate a child's potential height [42]. Some temporary deviation from the usual growth channel may occur if the pubertal growth spurt occurs particularly early (temporary increase in height velocity and height centiles) or late (temporary decrease in height velocity and height centiles).

Definitions of Impaired Growth

Within a large patient group, skewing of standard deviation scores (SDS) for height below population reference values is evidence of disease-associated growth impairment. Mean height SDS of a population characterized by normal growth approximates zero. Growth disturbance in an individual child is indicated by an abnormal growth rate [42]. A definition in terms of static height measurement, although sometimes used, may be misleading, since it is so influenced by parental heights. An individual child may be normally short; conversely a previously tall child may Not have increased his height in two years, but still be of average stature. A shift from higher to lower centiles on a growth chart of height attained more sensibly signifies growth faltering. Height velocity, expressed either as a centile or as a standard devia-

tion score for age and gender, is the most sensitive parameter by which to recognize impaired growth. In the absence of historical linear growth information, the identification of linear growth impairment is challenging. In this scenario, referencing a patient's predicted or "target" height can be helpful. Target heights and their corresponding centiles/*Z*-scores can be calculated from an individual's parental heights using the mid-parental height formula [43]. Impaired growth can then be defined by the difference between current and target centiles. This definition would take into account an individual's genetically predetermined growth pattern as a predictor for current as well as ultimate adult stature.

Growth in Pediatric IBD

Prevalence of Growth Impairment in IBD

Inflammatory disease occurring during early adolescence is likely to have a major impact on nutritional status and growth because of the very rapid accumulation of lean body mass that normally occurs at this time. Further, boys are more vulnerable to disturbances in growth than girls because their growth spurt comes later and is ultimately longer and greater [4, 44].

Crohn Disease

Several studies have characterized the growth of children with Crohn disease (CD) as treated in the 1980s and into the 1990s [1, 45–50]. These studies are important as a benchmark of outcomes with traditional therapy. It is to be hoped that the now better understanding of the pathogenesis of growth impairment, together with the greater efficacy of current therapeutic regimens in healing intestinal inflammation, may lead to enhanced growth of young patients diagnosed now.

As summarized in Table 12.1, the estimated percentage of patients with Crohn disease, whose growth is affected, varies with the time of assessment, the definition of growth impairment and with the nature of the population under study (tertiary referral center versus population-based) [1, 45–55]. It has nevertheless been consistently observed that impairment of linear growth is common prior to recognition of Crohn disease as well as during the subsequent years, and that height at maturity has often been compromised [1, 45–54, 56, 57]. More recent data from the UK, Sweden, and USA suggest that the degree of deficit at maturity may be slowly reducing [57–59]. It is also apparent that these problems are, and remain, more frequent among males than females, independent of disease location or severity [1, 55, 56, 60–63]. The basis of this observed gender difference is yet to be fully elucidated. Interestingly, as the incidence of CD increases in geographic regions where it was previously rare, reports demonstrate that similar patterns of impaired growth are being observed [64, 65].

At the time of diagnosis mean standard deviation score (SDS) for height is reduced among children with Crohn disease as a group compared to reference populations (Table 12.2), an indication of the growth retardation occurring prior to recognition and treatment of intestinal inflammation [1, 46, 47, 50–52]. During the decade 1990–1999 in Toronto, mean SDS for height at time of diagnosis among 161 Tanner stage 1 or 2 children was −0.74 ± 1.2 [50], indicating overall lesser growth delay in comparison to the earlier decade [1]. Nevertheless, the percentage of children with height less than the fifth centile (SDS score <−1.8), based on Center for Disease Control 2000 data, was still 22% [50]. Mean SDS for height among 333 patients aged less than 16 years was −0.54 (95% CI -0.67 to −0.41) in a 1998–1999 population-based surveillance study of incident IBD in the United Kingdom [51]. Thirteen percent were below the third centile (SDS < −1.96) for height based on data from Child Growth Foundation, London [51]. In Israel, SDS for height at diagnosis among a cohort of 93 patients aged less than 18 years was −0.56 ± 1.16, but 20% had SDS score <−2.0 [52]. Taken together, these data confirm that growth delay prior to diagnosis remains a challenge [50–52]. Reassuringly, data from a more recent Canadian inception cohort of children diagnosed with Crohn disease between 2014 and 2017 demonstrated a more modest reduction in mean height *Z*-scores (−0.30 [95% CI: −0.39 to −0.20], with no significant differences noted across the age spectrum or gender [66]. The basis of these epidemiological differences in linear growth outcomes compared to earlier studies is unclear. While it may be possible that this is related to an underlying change in the relative proportions of specific disease phenotypes, it is more likely attributed to reduced diagnostic delay in the recent decade. Indeed, a single center study in Toronto of 111 children diagnosed with IBD found that diagnostic delay was longer among Crohn disease than ulcerative colitis (median 6.8 vs 2.4 months) and height impairment was independently associated with diagnostic delay (odds ratio 0.59 for height-for-age *Z*-score) with height impairment persisting 1 year after initial presentation [67]. This reaffirms the importance of a prompt diagnosis of IBD with regard to growth outcomes. Given the frequency of linear growth impairment in Crohn disease, growth failure was introduced as a key phenotypic component in the Paris modification for the Montreal disease classification system in pediatric Crohn disease in 2011 [68].

Delay in epiphyseal closure allows growth to continue longer than normal. Hence SDS for height may improve over the course of treatment, if chronic inflammation can be controlled [1, 47, 50]. Additionally, due to the delay of epiphyseal closure, improvement of linear growth may be protracted beyond the typical chronological age of linear growth cessation.

Table 12.1 Prevalence of linear growth impairment in pediatric Crohn disease. Varying definitions and times of assessment (at the time of diagnosis and during follow-up) are applied

Study details (ref)	Time of assessment	Patients studied	*n*	Definition of linear growth impairment	Percentage with growth impairment (%)
Baltimore, USA 1961 to 1985 [46]	At diagnosis	Prepubertal (Tanner I or II)	50	Decrease in height velocity prior to diagnosis	88
Toronto, Canada 1980 to 1988 [1]	During follow-up	Prepubertal (Tanner I or II)	100	Height velocity ≤2 SD for age for ≥2 years	49
Sweden 1983 to 1987 [47]	During follow-up	Population-based cohort <16 years at Dx	46	Height velocity ≤2 SD for age for 1 year	65
New York, USA 1979 to 1989 [48]	At maturity	Children in tertiary care	38	Failure to reach predicted adult height	37
Toronto, Canada 1990 to 1999 [50]	During follow-up	Prepubertal (Tanner I or II)	161	Height velocity ≤2 SD for age for ≥2 years	54
United Kingdom 1998 to 1999 [51]	At diagnosis	Population-based cohort <16 years at Dx	338	Height SDS < −1.96	13
Israel 1991 to 2003 [52]	At diagnosis	Children in tertiary care	93	Height SDS < −2.0	20
France 1988 to 2004 [55]	At diagnosis	Population-based cohort <17 years at Dx	261	Height SDS < −2.0	9.5

Table 12.2 Mean height standard deviation scores for height in children diagnosed with Crohn disease prior to or in early puberty (Tanner stage I or II)

Study (ref)	Patients studied	*n*	Mean height SDS (SD)	
			At diagnosis	At maturity
Baltimore, USA 1961 to 1985 [46]	Prepubertal (Tanner I or II)	50	−0.48	Not assessed
Toronto, Canada 1980 to 1988 [1]	Prepubertal (Tanner I or II)	100	−1.1 (1.3)	−0.82 (1.1)
Sweden 1983 to 1987 [47]	Population-based cohort <16 years at Dx	46	−0.5 (1.4)	−0.4 (1.1)
Toronto, Canada 1990 to 1999 [50]	Prepubertal (Tanner I or II)	161	−0.74 (1.2)	−0.70 (1.2)
United Kingdom 1998 to 1999 [51]	Population-based cohort <16 years at Dx	338	−0.54	Not assessed
Israel 1991 to 2003 [52]	Children in tertiary care	93	−0.56 (1.16)	Not assessed
Leiden, The Netherlands Reported in 2002 [54]	Children in tertiary care	64	Not reported	−0.9 (1.2)
London, UK 1996 to 2002 [53]	Prepubertal children in tertiary care	20	Not reported	−0.57 (0.3)
Finland 1987 to 2003 [56]	Population-based cohort <17 years at Dx	128	Not reported	Male: −0.56 Female: −0.24
Canada 2014 to 2017 [66]	Children in tertiary care at Dx	698	−0.30 (1.23)	–

Indeed, a large retrospective cohort study of 3007 pediatric IBD patients showed continued linear growth beyond the time of expected growth plate closure in the majority (80%) of the cohort, with median height gain greater in those with Crohn disease than with ulcerative colitis [69]. A separate subcohort of patients within the same study diagnosed with IBD *after* the expected age of growth plate closure also exhibited continued statural growth. While the authors acknowledge the lack of baseline bone age assessment as a study limitation, the findings do verify a high prevalence of delayed bone maturation among childhood IBD patients, especially those with Crohn disease [70]. As children with IBD do have the potential for catch-up growth beyond the expected point of bone maturity, linear growth should continue to be a therapeutic target even after the point of transition to adult care.

No population-based cohort studies have compared pre-illness height centiles with final adult stature in order to determine how often catch-up growth is complete. In spite of gains, past and current reports suggest that the mean adult height of patients with prepubertal onset of disease remains reduced compared to population reference data [1, 47, 50, 53, 54, 56–58]. Studies suggesting otherwise have included patients with post-pubertal onset of disease, and therefore not at risk for growth impairment [71]. There are in general few population-based studies of final adult stature in childhood IBD patients. Varying results between such studies, as alluded to above, could be explained by differing proportions of patients with pre-pubertal onset IBD. A recent large population-based Swedish study of final adult heights in childhood Crohn disease patients demonstrated a modest adjusted mean height difference of −1.3 cm (equivalent approximately to a *Z*-score of −0.2) compared to their matched healthy peers and a similar pattern of height difference was also significantly observed relative to their healthy siblings. Compared to their healthy peers, patients with prepubertal disease onset had a more marked adjusted mean difference in final adult height: −1.6 cm compared to −0.8 cm in those with disease onset during or after puberty [59]. Another population-based cross-sectional study examined the linear growth of 2372 Jewish Israeli adolescents with childhood-onset IBD. Although showing no overall difference in heights at late adolescence, subanalysis showed Crohn disease patients with onset of disease earlier than 14 years of age were significantly shorter (male: 172.7 cm vs 174.0 cm, female: 160.6 cm vs 162.0 cm) [72]. These results suggest that the effects of chronic inflammation on growth in the pre-pubertal phase may not be completely irreversible. Further studies are required to determine whether better access to newer therapeutic modalities in IBD would be able to ameliorate the deleterious effects on long-term growth outcomes in these patient subgroups.

Ulcerative Colitis

Cohort data are sparse in comparison to Crohn disease, but in general at diagnosis no significant reduction is observed in height-for-age standard deviation scores among young patients with ulcerative colitis compared to the reference population [47, 49, 51]. As an example, SDS for height was not reduced (mean −0.12, 95%CI −0.30 to 0.05) in 143 children and adolescents with incident UC in the British pediatric surveillance study [51]. A Canadian inception cohort of 392 children with UC/IBD-U diagnosed between 2014 and 2017 similarly described heights measured as comparable to age- and gender-matched standard populations (mean height

Z-score 0.11 [95% CI −0.01 to +0.22]) [66]. As such, linear growth impairment in UC at diagnosis is considered a rare presenting feature (<5%) and should prompt consideration of an alternative diagnostic label [73, 74]. Growth delay thus does not feature as a key phenotypic component in the Paris modification of the Montreal disease classification system for UC unlike CD [68].

In follow-up, growth impairment remains a less frequent complication, although relatively few studies have carefully described linear growth in ulcerative colitis as compared to the abundance of studies in Crohn disease. Hildebrand et al. observed that 11 (24%) of 45 children had a height velocity <−2.0 SD during at least one year [47]. Final attained mean height was comparable to reference population data in this study [47]. In a recent large population-based study of 4201 childhood IBD patients in Sweden, there was a modest reduction in the adjusted mean height difference (AMHD) among UC patients (−0.6 cm) relative to their matched reference peers, although there was a stronger association with lower adult mean height in CD patients (AMHD: −1.3 cm) [59]. This is the first population-based study to demonstrate childhood UC patients attaining a slightly shorter final adult height, a finding which the authors attribute to the much larger number of patients compared to earlier studies. However, drug prescription data could only be retrieved from 2005 and thus steroid exposure status could be determined in less than one-third of the UC patients. Hence it is not certain to what extent steroid dependence could have contributed to the slight growth deficit witnessed in the Swedish UC subgroup. Gupta and colleagues similarly noted in a cohort study of 3007 patients from the ImproveCareNow database registry, a surprisingly high proportion of UC patients (75%) having continued statural growth beyond the expected age of growth plate closure [69]. This suggests that delayed bone maturation could also be a prevalent problem in UC, although it is also not certain whether iatrogenic steroid exposure was the main etiologic factor rather than the disease phenotype itself.

Interestingly, Ricciuto and colleagues observed in a retrospective study of 74 children with primary sclerosing cholangitis (PSC) and colonic-type IBD (UC or IBD-unclassified) that these patients had significantly lower height-for-age and weight-for-age *Z*-scores at presentation compared to matched UC/IBD-U controls. The male gender was associated with higher height-for-age Z scores over time, contrary to the male predilection for poorer growth outcomes in CD [75]. These findings suggest a unique disease phenotype in PSC-IBD distinct from non-PSC UC/IBD-U and correspondingly differing influences on growth outcomes. A plausible mechanistic explanation could be a hepatic-related impairment of the GH/IGF-1 axis, which has been described in other forms of chronic liver disease such as non-alcoholic fatty liver disease and liver cirrhosis [76].

Why linear growth impairment is less common in ulcerative colitis than in Crohn disease is not entirely clear. Certainly, the interval between symptom onset and diagnosis correlates with the degree of growth impairment [51, 58, 77]. The usual colitis symptom of bloody diarrhea in ulcerative colitis is more promptly investigated than the often subtle presenting symptoms of Crohn disease, particularly the non-specific abdominal pain and anorexia associated with small bowel Crohn Disease, and the resulting difference in time to presentation may account at least in part for the lesser effect on growth prior to diagnosis. Underlying disease-related differences in cytokine production are likely also important. Notably, pubertal delay can contribute to growth impairment, and Crohn disease is more frequently associated with delayed puberty [44, 78, 79].

Sex Differences in Linear Growth Impairment

As mentioned, growth impairment is both more frequent and more severe in boys compared to girls with Crohn disease [1, 63]. These differences persist post diagnosis [56]. Gupta and colleagues found in a large retrospective cohort study of 3007 childhood IBD patients that continued linear growth beyond predefined chronological ages of expected growth plate closure occurred in 79% of male CD patients versus 83% of female CD patients ($p = 0.012$). The median final adult height was greater in males with UC than CD but did not statistically differ in females with UC compared to females with CD [69].This further supports the current body of evidence that male CD patients continue to have worse linear growth outcomes than female patients with CD .

Pathophysiology of Growth Impairment in IBD

As summarized in Table 12.3, several interrelated factors contribute to linear growth impairment in children with IBD. The fundamental mechanisms have recently been comprehensively reviewed [80].

Table 12.3 Factors contributing to growth impairment in children with Crohn disease

Factor	Explanation
Pro-inflammatory cytokines	Direct interference with IGF-1 mediation of linear growth
Decreased food intake	Cytokine-mediated anorexia, fear of worsening gastrointestinal symptoms
Stool losses	Mucosal damage leading to protein-losing enteropathy; diffuse small intestinal disease or resection leading to steatorrhea
Increased nutritional needs	Fever; required catch-up growth
Corticosteroid treatment	Interference with growth hormone and insulin-like growth factor-1

Chronic Caloric Insufficiency

Growth requires energy. Chronic undernutrition has long been implicated and remains an important and remediable cause of growth retardation [81]. Multiple factors contribute to malnutrition [82]. However, reduced intake, rather than excessive loss or increased need, is generally the major cause of the caloric insufficiency [83, 84]. Kirschner et al. reported caloric intakes of growth-impaired patients to average 54% of that recommended for children of similar height age [85]. Food restriction may be deliberate to avoid symptoms. More importantly, cytokine-mediated disease-related anorexia may be profound. Work in a rat model of colitis suggests that tumor necrosis factor alpha (TNFα) and interleukin-1 interact with hypothalamic appetite pathways via serotonin receptors [86, 87]. Human studies have demonstrated an association between inflammatory cytokines and alterations in gut hormones related to appetite such as ghrelin [88] and polypeptide YY [89]. While clinical studies have demonstrated that significant intestinal fat malabsorption is uncommon [90], leakage of protein is frequent [91]. However, neither have been shown to be common causes of undernutrition in Crohn disease. In general, resting energy expenditure (REE) does not differ from normal in patients with inactive disease, but can exceed predicted rates in the presence of fever and sepsis [92].Moreover, malnourished adolescents with CD fail to reduce their REE as efficiently as comparably malnourished patients with anorexia nervosa [92]. Reduction in REE is a normal biologic response to conserve energy. This relative failure of a compensatory mechanism has, again, been attributed to the effects of pro-inflammatory cytokines.

Direct Cytokine Effects

A simple nutritional hypothesis, where adequate caloric delivery would remediate any growth impairment, fails to explain all the observations related to growth patterns among children with IBD. To date, a variety of cytokines have been implicated in the pathogenesis of IBD including tumor necrosis factor-alpha (TNF-alpha), interferon-gamma (IFN-gamma), and multiple interleukins (including IL-6, IL-12, IL-17, and IL-23). The direct growth-inhibiting effects of pro-inflammatory cytokines released from the inflamed intestine have been increasingly recognized [93–96].

Disruption of the GH/IGF-1 Axis

As described above, IGF-1, produced by the liver in response to GH stimulation, is the key mediator of GH effects at the growth plate of bones. An association between impaired growth in children with Crohn disease and low IGF-1 levels is well recognized [97]. However, GH production in this setting has been shown to be normal [98]. The molecular mechanisms by which cytokines induce this state of "GH resistance" have not yet been completely elucidated. Conceptually, they could involve downregulation of the GH receptor (GHR), upregulation of post-receptor inhibitory proteins, reduced protein synthesis, and/or increased protein degradation. Information from both animal models and/or human studies supports each of these potential mechanisms [15, 16, 93, 95, 99–112] (Fig. 12.3).

IGF-1 Independent Mechanisms

Inflammatory cytokines inhibit linear growth through pathways other than IGF-1 production [113–116]. Animal experiments have shown that TNF-α and interleukin-1 (IL-1) increase chondrocyte death, and thus may have a deleterious effect on growth [95]. In an organ culture model of fetal rat parietal bone, marked impairment in osteoblast function and bone growth was observed with the addition of serum from children with CD, but not from children with ulcerative colitis, nor from healthy controls [96]. Finally, cytokines appear to impair end-organ responsiveness to circulating testosterone, thereby compounding the effects of under-nutrition in delaying progression through puberty [107].

The Role of IL-6 in Growth Impairment

As with a number of chronic inflammatory conditions, IL-6 is known to be elevated in the serum of pediatric patients with active CD, and predictive of clinical relapse [117]. IL-6 activates STAT3 via the glycoprotein 130 signaling receptor (gp130); a process that is negatively regulated by SOCS-3 [118–120]. SOCS-3 is also a negative regulator of GH signaling. Very recently, it was confirmed that IL-6:STAT3 activation correlates with mucosal inflammation in active pediatric-onset CD [121, 122].

Transgenic mice with defective growth have been found to overexpress interleukin-6 (IL-6). Antibody to IL-6 partially corrected the growth defect, whereas administration of IL-6 led to a decrease in IGF-1 before food intake was affected [93]. Similar to CD, children with juvenile idiopathic arthritis (JIA) also present with linear growth failure [123, 124]. Of note, IGF-1 levels are negatively correlated with IL-6 among this patient group [93]. The exact mechanism underpinning this observation, however, is not completely clear. While these, and other data [125] suggest an IL-6-mediated decrease in IGF-1 *production* [93]; work by DeBenedetti et al. suggests that the primary mechanism is a reduction in IGFBP-3 levels due to reduced production and/or increased proteolysis of this binding protein [106]. Previously, low levels of IGFBP-3 have been associated with accelerated clearance, and hence low levels, of IGF-1 [106].

Studies in both of these pediatric patient groups have demonstrated a significant "uncoupling" of osteoblast and osteoclast activities [108, 126–128]. Concurrent mouse and human studies have shown that chronic IL-6 exposure promotes osteoclast maturation and activation, affects osteoblasts, is associated with osteoclast/osteoblast uncoupling

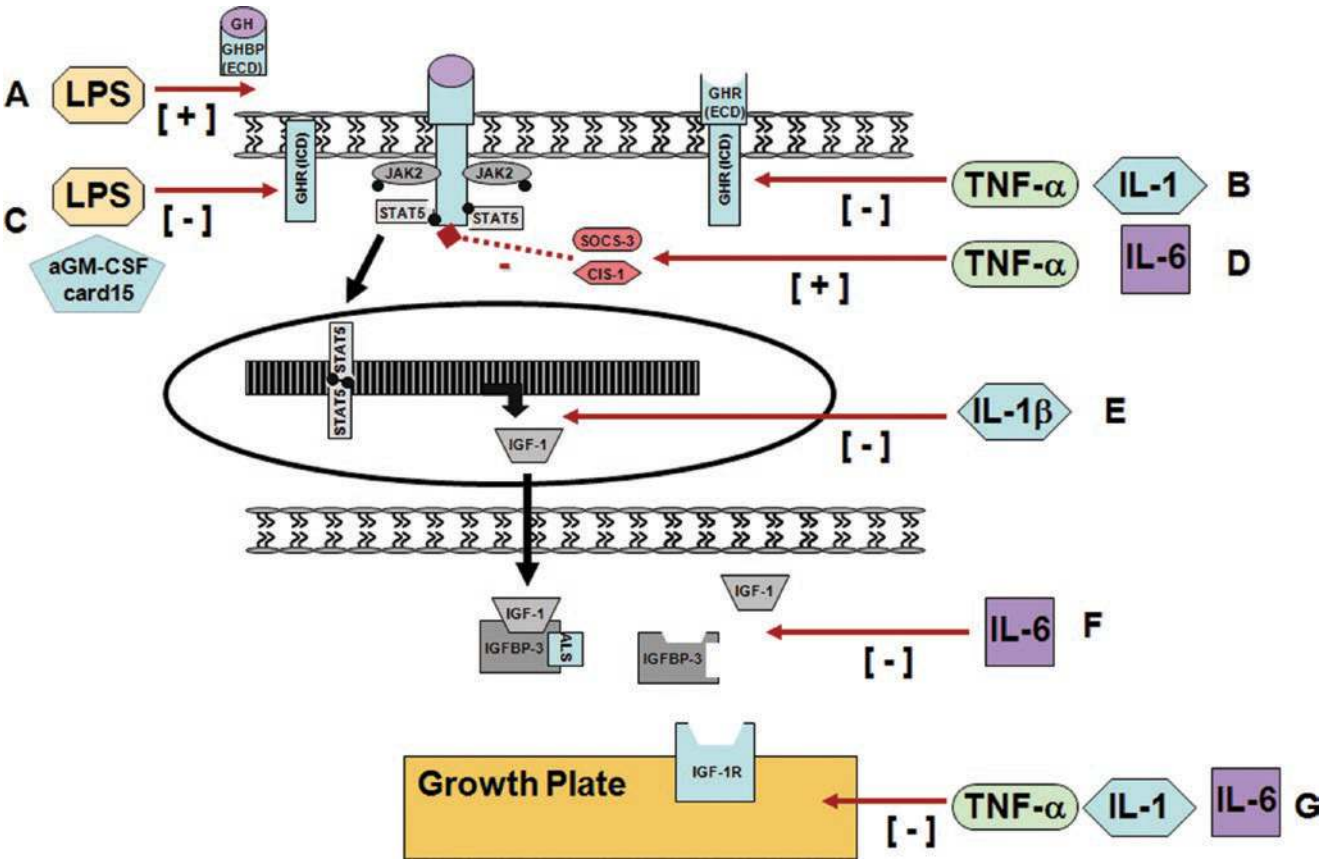

Fig. 12.3 Confirmed and potential molecular mechanisms that underpin the development of GH resistance in Crohn Disease: *At the Growth Hormone Receptor*: (**a**) Endotoxin exposure, specifically Lipopolysaccharide (LPS), reduces GHR density by inducing GHR proteolysis and increasing the shedding of GHBP [99] (mechanism not yet ascertained). (**b**) TNF alpha has been demonstrated to downregulate GHR formation via inhibition of Sp1/Sp3's ability to transactivate the GHR gene [100]. Il-1 suppresses GHR promoter activity [100]. (**c**) LPS can directly inhibit GHR gene expression via a cytokine-independent mechanism through the TLR-4/MD2 signaling pathway that results in a cytokine response, significant reduction in GHR promoter activity. Importantly, the addition of anti-TNF-alpha antibody failed to abrogate this effect [101]. Innate immune pathways associated with granulocyte-macrophage colony stimulating factor autoantibodies and card15 deficiency can also reduce GHR expression [112]. *Via post-receptor inhibitory proteins*: (**d**) IL-6 and TNF-alpha can upregulate the expression of SOCS-3 and cytokine-inducible SH2-containing protein (CIS)1 [15, 102]. Both of these proteins have, in turn, been shown to inhibit GH signaling by blocking the phosphorylation of STAT5 [16, 103, 104]. *Via reduced protein synthesis*: (**e**) IL-1β has been shown to reduce IGF-1 mRNA levels. The mechanism is yet to be elucidated, but does not appear to be via upregulation of SOCS nor by impairment of JAK2/STAT5 signaling [105]. *Via increased protein clearance*: (**f**) IL-6 has been implicated in a reduction in IGFBP-3 levels due to either reduced production and/or increased proteolysis [106]. Previously, low levels of IGFBP-3 have been associated with accelerated clearance, and hence lower levels, of IGF-1 [106]. *Via IGF-1 independent mechanisms*: (**g**) Animal experiments have shown that TNF-α and interleukin-1 (IL-1) increase chondrocyte death and thus may have a deleterious effect on growth [95]. Cytokines appear to impair end-organ responsiveness to circulating testosterone [107]. IL-6 exposure promotes osteoclast maturation and activation, affects osteoblasts, is associated with osteoclast/osteoblast uncoupling and results in thinning of the growth plate [93, 108–111]. Although the mechanism is yet to be determined, laboratory evidence suggests that it is independent of IGF-1 [108]

and results in thinning of the growth plate [93, 108–111]. Again, while the mechanism is yet to be determined, laboratory evidence suggests that it is independent of IGF-1 [108].

Taken together, these data suggest that increased IL-6 may represent a major generalized mechanism by which chronic inflammation affects the developing skeleton. This would imply that anti-IL6 therapeutic approaches, which have shown promising anti-inflammatory efficacy in CD, rheumatoid arthritis, and systemic JIA [129–132], may also specifically address the problem of growth impairment. Notably, in a rat model with TNBS-induced colitis and poor growth, treatment with an anti-IL6 antibody enhanced IGF-1 expression and growth without reducing intestinal inflammation [125].

The Interplay Between Nutrition And Cytokines

Thus, inflammation may have a direct effect on linear growth, via the mechanisms described above, as well as an indirect effect via its effect on the appetite centers of the brain and subsequent reduction in caloric intake. The relative contribu-

tions of malnutrition and inflammation to linear growth delay were explored by Ballinger et al. using a rat model of TNBS colitis [94]. Two control groups were used: healthy controls with free access to food, and a pair-fed group comprised of healthy animals with daily food intake restricted to match that of colitic rats [94]. In the colitic rats, IGF-1 levels were reduced to 35% of control values. Comparison with the healthy but undernourished pair-fed rats suggested that malnutrition accounted for 53% of the total depression of IGF-1 in colitic rats, with the remaining 47% directly attributable to inflammation [94].

Disruption of the GH/IGF-1 Axis by Cytokine-Independent Molecular Pathways

Impaired intestinal barrier function is a recognized feature in some patients with CD, and may predispose them to chronic, subclinical, endotoxin exposure, specifically lipopolysaccharide (LPS)[133]. Various groups are currently investigating whether LPS directly interferes with the GH/IGF-1 axis via cytokine-independent mechanisms. To date, in-vivo data from a mouse model have demonstrated that LPS exposure reduces GHR density by inducing GHR proteolysis, probably via the metalloprotease cleavage site, resulting in the increased shedding of GHBP [99]. More recent in-vitro data demonstrate that LPS can directly inhibit GHR promoter activity and subsequent expression through an effect on the TLR-4 signaling pathway[101]. Both mechanisms are seemingly independent of the inflammatory cytokine cascade and the addition of anti-TNF-alpha antibody failed to abrogate the effect [101]. Although intriguing, the clinical significance of these findings and their relative importance in the setting of growth impairment and CD are yet to be determined.

Interaction Between the Gut Microbiome and the GH/IGF-1 Axis

The interaction between the gut microbiome in inflammatory bowel disease, the GH/IGF-1 axis, and bone health could account for another mechanistic explanation for linear growth impairment in IBD. The anti-inflammatory properties of microbial metabolites, short-chain fatty acids (SCFAs), are of particular interest as potential therapeutic targets. Gut microbial dysbiosis with the reduction of SCFA-producing bacteria and consequently reduction in key SCFA concentrations such as butyrate, have been postulated mechanisms in the pathogenesis of inflammatory bowel diseases [113, 114]. There has been emerging research on the influence of the gut microbiome and the role of short chain fatty acids, on bone metabolism. Jing and colleagues report the induction of IGF-1 through colonization of germ-free mice with pathogen-free gut microbiota resulting in an increase in longitudinal and radial bone growth. Antibiotic treatment reduced IGF-1 production and bone formation in a mouse model, and SCFA supplementation of these antibiotic-treated mice restored IGF-1 levels and bone mass [115, 116]. Modulation of the gut microbiome could form the basis of future therapeutic targets for improving bone health and linear growth in IBD.

Corticosteroid Suppression of Linear Growth

The growth suppressive effects of glucocorticoids are multifactorial, and can occur at virtually any point along the growth axis (Table 12.4) [134]. In general, exogenous corticosteroids are considered to create a state of functional GH deficiency [78]. Dose, preparation, and timing of glucocorticoids all influence the degree of growth suppression observed. It appears that concentrations of glucocorticoids required to exert direct suppression on the growth plate may be lower than those required to suppress GH secretion. Growth, particularly in prepubertal children, can be impaired by relatively modest daily doses of prednisone (3–5 mg/m^2) [134]. This effect may be reduced, but is not necessarily eliminated, by alternate-day therapy. Selectively eliminating evening administration may avoid blunting of both nocturnal

Table 12.4 The effects of exogenous glucocorticoid therapy related to linear growth [134]

GH/IGF-1 axis
Inhibit endogenous GH secretion
Reduce pulsatile release of GH Increase somatostatin
Interference with the GHR
Reduce GHR expression Reduce GHR binding Uncouple GHR from signal transduction components
Reduce IGF-1 activity levels
Reduced activation of STAT5b Increased levels of IGFBP-3
Skeletal system
Growth plate
Inhibit chondrocyte mitosis Inhibit IGF-1 induced chondrocyte proliferation Inhibit epiphyseal maturation

GH secretion and/or ACTH induced adrenal androgen production [134]. Catch-up growth, following the cessation of glucocorticoid therapy, does not always fully compensate for growth deficits, particularly when treatment occurs during puberty. Although chronic daily dosing and frequent induction courses of steroids have been shown to lead to bone demineralization, at present, there is *not* good evidence that short-term use of steroids for the induction of remission in CD is detrimental to long-term growth.

The Pathogenesis of Pubertal Delay and Its Influence on Growth Impairment

Puberty is frequently delayed in young patients with CD [78]. It not only results in linear growth impairment, but also decreases bone mineralization and can significantly impact a patient's quality of life and psychological health [79]. In girls with Crohn disease, a delay in menarche is closely related to delays in skeletal maturity [135]. Pubertal delay is defined as the absence of testicular enlargement in boys or breast development in girls at an age that is 2–2.5 standard deviations later than the population mean [5]. Traditionally, the mean age has been 14 years in boys and 13 years in girls; however, with recent downward trends in pubertal timing in many countries, some observers are advocating for younger age cut-offs [5, 136, 137].

As alluded to earlier, the factors that trigger normal pubertal onset remain elusive [5], thus impeding our comprehension and complete understanding of the mechanisms that underlie pubertal delay in CD. Similar to linear growth impairment, although undernutrition has been frequently considered the main reason for delayed puberty in children with CD, there is a group of patients with persistently active disease who do not enter puberty despite the provision of adequate energy [138]. Experimental colitis models demonstrate that inflammatory mediators potentiate the puberty-delaying effects of undernutrition [78, 139–141] via alterations in gonadotropin-releasing hormone (GnRH) secretion patterns, although which specific inflammatory cytokines impact on puberty are yet to be determined. However, both human and experimental data suggest that there is also an element of gonadotropin resistance in pubertal delay, and in vitro studies implicate TNF-alpha in the downregulation of androgen gene expression [142]. Although Cushing's disease has been associated with pubertal delay [143, 144], it is not known whether the doses of corticosteroid used in the management of CD are sufficient to delay either the onset or progression of puberty [78].

Influence of Genetic Factors

A number of genetic polymorphisms have been implicated in CD susceptibility and pathogenesis, the most prominent of which are within the NOD2 gene. While some investigators [145, 146] have suggested that CD-associated NOD2 polymorphisms may be determinants of growth impairment, neither analysis controlled for disease location. A subsequent careful analysis of growth prior to and following diagnosis found no such association [52]. Scottish pediatric data suggest an association between polymorphisms in the IBD5 susceptibility locus and low anthropometric centiles at diagnosis [147]. Similarly, data from Boston examining 14 different CD susceptibility genes highlight a potential association with the CD susceptibility allele within ATG16L1 [148].

It is feasible that common genetic polymorphisms which alter cytokine expression may contribute to growth impairment but not influence overall susceptibility to CD. A recent study of Israeli patients suggests that relatively common variations in the promoter region for TNFα may have an independent effect on linear growth outcomes [149]. Similarly, data from Sawczenko et al. demonstrate a potential causal relationship between variation in the promoter region for Il-6, subsequent IL-6 expression, and a differential in linear growth impairment during active inflammation [125]. Confirmation of these and similar findings is awaited and may help better elucidate the complex molecular interactions pertinent to the pathophysiology of growth impairment.

Facilitation of Normal Growth in IBD

The Importance of Prompt Recognition of IBD

The clinical presentation of childhood Crohn disease may be subtle and varied. Impairment of linear growth and concomitant delay in sexual maturation may precede the development of intestinal symptoms and dominate the presentation. Prompt diagnosis is important in avoiding a long period of growth retardation. The greater the height deficit at diagnosis, the greater is the demand for catch-up growth.

The Importance of Monitoring Growth

In caring for children with IBD, it is important to obtain pre-illness and parental heights [57], so that the impact of the chronic intestinal inflammation can be fully appreciated. Following diagnosis and institution of treatment, regular measurement and charting of height, together with calculation of height velocity, are central to management. A properly calibrated wall-mounted stadiometer is required for accurate and reproducible serial measurements.

Part of the assessment of response to therapy in children with IBD is a regular analysis of whether rate of growth is normal for age and pubertal stage and whether catch-up growth to pre-illness centiles is being achieved. Height velocity should be appraised in the context of current puber-

tal stage, because of the variation in normal rates of growth before puberty, during puberty and near the end of puberty. If growth and puberty appear either delayed or very advanced, radiologic determination of bone age can be used to indicate the remaining growth potential. Delayed radiological bone age suggests greater potential for catch-up growth than may be anticipated for the subject's chronologic age. Conversely, in the subject with growth failure and a normal bone age, the potential window to achieve any growth catch-up may be very small.

One of the difficulties in evaluating growth in response to a therapy is the relatively long interval of time required for valid assessment. Published normal standards for height velocity throughout childhood are based on height increments during 12-month periods [150]. When growth velocity is calculated over short time periods, small errors in individual measurements are significantly magnified, and the normal seasonal variation in growth is overlooked. The consensus from pediatric endocrinologists is that height velocity should be calculated over intervals no shorter than six months [150]. On a research basis, efforts to reflect growth changes over intervals shorter than six months have focused on measuring changes in lower leg length by knemometry and on determination of circulating levels of markers of bone and collagen metabolism [150–152]. The clinical utility of routine serial assessment of the GH/IGF-1 axis is yet to be ascertained [153]. A valid indicator of contemporaneous linear growth would allow for a more timely change in therapy. A summary of techniques that should be employed to clinically assess and monitor linear growth through to adulthood, based on Heuschkel and colleagues management guideline, are presented in Table 12.5 [154].

Table 12.5 Techniques to assess and monitor linear growth in children with CD

Initial evaluation
Accurate measurement of the patient's height and weight by trained staff using reliable equipment
Accurate pubertal assessment
Accurate measurement of the biological parents' heights and calculation of mid-parental height (MPH) *Formula to estimate a subject's potential adult height* Male: MPH plus 6.5 cm; Female: MPH minus 6.5 cm
Obtain pre-illness anthropologic (height, weight) data on the patient
Radiological bone age estimation
Dietetic assessment of caloric, Ca, Vitamin D, and micronutrient intake
Ongoing monitoring
Accurate height and weight measurements by trained staff using reliable equipment
Calculate height velocity
Calculate *Z*-score for height, weight and height velocity data and/or plot sequentially on gender specific, ethnically appropriate reference curve
Accurate pubertal assessment
Consider repeat bone age estimation
Endeavour to follow until adult height achieved (Tanner stage 5 and <0.5 cm linear growth annually)

Psychosocial Impact of Impaired Growth

Growth impairment and accompanying pubertal delay have a significant psychosocial impact on adolescents, as the physical differences between them and healthy peers become progressively more obvious. In the development process of a disease-specific health-related quality of life instrument for pediatric IBD, body image issues including height and weight were among the concerns most frequently cited by adolescents with Crohn disease [155].

General Principles of Management

Prior to recognition of the direct influences of pro-inflammatory cytokines on linear growth, management of growth-impaired children focused on nutritional restitution [81, 85]. Improved growth following supplementary enteral or parenteral nutrition is well documented [156–158]. Decreases in inflammatory parameters and increases in IGF-1 occur very early during exclusive enteral nutrition and precede changes in nutritional parameters [159], highlighting that nutrition and inflammation constitute a bidirectional pathway [160]. Nevertheless, a subset of patients fail to grow despite nutritional repletion, presumably because intestinal inflammation remains chronically active. Hence, in the management or prevention of growth impairment, attention needs to focus on providing adequate nutritional support, as well as treating inflammatory disease using the most appropriate pharmacologic, nutritional, or surgical intervention available [154, 161] (Table 12.6). A comprehensive management guideline is available for children with IBD-related growth failure [154].

Anti-Inflammatory Treatments and Effects on Growth

Few interventions have been tested in the randomized controlled trial setting in children, and hence the effects of therapies on growth have seldom been rigorously assessed. The one exception is enteral nutrition as primary therapy of pediatric Crohn disease. For most other therapies, until recently, growth outcomes have been reported only in observational/retrospective studies. However, given the importance of persistent inflammation in the pathogenesis of growth impairment, it is intuitive that therapies which achieve mucosal healing are more likely to facilitate normal

Table 12.6 Strategies for managing growth failure in children with CD

Initial evaluation
Detailed assessment of disease activity and distribution
Ensure optimal nutrition (supplement energy and/or substrates as required)
Induction of remission
Aim for the rapid induction of a complete remission
Endeavor to avoid/minimize steroid usage (enteral therapy)
Consider surgical resection, especially in cases of limited localized ileal/ileocecal disease
Use biological therapies when other medical options have failed and surgery is not appropriate
Monitor closely and ensure remission is achieved in a timely fashion
Maintenance of remission
Aim for a prolonged, ongoing continuous remission
Consider the early introduction of immunomodulator therapy
Ensure optimal nutrition (supplement energy and/or substrates as required)
Monitor closely to ensure the persistence of remission and the timely re-induction of remission in the event of disease relapse
Persistent growth failure in the setting of clinically quiescent CD
Ensure optimal nutrition (supplement energy and/or substrates as required)
Detailed re-assessment of disease activity and distribution
Consider alternative causes of poor growth (including endocrinological and psychosocial)

growth. When assessing the available evidence of any treatment's impact on linear growth, two important questions need to be considered: were the population of patients being studied growth impaired prior to commencing therapy (recognizing that linear growth impairment is not a universal feature of all young patients with active CD); did the population being studied still have enough remaining "growth potential" for any therapeutic impact to be measurable. Below, treatments of pediatric IBD will be briefly discussed with respect to their potential effects on growth. A detailed Cochrane review by Newby and colleagues is available [162] for reference.

Enteral Nutrition

Prior to the availability of biologic therapies, acute treatment options for moderately to severely active Crohn disease were limited. "Exclusive enteral nutrition" (EEN) refers to the administration of formulated food as sole source nutrition. It has been shown to decrease mucosal cytokine production and induce endoscopic healing [163] . The appeal of EEN among pediatric patients primarily relates to avoidance of steroid therapy [161]. Amino acid-based and peptide-based formulae are administered by nocturnal nasogastric infusion, but more palatable polymeric formulae can be consumed orally, and appear comparably efficacious [164]. Some have argued that active Crohn disease occurring in children is more responsive than that occurring in adults, where corticosteroid therapy more often induces clinical remission [165, 166]. It seems likely, however, that other factors, such as small bowel localization and recent onset of Crohn disease, rather than young age per se, influence responsiveness of intestinal inflammation to exclusive enteral nutrition [167, 168]. Nevertheless, enteral nutrition does seem to be more feasible in pediatric patients. Children quickly become adept at swallowing the silastic catheter required for nasogastric feeding regimens and can remove it each morning before school.

If enteral nutrition is to facilitate growth, remission must be maintained. One of the limitations of liquid diet therapy has been the observed tendency for symptoms to recur promptly following its cessation [169]. Chronic intermittent bowel rest with nocturnal infusion of an elemental diet one month out of four has been reported as a means of sustaining remission and facilitating growth [157]. Another nutritional strategy, continuation of nocturnal nasogastric feeding four to five times weekly as supplement to an unrestricted ad lib daytime diet was also associated with prolonged disease quiescence and improved growth in a historical cohort study [158]. Maintenance EEN, however, is not always well tolerated by patients.

A recent multicenter Canadian inception cohort study of 377 pediatric CD patients from the CIDsCaNN[1] registry network compared long-term growth outcomes at 18 months post-diagnosis between patients receiving EEN induction versus those receiving corticosteroid(CS) induction stratified by baseline linear growth status [170]. Notably, within the subgroup of patients with no evidence of growth impairment at diagnosis (73% of the cohort), there was no detectable change in growth pattern by 18 months regardless of therapy group. In the smaller subgroup with baseline growth impairment (27%), while both treatment arms showed evidence of improved linear growth, the degree of improvement at 18 months was significantly greater in the EEN group compared to the CS group. Consistent with this finding, a propensity matched analysis of 111 patients in a single Canadian center similarly showed that while EEN-treated patients had a significantly greater linear growth recovery than CS patients at the 1-year follow-up (Δ Height *Z*-score 0.09 vs −0.14), this effect was not sustained over the 6-year follow-up period of the study [171]. These results suggest an initial advantage of EEN over CS in facilitating early catch-up growth in a selected subset of CD patients with baseline growth impairment. The apparent absence of any longer term linear growth advantage based on initial therapy choice is likely explained by current ongoing treatment paradigms that discourage recurrent steroid use and favor the early introduction of effective steroid-sparing therapies such as anti-TNF agents [170].

[1]CIDsCaNN: Canadian Children Inflammatory Bowel Disease Network

Corticosteroids

Conventional corticosteroids are still the most commonly used drug to treat acute disease exacerbations of pediatric Crohn disease and ulcerative colitis. Resolution of inflammation, if sustained following a short course of steroids, will be associated with normal linear growth. Chronic daily administration of corticosteroids to control intestinal inflammation is clearly contraindicated in pediatric IBD because of the interference with linear growth in addition to the other unwanted long-term adverse effects common to children and adults. Children with moderate symptoms of active Crohn disease localized to the ileum and/or right colon may respond to short-term treatment with controlled ileal release budesonide. Cosmetic effects of steroids are spared in this context, even if efficacy is overall less than with conventional corticosteroids[172, 173]. Studies in adults demonstrate little benefit in comparison to placebo in maintaining remission. Limited clinical experience with maintenance budesonide in children raised concern that linear growth was impaired during therapy in spite of good weight gain [174].

Immunomodulatory Drugs

The steroid-sparing roles of immunomodulatory drugs, azathioprine, 6-mercaptopurine, and methotrexate, are well documented [175, 176]. In a multi-center trial, newly diagnosed children with moderately severe Crohn disease treated with an initial course of prednisone were randomized to receive either concomitant 6-mercaptopurine or placebo [175]. A beneficial effect on linear growth was not clearly apparent in this study in spite of the steroid-sparing effect and improved control of intestinal inflammation, perhaps a function of sample size and difficulties inherent in comparing growth rates among patients of varying ages and pubertal stages [150]. Retrospective data have shown enhancement of linear growth, when methotrexate was given to young CD patients intolerant of or refractory to thiopurine therapy [176], a finding replicated in a recent prospective observational cohort [177].

Anti-Tumor Necrosis Factor-Alpha (Anti-TNFα)

The development of anti-cytokine therapies, such as infliximab and adalimumab, with the potential to achieve mucosal healing, even in otherwise treatment refractory patients constitutes a tremendous advance. The efficacy of anti-TNF agents in pediatric as well as adult patients is well established [178]. Considering the role cytokines, including TNFα, play in growth impairment, and the ability of anti-TNFα antibodies to achieve mucosal healing, it is of little surprise that both observational [177, 179–188] and clinical trial [189–191] data demonstrate a beneficial effect on linear growth, if treatment is undertaken early enough prior to or during puberty in children demonstrating evidence of linear growth impairment. Data from a clinical trial of adalimumab in pediatric Crohn Disease patients demonstrated a significant and rapid improvement in median height velocity *Z*-scores among those with baseline growth retardation (baseline −3.25 to −0.34) by week 26 and normalization (0.21) by week 52, but no such effect was seen in patients without growth delay [192]. Complementary data have demonstrated a restoration of hepatic GH signaling and improved anabolic metabolism in the setting of TNFα blockade [193]. Furthermore, and consistent with our evolving mechanistic understanding of IBD-related growth impairment, improvement in height velocity with the use of TNFα therapy has been correlated with increases in IGF-1 and IGFBP-3 levels with no accompanying change in serum GH levels [194]. These observations are cause for optimism that the medical therapy for Crohn disease available in the present decade will reduce the prevalence of sustained growth impairment in pediatric patients. As alluded to earlier in the chapter, the deleterious effects of uncontrolled chronic inflammation on growth during or prior to puberty may be partially irreversible, thus a "top-down" approach with anti-TNF therapy as primary induction should be strongly considered in patients who already present with severe growth retardation at diagnosis [195].

Surgery

Optimal management of young patients with IBD includes appropriate and timely referral for intestinal resection. Sustained steroid-dependency and associated impairment of linear growth should not be tolerated in children with ulcerative colitis, where colectomy cures the disease and restores growth [196]. For some children with Crohn disease, notably those with localized internal penetrating or stricturing disease, timely surgical intervention is a very attractive therapeutic option. Despite the almost inevitable endoscopic and subsequent clinical recurrence of CD, the significant period of post-operative remission that can be anticipated in many patients allows important catch-up growth in patients undergoing operation prior to or during early puberty [197–199].

Hormonal Interventions

The potential therapeutic role of GH and IGF-1 in pediatric IBD patients with persistent growth impairment is an alluring prospect. There have been increasing pediatric data exploring this over the last several decades [200–203] culminating in three small randomized trials [204–206]. These data have been recently reviewed by Vortia and colleagues [207]. The rationale for pursuing GH therapy (GHT) in growth impaired IBD patients is strengthened by the improved growth that has been recently observed following GHT in children with juvenile idiopathic arthritis [208] and cystic fibrosis [209] To date, while demonstrating that GHT

can improve short-term linear growth in select CD patients, it should be emphasized that there are no data yet available to suggest that GHT will alter the final adult height of children with IBD associated growth disturbance. There is a small experience with the supplemental use of GH during ongoing steroid therapy in a number of pediatric conditions [107] including steroid-dependent CD [210], again without evidence that final adult height is impacted.

Beyond its "anti-glucocorticoid" effects, it is possible that GHT has a direct anti-inflammatory effect in IBD. A randomized controlled clinical trial by Slonim in 2000 demonstrated a possible positive effect of GHT on disease activity in adults with Crohn disease [211]. Recent experimental data support this finding; wherein GHT was demonstrated to reduce mucosal inflammation in an experimental colitis via an IGF-1-independent mechanism that downregulated IL-6/STAT3 [212] but did not reverse local inflammatory resistance to the GH up-regulation of IGF-1 [212]. However, clinical data in pediatrics are scant and the observations conflicting [205, 206] Despite the possible benefits, GHT may also introduce a variety of risks and complications. Described adverse systemic effects of GHT include altered carbohydrate metabolism with glucose intolerance, a transient increase in total body fluid, hypertension, cardiac disease, stimulation of autoimmune disease, and increased malignancy risk. Given the variety of potential risks and complications, GHT, as either an adjunct to support linear growth or as a form of anti-inflammatory therapy, should be considered experimental in the setting of IBD, and is still best limited to formal investigative study settings.

Studies on the utility of recombinant IGF-1 on growth in CD have not been described to date. This is likely due to the theoretical risk of colon cancer with high circulating levels of IGF-1. A model has recently been formulated that allows for the calculation of a dose in children with active CD that would maintain IGF-1 levels within normal limits [213]. It remains to be seen whether future studies determine this to be any more effective than GH therapy.

Although there are no controlled clinical studies, three to six months of testosterone therapy, carefully supervised by pediatric endocrinologists, has been used in boys with extreme delay of puberty and has been associated with a significant growth spurt [78, 214].

It must be emphasized, however, that children requiring consideration of these adjunctive hormonal therapies should be encountered increasingly less commonly. Treatment of intestinal inflammation and assurance of adequate nutrition are of much greater importance. However, targeted therapies based on our current understanding of the GH-IGF-1 axis may be important for patients with significant linear growth impairment whose inflammation remains refractory to best current anti-inflammatory therapies.

Summary

Increased understanding of the mechanisms of linear growth impairment associated with chronic inflammatory disease points the way toward better management. Early recognition of Crohn disease remains an important challenge. Following diagnosis of IBD, restoration and maintenance of a child's pre-illness growth pattern indicate success of therapy. Current treatment regimens limit the use of corticosteroids, via optimization of immunomodulatory drugs, use of enteral nutrition in Crohn disease, and, if necessary, surgery for ulcerative colitis and for intestinal complications of localized Crohn disease. Biologic agents with the potential for mucosal healing hold promise of growth enhancement even among patients with otherwise refractory disease, whose growth was previously compromised. For all interventions, there is a window of opportunity, which must be taken advantage of before puberty is too advanced.

Inflammatory Bowel Diseases and Skeletal Health

13

Francisco Sylvester

Introduction

The skeleton is a scaffold for soft tissue but is also the largest calcium reservoir in the body. Bone marrow harbors and interacts with hematopoietic precursors. In addition, bone tissue is metabolically active and susceptible to regulation by local and systemic signals, including those generated during active intestinal inflammation. Moreover, mechanical strain exerted by skeletal muscle is anabolic to bone. Since muscle mass is frequently decreased in inflammatory bowel disease (IBD), anabolic strain by striated muscle can be weakened. In addition, children with IBD can have deficiencies in macro- and micronutrients that impact the availability of protein to synthesize bone matrix and calcium and phosphate to mineralize it. Consequently, the integrity of the skeleton is vulnerable to the effects of IBD on bone cell function and muscle mass. In addition, IBD may influence bone indirectly, by inhibiting key endocrine axes, such as insulin-like growth factor-1 (IGF-1) and sex steroids, which are critical for bone formation and maintenance of skeletal mass.

Childhood is characterized by active bone metabolism and growth in size and width due to the combined activities of bone cells and the growth plate. In the 2 years before and 2 years after the growth spurt in height, children gain about 33% of adult total bone mass [1, 2]. Since IBD typically strikes at this time in children, the skeleton is susceptible to the effects of IBD on bone mass and structure.

Bone modeling is the process responsible for bone tissue expansion in childhood until skeletal maturity is reached. Bone modeling involves bone-forming osteoblasts, bone-resorbing osteoclasts, and osteocytes. All three cell types are active *at the same time* on different bone surfaces, resulting in bone mass gains (Fig. 13.1) [3]. Osteoblasts, osteoclasts, osteocytes, and chondrocytes may be sensitive to disease and treatment effects in children with IBD, impairing bone formation and linear growth [4]. *Bone remodeling* is, on the other hand, a slower process that aims to repair and maintain existing bone mass and architecture. It involves the *sequential* activities of osteoclasts and osteoblasts under the direction of osteocytes on the same bone surface. Osteoclasts first dissolve stressed or microfractured bone. Osteoblasts then lay down bone matrix formation to fill the resorbed cavity. This process is orchestrated by osteocytes embedded in the bone matrix [5]. In children with active IBD, both bone metabolic activity and linear growth are impaired [6]. Both modeling and remodeling may be affected by multiple influences, including malnutrition, inflammation, inactivity, hypogonadism, and medications such as corticosteroids [4]. In this chapter, we will review current clinical and experimental evidence of the effects of IBD on the pediatric skeleton.

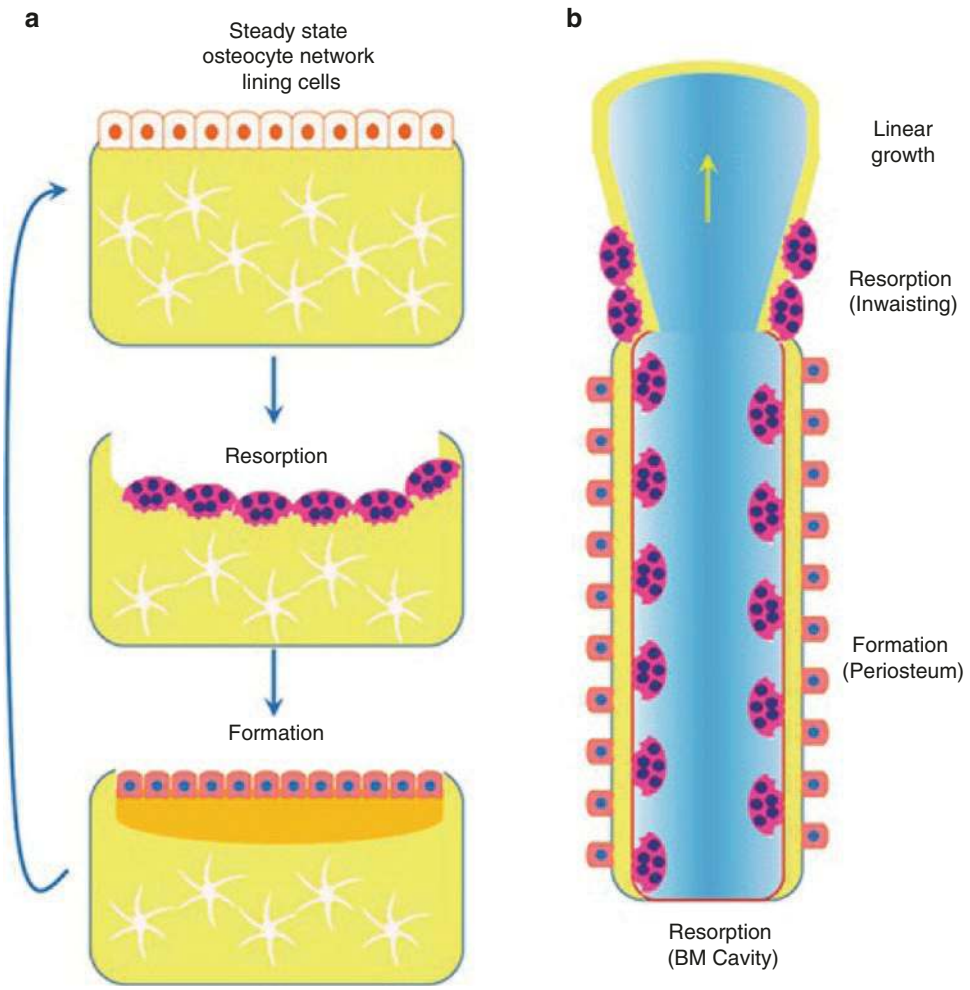

Fig. 13.1 Bone modeling and remodeling. (**a**) Bone remodeling takes place in both adults and children. It can occur in either trabecular or cortical bone as a consequence of microfractures, mechanical stress, or triggered to replace old bone. Small amounts of bone are dissolved by osteoclasts, which are followed by a wave of bone-forming osteoblasts. The protein matrix secreted by osteoblasts then becomes calcified, restoring the original bone mass. (**b**) Bone modeling occurs uniquely in children and results from the combined activities of osteoblasts, osteoclasts, osteocytes, and growth plate cells. As a result, bone grows in length and width and is reshaped. Compared to remodeling, bone modeling is a fast process in which all bone surfaces are active and osteoblasts and osteoclasts work at the same time

Growth and Bone Modeling and Remodeling

Childhood is a time of active skeletal growth and maturation. After rapid growth in the third trimester of gestation and in the early neonatal period, bone growth velocity falls sharply until puberty. Sexual maturation during puberty is associated with a dramatic acceleration in longitudinal bone growth. Liner bone growth ceases when growth plates closed. On average, growth plates close in girls between 14 and 15 years of age and in boys between 16 and 17 years of age. The structure of bone changes during growth, with expansion of the medullary cavity and thickening of the cortical shell and of existing bone trabeculae. Consequently, the mechanical properties of bone evolve rapidly during adolescence. Bone mineralization lags behind linear growth, resulting in a relative structural weakness that increases fracture risk during puberty [7]. After growth plate closure, bone mass gains continue. Peak bone mass that is achieved is usually achieved at the end of the second decade of life in females and at the beginning of the third decade of life in males [8]. After a period of stability that lasts for about two decades after the achievement of peak bone mass, bone loss occurs and is accelerated with aging in both males and females after menopause in women. In adults, loss of mineral mass is accompanied by deterioration of bone microarchitecture and increased propensity to fractures with age, leading to osteoporosis [9]. Bone deterioration may be enhanced by IBD in adults, but the effects of IBD in children may be unique due to their skeletal biology.

Bone mass is maintained by bone remodeling, characterized by the formation of a functional unit that consists of osteoclasts and osteoblasts, under the direction of osteocytes (the bone-remodeling unit) (Fig. 13.1) [5]. In response to damage or mechanical strain, osteoclasts resorb bone and form resorption pits. Ostecytes respond by decreasing the secretion of sclerostin [10], which removes a break for bone formation. As a consequence, osteoblasts differentiate locally and fill the resorptive cavity with osteoid (bone matrix), composed primarily of type I collagen. Osteoid becomes mineralized by deposition of hydroxyapatite, a calcium and phosphate crystal. Some osteoblasts then undergo apoptosis, while others become embedded in the newly

formed bone matrix and become osteocytes. Ostecytes are the most abundant cell type in bone and are long lived [11]. Osteocytes form a network interconnected by dendrites, which sense mechanical strain, and direct the cells of the bone-remodeling unit with mediators such as sclerostin, receptor activator of nuclear factor kappa-B ligand (RANKL) [12], osteoprotegerin (OPG), tumor necrosis factor-α (TNFα), interleukin (IL)-1β, IL-6, FGF23, DKK1, MEPE, PHEX, prostaglandins, nitric oxide, ATPs, and IGF-1 [11, 13]. The process of remodeling typically takes several months and generates small amounts of bone per remodeling cycle. In bone remodeling, the activities of osteoblasts and osteoclasts are coordinated and sequential. Only about 20% of bone surfaces in the body are actively engaged in bone remodeling at any given time. Bone remodeling occurs in adults and children and takes place in cortical and trabecular bone [14]. Importantly, bone cells involved in remodeling cross talk with bone marrow cells [15]. The bone marrow harbors T-cells that may be generated in the inflamed intestine. Colitogenic $CD4^+$ T central memory cells and T effector memory cells have been reported in the bone marrow of mouse models of colitis [16, 17]. Interleukin-7 (IL-7) produced by bone marrow stromal cells is required to maintain these cells [18]. In the IL-$2^{-/-}$ model of colitis, activated T-cells accumulate in the bone marrow and produce receptor activator of nuclear factor κB ligand (RANKL), which activated bone resorption [19]. T regulatory cells also exist in the bone marrow [20, 21]. Therefore, it is possible that T-cells that migrate from the inflamed gut to the bone marrow influence bone remodeling in mice and humans.

Gains in bone mass in childhood are largely due a combination of the action of the growth plate and bone modeling, which occurs predominantly in children (Fig. 13.1). Bone modeling can be compared to the process of erecting a skyscraper, which requires a large amount of new materials and connecting diverse structural elements. Bone remodeling, on the other hand, is akin to maintain the building's structural integrity over time by scheduled and unscheduled repairs (prompted by damage).

Longitudinal growth is triggered by hormonal signals and involves the production of a cartilaginous scaffold by the growth plate that is calcified, remodeled by osteoclasts, and turned into trabecular bone by osteoblasts. Trabeculae act as struts, plates, and joists to distribute mechanical load from the epiphysis to the compact bone shaft, which carries the majority of the load. Linear growth and bone modeling occur simultaneously, with osteoblasts laying down new osteoid in the periosteal surface, while osteoclasts reshape the bone by resorbing endosteal and metaphyseal bone (resulting in the expansion of the medullary cavity and metaphyseal inwaisting, respectively). Bone modeling occurs in 100% of bone surfaces, with both osteoclasts and osteoblasts active at the same time, and is faster than bone remodeling [22].

These significant physiological differences between pediatric and adult bone have important implications for children with IBD. Disease and treatment factors influence bone modeling and remodeling, but the major impact in children is likely to be on growth plate cells and bone modeling, the two most active processes in bone during growth. Moreover, IBD in children is associated with significant deficits in muscle mass, leading to a decrease in mechanical strain on bone and a consequent reduction in bone modeling. Moreover, weight loss associated with IBD decreases anabolic gravitational forces on the skeleton.

Measurement of Bone Mass

Dual X-ray absorptiometry (DXA) is a precise and accurate method commonly used to assess bone mass. DXA measures bone mineral content, which is divided by bone area (e.g., DXA "density" is expressed as g/cm^2, or "areal" bone density, not a true volumetric density). DXA produces a two-dimensional projection of the three-dimensional skeleton, so larger bones with equal density than smaller bones will appear "denser" in DXA. Therefore, diseases like IBD that can affect linear growth, and bone size may affect DXA measurements by underestimating bone mass in smaller children. This requires correction of DXA readings for patient's size, sex, and sexual maturation [23, 24]. The measurement of true volumetric bone density with peripheral computed tomography is available in some centers (please see Chap. 24 "Bone Health Assessment in Pediatric Inflammatory Bowel Disease" for more information).

Bone Cells and Inflammation

Osteocytes

Osteocytes are the most abundant bone cell. Osteocytes have a critical role in the regulation of osteoblast and osteclast activity. They originate from osteoblasts that become embedded in new bone after a bone-remodeling cycle. Osteocytes have an average half-life of 25 years, and their senescence affects bone cell function [11, 25]. Osteocytes form a mechanosensory network interconnected by cellular dendrites. Osteocytes are influenced by local and systemic factors. In turn, osteocytes secrete modulators of bone cell activity like RANKL, sclerostin, Notch, and DKK1. In addition, osteocytes can also secrete cytokines, including TNF-α and IL-6, which can affect osteoblast and osteoclast development and function [26]. In a rodent model of IBD, osteocytes increased their cytokine output [27]. This suggests that osteocytes not only respond to systemic cytokines but could also amplify the effect of inflammation on bone cells in IBD.

Osteoclasts and the *RANKL/OPG* System

Bone remodeling and modeling involve the activity of osteoclasts and osteoblasts. Osteoclasts secrete enzymes (e.g., cathepsin K) and acid that dissolve bone mineral and degrade the bone matrix. Osteoclast activity generates collagen-split products and growth factors (such as transforming growth factor-β) embedded in the bone matrix that stimulate osteoblast differentiation to fill the resorption site with bone matrix. Osteoclasts are cells from the macrophage/monocyte (myeloid) lineage, which are regulated by cytokines [26]. Osteoclasts are formed primarily by stimulation of hematopoietic precursors with RANKL in the presence of macrophage stimulating factor (M-CSF) (Fig. 13.2). RANKL, a member of the tumor necrosis factor receptor superfamily, is produced by osteocytes, osteoblasts, stromal cells, fibroblasts, and activated T-cells [28], and stimulates osteoclast differentiation, activation, and survival. A complex network of cytokines and immune receptors regulates osteoclast formation and activity either directly or indirectly via RANKL [26, 29, 30]. RANKL-deficient mice have hyperdense bones secondary to lack of osteoclasts [31]. RANKL has been implicated as a key factor in the pathogenesis of bone loss associated with increased resorption, including postmenopausal osteoporosis and rheumatoid arthritis. A monoclonal antibody to RANKL, denosumab, is used to treat postmenopausal osteoporosis and bone loss associated with rheumatoid arthritis [32, 33].

Osteoprotegerin (OPG) is a soluble decoy receptor for RANKL produced by osteoblasts and stromal cells [34]. OPG is a potent inhibitor of osteoclast development. OPG transgenic mice have hyperdense bones. Systemic administration of OPG also increases bone mass in normal mice. OPG-null mice, on the other hand, are profoundly osteopenic due to unopposed osteoclast activity [35, 36]. Besides OPG, another control switch in osteoclast development is interferon (IFN)-β, which is induced by RANKL binding to its receptor RANK on osteoclast precursors [37]. IFN-β interferes with the activity of c-fos, a transcription factor that is essential for osteoclast formation. Other factors,

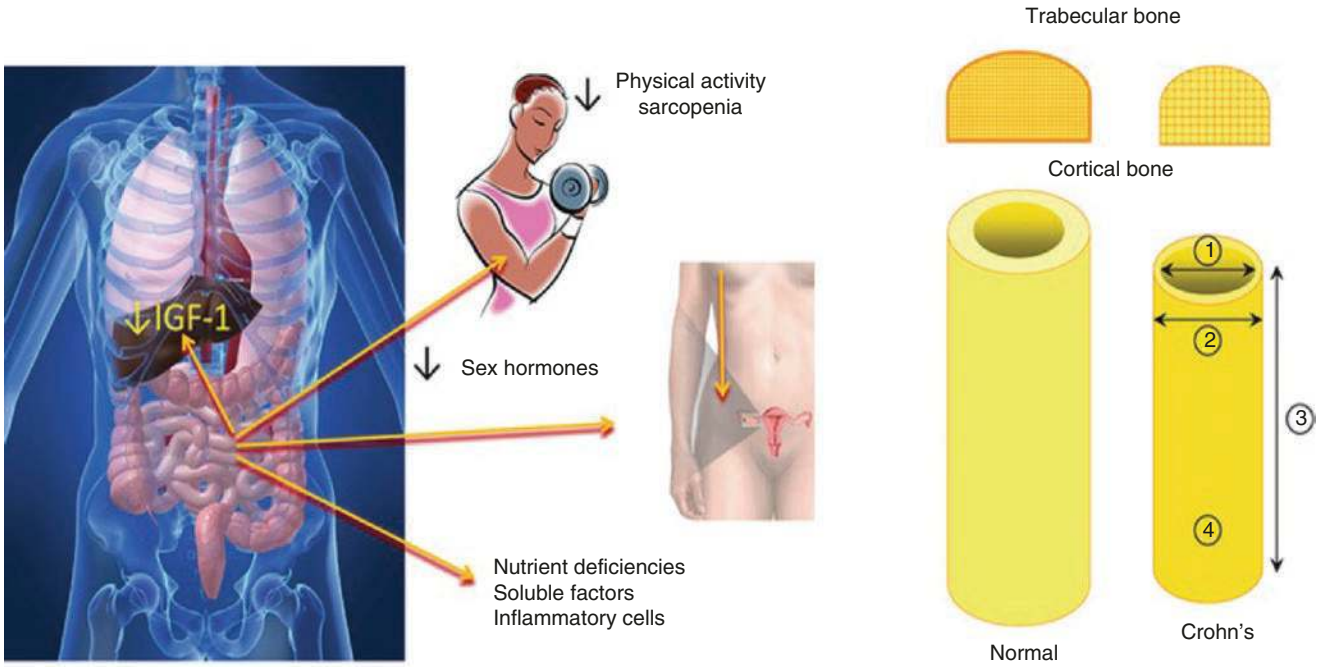

Fig. 13.2 Effects of IBD on the muscle-bone unit. (**a**) Active inflammation in IBD can affect the skeleton by multiple mechanisms, including blocking the formation of IGF-1 in the liver, delaying puberty, and affecting bone cell function via immune cells and cytokines. A decrease in muscle mass (sarcopenia) can impair bone development. Active IBD can also cause fatigue and decreased weight-bearing activity. Corticosteroids to treat IBD can primarily impair bone formation and secondarily increase bone resorption. Malnutrition can affect the availability of protein, calcium, and vitamin D; they are essential for normal bone formation. Therefore, IBD constitutes a multipronged attack on the integrity of the muscle-bone unit and puts at risk the acquisition of genetically programmed peak bone mass. (**b**) At diagnosis, children with Crohn disease have significant bone mass deficits and alterations in bone geometry. In cortical bone, these include ① increased endosteal surface probably due to increased bone resorption, ② decreased periosteal circumference secondary to decreased bone formation, ③ reduced bone length due to growth plate inactivity, and ④ increased cortical bone density, likely a result of reduced bone remodeling. Trabecular bone is less dense ⑤. Some of these abnormalities can be partially reversible with anti-inflammatory therapy (resulting in reduction in endosteal surface, improved bone length, increased trabecular bone density, and decreased cortical bone density), but periosteal circumference can remain lower than normal

such as transforming growth factor-β (TGF-β) and Wnt, inhibit osteoclastogenesis by upregulating the production of OPG by osteoblasts [38]. Wnt also directly represses RANKL expression via the Wnt canonical pathway [39, 40], while Wnt5a, a typical non-canonical Wnt ligand, enhances the expression of RANK in osteoclast precursors [41]. In addition, several cytokines relevant to the pathogenesis of IBD inhibit osteoclast differentiation, including interferon-γ (IFN-γ) [42], IL-10 [43, 44], IL-12 [45, 46], and IL-17 [47, 48]. Moreover, osteoclast differentiation involves transcription factors such as NFκB, AP-1, and NFATc1, as well as co-stimulation via immunoglobulin-like receptors and activation of the phosphatase calcineurin, which can be regulated by inflammation [47, 49–51]. Therefore, osteoclast formation is subject to multiple regulatory controls by cytokines, transcription factors, and enzymes that play key roles in IBD. In addition, osteoclasts interact closely with the hematopoietic stem cells niche [52, 53]. These pathways are an example of the close physiological ties between the immune system and bone cells. However, it is not yet known whether these mechanisms are engaged in regulating bone mass in children with IBD.

The RANKL/OPG system also plays important roles outside of bone. This is evidenced by the lack of peripheral lymph nodes and impaired development of lactating mammary glands in RANKL or RANK-null mice [54]. In addition, RANKL/OPG may be involved in the formation of calcified atherosclerotic plaques, and serum OPG is emerging as a marker of cardiovascular mortality [55, 56]. The balance between RANKL and OPG may affect the severity of bone metastases of several cancers [28]. RANKL contributes to normal dendritic cell function and survival and the early development of B- and T-cells [31, 57]. In addition, RANKL/RANK may play a role in intestinal mucosal tolerance [58]. OPG also has a role in the regulation of the immune response. Both B cells and dendritic cells secrete OPG, and this secretion is regulated by the CD40 receptor [59]. Also, dendritic cells isolated from $OPG^{-/-}$ mice more efficiently present antigen in vitro and secrete more inflammatory cytokines when stimulated with bacterial products or soluble RANKL in vitro [60]. In mice, M cells express OPG, which suppresses the differentiation of adjacent follicle adjacent epithelial cells into M cells. OPG deficiency ameliorates symptoms of experimental colitis, but OPG-deficient mice are highly susceptible to Salmonella infection [61]. Thus, OPG-dependent self-regulation of M cell differentiation is essential for the balance between the infectious risk and the ability to perform immunosurveillance at the mucosal surface. Collectively, this evidence suggests that RANKL/RANK/OPG plays an important role in the regulation of the immune response and in pathways involving the mobilization of calcium [62].

A role for the RANKL/OPG system is emerging in IBD. Circulating OPG levels are elevated in patients with IBD [63], and expression of OPG and RANKL is increased in colonic macrophages, dendritic cells, and epithelial cells [64, 65]. High-fecal OPG (which probably comes from the inflamed colonic epithelium or from activated vascular endothelium) predicts resistance to corticosteroids and to infliximab in patients with IBD [66, 67]. In addition, fecal OPG decreases in children with IBD in remission [68]. Currently, it is not clear whether circulating OPG in patients with IBD represents spillover from intestinal inflammatory activity or it comes from bone or other tissues (e.g., the endothelium or the liver). The function of RANKL/OPG in the pathogenesis of intestinal inflammation deserves further study.

Osteoclast differentiation is also regulated by Notch. There are four types of Notch, of which Notches 1–3 are expressed in skeletal cells. The effects of Notch on osteoclasts are complex and depend on the type of Notch. Notch1 inhibits osteoclastogenesis, whereas Notch2 enhances osteoclast differentiation and function by direct and indirect mechanisms. Notch3 induces the expression of RANKL in osteoblasts and osteocytes and as a result induces [69] osteoclast differentiation [70].

Osteoblasts

Osteoblasts are cells from mesenchymal origin that lay down bone matrix that is rich in type 1 collagen (osteoid). Several factors and hormones regulate osteoblast formation, both systemic and in the bone microenvironment [71]. Among the most important, there are factors secreted by osteocytes including sclerostin and Dkk1, which inhibit osteoblast differentiation and function, and Wnt and Notch, which stimulate osteoblast development [5, 40, 72]. The concentration of Wnt, Dkk1, and sclerostin is affected in mice with experimental colitis [27]. Insulin-like growth factor-1 (IGF-1) is secreted by the liver in response to stimulation by growth hormone from the pituitary gland. IGF-1 enhances the expression of the mature osteoblast phenotype [73]. Serum IGF-1 is frequently reduced in children with active IBD due to growth hormone insensitivity in the liver and malnutrition [74]. Consequently, relative IGF-1 deficiency in children with IBD may negatively affect osteoblast differentiation and function. Tumor necrosis factor-α (TNF-α), an important cytokine in the pathogenesis of IBD, inhibits osteoblast development by inducing the degradation of Runx2 [75], a critical transcription factor in osteoblast development and suppression of osteogenic factor signaling including Wnt [76] and bone morphogenetic protein-2 [77, 78]. TNF-α also regulates a number of inflammatory chemokines and cytokines, inflammatory genes, transcriptional regulators, bone-remodeling genes, signal transducers, cytoskeletal genes,

and genes involved in apoptosis in pre-osteoblasts [79]. TNF-α and colitis decrease the expression of *Phex* in osteoblasts which affects their mineralization function [80, 81]. TNF-α induces cAMP response element-binding protein H (CREBH), which blocks the anabolic effects of bone morphogenetic protein-2 on osteoblast precursors by inducing the Smurf1-mediated degradation of Smad1 [82]. In children, TNF-α blockade leads to a brisk increase in biomarkers of bone formation and significant linear growth, suggesting an activation of bone modeling [83, 84]. However, the effects of infliximab may be a product of improved disease control and not specific effects of this drug on bone metabolism in these patients.

T-Cells and Bone Loss

T-cells are emerging as important regulators of bone cell function [85]. Activated T-cells can regulate osteoclast formation and activity by several mechanisms, both RANKL dependent and independent. Activated T-cells secrete RANKL and consequently can promote osteoclast differentiation and survival. Both soluble and membrane-bound RANKL are produced by activated $CD4^+$ and $CD8^+$ T-cells [86]. T-cell-induced bone resorption has been implicated in tissue injury in animal models of arthritis and periodontal disease [87]. $CD4^+$ Th17 T-cells may be the most pro-resorptive T-cell in the bone marrow [47] probably due to their ability to secrete cytokines that stimulate osteoclast formation and activity [88], upregulation of RANK in osteoclast precursors [89], and increased expression of RANKL in osteocytes [90]. This is significant given the importance of Th17 cells in the pathogenesis of IBD [91]. However, γδ T-cells produce IL-17A, which promotes bone formation after fractures [92]. T-cells may also play an important role in bone loss associated with estrogen deficiency, where osteoclast activity is upregulated. This is suggested by experiments performed in ovariectomized mice, where the absence of T-cells prevents bone loss [69]. In this model, the expansion of a TNF-α-producing T-cell pool appears to be essential and may occur as a result of upregulation of antigen presentation. The nature of the activating antigen(s) is not yet known, but it is possible that both self and foreign epitopes (including intestinal bacterial products) may play a role [93]. The concept that T-cells activated by bacterial antigens may regulate bone cell function is intriguing in the setting of IBD, due to the defects in microbial recognition and processing that have been identified in this condition [94]. In IBD, it is possible that activated T-cells and T-cell memory cells may serve as "inflammatory shuttles" between the intestine and bone, since circulating T-cells produce cytokines that can regulate both osteoblasts and osteoclasts [95, 96]. Ciucci et al. have shown that bone marrow IL-17/TNF-α-producing $CD4^+$ T-cells from IL-$10^{-/-}$ mice with colitis (but not from IL-$10^{-/-}$ without colitis or wild-type mice) induce osteoclast formation in vitro without addition of RANKL/M-CSF. These cells express membrane-bound RANKL and secrete M-CSF [17]. In addition, it is possible that circulating antigens may trigger immune responses via T-cell memory cells in the bone marrow that affect bone cell function. The activation state of T-cells may also be important in their interaction with osteoclasts, since resting T-cells inhibit osteoclastogenesis [97]. T regulatory cells (Treg) are present in the bone marrow and are potent inhibitors of bone resorption [98] probably due to their secretion of IL-4, IL-10, and TGF-β. In addition, T-cells may also regulate bone formation by osteoblasts. For example, bone marrow $CD8^+$ T-cells stimulated by intermittent parathyroid hormone administration activate anabolic canonical Wnt signaling in pre-osteoblasts by $CD8^+$ T-cells [99]. Moreover, bone cells can influence T-cell differentiation and activity. Osteoclasts affect the differentiation and activity of γδ T-cells from peripheral blood in vitro via soluble factors and cell-to-cell contact [100]. Osteoclasts can function as antigen-presenting cells and direct the formation of effector $CD4^+$ and $CD8^+$ cells [101] and induce FoxP3 expression in $CD8^+$ cells [102]. Osteoclasts can also induce the formation of anti-resorptive $CD8^+$ Treg [103], in a process that involves permissive levels of RANKL [104]. Moreover, the effects of T-cells in the skeleton may be site specific [105]. Lastly, microbial metabolites generated in the gut may affect bone cells function via regulation of T-cells [106]. Examining these complex mechanisms in the context of IBD awaits additional research.

Novel Pathogenic Pathways in IBD: Osteoimmune Connections

Genome-wide association studies have identified a number of unsuspected pathogenic pathways in IBD. Among them, there are endoplasmic reticulum (ER) stress, the unfolded protein response (UPR), and autophagy [107]. These pathways regulate the function of highly secretory cells such as Paneth cells and goblet cells in the intestinal lining and innate immune cells in the intestinal lamina propria [108]. When there is an overabundance of unfolded and misfolded proteins in the ER, the ER becomes stressed. The UPR is triggered, involving the activation of inositol-requiring kinase 1 α (IRE1α), pancreatic ER eIF2α kinase (PERK), and activating transcription factor 6α (ATF6α) [109]. Each pathway leads to separate and distinct transcriptional events. The UPR aims to restore homeostasis to the ER by decreasing transcription and protein synthesis, degradation of proteins inside the ER, and shuttling of proteins away from the ER with chaperones. When ER stress is chronic and homeostasis cannot be achieved by the UPR, the cell goes into

apoptosis. Osteoblasts secrete large amounts of collagen (osteoid, the bone matrix) and other factors and might be affected by defects in ER stress and the UPR found in IBD [110, 111]. Bone morphogenetic protein-2 (BMP-2, a stimulator of osteoblast development and activity) induces the expression of ER stress transducers, such as old astrocyte specifically induced substance [112] and ATF [113]. The inositol-requiring protein 1α (IRE1α) and its target transcription factor X-box-binding protein 1 (XBP1) are essential for BMP-2-induced osteoblast differentiation [114]. The BMP-2-signaling pathway also activates the UPR during osteogenesis [113, 114], which induces the synthesis of RANKL and osteoclastogenesis. To date, it is not known whether defects in the UPR that occur in IBD affect osteoblast function. Mature osteoclasts actively secrete acid and proteolytic enzymes such as cathepsin K to degrade the bone matrix and are also sensitive to ER stress. The IRE1α/XBP1-mediated branch is important in osteoclast development [114] and is involved in parathyroid hormone-induced osteoclast formation. RANKL, which induces osteoclast differentiation and activity, is upregulated by the UPR in in cultures of primary osteoblastic cells and in osteoblast and osteocyte cell lines [115]. Therefore, defects in the UPR and ER stress present in IBD may affect the development and activity of both osteoblasts and osteoclasts.

Autophagy is a process by which cells recycle old proteins, damaged organelles, and other cellular debris. These elements are encircled by double-membrane vesicles called the autophagosomes, which fuse with lysosomes to become autolysosomes. Their content is recycled and returned back to the cell. Autophagy also plays a role in bacterial digestion after phagocytosis. The mammalian target of rapamycin (mTOR) is an important regulator of autophagy. In addition to controlling cell growth and metabolism, mTOR negatively regulates autophagy when nutrients and growth factors are abundant [116]. Autophagy has a role in bone cell development and function [117]. In IBD autophagy can be deficient, leading to persistence of bacteria inside of cells. It is possible that defects in autophagy in IBD may affect bone cell function [118]. Induction of autophagy in osteoclasts decreases bone resorption [119]. On the other hand, autophagy induces osteoclast formation during hypoxia [120] and microgravity [121]. Autophagy is important for osteoblast differentiation [122, 123] and bone mineralization [124]. A mouse model of conditional deletion of ATG7 (autophagy related 7) exhibits a reduced bone mass, indicating that autophagy may be important for normal bone formation [125]. Therefore, it is possible that altered autophagy in IBD impairs normal osteoid mineralization by osteoblasts. Moreover, GWAS suggests that genes involved in autophagy regulate bone mineral density in humans [126].

Cytokines produced by the inflamed intestine can regulate bone cell activity. IL-6, IL-17, and TNF-α induce osteoclast formation in vitro [17, 127, 128]. TNF-α induces osteocyte expression of RANKL, thus, promoting osteoclast formation and activity [129]. Cytokine effects on osteoclasts may also occur indirectly through osteoblasts. For example, IL-17 stimulates osteoblasts to secrete GM-CSF in the presence of vitamin D, resulting in inhibition of osteoclast formation in vitro [130]. IL-17 can also induce mesenchymal stromal cells and osteoblasts to secrete RANKL, which would stimulate osteoclastogenesis and bone resorption [47, 131]. In a mouse model of colitis, Th17 cells in the bone marrow that produce TNF-α and RANKL increase osteoclast formation; this effect can be blocked by an anti-IL-17 antibody, suggesting that IL-17 is an important pathogenic factor that reduces bone mass in this model [132]. Oncostatin M (OSM), a cytokine of the IL-6 family, is a major coupling factor produced by activated circulating CD14+ or bone marrow CD11b + monocytes/macrophages upon activation of toll-like receptors (TLRs) by lipopolysaccharide or endogenous ligands that induce osteoblast differentiation and matrix mineralization from human mesenchymal stem cells [133].

Notch plays complex roles in osteoblast and osteoclast differentiation. The effects of Notch on bone cells depends on context, cell type, and stage of development. As a consequence, Notch may either stimulate or suppress osteoblasts and osteocytes [134]. Isoforms of Notch 1–3 regulate osteoclasts differently [70]. In a TNF transgenic mouse model, Notch inhibitors increased bone mass [135], suggesting that the negative effects of TNF-α on bone formation may be blocked by Notch inhibitors. These findings open an avenue to explore the effects of Notch in IBD.

Innate immune responses can be activated by toll-like receptors (TLRs). The mechanism of pathogen-induced bone disease includes activation of TLRs in immune cells by pathogen-derived molecules [136]. This activation results in synthesis and release of inflammatory cytokines that are capable of stimulating osteoclastic bone resorption, thus, causing bone loss. Osteoclasts express functional TLRs. TLR ligands (CpG-ODN, LPS, Poly(I:C)) exert dual effect on osteoclast precursors. They inhibit the activity of the physiological osteoclast differentiation factor, RANKL, in early precursors, but strongly increase osteoclastogenesis in RANKL-pretreated osteoclast precursors [137–139].

The Gut Microbiome and Bone Health

The gut microbiome probably plays an important role in the pathogenesis of IBD, and IBD affects the microbiome [94]. The intestinal microbiota and their products may have effects on bone development and homeostasis. A recent study that compared estimated heel bone mineral density in 1126 twin pairs and their gut microbial genes suggested a causal relationship between specific microbial taxa and bone develop-

ment [140]. A report by Sjogren et al. suggests that gut bacteria are essential for normal postnatal bone remodeling [141]. Britton et al. showed that a strain of *Lactobacillus reuteri* can reverse osteoporosis caused by ovariectomy in mice [142]. The same group has treated bone loss associated by experimental type 1 diabetes in mice [143]. Glucocorticoid-induced osteoporosis in mice was prevented by an antibiotic cocktail, and treatment of mice exposed to glucocorticoids with *L. reuteri* prevented bone loss. Fecal microbial transfer from mice treated with glucocorticoids into untreated wild-type mice induced bone loss [144]. Collectively, this evidence offers proof of principle that enteric organisms have the potential to regulate bone mass. More research is needed in this important area that is very relevant to human IBD.

Effects of Intestinal Inflammation on Bone

Animal Models

IBD is a complex clinical entity, where multiple disease and treatment factors contribute to affect bone cell biology and ultimately skeletal health. In an effort to study mechanistic questions, animal models of intestinal inflammation have been used by several groups. A brief description of their observations follows.

Studies in rat and mouse models suggest that intestinal inflammation can decrease bone mass by impairing bone formation. Lin et al. induced colitis in rats by rectal instillation of TNBS [145] to study its effects on bone mass, assessed by quantitative histomorphometry. After 3 weeks, rats with colitis had a 33% loss of trabecular bone loss in the tibia compared with age-matched, pair-fed control animals. This was associated with a marked suppression of the trabecular bone formation rate. As the colitis healed, bone formation became more active and bone mass normalized after 12 weeks. In IL-10$^{-/-}$ mice with colitis, Dresner-Pollak et al. performed bone densitometry, ash weight, histomorphometry analysis, and mechanical fragility testing [146]. They observed that bone mass decreased secondary to decreased bone formation in 8- and 12-week-old mice; bone resorption was not increased in mice with colitis compared to wild-type controls. Long bones were more fragile in IL-10$^{-/-}$ with colitis, and ash weight was reduced. However, since these studies did not include IL-10$^{-/-}$ mice without colitis, it was not clear if at least, some of the observations in the skeleton of IL-10$^{-/-}$ mice were due to the IL-10 deficiency. More recently, Ciucci et al. addressed this gap and reported significant decreases in trabecular thickness, trabecular number, trabecular bone surface density, and trabecular bone volume per tissue volume in IL-10$^{-/-}$ mice with colitis, but not in IL-10$^{-/-}$ mice without colitis [17], suggesting that in this model, bone effects are due to colitis and not IL-10 deficiency. IL-10$^{-/-}$ mice with colitis harbor in their bone marrow IL-17/TNF-α-producing CD4^{+} T-cells that attract osteoclast precursors. In addition, bone marrow mesenchymal stromal cells produce chemokines that may attract additional osteoclast precursors in this model [17]. Harris et al. have demonstrated that the inhibition of bone formation and bone modeling is reversible with healing of colitis in mice [147].

In the dextran sodium sulfate (DSS) model of colitis in mice, bone formation is reduced [148] and the number of osteoclasts precursors and osteoclasts attached to bone surfaces is increased [149]. Interestingly, growth plate thickness and hypertrophic chondrocyte matrix components (collagen X) are reduced. Bone mass is reduced even when mice do not lose weight and their colitis is mild, suggesting that inflammation per se is responsible for suppressing bone formation [148]. In addition, sarcopenia associated with inflammation may also reduce anabolic muscle strain on the skeleton [150]. In the DSS model, an antagonist of IL-15 prevents bone loss [149].

Three reports using adoptive transfer models of colitis suggest that bone mass decreases secondary to increased bone resorption. In the first paper, Ashcroft et al. studied IL-2$^{-/-}$ mice with colitis at 4, 7, and 9 weeks of age and compared X-ray and histomorphometry with IL-2$^{-/+}$ and wild-type mice. IL-2$^{-/-}$ mice develop colitis and also have splenomegaly, anemia, and other signs of systemic inflammation [19]. They observed a decrease in trabecular bone volume in IL-2$^{-/-}$ with colitis compared with the other two groups of mice at 7 and 9 weeks of age. C57BL/6-Rag1$^{-/-}$ mice transplanted with CD3^{+} cells from IL-2$^{-/-}$ had significantly lower femoral BMD and % trabecular volume 6–8 weeks post-grafting. Serum OPG and osteoclast number were significantly higher in mice engrafted with T cells from IL-2$^{-/-}$ mice compared to IL-2$^{+/+}$. In this model, treatment with OPG was associated with both improved bone mass and decreased intestinal inflammation. These results point to a possible role of T-cells in bone loss in the context of intestinal inflammation and suggest a possible anti-inflammatory role for OPG. In the second study, Byrne et al. transferred CD4^{+}CD45RB^{Hi} or CD4^{+}CD45RB^{Lo} from CB6F1 mice to C.B.17 *scid/scid* mice [151]. CD4^{+}CD45RB^{Hi}, but not CD4^{+}CD45RB^{Lo}, caused colitis in recipient mice, and mice with colitis had lower bone mineral density in the femur/tibia. To treat bone loss, mice received Fc-OPG 3.4–5 mg/kg SC three times weekly for 34 days. OPG had no effect on the severity of colitis but significantly improved BMD. However, this may be a nonspecific effect of OPG on normally active osteoclasts and by itself does not establish that increased bone resorption is responsible for bone loss in rodent models of colitis. It is interesting that in the CD4^{+}CD45RB^{Hi} model, there is an inflammatory infiltrate in the bone marrow containing TNF-α-producing cells [151]. This provides proof of principle that intestinal inflammation is associated with the

presence of activated T-cells in the bone marrow that secrete pro-inflammatory cytokines which may influence the function of bone cells. In the third study, Ciucci et al. reported $CD4^+$T-cells in the bone marrow of mice with colitis that produce IL-17 and TNF-α, capable of stimulating osteoclastogenesis in vitro [17].

Collectively, these observations suggest that intestinal inflammation can directly affect bone mass in rodents. Mechanisms may include decreased bone formation or increased bone resorption, depending on the model. Calcium and phosphate homeostasis by the kidney may also be impaired by inflammation [152]. Additional studies are needed to further elucidate pathogenic mechanisms.

Human Studies

Many studies have measured bone mineral density in children with IBD, both in incident and in prevalent cohorts. The studies, which have been either longitudinal or cross-sectional and have used primarily DXA or pQCT to image bone, suggest that decreased bone mineral density is common in children with Crohn disease at the time of diagnosis, especially in patients with delays in growth and sexual maturation, active disease, and those with decreased lean tissue mass [6, 153–155]. Studies performed in incident cohorts of treatment-naïve patients suggest that disease factors can affect bone mass in children with IBD prior to the initiation of treatment. Collectively, this work suggests that children with Crohn disease are at greater risk for decreased bone mass than children with ulcerative colitis, probably because Crohn disease is more likely to affect linear growth and may be diagnosed less promptly than ulcerative colitis. Patients with low body mass index, low serum albumin, and active severe IBD appear to be at particular risk for decreased BMD. The role of corticosteroids on BMD in pediatric Crohn disease, however, is not clear. The attainment of peak bone mass in Crohn disease is at risk, which may affect fracture risk later in life [156].

According to the guidelines by the International Society for Clinical Densitometry (ISCD), children with IBD should have DXA of the whole body (less head) and the lumbar spine if in the clinician's judgment, the measurement may influence the patients' management [157]. The updated recommendations offer guidance concerning DXA at the distal forearm, proximal hip, and lateral distal femur in children who need additional information for clinical decision making, or in whom spine or whole body DXA scans cannot be obtained [157]. Pediatric Bone Mineral Accrual *Z*-Score data are available to help interpret DXA results [2], as well as equations to correct DXA BMD data for height *Z*-score [158]. Vertebral fracture assessment (VFA) can be performed in children by DXA images [157]. The annual rates of change for BMD in early-stage and late-stage adolescents are approximately 10% and 3%, respectively [159]. Therefore, follow-up DXA should be obtained at minimum intervals of 6–12 months to observe clinically meaningful changes.

In addition to measuring bone mass, body composition data provided by DXA may be helpful in guiding the nutritional rehabilitation of these patients. It is important to DXA BMD measurements to patient size, gender, and sexual maturation, because in any given patient with IBD, the challenge is to distinguish between small, normally mineralized bones and abnormally thin and weak bones [160]. Taken together, these studies indicate that the observed reduction of BMD in children with IBD can be attributed in part to decreased bone size due to growth delay. However, it is important to note that smaller bones may be weaker, and their physical properties may not be normal. It is not yet known whether smaller bone size leads to increased fracture risk in children with IBD. Conversely, increases in height track with significant improvements in BMD, especially in trabecular bone.

Indirect markers of bone cell function, including osteocalcin and bone alkaline phosphatase for osteoblasts and products of type I collagen degradation for osteoclasts, can be used to infer bone-remodeling activity in adults. In children, however, bone biomarkers cannot distinguish between bone modeling, bone remodeling, and bone growth. Nonetheless, significant reductions in the concentration of bone metabolic activity markers suggest that children with Crohn disease have decreased bone turnover at diagnosis [6]. This indicates that the observed reduction in BMD in children with IBD is probably secondary to a combination of decreased net bone formation and linear growth. A study reported the results of histomorphometry in transiliac bone biopsies of 20 children with newly diagnosed Crohn disease and confirmed that bone formation and resorption are reduced at diagnosis; in addition, there was cortical thinning, but trabecular thickness and number were unaffected [161]. Longitudinal studies of incident cohorts of children with Crohn disease have revealed significant alterations in bone geometry of long bones, including decreased periosteal circumference (due to reduced bone formation), expanded endosteal surface (due to increased bone resorption), and increases in cortical bone density (probably due to decreased cortical bone remodeling) [154, 162]. Treatment with anti-TNF-α antibodies for 12 months was associated with improved bone length, reduction of the endosteal surface, and decreased cortical bone density (likely due to increased bone cell activity and rapid growth, respectively), but not a significant increase in periosteal circumference compared to normal controls [84]. Periosteal circumference may be responsive to gains in muscle mass that occur as a result of sustained disease remission.

Laboratory observations suggest that systemic factors impair bone formation in human IBD. For example, serum

from newly diagnosed children demonstrates decreased markers of osteoblastic activity in bone explants [163] and in osteoblasts [164], while indicators of bone resorption are not increased. IL-6, a pro-inflammatory cytokine, appears to play an important role in these effects, in cooperation with other factors present in intact bone. Consequently, IBD may have systemic effects on linear growth and direct effects on bone cells in children, thereby decreasing bone mass. Although globally both bone formation and bone resorption appear lower in children with IBD at diagnosis, it is possible that in some regions of the skeleton, bone resorption may be increased, resulting in thinner bone cortices and mechanical fragility.

While systemic and local humoral factors can directly influence bone cell function in IBD, other influences, albeit indirect, may also be significant. For example, an important stimulus for bone formation is mechanical loading by the expanding muscle forces during puberty [165]. Muscle volume (lean body mass) normally expands during sexual maturation, and its expansion precedes gains in bone mass. Children with IBD often present with malnutrition, with significant losses in both the fat and lean tissue compartments and decreased body mass index. With treatment and clinical improvement, children gain weight but deficits in lean body mass persist [155, 166, 167]. This may result in decreased mechanical loading on bone and be a reason for decreased bone formation in children. In addition, children with IBD may be less active than their peers when they do not feel well, which may also affect gains in muscle and bone mass over time.

Nutritional factors can also negatively impact bone mass. For example, vitamin D is essential for normal calcium absorption and may have immunoregulatory effects in the gut [168, 169]. Vitamin D deficiency may be common in children with IBD, especially in high latitudes [170] and in African-American and Hispanic children [171]. Patients with IBD may spend more time indoors during disease exacerbations, affecting their exposure to sunlight and cutaneous synthesis of vitamin D. Their intake of dairy products fortified with vitamin D may be limited due to secondary lactase deficiency. Vitamin K deficiency is prevalent in children with IBD [172] and may compromise the normal γ-carboxylation of osteocalcin, a mineralization factor [173].

Osteoporosis and Fractures in Pediatric IBD

The ISCD in 2013 recommended the following diagnostic criteria for osteoporosis in pediatrics: (a) the presence of one or more vertebral compression fractures in the absence of local disease or high-energy trauma or (b) the presence of a clinically significant fracture history and BMD Z-score of ≤ -2.0. An abnormal BMD *Z*-score by DXA is insufficient by itself to make the diagnosis of pediatric osteoporosis. A clinically significant fracture history was defined as two or more long-bone fractures by the age of 10 years or ≥ 3 long-bone fractures at any age up to age 19 years [24].

More recent approaches to determine clinically significant fractures rely less on BMD *Z*-score cut-offs. The diagnosis of pediatric osteoporosis incorporates the presence of a family history of osteoporosis and osteogenesis imperfecta, ruling out rickets, and searching for signs of a genetic disorder that affects the skeleton (i.e., blue sclera, Wormian bones, joint hypermobility, etc.) [174]. Ascertaining the affected bone(s), and circumstances and mechanism of injury are essential to determine if a fracture is clinically significant for the diagnosis of osteoporosis. Stress fractures are not considered fragility fractures and should not be considered to count toward the diagnostic criteria for osteoporosis [174].

It is not clear whether children with IBD are at increased risk of fractures. One important confounder is that long-bone fractures are very common in children (mostly of the upper extremities). Consequently, demonstrating that IBD caused a in children may be very difficult. Moreover, children with IBD may have comorbidities such as rickets that are responsible for fractures. Nonetheless, fractures of the femur and vertebrae should be investigated thoroughly for underlying skeletal fragility. Population-based studies in adults with IBD suggest that the risk of clinically apparent fractures appears to be modestly increased [175] or not elevated [176]. Two pediatric studies examining the prevalence of long-bone fractures, one by a questionnaire and the other an analysis of an administrative database, found no increase in the frequency of fractures in children with IBD [177, 178]. However, a study of vertebral fracture assessment in adults with Crohn disease indicated high prevalence of asymptomatic vertebral fractures, even in patients with normal bone density by DXA [179]. Vertebral fractures have been reported in children as well [180]. Children who report back pain, have pain upon palpation of the spinal processes, or have a reduction in height should have spine films to screen for vertebral fractures.

Treatment

In all children with IBD, disease and treatment factors that can impair the acquisition of bone mineral should be identified and corrected when possible. These include active inflammation, malnutrition, specific nutrient deficiencies (calcium, vitamin D, and vitamin K), and corticosteroid exposure [181]. High doses of vitamin D may be required to replenish vitamin D stores [182, 183]. Weight-bearing physical activity should be encouraged [184]. Treatment modalities such as exclusive enteral nutrition and anti-TNF-α

antibodies have positive effects on linear growth and BMD [84, 185, 186] and should be considered in children with IBD with very low BMD.

In children with "clinically significant fractures" (see previous section) with or without low BMD, it is important to evaluate for primary bone disease in addition to establishing measures to optimize nutrition, reduce inflammation with corticosteroid-spearing strategies, and improve physical activity. The growing skeleton is highly capable of healing if the primary disease is adequately treated. Therefore, children with IBD and osteoporosis may not need to be treated with bone-specific therapy. If bone-active agents are being considered, it is important to partner with a pediatric endocrinologist with knowledge and experience in these therapies [187].

Conclusions

Inflammatory bowel disease can negatively affect bone development in children through multiple mechanisms. Due to differences in bone metabolism in children and adults, IBD impacts bone metabolism differently in these two age groups. In children, decreased BMD is probably the result of impaired growth, a primary decrease in osteoblast function, and reduced mechanical strain on bone. Current therapies, including corticosteroids and immunomodulators, may not be optimal for promoting normal body composition and skeletal health in children with IBD. Preliminary data indicate that TNF-α blockade may be more effective in this regard. In children, careful attention to disease control, nutrition (including calcium and vitamin D), and activity level is probably appropriate to improve skeletal mass. Anti-resorptive agents such as bisphosphonates may be helpful in selected children (e.g., those with fragility fractures, especially if they have growth potential) but should not be started in children without input from experts in pediatric metabolic bone diseases.

Puberty and Pediatric-Onset Inflammatory Bowel Disease

14

Jacquelyn Hatch-Stein

The Pubertal Process in Healthy Children and Adolescents

Puberty is the stage of growth during which sequential biological processes occur that ultimately lead to sexual maturity and reproductive capacity [1]. The onset of puberty is initiated following increased synthesis and secretion of gonadotropin-releasing hormone (GnRH) in the hypothalamus and its transport to gonadotrophs within the anterior pituitary. In response to pulsatile GnRH, the gonadotrophs secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which in turn regulate ovarian and testicular functions. Activation of the gonads by LH and FSH is termed gonadarche (see Table 14.1). Pituitary sensitivity to GnRH varies throughout life but increases prior to the onset of puberty. Around this time, LH is secreted in a pulsatile manner, primarily during sleep, but subsequently changes to a pulsatile pattern throughout the day as puberty progresses [2]. In females, LH stimulates theca cells in the ovary to produce androgens which diffuse to granulosa cells for conversion into estrogens. FSH causes growth of granulosa cells in the ovarian follicle and estrogen production (estrone or E1 and estradiol or E2), which leads to feminization in girls. In males, LH stimulates testosterone production by Leydig cells in the testis. Testosterone subsequently undergoes 5α-reduction to dihydrotestosterone, which induces secondary sex characteristics. FSH acts on Sertoli cells in the seminiferous tubules of the testes to stimulate sperm production and testicular enlargement.

Adrenarche, which frequently begins before gonadarche, is defined by a detectable increase in the secretion of adrenal androgens. Adrenarche most often occurs between 6 and 9 years of age [3] and results in the first appearance of pubic hair, often termed pubarche. Adrenarche is typically temporally related to pubertal maturation of the hypothalamic–pituitary–gonadal (HPG) axis and gonadarche but is not causally related to maturation of this axis. While adrenal androgen production is a minor component of the midpubertal male testosterone level, the adrenal gland contributes about half the total testosterone produced in the female. Since adrenal androgen production is ACTH dependent, this synthesis is subject to suppression with exogenous glucocorticoid therapy. In normal maturation, the adrenal androgen dehydroepiandrosteroine sulfate (DHEAS) is the most abundant circulating adrenal steroid after the onset of adrenarche and often reflects endogenous glucocorticoid secretory capacity. [4].

Table 14.1 Definitions of pubertal events

Gonadarche	Activation and maturation of the gonads in both sexes
Adrenarche	Maturation of the adrenal gland with detectable increase in adrenal androgen secretion
Pubarche	Pubic hair development
Thelarche	Breast bud development in females
Spermarche	Development of mature sperm in males
Menarche	Onset of first menstrual period

Since in early puberty, increased gonadotropin pulse amplitude increases first during sleep, gonadal steroid secretion at this point of development is maximal in the very early morning hours and may wane to low, prepubertal levels by 0900. Thus, it is important to assay gonadotropin and sex steroid levels in the early morning. In addition, it is important to perform these assays in a specialty laboratory with sensitive pediatric assays (as opposed to standard adult assays) to detect the normally low prepubertal and early pubertal levels. The adrenal steroid DHEAS does not follow this pattern because of its long plasma half-life, and a meaningful level may be determined throughout the day. A summary of normal hormone levels as they vary in puberty is seen in Table 14.2.

The factors in the brain that trigger the onset of the pulsatile GnRH secretion at the time of puberty are still not completely understood. Leptin is a peptide hormone expressed predominantly in adipocytes that regulates food intake and

Table 14.2 Hormone levels in puberty

Hormone	Stage/age	Male	Female
Dehydroepiandrosterone sulfate (DHEAS) (mcg/dL)	Tanner I	<89	<46
	Tanner II	<81	15–113
	Tanner III	22–126	42–162
	Tanner IV	33–117	42–241
	Tanner V	110–510	45–320
Luteinizing hormone (LH) pediatric (IU/L)	3–7 years	<0.26	<0.26
	8–9 years	<0.46	<0.69
	10–11 years	<3.31	<4.38
	12–14 years	0.23–4.41	0.04–10.8
	15–17 years	0.29–4.77	0.97–14.7
Follicle stimulating hormone (FSH) pediatric (IU/L)	5–9 years	0.21–4.33	0.72–5.33
	10–13 years	0.53–4.92	0.87–9.16
	14–17 years	0.85–8.74	0.64–10.98
Estradiol (E2) Pediatric (pg/mL)	Prepubertal	<4	<16
	10–11 years	<12	<65
	12–14 years	<24	<142
	15–17 years	<31	<283
Testosterone (Te) (ng/dL)	Tanner I	<5	<8
	Tanner II	<167	<24
	Tanner III	21–719	<28
	Tanner IV	25–912	<31
	Tanner V	110–975	<33
IGF-1 (ng/mL)	Tanner I	96–341	105–359
	Tanner II	101–478	99–451
	Tanner III	101–478	197–642
	Tanner IV	318–765	330–776
	Tanner V	318–765	330–776

Modified from Nakamoto and Mason [80], and Quest Diagnostics Reference Ranges, Quest Diagnostics Inc., San Juan Capistrano CA
Caution is suggested in differentiating puberty from prepuberty, especially with regard to LH, FSH, E2, and Te. The assays must be sufficiently specific as well as sensitive for the normally low prepubertal and early pubertal levels. In addition, these hormones are secreted episodically with short half-lives in the blood. Early morning testing is recommended

energy expenditure at the hypothalamic level [5]. Serum leptin levels have been shown to correlate closely with body fat content. Leptin is thought to be an important link between nutrition and the attainment and maintenance of reproductive function, as patients with leptin deficiency have been shown to not only be obese but to also have gonadotropin deficiency [6]. However, while leptin levels normally rise throughout childhood and puberty, a rise in leptin is not required to trigger puberty. Thus, leptin likely functions as a permissive factor rather than a trigger in the onset of human puberty. In late 2003, loss of function mutations of GPR54 (a G-protein-coupled receptor) was described in patients with hypogonadotropic hypogonadism [7]. This discovery led to the finding that GPR54 and its ligand (kisspeptin) act as a signal for pubertal GnRH release. Further research suggests that kisspeptin influences the timing of puberty and the integration of nutritional and energy status, likely indirectly through leptin expression. However, what controls the regulation of kisspeptin expression at the time of puberty is not completely known. Neuropeptide Y (NPY), a potent appetite-stimulating agent found in the hypothalamus, may also mediate the effects of leptin on puberty. Based on studies in prepubertal rats, Pralong et al. suggested that NPY may inhibit GnRH secretion and delay sexual maturation [8]. In a limited study, girls with constitutional delay in puberty were found to have higher levels of NPY than those with a normal course of puberty [9].

Physical changes associated with puberty are described by one of five Tanner stages. The onset of puberty is associated with Tanner stage II early-breast bud development in girls and testicular enlargement to a volume of 4 mL or length of 2.6 cm in boys [10, 11]. The current best estimates for the mean age of onset of puberty in healthy children in the United States are 10.2 years for girls and 11.5 years for boys [10]. The mean age of menarche is 12.6 years in Caucasian girls, 12.3 years in Mexican-American girls, and 12.1 years in African-American girls of normal weight. Adiposity is associated with earlier pubertal development [12]. The mean age for spermarche in boys is between 13.5 and 14.5 years [13]. The average duration of puberty in girls is 4 years (range 1.5–8 years) and for boys 3 years (range 2–5 years) [13]. The typical pubertal growth acceleration begins in girls at the start of puberty, and in boys in mid-puberty [14]. See Fig. 14.1 for a summary of the sequence of pubertal events in both males and females.

The standard deviation for all pubertal milestones is about 1 year [16, 17]. Thus, early or precocious puberty is defined

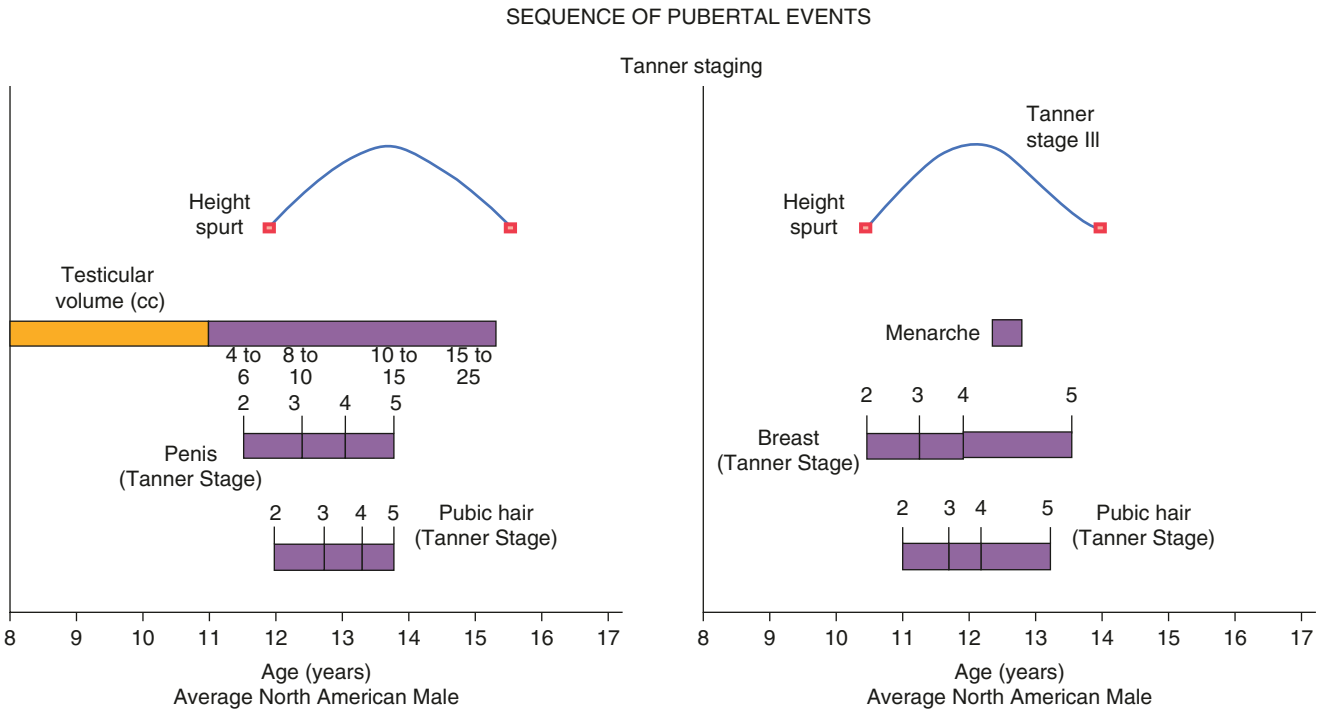

Fig. 14.1 Sequence of pubertal development in males and females. Reprinted from Radovick and Misra [15], Figure 26.4, page 593, with permission

as physical development prior to age 8 years in girls, and 9 years in boys, though these cut-offs do not necessarily account for racial differences. A diagnosis of delayed puberty applies to girls older than 13 years without evidence of breast development and boys older than 14 years without evidence of testicular enlargement . The most common cause of delayed puberty in otherwise healthy children is an extreme variant of normal known as constitutional delay of growth and puberty (CDGP). Children with CDGP are often referred to as "late-bloomers." This occurs due to an unexplained delayed activation of the hypothalamic–pituitary–gonadal axis. A family history of delayed puberty is common and a delay in skeletal age as visualized by bone age X-ray is expected. In a large case series, CDGP was found to be the cause of delayed puberty in 53% of the subjects (approximately 63% of boys and 30% of girls) [18]. The second most common cause of delayed puberty in the case series was functional gonadotropin deficiency, which affected 19% of subjects. Functional gonadotropin deficiency can be seen in chronic illness, especially in conditions that are also associated with decreased body fat (such as IBD). Other less common causes of delayed puberty include primary gonadal failure and gonadotropin deficiency.

The standards of Tanner staging are used for distinguishing different phases of pubertal development in both males and females [19–21] (see Table 14.3). In girls, palpation of breast tissue is more accurate than visualization for confirmation of attainment of true breast buds, as it can be difficult to distinguish adipose versus true glandular tissue. In similar fashion, measurement of testicular size in boys with a tool such as the Prader orchidometer is more accurate than visualization alone [22]. Most reports in the pediatric gastroen-

Table 14.3 Staging of Pubertal Development (Tanner) [14]

Staging—girls	Breasts	Pubic hair
1	Prepubertal	No pigmented hair
2	Palpable budding	Sparse hair along the labia
3	Enlargement of the breast mound beyond the areola	Coarser, with spread of hair over mons
4	Secondary mound of areola	Adult hair but does not spread to thigh
5	Fully mature	Full adult distribution

Staging—boys	Genital size	Pubic hair	Prader orchidometer (mL)
1	Prepubertal	No pigmented hair	1–3
2	Early testicular, penile, and scrotal growth	Sparse hair at base of penis	3–6
3	Increased penile length and width	Coarser, with spread of hair above penis	8–12
4	Further increase in penis size	Adult hair but does not spread to thigh	12–15
5	Fully mature	Full adult distribution	>15

terology literature have used Tanner stages which rely on visual observation of the progression of pubic hair character and distribution, breast size and contour, and testicular size [23]. In certain clinical scenarios, these visual observations may be an acceptable alternative when more accurate measures are not possible. Schall et al. studied the validity of self-assessment of sexual maturity in 100 patients with Crohn disease (CD) age 8–18 years [24]. Patients' self-assessments were compared with those of a designated pediatrician. Agreement varied between 74% and 85%, depending on the sex and sexual maturity status, with younger children and overweight boys tending to overestimate their sexual maturity status (SMS). Rapkin et al. also noted that self-staging of Tanner stage did correlate with circulating estradiol and FSH measurements in 124 healthy girls, aged 8–18 years [25]. However, caution must be taken when Tanner staging by visualization alone, and when clinically indicated more accurate measures should be considered.

Thus, puberty involves a change in the balance of inhibitory and stimulatory signals that impact the GnRH neuron. Genetic factors, ethnicity, nutrition, and environmental chemicals are important in the pubertal process. However, the mechanisms by which neuroendocrine and genetic factors control pubertal development are yet to be fully elucidated.

The Influence of IBD on Puberty

Delayed puberty and poor growth often complicate the clinical course of children diagnosed with IBD, especially children diagnosed with CD. In fact, some children with IBD, moreso in CD, may present with a slowdown of growth velocity and delayed puberty as the first sign of the onset of IBD [26]. As progression through puberty and increased growth velocity are intricately linked, most studies that look at the effects of IBD on puberty examine both growth and pubertal progress. Normal prepubertal growth velocity after 3 years of age averages about 5–6.5 cm/year. The pubertal growth spurt provides an additional 15–25 cm of growth [9, 12, 13, 16]. Delayed puberty is often associated with lower peak height velocity (PHV).

Hildebrand et al. [27] sought to assess the effect of IBD on puberty and obtained height and weight data from birth through final adult height in 46 patients with childhood-onset CD and 60 patients with childhood-onset ulcerative colitis (UC) in Sweden. In this study, the age at PHV was stated to represent the middle of puberty. The PHV for healthy children in Sweden was reported to be 12.05 ± 0.88 years for girls and 14.15 ± 0.98 for boys. Delayed puberty was defined as a delayed age at PHV of >2.0 SDS. No significant delay was noted in children with UC with age at PHV 11.9 ± 1.1 years for girls and 14.0 ± 1.2 years for boys. However, mean age at PHV was later in patients with CD: 12.7 ± 1.4 years for girls and 14.9 ± 1.2 years for boys, and 23% of these children with CD had a delayed age of PHV of >2.0 SDS. A retrospective study by Mason et al. analyzing serial height measurements in adolescents with IBD supports these findings, with the observation that an altered pubertal growth spurt is not uncommon in this age group, perhaps even moreso in boys. They also observed that the delay in PHV frequently depends on disease activity and adequate nutrition, in this case measured as erythrocyte sedimentation rate and body mass index [28].

Brain et al. also observed several alterations in the pattern of puberty among pediatric patients with IBD [11]. The mean age of onset of puberty was delayed for both female and male patients when compared to healthy controls: 12.6 years versus 11.1 years in girls and 13.2 years versus 12.4 years in boys. In addition, the duration of puberty was prolonged, especially in adolescents with frequent disease relapses during puberty [11]. Some patients with IBD took up to 4 years to progress from Tanner stage II to stage IV. Peak height velocities during puberty reached rates >12 cm/year in patients who remained in remission in contrast to as little as 1–2 cm/year in those with relapsing disease. When surgical resection was performed in 11 prepubertal children with CD, puberty started within 1 year of resection. The authors postulated that if the onset of puberty was delayed beyond 14 years, then the final height may be "irreparably compromised." The data from Kirschner et al. support that statement, as they observed that there is a strong correlation between age at menarche and height gain [29]. In this study, when menarche occurred at <13 years of age, the mean increment in height was 10 cm compared with only 3.0 cm in those aged >15 years at menarche. Homer et al. also noted that catch-up growth, even in prepubertal patients, occurred only in those with sustained clinical remission [30].

More recently, Gupta et al. compared the age at menarche in 34 patients with CD with that of 545 controls, using data from the National Health and Nutrition Examination Survey (NHANES) [31]. The authors found that the median chronological age at menarche (13.9 years) in CD was older than that in the NHANES sample (12.0 years). In CD patients, the cumulative incidence of menarche was 10% at chronological age 12 years, 51% at chronological age 14 years, and 100% at chronological age 16 years. Menarche occurred earliest in South Asians, followed by East Asians, and then Caucasians. They suggested if menarche has not occurred by bone age >14 years, endocrinology referral should be considered.

To determine if steroid sparing agents lead to improvements in growth and normal advancement in puberty in CD, Pfefferkorn et al. analyzed growth outcomes in children with

newly diagnosed CD [32]. They found that despite improvements in disease activity, mean height SDS scores did not change significantly, and pubertal progression remained slow. Children diagnosed with CD prior to 9 years of age had a higher mean growth velocity 2 years after diagnosis, as compared to children diagnosed after 9 years of age. Children who required prolonged corticosteroid therapy (longer than 6 months) had poorer growth outcomes. These data suggest that despite advances in nutritional and anti-inflammatory therapies for CD, growth and pubertal delays continue to persist in these children with CD.

In contrast, a study by Malik et al. suggested that children who had a clinical response to infliximab therapy had improvement in their linear growth that was independent of their pubertal progression [33]. In addition, children who had not been exposed to exogenous glucocorticoids also exhibited better growth with infliximab therapy, suggesting that the effect on growth was not simply related to a decrease in glucocorticoid use. In a more recent study, Cameron et al. also sought to examine whether antitumor necrosis factor (anti-TNF-α) therapy improves growth in pediatric IBD. This was a retrospective review of Scottish children with all subtypes of IBD on infliximab or adalimumab, with height measurements 12 months prior to anti-TNF-α initiation, at the start of anti-TNF-α therapy, and 12 months after the start of the therapy. In general, anti-TNF-α therapy was associated with improved linear growth. However, anti-TNF-α use was most likely to be associated with growth improvement when used at earlier stages of puberty, Greater disease control was the biggest factor influencing improvement in growth, with no improvement in growth seen in those who did not achieve remission [34].

Potential Causes of Pubertal Delay in IBD

Pubertal delay in IBD can have many etiologies. Poor nutritional status is often thought to be the major cause, as optimal nutrition is necessary for the initiation and maintenance of reproductive function. GnRH secretion is blunted in the malnourished state which leads to pubertal arrest, and secretion of GnRH normalizes with weight gain [35]. However, the delay of puberty in IBD presents a more complex issue, with weight not the sole independent variable. Stress and inflammation likely also have important roles. The complex interactions between severity of disease, fluctuations in inflammatory cytokines, and their effect on nutritional status and hormonal profile make it difficult to determine how individual factors influence the onset and progression of puberty in pediatric patients with IBD. As a consequence, while nutritional deficits are well described in patients, other aspects such as the potential role of inflammatory cytokines on puberty are often extrapolated from animal models [36].

Nutritional Causes of Pubertal Delay

In otherwise healthy children, undernutrition may cause a delay in sexual maturation and menarche. Important studies done by Frisch and colleagues demonstrated that the age of pubertal growth and menarche in girls correlated more closely to weight than to chronological age [37–39]. During the adolescent growth spurt prior to menarche, girls had a continuous decline in the percent body water and increase in body fat, resulting in a change in the ratio of lean body weight from 5:1 to 3:1 and a mean percent body fat at menarche of 22% [37–39]. The investigators noted that the mean weight at menarche in girls in the United States was 47.8 ± 0.5 kg [37–39]. A possible relationship between body fat and menarche was suggested by adipose tissue being a significant extragonadal site of estrogen production through conversion of androgen into estrogen. She postulated that the decrease in age at menarche (approximately 3–4 months each decade over the past 100 years) is due to girls reaching the "critical" weight earlier, secondary to improved nutrition. In girls with primary amenorrhea due to undernutrition, a minimal equivalent of 17% body fat may be necessary for menarche to occur [37–39]. For girls experiencing secondary amenorrhea, resumption of menses usually occurred when weight gain was 10% higher than the weight at menarche.

Dreizen et al. compared the age at menarche of 30 girls with "chronic undernutrition" with 30 "well-nourished" girls living in north central Alabama [40]. The average age at menarche was 14.5 years in the former group and 12.4 years in the latter group. Interestingly, standing heights that had differed by 9.2 cm at 12.5 years decreased to a difference of only 3.5 cm at 14.5 years and were not significantly different (1.1 cm) at 17 years. Similarly, skeletal age was delayed in the undernourished group, but at the time of menarche, the bone age in the undernourished girls was only 3.8 months more advanced than the well-nourished group. Complete fusion of the epiphyses was delayed in the malnourished group to 17.6 years versus 15.9 years for healthy controls. Therefore, although the timing of the adolescent growth spurt was delayed by undernutrition, final height (in the absence of underlying disease) was not significantly reduced. An earlier study by the same authors in undernourished boys also showed delayed epiphyseal fusion to 18.7 years versus 17.0 years and a mean difference in height between the groups of 2.68 inches at 16 years [41]. Unfortunately, final adult heights were not reported.

Similar delays in menarche (with onset averaging 15.1 ± 0.5 years) are seen in ballet dancers, swimmers, and runners whose training and low calorie intakes begin prior to menarche [38, 39]. Frisch postulated that these females have a raised lean/fat ratio. Both increased nutrition and reduction in the intensity of training may restore menses. Athletic amenorrhea is a hypothalamic reversion to a more immature

pattern in GnRH response. Normalization may occur with reduction in exercise and/or other stress without the weight change estimated by Frisch.

Reduction in calorie intake has been documented in many studies of pediatric-onset IBD, especially CD [42–44]. Kirschner et al. found that weight loss could be associated with prepubertal levels of circulating sex hormones despite previous physical signs of pubertal progression [45]. Thus, undernutrition is likely to be one of the contributing factors leading to delay in the onset and progression of puberty. Similarly, secondary amenorrhea seen in female patients with IBD may be caused by weight loss, a frequent complication of IBD in adolescents.

Sentongo et al. used dual-energy X-ray absorptiometry (DEXA) and anthropometric measures to compare fat mass (FM) and fat-free mass (FFM) in 132 pediatric patients with IBD and 66 healthy controls [46]. They found that patients had normal fat stores but reduced FFM, consistent with "inflammatory cachexia" [46]. They cited data suggesting that proinflammatory muscle-active cytokines may impair accretion of lean tissue.

Burnham et al. compared 104 North American patients with CD to 233 healthy control subjects and found delayed sexual maturation in the CD group [47]. Patients within Tanner stages II–IV averaged 1.4–1.5 years older than control subjects at the same pubertal stages. Lean mass was reduced by 8% in the patient CD group. Thus, the role of undernutrition in both growth failure and sexual maturation may be underestimated if these complications are compared only with documented weight loss. Failure to gain weight (without a history of weight loss) may also adversely affect the timing of menarche and the progression of puberty.

Advancement in puberty may also be related to excess weight gain [12, 48]. Early adrenarche appears to be related to excess weight gain and may be accompanied by skeletal advancement and possibly earlier true puberty. This may be related to peripheral aromatization of adrenal androgens to estrogens in fat.

Endocrine Aspects of Pubertal Delay

Most studies of endocrine function in children and adolescents with IBD have been performed to investigate the causes of growth failure rather than the onset and progression of puberty [42–44, 49–52]. An intact growth hormone (GH)/insulin-like growth factor I (IGF-I) axis is necessary for normal postnatal growth. Thyroid hormone and cortisol are also important, as are the sex steroids at the time of puberty. IGF-I is produced in the liver under the stimulation of GH and is thought to be the key mediator of the growth-promoting effects of GH. Reports in growth-impaired patients with IBD have generally demonstrated normal GH secretion, thyroid function, cortisol response to hypoglycemia, and gonadotropin response to GnRH. What changes were observed such as reduced amplitude of the GH pulse or increase in reverse triiodothyronine (rT3) were not associated with reduced growth velocity [51]. IGF-1 levels have been shown to be reduced in children and adolescents with IBD [36, 45, 53, 54]. This usually occurs despite the presence of adequate circulating levels of GH and is known as "growth hormone resistance." Since IGF-1 is modulated by both GH and nutritional status, it is not clear whether the reduction of IGF-1 seen in this population is secondary to active disease or to the decrease in calorie intake (or both). An increase in IGF-1 does occur following nutritional restitution in children with IBD [36, 45]. Corkins et al. also noted that the major binding protein for IGF-1 (IGFBP-3) was reduced at diagnosis in children with IBD which would result in a reduced half-life for circulating IGF-1 [53]. The use of IGF-1 as a potential therapeutic agent to enhance growth in childhood IBD is hampered by concerns regarding a potential increased risk for colon cancer and other malignancies in this population [55].

In a trinitrobenzene sulfonate (TNBS) model of experimental colitis in rats, Azooz et al. noted that puberty was delayed but plasma concentrations of gonadotropins were similar to healthy controls [56]. Interestingly, delayed puberty and reduced levels of plasma testosterone and 17β-estriol levels were present in both colitic and noncolitic pair-fed rats, compared to healthy controls, emphasizing the importance of caloric sufficiency. However, the frequency of delayed puberty was less in the food-restricted rats (28%) versus the colitis rats (57%), suggesting an independent role for inflammation in this process. The authors demonstrated that the administration of testosterone subcutaneously on a daily basis to the colitis rats normalized the onset of puberty. Similar results were recently reported by DeBoer and colleagues comparing pubertal progression in dextran sodium sulfate (DSS)-induced colitis, food-restricted mice, and free-feeding control mice. For both sexes, puberty was more delayed in the colitis model than the food-restricted animals, despite similar leptin levels [57, 58].

Proinflammatory Cytokines–Endocrine Interactions

Several in vitro studies have elucidated ways in which proinflammatory cytokines (such as TNF-α, interleukin-6 (IL-6), and interleukin-1β (IL-1 β)), elevated in patients with IBD, affect endocrine function. Elevations of these cytokines have been shown to lead to altered gonadal function and reduced sex steroid synthesis [59]. Several of these findings may be applicable to explaining pubertal delay in patients with chronic inflammatory bowel disease.

TNF-α has inhibitory effects on GH and sex hormone function. Transgenic mice overexpressing TNF-α (or IL-6) are growth-impaired and have low IGF-1 levels despite normal GH because of inhibition of GH signaling within hepatocytes [60]. Denson et al. showed that TNF-α suppressed GH receptor expression by inhibiting Sp1/Sp3 transactivators [61]. IL-6 inhibits hepatic GH signaling by inducing a suppressor of cytokine-inducible signaling (SOCS-3) and reduces the half-life of IGF-1 by increasing the catabolism of its binding protein, IGFBP-3. TNF-α and IL-6 also reduce IGF-1 action by inhibiting insulin receptor substrate 1 which influences IGF-1 binding to its receptors and interleukin-1β (IL-1 β). TNF-α and IL-1β have also been shown to induce anorexia. It has been suggested that GH therapy may overcome hepatic GH resistance induced by IL-6 [62].

TNF-α has also been shown to decrease androgen receptor protein as well as dihydrotestosterone activation. TNF-α, IL-6, and IL-1 β reduce testosterone synthesis in Leydig cells and steroidogenesis in cells in the ovary. DeBoer et al. reported partial normalization of puberty in female mice with dextran sodium sulfate (DSS) colitis treated with anti-TNF-α, when compared to a placebo-treated group. The authors utilized the day of life of the vaginal opening as the validated measure of puberty in female mice and found pubertal onset at day 30 in controls, day 31 in DSS colitis with anti-TNF-α, and day 33 or later in DSS and placebo. The DSS colitis mice controls and those treated with anti-TNF-α maintained similar weights throughout the study.[63].

Psychosocial Issues and Puberty

There is extensive literature describing dynamic changes in the psychosocial interests and concerns of adolescents. Shafer and Irwin addressed these issues and emphasized how they develop and are different among adolescents during early adolescence (ages 10–13 years), middle adolescence (ages 14–16 years), and late adolescence (ages 17–21 years) [13]. Nottelmann et al. studied the relationship between adolescent psychosocial adjustment and chronological age, pubertal status, and serum hormone levels [64]. In boys, adjustment problems were associated with low sex hormones or lower pubertal stage in conjunction with higher chronological age. These included sadness/anxiety and problems with body and self-image. In girls, adjustment problems in social relationships were also associated with lower pubertal stage and higher age. Both groups had elevated levels of androstenedione, an adrenal hormone responsive to stress, which the authors suggested may be due to self-comparison with same-age peers. They speculated that boys may be more sensitive to hormonal influences and girls to environmental influences.

Delayed sexual maturation may have significant adverse effects on self-esteem and socialization, as the child with delayed puberty looks younger than their chronological age and often is treated as such [65]. Thus, an adolescent with IBD must cope not only with the impact of having a chronic disease, but also with the psychological issues of delayed puberty.

In addition to the psychological response to pubertal delay, stress itself may interfere with the functioning of the brain–pituitary–gonadal axis. Evidence suggests that this may be mediated by elevated cortisol levels over a protracted period of time. Consten et al. noted that cortisol administration to male carp caused delayed testicular development, reduced testosterone levels, and impaired maturation of pituitary gonadotrophs [66].

Therapeutic Approach to Addressing Pubertal Issues in IBD

The observations and studies described above suggest that prolonged control of active inflammation and providing adequate nutrient intake are both essential in promoting normal puberty. Alperstein et al. reported that it took 2.5–10 years for five of nine children with growth delay who were in Tanner stage I to attain their pre-illness height percentile following surgery for CD [67]. Thus, optimal control of IBD and optimization of nutritional status are paramount in adolescents with IBD and delayed puberty.

When growth and puberty concerns persist in children with IBD, whether the disease is controlled or not, referral to pediatric endocrinology may be warranted. For the pediatric gastroenterologist, timely referrals regarding growth and puberty concerns to an endocrinologist are of great importance, as a delayed referral will potentially limit the time window in which limited treatment options may be considered.

While early puberty is not a known complication of IBD in children, it certainly can occur as it does in otherwise healthy children. Early puberty would be critical to identify in IBD, as treatment considerations would be warranted in the context of potential implications on final adult height, both from the disease and the early puberty. Thus, most girls with breast bud development prior to age 8 years and all boys with testicular enlargement prior to age 9 years should be referred to endocrinology for discussion of further work up and potential treatment options. Current treatment typically includes the use of GnRH agonists to temporarily halt puberty, which come in both injection (leuprolide) and implantable (histrelin acetate) formulations. Typically these medications are not used to halt puberty at older ages just for height related concerns, though some small studies have sought to investigate this use [68]. Most evidence does not

support the use of GnRH agonists for this indication, though some reports indicate potentially some effect on adult height when used in combination with GH. Potential downsides of the use of GnRH agonists outside of a central precocious puberty diagnosis could include deleterious effects on bone health [68, 69].

Of course, children with IBD are referred to endocrinology for linear growth concerns more commonly than puberty-specific concerns. Treatment options for short stature in IBD are limited, but when indicated GH therapy can be a consideration. Although experience with GH treatment in pediatric patients with IBD is limited, improvement of growth velocity may be observed when there is reasonable disease control with reduced corticosteroid exposure. Furthermore, steroid-related growth effects may be in part ameliorated with GH treatment [70–72]. Growth-related treatments in IBD are more fully described elsewhere in this book. However, it is important to note that response to GH in children with IBD may be related to pubertal staging. In one study, a trend was observed that improved growth velocity was greater in Tanner stage I and II patients who received GH as compared to those who were in the later stages of puberty [72].

When GH treatment is unavailable, or feared to be insufficient for optimal height outcomes, some pediatric endocrinologists consider the off-label use of aromatase inhibitors (such as letrozole and anastrozole) to augment final adult height in boys. Aromatase inhibitors are typically considered when there is concern that the eventual progression of puberty itself could limit the window of growth and ultimately negatively impact final adult height. Since estradiol (converted from testosterone) is primarily responsible for growth plate closure in late puberty, the goal of aromatase inhibitor use is to delay growth plate closure by slowing testosterone to estradiol conversion, potentially leading to an increased final adult height. The limited evidence on this use shows variable efficacy, and no known studies have looked specifically at the use of this in adolescents with IBD. The greatest effect of aromatase inhibitors on height outcomes seems to be when used in combination with GH [73].

For those children with delayed puberty secondary to the IBD disease process, pubertal induction may be considered. However, especially in children with IBD, final height preservation may be at odds with the child's desire to proceed through puberty. Artificial induction of puberty with estrogen or testosterone runs the risk of skeletal advancement without commensurate growth. An anabolic steroid such as oxandrolone, which does not advance bone maturation as much as testosterone in modest dose, might be of some small value. Mason et al. described a retrospective study of eight boys with IBD (seven of whom were prepubertal at 13.6–15.6 years of age) who received testosterone therapy for pubertal induction [74]. Testosterone dose and route of administration were either monthly injections of testosterone enanthate 50 mg (five patients) or transdermal testosterone patch 2.5 mg daily (two patients) or 5.0 mg daily (one patient). Following 6 months of treatment, seven out of eight boys progressed in puberty to Tanner stage II–IV, and the median height velocity increased from 1.6 to 6.9 cm/year. There was noted a negative correlation between C-reactive protein levels and height velocity, and so response to treatment was likely still quite dependant on disease control [74].

Ballinger et al. describe their approach to pubertal induction in IBD as including a 3- to 6-month course of 100–125 mg/month of intramuscular testosterone ester (enanthate or cypionate) in boys and ethynyl estradiol 4–6 mcg/day orally for the same length of time in girls [75]. Another approach to pubertal induction in selected male patients with delayed puberty consists of a 6-month course of 50 mg/m^2 intramuscular testosterone ester. For girls with either functional gonadotropin deficiency or constitutional delay of puberty, it is reasonable to offer a 6-month course of either a low dose of IM depot estradiol (0.2–0.4 mg monthly), or a low-dose estrogen patch (applying a 25 mcg patch twice weekly for 1 week out of the month) for pubertal induction [76]. As opposed to boys, there are few studies that report the outcome of a brief exposure to sex steroid therapy for girls with delayed puberty. The response to this approach in pediatric patients with IBD has not been studied.

The relationship between puberty and its effects on bone density in children with IBD has not been addressed in this chapter as the topic is discussed in depth elsewhere in this text. Although pubertal delay has been associated with reduced BMD in adult men, its impact on peak bone mass in pediatric patients with IBD has not been determined [77, 78]. Bernstein et al. compared BMD T scores of the lumbar spine, femoral neck, total hip, and total body in a series of 70 adult women with IBD, who were <45 years of age. They observed no significant differences between 12 patients with disease onset before puberty compared with 58 whose disease was diagnosed after puberty [79]. More long-range data are needed on the relationship between pubertal delay and bone mineralization in adulthood.

Delayed growth and sexual maturation are a frequently described potential consequence of IBD in children and adolescents. For the reasons stated above, assessment of pubertal staging should be an integral part of the monitoring of pediatric patients with IBD. Reasons to refer to a pediatric endocrinologist are many, but certainly should be considered in boys who have reached 14 years and girls who have reached 13 years without evidence of any physical changes of puberty. However, an earlier referral may be necessary in a child with early or normally timed puberty, if there is concern for a history of poor growth that may ultimately be affected further by pubertal timing and ultimate closure of growth plates.

Classification of Pediatric Inflammatory Bowel Disease

15

Lara M. Hart and Mary E. Sherlock

Introduction

Inflammatory bowel disease (IBD) comprises a group of disorders characterized by chronic inflammation of the gastrointestinal tract, with symptoms beginning during childhood or adolescence in about 25% of patients [1]. Although the labels ulcerative colitis (UC) and Crohn disease (CD) are applied to differentiate the two major phenotypic forms, it is recognized that both, and particularly CD, comprise a spectrum of chronic intestinal inflammation, with tremendous variation in phenotypic characteristics such as disease location and extent, behavior (inflammatory, stricturing, or penetrating), severity, responsiveness to therapies, and associations with extraintestinal manifestations [1, 2]. Between 5% and 13% of patients have colitis with clinical or histological features that make it difficult to assign a diagnosis of either CD or UC, and a diagnosis of inflammatory bowel disease-type unclassified *(IBD-U)* is assigned [3–5]. Rates of IBD-U may be higher in very young children, with one study describing this phenotype at diagnosis in 12 of 54 (22%) children presenting prior to 6 years of age [6]. Over time, the true type of IBD may become more evident, and the patient can be re-categorized as having either CD or UC [7]. The EUROKIDS registry, which prospectively collects data on newly diagnosed pediatric patients with IBD in Europe and Israel, found the rate of IBD-U decreased from 7.7% (265/3461) at diagnosis to 5.6% over the course of follow-up or when further diagnostic workup was complete [4].

The first question for the physician is whether the patient has inflammatory bowel disease or if the presentation represents an acute, self-limiting colitis, secondary to infection, ischemia, or other pathology. Increasingly we are recognizing a primary immune dysfunction or deficiency as a cause for the "IBD phenotype" in very young children presenting with IBD-like symptoms. This is an important group to recognize, as immunosuppressive medications may be harmful in this setting and patients may benefit from a more targeted treatment approach, and in some cases, bone marrow transplantation [8, 9].

IBD is confirmed using a combination of clinical, biochemical, endoscopic, and radiologic assessments (described in detail in other chapters in this book), and the patient is given a diagnostic label of CD, UC, or IBD-U. Where possible, the physician should strive to assign a diagnosis of either CD or UC, as this may have therapeutic implications, and is particularly important if a surgical intervention is being considered [2]. Deciding on the type of IBD can be challenging unless features which are diagnostic of CD are present, such as stenosing or penetrating disease behavior, macroscopic skip lesions or small intestinal disease, perianal disease, and granulomata (well formed, and remote from a ruptured crypt) on histology [10]. In addition, there are a number of features such as relative or absolute rectal sparing, peri-appendiceal inflammation (the "cecal patch"), backwash ileitis, and the presence of upper GI tract findings that can make determining the type of IBD challenging. These features are discussed in more detail later in this chapter.

Within each diagnostic category, of either CD or UC, phenotypic classification systems aim to delineate disease location and behavior in CD and disease extent and severity in UC. While classification systems were initially developed with adult patients in mind, a pediatric IBD classification system (the Paris modification of the Montreal classification, hereafter referred to as the Paris classification) was developed and is now in widespread use in both the clinical and research setting [10].

In 2007, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition, led by Dr. Athos Bousvaros (author of an earlier edition of this chapter), developed a detailed document that provided recommendations for assisting pediatric gastroenterologists in distinguishing CD from UC and provided detailed evidence-based directions for gray areas. The authors of this chapter would like to direct readers to this publication as well as the

Paris classification and the revised Porto criteria, all of which contributed to the drafting of this chapter [2, 10, 11].

The first part of the chapter will review the historical perspective, as well as the development and refinement of the IBD phenotypic classifications. The second part of the chapter will describe the challenges of assigning a diagnosis of UC or CD and the use of the IBD classes system to assist in the process.

Phenotypic Classification of IBD: A Historical Perspective

For decades, CD was considered a relatively homogeneous condition, without attempts to further subclassify the phenotype. In 1975, Farmer et al. hypothesized that sites of inflammation influenced outcomes and disease behavior. The group categorized CD into [1] ileocolonic, [2] small intestinal, [3] isolated colonic, and [4] isolated anorectal disease [12]. The authors attempted to correlate clinical symptoms at presentation with disease location. They also described the evolution of disease over time, including the development of rectal and internal intestinal fistulae, growth impairment, intestinal obstruction, and need for surgery. By using categories of disease location, the authors provide some of the earliest data on the potential relationship between phenotype and clinical outcomes and recognized that such correlations might facilitate therapeutic decisions for these patients. Even now, we use disease location to explain the constellation of symptoms (and biochemical marker abnormalities) that occur at diagnosis.

Further consideration toward a phenotypic classification of CD came from Greenstein et al. in 1988 who described two disease behavior patterns, perforating and non-perforating, using a cohort of 770 patients undergoing surgery. Site of inflammation, categorized as ileitis, colitis, or ileocolitis, was associated with type of surgery. Patients with ileal disease were more likely to require surgery for obstructive symptoms in comparison to those with ileocolonic disease, where fistulizing disease was the main surgical indication [13].

These observations that disease location and behavior influence outcomes became the basis of the more rigorously developed Vienna, Montreal, and Paris classifications for IBD [10, 14, 15].

The Vienna Classification [14]

Between 1996 and 1998, an international working group was established to develop and validate a phenotypic classification for CD [14]. The final categories were age at diagnosis (<40 or ≥40 years), disease location (terminal ileum, colonic, ileocolonic, or involvement of the upper GI tract), and disease behavior (non-stricturing non-penetrating, stricturing, or penetrating). While great efforts were made to develop a reproducible and validated phenotypic classification, there were some limitations. The Vienna classification could not distinguish disease location when disease was present in both the upper GI tract along with other intestinal regions or when it occurred in isolation. Likewise, perianal disease was not considered a separate category; rather it was categorized as "perforating" disease behavior, making it impossible to distinguish whether a patient had perianal disease, intestinal fistulizing disease, or both.

The Montreal Classification [15]

The Montreal classification was developed to provide a uniform system of designating subgroups of patients with IBD, with the aim of facilitating multicenter genotype–phenotype correlation studies. It remains the most used classification for adult patients. Unlike earlier classification systems, the Montreal classification includes a phenotypic classification for UC and makes recommendations for assigning the diagnostic label of "inflammatory bowel disease-type unclassified" (IBD-U).

For CD, modifications to the Vienna classification [1] include an additional category to classify children diagnosed at ≤16 years of age, [2] allow for upper GI tract disease to be classified independently of ileocolonic and colonic involvement, and [3] classify perianal disease as a category independent of the "penetrating disease behavior" category.

The group recommends that the maximal disease extent prior to first resection (in those undergoing surgery) is used when considering "disease location." Given the propensity for disease behavior to evolve over time [16], the recommendation of the working group is to wait a minimum of 5 years before definitively assigning a disease behavior for the non-stricturing, non-penetrating category, particularly when data are used as part of research studies.

For UC, the group proposed that patients be classified according to maximal extent of inflammation at any time during follow-up. Maximal disease extent is E3, which denotes any disease extending proximal to the splenic flexure.

When a principal diagnosis of UC or CD cannot be established, the group recommends that the term colonic "IBD-type unclassified (IBD-U)" be assigned. The term "indeterminate colitis" should be reserved for use only after colectomy has been performed, when features of both CD and UC coexist.

The Paris Modification of the Montreal Classification for Pediatric IBD [10]

In 2009, an international group of pediatric IBD experts took on the task of modifying the Montreal classification, to capture aspects of disease phenotype that are pertinent to pediatric patients. Following an extensive literature review, with attention focused on pediatric data, where available, and including recommendations from expert opinion and narrative review, the Paris classification of pediatric inflammatory bowel diseases was published in 2011. The committee also reviewed, and agreed with, the 2007 paper put forward by NASPGHAN and the Crohn and Colitis Foundation of America (CCFA), which provided recommendations for differentiating UC from CD [2].

Novel Features of the Paris Classification

1. *Age*: A new age category, differentiating between patients presenting prior to or after their 10th birthday, was introduced. The new classification proposed that children presenting prior to 10 years of age are designated to the age category A1a, and those presenting between 10 and 17 years are assigned to the category A1b. Disease location in CD at diagnosis appears to be different in these two age groups with the younger group being more likely to have isolated colonic disease rather than ileal involvement. In the older age group, ileal disease (whether isolated or in conjunction with disease in other locations) is more common [6, 17–20]. Phenotypic differences according to patient age are also evident in ulcerative colitis, with a Canadian population-based study finding lower colectomy rates in children diagnosed prior to 10 years of age [21].
2. *Upper GI tract*: The Paris group recognized that the Montreal classification did not optimally describe disease location, particularly regarding the Montreal upper GI tract category (L4), which is unable to distinguish between disease of the small intestine and disease proximal to the ligament of Treitz. The Paris classification recommends that the presence of upper GI tract disease only is assigned in the presence of macroscopic disease, as there is no literature to suggest that histologic involvement alone influences disease progression or phenotypic classification over time. The presence of mucosal erythema or granularity is not sufficient to be considered as macroscopic disease. The Paris group subdivided the L4 Montreal category for upper GI tract disease into L4a (denoting disease proximal to the ligament of Treitz) and L4b (denoting disease distal to the ligament of Treitz).
3. *Disease behavior*: Disease behavior is inflammatory (B1) at diagnosis for the majority of patients but may evolve into a more complicated phenotype, stricturing (B2), or penetrating (B3) over time. The Paris classification allows capture of patients with both concomitant stricturing and penetrating behavior (B2B3 category).
4. *Disease location*: Since most pediatric patients with UC have extensive disease at presentation [17] (especially in comparison to adult patients), the Paris classification includes an additional category for disease extension proximal to the hepatic flexure (E4).
5. *Disease severity*: The Pediatric Ulcerative Colitis Activity Index (PUCAI) is used to determine whether or not a patient has ever had severe disease (PUCAI $\geq$ 65) [22]. The Paris classification incorporates disease severity, as studies have found that colectomy rates are higher in this patient group [23].
6. *Growth impairment*: Pertinent only to pediatric patients is the ability to capture growth impairment as part of the classification of disease [24, 25]. A growth category was introduced, which identifies normal growth at diagnosis and over the course of follow-up (G0), or impaired linear growth (using height velocity *Z*-scores) at any time point (G1). *Z*-scores should be adjusted for age (or bone age when delayed) and sex.

The Paris group also described a list of features that should direct the physician to consider a diagnosis of CD:

1. Perianal disease
2. Microscopic skip lesions
3. Stenosis, cobblestoned mucosa, and linear ileal ulcers (even in the setting of pancolitis)
4. Macroscopic inflammation of the ileum in the absence of cecal inflammation
5. The presence of a well-formed granuloma at a site that is not adjacent to a ruptured crypt
6. Absolute rectal sparing (no macroscopic or histologic features of inflammation)

The group advised that the finding of a few small ulcers in the small intestine during capsule endoscopy should not preclude the diagnosis of UC (if other features point to this diagnosis) since these may be nonspecific and are sometimes seen in healthy people.

A summary of the Paris classification of pediatric IBD is represented in Table 15.1

Table 15.1 Paris classification of inflammatory bowel disease (Adapted from Levine at al. [10])

Crohn disease	
Age at diagnosis	Location
A1a <10 years A1b 10–≤17 years A2 17–40 years A3 >40 years	L1 Distal 1/3 ileum ±limited cecal disease L2 Colonic L3 Ileocolonic L4a[a] Upper GI disease proximal to Ligament of Treitz L4b[a] Upper GI disease distal to Ligament of Treitz but proximal to distal 1/3 ileum
Behavior	Growth
B1 Non-stricturing, non-penetrating B2 Stricturing B3 Penetrating B2B3 Stricturing **and** penetrating P Perianal disease modifier[b,c]	G0: No evidence of growth delay at diagnosis and subsequently G1: Growth delay at any time (at diagnosis or over the course of follow-up)
Ulcerative colitis	
Disease extent	Definition
E1 Ulcerative proctitis E2 Left-sided disease E3 Extensive disease E4 Pancolitis	Disease limited to the rectum Disease distal to the splenic flexure Disease proximal to the splenic flexure but not extending proximal to the hepatic flexure Disease extends proximal to the hepatic flexure
Severity	Definition
S0 S1	Never severe (PUCAI score never ≥65) Ever severe (PUCAI score ≥ 65 at least once during course of follow-up)

[a]L4a and L4b can coexist with L1, L2, or L3 or can occur in isolation
[b] Perianal disease can coexist with any behavior B1, B2, B3, and B2B3
[c] Perianal disease is present if there are fistulae, abscesses, or anal canal ulcers. Skin tags do not form part of the definition of perianal disease

The Porto Criteria and the Revised Porto Criteria

In 2005, the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) working group, consisting of 23 pediatric gastroenterologists from 12 European countries, published the Porto criteria which outlined criteria for diagnosing IBD and made recommendations for diagnostic workup [26]. The group recommended that symptoms should be present for a minimum of 4 weeks or that episodes have occurred at least twice within a 6-month period. Typical presenting symptoms of IBD, which are discussed in greater detail in another chapter of this book, include abdominal pain, diarrhea, weight loss, extraintestinal manifestations, and growth failure, the latter being more prominent in Crohn disease [27]. Other symptoms such as malaise, unexplained anemia (in the absence of gastrointestinal symptoms), and delayed puberty may also be manifestations of IBD, and physicians should maintain an index of suspicion when investigating patients with these symptoms.

The Porto criteria were revised in 2014, using an extensive evidence-based and iterative approach to develop recommendations and an algorithm for the evaluation of a pediatric patient with suspected IBD [11]. The new criteria consist of 12 recommendations, incorporating the Paris modification of the Montreal classification, the original Porto criteria, and consideration of fecal and serum biomarkers. The revised document also provided several practice points when suspecting the diagnosis of IBD:

(a) Enteric infections should be excluded before endoscopy; however, identifying a pathogen does not exclude the possibility of IBD, as the first episode or flare of disease can be triggered by an enteric infection (tests should include stool culture and C. difficile, as well as parasites such as Giardia lamblia, if in a high risk or endemic area)
(b) Fecal calprotectin is superior to blood markers for detection of gastrointestinal inflammation; however, it is not specific for IBD and does not differentiate UC from CD. Further, normal blood tests do not exclude the diagnosis of IBD (54% of mild UC and 21% of mild CD patients presented with normal labs in a study by Mack et al. [28].
(c) Low serum albumin can identify protein losing enteropathy, but also reflect disease activity and severity, as well as nutritional status.

The revised Porto criteria [11] introduced the idea of typical versus atypical UC as a new category for "type of IBD." The group felt that the previous definition of superficial disease, starting in the rectum and extending proximally, was too simplistic. Figure 15.1, from the Porto Group, provides an algorithm for assigning type of IBD, which considers atypical variants of UC. This creates four subtypes of IBD: UC, atypical UC, CD, and IBD-U.

Five different "atypical UC" variants are presented:

1. Macroscopic rectal sparing—the Paris classification [10] specifies that there must be at least microscopic inflammation in order to still consider a diagnosis of UC. However, macroscopically, there may be partial or complete rectal sparing. This was based on studies that found 5–30% of children with UC had macroscopic rectal sparing [11].
2. Histologically patchy disease—disease may be patchy (histologically), early in the disease course when the duration of symptoms is short. In addition, in children less than 10 years old or early in diagnosis, features of chronicity, such as architectural distortion may be absent.
3. Cecal patch—this can occur in children with left-sided UC and isolated inflammation in the cecum, usually periappendiceal in location, with normal intervening mucosa [29–31].

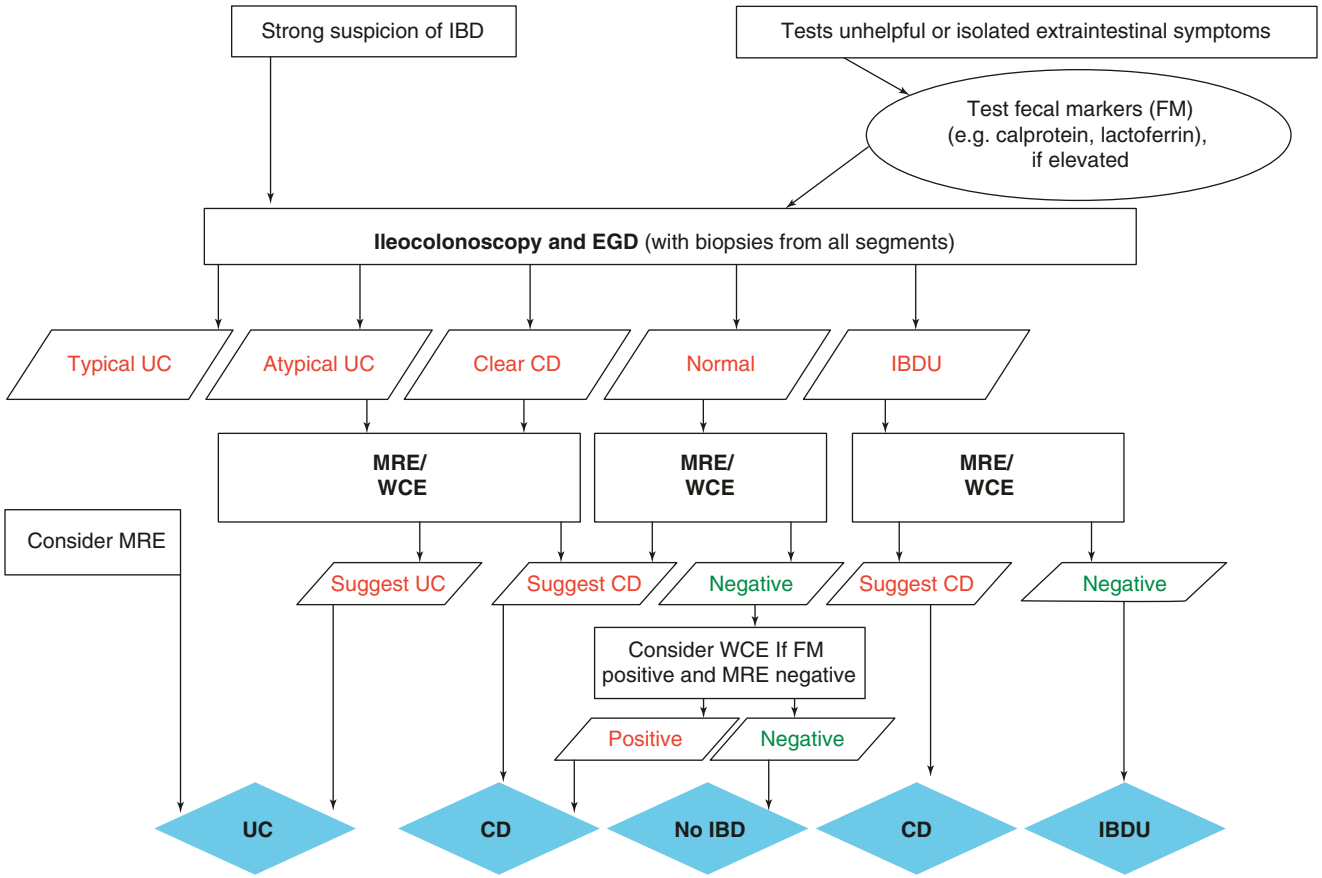

Fig. 15.1 Evaluation of child/adolescent with intestinal or extraintestinal symptoms suggestive of IBD. Atypical UC is a new IBD category consisting of five phenotypes defined in Table 15.1, and reflects a phenotype that should be treated as UC. IBD-U may be entertained as a tentative diagnosis after endoscopy, and can be used as a final diagnosis after imaging and a full endoscopic workup. UC is divided into typical and atypical UC. *CD* Crohn disease, *EGD* esophagogastroduodenoscopy, *FM* fecal marker, *IBD* infammatory bowel disease, *MRE* magnetic resonance enterography, *UC* ulcerative colitis, WCE wireless capsule endoscopy. Reprinted from Levine et al. [11], Fig. 1, page 797, with permission

4. Upper GI tract involvement—gastric erosions and mild ulcerations of the stomach (as well as microscopic involvement) can occur in UC. The presence of focal active gastritis or chronic gastritis can be present in both UC and CD [32]. The EUROKIDS registry described gastric erosions or small ulcers in 4.2% of pediatric UC patients [33].
5. Transmural inflammation with or without deep ulcers—this may be present in acute severe UC, as a marker of disease severity. In UC, the ulcers may be fissuring or V-shaped and lymphoid aggregates may be absent. However, most of these patients would likely be given the diagnostic label "IBD-U," but the disease may declare itself as UC over time.

The features of classic CD are described elsewhere in this book. However, even with isolated colonic disease, there would be no dispute on the diagnosis of CD for patients with cobblestoning of the mucosa, skip lesions (with microscopically normal mucosa in between), or well-formed non-caseating granulomas (remote from ruptured crypts). Other resolute features of CD include linear ulcers in the ileum, ileal inflammation with normal cecum, perianal disease (fistulae, abscesses, or large inflamed skin tags), and the presence of complicated disease behaviors such as stricturing or penetrating disease. Involvement of the small intestine with reliable interpretation of imaging would also point to a diagnosis of CD.

The Porto Group defined IBD-U as inflammation limited to the colon, but with features that make it difficult to differentiate between UC and CD. IBD-U is the phenotype chosen in children in 4–29% of cases (versus <10% in adults). Particularly in young children, colonic involvement in CD may be continuous, making it difficult to distinguish from UC (hence, the consideration for IBD-U classification). The group developed a general scheme of features of UC (or atypical UC) and classic CD. The latter was termed "class 1." As well, they identified and listed features that are "rare with UC" (<5%), termed "class 2" or "uncommon with UC" (5–10%), termed "class 3." If one "rare" (class 2) or two

"uncommon" (class 3) features are present, the group proposed that the IBD subtype should be labeled as IBD-U.

IBD-unclassified (IBD-U) and PIBD Classes

Using the previously defined IBD-U criteria,, the Porto Group validated the PIBD classes to provide a more comprehensive algorithm for labeling a patient as UC, CD, or IBD-U. This was done through a multicenter retrospective longitudinal study from 23 centers and involving 749 children with colonic IBD. A hypothesis-driven judgemental algorithm was chosen, with 80% sensitivity/84% specificity to differentiate UC from CD and IBD-U and 78% sensitivity/94% specificity to differentiate CD from IBD-U and UC [34].

The PIBD classes were further appraised and validated in a cohort of 184 children with all IBD subtypes (rather than just colonic). The group compared the PIBD classes classification to physician-assigned diagnosis. The criteria were also assessed for redundant and unnecessary items, and simplified to 19 items (from 23). In the proposed simplified PIBD classes, item 4 and 14 were removed. Further, items 12–13 were combined into one item, as were 17–18 [35].

Thus, the PIBD classes algorithm (Table 15.2 and Fig. 15.2) proposes to give a more consistent definition of IBD-U. This allows for a more standardized approach to IBD subtypes for both clinical and research purposes. While this tool is very helpful, it is important to remember that it is also relatively new. In a study that compared the PIBD classes to colectomy specimens of children, there was only fair agreement between PIBD class diagnosis and pathology diagnosis

Table 15.2 Original PIBD classes. Adapted from Birimberg-Schwartz et al. [34]

Class	Features
1 (not compatible with UC)	1. 1+ well-formed granuloma remote from a ruptured crypt (anywhere in the GI tract) 2. 1+ deep ulcers, cobblestoning, stenosis in small bowel, or esophagus 3. Fistulizing disease (internal or perianal) 4. Large inflamed perianal skin tags 5. Thickened jejunal or ileal walls or significant small bowel inflammation (on imaging) 6. Any ileal inflammation with normal cecum
2 (rare with UC)	7. Macroscopic and microscopic skip lesions (excluding rectal sparing and cecal patch) 8. Complete (macroscopic and microscopic) rectal sparing 9. Relative patchiness—macroscopically normal colon between areas of inflamed colon, but with microscopic inflammation 10. Significant growth delay with no alternative cause[a] (height velocity <-2SD) 11. Transmural inflammation of the colon without severe colitis 12. Small and not deep ulcers (includes aphthous ulcers) in the small bowel, duodenum, or esophagus, not explained by other causes 13. ≥5 small and not deep ulcers in the stomach or colon on the background of normal mucosa (and not explained by other causes[b]) 14. Backwash ileitis but with only mild inflammation in the cecum (therefore, not true backwash ileitis) 15. Positive ASCA and negative pANCA 16. Reverse gradient of mucosal inflammation in the colon (more severe proximally and milder distally) 17. Severe scalloping of the stomach or duodenum (without other cause[b]) 18. 1+ deep ulcer or severe cobblestoning in stomach (without other cause[b])
3 (uncommon with UC)	19. Focal chronic duodenitis on histology 20. 2+ biopsies with focal active colitis 21. <5 aphthous ulcers in the colon or stomach 22. Non-bloody diarrhea 23. Focal-enhanced gastritis on histology

[a]Other causes: celiac disease, prolonged steroid use, growth hormone deficiency
[b]Other causes: *H. pylori*, celiac disease, NSAIDs

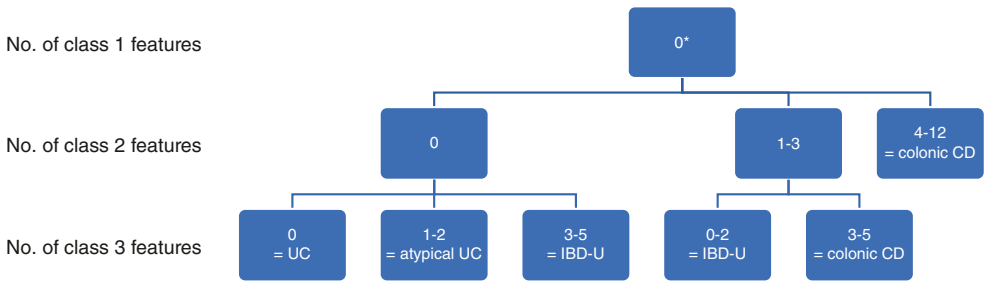

Fig. 15.2 Proposed algorithm for assigning "IBD subtype" using the PIBD Classes system. *If one or more class 1 features are present, this would be indicative of CD (and not compatible with UC). Adapted from Birimberg-Schwartz et al. [34].

[36]. Of note, three children were incorrectly given a diagnosis of CD based on a single class 1 feature. Further, two of the class 3 features were found to have a prevalence higher than the expected 10%—focally enhanced gastritis and focally enhanced duodenitis [36].

Special Considerations

Table 15.3 provides additional details around specific features that can help when assigning a diagnostic phenotype.

Evolution of Disease Phenotype

Disease phenotype in both adult and pediatric patents is not static [16, 53–55]. This represents a challenge when phenotyping both groups of patients. When the Montreal classification was proposed, the authors recommended waiting for 5 years, or until the time of surgery (whichever was sooner), before assigning a disease behavior. However, in reality, patients are being entered into prospective clinical and research registries requiring a phenotypic classification to be assigned at diagnosis.

Table 15.3 Special considerations when determining the IBD subtypes of CD versus UC

Cecal patch	
Described with variable frequency. The prevalence of a cecal patch in pediatric patients with UC is much lower than rates reported for adult patients. The EUROKIDS Registry assessed 643 pediatric patients with UC and found that only 2% met criteria for a cecal patch [33]. This likely reflects the fact that most pediatric patients with UC have pancolitis at presentation	
Macroscopic features Diffuse hyperemia (non-circumscribed margins) with discrete white punctate patches, erosions, or microulcers + friability Can be isolated to the cecum or include the ascending colon (but normal transverse colon)	**Histologic features** Crypt architectural changes of chronicity + findings of acute inflammation
Sources: Levine et al. (EUROKIDS registry) [33], de Roche et al. [37], Ekanayaka et al. [38]	
Backwash ileitis	
This is a nonspecific ileitis which can be seen only in the setting of pancolitis. There are no deep ulcerations, cobblestones, or strictures, which would be in keeping with Crohn ileitis and inflammation is typically limited to the distal 10 cm of terminal ileum. [2] In the absence of cecal inflammation, a diagnosis of backwash ileitis should not be made. Backwash ileitis has been described in close to 20% of adult patients with pancolonic UC [39, 40]. In the EUROKIDS registry, endoscopic evaluation of the terminal ileum was available in 296 of 397 (75%) patients with UC, with 10% having macroscopic terminal ileum abnormalities [33]. Sahn et al. have proposed a model that may be helpful to distinguish backwash ileitis from CD, using histologic and clinical variables [41]	
Macroscopic features Erythema, granularity; allowed to have aphthous ulcers but not deep or linear ulcers Only short segment of terminal ileum involved	**Histologic features** Neutrophilic cryptitis without surface ulceration Can have superficial small ulcers, mild villous atrophy and lymphocytic infiltration Generally, no erosions or ulcers Crypt abscesses uncommon No pyloric gland metaplasia No crypt distortion or features of chronicity No lamina propria (LP) expansion or acute LP inflammation May have mild degree of villous atrophy
Sources: Bousvaros et al. [2], Levine et al. (Porto Group) [11], Levine et al. (EUROKIDS registry) [33], Haskell et al. [39], Heuschen et al. [40], Sahn et al. [41], Fausel et al. [42], Putra et al. [43]	
Rectal sparing	
Absolute rectal sparing refers to normal macroscopic and microscopic findings in the rectum, while *relative rectal sparing* is said to be present when inflammation in the rectum is less severe than the remainder of the colon [2]. In the majority of patients, the presence of absolute rectal sparing will point a physician toward a diagnosis of CD or at least IBD-U. However, there are a minority of UC patients who have relative rectal sparing. Glickman compared mucosal biopsies from 73 pediatric and 38 adult patients newly diagnosed with UC. Among the pediatric group, relative rectal sparing was present in 23% of patients and absolute rectal sparing in 3% of patients, features which were not seen in the adult group [44]. Washington et al. [45] also examined rectal biopsy specimens from adult and pediatric patients with UC and found that children more frequently lacked classic histologic features and felt this may have been the result of shorter duration of inflammation in the pediatric group prior to diagnosis. In a small series of 30 pediatric patients with newly diagnosed UC, Rajwal et al. [46] found that 7% had macroscopic rectal sparing. The EUROKIDS registry described macroscopic rectal sparing in 28 of 553 (5%) UC patients. Rectal sparing was more common in younger patients (mean age of 9.9 years versus 11.8 years at diagnosis). The finding was also more prevalent in those with extensive (E3) or pancolitis (E4) than those with left-sided disease (6% vs. 1%, $P = 0.04$). Rectal sparing was also more likely to be present in patients diagnosed earlier in their disease course [33]

(continued)

Table 15.3 (continued)

Cecal patch	
Upper gi tract (UGIT) inflammation	
The reported prevalence of upper GI tract disease in pediatric IBD patients is variable and may be related to the definitions used, with some centers reporting upper GI tract disease only when macroscopic disease is present, whereas other investigators consider upper GI tract disease to be present even when findings are only histologic. While deep ulceration and granulomas in the esophagus, stomach, or duodenum are suggestive of CD, the presence of nonspecific or microscopic inflammation in the upper GI tract should not preclude a diagnosis of UC if other features best fit this diagnosis. Isolated upper GI tract inflammation was described in 4% of children with Crohn disease in the EUROKIDS registry	
Macroscopic features May see erosions or small gastric ulcers, but not linear or serpiginous ulcers in UC [11] Ulcers, erosions, aphthous lesions, and cobblestone mucosa described in approx. 18% of CD patients in the EUROKIDS registry. Nonspecific macroscopic upper GI tract inflammation is present in up to 30–64% of CD patients [27, 47] and up to 50% of patients with UC [48, 49]	**Histologic features** [50] Duodenitis (0–29% UC, 33–38% with CD)—cryptitis (chronic active duodenitis), villous blunting, IELs, eosinophils Lymphocytic esophagitis (7% UC, 12–28% with CD) Gastritis: Focal-enhanced gastritis + superficial plasmacytosis Granulomas, not associated with crypt rupture: CD, not a feature of UC
Sources: Levine et al. [11], Sawczenko et al. [27], Lenaerts et al. [47], Tobin et al. [48], Ruuska et al. [49], de Bie et al. (EUROKIDS registry) [51], Abuqteish et al. 2019 [50], Levine et al. (EUROKIDS registry) [33]	
Acute severe colitis (fulminant colitis)	
Fulminant ulcerative colitis may have features that appear similar to Crohn disease	
Macroscopic features [37, 52] Can have rectal sparing and linear deep ulcers Can have "well like" ulcers (aphthous ulcers that have penetrated through muscularis mucosa)	**Histologic features** Focal transmural inflammation near deeply ulcerated areas can be seen No transmural lymphoid aggregates (away from ulcerations)
Sources: DeRoche [37], Magro et al. [52]	

It is important to remember the potential for evolution of the IBD phenotype, both in terms of IBD subtype, as well as disease behavior and location in CD and disease extent in UC. Adult CD studies, particularly in the pre-biologic era, have described relatively high rates of progression to penetrating and stricturing disease [53]. In a pediatric CD cohort of over 700 patients, progression of disease location was seen in 20%, change in disease behavior to stricturing or penetrating disease in 38% and new perianal involvement was found in 20% of patients [56]. A large prospective study of new-onset pediatric Crohn disease, involving 28 sites in North America and Canada (the RISK study), found that early use of biologic therapy was associated with a decrease in the development of penetrating disease behavior, but did not influence the occurrence of stricturing disease [57]. Burisch et al. found that approximately a third of patients (predominantly adults) with limited UC progressed, in terms of disease extent, over a 7-year follow-up period [58]. In a pediatric UC study, disease extension has been reported in 30% of patients who initially had limited disease, although half of the children studied had extensive disease at the time of presentation [59].

For some patients, the type of IBD (CD, UC or IBD-U) will change over time. Everhov et al. studied over 44,000 (approx. 4600 were children) patients using health administrative data. For the pediatric patients, over time, the diagnosis of pediatric CD increased from 43% to 44%, while UC decreased from 45% to 38% and IBD-U increased from 12% to 18% [60].

It is important that patient registries continue to have the ability to capture change in disease phenotype and assessments at multiple time points should be recorded. This will allow assessment of natural history as well as the impact of therapies on disease evolution.

Future Directions

Classification of IBD has progressed well beyond the classic categories of CD, UC, or indeterminate colitis. The advent of the Montreal classification and the subsequent Paris modification for pediatric IBD have allowed for granularity in the description of IBD phenotype for both clinical and research purposes. While these classification systems have been extremely valuable, disease location, and severity do not tell the full story of IBD. Some have suggested adding histology to the macroscopic description of the Paris modification to improve descriptive capability [61]. Further modifications for age and inclusion of very early onset IBD (VEO-IBD) should also be considered, as this group of patients have different disease prognosis and response to therapy [8, 9]. In addition, with advances in characterization of the role of gene, environment, and microbiome interactions and their effect on disease phenotype, we anticipate that future classification systems will incorporate new disease location categories, histology findings, protein expression characteristics, microbiome and metabolomic patterns, and other factors. In

the era of personalized medicine, treatment choice will depend on many more factors than those described in current classification systems. We anticipate that definition of the inflammatory bowel diseases will consist of a continuum of categories resulting in even more power to describe the disease characteristics of a child with IBD.

Acknowledgments We are grateful to Dr. Athos Bousvaros and Dr. Eric Benchimol who authored earlier editions of this chapter and allowed their use as the basis for this latest edition.

Part III

Diagnosis

The History and Physical Exam

16

Steven Fusillo and Arthur J. Kastl Jr

Introduction

A thorough history and physical exam are essential elements in caring for all patients. A thoughtful interview with the patient and family will uncover clues which help focus not only the physical exam, but subsequent diagnostic evaluation. The history and physical exam also form the basis of indices like the Pediatric Crohn Disease Activity Index (PCDAI) (Table 16.1) and Pediatric Ulcerative Colitis Activity Index (PUCAI) (Table 16.2), among others, which are used in research and certain clinical settings [1, 2].

Table 16.1 Pediatric Ulcerative Colitis Activity Index (PUCAI) [1]

Item	Points
1. Abdominal pain:	
No pain	0
Pain can be ignored	5
Pain cannot be ignored	10
2. Rectal bleeding	
None	0
Small amount only, in less than 50% of stools	10
Small amount with most stools	20
Large amount (>50% of the stool content)	30
3. Stool consistency of most stools	
Formed	0
Partially formed	5
Completely unformed	10
4. Number of stools per 24 h	
0–2	0
3–5	5
6–8	10
>8	15
5. Nocturnal stools (any episode causing wakening)	
No	0
Yes	10
6. Activity level	
No limitation of activity	0
Occasional limitation of activity	5
Severe restricted activity	10
Sum of PUCAI (0–85)

History

A comprehensive patient history is the crucial first step in establishing clinical suspicion for IBD. Pediatric patients with IBD can present with an array of symptoms, including but not limited to abdominal pain, diarrhea, rectal bleeding, weight loss or growth failure, fever, fatigue, pallor, or extraintestinal manifestations. Presenting symptoms often differ based on the location and extent of disease involvement. Ulcerative colitis most commonly presents with bloody diarrhea, abdominal pain around bowel movements, and tenesmus, while Crohn disease involving the small bowel may have a more insidious course with progressive abdominal pain and weight loss. The frequency of presenting symptoms for ulcerative colitis (UC) and Crohn disease (CD) are summarized in Table 16.3 [3, 4].

Careful attention to pain patterns can reveal important clinical insights. Patients with esophageal ulcerations may complain of odynophagia or dysphagia while eating, or heartburn after meals. Gastritis or duodenitis may result in epigastric pain, early satiety, or vomiting. Small bowel inflammation is frequently associated with bloating and generalized malaise, while intestinal strictures may lead to abdominal distention, nausea, and vomiting developing an hour or so after meals. Crampy lower abdominal pain, often accompanied by defecation urgency, tenesmus, and hematochezia, typically reflects colonic and rectal inflammation. Nocturnal awakening due to abdominal pain is unlikely to be functional in nature and should raise suspicion for underlying pathology. It is important to note that children often underreport pain, and young patients may have difficulty characterizing or localizing their pain.

Table 16.3 Frequency of presenting symptoms in inflammatory bowel disease [3, 4]

Symptom	UC (%)	CD (%)
Abdominal pain	33–76	62–95
Diarrhea	67–93	52–78
Rectal bleeding	52–97	14–60
Weight loss	22–55	43–92
Fever	4–34	11–48
Delayed growth	6	30–33
Perianal disease	0	25
Extraintestinal manifestations	2–16	15–25

Information regarding patient bowel patterns can be difficult to ascertain but crucial to the clinical picture. Parents generally do not witness their child's stool beyond the toilet-training period. Many adolescents never look in the toilet or are apprehensive to discuss bowel habits. Parents may be able to provide useful clues such as observing their child making frequent trips to the bathroom or constantly cleaning residual loose stool or blood from the toilet bowl. Individuals may have different definitions of diarrhea, and thus, it is important to ask the patient or caregiver to describe the bowel movement in some detail. Directed questions such as whether stools are entirely watery, are partially formed but disintegrate when hitting the water may be helpful. The frequency of bowel movements as well as the presence of urgency, tenesmus, or blood can help assess the severity of colitis. When rectal bleeding is present, the frequency, quantity, and color (e.g., bright red versus maroon) should also be disclosed. As with awakening for pain, nocturnal bowel movements should never be considered normal and are a "red flag" for intestinal inflammation.

Patients with IBD often present with weight loss and, unique to the pediatric population, growth failure and pubertal delay. Growth failure is more common in Crohn disease, present in 10–40% of pediatric patients at the time of diagnosis, and less common in ulcerative colitis [5]. Growth curves from the primary care provider should be reviewed in detail, as decelerations in height or weight velocity may occur long

Fig. 16.1 Erythema nodosum

Fig. 16.2 Pyoderma gangrenosum

before the onset of clinical symptoms. Conversely, the presence of overweight or obesity should not preclude the diagnosis of IBD [6].

Extraintestinal symptoms are common in children with IBD and may involve dermatologic, ophthalmologic, musculoskeletal, hepatic, pancreatic, renal, or hematologic systems. These manifestations may predate gastrointestinal symptoms by several years, and as such, may be the sole presenting symptoms in some children [7]. Arthritis is most common, and approximately 4% of patients with IBD will present with arthritis as the predominant symptom. The arthritis associated with IBD is typically pauciarticular and involves large joints, and pain tends to be worse in the mornings. Some patients may first present to the pediatrician or dermatologist with painful, non-specific rashes, commonly involving the lower extremities. A large fraction of children presenting with erythema nodosum (Fig. 16.1) or pyoderma gangrenosum (Fig. 16.2) will be found to have IBD. Patient may also first come to medical attention with recurrent oral ulcers or other mucocutaneous lesions [8].

Patients with Crohn disease may present first to the surgeon with recurrent perianal abscess, small bowel obstruction, or an appendicitis-like picture. Free perforations are occasionally seen. Patients with Crohn disease may develop fistulae, or communications between bowel and bowel, bowel and skin, or bowel and genitourinary tract. Unless specifically asked, patients may not mention the presence of fecal material in the urine or vagina.

It is important to obtain detailed past medical and family histories, with a focus on gastrointestinal and autoimmune conditions. IBD is more likely in patients with a personal or family history of other autoimmune diseases, such as celiac disease, type 1 diabetes mellitus, autoimmune thyroid disease, primary sclerosing cholangitis, autoimmune hepatitis, lupus, or rheumatoid arthritis. Patients with first-degree relatives with IBD are 3–20 times more likely to develop IBD than the general population [9, 10]. A detailed history of infection and antibiotic use, as well as a thorough social history including any recent travel or potential exposures, should be routinely obtained.

Physical Exam

After taking a thorough history, the physical exam will often confirm or revise your impression. There are several key elements of an exam to focus on as you are evaluating a patient with IBD, including general appearance, vital signs, growth parameters, and several body systems. The first and most easily apparent part of the physical exam is the patient's general appearance, and having an accurate impression of this is

important in triaging the need for urgent care. Does the patient seem alert and energetic, or fatigued and withdrawn? Are they in distress? It may be helpful to ask for the parents' viewpoint on this matter, as they are likely the closest observers of the patient. It is also imperative to review vital signs, as active disease can contribute to fevers, tachycardia, and dehydration. The basis of these vital sign changes may be broad, including secondary to pain, anemia, and disease complications, among others. A patient with a toxic appearance and vital signs warrants urgent evaluation.

Careful review of growth metrics is important for characterizing a patient's global nutritional status, which often is closely linked to disease activity and subsequent symptoms. As a patient becomes malnourished, there will be a decrease, or "drifting" first of weight velocity, and if long standing, then followed by stunting of height velocity. While malnutrition is more common for patients with Crohn disease, particularly with small bowel involvement, patients with UC can lose significant weight through stool losses and poor appetite [11]. As mentioned in the History section above, for children affected during the peri-pubertal years, poor disease control can contribute to delayed sexual maturity. Thus, performing a genital exam for Tanner staging is an important part of growth and nutrition assessment.

The examination of the digestive system is central to diagnosis and monitoring of patients with IBD. Visceral pain is poorly localized, whereas parietal pain is more focal at the point of pathology. In patients with IBD, localized pain could arise due to inflammatory masses, abscesses, enterocutaneous fistulas, or mimickers like appendicitis, hernias, or ovarian pathology. Large inflammatory masses, which are often in the ileocecal region, may be palpated on exam. Abdominal distension with borborygmi, especially with the history of poor appetite, nausea, and vomiting, is a worrisome finding and should raise suspicion for bowel obstruction. Complete absence of bowel sounds in an ill-appearing child should increase suspicion for toxic enterocolitis, and trigger urgent evaluation.

The oral examination is also important in identifying ulcerations and/or orofacial granulomatosis [12]. Abnormal tongue appearance, poor gingival health, and tooth decay can be a sign of micronutrient deficiencies and can guide subsequent evaluation. For example, an enlarged and smooth-appearing tongue is characteristic of glossitis. Glossitis could result from B12 deficiency, which can occur in patients with distal ileal Crohn disease and/or in those with prior ileocecectomy [13]. Angular cheilitis may signify B vitamin and iron deficiency, which could suggest active disease and/or malabsorption. The perianal and rectal examinations may be overlooked but are of central importance in evaluating patients with IBD. Skin tags, particularly large ones and those not at the 12 o'clock position, may be present in a subset of patients with Crohn disease. The same is true for perianal abscesses and fistulae, which are often marked by erythema, induration, tenderness, and fluctuance [14]. Rectal examination may reveal stricturing disease which would also be characteristic of Crohn disease and less commonly UC. For patients with significant perianal and anorectal disease, it may be necessary to do an examination under sedation in order to have a thorough assessment.

Extraintestinal manifestations of IBD are present in roughly 15–20% of cases at presentation. They may develop later in the disease course, or particularly for erythema nodosum and arthritis, may be the only physical exam finding at presentation [12]. Extraintestinal conditions may involve the eye, skin, joints, other abdominal viscera, and other body systems. They are often associated with colonic disease but do not necessarily correlate with disease activity [7]. In some patients, they may be entirely idiosyncratic. In terms of ocular findings, episcleritis and/or scleritis may occur in <5% of patients with IBD, which on exam appears as redness of the ciliary vessels and injection of the episcleral tissue [15]. Uveitis is less common than episcleritis, but its consequences are potentially more severe [16]. Uveitis is often bilateral, posterior to the lens, and more common in females [17]. It is also important to be observant for cataracts, which may develop in patients who have been chronically treated with glucocorticoids and stress the importance of regular eye examinations. Several skin findings may be seen in patients with IBD, including not only most classically erythema nodosum and pyoderma gangrenosum, but also psoriasis and hidradenitis suppurativa. Erythema nodosum will appear as painful and raised lesions, about 1–3 cm in diameter, and most commonly occurring on the shins. It is more commonly seen in patients with Crohn disease compared to ulcerative colitis and usually resolves when therapy is started [12]. Pyoderma gangrenosum is a dramatic rash involving frank ulceration and is more often seen in patients with ulcerative colitis [12]. This rash similarly responds to immunosuppression. Psoriasis is also associated with IBD and may occur concurrently, or secondary to therapy, most notably the anti-tumor necrosis factor-alpha class [18]. Psoriatic lesions may occur anywhere on the skin. The painful axillary and inguinal nodules of hidradenitis suppurativa are reported most in adult literature but have been described in adolescents [19]. Lastly, the practitioner should consider a full dermatologic examination, at least yearly, paying close attention to any skin lesions concerning for malignancy. If present, additional evaluation by a Dermatologist should be considered.

Up to 20% of patients with IBD have arthralgia within the first few years or after diagnosis, and about 5% have arthritis [20]. Arthritis is more common in children with Crohn disease compared to ulcerative colitis, and particularly so with Crohn colitis. The arthritis usually affects the larger joints, is non-erosive, and mirrors the status of the intestinal disease [15]. By contrast, axial skeletal involvement including sac-

roiliitis or ankylosing spondylitis, is less common and may have its own trajectory independent of the gastrointestinal disease [15].

Jaundice and pruritis in a patient with IBD, particularly ulcerative colitis, may reflect primary sclerosing cholangitis (PSC) [21]. The severity of PSC is not correlated with the colitis disease activity. Other rarer conditions that are associated with IBD include thromboembolism, nephrolithiasis, cholelithiasis, osteopenia, pancreatitis, and granulomatous inflammation of other body sites.

Summary

A careful history and physical exam may reveal important information regarding the diagnosis of IBD, deciphering disease location, and activity level, and identifying complications of the disease.

Differential Diagnosis of Inflammatory Bowel Disease

17

Raphael Enaud and Thierry Lamireau

A diagnosis of inflammatory bowel disease (IBD) is usually suspected in patients with chronic digestive symptoms, especially diarrhea (with or without blood in the stools), abdominal pain, and poor weight gain. Numerous other diseases can have similar symptoms. For some of them, laboratory investigations, endoscopic and even histological features may be difficult to distinguish from those of ulcerative colitis (UC) or Crohn disease (CD).

In the short term, the most important challenge is to rule out an infectious disease. In the long term, the differential diagnosis with other chronic diseases, such as eosinophilic gastroenteropathy, vasculitis, lymphoma, or immunodeficiency syndromes, may cause some diagnostic difficulties.

In some cases, the possibility of IBD, mostly CD, is considered in a child presenting with abdominal mass, isolated esophagogastroduodenal, or perineal involvement.

Acute Onset Diarrhea

In 10 to 20% of adults with IBD, patients present with apparently transient diarrhea, abdominal cramps, and low-grade fever [1]. In this acute onset disease, the diagnoses to be considered are mostly intestinal infection, food allergy, and acute appendicitis.

Intestinal Infection

In the case of acute diarrhea, patients are thought to have *viral gastroenteritis* particularly if they appear to recover promptly. However, prolonged diarrhea, right lower quadrant tenderness, or a slow recovery should alert the physician to the possibility of early IBD. A *bacterial or parasitic infection* of the intestine can also be responsible for prolonged symptoms. Stool sample should, therefore, be collected for culture and toxin assays that can identify one of the numerous pathogens responsible for intestinal infection (Table 17.1). In the last years, development of multiplex gastrointestinal pathogen panel tests allows to simultaneously

Table 17.1 Laboratory tests used to detect enteropathogens

Laboratory test	Organism suggested or identified
Microscopic stool examination	
• Fecal leukocytes	Invasive or cytotoxin-producing bacteria
• Trophozoites, cysts, oocysts, or spores	*Giardia lamblia*, *Entameoba histolytica*, *Schistosoma mansoni*
• Spiral or S-shaped gram-negative bacilli	*Campylobacter*
Stool culture	
• Standard	*Escherichia coli*, *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*
• Specific selective medium	*Clostridium difficile*, *E coli O157:H7*
(to be specified to the laboratory)	*Aeromonas*, *Plesiomonas shigelloïdes*, *Klebsiella oxytoca*, *Vibrio parahemolyticus*
Stool cytotoxicity assay	*Clostridium difficile* (A or B toxin)
Stool Multiplex gastrointestinal pathogen panel tests (PCR)	*Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, *E coli*, *Klebsiella oxytoca*, *Clostridium difficile*
	Adenovirus, *Astrovirus*, *Norovirus*, *Rotavirus*, *Sapovirus*
	Cryptosporidium, *Cyclospora*, *Entameoba histolytica*, *Giardia lamblia*
Culture of colonic biopsy sample	*Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, *Klebsiella oxytoca*, *E coli O157:H7*
PCR on colonic biopsy sample	*Mycobacterium tuberculosis*, *Yersinia Adenovirus*, *Cytomegalovirus*
Circulating antibodies	*Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, *Entameoba histolytica*

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_17

identify common bacterial, viral and parasitic pathogens using molecular testing, with 100% sensitivity and 100% negative predictive value [2]. However, these tests also generate considerable additional positive results of uncertain clinical importance [3]. According to the age of the patient, the severity of symptoms and the type of bacteria, an appropriate antibiotic treatment may then be initiated. When no pathogen is present in the stools, imaging such as an abdominal ultrasound is usually performed. It can show enlarged mesenteric lymph nodes and thickening of the colonic and/or ileal wall, but these findings can be seen in infectious diseases as well as in IBD. In this setting, colonoscopy is useful, enabling the visualization of colonic lesions and collection of biopsy samples for histology and culture. The endoscopist should describe the lesions precisely without directly stating a final diagnosis of IBD. Besides *Clostridium difficile,* which is responsible for the typical pseudomembranous colitis, infection with numerous bacteria or parasites may lead to colonic lesions that can be very similar to those of UC or CD [4] (Table 17.2). Moreover, bacterial overgrowth or intestinal infection is part of initial manifestations in 10–20% cases of IBD. When symptoms are severe, it may be justified to propose a short-course empiric treatment with broad-spectrum antibiotics active against enteric pathogens (e.g., ceftriaxone or ciprofloxacin—usually after 15 years of age, and metronidazole).

If laboratory tests and evolution of symptoms do not confirm the hypothesis of infection, the diagnosis can be changed to IBD based on histological findings. Acute inflammatory changes of cryptitis, and crypt abscesses with neutrophilic infiltration, are not specific and are seen in both entities. The more discriminatory findings in favor of a first manifestation of IBD are the presence of glandular bifurcations and distortions, an infiltration of the mucosa with plasmocytes, and the presence of granulomata [5, 6]. However, these findings are rarely seen when endoscopy is performed at an early stage, and acute episodes of colitis may remain initially unclassified. Half of these patients will relapse in the following 3 years, leading to a diagnosis of IBD, usually UC [7]. When the diagnosis is uncertain, one should avoid starting long-lasting anti-inflammatory/immunosuppressive treatment and be cautious when giving information to the family.

Table 17.2 Main infectious agents responsible for IBD-like lesions during endoscopy

Microorganism	Possible Ileal involvement	Crohn-like aspect	UC-like aspect
Aeromonas	N	+	++
Campylobacter	Y	++	+
Clostridium difficile	N	+	+
Eschericchia coli	N	+	+
Klebsiella oxytoca	N	+	+
Mycobacterium tuberculosis	Y	+++	+
Plesiomonas shigelloides	N	+	+++
Salmonella enteritidis	Y	+	++
Shigella dysenteriae	Y	+	+++
Vibrio parahemolyticus	N	+	+
Yersinia enterocolitica	Y	+++	+
Entamoeba histolytica	N	+	+++
Cytomegalovirus	Y	+	+++

N = no; Y = yes

Food Allergy

Food proteins, usually milk or soy, may produce an allergic colitis which is typically encountered in infants under the age of 2 with a family history of atopy [8–10]. Rectosigmoidoscopy usually shows mucosal erythema and nodularity [11], but lesions may include aphthous ulcerations that mimic CD. The diagnosis of allergy is suspected if an eosinophilic infiltration of the mucosa is present on histology [12]. Allergy skin tests using a panel of the main allergens responsible for food allergy in children can be used to direct the exclusion of the offending protein. A rapid disappearance of symptoms will then confirm the diagnosis [12].

Acute Appendicitis

Acute appendicitis may cause some diarrhea, associated with the classic right lower quadrant pain and tenderness. If clinically warranted, then this diagnosis may be confirmed by ultrasound examination and/or computed tomography of the abdomen. In some rare cases, CD is discovered because of ileal involvement during operation [13, 14] or at the histological examination of the appendix [15, 16]. One should be aware of the possibility of CD in cases of ileitis associated to appendicitis because appendicectomy may lead to complications such as fistula, abscess, and peritonitis.

Chronic or Recurrent Intestinal Symptoms

Chronic or recurrent intestinal symptoms represent the most frequent presentation of IBD in the pediatric population and include symptoms such as abdominal pain and diarrhea lasting up to several months or years, especially in CD. This long delay until the diagnosis may be explained by the frequency in the general population of these non-specific symptoms, as up to 10% of children between 7 and 11 years old seek medical attention for recurrent abdominal pain [17]. A

periumbilical location of pain is typical in functional abdominal pain, but it is also present in most children with IBD. In patients with uncomplicated abdominal pain, constipation, lactose intolerance, peptic disease, food allergy, pathology of the urinary tract, or psychosocial causes should be considered and eliminated. The presence of fever, anorexia, weight loss or growth disturbance, perineal involvement, or blood in the stools suggests the possibility of IBD. This suspicion should be strengthened by laboratory investigations showing anemia and increased inflammatory markers (C-reactive protein, erythrocyte sedimentation rate), ultrasound examination of the abdomen showing a thickening of the intestinal wall, and/or elevated fecal calprotectin [18]. However, these features are not specific to IBD and further investigations are useful to eliminate other diseases (Table 17.3).

Intestinal Infection

Even in case of chronic digestive manifestations, an infectious etiology remains the most frequent differential diagnosis to be considered [4, 19]. It is, therefore, important to collect stools for bacterial and parasitic pathogens at the initial evaluation of a patient with suspected IBD. Contrary to acute presentation, an anti-microbial treatment is generally not considered until laboratory tests have confirmed a specific infectious disease. Depending on the pathogen, the part of the gut involved and the symptoms may vary, leading to consideration of either CD or UC (Table 17.2).

Table 17.3 Useful investigations for differential diagnosis of IBD in children with chronic diarrhea

Blood	Polynuclear count and morphologic features
	Lymphocyte count
	FACS enumeration of T and B lymphocytes
	Serum electrophoresis
	IgG, A, M
	Total haemolytic complement
	C_3, C_4 concentrations
	Anti-Neutrophil Cytoplasm antibody
	Anti-Saccharomyces Cervisea antibody
	Anti-Transglutaminase antibody
	Specific IgE against food allergens
	Anti-bacteria antibody (*Shigella*, *Salmonella*, *Campylobacter, Yersinia, Entameoba histolytica)*
Stools	Fecal leukocytes
	Microscopic examination
	Standard and specific medium culture
	Clostridium difficile cytotoxin assay
Skin tests for	Tuberculosis
	Food allergens
Imaging of the abdomen	US examination
	CT-scan or MRI
Endoscopy	Oesogastroduodenoscopy
	Biopsy for histology
	Ileo-colonoscopy
	Biopsy for histology, bacterial culture, PCR

Infection with *Yersinia enterocolitica* is usually associated with a mild illness in children [20] but subacute and chronic ileitis or ileocolitis has been reported [20, 21] and may resemble CD [22]. This can also be associated with erythema nodosum and polyarthritis. Endoscopic features include aphthoid lesions of the cecum and ileum with round or oval elevations with ulcerations. Ulcers are mostly uniform in size and shape, in contrast to CD [23]. Histological findings of Yersinia infection are not pathognomonic and usually are only indicative of acute and/or chronic inflammation. US examination or MRI show mucosal thickening and nodular pattern of the terminal ileum and colon that can mimic CD, but also enlarged mesenteric lymph nodes [24]. In contrast to CD, fistula formation and fibrotic stenosis are not observed. Stool or biopsy sample cultures may require a specific enrichment medium, are time consuming and not always positive. Identification and characterization of pathogenic Yersinia enterocolitica isolates by PCR in stools or in paraffin-embedded tissue block [25]. The diagnosis can also be made with the identification of serum antibodies (Western blot) against Yersinia outer protein antigens (YOP antigens), the concurrent presence of both IgG and IgA antibodies indicating an ongoing infection [26]. Infection with enteropathogenic and enteroaggregative *Escherichia coli* (EPEC, EAEC) may be responsible for chronic diarrhea in children, especially when they live or travel in developing countries [27, 28].

Infection with *Clostridum difficile* leads to digestive disease ranging from self-limited diarrheal syndrome, to severe pseudomembranous colitis [29]. Sometimes, sustained symptoms lead to consideration of the possibility of IBD. *Clostridum difficile* infection must be sought in children receiving antibiotics, especially beta-lactams, although it may occur without prior antibiotic therapy. Rectosigmoidoscopy, performed with care and minimal insufflation, reveals the presence of typical yellow-white pseudomembranes in approximately one third of patients [29] and infection is confirmed by the presence of the toxin A or B in stool or by polymerase chain reaction. Nevertheless, *Clostridium difficile* infection can occasionally occur in patients with UC or CD, even without the use of antibiotics, and stool toxin positivity has been reported in 5 to 25% of IBD patients with relapse, mostly after antibiotic exposure [30, 31]. Reductions in gut microbial diversity as well as an increase in pro-inflammatory species have been identified in IBD patients, a dysbiosis that may play a role in increasing *Clostridum difficile* infection risk in IBD patients. Due to an overlap in symptomatology, diagnosis and treatment of *Clostridum difficile* infection are also challenging in the IBD population, and it is recommended that stool assay for

Clostridium difficile is obtained in children with IBD during acute relapses [32, 33].

Giardia intestinalis infection can be associated with chronic diarrhea, abdominal pain, and weight loss [34] which may occasionally lead one to consider the possibility of IBD. Giardia is found in most countries in the world, the prevalence being highest in developing countries. Trophozoites or cysts of *Giardia intestinalis* can be found in fresh stool specimens, or rectal biopsies. In some cases, it may be necessary to examine duodenal aspirations or biopsies. Jejunal morphology may be normal, although partial or even total villous atrophy has been reported [35, 36]. Failure to eradicate giardiasis can be due to hypogammaglobinemia or deficit in secretory IgA.

Entamoeba histolytica infection occurs mostly in developing countries. Infection may be asymptomatic or lead to a dysenteric syndrome. Demonstration of *Entamoeba histolytica* trophozoites and cysts in stools remains the mainstay of diagnosis. Chronic amoebic colitis could lead to clinical, radiologic, and endoscopic findings that can be indistinguishable from those of IBD [37, 38]. However, this differentiation is important because amoebiasis can become fulminant if the patient is treated with immunosuppressive agents for a presumed IBD [39]. In these chronic manifestations, the parasite can be difficult to find in stools samples or in rectal biopsies, even using a concentration technique. The presence of high titers of antibodies in the serum may then be helpful in the diagnosis of chronic amoebiasis.

Intestinal tuberculosis accounts for 2% of tuberculosis worldwide and remains a challenging diagnosis in developing countries, because treatments used for CD may adversely affect tuberculosis [40]. Intestinal tuberculosis can affect any part of the intestine but more frequently involves the ileocecal region, isolated colonic location being present in only 10–25% of cases. Symptoms can be very similar to those of CD; these include diarrhea, abdominal pain, fever, weight loss, abdominal mass of the right iliac fossa, and even suppurative perineal lesions. The presence of intramural swelling, mesenteric thickness, stricture or fistula on US examination, or MRI can be encountered in both diseases [41], although the absence or minimal asymmetric thickening of colonic wall and the presence of enlarged necrotic lymph nodes favor the diagnosis of tuberculosis [41–44]. Nodules, ulcers, and strictures can be seen at ileocolonoscopy, or possibly at enteroscopy in the case of isolated jejunal lesions [45–47], but these lesions can be indistinguishable from those of CD. Usually, intestinal tuberculosis has less than four segments involved, a patulous ileocecal valve, transverse ulcers (longitudinal in CD) and more scars [48]. The characteristics of histologic lesions may also be helpful, needing to perform multiple biopsies [49]: in tuberculosis, granulomata are typically bigger, often confluent, located beneath the ulcerations, and absent in non-inflamed mucosa, and half of them contain caseum. Tuberculin skin test is positive in only 70–80% of patients with intestinal tuberculosis. The diagnosis may be facilitated by the presence of active pulmonary tuberculosis (but this is present in only 20% of cases), ascites, or large lymphadenopathy on imaging [40, 42]. Unfortunately, acido-alcoolo-resistant bacilli are very rarely present on direct examination of intestinal biopsies, and culture requires at least 4 weeks and is positive in only 40% of cases. Tissue PCR assays for *Mycobacterium tuberculosis* on intestinal biopsies are faster and show an accuracy of more than 80% for the diagnosis of intestinal tuberculosis [50]. Amplification of insertion element IS6110 that is specific for *M. tuberculosis,* in the fecal samples [51] and the Quantiferon-TB gold, a blood test using an interferon-γ-release assay, look to be promising tools [52] but their diagnostic value for the diagnosis of intestinal tuberculosis remains to be evaluated. Combination of Interferon-gamma releasing assay and anti-Saccharomyces cerevisiae antibody has a high specificity for the diagnosis of ITB [53]. New prediction models using of a CD prediction score combining colonoscopy, laboratory, and radiologic factors, can also be useful for calculating the probability of either CD or ITB at initial evaluation [54]. In cases of persistent doubt, empiric treatment with antituberculosis drugs has been proposed in countries where the prevalence of tuberculosis is high, reconsidering diagnosis of CD if the patient's condition does not improve [55]. Nevertheless, this approach is not recommended by others who advise to make every effort to reach an accurate diagnosis before starting specific therapy [42].

Primary intestinal infection with *cytomegalovirus* (CMV) can occur in immunocompromised children but is exceptional in immunocompetent children [56]. Endoscopy reveals ulcerative and hemorrhagic colitis, and histological examination of the biopsy will confirm the infection with CMV by finding typical intra-nuclear inclusions in the colonic mucosa, associated with immunostaining with a specific antibody. PCR of colonic tissue can also be used to detect viral DNA in the colon, although the significance of a positive result remains unclear in the absence of histological features of CMV disease. CMV colitis is rare in CD or mild-moderate UC [57, 58]. In patients with severe and/or refractory UC, local reactivation of CMV can be detected in inflamed colonic tissue in about 30% of cases but does not influence the outcome in most studies [58]. Nevertheless, treatment with ganciclovir has allowed some patients with severe colitis to avoid colectomy despite poor response to conventional IBD therapies [59]. It is recommended to test for CMV reactivation via PCR and/or immunochemistry on colonic biopsies in patients with severe colitis refractory to immunosuppressive therapy and treat with ganciclovir when CMV is detected [33, 60, 61].

Celiac Disease

Celiac disease is easily recognized in the classic mode of presentation of children who present with chronic diarrhea, anorexia, failure to thrive, and abdominal distension. Presentation is often less typical in older children who complain of abdominal pain, chronic diarrhea, anorexia, short stature, or iron-resistant anemia—symptoms that may also suggest IBD. In this situation, laboratory investigations should include specific antibodies against tissue transglutaminase, endomysium, or deamidated gliadin peptides. If these antibodies are positive, the diagnosis of celiac disease will be further confirmed by duodenal biopsy showing villous atrophy with increased number of intra-epithelial lymphocytes [62].

Eosinophilic Gastroenteropathy

Eosinophilic gastroenteropathy is a rare condition characterized by infiltration of the gastrointestinal tract with eosinophils [63]. Most common symptoms are vomiting, abdominal pain, and growth failure. Diarrhea associated with rectal bleeding is present in 23% of cases, especially in infants**,** and symptoms of protein-losing enteropathy are present in 33–100% of cases [64, 65]. Endoscopic examination may show nodularity, erythema, friability, erosions, and ulcerations in the upper digestive tract and/or in the colon [11, 66]. The diagnosis is strongly suggested by a context of food allergy or the association with hypereosinophilia in the blood, which is present in 70–100% of cases [65]. The presence of excessive eosinophils in the digestive mucosa will confirm the diagnosis although it may also be encountered in CD. Gastric biopsies may demonstrate eosinophilic gastroenteropathy more consistently, most patients having more than 10 eosinophils per high power field in the antral or duodenal mucosa [67]. Allergic skin tests or serum-specific IgE against main food allergens are useful to guide dietary recommendations [64].

Primary or Acquired Immunodeficiency Diseases

The importance of the intestine as an immune barrier is highlighted by the proximity of gut-associated lymphoid tissue to the luminal surface of the gastrointestinal tract, an external environment which is rich in microbial pathogens and dietary antigens. Significant gastrointestinal disorders, leading to chronic diarrhea, malabsorption, and failure to thrive, are frequently present in primary [68] or acquired immunodeficiency diseases [69]. In the recent years, advances in technology, such as whole-exome sequencing and targeted sequencing panels, allowed exploring young patients with IBD-like manifestations [70], and led to identify a significant number of monogenic diseases [71–73], affecting the epithelial barrier, the inflammatory response, or the immune response (Table 17.4). These diseases should be sought after, especially in cases of very early (<6 years) or infantile (<2 years) onset symptoms, and often present with a distinct phenotype, i.e., indeterminate pancolitis or severe ulcerative or fistulizing perineal disease [70]. Although the frontier between these monogenic diseases (still currently being discovered) and classic IBD is vague, the precise characterization of the genetic defect is of importance because therapeutic options may be different in some cases, like bone marrow transplantation, for example. This emphasizes the importance of a close collaboration between pediatric gastroenterologists, immunologists, and specialists in immunodeficiency syndromes for early efficient medical care and for active research to discover involved genes.

The most frequent manifestations of immunodeficiency syndromes are recurrent, persistent, and severe or unusual infections [74]. Disturbance of the immune system in the gut may also lead to auto-immune diseases, excessive production of IgE, or malignancies [75, 76].

Immunodeficient patients may present with chronic non-specific enterocolitis, characterized at small bowel biopsy by subtotal villous atrophy with acute and chronic inflammatory cell infiltration of the lamina propria [77–79]. This chronic non-specific enteropathy is not responsive to a gluten-free diet and occurs in several immunodeficiency disorders, affecting humoral response (X-linked agammaglobulinemia, IgA deficiency, common variable immunodeficiency), T-cell function (Wiskott-Aldrich syndrome, Acquired Immuno Deficiency Syndrome), or both (combined immunodeficiency). In some cases, strictures of the intestine may develop [77–79]. In these patients, it is important to rule out infection with opportunistic bacteria or parasites, and also with more common pathogens, such as rotavirus, adenovirus, and picornavirus [74]. In rare patients, the cause of the chronic enterocolitis is a disease affecting the epithelial barrier (Table 17.4).

Enterocolitis that resembles CD is mostly associated with neutropenia or defects of phagocytic function. Patients with chronic granulomatous disease may present with chronic colitis, perirectal abscesses and fistulae, and antral narrowing [80, 81]. The similarity with CD also includes endoscopic appearance, radiographic abnormalities, and even histologic features showing granulomata and giant cells in the digestive mucosa. Nevertheless, a paucity of neutrophils, an increased number of eosinophils, eosinophilic crypt abscesses, pigmented macrophages, and nuclear debris suggest chronic granulomatous disease [82]. Patients with Leukocyte Adhesion Molecule Deficiency, a rare disorder of phagocytic function, also present with oral and perineal involvement that may be mistaken for CD. These manifestations include stomatitis with pharyngitis, gingivitis with peridontis, ischiorectal abcesses, and distal ileocolitis [83]. Other disorders of neutrophils, such as congenital neutropenia, glycogen stor-

Table 17.4 Gastrointestinal manifestations in genetic defects associated with immunodeficiency syndromes

Disease	Gastrointestinal manifestations	Gene
Epithelial barrier function defects		
Dystrophic epidermolysis bullosa	Moderate to severe colitis	*COL7A1*
Kindler syndrome	Haemorrhagic UC-like colitis	*FERMT1*
X linked ectodermal dysplasia	Atypical CD-like enterocolitis, villous atrophy and epithelial cell shedding	*IKBKG*
ADAM-17 deficiency	First week of life non-bloody later bloody diarrhoea	*ADAM17*
Familial diarrhea	Partially neonatal onset of familial watery diarrhea. CD developed in adult age	*GUCY2C*
Neonatal inflammatory skin and bowel disease TTC7A deficiency Kindler syndrome Epithelial NADPH oxidases defect	IBD-like enterocolitis Colitis Colitis Colitis	*EGFR* *TTC7A* *FERMT1* *NOX1, DUOX2*
Phagocyte defects bacterial killing		
Chronic granulomatous disease	Stomatitis, perineal absesses, IBD like enterocolitis	*CYBB, CYBA, NCF1, NCF2, NCF4, LACC1*
Glycogen storage disease type 1b	Perioral and perianal lesions, CD-like ileocolitis	*SLC37A4*
Congenital neutropenia	Stomatitis, CD-like colitis	*G6PC3*
Leucocyte adhesion deficiency 1	Stomatitis, ileocolitis, perianal abscess, fistulas, CD-like colitis	*ITGB2*
Hyper- and autoinflammatory disorders		
Mevalonate kinase deficiency	IBD-like enterocolitis	*MVK*
Phospholipase Cγ2 defects	UC-like colitis	*PLCG2*
Familial Mediterranean fever	UC-like colitis	*MEFV*
Familial haemophagocytic lymphohistiocytosis	IBD-like enterocolitis	*STXBP2*
X linked lymphoproliferative syndrome 2	CD-like enterocolitis, fistulising perianal disease	*XIAP*
X linked lymphoproliferative syndrome 1	IBD-like enterocolitis, gastritis	*SH2D1A*
Hermansky–Pudlak syndrome Multisystem autoimmune disease	CD-like enterocolitis, perineal lesions	*HPS1, HPS4, HPS6* *STAT3*
B cell and antibody defects		
Common variable immunodeficiency	Persistent intestinal infections, food allergies, autoimmune diseases, malignancies (gastric cancer, lymphoma), CD-like colitis	*ICOS, LRBA*
Agammaglobulinaemia	Persistent intestinal infections, gastritis, malignancies (gastric cancer, lymphoma), CD-like colitis	*BTK, PIK3R1*
Severe combined immunodeficiency	Severe persistent opportunistic infections, IBD-like enterocolitis	*ZAP70, RAG2, IL2RG, LIG4, ADA, CD3γ*
IL-21 deficiency Hyper-IgM syndrome	Severe early onset colitis Oral ulcers, IBD-like	*IL21* *CD40LG, AICDA*
Wiskott–Aldrich syndrome	UC-like colitis	*WAS, WIPF1*
Omenn syndrome	Stomatitis, IBD-like enterocolitis	*DCLRE1C, DCLRE1X*
Hyper IgE syndrome	buccal granulomatous disease, UC-like colitis.	*DOCK8*
Trichohepatoenteric syndrome	Intractable diarrhoea, colitis	*SKIV2L, TTC37*
Regulatory T cells defects		
IPEX, IPEX-like Autoimmune lymphoproliferative syndrome type 5	Autoimmune enteropathy, colitis Enteropathy	*FOXP3, IL2RA, STAT1* *CTLA4*
CD122 deficiency DEF6 deficiency RIPK1 IL-10 signalling defects	Enteropathy Enteropathy IBD-like Stomatits, perianal abscesses and fistula, CD-like ulcerative colitis.	*IL2RB* *DEF6* *RIPK1* *IL10RA, IL10RB, IL10*
NOD2 signaling defects Anhidrotic ectodermodysplasia	IBD Colitis	*NOD2, TRIM22* *IKBKG*

Gene names were used according to HUGO gene nomenclature
CD Crohn disease, *IBD* Inflammatory bowel disease, *IPEX* X linked immune dysregulation, polyendocrinopathy, enteropathy, *UC* Ulcerative colitis

age disease type 1b, and the Hermansky–Pudlack syndrome [84], are responsible for CD-like enterocolitis. The same presentation may be caused by T- or B-cell defects, IgA deficiency, and acquired immunodeficiency syndrome [68, 85].

Severe ulcerative or fistulizing perineal disease occurring in a very young child is suggestive of IL-10-signaling pathway defect [86–88] or X-linked lymphoproliferative syndrome 2 [89, 90] and may also be encountered in phagocytic defects or Hermansky–Pudlack syndrome.

Auto-immune enteropathy is characterized by severe persistent diarrhea associated with circulating auto-antibody against gut epithelial cell and/or another auto-immune disorder [91, 92]. An additional consideration is X-linked familial disease which includes polyendocrinopathy (IPEX syndrome) [93–95]. Although the colon is frequently involved [93, 96, 97], the lesions are predominant in the small intestine, with inflammatory cell infiltration of the mucosa, and subtotal or total villous atrophy [93, 94, 97], leading to secretory, and protracted diarrhea in the first months of life [98, 99]. Nevertheless, antibodies to colonic epithelial cells have been also found in patients with UC [100], and 10% of IBD patients suffer from one or more auto-immune diseases [101], leading to some diagnostic difficulties in the older child.

Intestinal Neoplasm

Patients with *intestinal lymphoma* often present with chronic digestive symptoms, such as abdominal pain, distension, and/or diarrhea. Lesions are usually located in the small bowel although some cases may involve the colon [102, 103]. Ultrasound examination shows a thickening of the intestinal wall, and/or narrowing of the lumen of the gut which can be very similar to CD [104]. Extent of the lesions is more precisely seen with a MRI of the abdomen, and upper digestive endoscopy and/or ileocolonoscopy are mandatory to provide histologic confirmation. Nevertheless, if the lesions are limited to part of the small intestine, the biopsy may require an enteroscopy or even a surgical procedure, by laparoscopy or laparotomy. Predisposing conditions for intestinal lymphoma in children include inherited or acquired immunodeficiency syndromes, immunosuppressive therapy, and Epstein-Barr Virus infection [105]. In developing countries, Mediterranean lymphoma is characterized by the proliferation of IgA-secreting B lymphocytes. The diagnosis is usually suspected because of the presence of alpha heavy chain in the serum [106].

Vasculitis Disorders

Henoch–Schoenlein purpura is a frequent vasculitis, involving the gut, skin, joints, and kidney. Diagnosis is easily made in a child presenting with typical skin purpura, but gastrointestinal symptoms, i.e., colicky abdominal pain and bleeding, may precede the skin rash by a number of days. In some cases, isolated duodenojejunitis without purpura may occur [107], and terminal ileitis mimicking Crohn disease has been described [108, 109].

In other less frequent systemic vasculitides, such as polyarteritis nodosa [110, 111], Wegener granulomatosis [112], Behçet's disease [113, 114], and lupus arteriosus [115], intestinal involvement can lead to chronic abdominal pain associated with bleeding. Endoscopic and histological findings may be very similar to CD, even with the presence of granuloma. Extra-digestive manifestations, especially neurological, respiratory, renal, and cutaneous lesions suggest systemic vasculitis [116] (Table 17.5). On the other hand, extra-intestinal vasculitis can complicate IBD, involving the retina, brain, skin, muscle, joints, and lung [117–122]. The

Table 17.5 Extra-digestive manifestations and useful investigations for the diagnosis of systemic vasculitis in children with digestive symptoms resembling Crohn disease

Vasculitis	Extra-digestive manifestations	Investigations
Periarteritis nodosa	Multiple neuritis	Skin, muscle biopsy
	Myositis	Angiography
	Arterial hypertension	
	Skin ulcerations and gangrene	
Wegener granulomatosis	Epistaxis, sinusitis, otitis, hearing loss	Thoracic CT-scan
	Stridor, hoarseness	c-ANCA
	Cough, wheezing, dyspnea, hemoptysis	Nasal mucosa biopsy
	Necrotizing glomerulonephritis	
	Skin ulcerations and gangrene	
	Conjunctivitis, uveitis, optic neuritis	
	Pseudotumor cerebri	
Behcet's disease	Serious buccal aphtous	HLA-B5
	Genital ulcers	
	Uveitis	
	Thrombophlebitis	
	Menigoencephalitis	
Lupus arteriosus	Typical facial erythema	Antinuclear antibody
	Myocarditis, pericarditis, endocarditis	Anti-DNA antibody
	Pleuropneumonitis	
	Glomerulonephritis	
	Thrombophlebitis	
	Hemolytic anemia and thrombopenia	
	Keratoconjunctivitis, retinitis	

differentiation between primary systemic vasculitis and IBD can be clinically challenging but is important because their treatment and outcome are different [123]. The confirmation of the vasculitic process is more often evident on extra-intestinal biopsies (skin, muscle, kidney) than on intestinal biopsies and on angiography showing aneurysms and caliber variation of visceral arteries [110].

Abdominal Mass

The discovery of an abdominal mass has been found to reveal ileocolic CD in some adults and children [124–126]. Ultrasound examination and MRI of the abdomen are first-line investigations which will exclude extra-digestive malignant tumors, such as lymphoma, sarcoma, nephroblastoma, or neuroblastoma. When the mass is developed from the digestive tract, glandular lymphoma or adenocarcinoma of the colon, although rare in children, can be suspected [127–129]. Radiologic findings may be very similar in some benign lesions, like leiomyoma, pseudoinflammatory tumor, or tuberculosis [130, 131]. Nevertheless, surgical exploration is generally required, leading to correct diagnosis after histologic examination of the excised tumor. Intestinal tuberculosis may be a challenging diagnosis because histologic findings may be very similar to those of CD, although granulomata are typically larger and contain caseum in the case of tuberculosis [49]. Polymerase chain reaction for *Mycobacterium tuberculosis* should be systematically performed [50, 51].

Isolated Esophagogastroduodenal Involvement

Esophagogastroduodenal involvement is present in 25–40% of children with CD, usually discovered during upper digestive endoscopy with systematic biopsies, performed at initial work-up [132–136]. More rarely, patients may present with symptoms suggestive of peptic disease, including epigastric burning pain and early satiety, these often being relieved by antacids or antisecretory treatment [137, 138]. Endoscopy can show heterogeneous lesions, but a bamboo-joint like appearance is suggestive of CD [133, 137, 139–141]. Uncommonly, CD patients present with an isolated gastric or duodenal ulcer [134]. In the case of long-lasting symptoms or altered growth rate, the possibility of CD should be kept in mind and a biopsy of the edge of the ulcer looking for the presence of granulomata should be performed [133, 137]. The differential diagnosis for upper gastrointestinal CD includes *Helicobacter pylori* infection, peptic ulcer disease, viral gastritis, eosinophilic GI disease, Wegener's granulomatosis, sarcoidosis, carcinoma, gastric lymphoma, and tuberculosis [142].

Isolated Perineal Disease

Skin tags, anal fissures, and perianal fistulae or abcesses are frequent in infants who are in diapers and/or have a history of constipation with hard stools.

Such perianal lesions also occur in half of patients with CD, mostly in the context of colonic inflammation [143]. These lesions may precede other manifestations of intestinal disease in about one third of these patients [144]. In adolescents, perianal lesions can be severe [145, 146], hidden, and unrecognized for several months. The diagnosis of CD should then be considered in the case of extensive or refractory perianal lesions occurring in children. Confirmation of diagnosis will be obtained by MRI showing abscesses and fistulae and their relationship to the elevators [147], the presence of granuloma on biopsies of perianal lesions that required surgery, and/or colonoscopy that will show colitis [144, 146]. Severe ulcerative or fistulizing perineal disease occurring in a very young child is suggestive of monogenic diseases such as IL-10-signaling pathway defect [86–88], X-linked lymphoproliferative syndrome 2 [89, 90], phagocytic defects [80], or Hermansky–Pudlack syndrome [84]. More rarely, perineal lesions can occur after trauma or sexual abuse [148, 149].

Laboratory Evaluation of Inflammatory Bowel Disease

18

Amanda Wenzel, Benjamin D. Gold, and Jennifer Strople

Introduction

Although clinical history and physical exam may raise suspicion of Crohn disease (CD) or ulcerative colitis (UC), a focused laboratory evaluation can facilitate further differentiation between inflammatory bowel disease (IBD) and non-inflammatory bowel disease—in particular, distinguishing between IBD, infectious processes, and functional bowel disorders (Table 18.1). These blood and stool studies, in combination with clinical presentation (thorough history, including family history of IBD or other autoimmune conditions, and physical examination), can help determine which child may require more extensive or invasive testing, such as radiological and endoscopic evaluation to definitively diagnose IBD and provide information to facilitate IBD phenotype. Moreover, the blood and stool evaluations may also provide insight into the severity of disease, if indeed IBD (i.e., prognostication). The first part of this review will focus on the evaluation of blood tests in the work-up of a child with suspected IBD. Initially, the nonspecific markers of disease (e.g., anemia) and inflammation (e.g., C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR)) will be discussed. Subsequently, the more "specific" serological markers of IBD will be reviewed, and then, stool tests, which can be used to potentially delineate between IBD and non-IBD, will be discussed.

Table 18.1 Laboratory tests for suspected inflammatory bowel disease

Test	Findings	Significance
Complete blood count and differential	Anemia (microcytic, macrocytic, normocytic), thrombocytosis, leukocytosis	*Anemia:* Assess severity of blood loss, evaluate for iron and other macronutrient deficiencies. Reported prevalence 16–77% in Crohn disease and 9–67% in ulcerative colitis *Thrombocytosis:* Acute phase reactant, nonspecific measure of inflammation. Reported prevalence variable, occurring in up to 85% of patients with Crohn disease and 70% patients with ulcerative colitis.
ESR and CRP	Elevation	Nonspecific markers of inflammation, potential role in assessing disease activity, predicting disease relapse, and monitoring therapeutic response.
Liver function tests	Hypoalbuminemia Elevated transaminases Elevated alkaline phosphatase/GGT	*Hypoalbuminemia:* Surrogate marker of nutrition, possibly indicative of decreased liver production (negative acute phase reactant) or intestinal protein losses due to inflammation. *AST/ALT/Alkaline phosphatase/GGT:* Role in evaluating for extra-intestinal complications of inflammatory bowel disease.

Table 18.1 (continued)

Test	Findings	Significance
Stool Cultures—*E. Coli*, *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia* species	Infection	Evaluate for primary infectious colitis, which may mimic inflammatory bowel disease and exclude co-infection, which may complicate disease.
Clostridium difficile PCR	Infection	Evaluate for primary infection and co-infection. In patients with inflammatory bowel disease, *C. difficile* is the most common infectious agent identified
Stool calprotectin	Elevation	Alternative inflammatory marker, which appears to be a direct measure of intestinal inflammation. Role in assessing disease activity and predicting relapse in patients with inflammatory bowel disease
IBD serologies	Positive ASCA (IgA or IgG), pANCA, anti-OmpC, anti-CBir	May aid in classifying disease subtype and play a role in therapeutic decisions (prognostic factor). Inadequate screening tool due to low sensitivity compared to clinical history and routine laboratory tests

ESR Erythrocyte sedimentation rate, *CRP* C-reactive protein, *IBD* Inflammatory bowel disease, *AST* Aspartate aminotransferase, *ALT* Alanine aminotransferase, *GGT* Gamma glutamyl transpeptidase, *ASCA* Anti-Saccharomyces cerevisiae (ASCA), *pANCA* Perinuclear antinuclear cytoplasmic antibody, *OmpC* Outer membrane protein

Blood Tests

Most clinicians, adult and pediatric, will agree that blood tests should be part of the initial screening process in children with symptoms compatible with UC or CD [1–6]. The specific blood evaluations performed should, at minimum, consist of a complete blood count, including white blood cell number with a differential, hemoglobin and hematocrit, iron/red blood cell characteristics or indices such as mean corpuscular volume, as well as studies to further characterize iron deficiency including ferritin, total iron-binding content (TIBC), and iron. In addition, liver biochemistries: alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), gamma-glutamyl transpeptidase (GGT), albumin, and total protein, and systemic inflammatory markers, such as ESR and CRP, should be included in the initial laboratory evaluation of a child with suspected IBD [6, 7]. Although normal tests do not rule out the possibility of intestinal inflammation, if abnormalities are present, further diagnostic studies are generally warranted. In addition, serum biomarkers such as CRP and ESR can distinguish between quiescent and active disease, and in some studies, elevations in these biomarkers have correlated with endoscopic evidence of mucosal disease [7]. As several of these parameters are included in the Pediatric Crohn Disease Activity Index (CDAI) (e.g., albumin, ESR), these blood tests may offer additional insight into disease activity, and potentially, disease severity [6, 8, 9].

Anemia

Anemia is a well-known complication of inflammatory bowel disease occurring in both UC and CD [10–15]. Anemia is generally defined as a hemoglobin value <120 g/L. With respect to IBD, severe anemia is defined as a hemoglobin level <100 g/L. For reasons that are not well characterized, many patients with IBD are intolerant of oral iron replacement therapy or their anemia is refractory to such supplementation, with inflammation likely playing a role [15, 16]. Several studies in both adult and pediatric populations have shown that parenteral iron therapy is safe and more efficient than oral iron therapy, especially when active inflammation in present [17–20]. Further, there are some reports that suggest that oral iron therapy affects the gut microflora in a manner counter-productive to successful treatment compared to those receiving parenteral therapy [21].

The reported prevalence of anemia is variable in IBD, but anemia appears to be more prevalent in CD compared to UC [22, 23]. In one population-based adult Scandinavian study from Denmark, Norway, and Sweden, the overall prevalence of anemia in IBD was 19% with iron deficiency and anemia of chronic disease being the primary etiologies [22]. A retrospective review of pediatric patients diagnosed with IBD from 2005 to 2012 found that 67% were anemic at diagnosis, with 28% having either iron deficiency or a combination of iron deficiency and anemia of chronic disease, and 38% with isolated anemia of chronic disease [23]. At one-year follow-up, the prevalence of anemia decreased, but 20% of patients remained anemic despite treatment [23]. A larger retrospective review of a cohort of 2446 pediatric patients with IBD showed a similar high prevalence of anemia; of the patient that were screened for anemia, 51% with CD and 43% of patients with UC had anemia [24]. However, only a fraction of these patients (20–24%) were evaluated for iron deficiency as the etiology of their anemia.

Anemia may be more common in younger children compared to adolescents and adults [25]. Using the WHO age-adjusted definitions of anemia, Goodhand et al. [25] assessed the prevalence, severity, type, and response to treatment of anemia in patients attending pediatric, adolescent, and adult IBD clinics at a single center. These authors observed the prevalence of anemia to be 70% (41/59) in children, 42% (24/54) in adolescents, and 40% (49/124) in adults ($p < 0.01$). Overall, children (88% [36/41]) and adolescents (83% [20/24]) were more often iron deficient than adults (55% [27/49]) ($p < 0.01$). In other studies, anemia has been described occurring in 16–77% of patients with CD (16%, 58%, 70%, and 77% reported in pediatric cohorts) [13–15, 25–29] and 9–67% of patients with ulcerative colitis (30% reported in one pediatric cohort) [15, 26, 29].

The cause of anemia with or without iron deficiency is likely multifactorial in both CD and UC [30]. In CD, anemia may result from iron, folate, vitamin B12, and other micronutrient deficiencies from malnutrition secondary to small-bowel disease, particularly if the ileum is involved [30]. In addition, anemia may result from gross or occult gastrointestinal blood loss due to underlying intestinal inflammation. Finally, iron deficiency and/or anemia may be due to decreased overall iron stores from chronic disease and lack of appropriate dietary intake to replace iron stores [30]. The anemia observed in ulcerative colitis is generally the result of iron losses from chronic intestinal bleeding, but as with CD, anemia can be due to chronic disease.

The assessment of iron status in IBD in many cases is rather difficult due to coexistent inflammation of chronic disease [31]. For this assessment, several indices and markers have been suggested. Ferritin seems to play a central role in the definition and diagnosis of anemia in IBD and transferrin, transferrin saturation (Tsat), and soluble transferrin receptors have also been found to be useful markers in clinical practice. All these biochemical markers have limitations because they may be influenced by factors other than changes in iron balance. In addition, the iron metabolism regulators, hepcidin and prohepcidin, are still under investigation in IBD. Synthesis of hepcidin, which regulates iron metabolism, increases during systemic inflammation, and binds and inactivates ferroportin, inhibiting iron absorption from the bowel. While hepcidin synthesis is decreased in iron deficiency anemia, hepcidin overall appears to be increased in patients with inflammatory bowel disease [16, 32]. In a retrospective study of 50 children with IBD compared with an equivalent number of celiac disease and healthy controls, serum hepcidin was higher in patients with active IBD compared to celiac patients and healthy controls, with disease activity independently associated with elevated hepcidin levels [16]. A recent cross-sectional comparative study of newly diagnosis pediatric patients with CD or UC between 2012 and 2016 determined that patients with CD ($n = 53$) had significantly higher serum hepcidin levels (22.6 ng/mL, range 8.5–65.0) compared to patients with UC ($n = 23$) (6.5 ng/mL, range 2.4–25.8) ($p < 0.05$) [33]. In another cross-sectional study of 75 patients with IBD (46 UC, 29 CD) and 21 children with functional gastrointestinal disorders, hepcidin levels did not differ significantly among different subtypes of IBD, but mean serum hepcidin concentration was significantly decreased in IBD patients (5.98 ng/mL) compared with controls (10 ng/mL) ($p = 0.03$), likely related to iron deficiency in the IBD cohort [34]. In both the latter studies, hepcidin was correlated solely with ferritin in patients with IBD [33, 34].In addition to hepcidin, erythrocyte parameters like the red cell distribution width (RDW) and the percentage of hypochromic red cells as well as reticulocyte parameters such as hemoglobin concentration of reticulocytes, red blood cell size factor, and reticulocyte distribution width could be useful markers for the evaluation of anemia.

Anemia of chronic disease in IBD is also believed to be multifactorial in its etiopathogenesis. Three potential mechanisms leading to the anemia associated with chronic disease have been recently postulated, namely, (1) anemia results as a consequence of cytokine activation and subsequent alteration of iron homeostasis, (2) anemia occurs due to the inhibition of erythropoiesis, and (3) a shortened red blood cell half-life is associated with chronic disease and thereby results in the anemia [14, 35]. Additionally, the anemia of chronic disease such as that found in IBD involves erythropoiesis disturbance due to circulating inflammation mediators. In one study by Tsitsika et al. [36], erythropoietin (Epo) levels in children and adolescents with IBD were investigated and correlated to disease activity. Thirty-three patients with IBD were evaluated (18 boys, 15 girls) ages 4–15 years (median 11 years) [36]. Patients were separated into two study groups related to their disease activity: those with active disease ($n = 21$) and those in remission ($n = 12$). Chronic disease-associated anemia was present only in patients with active disease, and those patients also had a significantly higher possibility of low, altered Epo levels than expected compared with patients with inactive disease. Thus, it appears that impaired Epo production is another mechanism of anemia of chronic disease development.

Once the diagnosis of anemia is established, the etiology should be further investigated so treatment can be initiated. For macrocytic anemias, folate, vitamin B12, and methylmalonic acid levels should be obtained. Iron studies including ferritin, total iron-binding content (TIBC), and iron levels should be evaluated in cases of microcytic anemia. However, the results of these studies may be difficult to interpret, as ferritin, a measure of iron stores, is also an acute phase reactant and may be elevated in inflammatory conditions [16]. Thus, in patients with a microcytic anemia, obtaining a soluble transferrin receptor in addition to standard iron studies may be helpful in differentiating iron deficiency anemia and

anemia of chronic disease [37–39]. Soluble transferrin receptor (sTfR) concentration, which is not affected by inflammation, is elevated in iron deficiency anemia but remains normal in anemia of chronic disease [37–39]. Utilizing other indices along with sTfR may have better diagnostic utility than sTfR alone in detecting iron deficiency anemia in pediatric IBD. Krawiec et al. [40] assessed a small group of patients with iron deficiency anemia, anemia of chronic disease with iron deficiency, and anemia of chronic disease. STfR/log ferritin index was significantly higher in patients with iron deficiency anemia (median: 1.76) than in patients with anemia of chronic disease (median: 0.55), anemia of chronic disease with iron deficiency (median: 0.68), or patients without anemia (median: 0.72) [40].

In a recent analysis of 75 children with IBD, erythrocyte indices including MCV, MCH, MCHC, and RDW, and biochemical markers including iron, transferrin, sTfR, and sTfR/log ferritin, were evaluated for their sensitivity, specificity, accuracy, and positive and negative predictive values in identifying iron deficiency [41]. Utilizing receiver operating characteristic (ROC) analysis to compare the ability to predict iron deficiency, the best predictors for iron deficiency among these indices were STfR/log ferritin, followed by sTfR [41]. In addition to soluble transferrin receptor, intestinal ferroportin expression may be considered as a marker of anemia in relationship to inflammatory bowel disease and particularly Crohn disease in children. In a small study performed by Burpee et al. [42], intestinal iron exporter ferroportin expression was studied in subjects with and without CD. In this investigation, the authors evaluated duodenal mucosal biopsies from 29 pediatric subjects, 19 of whom had CD and 10 were without CD. The authors observed that intestinal ferroportin protein was higher in anemic CD subjects than in nonanemic CD subjects, whereas ferroportin mRNA levels were not significantly different. Thus, intestinal ferroportin protein appears to be upregulated in anemic CD subjects, suggesting yet another pathway for the iron deficiency and the anemia observed in children with CD [42].

Acute Phase Reactants: Platelets

In inflammatory conditions such as CD and UC, there is a rise in acute phase reactant proteins as a result of chemokine stimulation. The assessment of acute phase reactants has been employed as laboratory tests in the standard work-up of the child with suspected IBD, as well as other inflammatory conditions in pediatric patients (e.g., juvenile rheumatoid arthritis) [43, 44]. Reactive thrombocytosis, a nonspecific marker of inflammation, is a result of this acute phase response. Since the first published paper describing the association of thrombocytosis with chronic IBD by Morowitz et al. [45], the characterization of platelet elevation in the peripheral blood has been a "standard" part of the work-up of patients for suspected IBD, and in the monitoring of their disease activity. Some studies of the pathogenesis of IBD have implicated platelets in the propagation of intestinal inflammation. In a murine model of intestinal inflammation, CD40–CD40L appears to be involved in the pathogenesis of intestinal inflammation and suggests that modulation of leukocyte and platelet recruitment by activated, CD40-positive endothelial cells in colonic venules may represent a major action of this signaling pathway. In addition, Kayo et al. [46] evaluated the role of platelets in inflammation in peripheral blood and in the mucosa of a cohort of patients with active UC. These investigators compared the group of patients with active UC to patients with inactive UC and a small cohort of healthy controls. The authors observed a close association between activated platelets and neutrophils in both the affected colonic mucosa and peripheral blood of patients with active-phase UC compared to the normal volunteers (i.e., healthy controls) and those with inactive UC. The investigators inferred from their study results that a platelet–neutrophil association may play a role in the progression of inflammatory processes in UC [46].

There is also evidence that coagulation activation may mediate and amplify inflammatory cascades in IBD, especially via activating proteinase-activated receptor related pathways [47]. Patients with CD and UC are at increased risk of developing thromboembolic (TE) complications, especially during periods of active inflammation [47–50]. Although the etiology is multifactorial, thromboembolic phenomena in IBD is largely attributable to coagulation activation and platelet aggregation during systemic inflammation [47]. Thus, platelets may play more of a role in the propagation of intestinal inflammation and potentially some of the severe sequelae (e.g., thromboembolic processes) of the system inflammation of IBD, rather than being a simple "biomarker" of IBD [43, 47].

In children referred for endoscopy for evaluation of abdominal pain, diarrhea, rectal bleeding, weight loss, or mouth ulcerations, 85% of patients with CD and 70% of patients with UC had elevated platelet counts compared to 6% of children with normal endoscopic assessment [26]. The presence of thrombocytosis may be overestimated in this study, or a unique response in the child with IBD as a lower prevalence of increased platelets in IBD is reported in adults [51–53]. However, an elevated platelet count in a child with chronic intestinal symptoms should raise clinical suspicion of underlying intestinal inflammation. In one study evaluating pediatric patients with chronic abdominal complaints, the presence of an abnormal hemoglobin and/or elevated platelet count on a routine CBC was able to differentiate between IBD and healthy controls, with 90.8% sensitivity and 80.0% specificity [54]. Furthermore, the platelet count

may help differentiate between IBD and infectious processes, as thrombocytosis is a relatively uncommon finding in diarrhea associated with enteric pathogens [51]. In patients with a diagnosis of Crohn disease, platelet count may reflect the severity of disease independent of other disease markers (e.g., anemia). A recent study of 137 patients with CD, 69 with UC, and 412 healthy controls assessed differences in platelet counts; the effect of anemia, CRP, Crohn disease activity index (CDAI), and Mayo score were also analyzed [55]. CD and UC patients had higher platelet counts than healthy controls. Multivariate analysis revealed that platelet count and severity of CD were positively correlated ($p < 0.001$) after eliminating the interference of hemoglobin, with a cutoff value of 298 × 109/L. The authors found no such relationship in UC.

Mean platelet volume (MPV) is influenced by the degree and type of mucosal and system inflammation. One study analyzed overall accuracy of MPV in disease activity and compared MPV with other inflammatory markers in 61 UC patients and 27 healthy subjects [56]. MPV was compared to ESR, CRP, and white blood cell count. The authors found that MPV accuracy was roughly equivalent to standard acute phase reactants and was significantly lower in UC patients and particularly active UC patients than controls [56]. Thus, MPV may be another indicator of intestinal inflammation and a useful marker in patients with symptoms concerning for IBD.

There may be utility in tracking platelet count as a noninvasive marker of mucosal healing. A recent study by Furukawa et al. [57] assessed 345 Japanese patients with UC. Platelet counts were assessed for all study subjects and divided into quartiles (low, moderate, high, and very high). Mucosal healing (MH) and partial MH were evaluated by endoscopic specialists and defined as a Mayo endoscopic subscore of 0 and 0–1, respectively. The percentage of patients achieving partial MH was 63.2% and MH was 26.1%. After adjusting for age, sex, CRP, steroid use, an anti-tumor necrosis factor alpha (TNF-alpha) use, moderate and very high platelet counts were independently inversely associated with partial MH and MH.

Acute Phase Reactants: Erythrocyte Sedimentation Rate (ESR) and C-Reactive Protein (CRP) and Other Markers

ESR and CRP are two other nonspecific measures of inflammation which should be included in the evaluation of patients with suspected IBD [58]. Both ESR and CRP have been investigated in IBD for a number of reasons, namely, (1) diagnostic and differential diagnostic purposes, (2) assessment of disease activity (i.e., PCDAI) and risk of complications, (3) prediction of CD or UC relapse, and (4) for monitoring the effect of therapy. Under normal circumstances, CRP is produced by hepatocytes in low quantities but following an inflammatory stimulus, hepatocytes rapidly increase production of CRP under the influence of interleukin (IL)-6, tumor necrosis factor α, and IL-1β—all proinflammatory chemokines which are present in active IBD in both children and adults. CRP has a relatively short half-life (19 h) compared with other acute phase proteins and will, therefore, rise early after the onset of inflammation and rapidly decrease after the stimulus is resolved. Overall, CRP may be a better measure for assessing disease activity and predicting relapse. In CD in particular, CRP appears to correlate well with disease activity and, thus, is one objective marker that may be helpful in distinguishing IBD from noninflammatory conditions [59]. Additionally, in clinical trials with biological therapies, elevated CRP levels prior to initiation of therapy are associated with higher response rate, whereas normal CRP levels are predictive of higher placebo response rates [59]. However, despite the advantages of CRP over other markers, it is still far from ideal. Not all IBD patients, CD or UC, mount a CRP response, and this must be kept in mind when measuring inflammatory markers in individual patients. It is unclear if this is due to differences in cytokine levels such as IL-6 or due to mucosal as compared to transmural disease differences among UC and CD, or whether this acute inflammatory marker elevation is genetically driven.

Both ESR and CRP can be elevated to varying degrees in IBD and, therefore, are helpful in distinguishing inflammatory from functional disorders. In a study of 91 children referred for chronic gastrointestinal symptoms, the CRP was elevated in 100% of patients with CD and 60% UC, and ESR was elevated in 85% of patients with CD and 23% of patients with UC [26]. None of the patients with polyps or normal investigations had elevation of either marker. In adults with chronic abdominal symptoms, all patients with CD and 50% of patients with UC had elevated ESR and CRP, whereas none of the patients with functional disorders had elevation of both markers [60]. Therefore, using these markers in combination may increase the diagnostic yield [61].

Overall, the response of ESR and, in particular, CRP in UC appear to be less robust, with elevated values found in more extensive colitis compared to limited disease [62–65]. However, the development of highly sensitive CRP assays may improve the sensitivity of this test, even in patients with limited disease [66]. In a study by Poullis et al. [66], the authors evaluated 224 adult patients and determined the accuracy of the CRP in distinguishing IBD from functional GI disease. Using an enzyme-linked immunoassay approach to CRP measurement, the authors determined that a CRP cutoff value of 2.3 mg/L had a sensitivity of 100% and a specificity of 67% in differentiating functional bowel disease from new cases of IBD [66]. Compared to ESR, CRP has a

shorter half-life and, thus, returns to baseline values more rapidly once the inflammatory stimulus has resolved. Because of this rapid decline, CRP may be a better measure of remission and response to therapy than other inflammatory markers in patients with IBD [59].

Other laboratory markers, including leukocyte and platelet count, and albumin have been studied either less extensively in IBD, particularly in pediatric populations, or, have proven to be less useful than more traditional biomarkers such as CRP [59]. Conversely, more common laboratory markers are being used in novel ways to predict mucosal healing in patients with inflammatory bowel disease. Bertani et al. [67] evaluated 88 patients with ulcerative colitis who started anti-TNF monotherapy. Platelet-to-lymphocyte (PLR) and neutrophil-to-lymphocyte ratios (NLR) were calculated, and fecal calprotectin was collected both before treatment and after induction. The PLR and NLR values were correlated with clinical remission and mucosal healing at 54 weeks [67]. The authors determined that patients who reached mucosal healing after 54 weeks of therapy had lower baseline levels of both PLR and NLR ($p = 0.04$ and $p = 0.0001$, respectively). Patients who had active ulcers at baseline endoscopy displayed higher baseline levels of PLR and NLR compared to those who had no ulcers at initial endoscopy ($p = 0.0007$ and $p = 0.002$, respectively) [67]. Clearly as we continue to understand more about the pathogenesis of IBD, CD, and UC, these types of biomarkers and others to be developed can serve as noninvasive, objective biomarkers for the diagnosis, and monitoring of IBD.

Other Laboratory Evaluations

Liver function tests and electrolyte panels may add additional information to aid the clinician in differentiating IBD from non-IBD, in the determination of the IBD phenotype and, in particular, the presence or absence of extra-intestinal manifestations such as liver disease [68, 69]. Although severe liver disease can be the first presentation of IBD in pediatric patients, hypoalbuminemia is a more frequent finding at diagnosis [69]. Hypoalbuminemia is observed in both CD and UC; however, overall decreased serum albumin appears to be present at a much higher frequency in CD. In pediatric cohorts, hypoalbuminemia has been reported in 35–64% of patients with CD and 15% of patients with UC [26, 27, 70–74]. In a relatively small-sized ($N = 57$) pediatric study of children with UC from Saudi Arabia, hypoalbuminemia was observed in over half (54%) of the cohort evaluated, with disease severity correlating with the degree of hypoalbuminemia [75]. In addition to being useful in the diagnosis of IBD compared to non-IBD, as well as a factor in the assessment of the child's overall nutritional status, hypoalbuminemia when present, may have value as a prognostic factor for surgical risk [70]. Albumin can also be used as a marker for response to therapy. In an adult multicenter clinical trial evaluating one of the biologics for therapy of CD, the authors investigated the effect of adalimumab on changes in laboratory values using data from CHARM trial[76]. In a total of 778 adult patients, adalimumab every other week ($N = 260$), adalimumab weekly ($N = 257$), or placebo ($N = 261$), the authors observed significant improvements in nutritional, hematologic, and inflammatory markers, including and specifically albumin, in moderately to severely active CD [76].

Similar to the pathobiology of anemia associated with IBD, the etiology of hypoalbuminemia in the child or adolescent with IBD is multifactorial, with protein loss from intestinal inflammation, decreased albumin production (negative acute phase response), and long-term poor nutrition all contributing to the overall low circulating levels of this important protein [63, 71, 73].

Elevation of AST and ALT may also be present on initial screen in the evaluation of a patient with suspected IBD. In one study by Mendes et al. [77], the prevalence of abnormal hepatic biochemistries and chronic liver disease in a cohort of IBD patients was described in a retrospective case–control fashion. Patients with normal and abnormal liver biochemistries were compared, and in the cohort of 544 patients, abnormal hepatic biochemistries were present in nearly one third of these adult patients. Contrary to what the investigators hypothesized, abnormal liver biochemistries in this single center cohort were not associated with IBD activity. These authors recommended that persistently abnormal hepatic biochemistries should be evaluated, but to use caution and not immediately attribute these abnormal liver biochemistries to IBD activity [77]. Abnormal liver biochemistries may also be primarily related to poor nutrition as a result of active disease, and thus, spontaneous resolution of these transient elevations can occur [78].

When AST/ALT is persistently elevated or seen in association with an elevated alkaline phosphatase, elevated direct bilirubin, and/or γ-glutamyl transpeptidase, the extra-intestinal complication of primary sclerosing cholangitis (PSC) or autoimmune hepatitis/overlap syndrome should be considered. PSC is reported complication in 3–15% of children with IBD and can precede or occur coincident with diagnosis of IBD [79–82]. In a U.S. population-based health maintenance organization study, the prevalence of PSC in conjunction with IBD was characterized in addition to the demographic differences between racial/ethnic groups in patients with PSC compared to non-IBD and non-liver disease controls. Using the Northern California Kaiser Permanente (KP) database, the authors identified 169 (101 males) cases fulfilling PSC diagnostic criteria with a mean age at diagnosis of 44 years (range 11–81); age-adjusted point prevalence was 4.15 per 100,000 [83]. IBD was present in 64.5% (109/169) cases and was significantly more fre-

quent in men than women with PSC (73.3% and 51.5%, respectively, $p = 0.005$) [83]. In another small-sized single center study ($N = 29$), the incidence of IBD in PSC patients was 68.9% (20/29) [84]. The investigators showed two peaks in the age distribution of PSC with male PSC patients demonstrated a first peak and female patients a second peak. Male PSC-IBD patients were in their teens at diagnosis and 20s, and female PSC-IBD patients were in their 50s and 60s. Of note, the study demonstrated that PSC-IBD patents were significantly younger than the patients without IBD (33.6 vs. 58.9 years, $p < 0.001$) [84]. With regard to pediatric patients, Wilschanski et al. [81] demonstrated of 32 children with PSC, the majority were diagnosed in their second decade (median age: 13 years), and four children presented before the age of 2 years. Seventeen of the 32 patients had inflammatory bowel disease (IBD), all with colitis: 14 UC, and 3 CD [81]. Eight patients presented with chronic liver disease before clinical onset of IBD. Thus, of the hepatic pathologies reported associated with IBD in children and adults, PSC remains the more common presentation.

Other pediatric studies have demonstrated that even a mild elevation of GGT at diagnosis may raise suspicion of future risk of developing PSC. In a longitudinal, population-based study, Chandrakumar et al. [85] evaluated 95 children with UC/IBD-unclassified in Manitoba, Canada between 2011 and 2018 (median age at diagnosis, 14 years [IQR: 10.4–15.9 years]) . There were 9 total children in this cohort that developed PSC-UC; the authors noted that 8 of 11 children (72.7%) with high GGT levels at baseline developed PSC-UC compared to only 1 (1.2%) of 84 children with normal baseline GGT levels ($p < 0.001$) [85]. Further, all children with high baseline GGT had pancolitis, compared to 63.9% of children with normal GGT ($p = 0.01$). In another longitudinal, cohort study by Feldstein et al. [79], 52 children with cholangiography-proven PSC were followed to determine the long-term outcome (mean follow-up was 16.7 years) of children with PSC diagnosed over a 20-year period (34 boys and 18 girls; mean age 13.8 ± 4.2 years; range, 1.5–19.6 years). Two thirds presented with symptoms and/or signs of PSC and 81% had concomitant IBD [79]. During follow-up, 11 children underwent liver transplantation for end-stage PSC and 1 child died with the median (50%) survival free of liver transplantation being 12.7 years. Compared with an age- and gender-matched U.S. population, survival was significantly shorter in children with PSC ($p < 0.001$). Using a statistical regression model for analysis, the authors determined that lower platelet count, splenomegaly, and older age were associated with shorter survival. The presence of autoimmune hepatitis overlapping with PSC ($p = 0.2$) or medical therapy ($p = 0.2$) did not affect survival. Thus, the authors concluded that PSC, whether associated with IBD or not, significantly decreases survival in this child population [79].

The presence of PSC may also raise the risk of other morbidities. Ricciuto et al. [86] performed a retrospective study of 74 children diagnosed with PSC-IBD between 2000 and 2018; these children were age and sex matched to children with both UC and IBD-unclassified as a control group. Clinical parameters including evidence of clinical and endoscopic remission and patient growth were compared between groups. Patients with PSC-IBD more often had pancolitis, rectal sparing, and more severe right-sided disease compared to patients without PSC ($p < 0.05$) [86]. Patients with PSC were more often in clinical remission (OR, 2.94; 95% CI, 1.78–4.87), and risk of colectomy or biologic use was lower (HR, 0.24; 95% CI, 0.12–0.52). However, among all patients in remission, those with PSC-IBD were less likely to achieve endoscopic remission (OR, 0.44; 95% CI, 0.20–0.96) and were shorter with lower weights than their non-PSC controls [86].

Renal as well as pancreatic disease may also be important extra-intestinal manifestations of IBD or can be adverse events associated with IBD pharmacotherapy [87–92]. In a multicenter study from Israel, both adults and children presenting with acute pancreatitis as the first symptom of IBD were retrospectively identified (10 years, 7 university hospitals) [92]. These authors demonstrated that 10 of 460 pediatric patients with IBD (2.17%), compared with only 2 in 3500 adults (0.06%) presented with pancreatitis. Eight children had colonic disease (four CD, disease, four UC [three pancolitis]) with the mean amylase level being 1419 (range 100–1370) [92]. The median time between onset of the first episode of acute pancreatitis in relation to onset of IBD was 24 weeks (range 1–156), and the most common presentation in this cohort was abdominal pain. Amylase and lipase may, therefore, be considered at some point in the initial evaluation when clinical signs and symptoms raise suspicion of pancreatic disease, and prior to or after initiation of therapy particularly those medications with a predilection (e.g., thiopurines, 5-aminosalicylates) for pancreatitis as a side effect.

Similarly, renal disease may precede diagnosis of IBD, and this risk may change over the course of a person's lifetime. Despite small in sample size, Izzedine et al. [93] described that four patients with severe interstitial nephritis demonstrated on histopathological examination of kidney biopsy specimens. Renal failure was discovered before or simultaneously with the diagnosis of CD, and patients were not treated with mesalamine. More importantly, impairment of renal function progressed to end-stage renal failure in three of the four patients [93]. A similar small case series of two pediatric patients with renal disease occurring concurrently with diagnosis of IBD has been reported [94]. Recent studies with larger sample sizes provide more insight into potential relationships between renal disease and IBD. A recent retrospective review of 456 children with IBD (346 with CD and 110 with UC) found that the incidence of

kidney-related symptoms was 14.7%, which the authors noted were higher than in healthy children [95]. Renal biopsies performed in 7 children revealed immunoglobulin A nephropathy in 5/7 (71.4%) [95]. Vajravelu et al. [96] performed a retrospective cohort study in which 17,807 patients with IBD were matched for age, sex, and practice to 63,466 patients without IBD. After controlling for risk factors associated with chronic kidney disease (CKD), the authors found IBD to be associated with development of CKD in adolescent and adult patients' ages 16–77 years [96]. The adjusted hazard ratio for CKD decreased with increasing age (from 7.88 [95% CI 2.56–24.19] at age 16–1.13 [95% CI 1.01–1.25] at age 77). Thus, with respect to appropriate adjunct or complementary lab tests to obtain in the work-up of a child with suspected IBD, given the reports of kidney disease in patients with Crohn disease in the absence of 5-aminosalicylate exposure and risk of CKD in patients with IBD, a baseline comprehensive chemistry panel should be considered during the initial evaluation.

The above paragraphs highlight the standard evaluation that is recommended for all children with history and physical exam findings suspicious for IBD. These diagnostic tests may aid the clinician in the differentiation of UC and CD from functional bowel disorders and infectious etiologies. However, because the clinical presentation of IBD is so diverse and symptoms can be nonspecific, at times, it may be difficult to distinguish between inflammatory and functional disorders. In fact, since May 13, 1932, when Dr. Crohn and his colleagues, Oppenheimer and Ginzburg, presented a paper on terminal ileitis describing the features of Crohn disease to the American Medical Association, the average time from onset of symptoms to definitive diagnosis continues to be prolonged, ranging from 6 to 18 months [97, 98].

Several other noninvasive studies have been proposed to aid in the diagnosis of inflammatory bowel disease including IBD serologies and fecal calprotectin. The following section reviews these tests including a brief overview of the use of IBD serology and the evidence to support or disprove their use in the preliminary evaluation of the child with suspected IBD. In addition, this section will describe the stool tests which are an essential part of the initial work-up of the child with suspected IBD, and includes a discussion of fecal calprotectin, a marker of intestinal inflammation.

Specific Blood Tests: Inflammatory Bowel Disease Serologies

Anti-*Saccharomyces cerevisiae* (ASCA), an antibody response against *Saccharomyces cerevisiae* and perinuclear antinuclear cytoplasmic antibody (pANCA), an antibody response toward nuclear antigens with a perinuclear pattern, are two immunologic markers detected in IBD. There continues to be debate in both the pediatric and adult clinical settings regarding the proper use of these serologies in the evaluation of IBD, and there have been several studies assessing the accuracy and clinical utility of ASCA and pANCA in children with IBD [1, 5, 99–108]. Although these investigations differ in their study design and, in some cases, the type of serological profile obtained, overall, these markers appear to be reasonably specific for both CD and UC. In the reported studies, ASCA (IgG or IgA) specificity ranged from 88% to 97% for CD [101, 103–106] and pANCA specificity ranged from 65–95% for UC [100, 101, 103–106]. In children, the specificity of the combined serologies in differentiating IBD from non-IBD has been reported to range from 84% to 95% [1, 5, 101, 103, 107]. Unfortunately, the sensitivity of these serologies has been shown to be poor with overall sensitivity ranges reported between 55% and 78% [1, 5, 99, 101, 103, 107]. A meta-analysis of 60 adult and pediatric studies yielded similar findings and reported the sensitivity and specificity of ASCA IgG or IgA positive and pANCA negative for the detection of Crohn disease as 55% and 93%, respectively [109]. The sensitivity and specificity of positive pANCA for detection of UC were lower at 55.3% and 92.8%, respectively [109]. Therefore, a negative test result does not exclude the diagnosis of IBD, particularly in those patients with nonspecific symptoms such as abdominal pain and intermittent diarrhea. The addition of anti-OmpC, an antibody to the outer membrane porin of *Escherichia coli*, appears to add little to the diagnostic accuracy of this serologic panel in children [105, 106]. In two pediatric studies, the overall sensitivity of anti-OmpC for both CD and UC was very low [105, 106]. However, the use of the additional IBD serologies may help identify a small number of IBD patients who had negative ASCA and pANCA [105, 106, 110]. Younger children appear to have the greatest proportion of seronegativity to ASCA and ANCA, and therefore, these additional markers, particularly anti-cBir, may be most helpful in this population [110]. Moreover, with an increasing number of candidate genes identified in patients with IBD, particularly CD, other serological markers have been identified that may increase the overall sensitivity of the assays [111]. For example, patients carrying the NOD2 mutations have an increased adaptive immune response to commensal organisms as measured by higher titers of antimicrobial antibodies, such as anti-CBir and ASCA [111]. Thus, use of a combination of serologic, genetic, and inflammatory markers may further improve the diagnostic accuracy and utility of these tests for discriminating IBD from noninflammatory conditions [112].

Although their specificity is reasonable, overall ASCA and pANCA appear to be less sensitive than clinical history and routine laboratory tests (hemoglobin and ESR) in the

evaluation of pediatric IBD. In a retrospective study, Khan et al. [107] evaluated 177 pediatric subjects who had pANCA and ASCA, hemoglobin, ESR, and colonoscopy as part of their initial evaluation. In this study, 90 patients were diagnosed with IBD, and of those, 52 had UC and 39 had CD. Combining abnormal hemoglobin and/or ESR with rectal bleeding, the most distinguishing symptom for IBD in this study cohort, was more sensitive than positive ASCA and/or pANCA (86% versus 68%) and identified 86% of patients with IBD prior to endoscopy. A study by Sabery et al. [1] yielded similar findings. In this retrospective study which included 210 pediatric subjects, 40 with IBD, the sensitivity of ASCA and pANCA was again compared to hemoglobin and ESR [1]. The presence of an abnormal hemoglobin or ESR was the more sensitive screen, with a sensitivity of 83%, compared to 73% for the First Step® modified assay (Prometheus laboratories, San Diego, CA), and 60% for the confirmatory panel, which included anti-OmpC. In the subset of patients without rectal bleeding, a group whose symptoms may be more difficult to differentiate from functional disorders, the sensitivity of ASCA and pANCA decreased to 55% whereas the sensitivity of an abnormal hemoglobin or ESR remained high at 91%. In pediatric patients, the addition of antibodies to cBir flagellin to the serological panel does not appear to improve the diagnostic yield of this panel. A retrospective study of 304 pediatric patients with suspected IBD reported a sensitivity of 67% and specificity of 76% of the combined serological panel, and for anti-cBir specifically, the sensitivity and specificity were 50% and 53%, respectively [108]. As mentioned, combination of standard laboratory tests (hemoglobin, platelet count, and ESR) had higher predictive value, with sensitivity of 72%, specificity of 94%, and positive predictive value of 85% [108]. Additionally, as hemoglobin and ESR are both components of the PCDAI, they have added value as markers of disease severity and clinical response.

Given the cost of these tests and overall poor sensitivities documented in several pediatric studies, particularly compared to other clinical and laboratory parameters, currently, serology testing does not appear to have additive value as a screening test in the initial diagnostic work-up for patients with suspected IBD. However, these serologies may have a role in predicting disease course and identifying patients at risk for complicated disease. In a study by Targan et al. [113], 484 sera previously employed for a study evaluating other serological markers of IBD (namely, ASCA, pANCA, OmpC) were tested for anti-CBir1 by enzyme-linked immunosorbent assay. Interestingly, the authors observed that the presence and level of immunoglobulin G anti-CBir1 were associated with CD independently and were associated with a unique phenotype of CD, namely, small-bowel, internal-penetrating, and fibrostenosing disease. Papadakis et al. [114], also demonstrated that anti-CBir1 serum reactivity in CD patients is independently associated with fibrostenosing disease and complicated small-bowel CD. In a large prospective inception cohort of pediatric patients with newly diagnosed Crohn disease (n-913), CBir1 seropositivity was significantly associated with structuring disease behavior, whereas both CBir1 and ASCA IgA positivity were associated with penetrating complications [115]. As a single marker, ASCA may be most predictive of aggressive disease and several studies have demonstrated that ASCA positivity (IgG or IgA) alone was associated with complicated disease behavior, perianal disease, and risk for surgery in both pediatric and adult cohorts [105, 116–120]. In children with CD, the presence of multiple serologic markers and degree of antibody elevation has been associated with more severe disease phenotypes, with frequency of internal-penetrating and fibrostenosing disease increasing with the number of antibodies present [121, 122]. Similar to adult data, anti-Omp C and anti-IL2 were independently associated with these complications [122]. A cross-sectional study of adults with CD suggests that in addition to quantitative serologic markers, the presence of NOD2 genetic variants is associated with complicated disease [123]. Overall, the data for pANCA and disease stratification/course are less robust. While one study demonstrated no correlation between disease severity and pANCA titers [124], another recent multicenter study found that while pANCA did not correspond to a specific phenotype, a level ≥100 was significantly associated with pancolitis ($p = 0.003$) [125]. Additionally, pANCA reactivity may be associated with primary nonresponse to anti-TNF therapy in pediatric patients, and the absence of this marker may help predict long-term response to this medication [126, 127].

Approximately 10% of patients with IBD are diagnosed with IBD-unclassified (IBD-U), and this diagnosis may be higher in younger children as isolated colonic CD is more common [110]. There is interest in using these serologies to classify disease subtype in children with IBD-U and to assist in therapeutic decisions such as colectomy. In one longitudinal study of 406 children with Crohn colitis, UC, and IBD-U, ASCA positivity differentiated well between Crohn colitis, IBD-U, and UC (specificity 83%, PPV 96%); pANCA positivity had similar positive predictive value, but much lower sensitivity and specificity (65% and 66%, respectively) [128]. However, as the most common serologic profile in IBD-U is ASCA−/pANCA−, serology overall has lower utility in predicting subsequent disease type [128, 129]. Therefore, based on the above data the use of these serologies, particularly cBir and ASCA IgA, should be reserved as a potential prognosticator of a severe disease course and assessment for risk for stricturing and/or penetrating disease.

Stool Evaluation

The presentation of pediatric inflammatory bowel disease can be markedly variable. However, those children who present with "classic" gastrointestinal complaints such as diarrhea and abdominal pain should have a thorough stool evaluation for potential bacterial and parasitic etiologies of these symptoms. Standard stool cultures to look for enterohemorrhagic *Escherichia. coli*, *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter* species, *Clostridium difficile* assay, preferably by PCR, and ova and parasite studies to look for *Entamoeba histolytica* and other parasites are a necessary part of the work-up to differentiate infectious versus inflammatory enterocolitis and should be obtained prior to invasive procedures. In particular, *Yersinia enterocolitica* infections may mimic CD, and thus, specific emphasis should be placed on looking for this organism as isolation can be increased by using selective media [130, 131]. Also, defects in mucosal barrier function can predispose patients with IBD to infectious colitis, and *Clostridium difficile (C. difficile)* is the most common infectious agent identified [132, 133]. Overall *C. difficile* infection has been a growing problem and the rates of *C. difficile* infection have been increasing as have pediatric hospitalization due to this infection [134]. *C difficile* infections are important to identify in children with IBD as the presence of *C. difficile* infection (CDI) may have prognostic utility. A recent study of 261 children with IBD found that those with CDI were at increased risk of future escalation of IBD therapy compared with children who did not develop CDI [135]. Further, CDI has been associated with a more severe disease course subsequent to CDI diagnosis [136]. Clinical symptoms of *C. difficile* and IBD are similar and the prevalence of *C. difficile* is significantly greater in pediatric patients with IBD compared to children without this diagnosis [137, 138]. A positive stool test, therefore, does not rule out the possibility of IBD, and thus, patients with a suspicious clinical history who do not improve with appropriate treatment of stool pathogens should have further diagnostic evaluations.

Fecal Calprotectin

Calprotectin, a calcium-binding protein in the S100 family, is an abundant protein in neutrophils, and to a lesser extent, macrophages and monocytes, accounting for approximately 60% of the cytosolic protein in neutrophils [139–141]. Calprotectin has bacteriostatic and antifungal properties, and thus, likely contributes to neutrophilic defenses [142]. In healthy individuals, concentrations of calprotectin are approximately six times higher in stool than plasma [141]. In IBD, a spot fecal calprotectin level correlates well with fecal excretion of [111] indium white cells, and therefore, this protein can be an alternative marker of intestinal inflammation [143, 144]. Fecal calprotectin is easy to measure, resistant to proteolysis and stable in stool for 7 days, and thus, is a simple noninvasive investigative tool, which may help distinguish inflammatory from functional disorders [58, 141, 145–149].

Several studies have shown elevated fecal calprotectin levels in adult and pediatric patients with both UC and CD compared to healthy controls and patients with irritable bowel syndrome (IBS) [58, 145–149]. In one large study of 602 new patient referrals who had symptoms compatible with either irritable bowel syndrome or organic disease, including 189 patients later diagnosed with IBD, fecal calprotectin levels of >10 mg/L had a sensitivity of 89% and specificity of 79% for organic diseases [150]. This test was more sensitive than either ESR or CRP and an abnormal fecal calprotectin had an odds ratio for disease of 27.8 [150]. A subsequent meta-analysis of six prospective adult studies that assessed the diagnostic accuracy of fecal calprotectin in patients with suspected IBD revealed a pooled sensitivity and specificity of 93% and 96%, respectively [151]. A more recent meta-analysis of 19 studies with combined 5032 patients calculated a lower pooled sensitivity of 88.2% and specificity of 79.9% [152]. However, there was significant heterogeneity of the studies and 4 of the studies had a cutoff calprotectin level of >50 μg/g, which may have contributed to the lower pooled sensitivity and specificity in this analysis. Other studies have demonstrated that fecal calprotectin may be superior to CRP in discriminating between IBD and irritable bowel syndrome with a diagnostic accuracy of 80–89% compared to 64–73% for CRP [153, 154].

There have also been several studies evaluating fecal calprotectin in the pediatric population. Carroccio et al. [155] study cohort included 50 children with chronic diarrhea, and the assay had a higher sensitivity (70%) and specificity (93%) in pediatric patients than in adults. Some pediatric studies have reported even higher sensitivity of the fecal calprotectin assay. Fagerberg et al. [145] obtained fecal calprotectin levels in 36 pediatric patients with gastrointestinal symptoms who underwent colonoscopy for suspected inflammation. Using the standard upper reference limit of <50 μg/g for the modified assay, the test has a sensitivity and specificity for inflammation of 95% and 93%, respectively. Using an older assay, Bunn et al. [156] reported a sensitivity of 90% and specificity of 100% for identifying intestinal inflammation in 36 pediatric patients who underwent either colonoscopy or [99]Tc-labeled white blood scans for suspected inflammatory bowel disease. As there was a strong suspicion of IBD in these studies, there may be some selection bias, which resulted in these higher sensitivities and specificities. However, when used in the primary care set-

tings, sensitivity and specificity appear similar. Walker et al. studied 195 children ages 4–18 years in the primary care setting in the UK and found that fecal calprotectin had a 91% diagnostic accuracy with a sensitivity of distinguishing IBD from non-IBD of 100%, a specificity of 91%, utilizing a cut-off value of <100 μg/g. While the positive predictive value was low (43%), the negative predictive value was high (100%).

Other pediatric studies have reported similar sensitivities but lower specificities of the fecal calprotectin assay in differentiating IBD from other conditions [157, 158]. Two meta-analyses of prospective pediatric studies revealed a pooled sensitivity and pooled specificity of 92–97% and 70–76%, respectively [151, 159], whereas meta-analyses that also included respective pediatric case–control studies, which may introduce more bias, reported slightly lower pooled specificities (65–68%), with similar high pooled sensitivities [61, 160]. With relation to CD, disease location (small bowel versus colonic involvement) does not appear to limit the utility of this test [161–164]. Based on these collective results, it appears fecal calprotectin that correlates well with the presence of histologic inflammation in pediatric patients. In patients where symptoms overlap with both IBD and IBS, obtaining fecal calprotectin testing prior to endoscopy may be a cost-effective screening strategy, particularly when the suspicion of IBD is low [165].

Fecal calprotectin may offer some insight into the severity of inflammation in children with IBD, with levels correlating with severity of mucosal disease, with a correlation superior to clinical activity indexes and CRP [161, 162, 166, 167]. As it correlates with mucosal disease, fecal calprotectin may be surrogate for mucosal healing. In one small prospective study of 24 newly diagnosed children with CD, a drop in fecal calprotectin of >50% after therapy had a specificity of 82% for predicting inactive endoscopic disease [168]. In multicenter study of 151 pediatric patients with CD, calprotectin of 100 μg/g identified children with deep healing with 71% sensitivity and 92% specificity [169]. In this cohort, calprotectin of 300 μg/g identified children with mucosal healing with 80% sensitivity and 81% specificity. In adults, low FC also correlates well with histologic remission and mucosal healing [170–172]. In one study of 126 adult patients with IBD, a level ≤250 μg/g predicted endoscopic remission in CD with 94.1% sensitivity and 62.2% specificity, whereas, in UC, a level >250 predicted active mucosal disease with a sensitivity of 71% and specificity of 100% [170]. Additionally, there have been several studies evaluating fecal calprotectin's role in predicting disease relapse. One prospective study of 32 children with IBD found that 90% of patients with fecal calprotectin >400 μg/g experienced clinical relapse whereas 89% with fecal calprotectin below this threshold remained in clinical remission [173]. A larger prospective multicenter adult study also demonstrated that calprotectin concentrations in patients who relapsed were higher than those who did not, with a fecal calprotectin level of >150 μg/g having a sensitivity of 69% and specificity of 69% to predict relapse [174]. A recent systematic review of 6 studies showed similar findings with asymptomatic patients who had repeated elevated calprotectin (upper limit of normal 55–300 μg/g) having a 53–83% probability of disease relapse within thin next 2–3 months, whereas patients with a repeat normal calprotectin had a 67–94% probably to remain in remission during the same time period [175]. Therefore, the assay offers an advantage over other nonspecific inflammatory markers as appears to be a direct measure of intestinal inflammation and consequently may be followed prospectively in patients as a marker of disease activity and relapse. Although additional large prospective pediatric clinical studies are still needed, fecal calprotectin is valuable in the evaluation of patients with suspected IBD and for monitoring disease activity prospectively.

Summary

In the preceding paragraphs, we attempted to provide an overview of the laboratory tests, both blood and stool studies, available that can be used in the initial work-up of the child with suspected inflammatory bowel disease. Although a thorough clinical history and physical exam can raise suspicion of CD or UC, it is important to include a focused laboratory evaluation. A combination of blood and stool tests may further differentiate between IBD and non-IBD in particular, inflammatory disease, compared to infectious processes and functional bowel disorders. Not only can a carefully chosen combination of blood and stool studies help determine which child may require more invasive testing, but they can also be used in the initial phenotyping of the disease, i.e., CD versus UC. Moreover, there are laboratory tests available, specifically IBD serologic markers such as ASCA and anti-CBir1, which can be employed to subtype CD and potentially provide the clinician with the ability to prognosticate disease severity. The definitive diagnosis of IBD is made by combining historical features, physical examination, radiological findings, and endoscopy and biopsy. However, laboratory investigations provide important information about inflammation and function of other organ systems in the child with IBD, which ultimately helps guide the clinician toward more invasive testing, making a definitive diagnosis and even phenotyping the IBD that facilitates the ability for the clinician to employ more precise targeted optimal therapies.

Fecal Markers in Inflammatory Bowel Disease

19

Barbara Niklinska-Schirtz and Cary G. Sauer

Introduction

Inflammatory bowel diseases (IBD) include ulcerative colitis (UC) and Crohn disease (CD). These diseases are defined by mucosal inflammation. Endoscopy and histology are necessary for diagnosis and are often used as monitoring tools. For many years, symptoms and laboratory studies (C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and albumin) have been used to monitor disease activity, despite with relatively low specificity for mucosal inflammation or disease severity. Fecal calprotectin can detect mucosal inflammation, and an extensive body of literature has developed confirming its utility in detecting new inflammatory bowel disease and monitoring disease activity once diagnosed. While there are other stool markers such as lactoferrin, this chapter will focus on fecal calprotectin as it is the most well-studied stool marker including recent meta-analyses and systematic reviews, as well as current guideline suggestions for the use of fecal calprotectin testing. Table 19.1 includes selected recent meta-analyses, Table 19.2 includes selected systematic reviews, and Table 19.3 includes guideline recommendations for use of fecal calprotectin.

Table 19.3 Fecal calprotectin recommendations in guidelines

Reference/Organization	Guildeline	Recommendations
American College of Gastroenterology (ACG)	ACG Clinical Guideline: Management of Crohn Disease in Adults	Fecal Calprotectin is a helpful test that should be considered to help differentiate the presence of IBD from irritable bowel syndrome (Strong recommendation, moderate level of evidence)
PMID: 29610508		Fecal calprotectin and fecal lactoferrin measurements may have an adjuntive role in montoring disease activity
Lichtenstein GR, Loftus EV, Isaacs KL, et al. ACG Clinical Guideline: Management of Crohn's Disease in Adults. Am J Gastroenterol 2018;113:481-517.		As there is often a disconnect between clinical symptoms and underlying inflammation, it is of crucial importance to monitor disease and therapy at regular intervals based on objective and measurable markers [endoscopy, C-reactive protein [CRP], calprotectin, imaging].
European Crohn's and Colitis Organisation (ECCO)	Guideline for Diagnostic Assessment in IBD Part 1: Initial diagnosis, monitoring of known IBD, detection of complications	
PMID: 30137275		Response to treatment in active UC should be determined by a combination of clinical parameters, endoscopy and laborator markers such as CRP and fecal calprotectin
Maaser C, Sturm A, Vavricka SR, et al. ECCO-ESGAR Guideline for Diagnostic Assessment in IBD Part 1: Initial diagnosis, monitoring of known IBD, detection of complications. J Crohns Colitis 2019;13:144-164.		In patient siwth UC who clinically respond to medical therapy, mucosal healing should be determined endoscopically or by fecal calprotectin approximately 3 to 6 months after treatment initiation
Brtitish Societ of Gastroenterology	British Society of Gastroenterology consensus guidelines on the management of inflammatory bowel disease in adults	We recommend that, for patients aged 16–40 presenting in primary care with chronic diarrhoea and symptoms that may be consistent with either IBD or IBS, faecal calprotectin is a useful screening tool with a high negative predictive value. If significantly elevated, patients should have an infective cause excluded and be referred for further investigation (GRADE: strong recommendation, moderate-quality evidence. Agreement: 97.9%).
PMID: 31562236		
		We suggest that, in IBD patients where it is unclear if symptoms are due to ongoing inflammation or other non-inflammatory causes (such as bile acid malabsorption, functional bowel disorder or short bowel), faecal calprotectin measurement may be used to provide evidence of mucosal inflammation (GRADE: weak recommendation, low-quality evidence. Agreement: 97.8%).
Lamb CA, Kennedy NA, Raine T, et al. British Society of Gastroenterology consensus guidelines on the management of inflammatory bowel disease in adults. Gut 2019;68:s1–s106.		We suggest that faecal calprotectin is a validated biomarker for endoscopic and histological disease activity. It may therefore be a useful non-invasive parameter to inform decisions on treatment escalation or de-escalation (GRADE: weak recommendation, moderate-quality evidence. Agreement: 100%).

Table 19.3 (continued)

Reference/Organization	Guildeline	Recommendations
European Socitety for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)	The Medical Management of Paediatric Crohn Disease: an ECCO-ESPGHAN Guideline Update	
PMID: 33026087		In patients with luminal CD following induction therapy, a decrease of faecal calprotectin in the context of clinical improvement can be used as a marker of treatment response. LoE: 3 | Agreement: 100%.
van Rheenen PF, Aloi M, Assa A, et al. The Medical Management of Paediatric Crohn's Disease: an ECCO-ESPGHAN Guideline Update. J Crohns Colitis 2020.		In patients with luminal CD in clinical remission, a significant rise of faecal calprotectin should trigger further investigations and consideration of treatment escalation. LoE: 3 | Agreement: 92%.
European Socitety for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)	Management of Paediatric Ulcerative Colitis, Part 1: Ambulatory Care-An Evidence-based Guideline From European Crohn and Colitis Organization and European Society of Paediatric Gastroenterology, Hepatology and Nutrition	If available, fecal calprotectin should be obtained while in sustained clinical remission and endoscopic evaluation should be considered when calprotectin is high, as defined below [EL2, adults EL2]. (88% agreement)
PMID: 30044357		
		Fecal calprotectin may be used to assess pouch inflammation to minimize repeated pouchoscopies in recurrent pouchitis and to monitor response to treatment. Calprotectin >300 mg/g is suggestive of pouchitis while lower levels do not preclude pou- chitis (57% sensitivity, 92% specificity). (95% agreement)
Turner D, Ruemmele FM, Orlanski-Meyer E, et al. Management of Paediatric Ulcerative Colitis, Part 1: Ambulatory Care-An Evidence-based Guideline From European Crohn's and Colitis Organization and European Society of Paediatric Gastroenterology, Hepatology and Nutrition. J Pediatr Gastroenterol Nutr 2018;67:257-291.		There is no ideal cutoff value of fecalcal protectin to reflect mucosal inflammation and predict disease outcome (Tables 19.2 and 19.3). Values differ substantially in the different studies using different reference standards. Cutoff value <100 mg/g usually reflects remission while >250 mg/g more accurately predicts mucosal inflammation. The value that should trigger an endoscopic evaluation or a change in treatment should be, thus, individualized based on these values, especially when values increase over time. (98% agreement)

Overview of Stool Tests

Stool studies often help clinicians when non-specific symptoms such as diarrhea, bloating, weight loss, nausea, vomiting, and abdominal pain affect the patient. These symptoms can be found in many diseases and distinguishing between infectious, functional disorders such as irritable bowel syndrome, and inflammatory conditions such as inflammatory bowel disease, specifically Crohn disease and ulcerative colitis can be challenging. There is a need for sensitive, accurate, and non-invasive markers to help differentiate between functional and organic disorders.

Fecal biomarkers to detect gastrointestinal inflammation have been used for years, however, with decreased costs, increased insurance coverage, and an ever growing body of research that the use of fecal biomarkers has grown exponentially.

Fecal biomarkers include calprotectin (S100A8/S100A9), fecal leukocyte degranulation markers (lactoferrin, polymorphonuclear elastase, and myeloperoxidase), and calgranulin (S100A12). Fecal calprotectin and lacroferrin are the most commonly used and studies markers. These commercially available enzyme-linked immunosorbent assays (ELISAs) have become reliable non-invasive markers to aid with diagnosis and therapy trends in IBD.

Introduction to Calprotectin

Calprotectin is a 36-kDa protein, specifically a calcium- and zinc-binding heterodimer, belonging to the S100 family which was first described in 1980. Calprotectin is a major protein in n0eutrophilic granulocytes, specifically neutrophils, and macrophages, accounting for as much as 60% of the total protein in the cytosol fraction of these cells [1]. With its direct antimicrobial effect, it can facilitate the recruitment of monocytes and macrophages to sites of inflammation, specifically to the gastrointestinal tract [1]. Calprotectin is released into the gastrointestinal tract when inflammatory epithelial cells die. Calprotectin is resistant to bacterial degradation, remains stable in stool for up to 1 week, and is reliably measured by enzyme-linked immunosorbent assay (ELISA) [1]. A strong correlation of FC with active inflammation in the gut has been shown by many studies [2].

Fecal Calprotectin Collection

Fecal calprotectin measurement is influenced by both stool consistency and time between collection and measurement. Recent data suggest some instability of fecal calprotectin with a decrease in fecal calprotectin when stored at room temperature, and thus, there is a suggestion to freeze samples prior to submission when collected at home [3]. Meanwhile, stool consistency and specifically diarrhea are likely to falsely decrease the fecal calprotectin concentration. This is best demonstrated by low calprotectin when collected during bowel cleanout [4]. Infants have been described to have high fecal calprotectin in the first year of life; however, most are collected in diapers, and thus, there is the possibility that absorption of water in the diaper may falsely elevate the fecal calprotectin. A recent study demonstrated a high fecal calprotectin in healthy infants, but all samples were collected in diapers [5]. These findings are consistent with what one would suspect since, unlike blood volume, stool volume is highly variable with the amount of water present in stool which can affect the measurement of concentration in a sample.

Cuffoff Levels

Normal cutoff varies from 50 to 200 μg/g depending on laboratory and clinical practices. Many studies have shown FC to be helpful in distinguishing organic intestinal disease from functional disorders. Von Roon et al. assessed the diagnostic precision of FC for IBD in both adults and children [6]. They found that the diagnostic precision of FC was higher in children and adults with better accuracy at a cutoff level of 100 μg/g vs. 50 μg/g. In a recent meta-analysis, examining the optimum FC cutoff levels, the best sensitivity (90.6%) was achieved at 50 μg/g, whereas the best specificity (78.2%) was found at levels >100 μg/g [7].

Clinical prediction of IBD relapse can also be assessed using non-invasive biomarkers such as FC. This has been shown in patients with both CD and UC. Tibble et al. showed that a single FC level >50 mg/L that the sensitivity and specificity of calprotectin for predicting relapse in all patients with IBD were 90% and 83%, respectively [8].

Finally, another meta-analysis by van Rheenen et al. investigated whether FC use could reduce the number of unnecessary endoscopic procedure in both children and adults [9]. Their pooled sensitivity and specificity were 0.93 and 0.96, respectively, for adults, and 0.92 and 0.76, respectively, in children. Screening with FC resulted in a 67% reduction in the number of adults requiring endoscopy; however, this delayed diagnosis in 6% of adults because of a false-negative test result. They found that in children and teenagers, 65 instead of 100 would undergo endoscopy, and 9 of these 65 will not have IBD. Diagnosis was delayed in 8% of the affected children.

We suggest that FC cutoff level should be tailored to the specific patient and reason for use. For instance, when screening children for IBD, a low threshold such as 50 μg/g would limit those with IBD that are undiagnosed, although it would increase the number of unnecessary endoscopies. Likewise, with data on small bowel Crohn disease suggesting lower FC levels, a low threshold such as 50 μg/g to monitor disease may be ideal. Meanwhile, for colonic disease, one could consider a higher FC cutoff up to 250 μg/g to monitor disease.

Reliability, Sensitivity, and Specificity

FC has been compared to symptom-based clinical scoring systems as well as laboratory markers to study its sensitivity in evaluating disease activity. FC has higher sensitivity and specificity rates than CRP and stool lactoferrin [10]. A recent systemic review and meta-analysis aimed to determine the usefulness of FC in children with suspected IBD. The authors found a pooled sensitivity and specificity for the diagnostic utility of FC in suspected pediatric IBD of 0.978 and 0.682, respectively [11]. After induction therapy, FC was found to normalize in patients with clinical remission. Molander et al. aimed to evaluate whether a normal FC after induction therapy with TNF-alpha antagonist could predict the outcome of IBD patients during maintenance therapy [12]. With a cutoff concentration of 139 μg/g, they found FC had a sensitivity of 72% and a specificity of 80% to predict a risk of clinically active disease after 1 year.

Another more recent meta-analysis aimed to determine the diagnostic performance of FC in assessing IBD endoscopic activity in adults [7]. Rokkas et al. included 49 sets of data from 25 eligible studies, with 298 controls and 2822 patients with IBD. They found that FC in IBD showed a pooled sensitivity of 85%, specificity of 75%, and AUC of 0.88 in diagnosing active disease. FC performed better in UC than in CD (pooled sensitivity 87.3% vs 82.4%, specificity 77.1% vs. 72.1%, and AUC 0.91 vs. 0.84).

Fecal Calprotectin as a Screening Tool

The use of fecal calprotectin to differenctiate functional gastrointestinal disorders from inflammatory bowel disease has been well documented. There have been multiple meta-analyses in both adults and children that demonstrate excellent sensitivity and specificity for the use of fecal calprotectin in screening for IBD and, thus, differentiating between IBD and functional gastroeinterstinal disorders. In one of the largest adult meta-analysis including over 5000 patients, the

pooled sensitivity for use of FC to screen for IBD was 0.882 (95% CI 0.827–0.921), and the pooled specificity for use in screening was 0.7999 (95% CI, 0.693–0.876). Similarly, multiple pediatric meta-analysis demonstrated excellent sensitivity and specificity in the use for screening for possible IBD (sensitivity 0.97, specificity 0.70).

Fecal Calprotectin Comparison to Endoscopy

There is a large body of evidence comparing fecal calprotectin to endoscopy and endoscopic disease measures such as the CDEIS (Crohn Disease Endoscopic Index of Severity) and the SES-CD (Simple Endoscopic Score for Crohn Disease). In a large meta-analysis of over 3000 total patients, the sensitivity and specificity for assessing endoscopic activity were 0.85 and 0.75 respectively. Fecal calprotectin sensitivity and specificity vary in a systematic review with a sensitivity from 69% to 96% depending on the study; however, most studies demonstrate a sensitivity near 90%. Specificity also demonstrated a large range from 44% to 95% with most studies demonstrating a specificity near 80%. These data suggest excellent agreement between calprotectin and endoscopy.

Fecal Calprotectin and Comparison to MRI

MRI enterography (MRE) has become a common tool in the assessment of small bowel CD. Somwaru et al. investigated the correlation between all three biometric tests including FC, MRE, and colonoscopy, and found significant positive correlation between FC and MaRIA (Magnetic Resonance Index of Activity) as well as FC and CDEIS [13]. Another study found FC correlating with the degree of MRE inflammatory activity as well as surgical pathology damage in ileal CD for 120 patients [14]. The MaRIA score was significantly associated with FC levels, and FC reflected MRE inflammatory activity with an area under the receiver operating characteristic curve of 0.914 [14]. FC correlated well with MRE assessment of ileal CD in 104 patients with ileal CD [15]. An AUC is of 0.77 for FC and MRE score >1, with an optimal cutoff of 145 μg/g for severe inflammation on MRE with 69.3% sensitivity and 71.4% specificity [15]. This outperformed other serum markers such as CRP and helped predict biologic-free survival to 3 years but did not predict the risk of intestinal resection.

Fecal Calprotectin and Disease Location

Fecal calprotectin has somewhat decreased sensitivity and specificity when detecting small bowel disease as demonstrated by correlation with capsule endoscopy indices. However, most studies still demonstrated excellent sensitivity and specificity when using a lower cutoff value of 50 μg/g. A recent systematic review suggested that most studies demonstrated higher fecal calproetecin in colonic disease in 4 studies while 7 studies demonstrated no difference between small bowel and colonic disease [16]. While diagnostic accuracy of small bowel versus colonic disease varied and was lower in small bowel disease, the study that used a low 50 μg/g cutoff level demonstrated excellent sensitivity and specificity for both small bowel and colonic disease.

Fecal Calprotectin Use to Monitor Pediatric Inflammatory Bowel Disease

The prediction of relapse of inflammation in both CD and UC is important in clinical practice. Twenty five patients with CD and 19 patients with UC that relapsed over 12 months had increased concentrations of FC which can help predict clinical relapse of disease activity [8]. Six studies were found in a systematic analysis of repeated FC measurements in asymptomatic patients to predict IBD relapse, and found that two consecutive elevated FC values (within 2-3 months) are highly associated with disease relapse, urging to consider proactively optimizing IBD therapy plans [17]. ESPGHAN clinical guidelines for CD suggest a decrease in FC can be used as a marker of treatment response with 100% agreement. Similarly, ESPGHAN guidelines for UC suggest the use of fecal calprotectin to assess for remission and detect pouchitis if applicable (Table 19.3) [18, 19].

Fecal Calprotectin to Evaluate Post-Operative Recurrence

In adults, a meta-analysis of more than 600 patients demonstrated sensitivitiy of 0.82 and specificity of 0.61 in detecting post-operative recurrence after surgical resection [20]. Similarly, fecal calprotectin in children demonstrated excellent ability to detect post-operative recurrence [21].

Fecal Calprotectin to Evaluate for Pouchitis

Total colectomy with ileal pouch anal anastomosis (IPAA) is necessary in some children with severe refractory ulcerative colitis. Pouchitis can occur at any time following colectomy. A recent systematic clinical review in adults demonstrated excellent sensitivity for detection of pouchitis suggesting that fecal calprotectin can be used as a screening tool for pouchitis [22].

A small study in pediatic ulcerative colitis after colectomy demonstrated that calprotectin correlated positively

with the frequency of pouchitis. Mean fecal calprotectin was 71 ± 50 μg/g among patients with no history of pouchitis (n = 10), 290 ± 131 μg/g among patients with a single episode of pouchitis (n = 15), and 832 ± 422 μg/g among those with recurrent pouchitis (p = 0.019 between recurrent pouchitis and no pouchitis). [23]

Fecal Calprotectin to Predict Mucosal Healing

Given the high correlation of FC to endoscopy, it is not a surprise that FC predicts mucosal healing. A recent meta-analysis in adults demonstrated a diagnostic odds ratio of 16.0 in UC and 13.8 in CD for the use of FC to predict mucosal healing [24]. Similarly, a systematic review demonstrated similar findings with excellent sensitivity and specificity for mucosal healing in both ulcerative colitis and CD [25].

Fecal Calprotectin to Predict Histologic Remission

A recent systematic review described 12 studies and over 1000 patients and concluded that fecal calprotectin correlates with histologic remission in patients with ulcerative colitis. (PMID 32048751).

Fecal Calprotectin to Predict Relapse

A meta-analysis demonstrated a pooled sensitivity of 75% and specificity of 71% in use of FC to predict relapse within 12 months. Studies used a variety of cutoff values; however, they demonstrated reasonable ability to predict relapse using clinical and/or endoscopic measures if FC was elevated. The most recent study demonstrated excellent sensitivity (92.3%) and specificity (82.4%) for relapse in the following year when using a FC cutoff value of 327 μg/g [26].

Fecal Calprotectin as a Marker of Tight Control—CALM Study

The recent CALM study, a multicenter randomized control study performed in 22 countries compared endoscopic and clinical outcomes in adult patients with active Crohn disease, specifically moderate to severe disease based on clinical symptoms and biomarkers versus clinical management alone [27]. This study found that a significantly higher proportion of patients in the tight control group (followed via clinical symptoms and biomarkers, specifically FC and CRP) achieved the primary endpoint of mucosal healing versus the clinical management group (without biomarkers). In the tight control group, 50 patients met treatment failure criteria at 11 weeks, 39 at 32 weeks, and 20 at 35 weeks. An increased FC concentration escalated therapy for 31 of the 50 patients (at 11 weeks), and 22 of the 39 patients (at 23 weeks). A treatment algorithm in which FC was used to monitor inflammatory activity in the tight control group leads to superior outcomes. A higher proportion of patients achieved mucosal healing, no deep ulcers on endoscopy, deep remission, biological remission (FC <250 μg/g, CRP <5 mg/L, and CDEIS <4), and steroid-free remission. This study suggests that tight control of symptoms and fecal calprotectin results in improved outcome.

Fecal Calprotectin Recommendations in Clinical Guidelines (Table 19.3)

Given the extensive data on fecal calprotectin, multiple clinical guidelines now recommend use of fecal calprotectin for screening for IBD and monitoring of known IBD. Both the American College of Gastroenterology (ACG) and the British Society of Gastroenterology (BSG) recommend use of fecal calprotectin for screening patients with possible IBD. Additionally, the ACG guidelines, European Crohn's and Colitis Organisation (ECCO) guidelines, and European Society for Pediatric Gastroenterology, and Hepatology and Nutrition (ESPGHAN) guidelines recommend use of fecal calprotectin in monitoring pardigms for both UC and CD.

Summary

In summary, fecal calprotectin has been demonstrated to be an excellent marker for screening patients for inflammatory bowel disease and differentiating between IBD and functional gastrointestinal disorders. In addition, it has demonstrated excellent correlation with endoscopic (SES-CD, CDEIS) and MRE findings, and good correlation with capsule endoscopy (Lewis score). Furthermore, its utility has been demonstrated clinically with predicting clinical relapse, histologic remission in UC, post-operative recurrence in CD, pouchitis in UC, and response to therapy. Perhaps most importantly, tight control with the use of fecal calprotectin results in improved outcome and suggests the pro-active use to monitor mucosal disease.

Continued questions regarding cutoff values are becoming more clear, suggesting that cutoff values depending on purpose may be most appropriate. Similarly, data demonstrating good correlation with capsule endoscopy and small bowel disease suggest a use for small bowel CD, albeit with perhaps a lower cutoff value. While some may point to these two areas for uncertainty for the use of FC, the data are clear

that FC can screen potential patients, measure disease activity, and be used to improve outcome.

Fecal calprotectin as a non-invasive measure of disease activity should be used in the diagnosis and management of IBD. We suggest the use in screening patients for potential IBD, as well as the widespread use in monitoring IBD in both symptomatic and asymptomatic patients.

Radiologic Evaluation of Pediatric Inflammatory Bowel Disease

20

Michael R. Acord, Rebecca A. Dennis, Abhay S. Srinivasan, and Sudha A. Anupindi

Introduction to Imaging

Imaging is a standard component of disease evaluation in the child with inflammatory bowel disease (IBD). For these patients, imaging plays a vital role in diagnosis and in disease monitoring. At initial presentation, imaging aides in the diagnosis of IBD by assessing the location, extent, degree of inflammatory activity, and overall severity of disease. During disease monitoring, both throughout and after treatment, imaging provides insight into selecting the appropriate treatment options, planning surgical strategies, and evaluating complications that may prompt additional therapeutic interventions.

Given the current advances in imaging technology, plain radiographs and the small bowel follow-through exam are utilized with less frequency. At present, computed tomography enterography (CTE) and magnetic resonance enterography (MRE) are the dominant modalities used. In recent years, advanced expertise in ultrasound (US) and contrast-enhanced ultrasound (CEUS) has provided an alternative means of disease assessment, which may help decrease the over-utilization of CTE and MRE in the future.

This chapter will discuss the current role of these various modalities in the clinical management of pediatric patients with Crohn disease (CD) and ulcerative colitis (UC) with a focus on the techniques, benefits, and findings of each modality along with a brief discussion on the findings of extraintestinal manifestations of IBD. Finally, interventional radiology techniques in this setting will also be discussed, as minimally invasive options are becoming more available at pediatric hospitals.

Crohn Disease

The hallmark of CD is segmental, transmural bowel involvement with a chronic relapsing course, and the propensity to affect any portion of the gastrointestinal tract. The disease may be limited to a single segment of bowel, commonly the terminal ileum. However, multiple segments may be affected, with intervening normal bowel, known as "skip lesions." CD may also be complicated by perianal disease, strictures, fistulas, and abscesses. With several imaging modalities available, the age and clinical condition of the patient, availability of expertise for an imaging examination, and the clinical question to be answered will determine which techniques are utilized.

Ulcerative Colitis

Ulcerative colitis is a chronic, idiopathic, and inflammatory disease of the rectal and colonic mucosa that is characterized by mucosal inflammation, edema, and ulceration. Several distinguishing features permit clinical and radiological distinction from CD. As a rule, UC nearly always affects the rectum and extends proximally to involve a variable length of colon in a contiguous fashion. Other than the occasional "backwash ileitis" of the terminal ileum, the small bowel is not affected. On rare occasions, variants with transmural involvement or without rectal inflammation also occur. In the majority of cases, diagnosis is dependent on clinical presentation, laboratory tests, and findings on colonoscopy and biopsy. Imaging is usually utilized to confirm diagnosis and evaluate complications associated with UC.

Radiographs

Abnormalities in plain abdominal radiographs consistent with IBD are present in two thirds of pediatric patients, but these are non-specific findings such as mural thickening,

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_20

dilatation, and abnormal pattern of gas and feces [1]. As such the plain film has little role in the initial evaluation of the patient with IBD, rather, plain films remain the first-line investigation in the patient with an acute abdomen. Findings such as dilated bowel loops and air-fluid levels indicate acute intestinal obstruction and pneumoperitoneum signifies intestinal perforation.

In UC, the non-specific finding of submucosal edema, noted on plain films as thumb printing along the colonic wall, is occasionally supportive of the diagnosis. However, in the patient presenting acutely with symptoms of toxic megacolon serial abdominal radiographs may show marked colonic dilatation and may be considered for monitoring the response to treatment and for potential bowel perforation [1].

Fluoroscopic Examinations

The small bowel follow-through (SBFT) involves ingestion of contrast by mouth (or through a tube) to assess the bowel mucosa from the level of the esophagus through the colon. Particular attention is paid to the right lower quadrant and terminal ileum, where fluoroscopic compression images are obtained, and bowel pliability is assessed (Fig. 20.1). Bowel wall thickening and enteric fistulas can be identified during a SBFT; however, this technique is limited by its two-dimensional nature, and extraluminal extension of disease or extraintestinal manifestations may be missed. Further, due to the poor capability of detecting transmural inflammation, SBFT is poor at identifying terminal ileal disease when compared to MRE, CTE, or ileoscopy [2, 3]. For these reasons, the American College of Radiology (ACR) does not recommend SBFT as a primary imaging modality, but rather states it "may be appropriate" imaging at diagnosis, during suspected acute exacerbation, and for disease surveillance as utilization of this technique will likely depend on institution and surgeon preferences [4]. The trend in pediatric imaging has been to reduce the radiation burden; therefore, fluoroscopic examinations have an even more limited role to date and have largely been replaced by cross-sectional imaging. The reported sensitivity and specificity for the detection of terminal ileitis on barium studies are 76% and 67%, respectively, whereas MRE showed a sensitivity and specificity of 83% and 95% in the same cohort using histology as the gold standard [5].

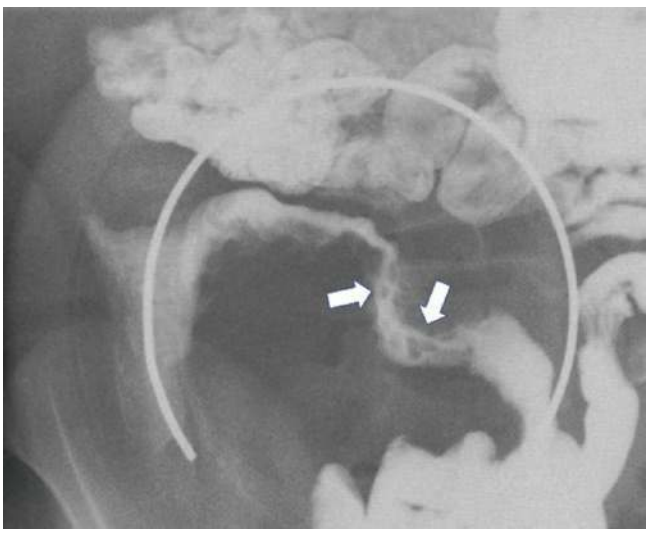

Fig. 20.1 Compression view of the terminal ileum from a small bowel follow-through in a 13-year-old male with Crohn disease presenting with IBD flare. The entire terminal ileum is involved (arrows) with luminal narrowing and irregularity, ulcerations, and nodularity representing the classic "cobblestone" appearance. Separation of the bowel loops is attributed to mesenteric inflammation and fatty proliferation

A historic imaging exam, small bowel enteroclysis, involved direct injection of contrast and air via a nasojejunal catheter placed under fluoroscopic guidance with a child under sedation. A double-contrast view of the small intestine was obtained to provide bowel distension and superior mucosal detail. This procedure, however, has several disadvantages that include a long exam time, the need for sedation/general anesthesia, a greater radiation dose, and the need for an experienced radiologist to perform and interpret the study. For these reasons, small bowel enteroclysis is avoided and has been replaced by CTE and MRE. Similarly contrast enema (CE), no longer called barium enema as barium, has been replaced with water-soluble contrast and may be used to evaluate the colon. This is a single-contrast examination performed on an unprepped colon. If reflux across the ileocecal valve is obtained, it also may provide a double-contrast view of the terminal ileum. Given the availability of endoscopic assessment, patient discomfort with an enema, radiation burden, and the risk for complicating toxic megacolon, CE has been largely replaced by colonoscopy. Additionally, although MRE is targeted to assess the small bowel, the colon can be adequately evaluated by this modality as well.

On fluoroscopic small bowel barium studies, early changes of CD include aphthous lesions, a coarse granular pattern, nodularity, and fold thickening that may progress to deeper ulceration, cobblestoning, and fissuring (Fig. 20.1). In practice, some of these findings can be challenging to identify without a double-contrast technique, not commonly employed in children. In the colon, ulceration occurs within a background of normal-appearing mucosa. Inflammatory edema produces mucosal elevations seen more commonly in the colon than the small bowel. In the patient with more severe CD, mucosal distortions and pseudopolyps may occur due to the elevation of submucosa at the margins of healing ulcers. As inflammation spreads in transmural and circumferential dimensions, the radiologic findings progress to strictures and shortening, with the most severe cases producing the characteristic "string sign." In addition, bowel may

appear adhered to adjacent loops or to other viscera and deep ulcers may extend to create fistulae. Mesenteric inflammation, thickening, and fibrosis may cause separation and shortening of bowel loops (Fig. 20.1).

A contrast enema should not be used to diagnose UC in a child due to its low-yield and high radiation burden; rather, the diagnosis is made with colonoscopy and biopsy. The contrast enema, performed with water-soluble contrast by standard in children, is useful when a child with the known diagnosis of UC may have a stricture. With long-standing disease, the colonic wall becomes rigid, shortened, and narrow due to fibrosis of the submucosa, giving the appearance of the "lead pipe" colon. A contrast enema should also not be performed in a child with an acute abdomen or toxic megacolon as the bowel is friable and such a procedure could lead to a perforation. Finally, unlike cross-sectional CT or MR exams, contrast studies are limited in their ability to image extraluminal extension of disease or extraintestinal manifestations [6]. Only indirect assessment of bowel wall thickening or mesenteric involvement can be made.

Ultrasound and Contrast-Enhanced Ultrasound of the Bowel

There are no set guidelines by the ACR for the use of US in the evaluation of IBD for children. The non-invasive nature, the lack of ionizing radiation, the lower cost compared to CTE and MRE, and the lack of patient preparation make ultrasound an ideal imaging modality in children. Ultrasound can be performed without sedation and results are more immediate and real time for the families to reduce anxiety. Despite these advantages, there are also several important disadvantages to the use of US including that it may not be widely available for this indication, requires experienced technologists and radiologists, and is limited in large body habitus patients, those with significant surgical history and excessive bowel gas. With US, the assessment of terminal ileal disease is excellent, and it is a helpful tool when evaluating fluid collections to distinguish abscess from an inflammatory mass. US, however, is poor at imaging the distal portions of the colon and superficial lesions seen in early disease can be missed in both adults and children [7–9]. In centers with experienced staff, US can be used as a first-line imaging modality especially in the very early onset IBD patients [10]. Patient preparation for bowel US is minimal with a four-hour fasting guideline for solids only, but patients are encouraged to drink clear non-carbonated liquids to help reduce bowel gas and fill the bladder, which helps displace small bowel loops out of the pelvis. Scanning begins in the right lower quadrant at the terminal ileum/ileocecal valve and then continues in a clockwise fashion around the whole colon to the left lower quadrant small bowel loops. Subsequently, the jejunum in the left upper quadrant is evaluated as well. For each segment of bowel, gray-scale and color Doppler images are acquired, and peristalsis of diseased segments can be assessed in real time. Elastography and intravenous contrast-enhanced US images can be performed and provide additional information.

The intramural and extramural features of IBD seen on US are similar to those seen on CTE and MRE. In general, normal bowel wall on US is less than 3 mm with very little vascularity of the bowel wall and surrounding mesentery. When a bowel segment is diseased, there is increased thickening, hyperemia, loss of stratification, and abnormal perienteric mesentery (Fig. 20.2a, b). Loss of bowel wall stratification and degree of hyperemia correlate well with active disease and the sonographic value of bowel wall thickening as an index of increased disease activity has been demonstrated in children [7, 11]. Assessment of disease severity can also be enhanced by measuring the vessel density in the affected bowel segment using color Doppler US [12]. In expert hands, US has been used to assess fistulae and strictures, and also monitor postoperative disease recurrence [8, 13, 14].

Differentiating active from fibrotic disease is a diagnostic challenge despite advances in technology as active inflammation and fibrosis co-exist in the same segments of bowel [14]. US elastography which assesses the stiffness of the bowel wall is still in its incipient stages, but a recent case report by Thimm MA et al. showed that US elastography was valuable in identifying bowel wall fibrosis with high stiffness values in specific diseased segments of bowel in pediatric patients with CD when correlating with surgery and histology [15]. Further validation of this technique is needed for it to be adopted widely.

Contrast-enhanced US (CEUS) is gaining traction recently and is another tool that can be combined with conventional gray-scale and color Doppler US [16]. The main disadvantages of CEUS in children are that it requires placement of a peripheral intravenous line, and it is not yet widely available and requires experience to perform and interpret. Using the main FDA-approved ultrasound contrast agent, Lumason® (Bracco Diagnostics, Monroe Township, NJ), is also considered an off-label use for evaluation of bowel. This agent, composed of non-nephrotoxic microbubbles, has a very high safety profile. Imaging of the bowel is performed after administering the microbubbles intravenously, and diseased loops are assessed for rapid and persistent hyperenhancement (Fig. 20.2c). Time–intensity curves can be generated using the available vendor software found on all US machines, thereby enabling one to analyze the magnitude of perfusion of the bowel wall and generate a more quantitative assessment of disease compared to gray-scale ultrasound alone. CEUS for bowel may be helpful in a variety of situations, including when evaluating severity of disease, deter-

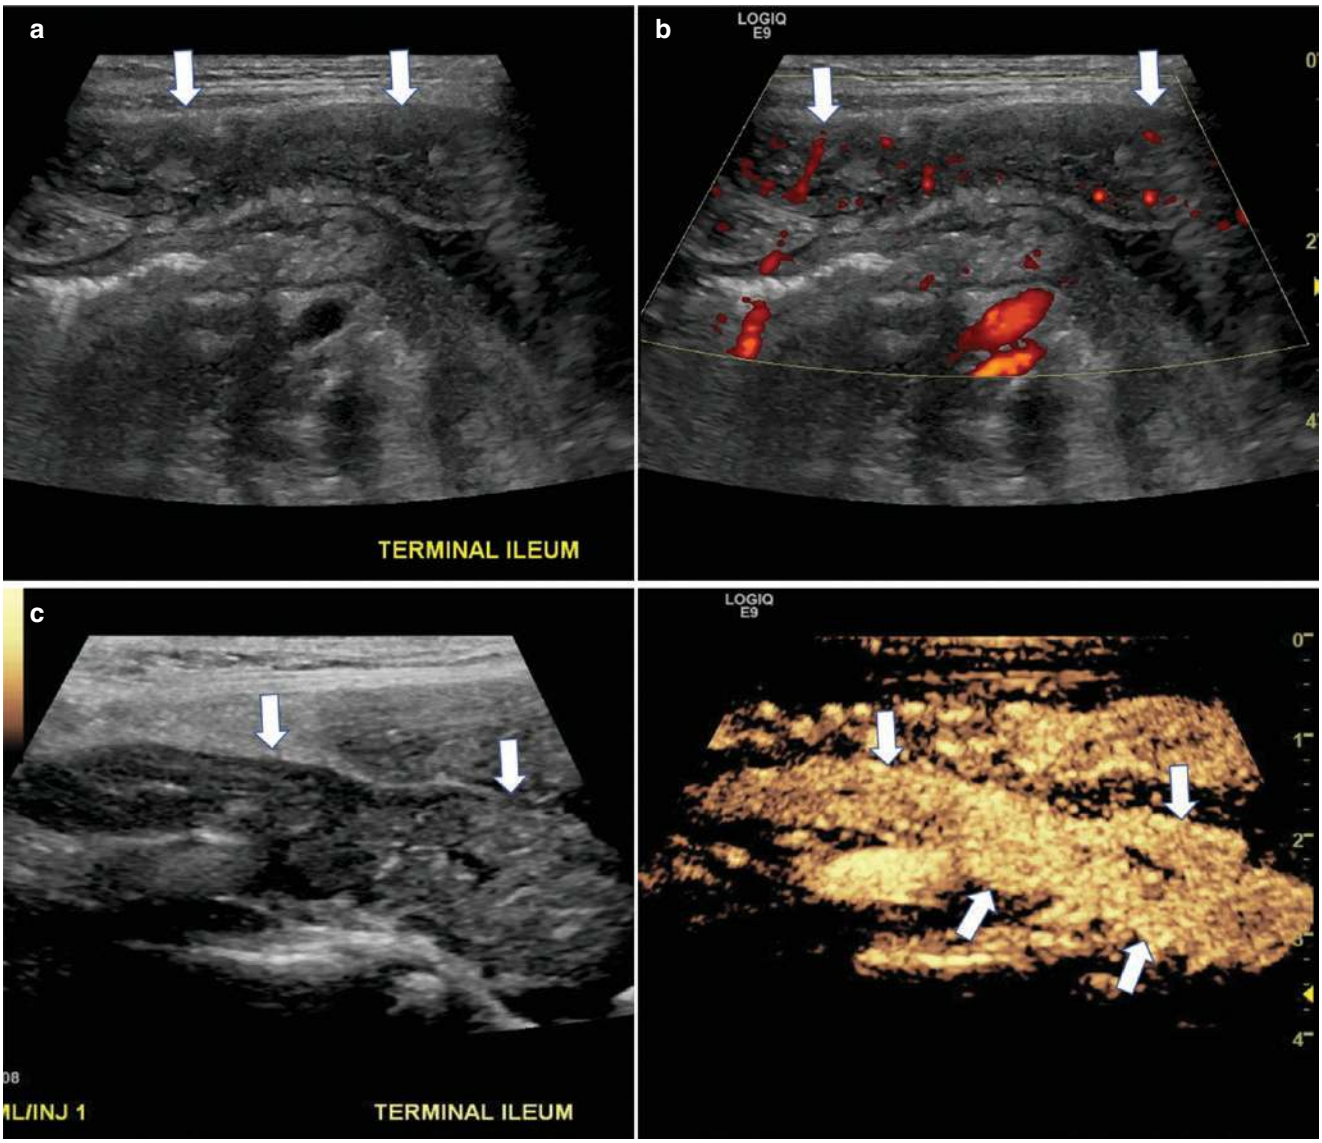

Fig. 20.2 6-year-old female with VEO-IBD confirmed by colonoscopy status post-infusion therapy and here for baseline bowel ultrasound with contrast. (**a**) Sagittal gray scale and (**b**) color Doppler ultrasound images of the terminal ileum (TI) show marked bowel wall thickening and hyperemia (arrows) indicative of active inflammation. The bowel wall thickness measures 6.5 mm, normal is less than 3 mm. (**c**) Dual gray-scale (left) and contrast screen (right) from a CEUS examination of the same loop of TI in the sagittal plane show rapid enhancement of the entire bowel wall (arrows). The inflamed bowel persistently enhanced with a slow wash-out over a period of 2 min

mining a treatment response, assessing for complications, and differentiating between an inflammatory mass and abscess more definitively [16]. Although CEUS is being used by many pediatric centers, the use of CEUS for pediatric IBD to date has been limited. Currently, most of the publications are in adults and experiences in children with IBD continue to be explored.

Computed Tomography Enterography (CTE)

For pediatric patients, the ACR considers CTE as "usually appropriate" imaging at diagnosis, during suspected acute exacerbation, and for disease surveillance due to the wide availability of CT among institutions [4]. Other major advantages over MRI include better spatial resolution, fewer imaging artifacts, and lower cost. While a major limitation of CTE in children is the use of ionizing radiation, modern techniques and reconstruction algorithms have led to a marked reduction in dose compared to historic levels. Therefore, CTE should not be avoided purely on the basis of radiation exposure as it is possible to obtain diagnostic quality images with doses less than background radiation [17]. Compared to the variable dose of small bowel fluoroscopic imaging, for example, CTE has been shown to have an overall lower gonadal dose [18, 19].

Indeed, if the dose of CTE can be lowered enough, one model determined that in the future, CTE may be the preferred, cost-effective modality, even for patients under the age of 30 years [20].

The ease and availability of CTE makes it useful in the acute setting, such as when evaluating for a bowel obstruction or free air. Additionally, the speed at which the exam can be performed often obviates the need for sedation, which is especially useful when imaging younger children who cannot tolerate an MRI awake. For example, patients with very early onset IBD are usually of an age that they are unable to hold still throughout an entire MRI exam (Fig. 20.3). Although CT has not been validated in this population and interpretation is limited by the paucity of intraabdominal fat, it might be considered after an inconclusive or abnormal small bowel ultrasound when MRE cannot be performed [10]. CTE, however, should not be used to routinely evaluate for small bowel disease involvement in these very young patients. In some institutions, a CTE may be performed at baseline with follow-up by MRE, especially if bowel US is not available.

The technique of pediatric CTE involves administration of a low-density oral contrast agent to distend the bowel lumen while simultaneously allowing evaluation of the mucosa. Contrast agents, such low-density barium sulfate, VoLumen, (Bracco, Princeton, NJ) or a flavored sorbitol and mannitol beverage, Breeza, (Beekley Medical, Bristol, Connecticut) are administered orally using a weight-based volume. The flavored nature of the latter agent has shown improved rates of complete ingestion in children without a decrease in diagnostic confidence compared to barium [21, 22]. CT enteroclysis, a technique that introduces oral contrast via a nasojejunal (NJ) tube, is usually not appropriate or tolerated by children and usually requires the use of sedation [4]. The sensitivity of CTE to depict small bowel findings is equal or better than SBFT and similar to that of capsule endoscopy but has the additional benefit of being able to depict extraintestinal findings [23, 24]. Due to the amount of barium ingested, children also tend to prefer CTE over SBFT [23]. In addition to oral contrast, intravenous contrast is always administered unless there is a contraindication, in which case consideration of an alternative modality is necessary.

CTE Features of CD

Changes readily detected by CT include bowel wall thickening, luminal narrowing, and mesenteric involvement. Small bowel changes and skip lesions are often present, and mesenteric findings include thickening due to fibrofatty infiltration, lymphadenopathy, and fatty encroachment of the affected loop of bowel (Fig. 20.3).

Fig. 20.3 5-year-old male with severe VEO-IBD with fever and extremely elevated inflammatory markers underwent a CTE without sedation but with the support of child life. (**a**) axial CT enterography image shows marked mural thickening of the distal sigmoid colon and rectum with mural stratification and hyperenhancement (arrows) and fatty proliferation of the mesentery (**b**) coronal CTE image shows that there is extensive involvement of the other areas of colon the hepatic and splenic flexure (arrows), mesenteric enhancing nodes (circle). No inflammatory mass or perforation was present to further explain the acute presentation

CTE Features of UC

Early mucosal changes of UC are difficult to detect on CT, but in chronic disease, bowel wall thickening and luminal narrowing are readily seen [25]. These, however, are rather non-specific and findings overlap with those of other colitides including Crohn colitis [18]. Characteristic CT features in UC include a symmetric, contiguous wall thickening involving the rectum and extending proximally in a contiguous manner. Small bowel changes and skip lesions are absent. Thickening of the mesentery or mesenteric lymphadenopathy are rare, but proliferation of perirectal fat can occur. In the diagnostic work-up of UC in a child, CTE is rarely used.

Extraintestinal manifestations of CD and UC in children are better depicted on MRE compared to CTE, especially those involving the liver, biliary system, pancreas, urinary tract, and musculoskeletal systems. In emergent cases where a child presents after hours with an acute abdomen with concerns for potential abscess or obstruction, a CT is most beneficial to quickly provide diagnostic information. However, given IBD patients who will likely need multiple studies throughout their lifetime to monitor disease, MR enterography should be considered for follow-up to keep overall radiation burden to a minimal.

Magnetic Resonance Enterography (MRE)

Similar to CTE, for pediatric patients, the ACR considers MRE as "usually appropriate" imaging at diagnosis, during suspected acute exacerbation, and for disease surveillance [4]. In addition to the absence of ionizing radiation, MRE has superior soft tissue contrast resolution, which is ideal for imaging bowel and perianal disease. These qualities have made MRE the dominant modality to image children today. Gee MS et al. in a prospective study concluded that MRE can be substituted for CTE as the first-line imaging modality in pediatric patients with CD [26]. This viewpoint is based on the ability of MRE to detect intestinal pathologic abnormalities in both small and large bowel as well as extraintestinal disease manifestations. A retrospective study, comparing the two modalities, showed that wall thickening and mural enhancement had a 91% and 96% specificity on MRI and 91% and 91% specificity on CT, respectively, without a statistically significant difference [27]. CTE, however, better depicted perienteric findings, such as fibrofatty proliferation and vasa recta engorgement, due to the ease at which the mesentery is visualized and the greater spatial resolution of this modality.

Optimal image quality with MRE depends on adequate luminal distention and limitation of motion artifacts. Bowel distension is achieved similar to CTE, with ingestion of oral contrast agents such as VoLumen and Breeza. Oral contrast is administered in large volumes ranging from 15 to 20 mL/kg, which the patient is instructed to begin drinking 60 min prior to the scan. If the patient is unable or unwilling to drink the contrast, a nasogastric (NG) tube can be placed to facilitate administration. MR enteroclysis, which requires placement of an NJ tube, has not been widely adopted in children due to the need for sedation. Similar to CTE, intravenous contrast is always given unless there is a contraindication.

Bowel motion artifacts may be overcome by a variety of techniques. Imaging may be performed in the prone position to limit bowel peristalsis and separate bowel loops. Prone positioning, however, is used with caution in children with (CD), such as those with ostomies, nausea, or those who are being imaged under anesthesia. Although not utilized at all institutions, an anti-peristaltic agent, such as glucagon, can be administered intravenously to further limit bowel motion artifact [28]. This is typically given in split doses of 0.25 mg at the start of the exam and 0.25 mg just prior to the administration of IV contrast. Allergies to glucagon, beef or pork products, lactose, diabetes mellitus, and adrenal insufficiency are contraindications to administration, and the most common side effects include nausea and vomiting, particularly in children less than 8 years old.

Most adolescent and teenage patients tolerate MRE well, without the need for sedation or anesthesia. Younger patients, however, may require sedation to limit patient motion and allow for diagnostic images. As oral contrast is necessary for bowel distention, this can lead to logistical challenges with anesthesia. Every effort should be made to avoid the use of anesthesia for these studies, which includes use of in-scanner video googles, utilizing child life staff, or choosing an alternative modality such as ultrasound or CTE. Abbreviated MRE protocols are also emerging, whereby avoiding the use of glucagon and IV contrast, the study can be completed in under 30 min and may be suitable for children as young as 4 years of age [6]. If the consensus between the radiologist and gastroenterologist is to proceed with an MRE under anesthesia, the patient should be intubated for airway protection and oral contrast administered via NG tube. At our institution, after confirming NG tube position by abdominal radiograph, 15 mL/kg of oral contrast is administered over 40 min. To decrease the risk of emesis and aspiration, glucagon is not administered, and the patient is imaged supine.

The field of view includes the entire abdomen and pelvis. The perineum may be included separately if needed, as high-resolution imaging can be performed to further characterize a perianal fistula. Prior to the administration of contrast, T2-weighted sequences to assess bowel wall thickening and edema and diffusion-weighted images are performed. After contrast, multiplanar images are obtained to evaluate enhancement pattern along with delayed images to highlight mural fibrosis. Most institutions will also perform dynamic

steady-state imaging to subjectively assess bowel peristalsis; however, in the future quantitative assessment of motility using emerging software technologies may also be possible, which will enable the radiologist to provide even further objective data.

MRE Features of CD

Findings of active inflammation of CD at MRE like that on CTE include asymmetric wall thickening, segmental mural enhancement and edema, restricted diffusion, engorgement of the vasa recta, and reactive prominent enhancing mesenteric nodes [29, 30]. (Figs. 20.4 and 20.5). These changes of CD may progress to deeper ulceration, fissuring, and transmural disease penetrating outside of the bowel wall. Discontinuous and asymmetric colonic mucosal changes are a hallmark of CD. Fibrotic lesions may show homogenous T2 hyperintensity although less than in active inflammation, variable contrast enhancement, and minimal adjacent inflammatory changes [31]. Delayed contrast-enhanced sequence has been utilized with some success to evaluate for late enhancement seen in mural fibrosis; however, this is not standard practice in pediatric imaging given that active inflammation is present in fibrosed segments.

MRE Features of UC

Characteristic findings of MRE in the active stage of UC include loss of haustral markings, thickening, and contrast enhancement of the colonic wall [32]. As with CTE, these findings overlap those of CD. The absence of small bowel disease, perianal disease, or fibrofatty proliferation can support the diagnosis of UC; however, mild terminal ileitis (backwash ileitis) is not uncommon and the ability of MRE to categorize disease into either CD or UC with high specificity remains a challenge.

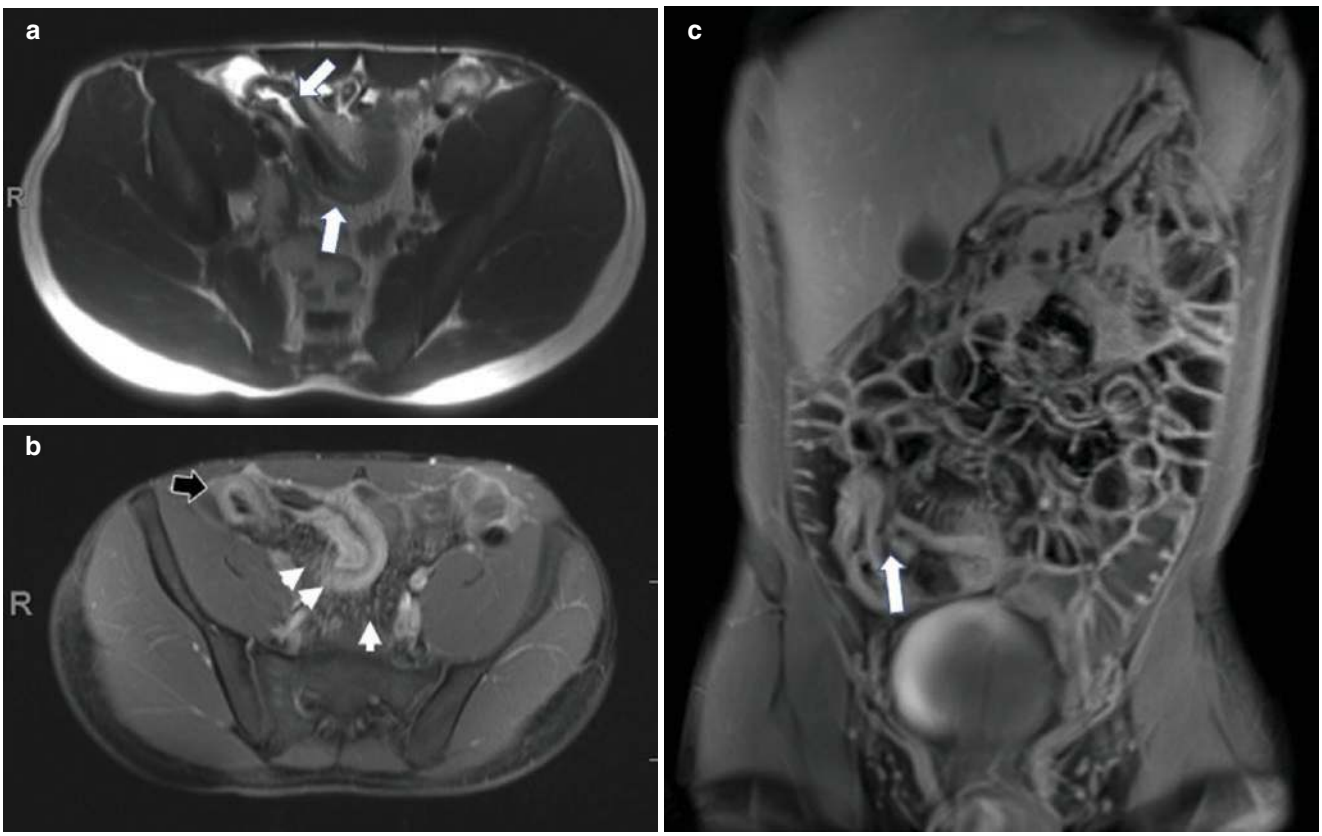

Fig. 20.4 19-year-old male with history of CD and worsening abdominal pain. (**a**) Axial T2 HASTE MRE image shows a thickened loop of distal ileum with mural edema (bright signal in the bowel wall) and surrounding fibrofatty proliferation (arrows), (**b**) axial post-contrast T1-weighted fat suppressed image slightly more cephalad shows marked enhancement of the terminal ileum (TI) (black arrow) and that same loop of distal ileum with engorgement of the vasa recta appearing as small vessels in the mesentery (arrowheads), (**c**) coronal post-contrast T1-weighted fat-suppressed image shows an entero-enteric fistula as a linear-enhancing tract between the inflamed TI and distal ileum (arrow)

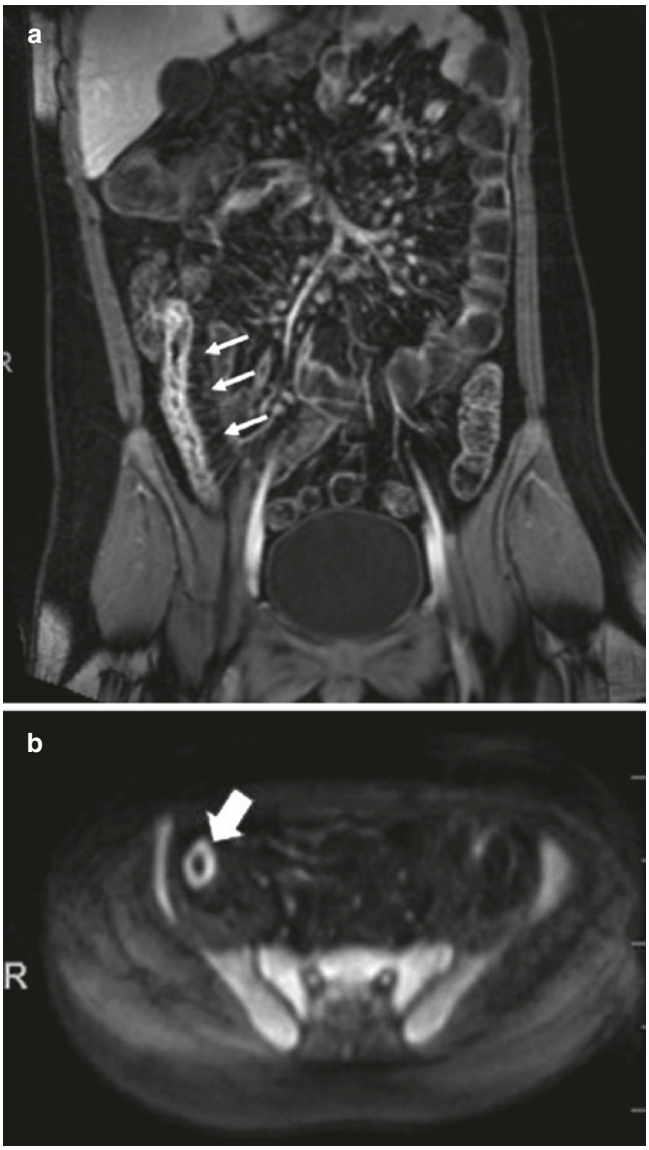

Fig. 20.5 14-year-old male with CD. (**a**) Coronal MRE post-contrast T1-weighted fat-suppressed image shows increased enhancement of the entire terminal ileum (TI) with engorged vasa recta depicted by prominent perienteric vessels, the classic "comb sign" (arrows) indicative of active inflammation, (**b**) axial diffusion-weighted image shows restricted diffusion of the TI (arrow) consistent with edema and active inflammation

Nuclear Medicine Imaging Studies

White Blood Cell Scans

Radionuclide-labeled autologous WBC scans are not used conventionally in the diagnostic work-up for a child with IBD or used in monitoring disease burden. The WBC scan is a helpful diagnostic tool for the detection of inflammation and abscesses; however, these studies are not used in our institution for assessment of IBD and will not be discussed further in this chapter.

PET and PET-MR Examinations

Positron emission tomography (PET) is a functional imaging technique that has been applied to the detection of inflamed areas of bowel. The high metabolic activity of inflamed tissue results in the uptake of the glucose analog, fluoro-2-deoxy-D-glucose (FDG), which has been radiolabeled with a positron-emitting isotope such as fluorine-18 (F-18). It is transported into cells at a rate proportional to the metabolic activity of the cell. Within an hour of the intravenous injection of F-18-labeled FDG, the scan is performed, with a total image acquisition time of less than a half hour. PET scans are functional studies and performed alone do not provide anatomical information. However, a novel noteworthy technique, PET-MR enterography, combines the functional with the anatomical data into one study (MRE with oral and IV contrast and a PET) and has been reported to be successful in the assessment of patients with CD with a high accuracy in detecting inflamed segments of bowel [33]. Catalano et al. reported that PET-MR enterography technique can help distinguish fibrotic from mixed fibrotic/inflamed strictures [34]. The current publications are few and in adult populations and, to date, the lack of availability of PET-MR, the added radiation dose and the greater overall cost, make this examination impractical in the assessment of children with IBD.

Imaging of Complications

Perianal Disease

At some point in their disease course, approximately 62% of children with CD will experience manifestations of perianal disease [35]. External manifestations are usually diagnosed by physical inspection and include skin tags, fissures, simple abscesses, and ulcerations. More complex abscesses and fistulas may need further evaluation under anesthesia or with imaging studies. Transperineal ultrasound with color Doppler may be used as the initial modality at diagnosis and can be useful in determining the degree of active inflammation present [36]. Transperineal ultrasound, however, only has fair agreement with MRI, which is the imaging modality of choice when evaluating perianal disease [37]. The poor soft tissue resolution of CT limits its reliability in assessment of perianal fistula and should not be used in this setting. MRI can provide exquisite soft tissue detail and anatomic relationships that yield high concordance with surgical findings to guide management [38]. Identifying the presence or absence of an abscess, describing the location using the Parks Classification, and assessing the length of the fistula, are all important characteristics that MRI is capable of discerning.

Stricture

A stricture is defined as focal luminal narrowing of bowel with upstream dilation of ≥3 cm [29]. These are best demonstrated on cross-sectional imaging and, however, can also be demonstrated on ultrasound. If severe, a stricture can result in an acute bowel obstruction, which on imaging is seen as unequivocal dilation of proximal bowel with a paucity of gas distally. In the acute setting, CTE is the preferred modality to assess bowel obstruction, as these patients may not be able to tolerate an MRE exam and CTE can be obtained quickly.

Penetrating Disease—Intraabdominal Abscesses and Enteric Fistulas

Manifestations of penetrating disease include intraabdominal abscesses and enteric fistulas and occur in approximately 27% of children within 5 years of diagnosis, usually in the setting of active inflammation and luminal narrowing [39, 40]. Although no comparative studies have been performed in children, CTE and MRE have comparable and moderately high accuracy for depiction of these findings in adults [30].

An inflammatory mass, formerly termed phlegmon, occurs adjacent to an inflamed bowel wall segment and appears as a poorly defined region of inflammation within the mesentery. An abscess, on the other hand, appears as a well-defined, walled-off fluid collection that can develop in the abdominal wall, peritoneal cavity, retroperitoneum or iliopsoas, and subphrenic region [29]. US may be the initial modality utilized when an abscess is expected; however, CTE, MRE, or CEUS are also appropriate for imaging in this setting.

Fistulas can be simple, a single sinus tract arising from the bowel and connecting to another epithelialized surface, or complex where multiple tracts arise from a single bowel loop appearing as an asterisk configuration on CTE or MRE. Demonstration of enteric fistula by imaging can be challenging, particularly with US and when the tracts are not filled with fluid.

Toxic Megacolon

Toxic megacolon is a complication more frequently seen with UC but may also occur in patients with severe CD. The clinical scenario is a patient with IBD presenting with an acute abdomen and signs of sepsis. Occasionally, toxic megacolon is the initial presentation of the patient with UC. The diagnosis can be made on a plain radiograph that shows marked colonic dilatation with absent haustral pattern is seen. The threshold for colonic dilation is age dependent and in adolescents, a colonic diameter >5 cm is considered abnormal. Following initial medical treatment, serial films are obtained to monitor for progression, evidence of perforation, or improvement. Contrast enema studies are contraindicated as they increase the risk of perforation.

Bowel Obstruction/Perforation

The radiologic hallmark of bowel obstruction is dilatation of proximal bowel with paucity of gas distally. Air-fluid levels may also be noted in proximal bowel. It is important to distinguish between partial obstruction where initial nonoperative treatment may be appropriate and complete obstruction, where surgical intervention is often required. The diagnosis of intestinal perforation is made when free extraluminal gas is detected by either plain film or CT.

Imaging of Extraintestinal Manifestations

As IBD is mediated by the immune system, there are numerous extraintestinal manifestations that may occur. In order of prevalence, the musculoskeletal (osteoporosis, arthritis), skin (erythema nodosum, psoriasis, pyoderma gangrenosum), ophthalmic (uveitis iritis), hepatobiliary (sclerosing cholangitis, gallstones, autoimmune hepatitis), and renal (urolithiasis) systems can be involved. Multiple extraintestinal manifestations may occur concomitantly, and the presence of one confers a higher likelihood in developing others [41]. The radiologic assessment of some of these manifestations is important in the comprehensive assessment of the patient with IBD. A discussion of other disorders will be found in the appropriate chapters in this book.

Musculoskeletal System

Osteopenia and osteoporosis are known complications of IBD with potential mechanisms including inhibition of remodeling and growth, malnutrition, and treatment with corticosteroids [42, 43]. The most common method for assessment of bone mineral density and bone mass (reported as bone mineral content) is dual-energy X-ray absorptiometry (DXA). The densities measured by DXA of the lumbar spine, femoral neck, and radius are expressed as Z-scores, the number of standard deviations of the measured density with respect to normal values for age and sex. Bone mineral content or density that falls >2 standard deviations below expected is labeled "low for age." Osteoporosis requires the presence of a non-traumatic and non-pathologic vertebral fracture, or low bone density with a history of multiple (2–3)

fractures. Pediatric reference data are now available for children and teenagers, but it is essential to select norms specific to equipment used, as there are manufacturer-specific differences [44].

IBD-related arthropathy may be axial or peripheral. Peripheral arthropathy presents as a seronegative arthritis and affects 10–20% of patients UC and 5–10% of patients with CD. It may be pauci-articular (mainly large joints such as the knee ankle) or poly-articular (propensity for smaller joints such as metacarpophalangeal joints). Peripheral arthropathy is generally a clinical diagnosis, as imaging is often normal and shows little or no joint destruction. Axial arthropathy is less common and can be categorized as ankylosing spondylitis or sacroiliitis [45]. Radiographs and T2-weighted MRI with fat suppression techniques are useful for assessing axial arthropathy, with MRI having greater sensitivity.

Hepatobiliary Disease

Primary sclerosing cholangitis (PSC) is the most frequent hepatobiliary manifestation of IBD, with a reported incidence of about 6% in children, and approximately 80% of patients with PSC will have IBD [41]. PSC is more strongly associated with UC than CD and presents clinically with cholestasis. It is characterized by inflammatory fibrosis of the intra- and extra-hepatic bile ducts, with progression to stricture, cholestasis, and cirrhosis, which then confers a risk of hepatocellular carcinoma and cholangiocarcinoma. While direct cholangiography via ERCP has high sensitivity for detecting early ductal changes, MRCP is favored as the means of assessment. Common findings of PSC include multifocal bile duct strictures, segmental or general duct dilatation, or beading. Advanced disease can show mural thickening, nodularity, and enhancement [46]. ERCP should be considered when MRCP is negative, but a strong clinical suspicion persists.

There is an increased incidence (about 2%) of gallstones in patients with IBD, but the association is stronger with CD than UC [41]. Ultrasound is the favored modality for assessing gallstones; if obstructive cholangiopathy or pancreatitis is suspected, MRCP or contrast-enhanced abdominopelvic CT is recommended.

Urolithiasis

The prevalence of symptomatic nephrolithiasis is higher in IBD patients compared to the general population, typically in patients who underwent extensive small bowel resection or in those with persistent severe small bowel inflammation. Patients present with signs and symptoms of urinary obstruction, and stones are typically of calcium oxalate [47]. Initial imaging assessment is often with renal ultrasound and further assessment with a non-contrast renal stone protocol CT scan should be considered.

Interventional Radiology in IBD

Percutaneous Abscess Drainage

Percutaneous drainage has been described as effective in children for the management of abscesses [48]. Although the reported average duration of drainage in IBD (about 20 days) is longer than for other etiologies, effective drainage may allow earlier resumption of immunomodulating medicine, obviate surgery, or render subsequent surgery easier and less invasive [48, 49]. Percutaneous drainage has also shown effectiveness in the drainage of post-surgical anastomotic leak in IBD patients [50].

Abdominopelvic CT or MRI is often required for pre-procedure assessment, to characterize the extent and number of collections. In general, abscesses greater than 3 cm are considered appropriate for drainage. Smaller collections may be aspirated, without the placement of a drain if specimens are needed for antibiotic tailoring. Multiple drains may be necessary when non-communicating collections are seen, but if there are more than 3–5 large collections, surgical exploration, and wash-out may be more effective. Abdominal abscesses are often drained with an anterior approach using US and fluoroscopic guidance. Deep pelvic abscesses may require a trans-gluteal or trans-iliopsoas approach, as trans-rectal drainage is not commonly performed in patients with IBD. It should be noted that abdominal wall abscesses may have a higher rate of failure of percutaneous drainage, and this is thought to be due to the presence of fistulous tracts [51].

The presence of a fistulous tract from bowel can complicate drainage. Principles of nonoperative fistula management include control of bowel efflux (e.g., bowel rest or diversion) and evacuation of abscess. Closure rates of fistulae (encompassing multiple etiologies) by percutaneous drainage alone are reported to be 50–60%, but this may be aided by immunomodulating medicine [52, 53].

Additional Applications of Interventional Radiology

Interventional radiology techniques, such as vascular and enteral access, may be applied for therapeutic and supportive care for IBD. For IBD-related arthropathy, steroid injections can be performed with greater confidence using image guidance. For example, image guidance is necessary for successful access of the sacroiliac joints for treatment of symptomatic

sacroiliitis [54]. Percutaneous biliary drainage and cholangioplasty may be required for treatment of dominant strictures that are not accessible by endoscopy, or in cases wherein endoscopic management was not successful [55]. Mesenteric vein thrombosis is a rare, but serious complication of IBD and can produce adverse sequelae such as venous bowel ischemia and pre-hepatic portal hypertension [56]. Fulminant mesenteric thrombosis may require catheter-directed thrombolysis and thrombectomy, which can be performed through trans-hepatic or trans-jugular intra-hepatic access.

Conclusion

The imaging arsenal for the evaluation of pediatric IBD is composed of many examinations from radiographs to sophisticated MR and PET imaging. Each imaging study has advantages and disadvantages with some modalities having very practical roles. MRE has become the first line of imaging over CTE and conventional fluoroscopic small bowel studies. In the future, we hope that bowel ultrasound and contrast-enhanced ultrasound will be embraced in many more pediatric centers. The development of faster and shorter MRE protocols will emerge to make these exams more comfortable and facile for the youngest of patients, perhaps avoiding sedation and contrast altogether.

Endoscopy and Inflammatory Bowel Disease

21

Shishu Sharma, Krishnappa Venkatesh, and Mike Thomson

Introduction

Safe, informative, and effective endoscopy performed in a child-friendly situation with the minimum of distress to child and parent alike is a sine qua non of a unit adhering to the best practice in the care of children and adolescents with pediatric inflammatory bowel disease (PIBD). The care of children and adolescents differs in important ways from that of adults. This is reflected in the emphasis placed on various aspects of endoscopy especially ileocolonoscopy (IC), such as the frequent use of general anesthesia, the number and location of mucosal biopsies, and the routine inclusion of ileal intubation during a complete examination. The question of who should conduct the procedure continues to receive attention among pediatric gastroenterologists. The current evidence and consensus recommend that endoscopy should be performed by a pediatric gastroenterologist or a gastroenterologist who has pediatric experience, under general anesthesia or deep sedation [1]. There can be few more satisfying experiences in medicine than making a clinical judgment and diagnosis in a child, confirming the nature and extent of the disease oneself by endoscopy, treating appropriately, and then visually demonstrating the success of such endeavors to child and parent by a follow-up procedure.

Endoscopy plays an important role in the initial diagnosis of inflammatory bowel disease (IBD), differentiation of IBD into Crohn disease (CD) and ulcerative colitis (UC), assessment of disease extent, monitoring of response to therapy, surveillance of cancer, and to perform endo-therapeutic procedures such as stricture dilatation [2].

Endoscopy: Background History

The evolution of endoscopy in the diagnostic armamentarium was initially a slow process. Rigid esophagoscopes and sigmoidoscopes were introduced in the late nineteenth century and semiflexible endoscopes in the 1930s. They remained the only endoscopes in use until the 1960s. This was partly because of the lack of understanding about inflammatory bowel disease, which was for a long time thought to be a disease mainly confined to the rectosigmoid region. However, the invention of fiber optics in the 1950s heralded a new era leading to the development of the first flexible sigmoidoscope in 1963 and colonoscope in 1966. This made it possible to visualize, take biopsies, and perform endo-therapeutic procedures and reach the duodenum and the ileo-colon. The next major breakthrough was the arrival of video-chip technology in the 1980s. This allowed digital images to be displayed on a monitor and further to be stored, analyzed, and transmitted as necessary. Further advances have seen the development of Sonde enteroscopy [3], which was limited by lack of therapeutic potential, and then push enteroscopy, allowing the therapeutic endoscopist an access of up to 70–100 cm small bowel beyond the pylorus. Intraoperative endoscopy (IOE) appeared to be the only means available to access the whole of the small bowel at the turn of the century until the development of wireless capsule endoscopy (WCE). This technological breakthrough allowed the direct visualization of the entire small bowel without the need of external wires, fiber-optic bundles, or cables but as yet is limited to diagnostic input alone. Double-balloon enteroscopy (DBE) is a more recent modality, which enables high-resolution endoscopic imaging of the entire small bowel, with the advantage over WCE of potential for mucosal biopsies and interventional endo-therapy.

Patient Preparation

Ideally, both the child and the parents should be offered a preparatory visit to the endoscopy unit to answer questions and defuse any potential concerns and anxieties regarding the procedure and admission. Children with greater knowledge of the procedure exhibit less distress and report less anxiety toward the procedure [4]. Younger children undoubtedly benefit from preadmission visits and the involvement of a play therapist to enable some understanding of what is to take place and why [5–7]. Diagrams may help in explanations to older children. Preparatory videotapes are also useful for informing the patient and parent regarding what to expect. Units can benefit from devising a sample videotape specific to their own facility. A reduction in anticipatory anxiety may even reduce the amount of intravenous sedation required [8].

A child-friendly decorated endoscopy room with age-appropriate videotapes and familiar faces is important at this time of high stress. Parents may stay to watch the procedure in some units when intravenous sedation is provided. Most anesthesiologists would object to having parents present during administration of a general anesthetic, beyond the initial induction. Improved medical compliance and belief in the treatment are potential advantageous consequences of allowing parents to directly view the initial disease and its remission at follow-up ileocolonoscopy [9]. Young children often request photographs or a videotape of the ileocolonoscopy, and older adolescents may view the procedure themselves.

A full screening is important to identify potential sedation or anesthetic risks. Although there is little correlation of mildly deranged peripheral coagulation indices with hemorrhage after mucosal biopsies, more pronounced bleeding diatheses may require forethought and appropriate blood product backup [10]. Properly informed consent should be obtained with an information sheet detailing potential complications and their incidence, and a separate consent should be signed in the event of research biopsies being requested.

Antibiotic Prophylaxis

Guidelines concerning antibiotic prophylaxis in children with lesions susceptible to endocarditis or in the immunocompromised child are available in the historical literature [11] but are now superseded by the American Society for Gastrointestinal endoscopy (ASGE) guidelines for antibiotic prophylaxis for gastrointestinal endoscopic procedure [12]. American Heart Association has also published new recommendations of antibiotic prophylaxis for infective endocarditis (IE) and does not advise antibiotics for routine diagnostic or therapeutic gastrointestinal endoscopic procedure, solely for prevention of IE [13]. AHA recommends antibiotic prophylaxis for patients undergoing gastrointestinal procedure with established gastrointestinal infections where Enterococcus is the suspected causative organism and with the following cardiac condition: (1) a prosthetic cardiac valve, (2) previous IE, (3) cardiac transplant recipients with valvulopathy, (4) unrepaired cyanotic CHD (including palliative shunts and conduits), (5) repaired CHD having residual defects at the site or adjacent to the site of a prosthetic device, and (6) completely repaired CHD with prosthetic device placed within the last 6 months of the gastrointestinal procedure. The recommended antibiotic regimen in the above situations should include ampicillin (50 mg/kg every 4–6 h, maximum 2 g every 4 h) or amoxicillin (50 mg/kg every 4–6 h, maximum 2 g every 4 h) in combination with gentamicin. Vancomycin or teicoplanin can be used in patients who are allergic to ampicillin/amoxicillin. The British Society of Gastroenterology recommends the above antibiotic prophylaxis in combination with metronidazole for patients with severe neutropenia (<0.5 × 109/L) and/or who are profoundly immunocompromised (e.g., advanced hematological malignancy) and are undergoing procedures that are known to be associated with a high risk of bacteremia (Table 21.1) [14]. The preferred choice of antibiotics for biliary procedures is either ciprofloxacin or gentamicin or ceph-

Table 21.1 Infection risk associated with various gastrointestinal procedures

High risk of bacteremia	High risk of infection unrelated to bacteremia	Low risk of infection
Dilatation of esophageal stricture	Endoscopic ultrasound with fine-needle aspiration (EUS-FNA)	Routine EGD, IC, or sigmoidoscopy
Sclerotherapy of esophageal varices	Percutaneous endoscopic gastrostomy (PEG) or jejunostomy (PEJ)	Polypectomy
ERCP in patients with: (i) Biliary disorders, e.g., cholangitis, primary sclerosing cholangitis (ii) Conditions where complete biliary drainage is difficult to achieve, e.g., cholangiocarcinoma (iii) Liver transplantation (iv) Pancreatic pseudocyst		

ERCP Endoscopic retrograde cholangiopancreatography, *EGD* Esophagogastroduodenoscopy, *IC* Ileocolonoscopy

alosporins given intravenously just before the procedure. In our unit, prophylactic intravenous cefuroxime or co-amoxiclav is given for 24 h for percutaneous endoscopic gastrostomy (PEG) or jejunostomy (PEJ). The other condition where routine use of antibiotic prophylaxis is recommended is cirrhosis with acute GI bleed. The above recommendations are primarily based on evidence from adult studies but are also used for pediatric population.

Bowel Preparation

Poor bowel preparation is a major factor that may prevent or impede successful ileocolonoscopy. Although administration of regimens is not always easy, modern protocols can be remarkably effective in clearing the colon and ileum. Until 5 or 6 years ago, large volumes of oral electrolyte lavage solutions were used with variable success, coupled with the significant disadvantages of nasogastric administration and potential for fluid-electrolyte shifts in smaller children and infants. In one study, 40 mL/kg/hr. resulted in clear fecal effluent after a mean of 2.6 h [15]. Subsequently, more favorable results and compliance were reported with low-volume oral agents and enemas, along with decreased oral intake [16–19]. Use of sodium phosphate preparations was associated with a transient rise in mean serum sodium and phosphate but with no change in serum calcium [17, 18]. Refinements were made to these oral and enema regimens as newer preparations, which were more acceptable to children, became available; low-volume nonabsorbable polyethylene glycol preparations are becoming increasingly popular in pediatric units and are well tolerated, with no observable electrolytic disturbance [20, 21]. Table 21.2 outlines several low-volume regimens that have been used successfully in children. The regimen employed in our unit, shown in Table 21.3, combines the beneficial effects of oral low-volume administration of Senna and combination of sodium picosulfate with magnesium citrate, with the backup of an enema 1–2 h beforehand if no clear fecal effluent is observed [22]. No clinically significant fluid shifts or electrolyte imbalances have been observed in over 2000 colonoscopies over a 5-year period in our unit.

The above medications are repeated 10 h apart with a backup of enema 1 h before procedure (1/2 h for infants). One Picolax sachet contains sodium picosulfate 10 mg with magnesium citrate (K^+ 5 mmol, Mg^{2+} 87 mmol).

The benefit of an antispasmodic agent administered directly before the ileocolonoscopy has recently been demonstrated in an adult study where hyoscyamine 0.5 mg was given intravenously [23]. An effective alternative could be hyoscine butylbromide 20 mg administered intravenously during the procedure. The use of such an agent given just prior to IC is determined by personal preference. The antispasmodic agents are certainly of benefit in spastic colonic situations as their use may facilitate ease of luminal visualization. On the other hand, these can turn out to be counterproductive, as they may also increase the compliance of the colon, theoretically allowing a greater chance of loop formation.

However, it should be remembered that the antispasmodic agents work only for a short period of time, perhaps as short as 5 min, and these may be readministered in certain situations, e.g., when one needs to relax a haustral fold to visualize a polyp which is just beyond and obscured by it or occasionally when one needs to relax a spastic ileocecal valve. Glucagon at a dose of 0.5 mg intravenously is also used as an alternative to Buscopan, especially while performing DBE.

Table 21.2 Successful low-volume regimens for the preparation of the bowel for colonoscopy

Study	Regimen	Diet	Success rate
Gremse et al. (1996) [17]	Oral sodium phosphate (45 mL/1.7 m^2) 6 pm and 6 am for am procedure	Clear liquid 24 h	18/19
Da Silva et al. (1997) [18]	Oral sodium phosphate (22.5 mL if <30 kg, 45 mL if >30 kg) pm and 5 am for am procedure	Clear liquid after first dose	10/14
Pinfield et al. (1999) [20]	Sodium picosulfate with magnesium citrate (2.5 g <2 years., 5 g 2–5 years., 10 g >5 years per dose) 24 and 18 h pre procedure	Clear liquid for 24 h	32/32 (3 vomited)
Dahshan et al. 1999 [21]	Magnesium citrate and X-prep	Clear liquid for 48 h	

Table 21.3 Bowel preparation for children undergoing colonoscopy

Medicine	<1 years	1–4 years	>4 years
Sodium picosulfate + Magnesium citrate (Picolax)	¼ sachet	½ sachet	1 sachet
Senna	1–2 mg/kg (maximum 30 mg)		

*M*onitoring and *S*edation

"Sedation and analgesia" comprise a continuum of states ranging from minimal sedation (anxiolysis) through general anesthesia. Moderate sedation is a medically controlled state of depressed consciousness that allows protective reflexes to be maintained and retains the patient's ability to maintain the airway independently and continuously. Deep sedation is a medically controlled state of depressed consciousness or unconsciousness from which the patient is not easily aroused and accompanied by a partial or complete loss of protective reflexes with inability to maintain a patent airway. General anesthesia is a controlled state of unconsciousness accompanied by a loss of protective reflexes [24, 25].

The aims of adequate sedation include patient safety, anxiolysis, analgesia, amnesia, as well as adequate endoscopic examination, time, and cost efficiency [26]. Debate has surrounded the relative merits and safety of sedation and general anesthesia for esophagogastroduodenoscopy (EGD) and IC in children for several years [27–29].

The risks of general anesthesia include those associated with intubation and administration of an anesthetizing agent, which can be minimized by proper preparation and good intubation technique. However, the benefits include complete amnesia and total avoidance of pain to the patient as well as freeing the endoscopist from managing airway, monitoring vital signs, and recovering the patient [27].

Intravenous sedation (IV-S) usually consists of a narcotic (meperidine or fentanyl) and a benzodiazepine (diazepam or midazolam), the former for analgesia and the latter for anxiolysis and amnesia. Ketamine and midazolam have also been used with reportedly lesser side effects [30]. Propofol is now being used increasingly as the preferred choice for controlled sedation. Table 21.4 lists some of the commonly used sedation regimens with the reversal agents. IV-S has been argued to be safe, effective, and less costly in comparison to general anesthesia with successful sedation achieved in more than 95% of elective procedures [32, 33]. However, careful monitoring of IV-S throughout the procedure is important [33–35]. In spite of the advantages of IV-S, pediatric gastrointestinal endoscopy has moved toward general anesthesia since it is now acknowledged that, to get the requisite cooperation, and therefore, a properly conducted procedure with minimum distress to the child, deep sedation is usually necessary. It is further recognized that there are attendant safety issues of airway maintenance in this situation, and at the very least, a specific individual with appropriate advanced pediatric life support skills should be responsible for the child's cardiorespiratory welfare during such a procedure. The vast majority of pediatric gastrointestinal endoscopy in the United Kingdom, for instance, now occurs under general anesthesia.

When a child is sedated, resuscitation equipment should be easily accessible, and one or more people trained in pediatric advanced life support should be responsible for maintaining the airway and monitoring respiration, heart rate, blood pressure, and oxygen saturation [24, 36]. Sedation of younger children can be aided by environmental comforts such as a soothing voice or dimmed lights [37]. In all age groups, it is often necessary to use deep sedation because of the pain that can be associated with this procedure [38]. With deep sedation, it is clear that the risks are significant, including hypotension, respiratory compromise, and even respiratory arrest.

Recent studies examining the safety of general anesthesia for day-case IC in children refute the claims that there may be more risk of perforation because the operator cannot judge the degree of discomfort as a marker of impending traction injury [39, 40]. There is indeed a lack of evidence to support the contention that there is a higher complication rate with a general anesthetic than with sedation [41]. In fact, the airway is protected in a more effective and safer manner than with sedation, especially in upper endoscopy, with an improved operator satisfaction [42].

Pre-procedural medication with a benzodiazepine has been found to be useful in reducing patient anxiety and improves patient and parent acceptance of the procedure without any significant adverse effects [31].

Table 21.4 Sedation and reversal medications commonly employed in pediatric endoscopy

Ketamine: IV 1–2 mg/kg as a single dose [30]
Propofol: IV 1–2 mg/kg for induction and then 1.5–9 mg/kg/h using 1% injection for maintenance
Midazolam: IV initial dose 25–50 microgram/kg, if necessary titrate to maximum 6 mg (1 month to 6 years), 10 mg (6–12 years), or 7.5 mg (12–18 years) [30, 31]
Fentanyl: IV initial dose 0.5–1.0 μg/kg and then titrate to max 5 μg/kg
Meperidine/pethidine: IV initial dose 0.5 mg/kg and then titrate to max 2 mg/kg or 75 mg whichever lower
Flumazenil: IV 0.02 mg/kg (max 0.2 mg) and repeat every minute to max of 0.05 mg/kg or max 1 mg
Naloxone: IV 0.1 mg/kg (max 2 mg) and repeat every 2–3 min to max 10 mg

Endoscopic Techniques in Inflammatory Bowel Disease

Upper Gastrointestinal Endoscopy

While it is generally accepted that ileocolonoscopy(IC) and biopsy have a central role in the initial diagnosis and differentiation of pediatric inflammatory bowel disease (PIBD) [43], it is now recommended that in nonemergency situations, the diagnostic workup for pediatric patients should start with a combined EGD and ileocolonoscopy [43–46] except in situations such as acute severe colitis, where a lim-

ited sigmoidoscopy is preferred over complete IC as the latter may increase the risk of perforation. However, a follow-up IC should be performed after the resolution of the acute attack.

The presence of upper gastrointestinal symptoms has been commonly considered as an indication to perform EGD [47]. Typically described upper gastrointestinal symptoms include dysphagia, nausea and/or vomiting, and aphthous lesions of the mouth. Diagnosis was often based on radiological changes [48], and EGD was reserved for those patients who had upper GI symptoms and/or uncertain diagnosis. However, several studies have shown a higher incidence of microscopic mucosal disease in the upper GI tract [47, 49–53] than previously thought even in the absence of any upper GI symptoms [44, 54]. Cameron et al. [49] in a prospective study described histological abnormalities on gastroduodenal biopsies in 71% of patients with CD. Histological abnormalities including granulomas are seen even when the gross appearance of the tissue is normal [43, 47, 53–55]. Therefore, it is important to take multiple biopsies (2 or more per section) from all sections of the visualized gastrointestinal tract, even in the absence of macroscopic lesions.

In a prospective 3-year study involving 420 patients with IBD from 27 centers, EGD was performed in 237 patients. Eighty percent of patients with CD had macroscopic and/or histologic changes in the upper GI tract, while in 9% of the patients, EGD was helpful in making a definitive diagnosis [56]. In another prospective single-center study, 24/45 patients with CD had an upper GI involvement and presented at an younger age, had more severe disease, and were more likely to have extraintestinal manifestations [57].

Esophageal disease in CD (Fig. 21.1) can vary from small erosions to transmural involvement resulting in perforation and fistulization into adjacent organs [58]. Granulomas are reported in 20–39% of esophageal biopsies in patients with CD [59, 60]. Other findings include erythema, ulceration, polypoid lesions, pseudomembranous formations, strictures, and mucosal bridges [59, 61–64]. Endoscopic findings in the stomach and duodenum include linear and serpiginous ulcers, diffuse superficial ulcers, aphthous lesions, nodularity, cobblestone appearance, rigidity of the GI wall, and narrowing of the lumen [65].

Focal-enhanced gastritis as an important feature of CD was first described by Schmitz-Moorman et al. [66] (Fig. 21.2). Further, several studies confirmed this finding with a positive predictive value of 71–94% [50, 52, 67, 68]. Parente et al. [68] found focal antral gastritis more frequently in *Helicobacter pylori*-negative adults with CD and then in those with UC or noninflammatory bowel conditions. Also, they reported focal antral gastritis to be specific in 84% of patients with CD. While the presence of focal antral gastritis is suggestive of Crohn disease, it is not pathognomonic of the condition.

Fig. 21.1 Crohn disease of the esophagus showing discrete ulcers

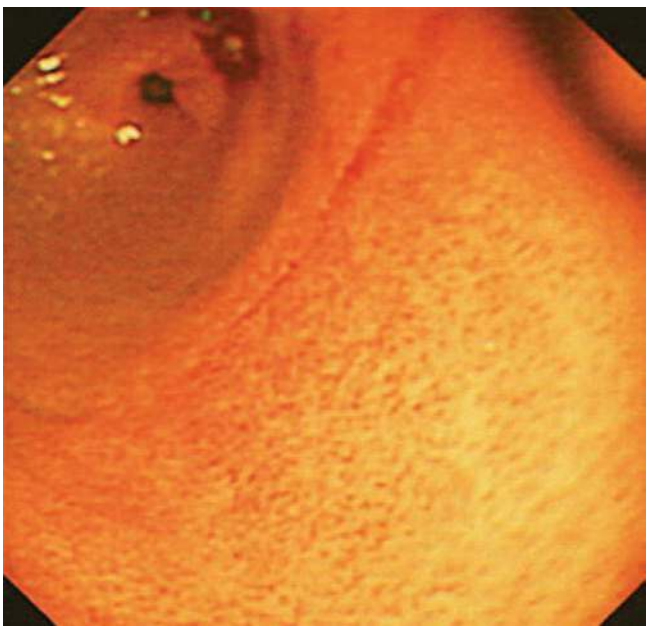

Fig. 21.2 Focal enhanced gastritis in Crohn disease

The presence of noncaseating granuloma is characteristic of CD. Granulomas are found in 7–68% of patients with CD in the upper GI tract [43, 47, 59, 65, 66] and often help in making a definitive diagnosis when none are found at other sites. Noncaseating granuloma in the upper gastrointestinal tract in the CD tends to occur in the superficial mucosa as

compared to ileal CD where the muscularis or the serosal layers are primarily involved.

Ulcerative colitis conventionally was thought to involve only the colon and possibly ileum (backwash ileitis). However, it is increasingly recognized that features of inflammation in the upper GI tract [44, 52, 53, 69, 70] are seen in UC. Ruuska et al. [53] in a prospective study reported either macroscopic or histological upper gastrointestinal lesions in 75% of patients with UC. Abdullah et al. [43] also reported an incidence of 70% of histological abnormalities in the upper GI tract in patients with UC. Tobin et al. [52] in a controlled blinded study described esophagitis in 72% and 50% of patients with CD and UC, respectively. Gastritis was, however, more common and seen in 92% of CD and 69% of UC.

Ileocolonoscopy

Equipment

Most modern units employ adult and pediatric videocolonoscopes, and the general technical specifications for the pediatric instruments differ little between manufacturers (Table 21.5). When and in whom to use a pediatric colonoscope is mainly a matter of personal preference. We use personal judgment based on age and/or body weight. In general terms, the lower limit for the adult colonoscope is 3–4 years of age and/or 12–15 kg. The extra stiffness of the adult versions diminishes the likelihood of forming sigmoid loops, but extra care must then be taken, especially in younger children and with general anesthesia, not to advance against undue resistance, to avoid the unlikely complication of colonic perforation. The larger diameter of the adult colonoscopes can also lead to problems of maneuverability within the smaller colonic lumen of a young child. The variable-stiffness colonoscope (Table 21.5) may negotiate some of these problems. A control dial on the upper shaft of this small-diameter colonoscope (Olympus XCF-240AL/I, Olympus Inc., Tokyo, Japan) allows an increase in the stiffness of the insertion tube when passing through the sigmoid and transverse colon to avoid looping [71].

Table 21.5 Technical specifications of various pediatric colonoscopes

Parameter	Fujinon (EC-410 MP15)	Olympus (PCF 240 L/I)	Olympus variable stiffness (CF 240AL/I)	Pentax (EC-3440PK)
Angle of vision	140°	140°	140°	140°
Depth of field	6–100 mm	4–100 mm	3–100 mm	6–100 mm
Distal end	11 mm	11.3 mm	12.2 mm	11.5 mm
Insertion tube	11.1 mm	11.3 mm	12.0 mm	11.4 mm
Channel	2.8 mm	3.2 mm	3.2 mm	3.8 mm
Angle up/down	180°/180°	180°/180°	180°/180°	180°/180°
Angle right/left	160°/160°	160°/160°	160°/160°	160°/160°
Working length	1520 mm	1330 mm (I) 1680 mm (L)	1330 mm (I) 1680 mm (L)	1500 mm

More recently, magnifying colonoscopes have been developed, and their value in combination with dye spray or chromoscopy in various gastrointestinal diseases has been described [72]. For instance, the decrease in the number of cryptal openings in ulcerative colitis can be observed and correlated to disease activity [73], but this does not substitute for histologic assessment.

For insufflation, there may be some advantage awarded by the use of carbon dioxide in place of air because it is more rapidly absorbed, leading to less patient discomfort and, theoretically, less risk of perforation [74, 75].

Ileocolonoscopy Basic Technique

Getting Started and Patient Positioning

The patient is usually positioned in the left lateral knee to chest position, although some operators prefer the right lateral position, citing easier sigmoid negotiation. Certainly, if the procedure is not subsequently allowing easy access to the splenic flexure, then patient repositioning from one side to the supine and then to the other side may be advantageous. In general, frequent turning of the patient is conducive to easier ileocolonoscopy as a whole and is to be advocated. An assistant stands on the operator's left to administer any abdominal pressure that may subsequently be deemed necessary to control, or try to prevent, loop formation in the sigmoid or transverse colon.

Practical Tips in Ileocolonoscopy

One important "trick" in learning ileocolonoscopy is to grasp the concept of the lumen and the positions of a clock face. For instance, if the lumen is at 9 o'clock, then to enter this requires anticlockwise rotation combined with upward deflection of the scope tip from the "neutral" position of 12 o'clock. Similarly, a combination of upward deflection of the tip with clockwise rotation of the colonoscope will allow

entry of the lumen, suggested by a dark crescent, if seen at anywhere clockwise from 12 o'clock to 6 o'clock. Obviously, one may equally use downward tip deflection combined with the opposite rotatory control to that with upward tip deflection, and the execution and teaching of this concept are at personal discretion. With either approach, this is the most important maneuver that can be learned to assist in three-dimensional spatial orientation in the colon.

Prolonged "side viewing" of the bowel wall as it slides by should be avoided. Generally, the only place where, very temporarily, the lumen should be out of view is the occasional difficult negotiation of the splenic flexure. The patient's position may be changed throughout the procedure to facilitate removal of loops and to allow a better view of the lumen because the gravity-dependent material in the colonic lumen changes position. Relatively minimal insufflation of air is desirable in the sigmoid colon because excess air may increase the chance of sigmoid loop formation (carbon dioxide, provided by a specific commercially available delivery system attached to the colonoscope, as the insufflating gas of choice may be preferable because it is absorbed much more quickly, decreasing the pain sensation and the very unlikely chance of perforation; see "Complications."

In handling the colonoscope, it is good practice to have a flat unimpeded surface on which to place the remainder of the colonoscope that is not yet inserted; this is particularly important since any resistance encountered by the operator to forward advancement of the colonoscope can be attributed to colonic obstruction or loop formation within the child's colon. Hence, relatively quickly, the trainee can acquire a realization of the normal expected resistance to scope advancement. This, in turn, allows understanding of the likelihood of loop formation, without any external resistance to scope advancement, causing confusion with regard to the behavior of the colonoscope within the patient.

Generally, in ileocolonoscopy, gentle scope advancement with clear lumen visualization is desirable, and, usually, only the forefinger and thumb will be required to advance the colonoscope. If greater pressure is required, then the operator is not performing an optimum procedure, and loop formation is likely to have occurred.

Rectal Intubation

Prior to any colonoscopy, it is considered good practice to perform an anal and then a rectal digital examination, the latter to avoid missing, by colonoscopy, very low-lying rectal polyps (although, where possible, retroflexion of the colonoscope in the rectum should occur prior to removal of the instrument to avoid missing lesions close to the anal margin). Adequate water-soluble lubrication, avoiding the tip of the instrument, allows easy passage into the rectum, which can occur with or without digital guidance from the operator's index finger. The tip of the scope aimed posteriorly toward the spine combined with air insufflation allows visualization of the rectal mucosa and the three semilunar folds, or valves of Houston, occurring on alternating sides of the lumen. Subsequently, direct visualization of the bowel lumen is mandatory, except in some circumstances at the splenic flexure. If, at any point, a maneuver results in loss of visualization of the lumen, then reversal of what the operator has just done will often return the lumen to view; if not, the gentle scope retraction combined with minor tip deflections using the wheels and minor rotation of the scope in both directions will usually result in reorientation in the lumen. Obviously, if luminal contents are blocking the view, then lens cleaning will help.

Sigmoid and Descending Colon

Gentle torquing of the shaft clockwise and anticlockwise combined with upward or downward tip deflection and scope advancement is ideal for negotiating the sigmoid colon, the so-called "torque-steering" technique. The initial sigmoid fold or valve can usually be passed by 90–120 of anticlockwise torsion. The different loops encountered in the sigmoid are demonstrated in Fig. 21.3. A so-called N loop may be overcome by transabdominal pressure by an assistant on the apex of the loop pushing toward the feet (see Fig. 21.3a). This often allows a so-called α loop to form, which can usually be tolerated as the instrument advances toward the splenic flexure (see Fig. 21.3b). Reducing an α loop is accomplished by initial clockwise rotation and then slow removal of the colonoscope, keeping the lumen in the center of the field of vision. This may not be possible until the transverse (or even ascending) colon has been entered, in which case, hooking the tip of the scope over the splenic flexure may assist it. Paradoxical movement of the tip forward may be observed as the instrument is withdrawn and the bowel "concertinas" over the colonoscope. Abdominal pressure in the left iliac fossa may be helpful. The sigmoid and descending colons are relatively featureless, with less haustral folds than more proximally in the colon.

Fig. 21.3 Diagram of colonoscope sigmoid loops that may form (**a**) an N loop in the sigmoid colon, (**b**) an α loop in the sigmoid colon, and (**c**) a γ loop in a redundant transverse colon

Splenic Flexure and Transverse Colon

Non-looped colonoscope length used at this point might be 40 cm in older children and even 20–25 cm in those under the age of 3–4 years. This is valuable in determining whether a loop is present. At the splenic flexure, the spleen may then be seen as a dark blue transmural discoloration. When negotiating the splenic flexure, the most successful combination of tip maneuvers is that of clockwise, right, and up followed by anticlockwise after passing the flexure. Occasionally,

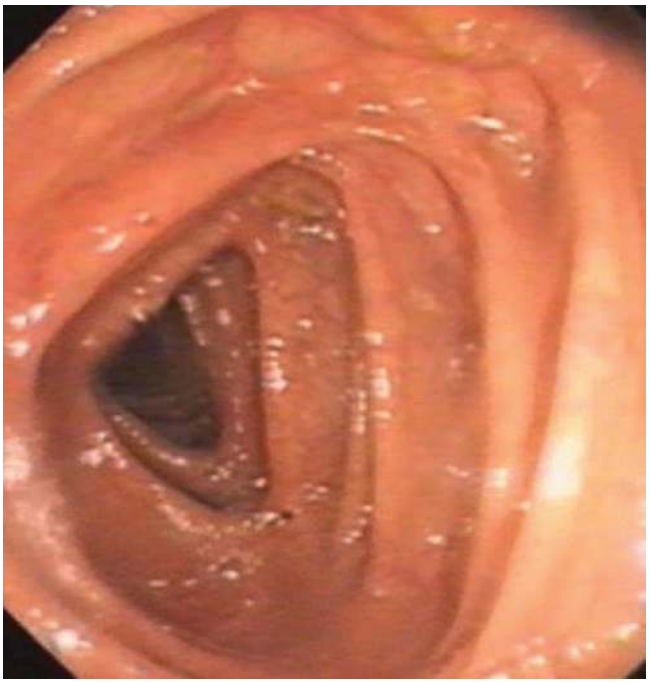

Fig. 21.4 Normal triangular appearance of transverse colon

placing the patient in the right decubitus position may assist. The transverse colon is recognized by the triangular haustral folds and is usually easily passed (Fig. 21.4). Supine or right decubitus positioning may ease this. A loop in the shape of a "U" may occur in a dependent transverse colon, which is supported by abdominal pressure. The more difficult γ loop may occur in a redundant transverse colon (Fig. 21.3c). In addition, a good bit of advice is to apply gentle suction as the tip is advanced in an attempt to concertina a potentially long-dependent transverse colon over the colonoscope, thus, maintaining a relatively short colonoscope and, hence, good control and maneuverability.

Hepatic Flexure and Ascending Colon

Non-looped colonoscope length used at this point might be 60 cm in older children and even 40 cm in those under the age of 3–4 years. This is valuable in determining whether a loop is present. The hepatic flexure is also recognized by the dark, usually blue, discoloration seen through the bowel wall, and positional change to the supine or right decubitus may again facilitate identification of the lumen. The combination of right, up, and clockwise followed by anticlockwise rotation and suction down into the ascending colon once around the sharply angled hepatic flexure is usually the most effective maneuver, but various combinations, including position change and scope withdrawal, may be required. Another tip is to remember that it is easy to be too far advanced into the vault of the hepatic flexure, leading to advance into a blind end, and often slight withdrawal of the instrument may reveal the fact that one is trying to negotiate this blind-ended area. The two or three sharp folds then observed may then be most successfully negotiated by tip deflection using both up/down and left/right wheels with minimal advancement of the scope. This is most easily performed in the supine patient position, however.

Once the hepatic flexure is negotiated, the transverse colonic γ loop may be reduced with anticlockwise or clockwise rotation followed by withdrawal of the colonoscope and suction. Loop withdrawal is essentially informed guesswork initially. Studies with the colon map guider (ScopeGuide®, Olympus, Inc. Tokyo, Japan), based on using a colonoscope with an inbuilt electromagnetic loop that allows accurate real-time colonoscope three-dimensional positioning by detection using an external positioning device and displayed on a screen next to the patient, have shown that even expert colonoscopists get the type of loop present wrong in half of the cases [76–78]. Once one starts to remove the loop, using rotation only initially, a tip is to gently start to remove the colonoscope and try to determine whether within-patient resistance is increasing or whether the colonoscope is trying to push your hand away from the patient as the loop unfolds. Usually, trying clockwise or anticlockwise combined with instrument withdrawal will, with experience, allow early determination of which rotation direction is likely to be successful in "de-looping" the colonoscope. It is best to try for maintaining good luminal vision during this procedure, but, not infrequently, the lumen is lost; however, if this loop removal technique is effective, it is then not unusual to find oneself then looking at the appendiceal orifice, and hence, the cecum because the scope will have naturally traveled down the ascending colon. It is important to remember that the ascending colon, which in children is of variable length, may be as short as 5 cm in some younger patients.

Cecum

Three useful ways to ensure that one has reached the cecum are as follows:

1. Observing the colonoscopic illumination in the right iliac fossa (using the specific high-intensity light transillumination application available with some colonoscopes is not usually necessary in children, except with some obese adolescents, for whom it can be helpful when applied in a dark environment).
2. Digitally indenting the abdominal wall over the right iliac fossa and observing the corresponding effect on the colonic wall with the colonoscope.

3. Identifying the triradiate fold, appendiceal orifice, and (especially if gas bubbles and ileal effluent are being excreted from it) the typical two lips-like appearance of the ileocecal valve or Bauhin's valve.

A good maxim is that if there is any doubt in the operator's mind about having reached the cecum, then one is usually at the hepatic or even splenic flexure. Only about 80 cm of scope from the anus is needed when all loops are removed in an adult, and in smaller children, only 40–60 cm may be needed. This assumes normal anatomy of the ascending colon and cecum. Obviously, cecal strictures can confuse the picture.

Ileal Intubation and Its Importance

The Bauhin's valve is present approximately 1–4 cm distal to the appendiceal orifice opening into a smooth asymmetric fold and opens perpendicular to the axis of the colon. Figure 21.5 shows the steps of the easiest technique for ileal intubation. Removal of any colonic loops is important to allow for a responsive scope with no paradoxical movement. Figures 21.5b and 21.6 show the valve maneuvered to the 6 o'clock position, usually after clockwise rotation of the scope and wheel–tip deflection to maintain a centered cecal view. Anticlockwise rotation can also be used but is less efficient. If too much gas is present, then the cecum may be

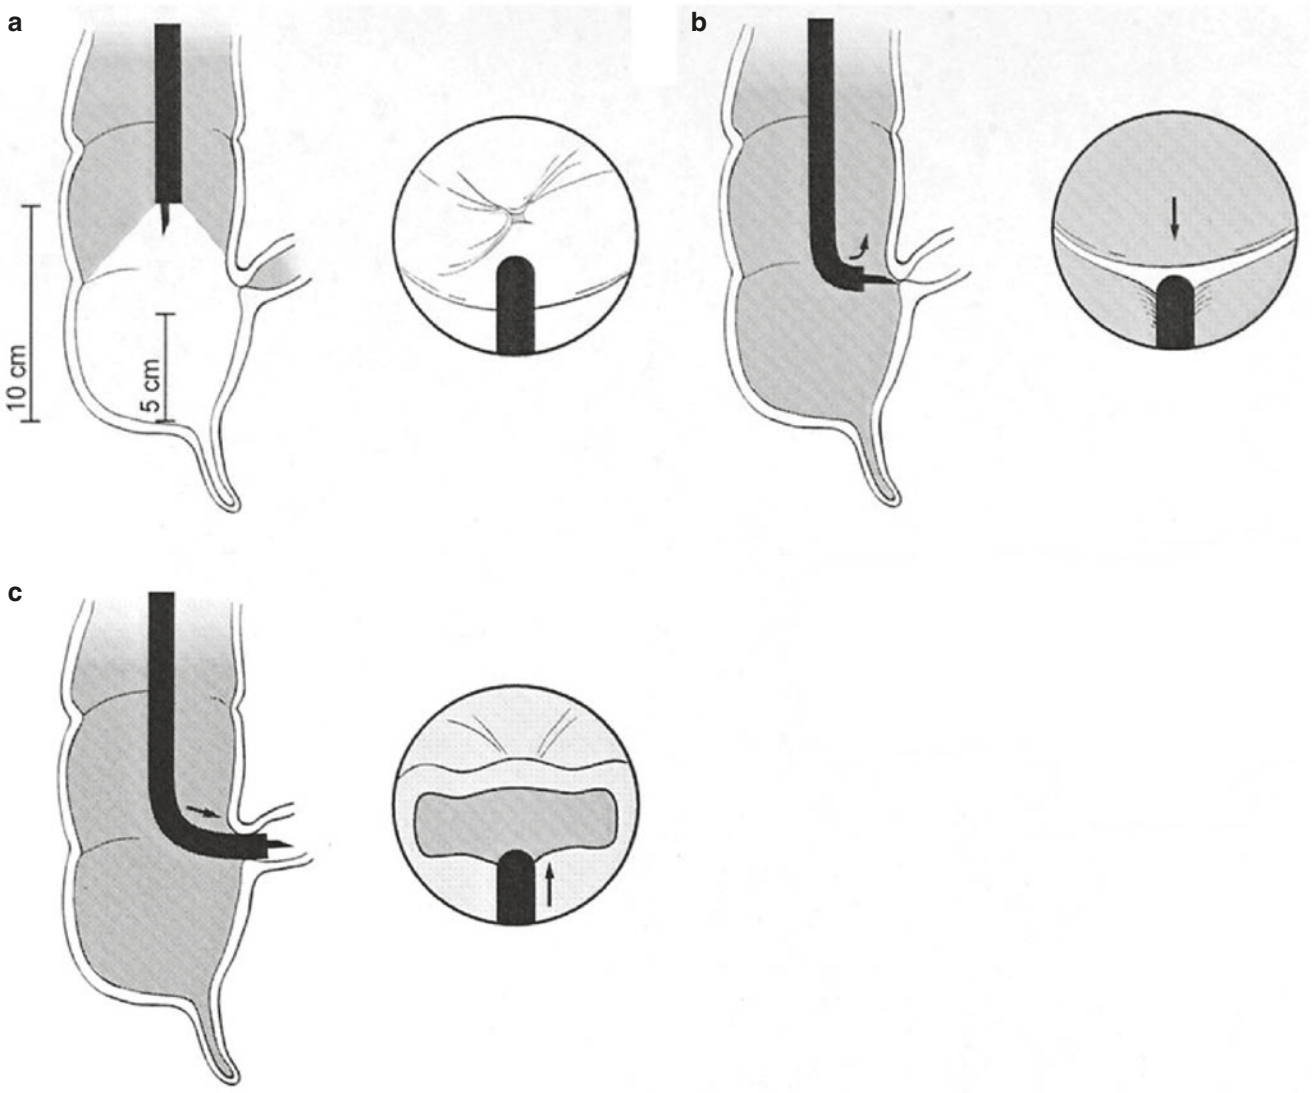

Fig. 21.5 (**a**) Identification of cecum with triradiate fold, appendiceal orifice, and ileocecal valve; (**b**) ileocecal valve at 6 o'clock position; (**c**) forceps opening up ileocecal valve with downward defection of colonoscope tip

"tented," and this should be suctioned prior to an ileal intubation attempt. Figures 21.5c and 21.7 show the insertion of the biopsy forceps such that just the tip or the first few millimeters are visibly exposed beyond the end of the scope. The scope is then inserted just beyond the fold (using the downward deflecting wheel with the scope as above already in the 6 o'clock position), and the tip is inclined downward so that the forceps gently press into the wall. Slight left inclination may be required at this point to open the valve like a pair of lips on slight withdrawal of the scope (Fig. 21.5c). Once the valve is opened, the scope may be passed into the ileum with further downward deflection. Often this is facilitated by small right and left deflections with an assistant pressing on the abdomen over the transverse colon to support a dependent transverse and also prevent loop formation. In the absence of ileocecal valve strictures, and with practice, this technique will allow an ileal intubation rate of up to 100%. Perforation of the cecum or ileum with this technique is a theoretical concern raised by some observers unfamiliar with this technique, but this has not occurred in our experience of over 5000 ileocolonoscopies and is extremely unlikely.

An alternative technique is "blind" intubation of the ileocecal valve. This involves the same positioning of the valve at 6 or 9 o'clock and then slowly withdrawing the scope back from just beyond the valve's fold while insufflating with air and deflecting the scope tip downward. The disadvantage of this technique is that it is not under direct vision.

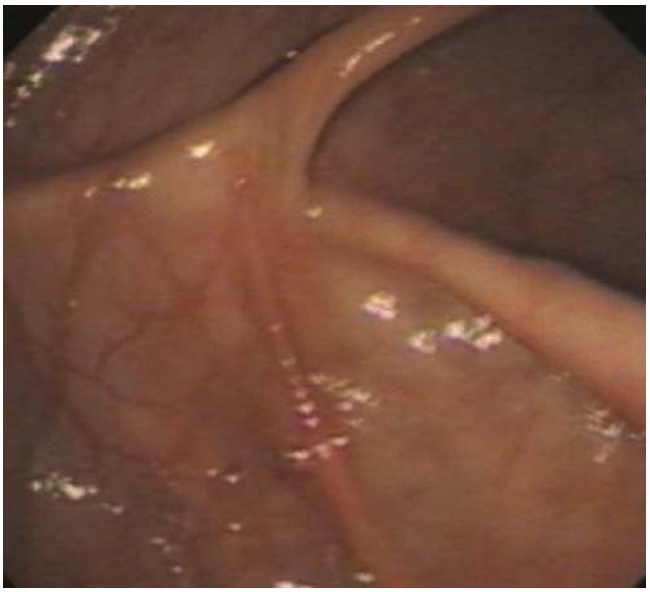

Fig. 21.6 Ileocecal valve at 6 o'clock

Ileum

The ileal mucosa will have the typical velvetlike appearance of small bowel (Fig. 21.8), with the presence of smoother raised areas, which are Peyer patches, and, occasionally, lymphonodular hyperplasia of varying degrees (Fig. 21.9). Villi are more easily seen if the lumen is flooded with water. The ileal surface is shown in greater relief with a spray of standard blue or black ink (methylene blue in a 1:20 dilution may also be used); this is also useful in showing the detail of

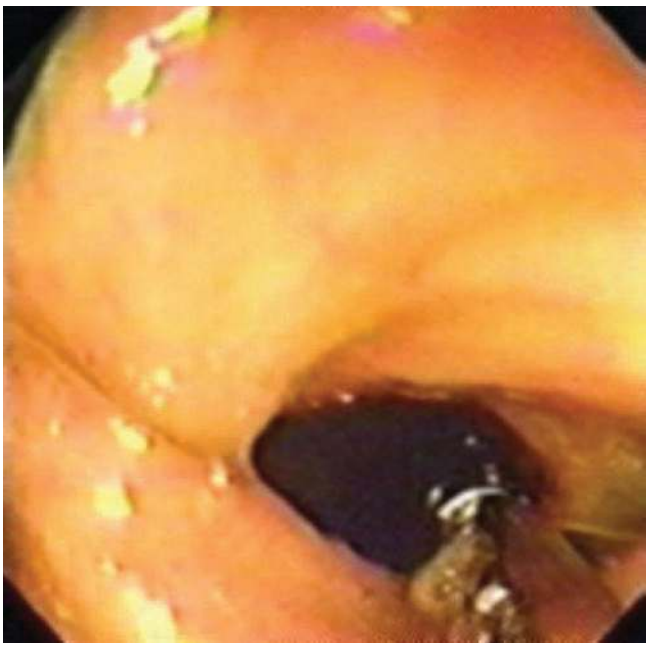

Fig. 21.7 Ileocecal entry using forceps

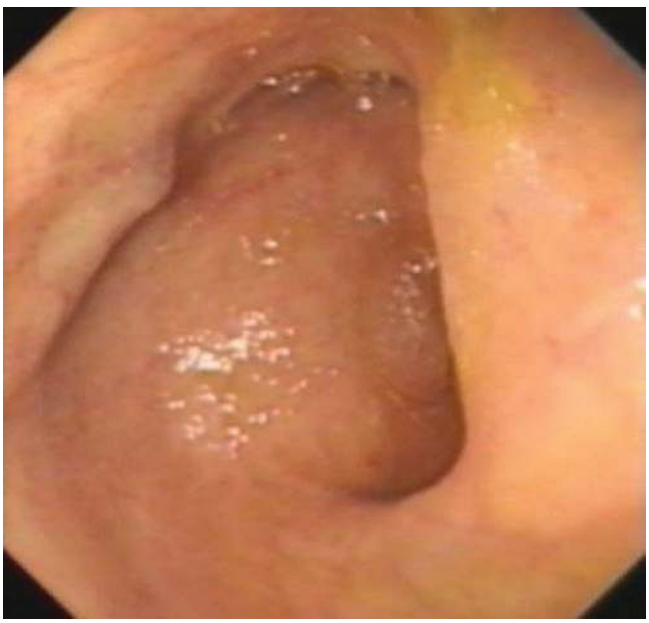

Fig. 21.8 Normal appearance of terminal ileum

Fig. 21.9 Lymphonodular hyperplasia of the terminal ileum

sessile polyps in the colon. Deeper intubation of the ileum by either technique is similar to duodenal negotiation during upper gastrointestinal endoscopy, and up to 40 cm of ileum can be observed.

It is pertinent here to discuss the diagnostic need for entering the ileum in children suspected of inflammatory bowel disease. Williams and colleagues, in 1982 [77], reported their experience of total ileocolonoscopy in children in which the terminal ileum was examined in 63 patients. In six children, ileitis detected by ileocolonoscopy was the sole finding of Crohn disease, which was previously unrecognized by radiologic contrast studies. Lipson and colleagues compared ileoscopy and barium studies, with an endoscopy specificity of 0.96 for diagnosis of Crohn disease in the terminal ileum [78]. In 14 of 46 children, ileoscopy revealed diagnosis, which would otherwise have been missed. This study also made clear that the endoscopic appearances could be completely normal, yet the diagnosis of Crohn disease could be made histologically by the presence of granulomata. Also, a pronounced lymphoid hyperplasia pattern was present radiologically in 24% of children and would have been a source of error in two cases that had contrast radiographs been relied on to make the diagnosis without ileoscopy. More recently, Deere and colleagues showed that sigmoid, colonic, and rectal biopsies confirm the diagnosis of inflammatory bowel disease in only 60% of cases, and diagnosis based on morphologic criteria was possible in only 85% of cases when the cecum was reached without ileal intubation [79]. Geboes and colleagues assessed 300 patients, including adolescents and children, and found endoscopic and histologic ileal lesions in 123 and 125, respectively, of whom no colonic disease was present in 44 [80]. Ileal biopsies were essential for the diagnosis in 15 patients and contributory in 53. The Porto criteria now mandate terminal ileal intubation for diagnosis of IBD [1].

The Eurokids registry reports terminal ileal intubation (TII) rate of up to 79%. In individual center studies, TII rate has been reported up to 89%. In our center, the TII rate is 98%, which is probably because of an active training environment and the use of ScopeGuide®.

There are, of course, other indications apart from the principal one, that is, diagnosis of chronic inflammatory bowel disease, for entering the ileum in children. For instance, ileoscopy will facilitate diagnoses of other causes of ileitis such as infection with tuberculosis or Yersinia [81–83]. In addition, therapeutic dilatation of short terminal ileal strictures by per endoscopic balloon catheter may be attempted.

Endoscope Withdrawal

A more careful inspection of the colon is necessary on withdrawal of the scope, especially for the presence of polyps, which may have remained hidden behind a haustral fold during the initial insertion of the scope. Biopsies should be taken from all areas, including normal-looking mucosa to allow for accurate histological diagnosis. Biopsy technique is similar to EGD, with the exception that many colonoscopic biopsy forceps have a central barb, allowing more than one biopsy to be taken each time the biopsy forceps are passed.

Lastly, before removing the scope from the anus, a retroflexion maneuver obtained by maximum upward and right- or left-tip deflection and slight advancement of the scope into the rectal vault, followed by rotation clockwise and anticlockwise through 180°, completes the examination. This is necessary to observe the anorectal junction and distal rectum. Distal ulcers, inflammation, or even polyps can be missed if this is not done.

Dilatation of Strictures

Trans-endoscopic balloon dilators are appropriate for ileocolonic dilatation, employing the same concept and method as for upper gastrointestinal strictures, employing radiologic screening control. Long-term symptomatic relief can be afforded in some carefully selected patients, including adolescents in reported studies [84, 85]. Pressures of 35–50 psi in balloons of 12–18 mm are available. Theoretically, as for neoplastic or diverticulitis-associated strictures in adults, stent placement could be used as a last resort in inflammatory bowel disease-type strictures, but there are no reported cases of this occurring in childhood as yet.

Complications of Ileocolonoscopy

Complications, excluding those due to sedation, are summarized in Table 21.6. Complications are more common following therapeutic procedures. The literature to date reveals over 3000 colonoscopies under 20 years of age reported, with five perforations—four post-polypectomy and one in a patient with severe ulcerative colitis. Ten procedure-related minor complications are noted, including four small post-polypectomy hemorrhages, three cases of post-procedure abdominal pain with spontaneous resolution, one common peroneal nerve palsy secondary to peri-procedure positioning, and two with a post-procedure fever for more than 24 h [39, 40, 86–91]. This equates to a complication rate owing to the procedure itself of approximately 0.3% and, without polypectomy, of about 0.05%. This is in keeping with the British definition of "minimal" risk and the American definition of "minor risk over minimal" [92].

A single case of a child with serosal surface tears owing to a rigid colonoscope and a large sigmoid loop was reported in 1974 [93]. Flexible pediatric colonoscopes or the new variable-stiffness colonoscopes may prevent this nowadays. The merits of conservative therapy for selected cases of colonic perforation have been discussed [94], and it would seem reasonable to adopt conservative management, for instance, in the case of silent asymptomatic perforations and those with localized peritonitis without signs of sepsis who continue to improve clinically without intervention [95]. In one study in adults, only 3 of 21 patients were managed non-surgically, and there was no difference in the morbidity or mortality between primary repair and resection and anastomosis [96]. In another, conservative management was successful in 13 of 48 patients, and 12 of the 13 were post-polypectomy perforations [97].

In contradistinction to adults, bacteremia is not often detected in children, and only a low rate of bacteremia owing to bacterial translocation across the bowel wall has been demonstrated following pediatric ileocolonoscopy [98]. In addition, modern cleaning machines seem to largely prevent the glutaraldehyde-associated colitis reported in the past [99].

Splenic rupture is rarely seen and will present with hypovolemia and shoulder tip or abdominal pain within 24 h of the ileocolonoscopy [100]. Similarly, direct trauma to the tail of the pancreas is the proposed mechanism of injury in the rare case of pancreatitis reported [101].

Because of the rarity of complications in pediatrics, most pediatric endoscopists, when presented with such a clinical situation, will be unfamiliar with the etiology of the symptoms, and colleagues' opinions should often be sought [102].

Table 21.6 Procedure-related and post-procedure complications in pediatric colonoscopy

Diagnostic procedure related
Vasovagal reactions
Hemorrhage
Perforation—traction serosal; direct transmural
Pancreatitis
Splenic trauma
Therapeutic procedure related
Perforation
Hemorrhage
Thermal injury—transmural
Post-procedure
Distension and discomfort (less if CO_2 insufflation used)
Delayed evidence of perforation or hemorrhage

Small Bowel Assessment

Wireless Capsule Endoscopy

The revised Porto criteria recommend small bowel imaging for completion of PIBD assessment and are essential in cases of CD, atypical UC, and IBD-U. Magnetic resonance enterography/enteroclysis (MRE) is a good tool to assess intestinal inflammation and damage, but there is no validated scoring tool for its use in PIBD [103]. Here, we would like to discuss the role of wireless capsule endoscopy (WCE) as an effective and feasible tool for small bowel assessment.

In patients where endoscopy and MRE have failed to reach a conclusive diagnosis, WCE has been proven to be beneficial in reaching or refuting a diagnosis and describing disease distribution. WCE findings have been shown to be contributory toward change in the management of IBD, especially CD in about 75–92% of the cases [104, 105].

WCE is approved for use in children above 2 years of age, though there are case reports of this to be used in children as young as 8 months. It is usually delivered in the duodenum with the help of an age-appropriate upper GI endoscope. However, in children aged 6 years or more, this can be easily swallowed under direct supervision. Some centers use the same bowel preparation as for ileocolonoscopy. Simethicone (20 mL) before capsule deployment has been shown to improve luminal visualization [106].

We do not routinely use patency capsule before deploying the WCE. The patency capsule has dissolvable open ends and is easily expelled, if its passage through the bowel is delayed.

In our center, the child is allowed only clear fluids for at least 2 h post-deployment of the capsule.

The capsule is usually expelled within next 24–48 h but can stay inside the bowel for up to 2 weeks. Capsule retention has been reported in the pediatric population but is more common in children with known small bowel pathology, malnutrition, or PIBD. In such situations, high-dose laxatives can be tried as a first resort to remove the capsule, and

in PIBD, steroids and other anti-inflammatory agents are often successful as they reduce the inflammatory component of the stricture—double-balloon enteroscopy (DBE) can be used to retrieve a capsule, but if no symptoms are occurring, the capsule is usually left in situ—surgery is rarely if ever required and only with stricture symptoms when it would be required in any case.

Enteroscopy

Enteroscopy (ES) is now a standard and recently reviewed [107] endoscopic procedure in adult medicine. Although ES plays a role in examination of the small bowel and it has a place in PIBD that defies diagnosis by standard endoscopy and WCE, it is not routinely used. Indeed, ES may be preferable to WCE if there is a clinical suspicion of obstruction, need for biopsy, or for a therapeutic procedure. It becomes a necessity when small bowel biopsy is required for differential diagnostic purpose or when both MRE and WCE fail to prove a strongly suspected small bowel pathology.

Push Enteroscopy

Sonde-type, intraoperative-assisted push enteroscopy [108–110] and more recently nonsurgical push enteroscopy [111] have been described in children. Sonde enteroscopy has largely been abandoned in favor of push enteroscopy [112, 113] given the desire for therapeutic capability. Push ES (PES) is endoluminal examination of the proximal jejunum using a long, flexible endoscope with or without an overtube.

The techniques of per oral push enteroscopy and laparoscopy-assisted enteroscopy continue to evolve and have been superseded by device-assisted enteroscopy (DAE).

Device-assisted ES (DAE) is either balloon assisted or spiral. Single-balloon-assisted ES (SBE) uses an overtube equipped with balloon, and double-balloon-assisted ES (DBE) allows examination of the whole small bowel (via oral or anal route) due to assistance of balloons at the distal end of both endoscope and overtube. DBE usually requires two individuals (operator and assistant). Spiral ES uses assistance of single-use overtube, which has helical spirals at its distal end and rotates independently from the enteroscope.

The term intraoperative ES (IOE) is used when ES is performed during abdominal surgery (orally or via enterostomy). In such case, progression of the endoscope (gastroscope, colonoscope, pediatric colonoscope, or enteroscope) is manually assisted by the surgeon.

Instruments and Technique

Although a pediatric colonoscope can be used for enteroscopy, specifically designed enteroscopes up to 230 cm in length are now available. The Olympus SIF Q140 (Olympus, Center Valley, Pennsylvania, USA) has a diameter of 10.5 mm and is 250 cm long. A push enteroscope, like a colonoscope, allows four-way tip deflection to 160°–180°. An overtube, typically 60–100 cm in length with a soft Gore-Tex tapered tip, stiffens the enteroscope within the stomach and upper duodenum limiting looping, thereby allowing deeper advancement into the small bowel [112]. A push enteroscope can be introduced 120–180 cm beyond the ligament of Treitz, and with laparoscopic assistance, even the terminal ileum can be reached, allowing lesions such as a Meckel's diverticulum to be found [110].

Preparation for enteroscopy is the same as for EGD, although the procedure may be substantially longer and more uncomfortable. Therefore, it is the practice at our unit to use general anesthesia even in adolescents. Patients are positioned left lateral or semi-prone. After normal examination of the esophagus and stomach, air is removed, and minimal insufflation of the stomach allows deeper penetration into the small bowel when not using an overtube. At 60–80 cm in older children and adolescents, the ligament of Treitz is found, and extreme tip deflection is needed to find the lumen. The first jejunal loop is more readily identified because it is straighter and travels down to the pelvis. If using an overtube, which has been threaded over the enteroscope prior to oral insertion, this is deployed down the esophagus and into the second part of the duodenum; prepyloric deployment will not aid in deeper small bowel penetration. Some exponents use fluoroscopy to aid in overtube tip positioning [107]. When advancing the overtube, the enteroscope needs to be pulled back with clockwise rotation to straighten it, similar to the maneuver used to achieve the shortened scope position during endoscopic retrograde cholangiopancreatography.

A number of reports demonstrate the utility of push enteroscopy in adults. One of few studies in children, using push enteroscopy, investigated the possibility of Crohn disease in children with growth retardation [114].

Double-Balloon Enteroscopy

Double-balloon enteroscopy (DBE) enables high-resolution endoscopic imaging of the entire small bowel. While push enteroscopy can aid in visualization of the proximal jejunum, DBE goes a step further making it possible to examine, take biopsies, and perform therapeutic procedures such as hemostasis and balloon dilatation throughout the

entire small bowel. The potential for mucosal biopsies and interventional endo-therapy provides significant advantage over WCE [115–117].

Instruments and Technique

The DBE system (Fujinon; Fujinon Inc., Japan) consists of a high-resolution video enteroscope (EN-450P5/20) with a flexible overtube. The video enteroscope has a working length of 200 cm and an outer diameter of 8.5 mm, while the flexible overtube has a length of 140 cm and outer diameter of 12 mm. The enteroscope has a 2.2 mm forceps channel that enables routine biopsy as well as other common therapeutic interventions. The enteroscope as well as the overtube is fitted with a balloon each at the tip. The overtube and balloons are disposable. The balloons can be inflated and deflated with air from a pressure-controlled pump system with maximum inflatable pressure of 45 mm (Figs. 21.10 and 21.11).

Both balloons are deflated at the start of the procedure. On reaching the duodenum, the overtube balloon is inflated to fix and stabilize the overtube within the lumen. Subsequently the enteroscope is advanced as far as possible. Then the enteroscope tip balloon is inflated, and the overtube balloon is deflated. The overtube is now advanced to reach the enteroscope tip. The overtube is again inflated, and both enteroscope and overtube are gently withdrawn together in order to "concertina" the small bowel over both. The whole procedure is repeated, and each set of maneuvers can allow up to 40 cm of small bowel to be examined, until the terminal ileum (TI) is reached. If the TI is not reached, then the distal most region reached is "tattooed" in the submucosal plane with an endo-

Fig. 21.10 Double balloon with balloon inflated

Fig. 21.11 Double balloon with balloon deflated

needle. The DBE can then be repeated via the trans-anal route and retrograde movement from the TI proximally up the ileum allowing full examination of the whole small bowel. On withdrawal in either procedures, close examination of the mucosal surface occurs as with standard endoscopy, but lesions are dealt with as soon as found, whether this is on intubation or withdrawal. Bowel preparation is as for standard IC. The procedure is carried out under general anesthetic or deep sedation in the presence of an anesthetist.

DBE has been extensively evaluated in adults with obscure GI bleeding and to a lesser extent in CD. In a retrospective study involving 40 CD adult patients, active small bowel CD was found in 24 (60%) patients, leading to a change in therapy in 18 patients (75%). After a mean follow-up of 13 months, 83% of patients had persistent clinical improvement [118]. In another study of 37 patients with CD, the overall diagnostic yield of DBE was 59.4% [119]. In a pediatric study conducted by one of the authors, the diagnostic yield was 78.5%, and therapeutic success rate was 64.2%. None of the patient had any complication, suggesting that DBE is a safe and effective procedure in pediatric population [120].

Since CD can be confined to the small bowel alone, DBE has a definite role in the evaluation of patients with suspected CD with negative ileocolonoscopy and radiological investigations. In one study comparing DBE to small bowel follow-through (SBFT) [121], DBE was able to detect early or faint lesions like aphthoid lesions, erosions, and small ulcers which were not found by SBFT. Also DBE was better in differentiating open and healed ulcers, thus, helpful in evaluation of response to treatment in CD. However, small strictures were difficult to detect with DBE since they could be mistaken for an intestinal band. Complications reported in the

literature include perforation, pancreatitis, bleeding, and aspiration pneumonia [122, 123].

Endoscopic Findings in Inflammatory Bowel Disease

It is important to recognize the normal appearance of the bowel macroscopically and histologically. The colonic mucosa when seen through an endoscope appears glistening salmon pink in color with a visible network of branching vessels seen beneath the mucosa. The smoothness of the mucosal surface is the hallmark of a healthy colon, and there is a lack of contact bleeding, friability, or exudates [124]. Microscopically the mucosa appears flat with normal crypt density, undistorted crypt architecture, intact surface epithelium, normal mucin content, and without any neutrophil infiltration [125].

Ulcerative Colitis

The earliest changes seen in UC are the presence of diffuse erythema and dull appearance of the vascular architecture consequent to the vascular congestion and edema. The engorged mucosa leads to contact bleeding and friability when touched with an endoscope. Progressively minute ulcers appear which coalesce to form large ulcers within a background of diffuse colonic inflammation with loss of vascular pattern and granularity [124]. The colonic mucosa is involved in a continuous fashion from the rectum extending further up the colon. Long-standing UC leads to the development of pseudopolyps (Fig. 21.12). The microscopic findings typical of UC include diffuse mucosal involvement from rectum up to cecum without granulomas. The presence of architectural distortion, basal plasmacytosis, cryptitis, and crypt abscesses are suggestive of chronicity. The severity of inflammation is worse distally, and reversal of this gradient should prompt for reconsideration of the diagnosis. However, there is no single set of microscopic or macroscopic findings for diagnosis of UC. At least five atypical phenotypes of UC have been described in the recently revised ESPGHAN Porto Criteria [103] (Table 21.7). The classic notion of noninvolvement of the upper GI tract in UC no longer holds true, as gastric erosions, ulcers, and microscopic features can be seen in 4–8% of patients with UC [126]. Therefore, the presence of focal gastritis or chronic gastric inflammation should not be a sole criterion to refute the diagnosis of UC. Besides, the EUROKIDS registry data suggest that rectal sparing can be seen in around 5% cases of pediatric UC [1].

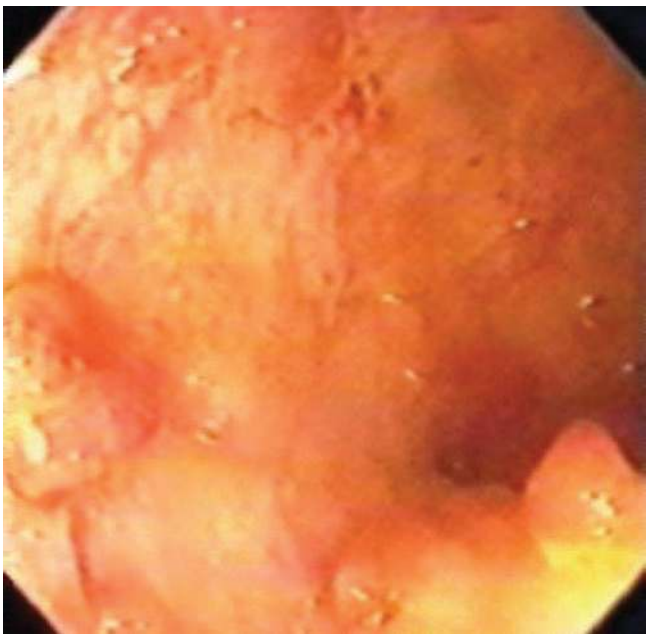

Fig. 21.12 Pseudopolyps in ulcerative colitis

Table 21.7 Phenotypes of pediatric UC at diagnosis

Presentation	Macroscopic	Microscopic
Typical	Contiguous disease from the rectum	Architectural distortion, basal lymphoplasmacytosis, disease most severe distally, no granulomas
Atypical		
1. Rectal sparing	No macroscopic disease in rectum or rectosigmoid	Same as typical, especially in the involved segment above sparing
2. Short duration	Contiguous disease from the rectum may also have rectal sparing	May have focal, plus signs of chronicity or architectural distortion may be absent; other features are identical. Usually occurs in young children with short duration of symptoms
3. Cecal patch	Left-sided disease from rectum with area of cecal inflammation and normal appearing segment between the two	Typical; biopsies from the patch may show nonspecific inflammation
4. UGI	Erosions or small ulcers in stomach, but are neither serpiginous nor linear	Diffuse or focal gastritis, no granuloma (except peri-cryptal)
5. Acute severe colitis	Contiguous disease from the rectum	May have transmural inflammation or deep ulcers, other features typical. Lymphoid aggregates are absent; ulcers are V-shaped fissuring ulcers

Crohn Disease

Typical macroscopic findings of CD commence as mucosal aphthous lesions, which enlarge to form linear or transverse serpentine ulceration (Fig. 21.13). Characteristically the ulcers are focal with normal intervening mucosa, the so-called skip lesions (Fig. 21.14). As the disease progresses, it leads to nodularity, giving a cobblestone appearance (Fig. 21.15) and stenosis/stricturing (Fig. 21.16) of bowel with pre-stenotic dilatation. Bowel wall thickening with luminal narrowing is typically seen on imaging, WCE, or during surgery. The other typical macroscopic findings are skip lesions and jejunal and ileal ulcers. The extraluminal findings include perianal fistulas, abscesses, anal stenosis, anal canal ulcers, and large and inflamed skin tags.

Nonspecific macroscopic findings of CD include edema, erythema, friability, and granularity. Terminal ileum is the most common site to be involved in CD (Fig. 21.17), hence,

Fig. 21.13 Deep aphthous lesion in Crohn disease

Fig. 21.15 Typical cobblestone appearance in Crohn disease

Fig. 21.14 Skip lesions in Crohn disease

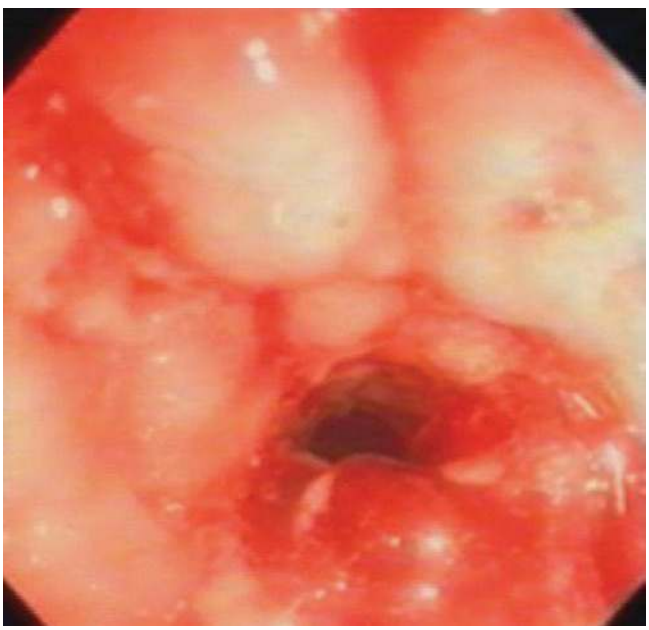

Fig. 21.16 Colonic stricture in Crohn disease

as has been stressed earlier; it is imperative that every attempt should be made to reach the terminal ileum at colonoscopy.

The presence of noncaseating granulomas on ileal biopsy is the classical histopathological finding in CD of the ileum.

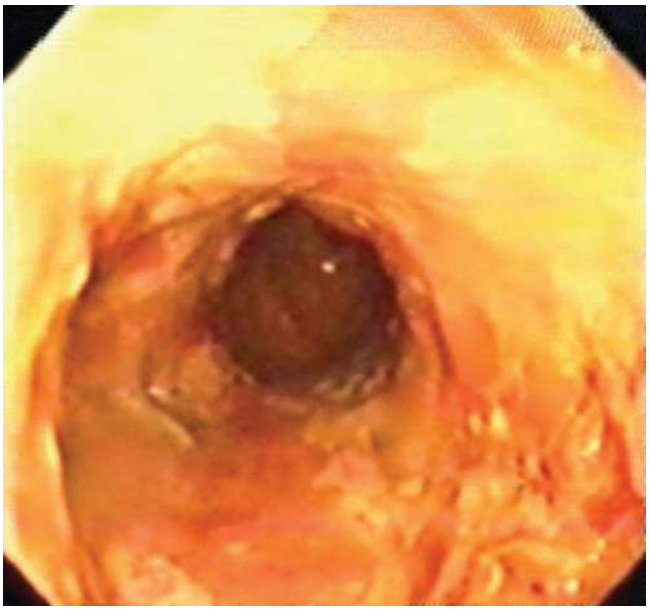

Fig. 21.17 Terminal ileal Crohn disease

The other typical microscopic findings of CD include focal chronic inflammation, transmural inflammatory infiltrate, and submucosal fibrosis.

Nonspecific microscopic findings of CD are granulomas adjacent to a ruptured crypt, mild nonspecific inflammatory infiltrate in the lamina propria, and mucosal ulceration/erosions. The signs suggestive of chronicity are crypt architectural changes, colonic Paneth cell metaplasia, and goblet cell depletion. The presence of epithelioid granulomas is sufficient to make a diagnosis of CD even without classical macroscopic findings.

Inflammatory Bowel Disease-Undefined (IBD-U)

In the recently revised ESPGHAN Porto Criteria for the diagnosis of inflammatory bowel disease in children and adolescents, it is suggested that the term IBD-U is used for patients with colitis and clearly defined findings that are atypical for either CD or UC. Colitis features in children with untreated colitis are categorized in three classes, and patients with at least one class II and two to three class III features are diagnosed as IBD-U (Table 21.8).

Table 21.8 UC v IBD-U v CD differentiation

Likelihood of UC	Features	Diagnostic approach
Class I: Nonexistent	Well-formed granulomas anywhere in the GI tract, remote from ruptured crypt	Diagnose as CD
	Deep serpentine ulcerations, cobblestoning, or stenosis anywhere in the small bowel or UGI tract	
	Fistulizing disease (internal or perianal)	
	Any ileal inflammation in the presence of normal cecum (i.e., incompatible with backwash ileitis)	
	Thickened jejunal or ileal bowel loops or other evidence of significant small bowel inflammation (more than a few scattered erosions) not compatible with backwash ileitis	
	Macroscopically and microscopically normal appearing skip lesions in untreated IBD (except with macroscopic rectal sparing and cecal patch)	
	Large inflamed perianal skin tags	
Class II: Rare with UC (<5%)	Combined (macroscopic and microscopic) rectal sparing, all other features are consistent with UC	IBD-U if at least 1 class II feature exists
	Significant growth delay (height velocity <2 standard deviation), not explained by other causes	
	Transmural inflammation in the absence of severe colitis, all other features are consistent with UC	
	Duodenal or esophageal ulcers, not explained by other causes (e.g., *Helicobacter pylori*, NSAIDs, and celiac disease)	
	Multiple aphthous lesions in the stomach, not explained by other causes (e.g., *H. pylori* and NSAIDs)	
	Positive anti-Saccharomyces cerevisiae antibody (ASCA) in the presence of negative pANCA	
	Reverse gradient of mucosal inflammation (proximal >distal) (except rectal sparing)	
Class III: Uncommon (5–10%)	Severe scalloping of the stomach or duodenum, not explained by other causes (e.g., celiac disease and *H. pylori*)	Diagnose as IBD-U if at least 2–3 features exists
	Focal chronic duodenitis on multiple biopsies or marked scalloping of the duodenum, not explained by other causes (e.g., celiac disease and *Helicobacter pylori*)	
	Focal active colitis on histology in more than one biopsy from macroscopically inflamed site	
	Non-bloody diarrhea	
	Aphthous lesion in the colon or UGI tract	

Follow-Up and Surveillance Ileocolonoscopy

Intraluminal disease should be reassessed electively as guided by biochemical markers including fecal calprotectin. However, patients who do not respond to therapy or who are treatment dependent or who have doubtful diagnosis should have an early reassessment. It is the practice in many units to perform a follow-up ileocolonoscopy 2–3 months after the start of treatment in a newly diagnosed case of inflammatory bowel disease since Modigliani and colleagues showed that only 29% of adults with Crohn disease in clinical and biochemical remission actually achieved endoscopic remission [127]. It allows the physician to observe the mucosal efficacy of the therapy, because, in many instances, such as steroid use in colitis, the clinical improvement of the patient may not be mirrored by the mucosal improvement, which is regarded by most as the most important meter of a successful treatment regimen [9]. Ileocecal transcutaneous Doppler ultrasonography may be of benefit as a noninvasive alternative to repeat ileocolonoscopy in this situation, as noted above. In addition, the activity of mucosal inflammation may determine the long-term risk for carcinogenesis in the bowel.

Treatment Targets

The Selecting Therapeutic Targets in Inflammatory Bowel Disease (STRIDE) [128] program initiated by the International Organization for the Study of Inflammatory Bowel Diseases (IOIBD) has recommended treatment targets for IBD to be used for a "treat-to-target" clinical management strategy based on clinical/patient reported outcome (PRO) and endoscopic remission.

The clinical/PRO remission for Crohn disease is defined as resolution of abdominal pain and diarrhea/altered bowel habit, which should be assessed at a minimum of 3 months during active disease, and endoscopic remission defined as resolution of ulceration at ileocolonoscopy (or resolution of findings of inflammation on cross-sectional imaging in patients who cannot be adequately assessed with ileocolonoscopy), which should be assessed at 6–9-month interval during the active phase.

Similarly for ulcerative colitis, the clinical/PRO remission is defined as resolution of rectal bleeding and diarrhea/altered bowel habit, which should be assessed at a minimum of 3 months during active disease, and endoscopic remission defined as resolution of friability and ulceration at flexible sigmoidoscopy or colonoscopy, which should be assessed at 3-month interval during the active phase.

Although the CRP and fecal calprotectin are not the treatment targets, these can be used as adjunctive measures of inflammation for monitoring in CD. Failure of CRP or fecal calprotectin normalization should prompt further endoscopic evaluation, irrespective of symptoms.

Scoring Systems for Endoscopic *PIBD* Disease Activity

The focus is increasingly being shifted to mucosal healing as an important aspect of the treatment target of PIBD. This is further stressed upon by the STRIDE recommendations as above. There are various scoring systems currently in practice, namely, Mayo score, UCEIS, UCCIS, CDEIS, SES-CD, and Rutgeerts score. The standard scores used for Crohn disease are the Crohn Disease Endoscopic Index of Severity (CDEIS) and the Simple Endoscopic Score for Crohn Disease (SES-CD). Of these two, SES-CD seems to be more simplistic and also correlates well with CDEIS. The interobserver variability for SES-CD is less as compared to CDEIS [129–131]. The Rutgeerts score is primarily used in postoperative patients. None of these scores are fully validated in the pediatric population.

For UC, the STRIDE Committee recommends the use of the Mayo score which, though not fully validated, has less inter- and intra-observer variation, is easy to use, and has well-established predictive values [132, 133]. The Ulcerative Colitis Endoscopic Index of Severity (UCEIS) also has less interobserver variability but is not fully validated. The Ulcerative Colitis Colonoscopic Index of Severity (UCCIS) assesses four variables: vascular pattern, granularity, bleeding/friability, and ulceration. All are assessed in five segments throughout the colon. This index also needs further validation and cutoff values are not well defined.

Endosonography

Endoluminal ultrasonography of the rectum has been an established technique for years; however, more recently, an echocolonoscope has allowed combined examination of the mucosa and the bowel wall. This is a forward-viewing colonoscope with the transducer (7.5 MHz) situated in the rigid tip of the scope [134]. Alternatively, an ultrasound miniprobe can be introduced via the biopsy channel (7.5 or 12.5 MHz). A fluid interface is necessary for all endosonography, and this can be achieved either with a fluid-filled balloon or filling the relevant colonic segment with water. Because this may be time consuming, it is easier to concentrate on the region of interest rather than attempt to examine the entire colon. In adult practice, staging of cancers is the major indication for endosonography. In children and adolescents, indications for this technique might include suspicion of early invasive cancer arising from an adenoma, assessment of the extent and depth of sessile polyps to guide reception

technique, assessment of colonic strictures/fistulae/anastomoses, assessment of the extent and depth of inflammatory bowel disease, assessment of the extent and depth of vascular lesions, examination of rectal and colonic portal hypertension with varices, and suspicion of lymphoma.

Inflammatory bowel disease appears as wall thickening and subsequent loss of the normal layer structure of the colon with progressive inflammation. Although theoretical differentiation between ulcerative colitis and Crohn disease is possible owing to the transmural nature of Crohn disease, it has been shown recently that active ulcerative colitis can have echo-texture changes extending into the submucosa and that these changes correlate with disease activity [135]. Surgical decisions were made in one study of patients with Crohn disease in which endoscopic ultrasonography was used to differentiate between superficial and transmural involvement [136]. An ileo-anal pouch was undesirable when transmural disease was identified. Perirectal and peri-colonic fistulae and abscesses have been seen using the rigid rectal ultrasound probe, and this is a potential application for endoscopic ultrasonography [137]. Catheter probe-assisted endoscopic ultrasonography in inflammatory bowel disease has advantages over an echocolonoscope, which may be technically difficult to use. One study recently showed that wall thickness was twice as great in active inflammatory bowel disease, but ulcerative colitis could not be differentiated from Crohn disease [138]. Loss of wall structure correlated with disease activity score in the Crohn disease group, and wall thickness correlated with disease activity in the ulcerative colitis group. Other parameters, such as superior mesenteric artery maximum flow velocity and increased Doppler ultrasonography demonstrating mural blood flow, are being examined as viable noninvasive substitutes for the determination of posttreatment ileocecal Crohn disease activity, thus, potentially avoiding the need for follow-up ileocolonoscopy, as some units advocate.

New Endo-Diagnostic Methods

High-Magnification Chromoscopic Colonoscopy (HMCC)

Recent improvements in technology have led to the development of a generation of endoscopes with the ability to magnify endoscopic images. The high-magnification endoscope allows conventional video imaging with the facility to increase magnification instantaneously up to 100 times by a thumb-activated lever. By pushing the lever downward, the magnified picture is obtained immediately, and by reverting back to the normal position, the image is returned to normal [139]. A topical dye-like indigo carmine 0.2–2% is sprayed on the mucosa helping further to delineate the pathology. During magnification chromoscopic colonoscopy, pit patterns are observed. These pit patterns are classified according to the modified Kudos' criteria [140], and based on the pit patterns, it is possible to predict the histology as well as take targeted biopsies.

This technique has been extensively used in cancer surveillance in adults [141, 142]. Matsumato et al. [73] observed that the presence or absence of network pattern (NWP) and crypt opening (CO) highly correlated with the severity of disease in ulcerative colitis both clinically and histologically. Fujiya et al. [143] devised a classification system based on minute findings. In a prospective study, they compared HMCC with the established Matt's criteria [144] and histopathological findings and found that while colonoscopy correlated well with histopathology and correctly identified normal and clearly defined abnormal mucosa, it was insufficient for the assessment of minute mucosal changes that reflect smoldering histopathological changes. HMCC, on the other hand, not only helped to recognize distinctive features in such mucosa predicting the severity of the disease state, but it also helped in predicting relapses in those who were in a quiescent state. Further, in another prospective study, Sugano et al. [145] have found HMCC effective in the evaluation of minute mucosal changes in patients with UC in remission. HMCC has also been evaluated in cancer surveillance in UC [146] and has been shown to assist in taking targeted biopsies.

Confocal Laser Endomicroscopy

Confocal laser endomicroscopy (CLE) is an exciting new technology developed in the recent years. It is an adaptation of light microscopy, whereby a low-power laser illumination is focused to a single point in a microscopic field of view. Light emanating from that specific point is focused to a pinhole detector. Light emanating from outside the focally illuminated spot is not focused to the pinhole and, therefore, is geometrically rejected from detection. The beam path is scanned in a raster pattern, and measurements of light returning to the detector from successive points are digitized to produce two-dimensional images. Each such image, thus, is an optical section representing one focal plane within the specimen [147–149].

The components of the confocal laser endomicroscope are based on the integration of a confocal laser microscope mounted in the tip of a conventional colonoscope (EC3870K; Pentax, Tokyo, Japan), which enables confocal microscopy in addition to standard videoendoscopy. The diameter of the distal tip and insertion tube is 12.8 mm. The distal tip contains an air and water jet nozzle, two light guides, a 2.8 mm working channel, and an auxiliary water jet channel. The water jet channel is used for the topical application of the

contrast agent. During CLE, an argon ion laser delivers an excitation wavelength of 488 nm with a maximum laser output of <1 mw at the surface mucosa. Confocal images can then be collected at a scan rate of 0.8 frames/second (1024 × 1024 pixels) or 1.6 frames/second (1024 × 512 pixels). The optical slice thickness is 7 μm with a lateral resolution of 0.7 um and z-axis range of 0–250 um below the surface layer. Sodium fluorescein is given intravenously at the time of the procedure as a contrast agent. Thus, it is possible to get cellular and subcellular microscopic images at the time of endoscopic procedure. Features of IBD seen at CLE include bifid crypts, crypt distortion and destruction, crypt abscess/cryptitis, goblet cell depletion, inflammatory cell infiltration, and enlarged tortuous vessel architecture [150]. In a recent prospective study involving 21 patients with IBD, CLE was able to identify intramucosal bacteria with a sensitivity of 89% and specificity of 100% using fluorescence in situ hybridization (FISH) as gold standard. The authors further performed a retrospective study in 113 patients with CD and UC and found intramucosal bacteria significantly more often than in control patients (66% vs 60% vs 14%, $p < 0.001$) [151].

The advantages of using CLE are that as it is less invasive, there are potentially significant time, histopathology input, materials, manpower, and consequent financial savings to institutions conducting pediatric endoscopic services. There is no doubt that this new technique will be useful in taking targeted biopsies in patients with IBD and reduce the need to take biopsies.

Therapeutic Endoscopy in IBD

Besides being essential for the diagnosis and reassessment of IBD, endoscopic expertise is also required for therapeutic procedures in PIBD. It is estimated that about half of pediatric Crohn disease patients require some kind of surgical intervention within a decade of diagnosis [152, 153], the common indications being structuring or penetrating disease of the terminal ileum and colon or at an anastomotic site [154–156].

Traditionally, the strictureplasty and bowel resection have been the mainstay of treatment for stricturing disease, but recently, endoscopic balloon dilatation (EBD) is emerging as a safe and effective alternative to the above surgical procedures in patients with Crohn disease with ileocecal and anastomotic strictures [157–163]. The decision to perform EBD depends on patient choice, endoscopist expertise/experience, procedural feasibility, and the stricture characteristics, e.g., number, nature, and length.

The success rate of EBD in adults has been reported to vary from 83 to 87% at 1 year to 64–58% at 5 years [157–163]. There is a lack of evidence and controlled trials to compare the recurrence rate post-EBD and postsurgical procedure.

A surgery-free outcome is reported to be highest when stricture length is <4 cm and when EBD is performed for anastomotic strictures [157, 164, 165]. There is an increased need of post-procedural surgery with prolonged Crohn disease duration and high C-reactive protein [157]. The success rate is demonstrated to be poor if the stricture is present at the Bauhin's valve [160, 166].

Although there is no reported use of EBD for duodenal strictures in PIBD, the authors have recently performed trans-endoscopic balloon dilatation of a duodenal stricture in an 11-year-old boy with Crohn disease.

The possible complications associated with EBD are bleeding and perforation. The presence of fistulizing disease and abscesses at or adjacent to the site stricture increases the risk of perforation and is, thus, considered to be a contraindication [167].

Intraluminal stenting has also been reported as a possible alternative to surgery to treat strictures, but current date does not suggest its routine or safe use.

Colon Capsule Endoscopy

Colon capsule endoscopy (CCE) is still in a nascent stage and is considered to be useful in situations where full colonoscopy could not be achieved or where patient is not compliant for an endoscopic procedure. The colon capsule when deployed goes into a sleep mode as it traverses through small bowel and gets reactivated as it reaches colon. It has been reported to have high specificity and sensitivity as compared to routine colonoscopy [106], but further randomized clinical trials are required to recommend its routine use.

Conclusions

Pediatric endoscopy differs significantly from their adult parallels in nearly every aspect, including patient and parent management and preparation, selection criteria for sedation and general anesthesia, bowel preparation, expected diagnoses, instrument selection, imperative for terminal ileal intubation, and requirement for biopsies from macroscopically normal mucosa.

The chapter has highlighted the importance of endoscopy in general and ileocolonoscopy in particular in the diagnostic and therapeutic management of IBD. Also, the role of other advanced diagnostic techniques like DBE has been discussed, while wireless capsule endoscopy is discussed in a separate chapter.

Endoscopy is a necessary and important investigation in the various stages of management of inflammatory bowel disease from diagnosis to surveillance of cancer. There is no dispute in the use of ileocolonoscopy in the initial assessment

of patients with IBD. Recent data have shown that upper GI endoscopy also has an important role in the initial diagnosis and differentiation of IBD and, hence, is recommended as a part of initial investigation of all cases presenting with symptoms suggestive of IBD. Other endoscopic investigative modalities like WCE, DBE, HMCC, confocal endomicroscopy, and endosonography aid in further management of IBD. Apart from diagnosis, endoscopy also has an important role in the therapeutic management of IBD.

The Pathology of Chronic Inflammatory Bowel Disease

22

Pierre Russo

Major Histologic Features Noted in Mucosal Specimens

Preparation and Procedure-Induced Artifacts

Nondisease-related alterations in the colonic mucosa may be induced by certain enemas used in bowel preparation or by the procedure itself. For example, soap suds enemas may result in hyperemia and edema of the bowel, especially noted on endoscopy [1]. Oral sodium phosphate solutions (oral FLEET™) may cause aphthoid-like erosions endoscopically similar to Crohn disease (CD) [2]. These correspond histologically to large lymphoid aggregates, although edema, hemorrhages, or mild acute inflammation have also been described [3] (Fig. 22.1). Mucin depletion and increased cell proliferation can be noted in the crypts [4, 5]. Hypertonic saline and biscodyl enemas can cause mucin depletion, focal disruption of surface epithelium, mild acute inflammation, and edema, which usually resolve within 1 week [6]. Minor trauma to the mucosa may allow penetration of gas insufflated into the bowel during endoscopy, resulting in "pseudolipomatosis," characterized by the formation of numerous clear spaces in the mucosa [7] (Fig. 22.2). Cleansing solutions used to disinfect endoscopes, such as hydrogen peroxide, may produce adherent mucosal plaques, mucosal vacuolar changes, congestion, hemorrhage, and even pseudolipomatosis [8, 9] (Table 22.1).

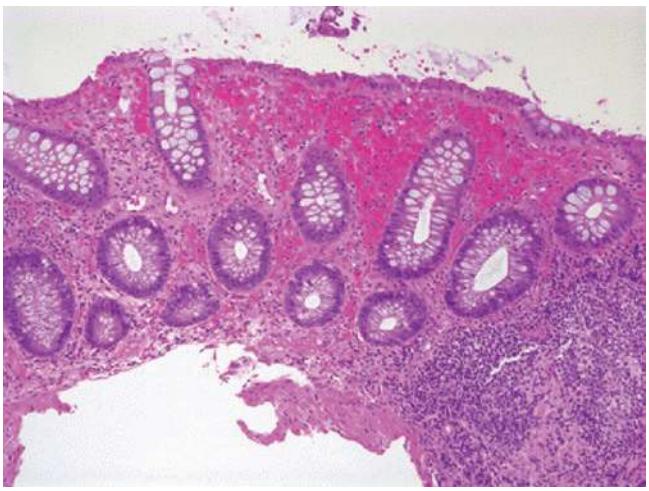

Fig. 22.1 Histologic features of phosphate enema effect. Superficial mucosal hemorrhage and focal mucin depletion of the colonic surface epithelium are noted. There is no inflammation of the crypts (hematoxylin-eosin (H + E), ×100)

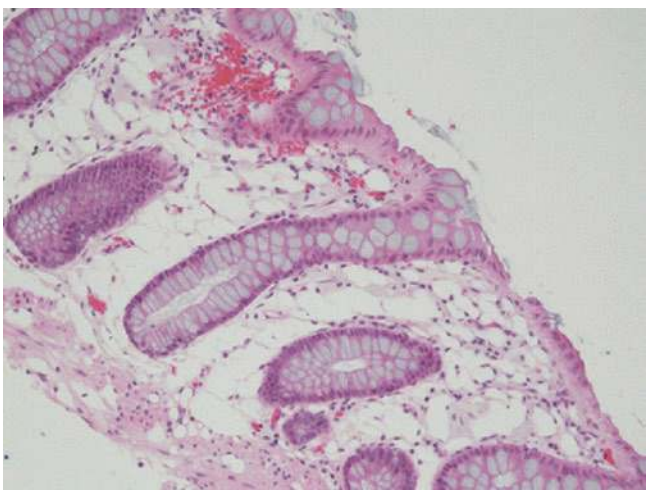

Fig. 22.2 Pseudolipomatosis. Numerous clear spaces in the lamina propria resulting from infiltration of the mucosa by insufflated gas during endoscopy suggests the presence of fat vacuoles (H + E, ×200)

Treatment related	Antibiotic-associated colitis Changes induced by other drugs Diversion colitis Neutropenic colitis Pouchitis Graft versus host disease Fibrosing colonopathy

Histologic Patterns in Colitis

Active colitis refers to the presence of neutrophils either in the lamina propria, in crypt epithelium (cryptitis) or within the lumen, forming small abscesses (crypt abscesses). Neutrophils confined to the lumen of mucosal vessels are not considered part of the process of active colitis. A predominantly neutrophilic infiltrate without significant architectural changes is generally a feature of diseases with a self-limiting course, such as infections and drug reactions. Neutrophils in these cases are frequently confined to the superficial portion of the mucosa, and may be associated with small erosions or ulcers (Fig. 22.3).

Focal active colitis (FAC) is observed in acute self-limited colitis and can be an early manifestation of idiopathic inflammatory bowel disease. In a recent report of 29 pediatric patients with FAC, 8 developed Crohn disease, whereas the other patients had either infectious colitis or remained idiopathic [10].

Eosinophilic colitis refers to a patchy or diffuse infiltrate dominated by eosinophils, usually with infiltration of the crypt or surface epithelium. Wide variations in the number of eosinophils in the normal colonic mucosa are due to differences in specimen site (greater numbers of eosinophils in the cecum as opposed to the rectum), age, and geography [11, 12]. In infants, the main consideration is milk allergy; parasitic infection and chronic inflammatory bowel disease (very early-onset IBD) are also possibilities.

The features of ***chronic colitis*** are based on the recognition of architectural changes in the mucosa, such as a "villiform" aspect of the surface epithelium, crypt destruction, and atrophy, and shortening of the crypts with irregular branching and loss of their regular outline. Shortening of the crypts is most often due to the presence of a basally situated chronic inflammatory infiltrate (basal plasmacytosis), which separates the base of the crypts from the muscularis mucosae (Fig. 22.4). Paneth cell metaplasia and pyloric metaplasia are other useful findings (Fig. 22.5). In the normal colon, Paneth cells usually extend into the right colon, but their presence in the left colon is a feature of chronic damage, especially in the

Fig. 22.3 Colitis in a 3 year old due to Salmonella. There is a superficial, mild inflammatory infiltrate with small crypt microabscesses without significant crypt architectural changes, associated with superficial hemorrhages. Hematoxylin-eosin (H + E), ×100

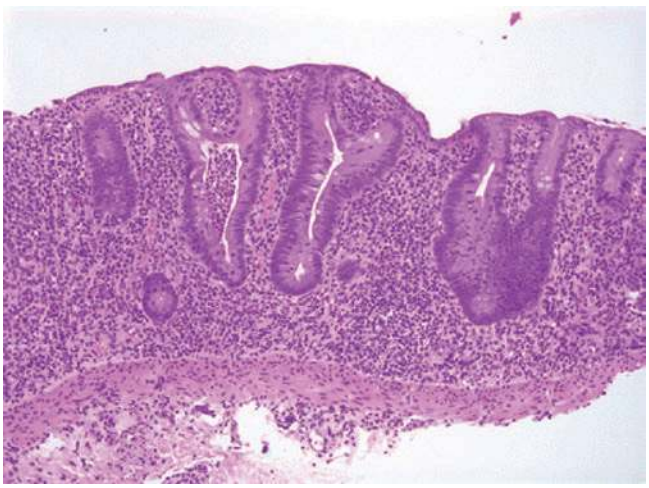

Fig. 22.4 Histologic features of IBD. Chronic mucosal damage is characterized by irregular branching of the crypts, increased intercryptal distance, and shortening of the crypts due to the presence of an inflammatory infiltrate in the deep mucosa separating the base of the crypts from the muscularis mucosa (basal plasmacytosis). In addition, there is goblet cell depletion and a microabscess. H + E, ×100

older child. Pyloric metaplasia is the presence of mucous glands normally present in the gastric antrum and pylorus. It is more frequently noted in Crohn disease than ulcerative colitis (UC) but is also a useful feature of chronic damage. The presence of an increased mononuclear inflammatory cell infiltrate, usually an integral part of the process, is the least useful histologic parameter given the wide range in numbers of lymphocytes and plasma cells in normal specimens. Although considered a hallmark of chronic idiopathic inflammatory bowel disease, histologic features of chronicity may also be seen in other settings in pediatrics, such as immunodeficiency disorders, metabolic diseases such as glycogen storage disease type Ib, or result from mucosal injury due to ischemia or Hirschsprung's disease. ***Chronic active colitis*** refers to the presence of a neutrophilic infiltrate superimposed on the above changes and is usually seen during exacerbations of IBD.

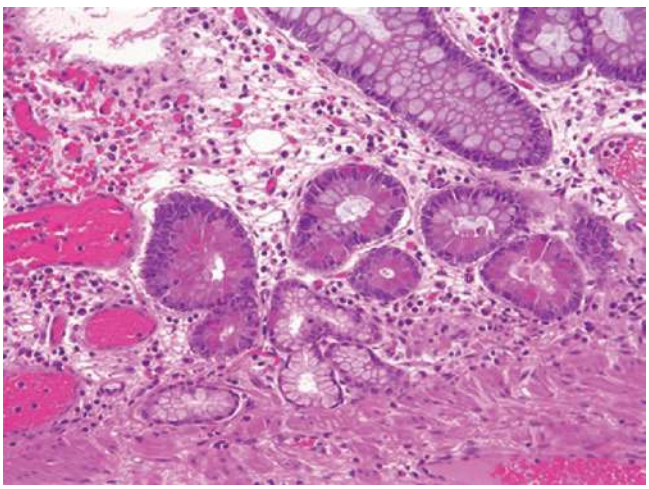

Fig. 22.5 Pyloric metaplasia and numerous crypts containing Paneth cells are noted in the deep mucosa of a patient with Crohn disease

Acute Self-Limited Colitis and its Distinction from IBD

Endoscopic features alone may not reliably distinguish acute self-limited colitis (ASLC) from IBD. Stool cultures and duration of diarrhea may help, as patients without an identifiable pathogen or in whom diarrhea lasts more than several weeks are more likely to have IBD. However, microbiologic investigations can reveal a colitis-causing pathogen such as *Salmonella*, *Campylobacter*, and *Yersinia* in up to 15% of patients with IBD [13]. ASLC is characterized by a predominantly neutrophilic infiltrate without significant crypt architectural changes. Neutrophils in these cases predominate in the superficial portion of the mucosa, and may be associated with small erosions or ulcers [14]. Neutrophils may also invade the crypt epithelium (cryptitis) or form small abscesses within the crypt lumen (crypt abscesses). Although numerous crypt abscesses suggest UC, they may be noted in CD as well as in infections and *Clostridium difficile*-related injury. The histologic diagnosis of IBD rests on the recognition of chronic mucosal damage, *chronic colitis*. Multiple biopsy studies of new-onset IBD in adults have shown that histologic features of chronic damage as noted above can reliably distinguish IBD from self-limited colitis [14–17].

Histologic Features of Early IBD

Despite the importance of recognizing chronic mucosal changes in the biopsies of patients with IBD, it has been well documented that initial colonic or rectal biopsies from 10% to 34% of pediatric patients ultimately shown to have UC lacked architectural distortion or other histologic features of chronic colitis [18–23]. This is seen particularly in younger patients (<10 years) and may be due to shorter duration of symptoms or longer progression to chronicity in children [24] (Fig. 22.6a, b). Focal active colitis may be a feature of

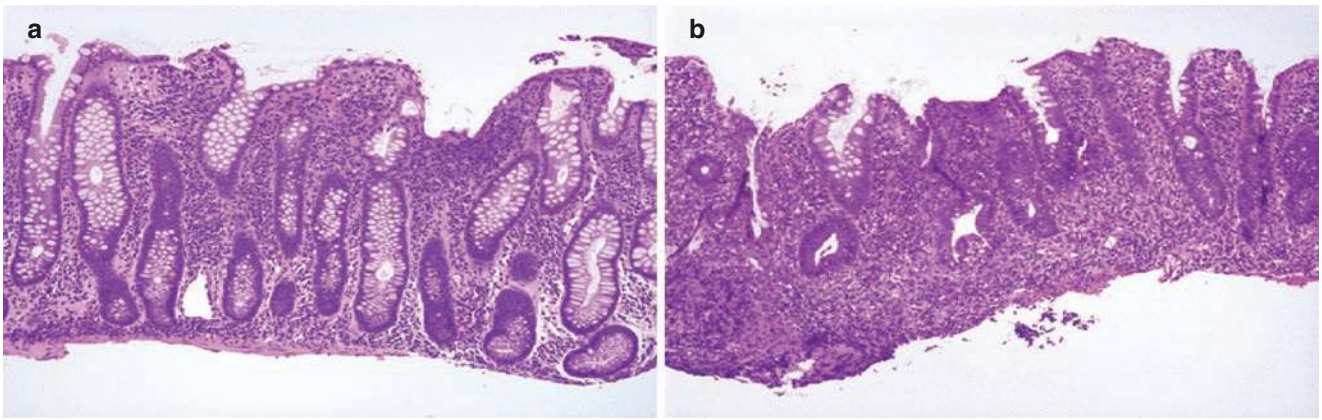

Fig. 22.6 (**a**) Colon biopsies of a 3-year-old girl with several months onset of diarrhea and abdominal pain. There is a lymphoplasmacytic inflammatory infiltrate with mild architectural distortion manifested by a slight irregularity in the outline of the crypts. (**b**) Follow-up biopsies several months later show more advanced disease with crypt atrophy and basal plasmacytosis (H + E, ×100)

self-limited colitis but may also be an early manifestation of IBD [10]. Close follow-up and repeat biopsies may be necessary in these cases. Increased mucosal eosinophils may be seen in the earliest biopsies of children eventually proven to have IBD, prompting a diagnosis of food allergy. In a case series of IBD diagnosed in 16 children less than 2 years of age, six children had an initial diagnosis of allergy [25]. On the other hand, histologic features similar to IBD may be seen in patients with primary immunodeficiencies and autoimmune enteropathy [26]. These conditions should always merit consideration when clinical manifestations of IBD occur in younger children. Histologic features that may point to a correct diagnosis in these patients include lack or paucity of plasma cells in the inflammatory infiltrate (as in Common Variable Immunodeficiency or Severe Combined Immunodeficiency), extensive crypt apoptotic activity, or absence of goblet and Paneth cells (as in autoimmune enteropathy). [27].

Very Early-Onset IBD

An increasing number of rare monogenic diseases have been observed in patients with very early-onset inflammatory bowel disease, which has been defined as onset of IBD before the age of 6 years, and which may account for 3%–15% of all pediatric IBD [28]. Many of these cases demonstrate histologic features not typically seen in older-onset IBD, such as increased apoptosis, unusually severe crypt architectural changes, conspicuously increased eosinophils in the lamina propria, crypt and surface epithelium, and small bowel villous atrophy [29] (Fig. 22.7).

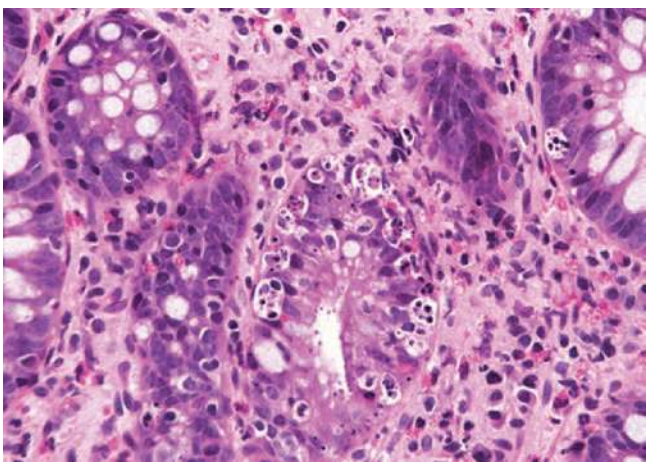

Fig. 22.7 Biopsy from a 3-year-old patient with a mutation in *DOCK8* and early-onset inflammatory bowel disease. Unusual features of this biopsy include extensive crypt apoptosis and numerous eosinophils. Cryptosporidia are noted in the crypt lumen

Characteristic Features of Ulcerative Colitis and Crohn Disease

The macroscopic and microscopic features which distinguish UC and Crohn disease are, in most respects, similar in children and adults, and are outlined in Table 22.2. Biopsy features helpful in differentiating these two entities in mucosal biopsies are outlined in Table 22.3. It should be noted, however that, especially in early stages of disease, biopsies, even in combination with clinical and radiologic features, may not allow distinction between these two entities. The absence of ileal involvement does not rule out CD and appears to be more frequent in younger patient with CD than older children or adults [30]. Similarly, diffuse colitis may be a manifestation of both CD and UC in children.

Table 22.2 Distinguishing features of ulcerative colitis and Crohn disease

	Ulcerative colitis	Crohn disease
Macroscopic		
Rectal involvement	Yes[a]	Variable
Distribution	Diffuse[a]	Segmental or diffuse
Terminal ileum	"Backwash" ileitis	Often thickened and stenosed
Serosa	Usually normal	"Creeping fat"
Bowel wall	Normal thickness	Frequently thickened
Mucosa	Hemorrhagic	Cobblestone and ulcers linear
Pseudopolyps	Frequent	Less common
Strictures	No	Common
Fistulas	No	Common
Involvement of gut proximal to colon	No[b]	Common
Microscopic		
Inflammation	Confined to mucosa and superficial submucosa	Transmural
Lymphoid hyperplasia	Infrequent	Common
Crypt abscesses	Extensive	Focal
Mucus depletion	Frequent	Infrequent
Deeply situated sarcoid-like granulomas	No	Yes
Fissures and sinuses	No	Yes
Villous surface transformation	Common	Infrequent
Submucosal fibrosis	Rare	Common
Neuromatous hyperplasia	Rare	Common

[a]Treatment may create the appearance of rectal sparing and discontinuous involvement
[b]See text

UC is classically defined as diffuse chronic mucosal inflammation limited to the colon, which invariably affects the rectum, and extends proximally in a symmetric uninterrupted pattern to involve part or all of the large intestine. The mucosa characteristically exhibits a diffuse hemorrhagic appearance (Fig. 22.8).

Microscopically, ulcerative colitis is characterized by inflammation limited to the mucosa and superficial submucosa (Fig. 22.9); deeper layers of the bowel are only exceptionally involved, as in toxic megacolon. Infiltration of the mucosa by neutrophils, with cryptitis, epithelial degeneration, goblet cell depletion, and crypt abscesses are characteristic though relatively nonspecific microscopic features of active UC. Chronicity, as previously defined, is characterized by crypt architectural changes such as irregular branching and atrophy, usually accompanied by a mononuclear inflammatory infiltrate. Increased crypt epithelial turnover in UC results in goblet cell depletion and Paneth cell metaplasia [31], less frequently observed in CD. The latter must be interpreted with caution in pediatric cases, as Paneth cells can be present in the distal colon in normal young children. Crypt abscesses are not specific, but when diffuse are suggestive of UC, whereas they tend to be more isolated in Crohn disease [32]. Rupture of crypt abscesses into the lamina propria or erosions may result in collections of histiocytes which may simulate but should be distinguished from true granulomas (Fig. 22.10).

Table 22.3 Distinguishing features of ulcerative colitis and Crohn disease in biopsies

	Ulcerative colitis	Crohn disease
Distribution of inflammation	Diffuse	Frequently focal
Rectal involvement	Yes[a]	Variable
Proximal > distal colonic involvement	No[a]	Frequent
Crypt abscesses	Diffuse	Variable, often focal
Villous surface appearance	Common	Occasional
Pyloric metaplasia	Infrequent	Typical
Mucin depletion	Frequent	Infrequent
Granulomas	Superficial; foreign body	Deep; sarcoid-like

[a]See text

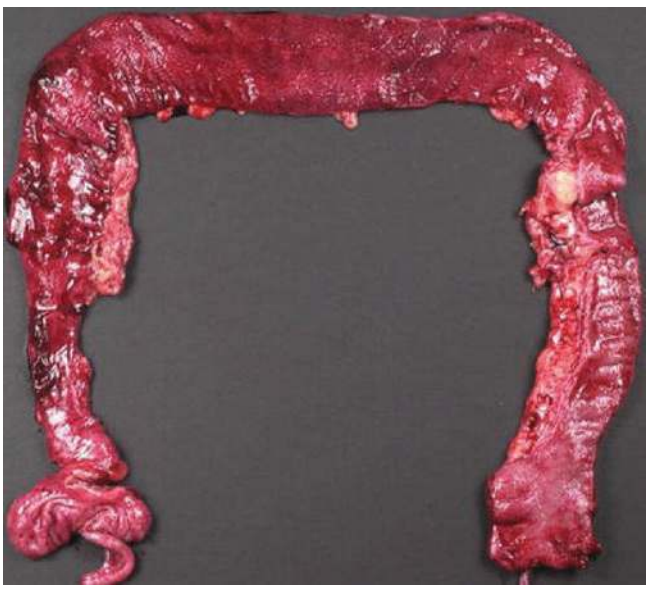

Fig. 22.8 Ulcerative colitis. Specimen from a total colectomy reveals a diffusely hemorrhagic granular mucosa from the rectum (*on the right*) to the ascending colon (*on the left*). The process is macroscopically continuous, without "skip" areas. Uninvolved appendix with a small amount of terminal ileum is also present

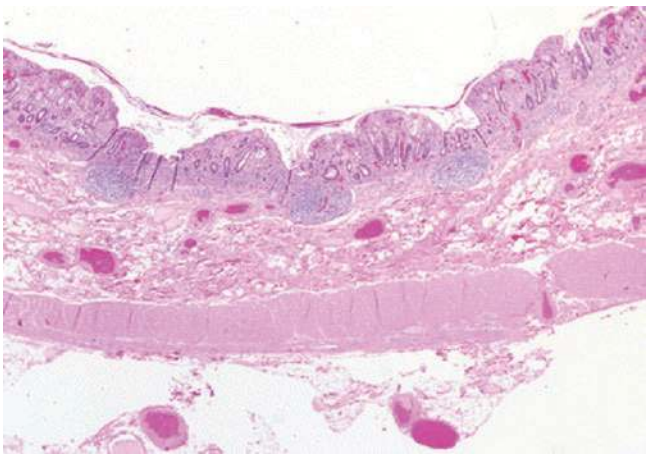

Fig. 22.9 Histologic section from the specimen in Fig. 22.6 is characterized by a diffuse inflammatory process limited to the mucosa and superficial portion of the submucosa. The colonic wall is of normal thickness

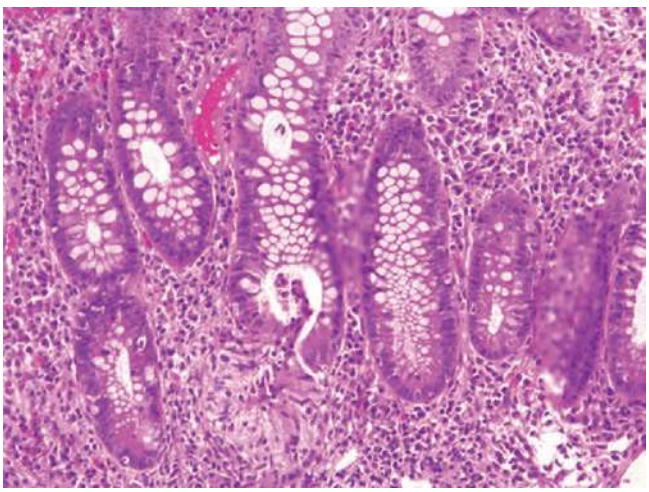

Fig. 22.10 Crypt microabscess with rupture resulting in a histiocytic reaction around the base of a crypt in a colonic biopsy from an 8-year-old girl with ulcerative colitis. H + E, ×200

Pseudopolyps, more commonly found in UC than CD, are discrete areas resulting from surviving islands of mucosa or heaped-up granulation tissue. The latter are more accurately referred to as "inflammatory polyps." Occasionally, regenerating mucosa within such an inflammatory polyp may form irregular, dilated glands, which bear a marked resemblance to retention or "juvenile" polyps [32]. In contrast to adenomas, pseudopolyps have a short stalk and are generally smooth surfaced (Fig. 22.11). Extensive arborization and fusion of the polyps may result in mucosal bridging.

In contrast to UC, *CD* features segmental intestinal involvement, with thickening of the bowel wall consequent to transmural inflammation and fibrosis, resulting in obstructive strictures, especially in the ileocecal area. The serosa is typically congested, with the presence of adhesions and fat wrapping, or "creeping fat." Mucosal involvement can be patchy and discontinuous. Aphthous ulcers overlying lymphoid tissue are among the earliest lesions observed endoscopically but are nonspecific and may be seen in other conditions. Uneven involvement of the mucosa results in a typical "cobblestone" appearance (Fig. 22.12). Transmural involvement in resected specimens and the presence of granulomas are the major histologic features which distinguish CD from UC and other colitides. Transmural disease in CD usually results from submucosal edema, fibrosis, and inflammation, typically in the form of lymphoid aggregates, also involving the muscle layers and the serosa (Fig. 22.13). Intramural abscesses are also noted, with fistulae, perforations, and adhesions, which can involve multiple loops of bowel and form a mass. The identification of pyloric metaplasia indicates chronic damage [33] and is seen more frequently with Crohn disease than with UC. Lymphangiectasia, neural hyperplasia, and vascular changes are frequently observed in CD and are almost never seen in UC.

Fig. 22.11 Inflammatory "pseudopolyps" in a patient with ulcerative colitis. The base of the polyps are broad, and the polyps consist of heaped-up regenerating mucosa with an inflammatory infiltrate

Granulomas are virtually diagnostic of CD when they are well formed, nonnecrotic, basally situated, and remote from areas of active inflammation (Fig. 22.14). Their presence in biopsies may predate radiologic evidence of disease, and prolonged follow-up is necessary when they are observed in the absence of grossly evident disease [34]. The likelihood of finding granulomas is clearly a function of the diligence with which they are sought, increasing with the number of biopsies and sections examined [35]. Granulomas appear to be more frequently observed in the pediatric age group. One large study in Germany found them in 26% of biopsy specimens from 42% of patients, twice as commonly as in adults [36]. Comparison of initial biopsies of children with and without rectosigmoid granulomas showed similar age of onset of disease in the two groups, though those with granulomas tended to have more extensive disease and perianal complications [37]. Shepherd and colleagues observed granulomas more frequently in their younger patients and those with a shorter clinical course, with an increased prevalence in the more distal por-

Fig. 22.12 Crohn disease. Ileocecectomy specimen is characterized by a stricture in the area of the ileocecal valve. The mucosa has a "cobblestone" appearance, and the wall appears thickened with prominent and extensively adherent serosal fat. Contrast with Fig. 22.6

tion of the gastrointestinal tract [38]. In a recent study at The Children's Hospital of Philadelphia, granulomas were identified in 61% of pediatric CD patients undergoing upper and lower endoscopy and were more frequent in untreated patients [39]. In nearly half of those patients, granulomas were present in the upper GI tract, in the terminal ileum, or both, but not in the colon.

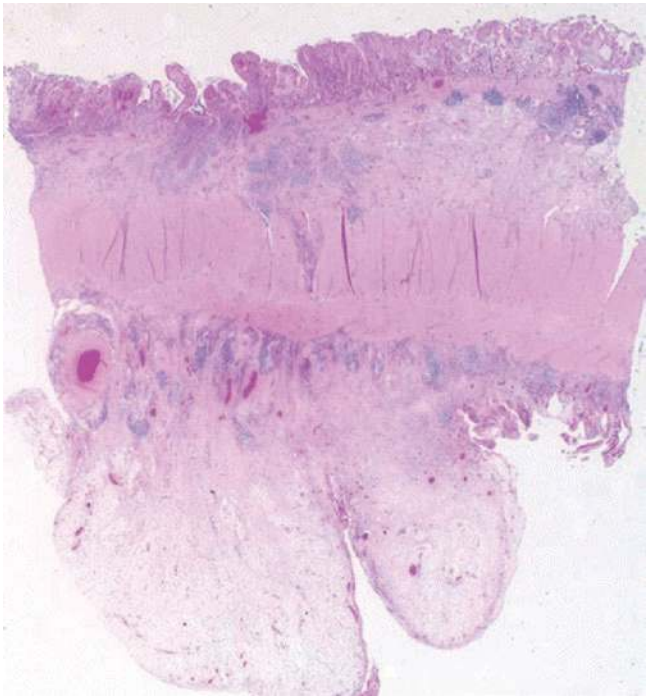

Fig. 22.13 Crohn disease. Low-power microscopic section demonstrates transmural involvement. Inflammation, in the form of lymphoid aggregates, extends through the muscularis propria into thickened serosal fat. Contrast with Fig. 22.9. H + E, ×10

Granulomas can also be seen, however, in a number of other conditions (Table 22.4). The granulomas seen in tuberculous infections of the gastrointestinal tract are typically multiple, large, and have caseous necrosis [40]. Those associated with yersiniosis are also necrotic and frequently present in mesenteric lymph nodes [41]. Chronic granulomatous disease (CGD) can present with a colitis similar to CD [42]. Numerous necrotizing granulomas may be observed; in non-inflamed or quiescent cases, collections of pigmented macrophages may be noted in the mucosa (Fig. 22.15).

Colonic malignancy is a well-recognized long-term complication of UC. Recent evidence suggests that patients with Crohn colitis incur a similar risk of colorectal cancer [43]. Duration of disease and pancolitis are well recognized as risk factors for the development of malignancy, with the risk of cancer increasing over that of the general population by 1% each year after 10 years of disease [44,

Table 22.4 Differential diagnosis of granulomas in colon specimens

Crohn disease
Infections
Salmonella (microgranulomas)
Campylobacter (microgranulomas)

Brucellosa
Tularemia
Schistosomiasis
Fungal infections
Mucin and foreign body granulomas
Chronic granulomatous disease
Pneumatosis intestinalis
Malakoplakia
Sarcoidosis

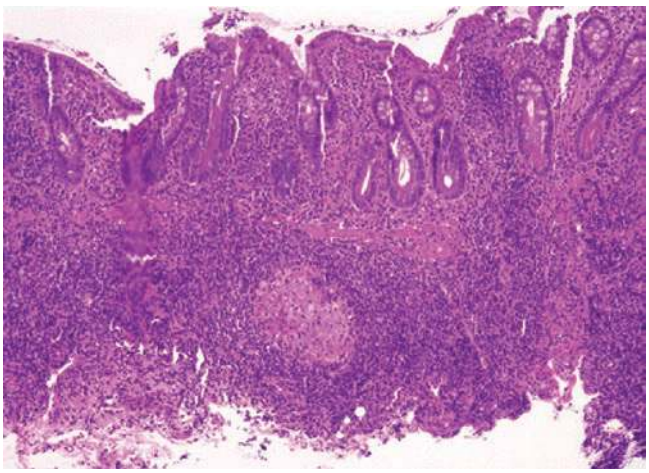

Fig. 22.14 Crohn disease, terminal ileum. A well-formed, nonnecrotic granuloma is present in the superficial submucosa, away from any ruptured crypt. Contrast with Fig. 22.10. H + E, ×100

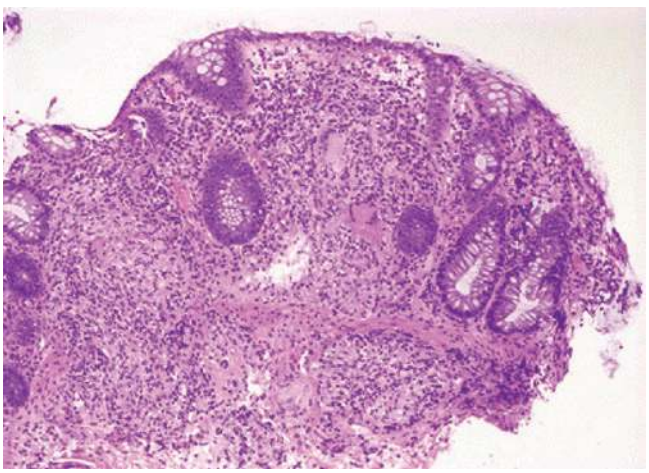

Fig. 22.15 Chronic granulomatous disease. Colon biopsy from a 5-year-old boy reveals numerous granulomas throughout the mucosa and submucosa. H + E ×100

45]. Unfortunately, there is a paucity of prospective data describing long-term inflammatory bowel disease with early-onset ulcerative colitis and ultimate cancer risk in pediatric patients. Other less well-characterized risk factors include concomitant sclerosing cholangitis, an excluded, defunctionalized or bypassed segment and depressed red blood cell folate levels [44]. Children who develop colitis before the age of 10 years should undergo colonoscopy screening during their adolescence, and dysplasia and adenocarcinoma have been documented in adolescents and young adults with long-standing colitis [46]. Dysplasia in colitics is generally plaque-like or nodular, frequently referred to as the DALM (dysplasia-associated lesion or mass) lesion [47] (Fig. 22.16a, b). Epithelial dysplasia generally precedes carcinoma; therefore, yearly surveillance colonoscopy is recommended. Since reliability and patient compliance of serial colonoscopy to detect dysplasia are not perfect, prophylactic colectomy should be considered in any individual who developed ulcerative colitis during childhood.

"Atypical" Features in the Diagnosis of Ulcerative Colitis

Rectal Sparing and Patchiness

Although ulcerative colitis is traditionally considered to be a diffuse process that begins in the rectum and extends proximally in a continuous fashion, a number of studies suggest that initial rectal biopsies in children with UC may not demonstrate mucosal architectural changes as consistently as in adults or may even be "normal" (rectal sparing) (Fig. 22.17). An unequivocal diagnosis of IBD may be more difficult in these cases, as may be distinction between UC and CD.

Five of twelve children with untreated UC in one study were found to have mild patchy inflammation or normal histology in the rectum [21], whereas relative rectal sparing compared to adults was found in one study of 53 children [23]. In one study, "absolute" rectal sparing, in which evidence of both inflammation and chronicity is absent, is infrequent in children with UC (4% of 73 pediatric cases), though

Fig. 22.16 Dysplasia in 16-year-old boy with 10 year history of ulcerative colitis. (**a**) plaque-like lesions present in the colon. (**b**) Histologic section through area of dysplasia in crypt and surface epithelium shows piled-up enterocytes with hyperchromatic nuclei and loss of polarity

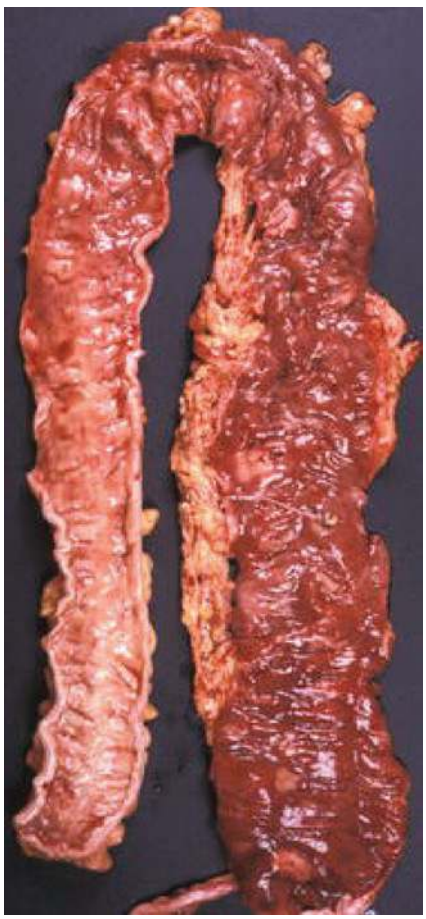

Fig. 22.17 Rectal sparing in ulcerative colitis. A 15-year-old female with several years history of ulcerative colitis which became refractory to medical therapy. The colectomy specimen reveals a diffuse colitis, much milder in the rectum than proximally

Fig. 22.18 "Quiescent" colitis. Rectal biopsy in an 11-year-old boy with history of ulcerative colitis while on therapy. Mild-crypt architectural changes are present without active inflammation. H + E, ×100

"relative" rectal sparing, defined as the presence of inflammation without changes of chronicity, is more frequent, noted in 26% of cases [19]. Faubion et al. identified a 27% prevalence of rectal sparing in children with IBD and sclerosing cholangitis, suggesting the possibility that rectal sparing may be more common in this subset of patients [48]. Moreover, discontinuous involvement and rectal healing have been reported during the course of long-standing disease in adults, which likely results from treatment effect or natural variation in the course of disease and also reflects the current clinical practice of sampling multiple mucosal biopsies over time [49, 50]. *Medical therapy* can have a profound but variable effect on mucosal histology, ranging from decreased intensity of the inflammatory infiltrate to complete normalization of the mucosa, including discontinuity of mucosal disease in UC [51]. Quiescent colitis is characterized by mucosal atrophy and crypt architectural changes in the absence of the acute inflammation, ulceration, and mucus depletion seen in the active phase (Fig. 22.18).

Backwash Ileitis

"Backwash ileitis" refers to an abnormal radiologic or endoscopic appearance of the terminal ileum, usually in patients with an ulcerative pancolitis, which is postulated, as the name implies, to result from reflux of inflamed colonic contents into the terminal ileum. Strict morphologic criteria for this diagnosis, though not defined, rest mainly on a combination of length of involvement of the ileum (usually <10 cm), a normal ileocecal valve without radiologic and/or endoscopic signs of transmural disease or stenosis, and mild mucosal inflammation without granulomas. In a study by Heuschen, 22% of patients with pancolitis had evidence of backwash at colectomy, whereas none of those with left sided colitis had evidence of backwash [52]. However, ileitis in UC may also represent primary ileal disease [53]. Recently, Haskell and colleagues found a 17% (34 of 200 patients) prevalence of inflammation in the terminal ileum of ileocolectomy specimens from patients with ulcerative colitis [54]. These changes were generally mild, consisting of villous atrophy, increased mononuclear cells in the lamina propria, and scattered crypt abscesses. Of these 34 patients, 32 had pancolitis, but in two patients colonic inflammation was subtotal or left sided. Furthermore, in the absence of granulomas, differentiating "backwash ileitis" from CD of the ileum can be problematic. Pyloric gland metaplasia has been suggested as a useful differentiating feature, if present [33]. "Backwash ileitis" is not believed to be a contraindication to the use of the ileum as a pouch nor to predispose to pouchitis after ileoanal anastomosis [55]. In one pediatric study, the presence of backwash ileitis, defined as a mild mixed inflammatory infiltrate of the lamina propria without crypt distortion, atrophy, or epithelial changes, and contiguous to active inflammation in the colon, did not increase the risk of pouch failure [53].

Upper GI Tract Involvement in UC

Disease of the upper intestinal tract in CD is well documented and present in 30% of patients, in whom it may cause functional abnormalities such as delayed gastric emptying [56–59]. Endoscopic biopsies of the upper GI tract in children with IBD have revealed esophagitis, duodenal ulcers, and villus atrophy, with a comparable prevalence in both CD and UC in some prospective studies [60, 61]. Upper GI tract disease with extensive duodenal involvement has been reported to occur concomitant with or many years after a well-established diagnosis of UC [62]. Whether upper GI tract disease reflects aberrant anatomic expression of UC, misdiagnosed CD or a coexisting illness is still debatable. In one study by Kundhal et al., granulomas were present on antral biopsy in 5 of 39 children with a diagnosis of ulcerative or intermediate colitis (14%), thus, changing the diagnosis to CD [63]. On the other hand, conditions such as reflux esophagitis and *Helicobacter pylori*–associated gastritis are common and may be coincidental in patients with UC [64], to which must be added the confounding effects of long-standing use of medications such as corticosteroids.

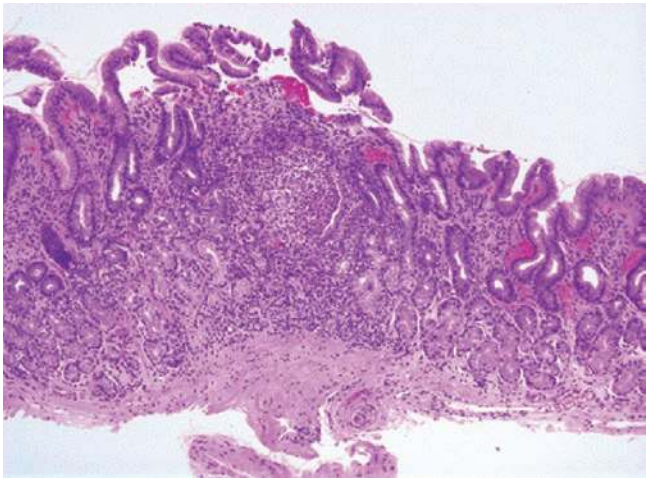

Fig. 22.19 Focal gastritis. Antral biopsy in a 14-year-old boy with IBD reveals a clustering of neutrophils and mononuclear inflammatory cells around several glands, in a background of diffuse mild chronic inflammation. H + E, ×200

Lymphocytic esophagitis, defined histologically as >20 lymphocytes per high power field without neutrophils, has been associated with IBD in pediatric patients, particularly Crohn disease, where it may be prevalent in up to 28% of patients [65]. Focally enhanced gastritis, defined as a perifoveolar or periglandular mononuclear or neutrophilic inifiltrate around gastric crypts, appears to be significantly more common in CD than in UC in patients without *H. pylori* [63, 64] (Fig. 22.19). In a retrospective study of 238 children with UGI biopsies, focal gastritis was present in 65% of patients with CD and in 20.8% of patients with UC, compared to 2.3% of controls without IBD and one of 39 with *H. pylori* [66]. Pascasio reviewed 438 consecutive biopsies in children with gastritis looking for histologic markers for CD such as granulomas, and focal glandulitis [67]. Of 58 patients diagnosed as having CD by colonic biopsy and other standard criteria, 34 (77%) were predicted to have CD by gastric biopsy alone. Eosinophils were a significant component in many of the inflammatory foci. In their experience, none of the focal glandulitis biopsies had a history of UC. Duodenal inflammation, with villous blunting, lamina propria eosinophils and increased intraepithelial lymphocytes may also be noted in a significant proportion of patients and need to be distinguished from other causes such as celiac disease [65].

Periappendiceal Inflammation in Ulcerative Colitis

Ulcerative colitis is classically regarded as a diffuse disease beginning in the rectum and extending proximally in a continuous fashion without skip areas. However, studies have documented *discontinuous mucosal disease*, or "skip" areas, in patients with ulcerative colitis: cecal involvement (cecal patch) separated by normal mucosa from distal colitis in 15–86% of patients undergoing surgery [68–72], and appendiceal involvement [73, 74]. D'Haens et al. found that 75% of patients had periappendiceal involvement at the time of diagnosis of distal UC, in whom inflammation was limited to the left side of the colon [69]. In a more recent study, 29 of 367 patients with UC who did not have a pancolitis and had no prior appendectomy were found to have periappendiceal inflammation, the severity of which paralleled that of the distal colon [75]. Yang et al. reported that involvement at the appendiceal orifice is not a consequence of therapy for extensive UC, but rather a distinctive "skip" lesion in patients with distal UC [76]. It has been suggested that the appendix may be a "priming" site for UC by acting as a reservoir for early-activating T-cells [77]. One pediatric study examined appendices from resected intestinal specimens of patients with IBD who failed medical therapy and found that all the patients in the study (17 UC, 24 CD) had appendiceal involvement [78]. Appendiceal inflammation in these cases of UC is usually described as superficial, whereas inflammation in typical acute appendicitis is transmural.

Fulminant and Indeterminate Colitis

Severe fulminant colitis, also referred to as toxic megacolon, is a medical and surgical emergency, which, although reported to occur in up to 5% of all ulcerative colitis patients, is relatively uncommon in pediatric patients. Toxic megacolon usually occurs in the presence of severe pancolitis and results in profound dilatation of the colon secondary to severe intestinal inflammation with consequent disturbed intestinal motility. Under these conditions, disrupted mucosal integrity may allow entry of bacteria to submucosal tissues which may lead to necrosis, perforation, and peritonitis. The use of antidiarrheal agents, a recent barium enema or colonoscopy, has been implicated [79]. Histopathologic examination of these cases at presentation may not always adequately distinguish between UC and CD. Deep linear ulcers and fissuring with a "cobblestone" mucosa are commonly observed in these cases (Fig. 22.20a, b). Identification of small bowel involvement (other than "backwash ileitis") and deep lymphoid aggregates away from areas of mucosal ulceration and epithelioid granulomas are useful indicators in making a diagnosis of CD [80].

The term "indeterminate colitis" (IC) has been used for years to identify patients with IBD limited to the colon, but with features that do not allow distinction between UC and Crohn disease. As originally used by Price, IC was applied to cases presenting as fulminant colitis with overlapping features of UC and CD [81]. An extended study by Wells et al.

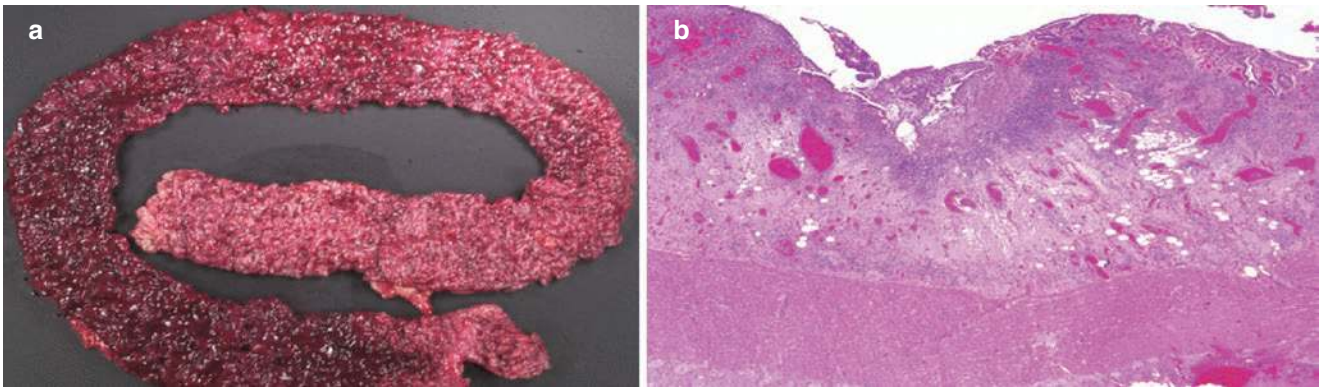

Fig. 22.20 Fulminant colitis. (**a**)Total colectomy specimen from a 17-year-old boy shows a granular diffusely hemorrhagic mucosa, predominantly towards the proximal portion of the colon (*left side* of the photograph). (**b**) Low-power histologic section

of the cohort of patients initially published by Price revealed that after histologic re-examination of 46 cases initially diagnosed as IC, 19 cases were considered to have CD, and 11 cases were classified as probable UC, leaving 16 cases of IC. Four patients were further classified as UC or CD after a follow-up period of 2.5 years [82]. Thus, long-term follow-up studies of mostly adult patients initially classified with IC suggest that an eventual diagnosis of either UC or CD can be obtained in most patients. Silverberg et al., in a report of the Working Party of the 2005 World Congress of Gastroenterology, have suggested that the diagnosis of "indeterminate colitis" is rendered only in patients with suspected IBD after colectomy, and "unclassified IBD" for patients diagnosed after a biopsy that did not suggest UC or CD [83]. Epidemiologic studies cite a prevalence rate of IC of 5–10% in adults [84]. The outcome of ileal pouch procedures in patients with a diagnosis of IC (mainly adults) is also controversial, some studies reporting a higher rate of complications [85–87], others suggesting no difference in outcome between patients with IC and UC [88, 89]. The prevalence rate of IC may be higher in children, though there is a paucity of reliable epidemiologic data regarding that issue. In a Swedish study, 27% of cases of pediatric IBD were initially diagnosed as IC. During a 12-year period, diagnoses were changed in 32 of these 171 cases, 23 to UC [90]. One fifth of cases of IBD in children less than 5 years of age were classified as IC in a study at the Children's Hospital of Philadelphia [91]. After a median follow-up of 7 years, 5 of 19 cases initially assigned to the IC group were reclassified as either CD or UC. Changes in diagnosis were made more frequently in those cases diagnosed before 1990, which could either be due to longer duration of follow-up, or to technical improvements in pediatric colonoscopy. A longitudinal study of 250 pediatric IBD patients reported that 74 (29%) were initially classified as IC, and only 29 were reclassified after a 7-year follow-up [92]. According to recent recommendations from a working group of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition, and the Crohn and Colitis Foundation of America, a diagnosis of IC may be rendered in a pediatric patient with disease limited to the colon in cases where there is absolute rectal sparing, the presence of ileitis with disease limited to the left colon, severe focal gastritis or colitis with growth failure [93].

Pouchitis

In UC patients who undergo ileal pouch anal anastomosis (IPAA), the ileal mucosa commonly undergoes histologic modifications to a colon-like appearance resulting from changes in bacterial population, short-chain fatty acid, and bile salt concentrations [94, 95]. Morphological similarity to an inflamed colon is reinforced by the detection of a mucin histochemical profile similar to that of colonic epithelium and by an inflammatory immunoprofile like that seen in ulcerative colitis [95]. At endoscopic examination, pouchitis may be mild, with mucosal hyperemia and edema, to severe, with ulcers, hemorrhage, and pseudomembrane formation [96–98]. A minority of patients develop inflammation of the ileal limb proximal to the pouch, strictures (typically in the proximal pouch) and fistulas, and even extraintestinal disease which can mimic CD. Histologic examination of mucosal biopsy specimens obtained from these pouches typically demonstrate partial to complete villous blunting with crypt hyperplasia and increased mononuclear inflammatory cells and eosinophils in the lamina propria (Fig. 22.21). Areas of pyloric gland metaplasia may be present. Active inflammation, usually focal, is characterized by neutrophils in the lamina propria, cryptitis, crypt abscesses, and, in severe cases, erosions, or ulcers. Deep or transmural inflammation may be observed [95, 99–101]. Granulomas of the mucin or foreign body type may also be identified [95, 101]. Although these granulomas are not diagnostic of CD, as previously noted,

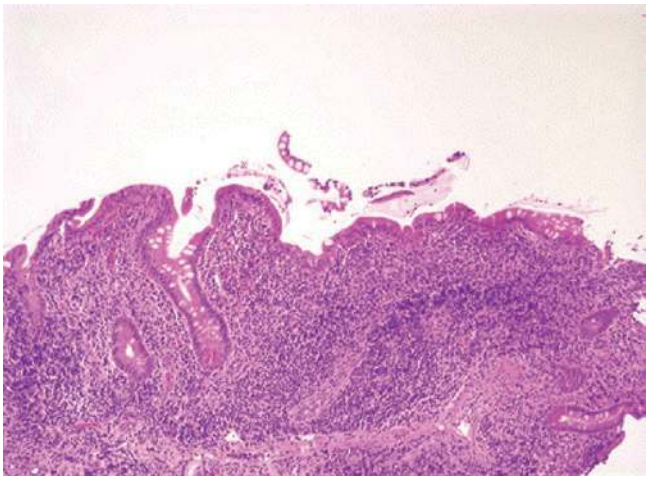

Fig. 22.21 Pouchitis. Biopsy from the neorectum in an 18-year-old female following an ileoanal pull-through reveals active chronic inflammation of the ileal mucosa with crypt loss and distortion

they nonetheless cause concern; however, if such granulomas are found only in the pouch and not upon review of the colectomy specimen, it suggests that these granulomas may have arisen as a result of the abnormal luminal environment of the pouch and not from unrecognized CD. In addition, ischemic changes secondary to vascular compromise and pouch mucosal prolapse may occur, such as crypt hyperplasia, extension of smooth-muscle fibers from the muscularis mucosae into the lamina propria and superficial erosions with a fibrino-inflammatory exudate.

In view of the previous discussion, a diagnosis of CD should be considered only when review of the prior colectomy specimen reveals unequivocal features of CD, such as nonmucin granulomas, or when unequivocal CD develops in parts of the gastrointestinal tract distant from the pouch [99]. No single histologic feature in the colectomy samples of patients with UC or IC seems to be associated with pouch-related complications [102].

Capsule Endoscopy in Pediatric Inflammatory Bowel Disease

23

Stanley A. Cohen and Salvatore Oliva

Introduction

Since capsule endoscopy (CE) was introduced in 2001, this tool has been adopted widely for the evaluation of mucosal small bowel (SB) disease. Its use particularly increased after North American and European marketing clearance for patients 10 years of age and older was obtained in 2003 and expanded to 2 years of age and older in 2009, with patency capsule use approved the same year [1].

Advances in the video capsule's technical aspects (dual or rotational cameras, wider field of vision, longer battery life), the software (dynamic imaging speed, real-time viewing), and better bowel cleansing have all contributed to improved diagnostic accuracy. Currently, 5 CE systems are marketed and available internationally (PillCam, Medtronic, formerly Given, US; Endoscapsule, Olympus, Japan; MiroCam, Intromedic, Korea; CapsoCam, Capso Vision, US; and OMOM, Chongqing, China), though not all are available in every country.

The desire to expand CE beyond the small intestine has led to the development of a colon capsule (Medtronic) and a pan-enteric capsule (dubbed the Crohn's capsule, Medtronic) to evaluate the small and large intestine in the same procedure, both available in Europe.

Indications

The suspicion of small intestinal Crohn disease (CD) and evaluation of existing inflammatory bowel disease (IBD) are the most common pediatric indications for CE in pediatrics accounting for 63% of the total procedures according to a meta-analysis of 723 procedures, with subsequent articles bringing the total to 1013 analyzed procedures [2–23]. Together with the presentation of abdominal pain and diarrhea in another 10%, this accounts for 73% of pediatric evaluations with CE. Additionally, 16% of the total CE examinations are performed in order to monitor those with known CD, while evaluation of indeterminate colitis (IC) represents 2% of total, and ulcerative colitis (UC) 1% of the total procedures.

The clinical indications vary with age [20]. Among 83 children ages 1.5–7.9 years who underwent CE, the most common indication was occult gastrointestinal bleeding (OGIB) amounting to 36% (30/83) of patients in the cohort. Suspected CD indication after negative endoscopic evaluation accounted for 20 patients (24%) with 11 (55%) positive findings, while CD monitoring was performed in an additional 3 patients. Abdominal pain was the primary indication for another 12 patients (14%), while protein loss and malabsorption were the indications for 9 and 12 patients, respectively (11% and 14%). In contrast, OGIB in older children (10–18 years of age) accounts for only 13–24% overall, while CD accounts for 40–86% of the indications [2, 7, 9, 14, 16, 20].Of note, patients with protein losing enteropathy and malabsorption are younger than those with recurrent abdominal pain or suspected CD [20]. Of further interest, the indication for CE in both of these pediatric cohorts differs from the adult population where 66% of CE use has been for OGIB, including iron deficiency anemia (IDA); 10.6% for clinical symptoms, such as pain, diarrhea, and weight loss without OGIB; 10.4% for CD; and the balance (13.0%) for other indications [24].

Small Bowel Capsule Endoscopy in IBD

Pediatric European and North American GI societies' guidelines suggest full evaluation of the gastrointestinal tract at the approximate time of CD diagnosis in pediatric patients in

order to assess the extent and severity of the disease since as many as 70% of patients will have SB involvement with 40% estimated to have active disease exclusively in the SB [25–27]. This cannot be accomplished by routine upper endoscopy or colonoscopy since neither traverses more than about 25 cm of the small intestine at either end. Since CE does not require ionizing radiation, sedation, or general anesthesia required by some other imaging methods, it has the potential to be particularly valuable in pediatric IBD assisting in the initial diagnosis and classification of the disease (Figs. 23.1 and 23.2) and providing a mechanism for the mucosal healing (MH) assessment.

Whether or not CE is utilized, another modality is often needed to assess the small intestine. The options include upper GI with SB follow-through (with or without enteroclysis), CT, MRI, push enteroscopy, or small intestine contrast-enhanced abdominal ultrasound (SICUS) as listed in Table 23.1.

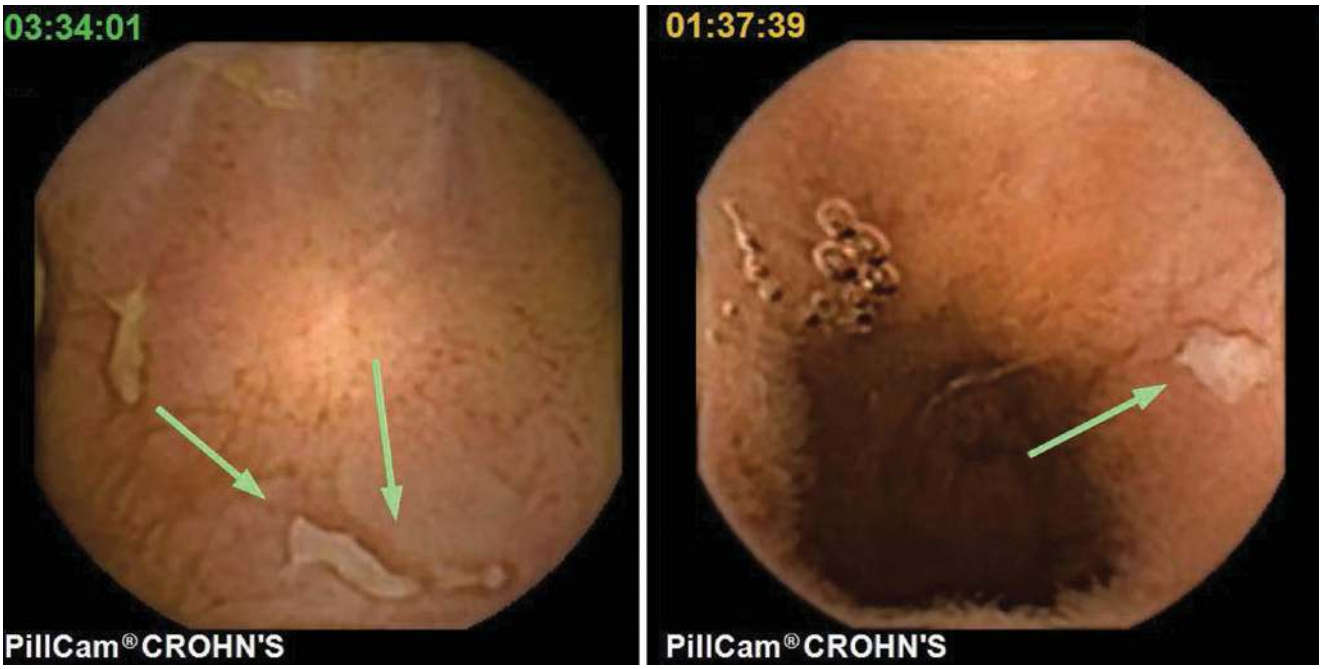

Fig. 23.1 Mild small intestinal Crohn disease, demonstrated by superficial ulcers with minimal surrounding erythema

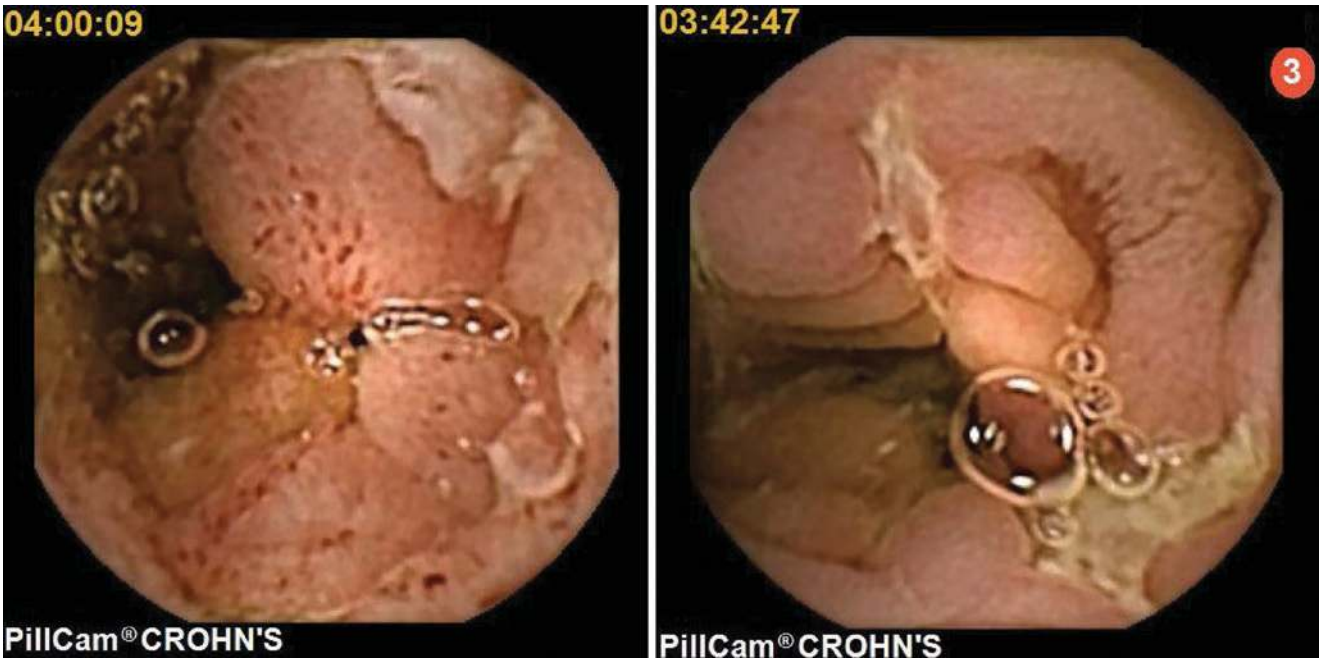

Fig. 23.2 Moderate–severe Crohn disease, with edema and narrowing (stenosis) ulcerations, and superficial hemorrhage

Table 23.1 Comparison of modalities to detect small bowel Crohn disease

Modality	Advantages	Disadvantages	Comparison to CE (Diagnostic yield)
UGI/SBFT/ enteroclysis	Easily obtained, least expensive	Radiation Misses early lesions	CE 63% / SBFT 23% [32]
SICUS	Focuses primarily on ileocecal	Primarily available in Europe, oral contrast	CE 85% / SICUS 81% [33]
CT enterography	Detects strictures and disease external to bowel	Radiation, oral contrast	CE 69% / CT 30% [29, 30]
MR enterography	Differentiates active disease and scarring, detects disease external to bowel	Long procedure, requires no movement	CE 93% / MRE 79% [31–33]
Enteroscopy	Can biopsy tissue	Anesthesia or sedation required, radiation. Long procedure with insertion above and below, can be technically difficult. Not widely available in pediatrics	Studies not reported for detection of IBD
Capsule endoscopy	No radiation or anesthesia, detects early disease, best at jejunal disease	Rare incomplete studies or capsule retention, can have false positives, should not be done if strictures	–
Ileoscopy	Obtain biopsies	Anesthesia or sedation required	CE 61%/Ileoscopy 46% [7]

The initial standard in SB imaging was an upper GI X-ray with fluoroscopic follow-through of barium through the entire small intestine (SBFT). This technique can be modified (enteroclysis) to include an enteric tube placement and double contrast (air or methylcellulose) in order to provide enhanced mucosal imaging. However, a meta-analysis reported that CE was able to detect SB abnormalities more often in those with suspected or known CD (OR 13.0 with a 95% confidence interval of 3.2–16.3) compared to routine SBFT and enteroclysis (OR 5.4 with a 95% CI 3.0–9.9) [28]. Computerized tomography (CT) with intestinal contrast (enterography) administered orally largely replaced fluoroscopy and has been better able to detect the degree or inflammation, the severity of strictures, and the presence of fistula. However, it also requires ionizing radiation and has a lower diagnostic yield than CE in adults and in children [29, 30]. Magnetic resonance imaging can be similarly employed with oral contrast and it is often referred to as magnetic resonance enterography (MRE). The advantages include greater clarity of the imaging findings, the ability to recognize extraintestinal disease manifestations (phlegmon/abscess), and differentiation of active inflammation from fibrosis. The disadvantage is the need for a patient to remain still for 30–45 min in order to allow the image capture, which may be difficult for some pediatric patients, especially at an early age. In large studies, the diagnostic yield is often comparable (CE 93% vs. 79% with MRE) with the sensitivity greater for CE and variable specificity [31, 32]. In a meta-analysis of 13 European studies, the diagnostic yield of CE for detection of active SB CD was similar to that of MRE (10 studies, 400 patients, OR 1.17; 95% CI 0.83–1.67) and SICUS (5 studies, 142 patients, OR 0.88; 95% CI 0.51–1.53). The outcomes were similar for the subgroups, including suspected versus established CD and adult versus pediatric patients. When looking at just the proximal SB, CE was superior to MRE (7 studies, 251 patients, OR 2.79; 95% CI 1.2–6.48), though the difference versus SICUS was not significant [33]. Another adult study demonstrated that CE often changes the disease classification. Using CE, SB lesions were found in 36 of 47 patients, while MRE showed SB involvement in 21 of 47 patients (76.6% vs. 44.7%, $p = 0.001$). Jejunal inflammation was detected by CE in 31.9% of patients and by MRE in 6.4% of patients (15/47 vs. 3/47; $p = 0.03$); lesions in the ileum were detected in 57.4% of patients by CE and in 21.3% of patients by MRE (27/47 vs. 10/47; $p = 0.04$). Finally, in the terminal ileum, CE showed lesions in 68.1% (32/47) of patients, whereas MRE detected lesions in 38.3% (18/47 patients; $p = 0.001$). The original Montreal classification was changed in 53.1% of patients (25/47) based on CE findings and in 12.7% of patients (6/47) based on MRE findings ($p < 0.05$) [34].

By comparison to these primarily adult studies, a group of pediatric investigators in Italy compared multiple modalities and surrogate markers using a consensus reference panel as a gold standard (Table 23.2). The study panel included an investigator representing each modality and the referral pediatric gastroenterologist; and an exam was considered positive only if the whole panel agreed with the evaluation. CE was found to be superior in evaluating proximal SB lesions compared to other imaging tools [30, 35].

An additional prospective pediatric study of 20 patients with CD and 7 with IC showed the sensitivity of MRE and CE of 100% and 83%, respectively, while the specificity of MRE and CE was 57.14% and 78.6%, respectively, using the Pediatric Crohn Disease Activity Index (PCDAI) as a reference. When histology in the ileum or/and duodenum was

used as the reference for active SB involvement, CE had a higher specificity compared to MRE (83.3% vs. 50%). In patients with CD, those with an elevated PCDAI (>10) were more likely to have a positive CE as compared to those with a normal PCDAI (83% vs. 21%; $p = 0.018$) [36].

Inflammatory Bowel Disease Undetermined and Ulcerative Colitis

IBD undetermined (IBDU), is twice as common in pediatrics compared to adult-onset IBDU occurring in approximately 13% of pediatric cases and 6% of adults. One-fifth of pediatric cases younger than 6 years and one-third of cases aged under 3 years receive an initial IBDU diagnosis [37].

In a pediatric study, including 26 cases of IBDU, CE detected typical SB CD findings in 16 (62%), whereas SB imaging only detected 7 of those ($p < 0.05$) [38]. In another study of 18 subjects with a mean age of 13.8 years, two of four (50%) UC/IC patients were reclassified as having SBCD. In the four subjects with known CD, two (50%) had CE evidence of more proximal SB mucosal disease than previously recognized. In the 10 subjects with suspected IBD, 8 (80%) had SB ulcerations leading to a definitive diagnosis of CD. The treating physicians reported that CE helped to diagnose CD in 15 of 18 (83.3%) subjects and impacted medical decision-making in 13 of 18 (72.2%) leading to a change in medical management in 14 of 18 (77.8%) [4].

Pan-Enteric Capsule Endoscopy

A colon capsule was developed in 2006, with a second iteration released in 2009. This second-generation colon capsule (CCE-2) has a slightly larger size (11.6 × 31.5 mm) compared to SB capsule; the two cameras contain wider angles (up to 172°) enabling nearly 360° imaging of the colonic mucosa; and like the newest version of the SB (SB3), it has an adaptive image acquisition rate depending on the speed of capsule propulsion. CCE-2 captures 35 frames per second during active movement of capsule, while four frames per second are captured during the stationary period of capsule movement. The CCE-2 also has a battery saving system, with only 14 images per minute captured until SB images are recognized. High-resolution imaging below 0.1 mm, with a magnification of about 1 to 8, and a color enhancement feature improve the detection rate of colon lesions [39].

While the system was originally designed to more readily detect colon cancer, which has little applicability in pediatrics, it has led to pan-enteric capsule endoscopy (PCE), which can be used to evaluate both the small and large intestine in a single procedure. The disadvantages are that the capsule is larger than the SB3 capsule (though the same size as the colon capsule); bowel cleansing resembles that for a colonoscopy with an additional booster dose needed during the actual procedure; and procedure and reading times are understandably longer.

The first published study of 40 pediatric patients (age 13.1 ± 3.1 years) with known CD underwent protocolized, comparative procedures as part of disease course re-evaluation. The sensitivity of PCE to detect colon inflammation was 89% and the specificity was 100%. The positive predictive value (PPV) and negative predictive value (NPV) of PCE for colon inflammation were 100% and 91%, respectively. In the small bowel PCE showed 90% sensitivity, 94% specificity, with PPV and NPV of 95% and 90%, respectively. Accuracy parameters for SICUS (sensitivity 90%, specificity 83%) and MRE (sensitivity 85%, specificity 89%) were lower than those for PCE. No serious adverse events related to PCE procedure or preparation were reported [30].

Subsequently, the results of PCE and ileocolonoscopy (IC) in 66 adult subjects with known CD were reported. The diagnostic yield for active CD lesions was 83.3% for PCE and 69.7% for IC (yield difference, 13.6%; 95% confidence interval 2.6%–24.7%) and 65% of subjects had active CD lesions identified by both modalities. Of the 12 subjects who were positive for active CD by PCE only, 5 had active CD lesions in the terminal ileum. Of note, 3 subjects were positive for active CD by IC only [40]. Two other larger studies of 99 and 93 adult patients, respectively, subsequently reached similar conclusions also showing the superiority of PCE over MRE and found that raised C-reactive protein and fecal calprotectin were poorly sensitive in detecting active disease (0.48 and 0.59, respectively) [41, 42].

Monitoring the Mucosa

Mucosal healing (MH) defined endoscopically is predictive of decreased disease activity, hospitalizations, and surgery [43]. CE's diagnostic precision and minimally invasive nature makes it a logical tool to provide the information on MH and several studies have borne that out. The first was a cohort of 40 subjects with known or suspected non-penetrating and non-stricturing CD who underwent CE before treatment and after they clinically improved (after at least 1 month). The parameters used were the number of aphthous lesions and large ulcers and the presence of any endoscopic lesions [44]. Since only the number of large ulcers improved significantly with treatment, the authors concluded that the clinical response did not seem to correlate with the MH in patients with CD of the SB.

A small, prospective pediatric study utilized sequential CE to evaluate the mucosal response and PCDAI as one of the parameters to evaluate clinical improvement during a trial of a specific carbohydrate diet in ten patients with active CD (PCDAI ≥15). Nine patients completed the initial 12-week trial, with PCDAI decreasing from 21.1 ± 5.9 to 7.8 ± 7.1 (p = 0.011). CE showed improvement using the Lewis Score (LS), which declined from 2153 ± 732 to 960 ± 433 (p = 0.012). Seven patients continued the SCD up to 52 weeks; the PCDAI (5.4 ± 5.5) remained improved (p = 0.027) compared to baseline with mean LS at 1046 ± 372, which was similar to the 12-week score. Two patients showed sustained MH. Subsequent studies have confirmed the feasibility and safety of using CE as a minimally invasive method to evaluate mucosal response to treatment [45–48].

Even more exciting is the prospect of taking monitoring to the next level where the capsule is used to modify therapy for CD. This was first shown as a possibility in adult study by Efthymiou et al. [44] and in pediatrics by Gralnek et al. [4]. The effectiveness of this strategy has been demonstrated in a cohort of 48 pediatric patients with CD, first over 24 and then 52 weeks. PCE detected inflammation in 34 patients (71%) at baseline, 22 patients (46%) at week 24, and 18 patients (39%) at week 52 (p for comparison among time points <0.05). Findings from PCE led to a change in therapy for 34 patients (71%) at baseline and 11 patients (23%) at 24 weeks, whereas only two patients with negative results on PCE (4%) changed therapies based on findings from imaging. When the treat-to-target strategy was applied, proportions of patients with MH and deep remission (DR, clinical, and mucosal normality) increased from 21% at baseline to 54% at week 24 and 58% at week 52 (p for comparison among baseline and 52 weeks <0.05), while two patients (4%) did not respond to treatment. The DR and MH rates increased over time (21% to 58%) using treat-to-target strategy [49, 50]. Of note, comparisons were made to other modalities at each of the time points. The overall diagnostic yield of PCE, MRE, and biomarkers were 54%, 37%, and 33%, respectively ($p < 0.05$). PCE showed DR in 28 (58%) patients with the detection of new lesions in four and a complete MH in six (with previous partial MH at 24 weeks). MRE and SICUS had good concordance in evaluating DR (24/28, 86%), but did not identify mucosal improvements after therapy ($p < 0.05$). Fecal calprotectin and C-reactive protein were not able to accurately evaluate DR in either groups at 24 and 52 weeks (BR in 65% and 69%, respectively).

A 104-week PCE evaluation of the 42 subjects left in the cohort (two developed an ileocecal valve stricture at 52 weeks; four were lost to follow-up) was performed. There was only 7% drop-off in MH compared with one-year assessment. In intention-to-treat (ITT) analysis complete MH at 52 weeks was associated with decreased clinical relapse rate ($p < 0.003$), reduced steroid use ($p < 0.0005$), fewer treatment escalation ($p < 0.0003$), and diminished hospitalization rates ($p < 0.0001$). There was a trend toward decreased need for surgery, but this did not reach statistical significance ($p = 0.065$) (Fig. 23.3).

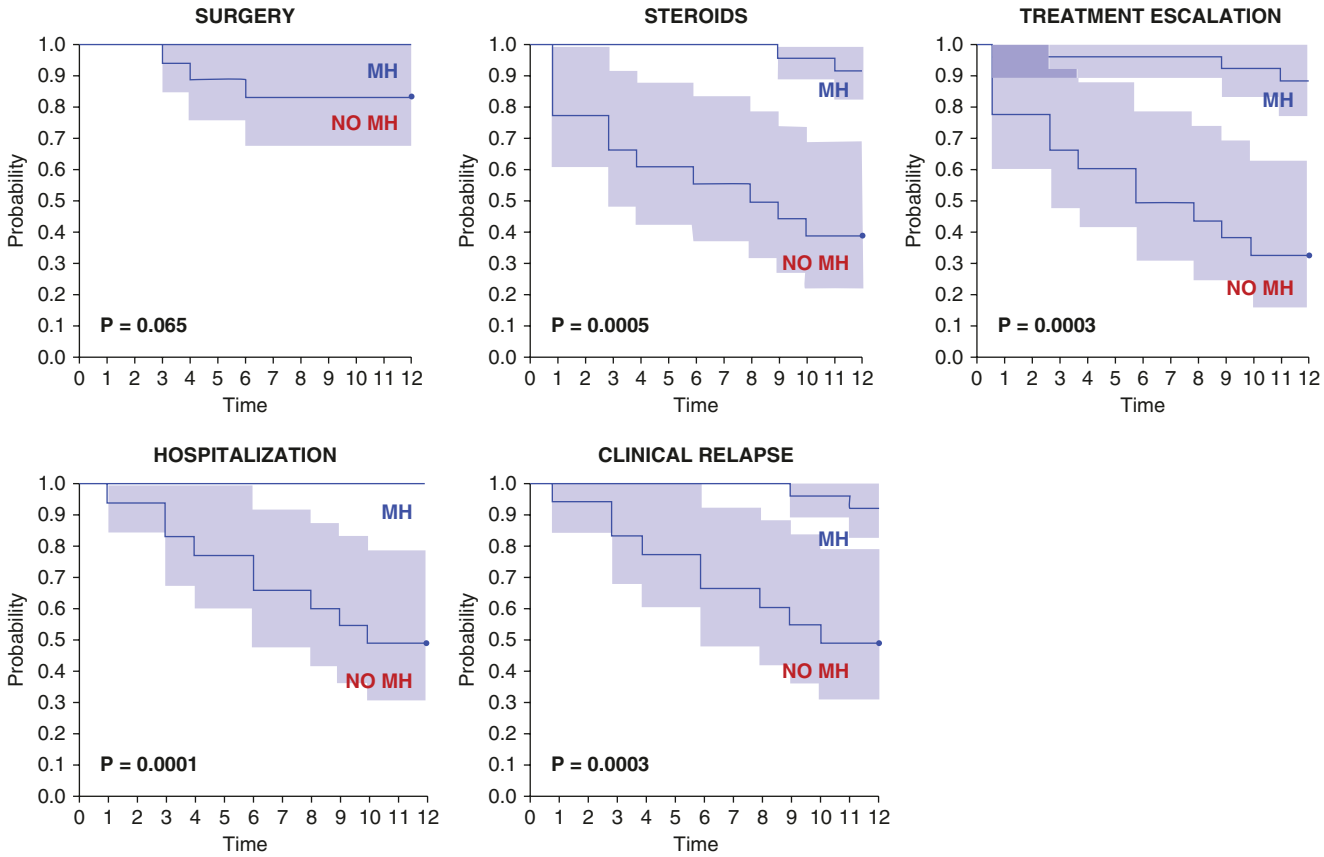

Fig. 23.3 Two-year outcomes when employing pan-enteric endoscopy in a treat-to-target strategy [50]

Capsule Topics of Interest

While much has evolved over the nearly two decades since CE has been in clinical use several issues remain, especially in pediatrics [51]. Therefore, the following topics need to be considered:

- Contraindications
- Capsule swallowing versus endoscopic placement
- Bowel preparation
- Interpretation consistency and scoring methods
- Capsule retention

Contraindications to Capsule Endoscopy

Many of the initial concerns and contraindications have been reevaluated and addressed over the years; however, certain precautions still need to be considered. Known stenosis of the gastrointestinal tract is the most obvious contraindication for CE, but even that is obviated if surgery is scheduled or recognized as the potential treatment. In at least one case [52], CE was performed specifically to help the surgeon identify the stricture intraoperatively. In patients with CD those who have had intestinal resection or have undergone radiation to the abdomen clinical signs of obstruction are a contraindication unless the passage of self-dissolving patency capsule within timed guidelines (discussed below) and radiographic evidence of patency is proven, or surgery is considered pre-procedure.

Although CE is approved for use in children over 2 years of age, there have been reports of younger children who have safely undergone the procedure with endoscopic capsule placement. Initially, swallowing and motility disorders were considered contraindications. However, endoscopic placement of the capsule can be considered in patients with swallowing disorders. For those with esophageal or gastric motility disorders endoscopic capsule placement and/or application of prokinetic agent could be considered.

CE should be restricted to urgent cases in pregnant females where diagnosis cannot be postponed after delivery, since safety data are not available. The capsule manufacturers state that the study is contraindicated in patients with implanted cardiac devices such as a pacemaker, cardioverter,

or left heart assist device, though theoretical and clinical evidence suggest that CE can be performed safely. Although video capsules are not proven safe with magnetic resonance imaging (MRI), incidents of patients undergoing MRI with a capsule in the abdomen have been reported, showing susceptibility artifacts, but no clinical harm [53].

Swallowing the Capsule/Endoscopic Placement for Those Who Cannot Swallow

Patients of any age may be unable to swallow the capsule similarly to the inability or unwillingness to ingest pills. These patients can use stimulus fading to learn and practice swallowing, first small and then progressively larger gelatin capsules or candies with water, other liquids, or even a small amount of yogurt, pudding, or applesauce [54]. For those unable or unwilling to swallow a capsule and those with motility disorders, a capsule can be placed endoscopically into the stomach, or preferably the duodenum, under direct vision. This should be performed under general anesthesia, since there are instances where capsules have been placed in the trachea when deep sedation was used. The front-loading capsule delivery device (AdvanCE TM, US Endoscopy) can be used for older SB2 capsules. However, the newer SB and PCE capsules have cameras at each end, so launching them with the extruder that pushes them out may impair the lens cover and eventually interfere with image interpretation. The alternative, a Roth Net (US Endoscopy) use has been shown to be associated with mucosal trauma in 50% of placements, and it may be difficult to launch in the duodenum [20].

A recent pediatric study compared the success rates and the differences between 51 swallowed and 53 endoscopically placed CEs. The median age was 12.8 years (range 1.6–18.5) among the 88 subjects. Children requiring endoscopic placement were significantly younger (9.8 vs. 14.2 years; $p < 0.001$), lighter (34.5 vs. 54.9 kg; $p < 0.0001$), and had longer small intestinal transit time (308 vs. 229 min; $p < 0.0001$). Positive findings were more likely in those who swallowed the capsule (50% vs. 30%, $p = 0.017$). Poor views were found in 30% (16/53) of patients in the endoscopic placement group due to iatrogenic bleeding from biopsies taken during concurrent procedures, but that was not thought to affect outcome or subsequent patient management [55].

Bowel Preparation

Due to the inability to flush or suction fluids or gas, adequate bowel cleaning is essential for successful CE. Debris, biliary secretion, bubbles and blood, especially in the distal SB, and failure of the capsule to reach the cecum have the potential to limit the diagnostic yield [56] So far, the optimal preparation regimen has not been established. A clear liquid diet the evening before CE and an overnight fast appear to be associated with poor visibility of the terminal ileum in most patients [57]. Since simethicone seems to improve mucosal visualization by reducing air bubbles and gas, a combination of simethicone and polyethylene glycol (PEG) has frequently been promulgated as an effective means to increase the visibility of the small intestine [58, 59]. The only pediatric study to date prospectively evaluated 198 patients with five different preparation regimens [60]. The least amount of PEG solution tested, 1.75 g/25 mL per kg (up to 1 L) of PEG solution (70 g/1000 mL) the night before the procedure plus 20 mL (376 mg) of oral simethicone 30 min before capsule ingestion, appears to be the preparation of choice for SB CE in children. Discomfort was lessened and mucosal visualization improved significantly in the distal ileum, which is the portion most often affected by debris.

A specific score to evaluate cleansing for CE has recently been developed and validated by 20 readers who independently read 1233 images in duplicate, 4 weeks apart. Each individual image was scored on two domains: visualized mucosa (VM) defined as the percentage of mucosa visible in the image and degree of obstruction (DO) defined as the percentage of the image obscured by debris, bubbles, and bile. Each domain was assigned a score between 0 and 3, and the overall score was the mean of the two domain scores. Almost perfect inter-rater and intra-rater reliability was observed for what is to be known as the KODA score and used for clinical trials [61].

A similar effort has been occurring for colon capsule cleansing. In this grading scale (CC-CLEAR), the colon is divided into three segments: right, transverse, and left colon. Each segment is classified according to an estimation of the percentage of mucosa clearly visualized (0: less than 50%; 1: from 50 to 75%; 2: more than 75%, and 3: more than 90%). The overall cleansing classification is a sum of each segment scores with grading defined as inappropriate (0 to 5 points); good (5 to 7 points) and excellent (8–9 points). If any segment presents a classification of 1 or less, the overall classification given was considered inappropriate independently of the overall score. This scale was considered superior to a previously developed score, the Leighton scale, on 58 consecutive colon capsules, with excellent inter- and intra-observer agreement [62].

The regimen devised for pediatric pan-enteric cleansing is based on what was used for the treat-to-target studies achieving an adequate cleaning level in >80% of cases [49]. This regimen is based on PEG and sodium phosphate (NaP) as boosters to speed up the capsule during the exam (Table 23.3). This scheme was able to obtain completion and excretion rates higher than 95% and 84%, respectively.

Table 23.3 Bowel cleansing technique for pan-enteric capsule endoscopy [30]

Day	Hours	Action
−1	All day	Liquid diet
	6–9 pm	50 mL/kg up to 2 L of **PEG**
0	6–7 am	50 mL/kg up to 2 L of **PEG**
0	8:00 am	**Ingestion of CCE**
0		**Domperidone** 20 mg (or metoclopramide when unavailable) If capsule remained in stomach >1 h
0	Upon SB detection	30 mL **NaP** + 1 L water
0	3 h later	30 mL **NaP** + 1/2 L water
0	3:30 h later (if necessary)	10 mg **bisacodyl** suppository

Table 23.4 Capsule endoscopy–Crohn Disease Score

Capsule endoscopy-Crohn diease (CE-CD) Score and Simple endoscopic score for Crohn disease (SES-CD)				
Variable	0	1	2	3
Size of ulcers	None	Aphthous ulcers (0.1–0.5 cm)	Large ulcers (0.5–2 cm)	Very large ulcers (>2 cm)
Ulcerated surface	None	<10%	10-30%	>30%
Affected surface	Unaffected segment	<50%	50-75%	>75%
Presence of narrowing (stenosis)	None	Single, can be passed	Multiple, can be passed	Cannot be passed

Interpretation and Scoring Methods

The diagnosis of CD in the SB is difficult to establish consistently by any single test. Certain features may be present: granuloma on histology, bowel wall thickening on imaging, or severe ulcerations throughout SB on CE, but even these can be non-specific if infectious or other inflammatory conditions are present. As a result, several endoscopic scoring systems have been implemented to standardize the assessment of endoscopic findings. Two main CE scores have been developed for CD: the Lewis score (LS) and CE Crohn Disease Activity Index (CECDAI) [63, 64]. Both indices have been used in small pediatric series, but remarkable discrepancies between the two were reported, with CECDAI better reflecting intestinal inflammation than LS [65]. LS is currently the most widespread and known CE score with well-defined cutoff values for disease activity. The LS total value is largely driven by stenosis and also includes villous edema, which is not considered a major feature of CD, and it leads to the risk of errors in the assessment of MH. Many endoscopists are not familiar with the current available CE scores since they mostly use scoring for standard colonoscopy, which uses different items in assessing inflammation [66]. This difference makes objective evaluation of CE lesions using available scores more complicated.

To rectify the situation and to create a seamless CE score for both the small and large intestine that aligns with colonoscopy scoring the Capsule Endoscopy–Crohn Disease (CE-CD) index was devised adapting the Score and Simple endoscopic score for Crohn disease (SES-CD), which is validated for ileocolonoscopic findings [67]. Similar to SES-CD, CE-CD considers ulcers as elemental lesions of CD and takes into account the number of ulcers, size of the largest ulcer, percentage of affected surface, and the presence of stenosis in both the small and large intestine (Table 23.4) [68]. To date, the CE-CD has proven to be simple, reliable, and reproducible in the evaluation of SB inflammation in 312 pediatric patients with CD. This score seems also predictive of disease outcomes over time. There appeared to be a good correlation between PCDAI and CE-CD (r: 0.624), LS (r: 0.633) and CECDAI (r: 0.651). PCDAI appears to be a moderately accurate classifier of SB inflammation (CE-CD ≥ 9; AUC: 0.779) with a high specificity (90.1% for PCDAI ≥ 15) and low sensitivity (60.5%). In accordance with this, we observed that 35 out 132 (26.5%) patients in clinical remission (PCDAI < 10) had a surprisingly severe endoscopic patterns (CE-CD > 13), suggesting that CE-CD might be a useful pre-clinical predictor of CD exacerbations rather than overestimating disease severity [66]. However, all interpretation is subject to the experience and skill of the reader. As a result, the American Society of Gastrointestinal Endoscopy (ASGE) recommends that the use of CE be limited to practitioners already competent and privileged to perform standard upper and lower endoscopy and who have extensive experience viewing gastrointestinal mucosa. ASGE guidelines 2006 recommended additional specific training in CE, as well as review of the initial 10 procedures to verify competence [69], while the newer European Society of Gastrointestinal Endoscopy (ESGE) recommends at least 30 CE readings [70].

Capsule Retention and Incomplete Procedures

A meta-analysis of 1013 pediatric procedures documented capsule retention in SB in 18, and gastric retention in four procedures, producing a pooled retention rate of 2.3% ($n = 22/1013$; 95% CI: 1.5%–3.4%) [2]. Endoscopy was used to remove five capsules, including four from the stomach and one from an ileal pouch; 13 were retrieved surgically while taking appropriate measures to mitigate the cause of the retention. A retained capsule was successfully evacuated by bowel prep at 22 days post-ingestion.

The greatest risk factors for capsule retention include known IBD (5.2% risk), previous SBFT demonstrating SBCD (35.7% risk), and a body mass index below the fifth percentile combined with known IBD (43% risk), although retention has occurred despite the absence of stricture on

SBFT [12]. Among four patients with CD having capsule passage lasting longer than 5 days (with three continuing on to retention), age was significant (18.8 ± 0.9 vs. 14.6 ± 3.5), but not height or weight, compared to patients who did not have retention [14]. Retention rates for OGIB, CD, and neoplastic lesion indications were 1.2% (95%CI: 0.9%–1.6%), 2.6% (95%CI: 1.6%–3.9%), and 2.1% (95%CI: 0.7%–4.3%), respectively, with a pooled rate of 1.4% (95%CI: 1.2%–1.6%) [69]. On a per-procedure basis, this pattern is similar in adults, where retention in OGIB, CD, and polyps occurs at rate of 1.4%, 2.2%, and 1.2%, respectively [24]. Thus, it appears that the risk of retention is dependent on the clinical indication, with a higher incidence in patients with a suspected chronic SB obstruction [71]. Rare cases of perforation, aspiration, or SB obstruction have been reported in adults, but none have been reported in children.

In a recent meta-analysis of 35 papers and 4219 adult and pediatric patients with CD, retention rates were 3.32% (95% confidence interval [CI], 2.62%–4.2%) with 4.63% (95% CI, 3.42%–6.25%) and 2.35% (95% CI, 1.31%–4.19%) in established CD and suspected CD, respectively. Retention rates were 3.49% (95% CI, 2.73%–4.46%) and 1.64% (95% CI, 0.68%–3.89%) in adult and pediatric CD, respectively. Retention risk in adults with established CD was 3.4 times higher than suspected CD, but there was no difference in retention risk in pediatric established CD compared with suspected CD. Retention rates in established CD were decreased after patency capsule (2.88%; 95% CI, 1.74%–4.74%) and MR/CT enterography (2.32%; 95% CI, 0.87%–6.03%) [72].

Patency Capsule

The majority of SB capsule retentions have occurred in patients with normal SB radiological studies, yet functional patency may be present in patients with radiologically documented strictures. To avoid this concern, a patency capsule (PC) identically sized to SB capsule was developed containing a mixture of barium, lactose, and a radiofrequency identity tag. The first version had a single timer plug that degraded at 40 h. The currently available version has dual timer plugs that gradually disintegrates if passage does not occur within 30 h.

Both a retrospective [2] and a prospective study [73] have been performed in pediatric IBD using the first iteration of the PC prior to SB CE. Of the 19 patients who were evaluable in the retrospective analysis, patency was established, and subsequent CE was performed successfully in all but 1 patient who had a retained capsule the following week. The prospective trial of 18 patients (age 10–16 years) who ingested the PC showed that 15 excreted an intact PC (mean 34.5 h) without any PC or CE retention or adverse events [71]. CD was eventually diagnosed in all patients having PC transit of more than 40 h and in nine out of 12 who passed the patency capsule in 40 h or less. There were no capsule retentions or adverse events. Thus, the PC can serve as a useful guide and may lessen the likelihood of CE retention, particularly in known CD where the risk of retention is greatest.

Conclusion

Capsule endoscopy provides a useful tool in the diagnosis and management of pediatric IBD. Although CE is often seen as an adjunctive procedure rather than the test of choice, with the advent of the Crohn capsule, there is a potential for more widespread use, especially when employing a treat-to-target strategy. Perhaps the best indicator of this is a recently released study designed to identify a cost-effective treatment strategy in CD, considering the patient outcomes and cost impact of PCE in the English National Health Service (NHS), utilizing a protocolized CD care pathway, informed by guidelines and expert consensus on 4000 simulated CD patients. Costs were taken from the NHS and Payer Provided Services (PSS) 2016–17 tariffs for England. The results showed PCE costs less and delivers a higher quality of life compared to colonoscopy ± MRE when looking over 20 years, as well as a lifetime time horizon [74].

Bone Health in Pediatric Inflammatory Bowel Disease

24

Dale Lee and Edisio Semeao

Introduction

Throughout childhood and adolescence, bone mineral accrual results in ethnic-, gender-, maturation-, and site-specific increases in bone dimensions and density. During the critical two-year interval surrounding the time of peak height velocity, approximately 25% of skeletal mass is laid down, with 90% of peak bone mass is established by 18 years of age [1]. This rapid accumulation of bone mass correlates with the rate of growth and requires the coordinated actions of growth hormone, insulin-like growth factor-I (IGF-I), and sex steroids in the setting of adequate biomechanical loading and nutrition. Individuals with higher peak bone mass in early adulthood have a protective advantage against fracture when the inexorable decline in bone mass associated with older age or menopause occurs. Accordingly, the National Institutes of Health (NIH) Consensus Statement on Osteoporosis Prevention, Diagnosis and Therapy concluded "bone mass attained early in life is perhaps the most important determinant of life-long skeletal health" [2]. Furthermore, the Consensus Statement specifically called for research to determine the impact of chronic diseases and glucocorticoid therapy on bone accrual in children and to determine the effects of bisphosphonates on the growing skeleton.

Children and adolescents with inflammatory bowel disease (IBD) have multiple risk factors for impaired bone development, including poor growth, delayed maturation, malnutrition, decreased weight-bearing activity, chronic inflammation, genetic susceptibility, and glucocorticoid exposure. The impact of these threats to bone health may be immediate, resulting in fragility fractures during childhood and adolescence [3–5], or delayed, due to suboptimal peak bone mass accrual [6]. Numerous studies have demonstrated the effects of IBD on bone accrual during childhood and adolescence. Although the short- and long-term implications for fracture risk in pediatric IBD have not been characterized prospectively, a retrospective database study found that prepubertal children with IBD had an increased risk of fracture compared with controls [7].

This chapter summarizes the normal changes in bone density and structure during growth, as well as the risk factors for poor bone accrual in childhood IBD. The classification of bone health in children and adolescents is discussed, as are the advantages and disadvantages of available technologies for the assessment of bone in children and adolescents. The difficulties in assessing and interpreting bone measures in pediatric IBD are underscored in a review of selected studies, and an example is provided for a stepwise approach to identify discrete determinants of bone deficits in pediatric IBD [8]. Finally, potential therapies are described and discussed.

Skeletal Modeling and Bone Accrual During Childhood

Skeletal development is a complex process that is sensitive to the hormonal, mechanical, cytokine, and nutritional milieu of the bone. The bones are continuously modified and renovated by the two processes of modeling and remodeling: both result in the replacement of old bone with new bone. Remodeling is the major process in adults and does not result in a change of the bone shape. Remodeling takes place in the basic bone multicellular units on the trabecular surface and within the cortical bone. Normally, bone resorption by osteoclasts is followed by bone formation by osteoblasts; teams of osteoclasts and osteoblasts are juxtaposed in the bone multicellular units and bone resorption and formation are tightly

coupled. For example, treatment of postmenopausal women with bisphosphonates (an antiresorptive agent) resulted in significant reductions in bone resorption within 6 weeks, followed by a reduction in bone formation in 3 months [9, 10]. Skeletal remodeling is vital to microdamage repair. However, after mid-adulthood, the amount of resorption exceeds formation, resulting in a negative bone balance.

In contrast, modeling during growth and development results in new bone formed at a location different from the site of bone resorption; formation and resorption are not coupled within a bone multicellular unit. For example, a small study of bisphosphonate therapy in children reported significant reductions in bone resorption markers with no changes in formation markers [11]. Modeling results in an increase in bone diameter and modification of bone shape. Figure 24.1 summarizes the complex interplay of site-specific bone resorption and formation activities that are necessary to achieve bone growth from length A to B [12]. Growth in the diameter of the cortical shaft is the result of bone formation at the outer (periosteal) surface and bone resorption at the inner (endosteal) surface. Simultaneously, the growth plate moves upward and the wider metaphysis is reshaped into a diaphysis by continuous resorption by osteoclasts beneath the periosteum.

Changes in Cortical and Trabecular Bone with Growth

Cortical and trabecular bone do not respond in the same way to diseases, medications, or mechanical loading and should be considered two functional entities. Cortical bone forms the outer shell of most bones, while trabecular bone is more porous and filled with marrow and blood vessels. Trabecular volumetric bone mineral density (BMD), as measured by three-dimensional quantitative computed tomography (QCT), does not increase before puberty [13, 14]. During puberty trabecular BMD increases significantly in healthy children due to increases in trabecular thickness. The increase in BMD is comparable in girls and boys [15], but the increase is significantly greater in black adolescents than in white adolescents [16].

Sex differences in cortical dimensions are established during puberty (Fig. 24.2): [17] cortical width increases by periosteal bone formation in boys and by less periosteal bone formation but more endocortical apposition in girls. Androgens stimulate periosteal apposition, while estrogens inhibit periosteal apposition and stimulate endosteal apposition. These sex differences have important implications for

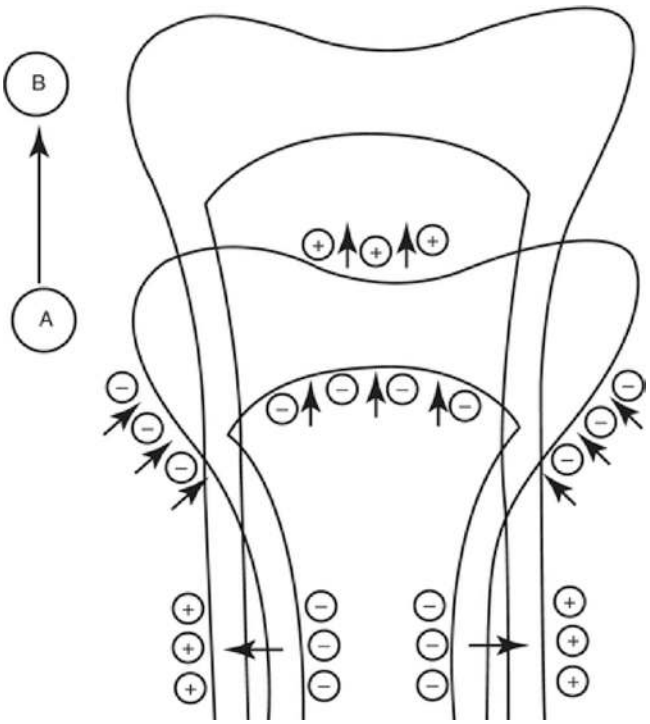

Fig. 24.1 Bone formation (+) and resorption (−) during growth (From: Baron [12])

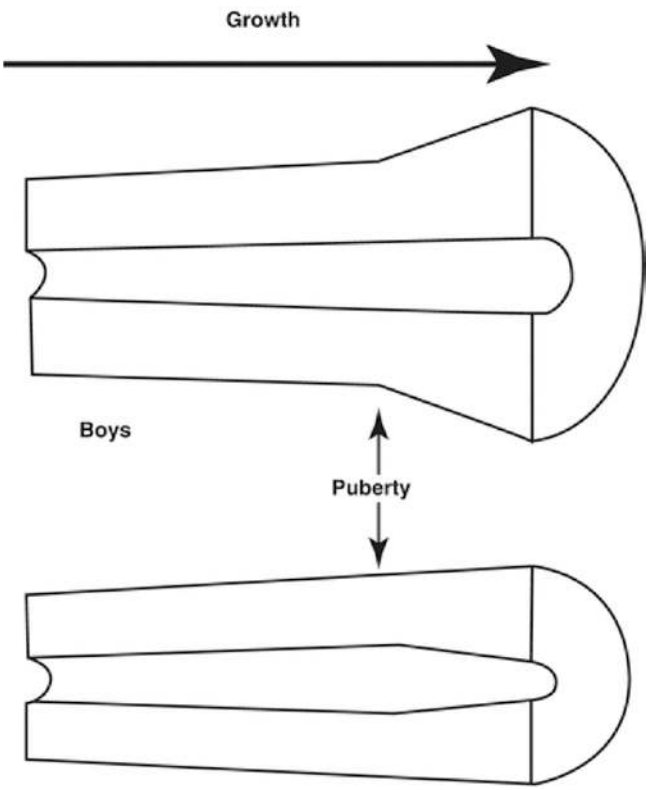

Fig. 24.2 Sex-specific increases in cortical bone dimensions during growth and maturation (Adapted from: Seeman [17])

bone strength; the greater periosteal radius (R_p) in males results in greater bone strength. The long bones are tubular structures that are loaded mainly in bending. The resistance of long bones to bending (i.e., bone strength) is represented by the cross-sectional moment of inertia (CSMI) = $\pi/4$ ($R_p^4 - R_e^4$); R_p and R_e indicate the periosteal and endosteal radius, respectively [18]. These power relationships indicate that small increases in R_p result in marked increases in bone bending strength.

Because the patterns of modeling on the periosteal and endocortical envelopes during growth produce changes in cortical geometry that impact life-long fracture risk [19, 20], the long-term effects of chronic childhood diseases, such as IBD, likely depend on the stage of skeletal maturation at disease onset and the disease effects on the periosteal and endosteal surfaces. Children further from peak bone mass at Crohn disease onset may have irreversible deficits not seen in adult-onset Crohn disease.

Biochemical Markers of Bone Metabolism

Biochemical markers of bone metabolism are released into the circulation during the process of bone formation and resorption, providing information about the dynamic process of bone metabolism. Biomarkers of formation, such as bone-specific alkaline phosphatase (BSAP) and osteocalcin, are by-products of osteoblast activity. Biomarkers of bone resorption are related to collagen degradation products, including pyridinium cross-links and C-telopeptide of collagen cross-links (β-CTX) [21]. In adults, biochemical markers of bone turnover correlate well with formation and resorption, as measured by bone biopsy, and are independent predictors of fracture risk [22]. Further, bone biomarkers can be used to monitor the effectiveness of bone therapies [9]. Because formation and resorption are tightly coupled in adults, drugs that increase bone formation (e.g., teriparatide, which is a synthetic form of parathyroid hormone) increase markers of formation and resorption, while drugs that inhibit resorption (e.g., bisphosphonates) decrease markers of formation and resorption [23].

In adults, bone metabolism is primarily due to remodeling. However, in children biomarkers of bone metabolism in children represent the aggregate turnover due to (1) endochondral bone formation (longitudinal growth of bone), (2) increase in bone circumference, and (3) bone remodeling [24]. The pubertal growth spurt is reflected by marked increases in bone biomarkers [25]. Therefore, the use of bone biomarkers in children and adolescents requires consideration of gender, pubertal maturation, and growth velocity [25] and is most appropriately limited to short-term longitudinal studies to assess the impact of specific interventions [24].

Potential Threats to Bone Health in Pediatric IBD

Osteopenia has been well documented in children and adults with IBD [26–30]. Vertebral compression fractures have been reported in children with IBD [3–5], and hip, spine, and forearm fracture rates are significantly increased in adults with Crohn disease [31–36]. Kappelman et al. found that children with IBD <12 years of age had an increased risk of fracture (odds ratio [OR] 2.2, 95% confidence interval [CI] 1.2–3.8) and children with Crohn disease (CD) had a trend toward an increased risk of vertebral compression fracture, both compared with controls [7]. The osteopenia in IBD is multifactorial; likely etiologies include growth failure, delayed maturation, anorexia, malabsorption, cytokine effects on bone cells, and glucocorticoid therapies.

Malnutrition

Children with IBD are at risk for inadequate intake of calories as well as micronutrients, including calcium, vitamin D, and zinc, secondary to anorexia due to active disease, malabsorption, increased metabolic demands, lactose intolerance, abdominal pain, or depression. Even in the setting of adequate caloric intake, malabsorption can cause deficiency states of the above micronutrients depending on location and severity of disease. Diarrhea can result in zinc deficiency, which has the potential to impact growth. Vitamin D deficiency may result from malabsorption as well as decreased exposure to sunlight due to disease flares. Vitamin K deficiency may result from malabsorption and altered bowel flora due to antibiotic use and IBD-associated dysbiosis, which may result in increased concentrations of undercarboxylated osteocalcin, which is associated with decreased bone turnover and fractures [37]. Nutrient deficiencies that may contribute to impaired bone acquisition in pediatric IBD include calcium, vitamin D, vitamin K, and magnesium [38].

Multiple studies have reported that vitamin D deficiency frequently complicates pediatric IBD [39–42]. For example, Pappa et al. examined vitamin D levels in 130 children and young adults with IBD, 94 with Crohn disease, and 36 with ulcerative colitis. The prevalence of vitamin D deficiency (serum 25 (OH) vitamin D concentration ≤15 ng/mL) was 34.6%, and the mean serum 25 (OH) vitamin D concentration was similar in patients with Crohn disease and ulcerative colitis, 52.6% lower among patients with dark skin complexion, 33.4% lower during the winter months (December 22 to March 21), and 31.5% higher among patients who were taking vitamin D supplements. Patients with Crohn disease and upper gastrointestinal tract involvement were more likely to be vitamin D deficient than those without it. A similar study reported that 45% of children with IBD had vitamin D levels

less than 20 ng/mL [39]. Of note, none of these studies detected a relation between vitamin D levels and spine BMD, as measured by dual-energy X-ray absorptiometry (DXA) [39–41]. A study by Augustine et al. demonstrated an association between greater inflammation and lower PTH and serum 1, 25 (OH) vitamin D concentration. Treatment with anti-TNF resulted in higher PTH levels and higher 1, 25 (OH) vitamin D concentrations, suggesting the negative role of inflammation on PTH and thus decreased renal conversion of 25 (OH) vitamin D to 1,25 (OH) vitamin D [43].

Decreased Muscle Mass and Biomechanical Loading of the Skeleton

Bone adapts its strength in response to the magnitude and direction of the forces to which it is subjected. Mechanical forces on the skeleton arise primarily from muscle contraction. This capacity of bone to respond to mechanical loading with increased bone size and strength is greatest during growth, especially during adolescence [44]. Numerous studies have documented the beneficial effect of physical activity and biomechanical loading on bone geometry in healthy children [45–50]. These relationships dictate that studies of bone health in chronic childhood diseases consider the effects of alterations in muscle mass and strength.

Weight-bearing physical activity and biomechanical loading of bone are critical determinants of bone mass in growing normal children [51]. The influence of skeletal loading on bone accretion is illustrated in two exercise trials in healthy children. An easily implemented school-based jumping intervention augmented cortical thickness in the femoral neck of healthy children [52]. A randomized clinical trial of physical activity and calcium supplementation in prepubertal children resulted in a significant, positive interaction between calcium supplements and physical activity in both cortical thickness and cortical area [53]. Harpavat et al. reported that none of the subjects in a small series of children with IBD were participating in weight-bearing physical activities [54]. Werkstetter et al. compared 39 children with quiescent or mild IBD to 39 healthy controls and found decreased physical activity and lean mass in the children with IBD despite no differences in the measurements in quality of life or energy intake [55]. We reported that in children with incident Crohn disease, both muscle cross-sectional area and muscle strength are independently associated with cortical section modulus, a summary measure of cortical bone dimension and strength [56]. The reports of decreased lean mass and muscle strength in pediatric IBD suggest that decreased biomechanical loading of the skeleton may contribute to impaired bone accrual in this disorder, but additional studies are needed.

The relations between bone and muscle mass have been demonstrated in multiple studies in children and adolescents with Crohn disease. Burnham et al. reported that Crohn disease was associated with a 0.50 SD deficit (p = 0.006 compared with controls) in whole body bone mineral content (BMC) relative to height in males, adjusted for age, race, and Tanner stage [8]. Adjustment for whole body lean mass attenuated this deficit to 0.19 SD (p = 0.13 compared with controls). The authors noted that the absence of a bone deficit after statistical adjustment for lean mass does not imply that the bones are normal or adequate. In a similar study, deficits in DXA estimates of femoral neck subperiosteal width were not statistically significant after adjustment for lean mass [57]. Our study of children with newly diagnosed Crohn disease found that cortical section modulus was 6.8% greater than predicted compared to healthy controls, given muscle cross-sectional area and strength deficits [56]. A prospective cohort study using tibia peripheral QCT in children with newly diagnosed Crohn disease reported that muscle mass improved significantly over 1 year following diagnosis, but cortical section modulus worsened significantly [58]. This apparent disconnect between changes in bone and muscle mass over time illustrates the limitations of the functional muscle bone unit paradigm in chronic inflammatory disease. In addition to lean mass and muscle strength, the role of inflammatory cytokines, physical activity, and therapeutic agents on bone outcomes must be further studied.

Glucocorticoid-Induced Osteopenia

Glucocorticoids are widely used in the treatment of IBD and impact bone formation and resorption. Decreased bone formation is the primary mechanism for bone loss in glucocorticoid-induced osteopenia [59]. Mesenchymal stem cells, which also give rise to adipocytes, myoblasts, and chondrocytes, differentiate into osteoblasts. Glucocorticoids shift the cellular differentiation away from osteoblasts and toward adipocytes, and prevent the termination differentiation of osteoblasts [60]. Osteoblast numbers are decreased further by glucocorticoid-induced increases in osteoblast apoptosis [61]. In addition, glucocorticoids inhibit osteoblast production of bone matrix components [62]. Finally, glucocorticoids suppress the synthesis of insulin-like growth factor-I (IGF-1), a hormone important in bone formation [63]. The cellular response to glucocorticoids also includes an early phase of increased bone resorption, probably a result of the increased expression of receptor activator of nuclear factor-κ-B ligand (RANKL) and decreased osteoprotegerin (OPG)—increased RANKL and decreased OPG both promote osteoclastogenesis, as detailed below [64]. However, typically a more chronic state of decreased bone resorption develops due to loss of cell signaling to osteoclast progenitors and apoptosis [65].

Patients treated with glucocorticoids have an underlying disease, which frequently also carries a risk of osteoporosis. Therefore, the independent effects of glucocorticoids on bone turnover and bone structure during growth are not readily apparent from clinical studies. However, recent animal models demonstrate that glucocorticoid administration during growth resulted in decreased bone formation, decreased bone resorption, reductions in the age-dependent increases in trabecular thickness, and reductions in linear growth and accrual of cortical thickness in the femur [66, 67]. These deficits were associated with decreased bone strength in the vertebrae and femur in mechanical testing [66, 67]. Of note, it is unclear if the reductions in femoral cortical thickness were proportionate to the significant reductions in bone length. That is, did the bones have normal cortical thickness and strength relative to the shorter length?

Inflammation and Bone Loss

Cellular inflammatory pathways in Crohn disease activate the protean transcriptional regulatory factor nuclear factor-κB with increased production of a variety of cytokines, such as interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) [68]. Three groups of cytokines are particularly important in bone physiology: interleukin-6 (IL-6), TNF-α, and IL-1 [64]. Inflammatory cytokines promote osteoclastogenesis and accelerated bone resorption. TNF-α induces the expression of receptor activator of NF-κB ligand (RANKL). RANKL stimulates osteoclast differentiation and activation and inhibits osteoclast apoptosis, thereby dramatically prolonging osteoclast survival and increasing bone resorption [69, 70]. Additionally, TNF-α decreases expression of OPG, a decoy receptor that blocks RANKL [71, 72]. Inflammatory mediators, including IL-1 and IL-6, also increase RANKL secretion and contribute to bone loss [73]. TNF-α also has direct effects on bone formation; it inhibits osteoblast differentiation, inhibits osteoblast collagen secretion, causes increased resorption by inducing osteoblasts secretion of IL-6, and induces osteoblast apoptosis [74, 75]. These effects on bone formation are strikingly similar to the effects of glucocorticoids [59, 60].

Assessment of Bone Status in Children and Adolescents

Classification of Bone Health and Relation to Fracture Risk

DXA is widely accepted as a quantitative measurement technique for assessing skeletal status. DXA scans involve the use of two X-ray beams and measurement of X-ray penetration through bone. The radiation exposure from a conventional DXA examination is less than 10 microsieverts (μSv), while a two-view chest X-ray would be 60 μSv, and a CT exam of the pelvis 5000 μSv [76]. In elderly adults, DXA BMD is a sufficiently robust predictor of osteoporotic fractures that it can be used to define the disease. The World Health Organization criteria for the diagnosis of osteoporosis in adults is based on a T-score, the comparison of a measured BMD result with the average BMD of young adults at the time of peak bone mass [77]. A T-score ≤ -2.5 SD below the mean peak bone mass is used for the diagnosis of osteoporosis, and a T-score ≤ -2.5 SD with a history of a low-impact fracture is classified as severe osteoporosis. While the T-score is a standard component of DXA BMD results, it is clearly inappropriate to assess skeletal health in children through comparison with peak adult bone mass. Rather, children are assessed relative to age or body size, expressed as a *Z*-score. In adults, low-impact fractures are defined as fractures that occur after a fall from standing height or less. This definition is often difficult to apply to fractures in children that occur during play or sports activities.

While there are no clear evidence-based guidelines for the definition of osteoporosis in children. The International Society for Clinical Densitometry has suggested that the diagnosis of osteoporosis in children and adolescents should include a history of clinically significant fracture and BMC or density *Z*-score ≤ 2.0 (adjusted for age, sex, and bone size) [78]. Fractures occur commonly in otherwise healthy children with a peak incidence during early adolescence around the time of the pubertal growth spurt [21]. Faulkner et al. recently reported that peak gains in bone area preceded peak gains in BMC in a longitudinal sample of boys and girls, supporting the theory that the dissociation between skeletal expansion and skeletal mineralization results in a period of relative bone weakness [79]. This may be due to increased calcium demands during maximal skeletal growth.

Several studies have compared the DXA BMD of normal children and adolescents with forearm fractures to that of age-matched controls without fractures. Most [80–84], but not all [85, 86], found that mean DXA BMD was significantly lower in children with forearm fractures than in controls. One study reported that 69% of fractures in healthy children were due to low-energy falls at home [85], illustrating the difficulties defining low-energy fractures in children. Studies using QCT or metacarpal morphometry to characterize cortical geometry showed that decreased cortical thickness was associated with significantly increased fracture risk [84, 87]. Finally, television, computer, and video viewing had a dose-dependent association with wrist and forearm fractures [88]. A recent prospective cohort study in over 6200 children in the United Kingdom reported a weak inverse relationship between whole body (less head) BMD at 9.9 years of age and subsequent fracture risk [odds ratio

(OR) per SD decrease = 1.12; 95% CI, 1.02–1.25] [89]. The association between fracture risk and BMD was much stronger when adjusted for bone and body size; fracture risk was inversely related to BMC adjusted for bone area, height, and weight (OR = 1.89; 95% CI, 1.18–3.04).

These data suggest that low DXA BMD can be a contributing factor for pediatric fracture in healthy children; however, bone geometry and non-skeletal factors, such as sports participation, body size, and sedentary activities, may have an independent contribution to fracture risk. Importantly, the relationships between DXA BMD, bone geometry, and fracture risk in children with chronic diseases, such as IBD, may be different than those observed in healthy children.

Limitations of DXA in Children and Adolescents

DXA is, by far, the most commonly employed method for the assessment of bone health in children. However, DXA has several limitations that are pronounced in the assessment of children (Table 24.1). A study highlighting the importance of these limitations evaluated children referred for enrollment in a childhood osteoporosis protocol based on low DXA spine BMD and found 80% had at least one error in interpretation of the DXA scan [112]. The most common error was the use of T-scores, and ultimately, only 26% retained the diagnosis of low BMD.

The significant limitation of DXA is the reliance on measurement of areal rather than volumetric BMD (vBMD). DXA provides an estimate of BMD expressed as grams per anatomical region (e.g., individual vertebrae, whole body, or hip). Dividing the BMC within the defined anatomical region (g) by the projected area of the bone (cm^2) then derives "areal BMD" (g/cm^2). This BMD is not a measure of volumetric density (g/cm^3) because it provides no information about the depth of bone. Bones of larger width and height also tend to be thicker. Since bone thickness is not factored into DXA estimates of BMD, reliance on areal BMD inherently underestimates the bone density in individuals with short stature. Despite identical volumetric bone density, the child with smaller bones appears to have a mineralization disorder (decreased areal BMD). This is clearly an important artifact in children with chronic diseases, such as IBD, that are associated with growth delay and short stature [113]. An analysis by Zemel et al. found that adjustment of age-specific BMC and BMD *z*-scores for age-specific height *Z*-scores were the least biased methods to correct for the confounding effect of height [114].

Table 24.1 Limitations of DXA techniques in infants and children

Scan acquisition	Fan beam results in magnification error with apparent differences in bone area and BMC as body size varies [90]
Scan analysis	Difficult to define landmarks and region of interest in the immature hip [91]
	Software developed to improve bone detection in the infant and child result in significantly different results for BMC and body composition [92–94]
Reference data [95–108]	Limited data in young children
	Analysis methods not standardized
	Variable hardware and software across published reference data sets
	Some are not gender specific [109] Some presented relative to age, others relative to height, Tanner stage, and weight
Interpretation	Underestimates volumetric density in children with short stature [110, 111]
	Unable to distinguish between changes in bone dimensions and density
	Unable to distinguish between cortical and trabecular bone

The confounding effect of skeletal geometry on DXA measures is now well recognized and multiple analytic strategies have been proposed to express DXA bone mass in a form that is less sensitive to differences in skeletal size [95, 96, 115–117]. The technique developed by Carter et al. is based on the observation that vertebral BMC scaled proportionate to the projected bone area to the 1.5 power [115]. Therefore, vertebral volume is estimated as $(\text{area})^{1.5}$ and bone mineral apparent density (BMAD) is defined as $\text{BMC}/(\text{area})^{1.5}$. Kroger et al. proposed an alternative estimate of vertebral volume: the lumbar body is assumed to have a cylindrical shape and volume of the cylinder is calculated as $(\pi)(\text{radius}^2)(\text{height})$, which is equivalent to $(\pi)((\text{width}/2)^2)(\text{area/width})$ [118, 119]. This approach was validated by comparison with MR measures of vertebral dimensions in 32 adults [116]; DXA-derived vBMD correlated moderately well with BMD based on MR-derived estimates of vertebral volume ($R = 0.665$). Although these methods provide estimates of vertebral volume, the BMC includes the bone content of the superimposed cortical spinous processes.

A study by Wren et al. sought to evaluate the usefulness of DXA spine correction factors based on published geometric formula and anthropometric parameters, compared with three-dimensional QCT [120]. Subject height, weight, body mass index, skeletal age, and Tanner stage were assessed in 84 healthy children. While DXA and QCT measures of BMC were highly correlated ($r^2 = 0.94$), DXA areal BMD only moderately correlated with CT vBMD ($r^2 = 0.39$), illustrating the potential confounding effects of bone size on DXA areal BMD. The correlations between QCT vBMD and DXA estimates were particularly poor for subjects in Tanner stages 1–3 ($r^2 = 0.02$ for areal BMD), but multiple regression accounting for the anthropometric and developmental parameters greatly improved the agreement between the DXA and CT densities ($r^2 = 0.91$). These results suggest that DXA BMC is a more accurate and reliable measure than

DXA BMD for assessing bone acquisition, particularly for prepubertal children and those in the early stages of sexual development. The use of DXA BMD would be reasonable if adjustments for body size, pubertal status, and skeletal maturity are made, but these additional assessments add significant complexity to research studies, and to clinical interpretation.

An additional shortcoming of DXA is that the integrated measure of bone mass in a given projected area does not allow distinction between cortical and trabecular bone. DXA-based measures provide no information on bone architecture and are limited in their usefulness to differentiate the spectrum of bone accrual during growth.

Comparisons to appropriate pediatric reference data are essential to describe accurately the clinical impact of childhood disease on bone development, to monitor changes in bone mineralization, and to identify patients for treatment protocols. Multiple sources of pediatric DXA reference data are now available for the calculation of DXA *Z*-scores. These include varied approaches, such as gender-specific centile curves, age- and height-specific means and standard deviations, Tanner- and weight-specific percentiles, age-, sex-, weight-, and height-adjusted curves, and *Z*-score prediction models [95–108]. Differences in reference data have a significant impact on the diagnosis of osteopenia in children with chronic disease [109]. For example, the use of reference data that are not gender-specific results in significantly greater misclassification of males as osteopenia [109]. In addition, the use of published pediatric reference ranges has been complicated by differences in scanner manufacturers, and frequent changes in hardware and software technology, including fan-beam technology, low-density software analysis modes and specialized pediatric software. These technical changes result in clinically significant alterations in DXA results [92]. The use of adequate reference data and validated classification schemes is important in the study of bone health in children.

Peripheral Quantitative Computed Tomography

A three-dimensional structural analysis of trabecular architecture and cortical bone dimensions can be obtained by computed tomography (CT). This technique offers an opportunity to overcome the limitations of two-dimensional imaging with DXA and advance our understanding of bone mineralization in children. CT provides an image unobscured by overlying structures [121]. The CT attenuation of different bone tissues provides quantitative information, referred to as quantitative CT (QCT). In contrast to DXA, this technique describes authentic vBMD, accurately measures bone dimensions, and distinguishes between cortical and trabecular bone. In order to minimize radiation exposure, special high-resolution scanners were developed for the peripheral skeleton (pQCT), specifically, the radius or tibia. The distal site is largely trabecular bone, while the mid-shaft is almost entirely cortical bone. The volume of each component is calculated from the scan thickness and cross-sectional area, and the density by attenuation of the X-ray beam. Bone strength can also be estimated by pQCT from the total bone area, and cortical thickness and density [122]. QCT studies of bone mineral accretion and bone strength demonstrated gender, maturation, and ethnic-specific patterns of development of bone strength during childhood and adolescence [123]. A study longitudinal in children with Crohn disease comparing QCT measured vBMD versus DXA-derived measures of BMD demonstrated greater BMD deficits at diagnosis and greater improvements over 12 months with the PQCT vBMD approach [124].

Clinical Studies of Bone Health in Pediatric IBD

Accounting for Body Size Differences

Numerous studies have reported decreased DXA BMD in children with IBD [39]. However, as detailed above, DXA studies are frequently confounded by disease effects of growth. For example, two studies reported that DXA BMD for age *Z*-scores were significantly correlated with height for age *Z*-scores in children with IBD [39, 125]. Furthermore, expression of DXA results as BMAD (an estimate of volumetric BMD) eliminated the correlation with height *Z*-scores [125]. Another study addressed the confounding effect of short stature by expressing the spine DXA results as percent predicted BMC for bone area for age and gender in 73 children with Crohn disease or ulcerative colitis [126]. The percent predicted bone area for age and gender was decreased in IBD, compared with controls, consistent with shorter stature. While the median BMD for age and gender *Z*-score was significantly decreased in IBD (mean *Z*-score in spine = −1.6, in whole body = −0.9), the percent predicated BMC for bone area, age, and gender was normal. The authors concluded that children with IBD have small bones for age due to growth retardation, but adequate bone mass relative to bone size. Finally, Herzog et al. reported that BMD *Z*-scores were less than −2.0 in 44% of children when expressed relative to chronologic age, but were less than −2.0 in only 26–30% when expressed relative to bone age of height age [127].

The above studies illustrate the varied approach used to adjust for the confounding effects of poor growth. Leonard et al. reported that whole body BMC relative to height predicted bone strength (estimate by stress–strain index) as measured by QCT [117]. From the same group, Burnham

et al. assessed whole body BMC, lean mass, and fat mass (as measured by DXA) relative to height in 104 children and young adults with established Crohn disease, and 233 healthy controls, 4–26 years of age. The studies demonstrated significant bone and muscle deficits [8, 128]. Individuals with Crohn disease had significantly lower height-for-age, body mass index (BMI)-for-age, and whole body lean mass-for-height *Z*-scores than healthy controls (all $p < 0.001$). Table 24.2 summarizes four sequential models in males and females. The least adjusted models assessed whole body BMC in Crohn disease, compared with controls, adjusted for age and race, and revealed substantial deficits. Assessment of BMC without consideration of the decreased skeletal size for age in subjects with Crohn disease group may overestimate bone deficits. Accordingly, the second model was also adjusted for height. Figure 24.3 demonstrates that the marked BMC deficits relative to age (A) are less pronounced when assessed relative to height (B). Adjustment for height attenuated the Crohn disease effect in the multivariate regression model; however, significant BMC deficits persisted in males and females with Crohn disease, compared with controls. In the third model in Table 24.2 Tanner stage was added to determine if delayed pubertal maturation for age contributed to the decreased BMC in Crohn disease. Adjustment for delayed pubertal maturation did not appreciably change the estimate of BMC deficits in Crohn disease. The fourth and final model, adjusted for lean mass, eliminated significant BMC deficits in Crohn disease.

None of the glucocorticoid measures were significantly correlated with BMC-for-height *Z*-scores. However, height *Z*-score was negatively and significantly associated with duration of glucocorticoid therapy ($r = -0.24$, $p = 0.02$), and cumulative (mg/kg) glucocorticoids ($r = -0.36$, $p < 0.001$). Parenteral nutrition, isolated upper tract disease, hypoalbuminemia, nasogastric feeding, and decreased BMI *Z*-scores were associated with decreased BMC-for-height *Z*-scores, but these factors have the potential to be confounded by greater disease severity. Whereas BMC and BMD *Z*-scores for age may overestimate bone deficits, bone *Z*-scores for height have the potential to underestimate bone deficits. This can occur because children and adolescents with IBD may be of more advanced pubertal status than their comparators of similar height. As such, adjusting age-specific BMD or BMC *z*-scores for age-specific height *Z*-scores may be a more accurate approach [114].

Table 24.2 Hierarchical models of whole body BMC *Z*-scores in Crohn disease [8]

	Males		Females	
Models	*Z* (95% CI)	*p*	*Z* (95% CI)	*p*
1. Age, race	−1.16 (−1.51, −0.82)	<0.001	−0.61 (−0.95, −0.27)	0.001
2. Height, age, race	−0.63 (−0.95, −0.30)	<0.001	−0.44 (−0.81, −0.06)	0.02
3. Height, age, race, tanner	−0.50 (−0.85, −0.15)	0.006	−0.35 (−0.72, 0.02)	0.06
4. Height, age, race, tanner, lean mass	−0.19 (−0.43, 0.06)	0.13	−0.05 (−0.34, 0.25)	>0.2

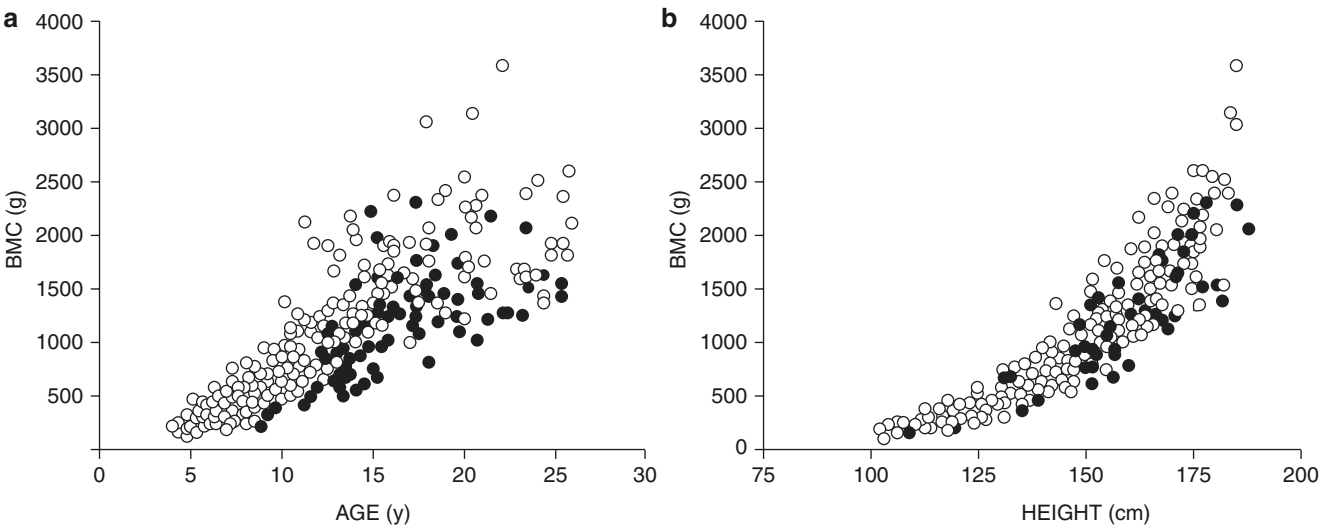

Fig. 24.3 Distribution of whole body BMC relative to age (**a**) and relative to height (**b**) in children and young adults with Crohn disease, compared with healthy controls (From Burnham et al. [8])

Glucocorticoid Effect

Over 90% of the children and young adults in the prior study had a history of glucocorticoid exposure; therefore, it was not possible to distinguish between disease and glucocorticoid effects on bone. The impact of the underlying IBD process is best assessed in subjects with newly diagnosed disease. The largest study of DXA BMD in newly diagnosed subjects was reported by Gupta et al. [129]; however, the study was complicated by the observation that BMD was markedly decreased in controls, compared with the DXA reference database. Overall, DXA spine BMD was comparable in the 41 children with ulcerative colitis and the controls, while results were significantly lower in the 82 subjects with Crohn disease. Laakso et al. reported on a longitudinal study of children and adolescents followed over a median of over 5 years and found greater lifetime glucocorticoid exposure to be associated with lower lumbar spine BMD [130]. The authors conclude that the findings may likely reflect both glucocorticoid effect and glucocorticoid exposure as a surrogate of more severe disease. In steroid-sensitive nephrotic syndrome, a condition without underlying inflammation but involving glucocorticoid therapy, no deficits in BMC are seen, but this may be related to the increase in skeletal loading associated with increases in BMI [131]. This demonstrates the complex interaction between medication exposures, side effects of therapy, and underlying disease pathophysiology.

Impact of Disease Activity

Walther et al. recently compared lumbar spine BMAD *Z*-scores in 34 steroid-naïve and 53 steroid-treated children with IBD in order to obtain information about the influence of non-steroidal factors [125]. Overall, 56 had Crohn disease and 30 had ulcerative colitis. Reference data were obtained in 52 controls. The mean BMAD *Z*-scores in the subjects with Crohn disease were −0.76 ± 1.25 in females and −0.79 ± 0.92 in males. The mean BMAD *Z*-scores in the subjects with ulcerative colitis were −0.30 ± 0.75 in females and −1.08 ± 1.23 in males. Among the steroid-naïve subjects, the duration of treatment ranged from 0 to 8 years, but the majority (approximately 80%) were within the first 5 weeks of therapy. Among the steroid-treated subjects, the cumulative steroid exposure averaged 4600 mg (range 0.05–25,000 mg) over the treatment duration of several days to 7.6 years. The mean BMAD *Z*-scores were comparable in steroid-naïve (−0.74 ± 1.08) and steroid-treated (−0.66 ± 1.08) subjects. The 19 subjects that had been treated with calcium and/or vitamin D supplements were all within the steroid-treated group. The study is limited by the small number of controls and the lack of data on disease activity between the steroid-naïve and steroid-treated groups. Nonetheless, these data demonstrate bone deficits in the absence of steroid therapy. The studies listed above were all based on DXA estimates of BMC and BMD and did not distinguish between cortical and trabecular bone.

Sylvester examined DXA BMD and bone biomarkers in 23 children with newly diagnosed Crohn disease [132]. Although BMD *Z*-scores did not differ between Crohn disease subjects and controls in this small sample, bone biomarkers were significantly lower in Crohn disease. This may be due to reduced bone remodeling, or reduced growth velocity. Importantly, activated T cells produced greater concentrations of interferon-γ, which may contribute to lower bone turnover. DeBoer et al. found that IGF-1 levels increased significantly over 10 weeks after initiating anti-TNF-alpha therapy and greater improvements in IGF-1 level predicted superior gains in DXA and pQCT measures of BMD and BMC [133].

Longitudinal Studies

Dubner et al. performed tibia pQCT in 78 CD subjects (ages 5–18 year) at diagnosis and followed them for 12 months [58]. At diagnosis, CD subjects had significant deficits in trabecular vBMD (*Z*-score: −1.32 ± 1.32, $p < 0.001$), section modulus (a summary measure of cortical bone dimensions and strength) (−0.44 ± 1.11, $p < 0.01$), and muscle cross-sectional area (−0.96 ± 1.02, $p < 0.001$), compared with controls. Over the first 6 months, trabecular vBMD and muscle *Z*-scores improved significantly (both $p < 0.001$); however, section modulus worsened ($p = 0.0001$) and all three parameters remained low after 1 year. Improvements in muscle were associated with improvements in section modulus and improvements in trabecular vBMD were greater in prepubertal subjects. Werkstetter et al. in a longitudinal study using forearm pQCT of 102 pediatric IBD patients (82 CD, 30 newly diagnosed) showed similar findings at diagnosis and median follow-up interval of 2.6 (0.9–5.8) years [134]. In a study from Sweden following children with IBD over 2 years, at baseline mean disease duration was 41.3 months and mean lumbar spine BMD *Z*-score of −0.9 ± 2.8 and this did not change significantly over the 2 years [135]. The authors note that corticosteroid and azathioprine exposures were not significantly associated with changes in BMD. A study from Italy evaluated children with Crohn's receiving 8 weeks of therapy with exclusive enteral nutrition (EEN) and continuing either aminosalicylate or azathioprine for a year. This study demonstrated improvement, but not normalization, in whole body (less head) DXA BMD over the course of a year [136]. Whereas the role of anti-TNF-alpha agents was not evaluated in the studies from Sweden or Italy, Griffin et al. described the

changes occurring over 12 months using QCT in children and adolescents initiating therapy with anti-TFN-alpha [137]. In this study, 74 subjects with median disease duration of 2.1 years (range 0.2–9.7) had baseline trabecular BMD *Z*-score −1.44 ± 1.11, cortical BMD *Z*-score 0.19 ± 1.08, and cortical area *Z*-score −0.97 ± 1.35. After 12 months, trabecular BMD and cortical area increased significantly (0.45 ± 0.76 and 0.29 ± 0.65, respectively, both $p < 0.001$), but cortical BMD decreased. Bone biomarkers were significantly increased over the first 10 weeks of anti-TNF therapy and the authors hypothesize that the decline in cortical BMD is a consequence of rapid increase in periosteal bone formation necessary in catch-up growth. This study highlights the value of QCT distinction of cortical versus trabecular bone and also demonstrates the role of anti-TNF-alpha therapy in the bones of children with IBD.

Finally, the impact of childhood IBD on peak bone mass and risk of osteoporosis is not yet clear but has been described. Bernstein et al. assessed spine, proximal femur, and whole body BMD in 780 premenopausal adult women (age <45 year) who were diagnosed with IBD prior to 20 years of age [138]. The mean BMD T-scores were normal in the spine (−0.14 ± 1.05), femoral neck (−0.15 ± 1.04), and whole body (0.09 ± 1.04) and results did not differ between the 12 subjects with disease onset before puberty, and the 58 subjects with disease onset after puberty. Alternatively, Azzopardi et al. recently described 83 adult subjects with Crohn disease (mean age 39) and found that age of diagnosis <17 years was significantly associated with lower BMD ($p = 0.0006$) [139].

Potential Therapies for Bone Health in Pediatric IBD

Physical Activity

Physical activity is an important determinant of bone mass accretion during growth; simple loading exercises promote bone accretion in healthy children. Numerous studies have documented the beneficial effect of physical activity and biomechanical loading on bone geometry in healthy children [45–47, 49, 50, 140]. Bone adapts its strength in response to the magnitude and direction of the forces to which it is subjected. This capacity of bone to respond to mechanical loading with increased bone size and strength is greatest during growth, especially during adolescence [44]. Physical activity affects the skeleton via two distinct mechanisms, which function as osteogenic stimuli: (1) "muscle pull" involves the force of contracting muscles upon their bony attachments and (2) weight-bearing exercise results in the mechanical loading of the bone with compressive forces. A physical intervention trial in adults with CD utilizing a home-based program of low-impact dynamic muscle conditioning exercises did not show a statistically significant difference in BMD of the lumbar spine and hip between cases and controls; however, analyses limited to those subjects achieving 100% adherence to the program did show a significant increase in trochanteric BMD [141]. A recent systematic review on the influence of physical activity on bone strength in children and adolescents concluded that physical activity has a significant positive impact on bone strength in the growing skeleton (36/37 studies) and that weight-bearing activity specifically enhances bone strength [142]. These findings were in healthy children, and the potential for physical activity to modulate the relationship between disease and bone metabolism will require further study. Based on existing evidence, a program consisting of resistance training (muscle-building) activity in addition to high-impact weight-bearing activity may result in positive impacts on skeletal health. The protocol for a multicenter, randomized controlled study on the effect of physical activity on whole body BMD as assessed by DXA has been published and will potentially be the first study to assess the role of physical activity in pediatric bone health in a children with IBD in a prospective randomized fashion [143].

Vitamins and Minerals

Multiple prospective randomized double-blind intervention trials have documented that calcium supplementation promotes bone accretion in normal children and adolescents [144–149]. Subjects with Crohn disease involving the small bowel are at increased risk for calcium oxalate kidney stones. Normally dietary calcium binds with oxalate in the gut to form a complex that is poorly absorbed. In small bowel disease, fat malabsorption results in increased binding of fatty acids with calcium to form insoluble soaps, thereby increasing the soluble oxalate for absorption [150]. Calcium supplements result in decreased urinary oxalate without increasing urinary calcium above normal; therefore, calcium is recommended to prevent enteric hyperoxaluria [151]. To our knowledge, no calcium balance studies or calcium supplementation trials have been conducted in children with chronic illness.

Vitamin D is essential for the maintenance of adequate calcium levels for bone mineralization and functioning of the immune functioning and all pediatric IBD patients are at risk for vitamin D deficiency. In 1997, the Institute of Medicine concluded that the adequate intake of vitamin D in children and young adults in 200 IU per day [152]. However, in the years following the Institute of Medicine report, a series of publications have argued that 200 IU is not adequate in healthy children and adults [153–160]. A study of the serum 25-hydroxyvitamin D (25(OH)D) response to oral cholecal-

Table 24.3 Institute of medicine 2011 dietary reference intakes for calcium and vitamin D

	Calcium (mg/day)		Vitamin D (IU/day)	
Age (year)	RDA	UL	AI	UL
4–8	1000	2500	600	3000
9–18	1300	3000	600	4000
19–30	1300	3000	600	4000

ciferol reported that each additional 100 IU of cholecalciferol resulted in a 0.7 ng/mL increase in serum 25(OH)D over a two–three-month period, then plateaued [155]. The exact dose required to achieve adequate serum 25(OH)D levels is children with IBD is unclear, but Weaver et al. reported that 863 IU/day would be required in healthy adolescent girls, on average to achieve a serum 25(OH)D of 32 ng/mL [157].

In 2011, the Institute of Medicine updated Recommended Daily Allowances (RDA) and Tolerable Upper Intake Levels (UL) for calcium and vitamin D, and these values are summarized in Table 24.3 [161]. These recommendations reflect the need for increasing calcium intake with age in order to accommodate the calcium needs for the rapidly growing skeleton, especially during the years of the adolescent growth spurt. A national dietary intake survey showed that calcium intake of children declines in all ethnic groups at the ages when calcium requirements increase [162]. Additional practice guidelines from the Endocrine Society propose that patients at risk for vitamin D deficiency require higher doses of vitamin D, specifically, 600–1000 IU/day for patients 4–18 years of age (UL 4000 IU), and 1500–2000 IU/day for patients 19–30 years of age (UL 10,000 IU) [163]. Pappa et al. conducted a six-week trial in children with IBD and found supplementation with cholecalciferol (D3) 2000 international units daily to be superior to ergocalciferol dosed similarly at raising 25 (OH) vitamin D levels [164]. Serum 25-hydroxyvitamin D levels should be measured and optimized, especially in subjects at northern latitudes in the winter months. Future studies will need to further evaluate the role of inflammation on decreased PTH and decreased renal conversion of 25(OH)D to $1,25(OH)_2D$ as has been described by Augustine et al. [43].

Bisphosphonates

The beneficial effects of bisphosphonates in adults with postmenopausal osteoporosis and corticosteroid-induced osteoporosis are well recognized. However, concerns regarding the impact on the structure of the modeling skeleton initially tempered enthusiasm for these medications in children, in particular in IBD where secondary bone deficit can be addressed by treating underlying inflammation. Bisphosphonate therapy results in distinctive radiographic metaphyseal bands in children; the significance of these bands is unclear. Furthermore, some have suggested drug holidays for those receiving bisphosphonate therapy due to concern for over suppression of bone turnover and risk of avascular necrosis of the jaw [165]. Pamidronate proved effective in uncontrolled observational studies of children with osteogenesis imperfecta; bone density and size increased and the incidence of fractures decreased [166–168]. The treatment did not alter fracture healing, growth rate, or growth plate appearances. A report of osteopetrosis in a child treated with a cumulative pamidronate dose approximately seven-fold greater than recommended raised concerns regarding the safety of this treatment in growing children [169, 170]. Similar complications have not been observed in children on lower doses [171].

Numerous case series and case reports have been published describing bisphosphonate therapy in children with disparate chronic diseases [172–180]. The two largest studies conducted in children with chronic inflammatory conditions are summarized in Table 24.4. Both of these studies demonstrated significant improvements in DXA BMD; however, only one was a randomized trial [11]. The trial had many important limitations. First, the study population included 22 children with highly disparate conditions, including juvenile arthritis, lupus, dermatomyositis, IBD, renal transplantation, autoimmune anemia, and cystic fibrosis; only 18 completed the protocol. Second, baseline height *Z*-scores and subject age differed significantly between the intervention and placebo group. Third, the spine and femur BMD was assessed using DXA and was likely confounded by bone size. These data highlight the growing use of bisphosphonates in children, and the need for controlled trials using three-dimensional imaging techniques.

Insufficient data are available on the long-term effects of bisphosphonates to recommend its routine use in pediatric IBD, especially in patients at risk for low bone turnover due to cytokine effects [132, 182]. Furthermore, a recent study has demonstrated improvements in BMD and bone metabolism in IBD using anti-TNF-alpha therapy and controlling inflammation [137]. This suggests that addressing underlying inflammation should be the focus in addressing bone deficits in IBD. A recently published position paper from Australia did not give guidance on usage of bisphosphonates in IBD, instead focusing on primary etiologies of bone fragility or secondary etiologies without specific remedy [183]. However, future studies may demonstrate an important role for bisphosphonate treatment in patients requiring long-term glucocorticoid therapy.

Table 24.4 Bisphosphonate studies in children and adolescents with chronic inflammatory disease

Study/subjects	Intervention/outcome	Comments and results
Bianchi et al. [181] *Chronic rheum disorder and ↓ spine BMD* $N = 39$[a], age 5–18	*Design*: 12-month case series Oral alendronate Weight <20 kg: 5 mg q day Weight >20 kg: 10 mg q day Instructed to ↑ calcium to RDA *Outcome*: DXA spine areal BMD	Serum alkaline phosphatase levels decreased by 16.5 ± 10.8%. Urinary excretion of NTX decreased by 17 ± 16.5%. Mean spine areal BMD *Z*-scores (adjusted for sex, age, body surface area) increased from a mean of −2.7 at baseline to −1.9 at 6 months ($p < 0.01$ compared with baseline) and to −1.05 at 12 months ($p < 0.001$ compared with baseline).
Rudge et al. [11] *Chronic glucocorticoids* $N = 22$[b], age 4–17	*Design*: 12-month RCT Oral alendronate vs. placebo 1–2 mg/kg weekly No calcium supplements Rx Vit D if level <20 ng/mL *Outcome*: DXA of spine and femur shaft	Baseline height *Z*-score significantly greater in placebo group (−0.2 vs. −2.0). 18 completed study. Significant ↓ in bone resorption markers in alendronate group ($p < 0.01$) Lumbar spine: significant ↑ in BMAD in alendronate group ($p = 0.013$) compared with baseline, but not in placebo group ($p = 0.16$) Femur mid-shaft: marginal ↑ in CSMI in alendronate group ($p = 0.08$) compared with baseline, but not in placebo group ($p = 0.18$)

[a]16 juvenile arthritis, 11 systemic lupus erythematosus (*SLE*), 6 dermatomyositis, 2 Behcet's syndrome, 2 granulomatosis with polyangiitis (formerly known as Wegener granulomatosis), and 2 undefined
[b]7 juvenile arthritis, 6 SLE, 4 dermatomyositis, 2 IBD, 1 renal transplant, 1 autoimmune anemia, and 1 cystic fibrosis

Summary

In conclusion, children with IBD are at risk for impaired bone mineral accrual. However, additional studies are needed to fully appreciate the magnitude of bone disease in pediatric IBD, as well as the implications for lifetime fracture risk and targeted therapies. Currently, the prevention of bone disease is best accomplished by controlling inflammation, providing adequate calcium and vitamin D supplementation, and encouraging physical activity. Prospective trials of therapeutic agents need to be performed to assess efficacy and safety in the developing skeleton.

Part IV

Medical Therapy

5-Aminosalicylate Therapy

25

Michelle Gonzalez and Michael Stephens

Introduction

Aminosalicylates are a class of medications commonly used as first-line therapy for induction and maintenance of remission in mild to moderate inflammatory bowel disease (IBD) [1]. Although their use in ulcerative colitis (UC) is well established, their role in Crohn disease (CD) remains controversial. Aminosalicylates were derived from sulfasalazine (SASP, salicylazosulfapyridine), a sulfa drug originally developed for the treatment of rheumatoid arthritis. The SASP molecule comprises two moieties with antimicrobial and anti-inflammatory properties, sulfapyridine and 5-aminosalicylic acid (5-ASA), respectively [2, 3]. In the colonic lumen, bacteria metabolize the azo bond that joins the subunits, thereby releasing the therapeutically active 5-ASA and the inactive sulfapyridine [4]. Although effective for the treatment of IBD, the dose-related adverse effects and hypersensitivity reactions associated with sulfapyridine led to the development non-sulfa aminosalicylates. These modern formulations have similar efficacy as their predecessor and have improved side effect profiles.

Although the use of 5-ASAs in adults with IBD is well established, there is limited evidence for their safety and efficacy in the pediatric IBD population. This shortcoming is further accentuated by mounting evidence that suggests important differences between adult and pediatric IBD. Nonetheless, 5-ASAs are commonly used in pediatric IBD patients. More recently, prospective pediatric data have emerged regarding mesalamine therapy response, specifically in pediatric UC [5].

Mechanism of Action

The exact mechanism of action of aminosalicylates in IBD remains unclear. The primary therapeutic effect of 5-ASA over the gastrointestinal mucosa is thought to be topical rather than systemic [6]. Colonic epithelial cells absorb 5-ASA and its effectiveness is in turn related to colonic mucosal concentrations. Systemic exposure remains low after oral and rectal administration. Current data suggest that 5-ASA induces the expression of a class of nuclear receptor genes, with resulting increased peroxisome proliferator-activated receptors (PPARs) in colonic epithelial cells. PPAR expression is particularly high in the colonic epithelium, and activation is largely driven by intestinal bacteria [7, 8]. PPAR-γ is involved in the control of inflammation, cell proliferation, apoptosis, and modulation of cytokine production. It has also been shown to have antitumorigenic effects [9]. As a result of these interactions, PPAR-γ may be the basis for future chemopreventive strategies against colorectal cancer (CRC) [10]. In turn, PPAR-γ expression has been shown to be downregulated in patients with active UC [11]. One randomized placebo-controlled clinical trial of a PPAR-γ ligand (rosiglitazone) demonstrated efficacy in treating mild to moderate UC [12]. Cardiovascular side effects, however, have dampened enthusiasm for rosiglitazone.

Other proposed mechanisms of action of 5-ASA have been described. One includes the inhibition of cyclooxygenase (COX) and 5-lipoxygenase pathways of arachidonic acid metabolism, resulting in a decrease in pro-inflammatory prostaglandins and leukotrienes, and inhibition of interleukin-1, interleukin-2, and tumor necrosis factor (TNF)-alpha [13]. Furthermore, 5-ASA has also been described as a potent antioxidant and free radical scavenger [6, 13]. Furthermore, data support the role of 5-ASA in restoration of the imbalance between angiogenic (VEGF) and antiangiogenic factors (endostatin and angiostatin) in experimental UC, potentially by modulation of metalloproteinases (MMP2 and MMP9), and again implicating TNF-alpha [14].

Pharmacokinetics

5-ASA is absorbed in the stomach and small intestine unless bound as a prodrug or combined with another delivery system [2]. As 5-ASA is thought to act topically, the clinical goal is to maximize delivery of the active drug to the site of inflammation in the colon while minimizing systemic absorption in the small intestine. Rectal gels, liquids, and foam enemas have been formulated to this effect [15]. However, these formulations have the undesirable side effects of leakage and abdominal bloating and many patients find them impractical. As a result, adherence to the dosing regimen is often poor, limiting their use as an adjunct therapy in many cases [16].

Oral 5-ASA agents are much better tolerated and are thought to be more practical and patient friendly. SASP was the first prodrug that delivered 5-ASA to the colon via an azo bond linked to sulfapyridine. This bond is cleaved by bacteria in the colon to release the active drug [2]. 5-ASA is primarily excreted in the stool, as it is poorly absorbed in the colon. The sulfapyridine component, however, is absorbed from the colon and then metabolized in the liver, with excretion through the urine. Due to the multiple dose-limiting side effects of sulfapyridine, newer formulations of 5-ASA have been created, with specific compositions to ensure delivery to the targeted area of inflammation. Some are bound to other prodrugs, while others are time-release preparations and pH-dependent release formulations [17–19]. The other prodrug formulations are olsalazine and balsalazide, which are bound by distinct azo bonds, and, like SASP, are then cleaved by intestinal bacteria, releasing the active medication into the colon. Olsalazine is a 5-ASA dimer linked by a diazo bond and balsalazide is 5-ASA linked to an inactive carrier molecule by a diazo bond.

The pH-dependent delivery systems have been developed to target release of the active medication into the small bowel and colon. An acrylic-based resin, Eudragit, is used to coat these tablets. Asacol® and its newer bioequivalent, Delzicol® (mesalamine), are examples of such medications, and have been designed to release 5-ASA at a pH of 7 or higher in the terminal ileum and colon. Other preparations have been formulated to release 5-ASA at a lower pH of 6 or greater (Apriso®), which are released more proximally in the ileum and through the colon.

Pentasa® (mesalamine) is a time-dependent release formulation in which the active drug is packaged into microgranules that are coated by ethylcellulose. The ethylcellulose coating dissolves when hydrated and the drug is released throughout the small intestine and colon.

Luanda® is a once-daily, high-strength formulation of mesalamine, utilizing a Multi Matrix System (MMX) technology designed to deliver the active drug throughout the colon. The matrix is enclosed within a resistant coating which also disintegrates at a pH of 7.0 or greater, releasing the active medication within the terminal ileum and colon. Once the matrix is exposed to gut fluid, it expands and forms a viscous gel mass that is slowly released throughout the colon.

Most of the older formulations are limited by the amount of 5-ASA that can be delivered per capsule, which required that patients take multiple doses per day and several tablets per dose. However, the newer formulations allow for less frequent once to twice a day dosing and fewer pills. Table 25.1 and Fig. 25.1 outline the formulations more commonly used in the United States, sites of action, and delivery system.

Table 25.1 Preparations of 5-ASA

Drug	Formulation	Delivery System	Dosage Form	Release Location
Azo-bonded Formulations				
Sulfasalazine (Azulfidine®)	Azo bond of 5-ASA to sulfapyridine	Broken down by colonic bacteria to release active 5-ASA moiety	Tablet 500 mg	Colon
Olsalazine (Dipentum®)	Diazo bond of 5-ASA dimer	Broken down by colonic bacteria to release active 5-ASA moiety	Capsule 250 mg	Colon
Balsalazide (Colazal®)	Azo bond of 5-ASA and inactive carrier	Broken down by colonic bacteria to release active 5-ASA moiety	Capsule 750 mg	Colon
Mesalamine Formulations				
Pentasa®	Controlled release	Time release	Capsules 250 mg, 500 mg	Small intestine, colon
Asacol®	Enteric coated; delayed release	pH-dependent (≥7)	Tablet 400 mg	Terminal ileum, colon
Asacol HD®	Enteric coated; delayed release	pH-dependent (≥7)	Tablet 800 mg	Terminal ileum, colon
Lialda®	Delayed release	pH-dependent (≥7)	Tablet 1200 mg	Terminal ileum, colon
Delzicol®	Delayed release	pH-dependent (≥7)	Capsule 400 mg	Terminal ileum, colon
Apriso®	Delayed and extended release	pH-dependent (≥6)	Capsule 375 mg	Terminal ileum, colon
Rowasa®	Topical		Rectal suspension 4 g/60 mL	Left colon
Canasa®	Topical		Suppository 1000 mg	Rectum

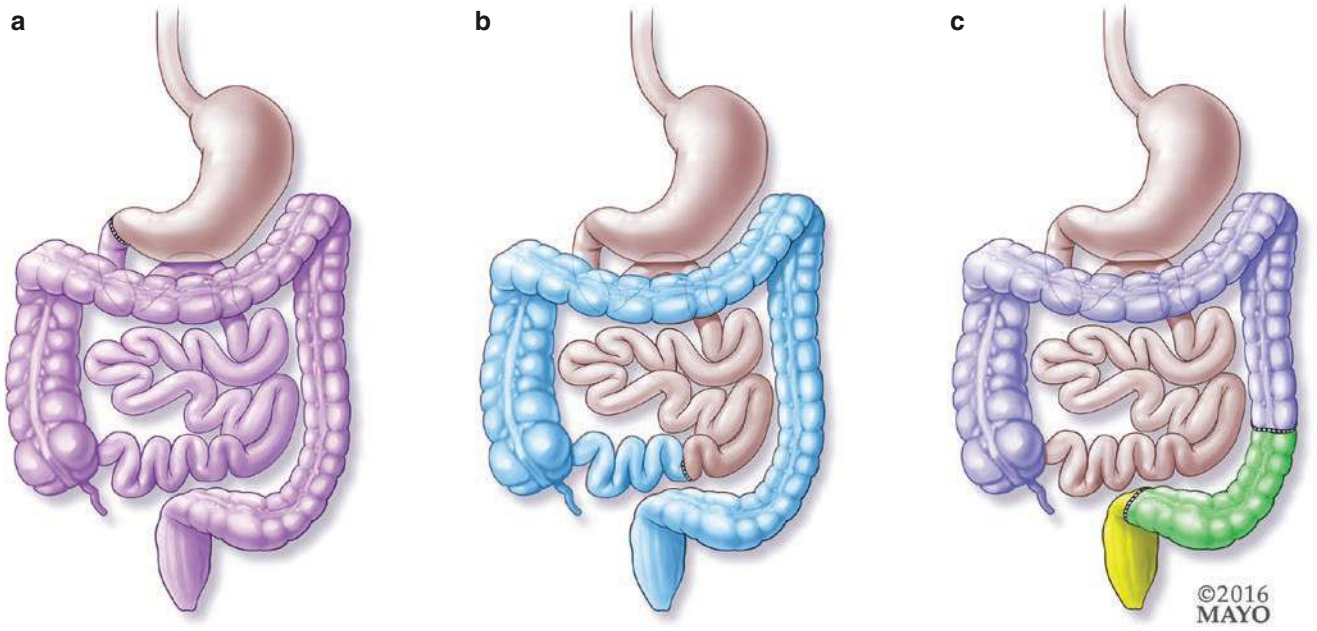

Fig. 25.1 (**a**) Purple shading: Pentasa (**b**) Blue shading: Asacol, Asacol HD, Lialda, Apriso (**c**) All three shaded areas (purple, green and yellow): Azulfidine, Colazal, Dipentum; Green shading only: Rowasa; Yellow shading only: Canasa

Indications and Efficacy

Ulcerative Colitis

The efficacy of aminosalicylates for the induction and maintenance of remission of UC is well established in the adult literature and these medications remain the first-line treatment for mild to moderate disease [20, 21]. Although there is very little pediatric UC data, oral 5-ASA formulations are recommended as the first-line induction therapy for mild to moderately active pediatric UC as well [22].

In a recent systematic review and meta-analysis, both oral and rectal preparations of 5-ASAs were found to have modest efficacy at inducing remission in mild to moderate UC compared to placebo with no statistically significant difference between the preparations [23]. There is no standardized dosage or frequency of dosing for rectal preparations in inducing remission of UC. In the most recent Cochrane Review, rectal 5-ASA was superior to rectal steroids for inducing remission of UC [24]. There is improved efficacy with combined rectal and oral 5-ASA therapy compared with oral 5-ASA therapy alone [25]. In fact, in a recent prospective open label study, 42% of children with mild to moderate UC that had been previously refractory to oral mesalamine obtained clinical remission on addition of rectal mesalamine (Pentasa enemas), with a 71% clinical response rate at week 3 [26]. Although there is no standard dosing of oral 5-ASA for inducing remission, doses of 1.5–4.8 g/day have been shown to be effective depending on disease severity and mesalamine preparation in adults. The result of the ASCEND I and II trials shows a statistically significant higher rate of mucosal healing in UC at 6 weeks with a dose of 4.8 g/day of delayed-release oral mesalazine over 2.4 g/day dosing [27]. However, a recent randomized control trial in pediatric UC patients showed equal effectiveness of high- and low-dose oral delayed-release mesalamine for achievement of clinical remission [28]. The reduction in fecal biomarkers, calprotectin and lactoferrin, was not statistically significant between the groups. Despite improved efficacy of combined oral and rectal 5-ASA therapy for inducing remission over oral 5-ASA alone, the remission rates are still significantly lower than with corticosteroids alone [24]. In UC, mesalamine has similar efficacy to SASP at equimolar doses.

Both oral and rectal mesalamine are more efficacious in preventing relapse of quiescent UC than placebo [21]. There are many randomized control trials that show topical 5-ASAs have comparable efficacy at preventing relapse of quiescent UC. On the other hand, in one recent meta-analysis, intermittent rectal mesalamine was superior to oral 5-ASAs with a NNT of 4 [25, 29]. In another recent meta-analysis, topical (rectal) mesalamine was more effective at preventing relapse of quiescent UC compared to placebo with a NNT of 3 [30]. This study also showed a trend toward a greater effect size with continuous topical therapy compared with intermittent topical therapy. The analysis showed lower relapse rates when an overall higher total weekly dose of topical mesalamine was used, similar to the occurrence with higher doses of oral 5-ASA therapy for preventing relapse of quiescent

UC. However, the majority of the patients in this study had only left-sided disease or proctitis.

In the adult population, oral 5-ASA has modest efficacy in maintaining remission of quiescent UC with good adherence, but there is no standardized dosing regimen. Some studies assessed not only efficacy in maintaining remission in UC but also adherence to the prescribed treatment. In a study of MMX mesalamine at 2.4 g/day, there was only a 30% recurrence rate at 12 months for patients who were adherent to the medication more than 80% of the time, as compared to a 53% relapse rate at 12 months for patients who were less than 80% adherent to the medication regimen [31]. A meta-analysis showed that once-daily dosing of oral mesalamine was equally as effective as conventional dosing in preventing relapse in quiescent UC over 12 months of therapy [32, 33]. Although 5-ASA has proven to be effective in maintaining remission in quiescent ulcerative colitis, adherence must be considered when developing an individual's treatment plan.

There are a few studies evaluating the efficacy of 5-ASA for the treatment and maintenance of remission in pediatric UC. One recent multicenter prospective study (PROTECT) aimed to determine initial response to oral mesalamine in treatment-naïve pediatric UC patients. Overall, 34% of children achieved the 12-week outcome of corticosteroid-free remission (PUCAI <10). Initial treatment solely with mesalamine was reserved for patients with mild UC (PUCAI <35) with an observed corticosteroid-free remission of 48%, whereas the moderate and severe groups were initially started on oral or IV corticosteroids, respectively, and with a 33% and 21% achieving the 12-week outcome as previously stated. The most significant clinical predictor of corticosteroid-free remission was clinical remission at week 4. Histological features were also predictive of response with baseline rectal biopsy peak eosinophil count of >32 cells per high-power field associated with better outcomes, and surface villiform changes associated with worse outcomes. Worse outcomes also were observed in patients with increased disease activity, as well as laboratory markers suggestive of increased disease severity (i.e., lower initial serum albumin). Per the study, age, sex, ethnicity, BMI, pANCA positivity, and baseline fecal calprotectin were not associated with outcome.

A study on the efficacy of mesalamine 500 mg suppositories for the treatment of ulcerative proctitis in children showed a statistically significant decrease in the disease activity index at 3 weeks for the 49 patients enrolled. 41 patients had a mild or an unrelated adverse event [34]. Another pediatric study compared the efficacy of oral beclomethasone dipropionate (BDP) to oral 5-ASA in the treatment of mild to moderate pediatric UC. The results of the study showed clinical remission was achieved after 4 weeks in 12 of 15 patients treated with BDP but only 5 of 15 patients treated with 5-ASA, suggesting BDP may be more efficacious at inducing remission in mild to moderate pediatric UC than 5-ASA [35].

In general, the preparation of 5-ASA used is dependent on the location and severity of disease. In addition, particularly in the younger age groups who may have greater difficulty in swallowing pills, the mode of delivery is also crucial. There are currently no 5-ASA liquid formulations. However, certain capsule formulations, namely, Pentasa® and Colazal®, may be opened and the contents are emptied into foods, such as yogurt and peanut butter. Data on the efficacy of this practice, have not been published to date.

Rectal formulations are usually a reasonable starting choice in patients with mild disease limited to the rectum or left colon [36]. Adherence needs to be considered when using these formulations. Patients with more extensive disease involving the transverse and ascending colon may require the addition of an oral preparation.

Dosing of oral 5-ASA in the pediatric population is variable, but the dosages usually fall in the range of 30–100 mg/kg/day. Guidelines established by ESPGHAN and the European Crohn's and Colitis Organisation (ECCO) suggest a dose of 60–80 mg/kg/day in 2 daily doses up to 4.8 g daily for mesalazine, and 40–70 mg/kg/day in two divided doses with a maximum of 4 g per day for SASP. Higher doses have been used, although it is not evidence based. For rectal dosing, 25 mg/kg up to a maximum of 1 g may be used once daily [37].

Crohn Disease

The efficacy of 5-ASA in the induction and maintenance of remission in Crohn disease (CD) is controversial. Currently, their use in treatment of pediatric CD is limited and only recommended in selected patients with mild disease [38]. In a Cochrane review consisting of adult studies, SASP showed only a modest effect over placebo in inducing remission in mild to moderate CD at a dose of 3–6 g/day [39]. It showed a 38% higher chance of inducing remission compared to placebo-treated patients. However, this effect was limited to patients with Crohn colitis. SASP was 34% less effective at inducing remission than corticosteroids alone and it was less effective than combination therapy with corticosteroids and SASP. Two studies, the Trial of Adjunctive Sulfasalazine in Crohn disease (TAS) and the European Cooperative Crohn Disease Study (ECCDS), showed that SASP was not a useful adjunct to corticosteroid therapy in achieving remission [40, 41].

A systematic review and meta-analysis of randomized controlled trials that excluded the Crohn's III trial data also suggest a modest effect of 5-ASA drugs inducing remission of active CD over placebo-treated patients with a number needed to treat (NNT) of 11 to prevent one patient's disease

remaining active [42]. The effect was based on a mean reduction in CDAI scores. Had the data from the Crohn's III trial been available, the authors suspect there would have been no statistically significant difference between the 5-ASA-treated group and the placebo-treated group. According to the latest Cochrane review, low-dose controlled-release mesalamine (1–2 g/day) was less effective at inducing remission in active CD compared to placebo-treated patients [39]. As with sulfasalazine, delayed-release mesalamine (2 g/day) was less efficacious than corticosteroids [43]. Trials evaluating higher doses of mesalamine (3–4.5 g/day) show inconsistent results. The majority of the studies show no difference in induction of remission in mild to moderately active Crohn disease relative to placebo [39]. Two of the studies showed statistically significant changes in CDAI scores, but they were found to be clinically insignificant. In a single trial, high-dose mesalamine was less effective than budesonide [44]. Many of these studies were small and had several methodological weaknesses, which may limit the generalizability of the effects of mesalamine at inducing remission in mild to moderately active Crohn disease.

Nonetheless, another more recent network meta-analysis did show that at doses above 2.4 g/day there was some benefit in induction of remission of Crohn disease over placebo, although this effect is not as significant as budesonide or corticosteroids [45]. This study attempted standardization in the definition of clinical remission as defined by a CDAI score of <150.

One pediatric study reviewed disease activity at diagnosis in 43 patients and treatment provided. Ten of 25 patients in the mild group and 3 of 18 patients in the moderate to severe group received 5-ASA monotherapy immediately after diagnosis. These patients tended to have more exacerbations, shorter duration of the first remission, and longer total duration of systemic steroid use than patients receiving combination therapy, immunomodulators, or systemic steroids [46].

The role of 5-ASAs in maintaining remission in quiescent CD was also assessed in the review by Ford et al. No statistical significant benefit over placebo was found, although subgroup analysis of trials with low risk of bias showed mesalamine to be of benefit in preventing relapse with a NNT of 13 [42, 47]. This was the same result when a more conservative protocol analysis was completed, in which dropouts from individual studies were not considered treatment failures. There is one pediatric study evaluating maintenance of remission in CD patients after successful flare-up therapy with either nutrition or medications that showed that the relapse rate was similar with mesalazine and placebo [48].

Overall, evidence does not support the use of mesalamine for maintenance treatment in pediatric CD.

Many gastroenterologists continue to use aminosalicylates in CD despite multiple studies showing at best a modest benefit over placebo [39]. The dosing of oral 5-ASA for pediatric CD is similar to that for pediatric UC with 50–80 mg/kg/day up to 4 g daily [38].

Surgically Induced Remission of Crohn Disease and Prevention of Postoperative Recurrence

Surgical resection can induce remission in CD. However, endoscopic and clinical relapse of CD after surgical resection is common and has been reported to be as high as 75–90% and 20–30%, respectively, within 1 year [49, 50]. There is currently no standard therapy for preventing relapse postoperatively. Aminosalicylates in the postoperative setting have been extensively studied, but their effectiveness at preventing relapse after surgical resection remains controversial. In a systematic review and meta-analysis of 11 randomized controlled trials, the effect of mesalamine appears to be modest with a NNT of 13 compared to placebo or not treating after surgery [51]. The previously referenced Cochrane review on the effectiveness of mesalamine in surgically induced remission in Crohn disease published their updated study to include more recent RCTs up to 2018 [52]. They suggest benefit of mesalamine over placebo in the maintenance of clinical remission with a NNT of 13 patients to prevent one relapse. There continues to be little evidence to support maintenance of endoscopic remission. Similar to the previous review, this potential benefit was not seen with the use of sulfasalazine.

There is heterogeneity in all of these studies, including the dosage and preparation, the length of treatment post-surgery, and the definition of remission. In another network meta-analysis comparing different pharmacologic interventions in preventing relapse of CD after surgery, mesalamine was shown to reduce the risk of clinical relapse (RR 0.60; 95% credible interval 0.37–0.88), but not endoscopic relapse (RR 0.67; 95% CrI 0.39–1.08) when compared to placebo [53].

Chemoprevention of Colorectal Carcinoma

Due to their structural similarity to aspirin, which has been shown to reduce the risk of colorectal cancer (CRC) and adenomas in patients without IBD, it was believed that 5-ASAs had a similar effect on patients with a diagnosis of IBD [54]. However, more recent studies suggest that they may not provide much, if any, chemoprophylaxis for CRC. A population-based study including more than 8000 patients found that there was no protective effect of 5-ASA against CRC [55, 56]. This study evaluated the cumulative use of 5-ASA at 1, 5, and 7.5 years. Adherence to 5-ASA therapy was based on the frequency of prescription refills. It is possible that the cumulative use for longer than 7.5 years could be chemopreventive, but this has not been studied. In con-

trast, one small case-controlled study found that cumulative mesalamine doses decreased the risk of CRC in patients with IBD [57]. There are also several studies that have observed a significant chemopreventive effect of mesalamine compounds, especially at doses of >1.2 g/day. However, these have been criticized because of the design, outcomes measured, and variables controlled for [58]. A more recent meta-analysis did show a chemopreventive effect of mesalamine, and not sulfasalazine, against CRC only in clinical-based studies, but not population studies [59]. Furthermore, this effect was only seen in UC but not in CD, and was more pronounced in doses of ≥1.2 g/day. Results of these studies are again limited by the heterogeneity of the studies included. A chemopreventive effect was not seen in patients who received sulfasalazine regardless of setting (referral versus non-referral).

As noted above, the exact mechanism of action of 5-ASA in the treatment of IBD is unknown, and the same can be said regarding chemoprophylaxis. One retrospective cohort study attempted to determine the precise moment in the dysplasia-carcinoma sequence where mesalamine would potentially exert its protective effect. The study identified patients with UC with no dysplasia, indefinite dysplasia, or flat low-grade dysplasia (LGD) and followed them for the development of high-grade dysplasia (HGD) or CRC. The data suggest that if mesalamine has any chemopreventive effect, it may act early in the neoplastic process before the development of LGD [58]. There are many in vivo and in vitro studies currently looking at the anti-inflammatory and anti-neoplastic effects on different proposed mechanism of action pathways, including inhibition of cyclooxygenase activity, enhanced apoptosis through inhibition of NF-κB and MAP kinases, improvement in the DNA replication process, inhibition of reactive oxygen species, and downregulation of oncogenes and transcription factors [54, 60]. 5-ASA is now thought to be involved in inhibition of protein synthesis, which may contribute to its anti-inflammatory and anti-neoplastic properties [61]. A recent observational study utilizing colonic biopsy specimens from UC patients undergoing long-term 5-ASA therapy studied gene expression levels of 5-ASA targets. Basically, specimens were collected at initial colonoscopy and at a follow-up colonoscopy at 2–6 years in patients with mild to moderate UC on 5-ASA for their maintenance. They observed significant reduction in the transcript levels of inflammatory and CAC-associated 5-ASA targets after prolonged 5-ASA therapy, including Ki-67, p53, CEACAM-1, BCL2L1, NF-kB, and PPARγ [62].

Side Effects

Sulfasalazine (SASP) therapy is usually accompanied with more side effects than the 5-ASA formulations due to the sulfapyridine moiety [2]. Up to 80–90% of patients who cannot tolerate sulfasalazine tolerate 5-ASA preparations [63]. In addition, patients who experience adverse reactions to a particular 5-ASA formulation often tolerate a different preparation.

Side effects of 5-ASA are listed in Table 25.2. The most common side effects of both SASP and 5-ASA are nausea, abdominal pain, diarrhea, dyspepsia, rash, and fever [64, 65]. Some of these effects, such as diarrhea, can be mitigated by a gradual increase in the dose [66]. Rare, but more serious side effects include interstitial nephritis, pancreatitis, pericarditis, pneumonitis, hepatitis, neutropenia, and rarely, worsening colitis [63–65]. The risk of interstitial nephritis and pancreatitis is higher with 5-ASA, while the risk of hepatitis is higher with SASP. Agranulocytosis, hemolytic anemia, and oligospermia have also been reported with SASP [65].

The safety profile of these medications in the pediatric literature is similar in adults [34, 67, 68]. As there are reports of hypersensitivity to 5-ASA causing worsening colitis, it can be challenging to clinically differentiate the gastrointestinal symptoms of diarrhea and abdominal pain as medication side effects from worsening underlying disease. There are no standard guidelines for monitoring these medications and the possible hypersensitivities. However, most studies and literature suggest regularly monitoring renal function.

5-ASA appears to be safe in pregnant and breastfeeding women [69–71]. Only a small amount of the drug is transferred to breast milk. There are reports of allergic reactions in nursing infants in the form of acute watery diarrhea [72, 73]. This usually resolves with cessation of the drug.

Table 25.2 Side effects of 5-ASA and sulfasalazine

5-ASA	Sulfasalazine
Common	*Common*
Headache	Headache
Diarrhea	Nausea
Nausea	Vomiting
Flatulence	Abdominal pain
Abdominal pain	Diarrhea
Rash	Anorexia
	Dyspepsia
	Rash
	Fever
Less common	*Less common*
Nephritis	Pancreatitis
Interstitial pneumonitis	Hepatitis
Worsening of colitis	Drug-induced connective tissue disease
Pancreatitis	Bone marrow suppression
Myopericarditis	Nephrotoxicity
	Interstitial nephritis
	Oligospermia
	Hemolytic anemia
	Folate deficiency
	Alveolitis

Adherence

Adherence to long-term 5-ASA therapy is of great concern in clinical practice. Approximately 40–60% of patients with UC do not take their oral 5-ASA therapy as prescribed [74]. Despite the benefits, the lowest adherence rates are in patients with quiescent UC, who may not understand the importance of continuing treatment when they are in clinical remission. Patients who are non-adherent have an increased risk of disease relapse than those patients who are adherent at least 80% of the time. Many factors contribute to non-adherence including dosing frequency, the number of pills, fear of side effects, and disease extent and duration [75, 76]. Before the introduction of delayed-release and high-dose formulations, 5-ASA was given in three to four divided doses per day. However, these newer formulations require twice daily or daily dosing with the same efficacy of conventional dosing. In a study looking at the persistency of oral 5-ASA therapy, patients receiving Lialda (MMX mesalamine) had significantly higher persistency at 12 months compared with patients receiving other oral 5-ASA formulations [77]. This study was from a large pharmacy database, but correlates with the understanding that simpler treatment plans lead to improved adherence in a number of chronic diseases, including UC [75]. There are few studies on adherence to medical regimens in the pediatric IBD population. Limited data suggest that patient age and emotional and behavioral functioning make a substantial contribution toward predicting adherence to oral 5-ASA [78]. Adolescents in the older age group (15–18 years old), for example, have been found to have lower rates of adherence than younger age groups. Further analysis of the previously mentioned PROTECT study (pediatric UC patients) utilized pill bottles with electronic caps to measure adherence and found that declining adherence over time strongly predicted treatment escalation [79].

A retrospective analysis on long-term mesalamine maintenance in adult patients with UC suggests that adherence, rather than daily dose, reduces long-term flare risk [80]. Thus, it is essential to take the time and discuss with each patient the importance of compliance and persistency.

Conclusion

5-ASA is a well-established first-line therapy for mild to moderate UC in the adult population. This remains an important option for children with mild to moderate UC. Its role in pediatric CD is limited given the lack of data supporting its efficacy. Few studies have addressed the use of 5-ASA in the pediatric population. An important step forward was observed following the Predicting Response to Standardized Pediatric Colitis Therapy (PROTECT) Study. Overall, 5-ASA are deemed effective in specific scenarios and considered generally safe.

Antibiotic Therapy

26

Jessica Breton and Lindsey Albenberg

Introduction

The pathogenesis of inflammatory bowel disease (IBD) is thought to involve an inappropriate inflammatory response to commensal gut microbes in a genetically susceptible individual [1]. Many genetic risk alleles for IBD involve regulation of the epithelial barrier or innate host immune responses to microbial invasion [2]. A multitude of animal studies show that bacterial colonization of the gut is critical for the development of intestinal inflammation [3, 4]. Observations in patients with IBD also support a role for the gut microbiota as IBD usually affects intestinal regions with the highest abundance of bacteria [5] and diversion of the fecal stream can be effective in the management of Crohn disease (CD) [6]. Furthermore, over the past decade, molecular analysis of the human intestinal microbiome using culture-independent DNA sequencing methods has accelerated our understanding of the alteration in microbiota composition and function that contributes to intestinal inflammation [7]. With these advances, dysbiosis characterized by a decrease in community richness, reduced proportions of Bacteroides and Firmicutes thought to have anti-inflammatory properties, and a relative increase in Enterobacteriaceae, including *Escherichia coli* and Fusobacterium, has been described in IBD [7]. Based on our current knowledge of IBD pathogenesis, antibiotics could therefore benefit patients with IBD through different mechanisms, including reducing luminal bacterial content, altering the composition of the gut microbiota, favoring beneficial bacteria, reducing bacterial invasion of intestinal tissue and translocation, as well as targeting an unknown specific pathogen in IBD.

There is clear evidence for the effectiveness of antibiotics in the treatment of inflammation in multiple animal models of IBD [3]. Unfortunately, the evidence for the effectiveness of antibiotics in the treatment of humans with IBD has been inconsistent. This may be partially explained by the various antibiotics trialed, treatment duration, outcome measures, and potentially also by variable level of antibiotic resistance [8]. Nonetheless, recent meta-analyses of randomized controlled trials, all performed in adult populations, have documented a small but statistically significant benefit of antibiotics to induce remission in both CD and UC [9, 10]. Since then, accumulating evidence from uncontrolled and controlled studies, including two important RCTs performed in pediatric IBD [11, 12], have provided additional data to support the role of antibiotics in treating IBD.

We aim to review the current evidence relating to antibiotics in IBD management, evaluating both the available data from previously published adult and pediatric studies, while focusing on specific clinical scenarios. Taken together, this summary of the currently existing efficacy and safety data may help pediatric gastroenterologists integrate antibiotics in current IBD practice.

Antibiotic Use in Crohn Disease

Despite the aforementioned theoretical basis for the role of the microbiome in CD and supportive animal models, the therapeutic role of antibiotics in CD remains controversial. Evidence points towards use of antibiotics in perianal CD, utilizing ciprofloxacin with or without metronidazole as an adjunct to biological therapy, and perhaps post-operative therapy following ileal resection to prevent or delay recurrence, although long-term benefits remain unknown. Recent pediatric studies, including a RCT, also suggest a modest role for antibiotics in luminal CD. We summarize here the evidence for the use of antibiotics in CD, focusing on specific clinical scenarios.

Active Crohn Disease

Several human studies, including RCTs and uncontrolled studies, have been carried out over the last 30 years evaluating the use of antibiotics to induce remission in active CD using different antibiotic combinations, course duration, and end points. Overall, studies have either used antimycobacterial agents targeting Mycobacterium avium subspecies paratuberculosis (MAP) or broad-spectrum antibiotics.

While there are conflicting results for many of these studies, a meta-analysis of 15 randomized controlled trials, all performed in adult populations, demonstrated a small but statistically significant benefit of antibiotics in the treatment of CD (RR 1.33, 95% CI 1.17–1.51, $P < 0.00001$) [13]. Notably, all RCTs utilized clinical indices as the primary outcome measure. More commonly used antibiotics were ciprofloxacin, rifaximin, metronidazole, and clarithromycin. Rifaximin, a minimally absorbed, non-systemic antimicrobial agent showed significant benefit (RR 1.28, 95% CI 1.02–1.62, $P = 0.03$). In the largest study evaluating this antibiotic, Prantera et al. demonstrated that rifaximin for 12 weeks induced clinical remission with few adverse events in patients with moderately active CD (45). The meta-analysis also showed a significant difference in clinical improvement between antibiotic-treated patients and controls, especially in the rifaximin and metronidazole groups. Clarithromycin showed a signal of minimal clinical benefit (RR 1.29, 95% CI 1.03–1.63, $P = 0.03$), hampered by conflicting results among the 2 RCTs included. Among the ciprofloxacin trials, subgroup analysis conducted for treatment of active CD showed a significant difference in the clinical remission or response rate in patients treated with ciprofloxacin for no more than 10 weeks (RR 2.84, 95% CI 1.46–5.52, $P = 0.002$). Indeed, longer treatment duration did not result in any clinical benefit.

Pediatric studies evaluating the use of antibiotics in active luminal CD are limited; however, three recent studies have suggested a modest signal for clinical and biochemical benefits, all using combination antibiotics [11, 14, 15]. In the only available pediatric RCT [11], Levine et al. evaluated if azithromycin-based therapy could improve response and induce remission compared with metronidazole alone. Here, 35 children were randomized to azithromycin 7.5 mg/kg, 5 days/week for 4 weeks, and 3 days/week for another 4 weeks with metronidazole 20 mg/kg/day and 38 children to metronidazole alone, daily for 8 weeks. The combination of azithromycin and metronidazole was superior to metronidazole alone for induction of remission (66% vs. 39% ($P = 0.025$), as defined by a Pediatric Crohn Disease Activity Index (PCDAI) <10, though it did not reach superiority for response. Moreover, significant reduction in calprotectin ($P = 0.003$) in combination therapy only was also observed. These results replicated the success reported in a previous retrospective study ($n = 32$) using the same antibiotic combination [15]. Finally, in a recent retrospective study published by Breton et al. [14], benefit of combination of three–four antibiotics used as salvage therapy in refractory colitis was demonstrated in a cohort of 63 children, including 27 (43%) with colonic or ileocolonic CD. Use of combination antibiotics led to significant decrease in mean Pediatric Ulcerative Colitis Activity Index (PUCAI) from 52 ± 17 to 23 ± 25 ($p < 0.0001$), with 25/63 (39.7%) patients achieving clinical remission (PUCAI <10 points). Clinical benefits of oral antibiotics were independent from IBD diagnosis (CD vs. UC) as shown in multilinear regression analysis.

Anti-MAP Therapies

The association between CD and infection with MAP dates back to the 1930s. MAP causes Johne's disease in ruminants, a granulomatous enteritis which shares clinical and pathological features with CD. These observations suggested a positive causative role for MAP in CD and consequently, led to the hypothesis that a specific anti-MAP therapy would benefit patients with CD [16]. However, multiple groups have tested thousands of IBD tissue samples for MAP without reaching a definitive conclusion [17]. Despite this, some uncontrolled studies have documented a favorable therapeutic response to anti-MAP antibiotics [18–20], and three trials utilizing anti-MAP therapy showed a small but significant signal for prevention of relapse in quiescent CD during prolonged treatment of 8–24 months (RR, 0.62; 95% CI, 0.46–0.84; number needed to treat (NNT), 4) [9]. It should be noted that not all patients had documented MAP infection.

Recently, RHB-104, a novel oral formulation containing a fixed-dose combination of clarithromycin, clofazimine, and rifabutin and showed encouraging in vitro data with synergistic inhibitory activity on MAP strains isolated from CD patients. This antibiotic combination is currently being investigated in a randomized, placebo-controlled phase III trial aimed at evaluating its efficacy and safety in CD [21]. Preliminary analysis, including 331 randomized patients with active luminal CD treated with either corticosteroids or immunosuppressives (50%) or anti-TNF (20%), showed promising results. After 26 weeks of treatment, 36.7% of patients in the RHB-104 group had attained clinical remission (primary endpoint) as compared with 23.0% of the placebo group (P = 0.007). Additionally, 42.2% of the RHB-104 group achieved early remission (week 16) vs. 29.1% of the placebo group ($P = 0.015$). Moreover, in a subgroup of 35 patients assessed endoscopically at 26 weeks, 35.7% of the RHB-104 group had at least 25% improvement in the Simple Endoscopic Score versus 9.5% for the placebo group ($P = 0.048$) [22]. Data on documented MAP infection were not provided in this abstract.

Overall, results from previous adult studies evaluating the therapeutic role of anti-MAP therapy in luminal CD have demonstrated clinical improvement, with some preliminary data suggesting endoscopic recovery. However, additional studies, particularly in pediatrics, are needed before this antibiotic combination take a relevant position in the therapeutic armamentarium for CD management.

Perianal Disease

Population-based studies indicate that 25–40% of patients with CD will develop perianal fistulas during their disease course [23], while the specific prevalence in pediatric patients has been estimated to be between 10 and 15% [24, 25]. One of the primary therapies for perianal fistulizing disease has been antimicrobial treatment, more commonly ciprofloxacin and/or metronidazole. A total of three RCTs have been performed in active perianal fistulizing CD, all in adult populations, and were analyzed in a recent meta-analysis [26]. Only one included antibiotics alone ($n = 25$) [27], while the other two compared the efficacy of ciprofloxacin vs. treatment with a TNF-α antagonist and placebo ($n = 96$) [28, 29]. Thia et al. provided data on remission and response in patients assigned to treatment with ciprofloxacin, metronidazole, or placebo [27]. However, despite trend to response to ciprofloxacin, the study was underpowered to detect statistical significance. Two trials [28, 29] compared combination therapy with a TNF-α antagonist and an antibiotic to TNF-α antagonist monotherapy. The pooled RR demonstrated that a TNF-α antagonist coupled with an antibiotic was more effective than a TNF-α antagonist administered alone for induction of fistula response (RR, 1.58; 95% CI, 1.09–2.28; $P = 0.01$) and healing (RR, 1.94; 95% CI, 1.14–3.29; $P = 0.01$). In summary, these results suggest that antibiotics, in particular ciprofloxacin, may be used as an adjunctive induction treatment in active perianal CD, but not as monotherapy.

Postoperative Recurrence of Crohn Disease

A large proportion of patients with CD require surgery at some point during the course of their disease, and a majority of these patients will eventually develop recurrence of disease requiring additional surgery [30]. Previous studies have suggested that bacteria may play a role in the recurrence of disease as inflammation recurs when the mucosa is reexposed to luminal contents and bacteria [31]. Based on these observations, antibiotics may be beneficial in the prevention of postoperative recurrence of Crohn disease.

A total of five RCTs have evaluated the efficacy of antibiotics in preventing postoperative recurrence of CD, predominantly using metronidazole or nitroimidazole [32–35]. In a meta-analysis of medical therapies used to prevent recurrence of postoperative CD [36], nitroimidazoles (e.g., metronidazole) alone (two RCTs, $n = 81$) showed no improvement compared to placebo in preventing postoperative endoscopic recurrence of CD at 12 months according to a Rutgeerts score of ≥i2. However, nitroimidazole combination therapy with an anti-TNF-α or a thiopurine was more effective than placebo ([RR 0.22; 95% CI 0.07–0.72] and [RR 0.56; 95% CI 0.40–0.80], respectively). When evaluating the efficacy of medical therapies at preventing clinical recurrence at 12 months postoperatively, combination therapy with anti-TNF-α and a nitroimidazole (1 RCT, $n = 45$) was ranked as the most effective treatment and was significantly more effective than placebo [RR 0.06; 95% CI 0.01–0.42]. Thiopurine and nitroimidazole combination therapy (2 RCTs, $n = 80$), and nitroimidazole monotherapy (three RCTs, $n = 111$) were also more effective than placebo. One additional RCT ($n = 33$), not included in this meta-analysis, showed a non-significant trend to reduced endoscopic recurrence with ciprofloxacin monotherapy when compared to placebo [35].

Taken together, a moderate signal for effectiveness in preventing postoperative recurrence has been shown with antibiotics, particularly nitroimidazoles/metronidazole; however, long-term effects are unknown.

Antibiotics in Active Ulcerative Colitis

A number of RCTs and uncontrolled studies have been performed in patients with acute severe colitis (ASC) or chronically active ulcerative colitis (UC) with varying results. Two meta-analyses have demonstrated a higher rate of remission in patients with active UC treated with antibiotics [9, 37]. Since then, data to support the role of antibiotics in treating patients with refractory UC have been accumulating. The heterogeneity of studied regimens and treatment protocols, however, have limited our ability to formulate recommendations for clinical practice. While current adult guidelines [9, 10] recommend the use of antibiotics only if infection is considered, or immediately prior to surgery, the recently published pediatric guidelines for management of ASC specify that a short course of antibiotics may be considered in selected patients refractory to conventional therapies while preparing for colectomy [11]. Here, we focus specifically on pediatric studies illustrating the role of antibiotics as salvage therapy in refractory colitis.

Two Japanese RCTs using a combination of oral antibiotics, amoxicillin, tetracycline, and metronidazole (ATM) against Fusobacterium varium (F. varium) for 2 weeks showed improvement in clinical and endoscopic remission rates in patients with chronic relapsing UC [5, 6]. Likewise, almost

half of the 15 included children (7/15) with moderate to severe refractory UC responded to a two–three-week course of an oral broad-spectrum antibiotic cocktail (including metronidazole, amoxicillin, doxycycline, and—in hospitalized patients—also vancomycin; hereafter referred as the "Jerusalem cocktail") in a pediatric cohort study by Turner and colleagues [7]. Subsequently, a smaller pediatric case series showed similar benefit when using the same antibiotic cocktail in children with refractory UC, reporting a 38% clinical remission rate (3/8 children) [8]. Further, data from a retrospective study of 63 children treated with various versions of the "Jerusalam cocktail" showed a 40% clinical remission rate at 3 weeks. Twenty-six individuals were hospitalized with ASC, of whom seven (27%) entered remission at 3 weeks, with response seen typically within 5 days. Importantly, in this cohort, including patients with either UC, IBD-U, or colonic or ileocolonic CD, with previous or current loss of response to anti-TNFα therapy at the time of antibiotic initiation, clinical benefits of oral antibiotics were found to be independent from anti-TNFα therapy optimization [14].

The results of the only available pediatric RCT evaluating the effectiveness of antibiotic combination in ASC, the PRASCO trial (Pediatric Randomized trial of Antibiotics in acute Severe Colitis), were recently published [12]. Here, pediatric patients (n = 28) hospitalized with ASC were randomized to receive intravenous corticosteroids (IVCS) alone versus IVCS plus the "Jerusalem cocktail." Day-5 PUCAI was significantly lower in the combination antibiotics+IVCS arm vs. IVCS alone (25 ± 16.7 vs. 40.4 ± 20.4, P = 0.037). It should be noted that the trial was not powered to detect differences in need for second-line therapy or colectomy and there were only 2 children in the IVCS arm and 3 children in the antibiotics + IVCS arm who required colectomy during 1-year follow-up (P = 0.89). Interestingly, microbiome data at time of admission showed a decreased in diversity in those with day-5 response in the IVCS arm. Taken together and in agreement with the recently published guidelines for management of pediatric UC [11], a short course of combination antibiotics may be considered as salvage therapy in this refractory population left with limited therapeutic options. Clinical response should be assessed frequently and therapy discontinued if no improvement is documented. Further studies leading to an understanding of the changes in the composition and functions of the gut microbiome in responders and non-responders to combination antibiotic therapy are needed to develop better antimicrobial-based strategies.

Antibiotics in Extra-Intestinal Manifestations of IBD

Limited data exist on the use of antibiotics for extra-intestinal manifestations associated with IBD. Oral vancomycin has shown some promise in treating the subset of pediatric IBD patients with primary sclerosing cholangitis (PSC). Davies et al. treated 14 IBD patients (11 UC) diagnosed with PSC with 50 mg/kg/day of oral vancomycin for 14 days. All showed significant improvement in their alanine aminotransferase, gamma-glutamyl transpeptidase, erythrocyte sedimentation rate, and clinical symptoms. Three patients who were rebiopsied demonstrated reversal of their fibrosis [38]. While this initial study was promising, further studies are needed to verify whether oral vancomycin is an effective long-term treatment in preventing the progression of PSC to cirrhosis in IBD patients.

Additional Considerations

While generally well tolerated, antibiotics can lead to adverse effects that may require discontinuation and should be monitored closely. Ciprofloxacin has been noted to cause arthropathies in immature animals, and long-term use is generally avoided among very young children. There is also one pediatric study which evaluated the side effects associated with long-term metronidazole use. Duffy et al. reported on their experience among 13 patients with pediatric Crohn disease who received metronidazole for 4–11 months [39]. The authors reported that 85% (11 of 13) had peripheral neuropathies based on abnormal nerve conduction velocities or neurological examinations, although only 6 of 11 were symptomatic. Complete resolution of the neuropathy occurred in five children, improvement occurred in three children, and there was no change in one child.

Concerns regarding development of antibiotic resistance with antibiotic exposure have also been raised. Previous data have demonstrated higher prevalence rates of methicillin-resistant Staphylococcus Aureus (MRSA), vancomycin-resistant Enterococcus (VRE), and extended-spectrum beta-lactamases (ESBL) are significantly higher among IBD patients [40, 41]. Certain antibiotics are also associated with increased dysbiosis, resulting in relatively higher fungal abundancy, as shown in an observational pediatric CD cohort initiating therapy for induction of remission [42]. The long-term effects of these antibiotics on the microbiome remain to be studied. Finally, a theoretical increased risk for infection with C. difficile exists and should be considered in patients with prolonged antibiotic use. Interestingly though, a previous study [43] has reported a lower C. difficile infection rate in patients chronically exposed to antibiotics.

Summary

In summary, the current literature, including recent meta-analyses, supports a modest clinical effect of various antibiotics classes in luminal, perianal disease and postoperative prevention in CD, as well as in ASC and refractory

UC. However, much remains unclear, including which antibiotic(s), the duration of therapy, and long-term benefits. When integrated into clinical practice, the use of antibiotics should be judiciously balanced against potential adverse effects and resulting alterations of the microbiome for which the long-term sequelae are unknown.

Nutritional Management of Inflammatory Bowel Disease

27

Anthony Otley, Andrew S. Day, and Mary Zachos

Introduction

While similar in many respects, the inflammatory bowel diseases (IBD) can be classified based on certain distinctive endoscopic and histological characteristics. Clinical manifestations also vary between Crohn disease (CD) and ulcerative colitis (UC), including their impact on nutritional status. A history of weight loss or poor weight gain is a very common symptom at presentation particularly with CD and severe UC [1, 2]. Linear growth impairment is reported even before the onset of intestinal symptoms in almost half of children with CD [3]. Given the early age of onset, such impairment of growth is particularly problematic, with subsequent impact on onset of puberty, self-esteem, and quality of life.

In the treatment of IBD in children, nutrition and growth outcomes are critical indicators of overall well-being and therapeutic success in addition to other therapeutic targets of symptom resolution and mucosal healing. In addition to a multitude of pharmacologic approaches to therapy, there is extensive evidence supporting the efficacy of nutritional therapy in CD. Current guidelines support exclusive enteral nutrition (EEN) as the first-line therapy to induce remission in children with active CD [4]. Despite the obvious advantages, including the direct impact on growth and nutrition and the avoidance of adverse drug effects, nutritional therapy has not been as widely accepted in North America as other parts of the world [5, 6].

Since anemia, linear growth and bone disease have been addressed in alternate chapters, this chapter will focus on nutritional deficiencies and the role of nutritional management in the treatment of IBD, highlighting updates since the last edition.

Nutritional Impairment in Pediatric Inflammatory Bowel Disease

Malnutrition is common in IBD. In a recent systematic review, the main nutritional consequences of pediatric IBD included growth stunting, slower pubertal development, underweight, and vitamin deficiencies. Nutritional impairments were more significant in CD, while overweight and obesity were more common in patients with UC [7]. Several cohort studies have demonstrated weight loss or poor weight gains at the time of initial diagnosis of CD. Griffiths et al. [8] reported that 80% of the 386 children diagnosed with CD over a period of 10 years had a history of weight loss. A registry cohort of 261 patients in northern France found that 27% of children were underweight and 32% had BMI below two standard deviations of normal at diagnosis. At maximal follow-up, 15% continued to suffer from malnutrition. A Danish prospective population-based cohort study reported that children with CD had poor nutritional status at diagnosis compared with the general pediatric population [9]. Among Australian children, a case–control study by Aurangzeb et al. [10] assessing nutritional status found that children with newly diagnosed IBD had lower mean body mass index (BMI) Z scores and weight-for-age percentiles than controls.

Weight loss is seen less commonly, particularly through the course of established UC, but has been seen in up to 65% of children at diagnosis [1]. Kugathasan et al. [11] conducted

a systematic review of 783 children with newly diagnosed IBD from two prospective inception cohorts to examine BMI status at presentation. Most children with CD and UC had a BMI in the normative range (5–84%). Low BMI (<5%) was seen in 22–24% of children with CD and 7–9% of children with UC.

Several interrelated factors contribute to growth impairment in IBD. Chronic suboptimal nutrition has long been implicated as a cause of growth retardation [1, 12–16]. In addition, direct growth-inhibiting effects of pro-inflammatory cytokines (such as Tumor Necrosis Factor (TNF)-α) released from the inflamed intestine have been more recently recognized for their role in growth impairment, as well as indirectly resulting in anorexic effects and early satiety [17]. Symptoms, including nausea, abdominal pain, or diarrhea in association with meals, also limit caloric intake. Localization of disease in the small bowel may lead to partial obstruction and early satiety. Small intestinal involvement may also lead to disaccharide intolerance resulting in shorter gut transit times, pain, and exacerbation of diarrhea. Malabsorption of food components and the diversion of calories to sites of gut inflammation may also lead to impaired weight gain and growth [18]. Thus, enhancement of growth is best achieved through control of intestinal inflammation and assurance of adequate nutrition [19, 20].

Dietary Intake and Body Composition in Children with IBD

Dietary Intake

The impact of CD on growth and body composition is determined by an interaction between the duration and severity of the inflammatory disease process, genetic predisposition, and the extent to which the demands for energy and nutrients are met. It is imperative that the management of children and adolescents with CD combines the control of inflammation while providing optimal nutrition support with adequate protein and sufficient calories to support growth.

The mean energy intake of patients with CD is less than age-matched controls particularly during symptomatic relapses [13] but also while asymptomatic [8]. Pons et al. [21] evaluated the dietary intake of 41 children with CD (18 active, 23 in remission) and compared them with the intakes of 22 age-matched control children without IBD. The energy intakes of the children with CD were less than the estimated energy requirements regardless of disease activity. Fat and carbohydrate intake were found to be lower in patients with CD than in controls, while protein intake was similar in patient and control groups [21].

A recent study from Brazil found that total energy intake was lower than the daily recommended intake (DRI) in 50% of the adolescents with active CD compared to 3.5% in inactive CD and 5.7% in the control group. Protein intake was found to be low in all three groups but significantly lower in the active CD group than in the inactive CD and control groups (68.2% vs. 17.2% and 14.3%, below the DRIs, respectively) [22].

Body Composition

A systematic review, reporting on a total of 1479 children with IBD (1123 CD, 243 UC), attempted to define the alterations in non-bone tissue compartments in children with IBD [23]. Data were highly heterogeneous, in terms of methodology and patients. In this systematic review, six studies were prospective and 11 cross-sectional in design. Body composition methodologies included whole-body dual X-ray absorptiometry (DXA) most commonly, as well as peripheral quantitative computerized tomography (p-QCT), skinfold thickness, isotope dilutional studies, whole-body potassium measurement, total body potassium counting (n = 30), and bioelectrical impedance. Overall, the review concluded that almost all children with CD (~94%) and half with UC (~47%) have reduced lean mass; however, body fat alterations are not well defined. Deficits in female children persisted well after disease treatment.

Deficits in protein-related compartments were reported with lean mass deficits documented in 93.6% of patients with CD and 47.7% of those with UC when compared with healthy control populations. Several studies have confirmed that children with CD have significant deficits in lean body mass (or fat-free mass), which is consistent with cachexia [24–27]. Wiskin [26] found that fat-free mass was related to disease activity regardless of changes in weight and concluded that weight or BMI may mask deficits in lean tissue in the presence of normal or increased proportions of body fat.

Lean mass deficits can persist for many years despite improvements in disease activity and improvement in fat mass [20, 28]. In a study evaluating the role of physical activity and dietary intake on lean mass and muscle torque in 138 children and adolescents with CS, time in moderate to vigorous physical activity was found to be positively associated with both lean mass and muscle torque. Neither caloric intake nor protein intake was associated with either lean mass or muscle torque. Thus, physical activity may play a role in lean mass, muscle torque, and the management of inflammation in CD [29]. Further studies on the role of diet and physical activity on lean mass and disease activity are required.

Body fat composition findings have been inconsistent [23]. Some studies report reductions in body fat in new diagnosis or active CD. For example, Boot et al. [30] suggest proportional reductions in lean and fat mass, as shown by

percentage body fat that did not differ significantly from zero in their combined IBD cohort. In contrast, in an all CD cohort, Burnham et al. [24] report that fat mass adjusted for age and fat mass adjusted for height were not significantly different from controls. Similarly, in 42 children with CD, weight gain over a two-year period was explained by gains in fat mass raising concerns regarding the long-term impact of disease on growth and bone health [31].

In addition to circulating inflammatory cytokines, there are several other factors that are likely to contribute to the reduction in protein compartments in patients with IBD (Table 27.1).

Body composition studies have often been limited by the large proportion of participants that had received concomitant systemic corticosteroids at the time of body composition assessment. Glucocorticoids instigate remission but also promote muscle proteolysis and alter whole-body adiposity [32]. Variations in the glucocorticoid treatment the participants received may have influenced some of the discrepancies in the fat-related data across the studies in this review. Future studies should attempt to differentiate between the effects of therapy and the disease process itself.

There is conflicting data from studies reporting resting energy expenditure (REE) in children with CD. Azcue et al. [25] demonstrated that per unit of lean body mass, there was no difference between REE in patients with CD and controls, whereas patients with anorexia nervosa had significantly reduced REE. In contrast, Zoli et al. [33] found elevated REE in growing children with CD. Surprisingly, the latter study did not reveal any further increase in REE with relapse of disease and suggested that energy may be "diverted" from growth to disease activity during relapse. Varille et al. [34] showed that a lower fat-free body mass in pediatric IBD was associated with higher REE. Thus, these energy imbalances may explain the cachectic changes seen in children with IBD even when disease is in remission. This REE imbalance is most likely driven by nutritional insufficiencies and chronic inflammation.

Height, age, and pubertal status may also influence body composition. Puberty affects fat and muscle compartments and should be accounted for in analysis of body composition. In children with IBD, height is reduced, and bone age and puberty are delayed when compared with healthy children of the same age, possibly explaining some of the body compositional deficits seen [23].

Table 27.1 Factors affecting body composition

Circulating inflammatory cytokines
Medications, particularly glucocorticoids
Malnutrition
Resting energy expenditure
Height, weight, and pubertal status
Sex
Physical activity

Sex differences can also influence body mass composition, as reported by Thayu et al., [27] who studied the body composition of 74 children with CD at diagnosis. They found that boys with CD at diagnosis had significant fat-free mass deficits consistent with cachexia, whereas girls demonstrated both fat mass as well as fat-free mass deficits consistent with wasting. In a recent systematic review, lower lean mass was common to both sexes in CD and UC, but deficits in females persisted for longer, possibly because males are known to accumulate lean tissue at puberty, while females reach peak lean mass before puberty [23].

The effect of malabsorption may lead to reduction in protein compartments due to protein-losing enteropathy that result in fluid shifts [25]. In addition, physical activity is important for muscle and bone strength in growing children and may be limited in children with IBD even when their disease is asymptomatic. Werkstetter [35] compared 39 patients with IBD in remission (or with only mild disease activity) with 39 healthy controls. Muscle function assessed by measuring handgrip strength was reduced in children with CD, which corresponded to deficits found in muscle cross-sectional area of the upper limb. In addition, individuals with IBD tended to take fewer steps per day and engage in shorter periods of physical activity, particularly among females and patients with mild disease. Exercise studies in adolescents with CD have shown impaired fat metabolism during activity with a greater reliance on carbohydrates to meet the energy demands of submaximal exercise [36].

The clinical significance of muscle deficits in children with CD is not known; however, lean mass deficits may be associated with poor physical functioning and greater infection risk during childhood and compromised peak bone mass by young adulthood. Adult studies suggest that body fat composition predicts infectious complications following bowel resection in CD [37]. In adults, low muscle mass and sarcopenia are common and may be predictive of osteoporosis [38]. Further study of the long-term impact of altered body composition in children with IBD is required, as this may have clinical importance in terms of nutritional and pharmacological management, even when disease is in remission.

Because of the difficulty ensuring adequate energy and nutrient requirements of children with IBD, particularly during flares, active monitoring of nutritional status must be undertaken throughout childhood but especially in adolescence. Hannon et al. [39] demonstrated that in stable adolescents with CD, enteral nutrition promotes anabolism by suppressing proteolysis and increasing protein synthesis. Thus, where indicated, aggressive nutritional intervention should be initiated before puberty, whether disease is active or in remission, to correct the energy deficits and maximize growth potential.

Micronutrient Deficiencies

Low concentration of plasma micronutrients is commonly reported in patients with IBD. Dietary intakes of children and adolescents with IBD may be compromised in micronutrient content in addition to protein and energy due to many factors, including decreased food intake, intestinal losses, malabsorption, and drug effects [40].

Specific micronutrient and vitamin deficiencies are encountered more commonly with CD than with UC. Hendricks et al. [13] compared a group of adolescents with CD and growth failure with a control group of adolescents with CD who were growing normally. Mean serum ferritin levels were significantly decreased in both groups, and mean plasma zinc levels were borderline low in the growth failure group and low in the control group. Dietary zinc intake was below the recommended dietary allowance (RDA) in 88% of the group with growth failure and 44% of controls (64% combined) and less than 75% of the RDA in 41% of all adolescents with CD. Dietary iron intake was also below the RDA in 24% of all adolescents with CD, with one adolescent in the growth failure group consuming less than 75% of the RDA. One-third of adolescents were consuming less than 75% of the RDA for calcium. In evaluation of 41 children with CD compared to age-matched controls, calcium intake was significantly less than the Australian recommended daily intake (RDI), and iron intake approached less than RDI [21]. Vitamin D is a key factor in both bone mineralization and immunomodulation. Levin et al. [41] retrospectively assessed vitamin D in a group of 78 Australian children with IBD (70 CD, 5 UC, 3 IBDU) and explored associations between vitamin D status and clinical factors. Using a level of 50 nmol/L or less to indicate deficiency and 50–75 nmol/L to indicate insufficiency, 19% of children were vitamin D deficient and 38% were insufficient, respectively. Levels were not found to be associated with disease location or use of immunosuppressive drugs. Children with vitamin D deficiency had significantly greater corticosteroid exposure than those with normal status. In Canadian children with newly diagnosed IBD, vitamin D deficiency was seen in 52% ($n = 44$) of children, and correlated with the greatest frequency of sarcopenia in children younger than 13y with CD [42].

Alkhouri et al. [43] investigated the prevalence of vitamin and zinc deficiencies in 61 children with newly diagnosed IBD (80% with ileal inflammation) compared to age- and sex-matched controls. Sixty-two percent had vitamin D deficiency (vs. 75% in the controls). In contrast to other studies, this report did not demonstrate folate or vitamin B12 deficiency in any subjects with IBD suggesting no reason for routine monitoring. However, vitamin A (16% deficient) and zinc (40% deficient) deficiencies were statistically more prevalent among those with IBD than controls, suggesting that levels should be assessed at the time of diagnosis. In addition, since vitamin D deficiency was so common in the population tested, routine screening and supplementation are warranted [43].

Older studies of micronutrient intakes in CD have found mean intakes of zinc, copper, iron, calcium, folic acid, vitamin C, and vitamin D to be significantly ($P < 0.05$) lower than age-matched controls and RDAs [17]. Essential fatty acid status may also be altered, in association with low body mass index and disease activity [44]. Malabsorption of fat-soluble vitamins can be an issue in patients with ileal disease [45, 46]. Gerasimidis et al. [47] looked at the impact of Exclusive Enteral Nutrition (EEN) on body composition and circulating micronutrients in plasma and erythrocytes of 17 children with active CD. At baseline, several children presented with suboptimal concentrations of carotenoids, trace elements, vitamins C and B6, and folate in plasma but not in erythrocytes. The same group later reported anemia in 72% of children with IBD at diagnosis. Children with CD at diagnosis had significantly shorter diagnostic delay and a lower BMI than those who were not. After EEN, the frequency of severe anemia decreased (32–9%; $P = 0.001$). Extensive colitis was associated with anemia in UC [48]. Several additional studies have evaluated the prevalence of anemia in children with IBD, both at diagnosis and follow-up. Using the WHO definition of anemia, prevalence ranges from 44% to 74% at diagnosis and 25% to 58% at one-year follow-up [49]. Anemia should therefore be routinely monitored and treated as it is the most common extraintestinal manifestation of IBD (refer to Chap. 10 for further details).

Fritz et al. [50] recently performed a systematic review to critically analyze the current research on micronutrient deficiency in children with IBD and synthesized these data to provide evidence-based guidelines for nutritional surveillance in this population. From the 39 studies included in the final review, the data demonstrated iron and vitamin D as the most common deficiencies in children with IBD. Vitamin B12 and folate deficiency are rare. Zinc deficiency, while uncommon, occurs at a higher rate in patients with CD than in healthy controls. There were limited data on vitamins A, E, and C, and selenium, but deficiency of these micronutrients seems rare.

In a recent study by Ehrlich et al., [51] the status of trace elements, minerals, and vitamins was retrospectively evaluated in a large cohort of children with IBD. Out of 359 children with IBD with a median age at diagnosis 14.1 years, 240 (67%) were diagnosed with CD and 119 (33%) with UC. Median follow-up time was 7 years (IQR 5–10). The prevalence of deficiencies in patients with CD at diagnosis and last follow-up, respectively, were iron (88% and 39.5%), zinc (53% and 11.5%), vitamin D (39% and 36%), and folic acid (10% and 13%). In patients with UC, frequencies were as follows: iron (77% and 40%), vitamin D (49% and 33%), zinc (31% and 10%), and folic acid (3.8% and 9.7%).

Deficiency of magnesium or vitamin B12 was rare. For both diseases, iron deficiency was associated with hypoalbuminemia. Deficiencies in iron and zinc were more common in patients with CD than those with UC [51]. They concluded that deficiencies in iron, zinc, and vitamin D are common at diagnosis of IBD in childhood and persist during follow-up requiring ongoing assessment throughout the course of disease.

Vitamin B12 (cobalamin) is selectively absorbed in the distal ileum, bound with gastric-derived intrinsic factor. Patients with ileal CD and/or ileal resection and/or clinical deficiency features should be screened yearly for B12 deficiency [52] . Patients with clinical deficiency should receive 1000 mg of vitamin B12 by intramuscular injection every other day for a week and then every month for life [53] . Patients with more than 20 cm of ileum resected should receive 1000 mg of vitamin B12 prophylactically also every month and indefinitely [54].

Despite recognition of the occurrence of potential nutritional deficiency in individuals with IBD, only ESPEN has recommended nutritional deficiency screening in this population [54, 55] stating that patients with IBD should be checked for micronutrient deficiencies on a regular basis and specific diets should be appropriately corrected. The extent of micronutrient deficiency screening and whether or not to supplement a child's diet should be considered on an individual basis, following dietary assessment, as firm recommendations for vitamin and mineral supplementation await future studies [19]. Kleinman and colleagues [56] have suggested that patients should be recommended a multivitamin/mineral to meet 100–150% of the RDA when dietary intake is less than expected. Santucci et al. [57] also suggested that a daily multivitamin supplement may correct most deficiencies but is no guarantee of adequacy and iron, zinc and Vitamin D are likely to require specific replacement regimens.

Vitamin and mineral supplement adherence has been examined by two studies. In a cross-sectional study examining self-reported adherence to IBD maintenance medications as well as supplements, an average adherence rate of 80% was reported across all medications and supplements combined [58]. More recently, adherence specifically to vitamin and mineral supplements was assessed in 49 youth with IBD aged 11–18 years using a validated interview [59]. Mean adherence rates ranged from 32 to 44% across supplements, which included multivitamins, calcium, or iron. Youth who did not know the reason for supplementation (approximately 25% of the sample) displayed substantially poorer adherence than did those with moderate or high levels of knowledge, across all supplements. Poor compliance, particularly in adolescents, is common with multivitamin supplements and patient education about the rationale behind their use is important [59].

Elevated Body Mass Index in Inflammatory Bowel Disease

Although most emphasis of the nutritional aspects of IBD is focused upon impaired nutritional status, the increasing rate of childhood obesity is also relevant in children presenting with acute IBD. Several cohorts have found that children with IBD are at comparable risk of overweight and obesity as the general population. Observations by Kugathasan et al. [11] from two large multicenter North American cohorts revealed that 10% of children with CD and 20–30% of children with UC had a BMI at diagnosis consistent with overweight or risk for overweight. A large multicenter cohort of 1598 children with IBD found that approximately one in five children with CD and one in three with UC are overweight or obese [60]. Rates of obesity in UC are comparable to the general population. Attempts to evaluate whether overweight and obese status is associated with patient demographics or disease characteristics found that sociodemographic risk factors for obesity in the IBD population were similar to those in the general population. Prior IBD-related surgery was the only disease characteristic associated with overweight and obesity in children with CD (OR 1.73, 95% CI 1.07–2.82) [60]. In a multicenter retrospective study of 675 patients there were no differences in age, weight, height, and disease activity between the 368 children with CD and the 307 with UC. [61] The prevalence of overweight and obesity in newly diagnosed children with IBD was 8.4% and was higher in patients with UC than in patients with CD.

Obesity is associated with a pro-inflammatory state that may be involved in the etiology of IBD. However, a prospective cohort study conducted on a sample of 300,724 participants recruited for the European Prospective Investigation into Cancer and Nutrition study found no association in obesity, as measured by the BMI with the onset of incident UC or CD [62]. However, obesity has been found to be independently associated with worsening disease activity [63]. In this adult cohort study of the impact of obesity on disease activity and Patient-Reported Outcomes Measurement Information System (PROMIS), 7296 patients with IBD were included in a much larger cross-sectional and longitudinal study of an Internet-based cohort of >15,000 patients living with CD and UC. Obesity prevalence was 19.5% in 4748 patients with CD, and 20.3% in 2548 patients with UC with intact colon. Obesity was independently, and in a dose-dependent fashion, associated with an increased risk of persistent disease activity or relapse in both patients with CD (class II or III obesity vs. normal BMI: adjusted odds ratio, 1.86; 95% confidence interval, 1.30–2.68) and UC (adjusted odds ratio, 2.97; 95% confidence interval, 1.75–5.17). Obesity was also independently associated with higher anxiety, depression, fatigue, pain, and inferior social function scores in patients with CD and

UC at baseline and with worsening depression, fatigue, pain, and social function in patients with CD on longitudinal assessment [63]. Similar detrimental effects have been reported in a study of 152 children, 85 with CD and 67 with UC, where BMI in the lower and upper quartiles was significantly associated with higher risk of disease exacerbation in the year following diagnosis [64].

General Management of Nutrition in Inflammatory Bowel Disease

Monitoring Nutritional Status

Assessment for under- (or over-)nutrition is an essential component of medical care of children with IBD. According to ESPEN guidelines [54], patients with IBD are at risk and therefore should be screened for malnutrition at the time of diagnosis and thereafter on a regular basis.

At a minimum, screening should include measurement of body weight and height for age, with calculation of BMI. Although a variety of screening tools exists, the tools have poor ability to discern different levels of nutrition risk for children with IBD [65].

Nutritional status can be expressed in terms of the degree of height deficit (shortness), weight deficit (underweight or lightness), or relative weight for height or BMI for age (thinness). Each component captures a different aspect of growth, and interpretation is further complicated during puberty when differences in measures for thinness can be driven by changes in lean muscle and/or fat [26]. Growth parameters should be routinely collected and graphically recorded on standardized charts. It is important to obtain information on familial growth patterns, particularly parental heights, as well as pre-illness measurements to assess growth potential and the impact of disease on growth, respectively.

Ongoing assessment of nutritional status includes history, physical examination, and laboratory testing. History should attempt to obtain information on appetite, weight changes, and dietary intake (often with the assistance of a registered dietician), as well as identification of medications and nutritional or herbal supplements, including vitamins and minerals. Review of psychosocial factors such as economic and cultural or environmental influences may be useful.

Physical examination, in addition to growth parameters and BMI, should include anthropometric assessment of body habitus along with recordings of sexual maturation by Tanner staging. Examination may reveal signs of generalized malnutrition or specific nutrient deficiencies.

Laboratory tests are valuable in assessment of specific nutrient deficiencies; however some measures of nutritional status can also be affected by inflammation (e.g., serum albumin and ferritin). Serum pre-albumin has a much shorter half-life (2 days) than albumin (18–20 days) and may be more useful in the assessment of nutritional status changes with nutritional support [66].

Other potential tests of nutritional status are urinary creatinine/height ratio or 3-methylhistidine determinations which reflect somatic (muscle) protein status and 24-h urine urea nitrogen which reflects protein catabolism. However due to the difficulty obtaining accurate specimens and assumptions required for interpretation, these lab tests are not used in routine clinical practice. Additional research techniques for assessment of nutritional status are dual-energy X-ray absorptiometry [24], bioelectric impedance analysis, and total body electrical conductance to determine total body water and fat mass and isotopic labeling of various molecules to determine energy expenditure and metabolic turnover rates [19].

Serum leptin may also have a role in nutritional assessment as a marker of fat stores [67–69] and has been found to be lower in children with severe protein energy malnutrition [70]. Controversy exists in the literature regarding the correlation of leptin levels with inflammation or whether it simply reflects nutritional status regardless of underlying disease. Hoppin et al. found no difference in serum leptin levels between children with IBD and controls and concluded that serum leptin levels depend on BMI and sex and not on disease activity or severity [71].

Aurangzeb et al. [10] explored the relationship between leptin and BMI in newly diagnosed children with IBD in comparison to controls. Significantly lower mean serum levels were found in 28 newly diagnosed patients compared to 56 controls (2.32 pg/mL ± 1.88 vs. 5.09 pg/mL ± 4.86, p +0.009). In this group of children with IBD, leptin levels did not correlate with the degree of inflammation, as defined by serum markers of inflammation. Further studies are required to elucidate the role of leptin in nutritional assessment of patients with IBD.

Following diagnosis of IBD, there are numerous ongoing aspects of nutritional management to address. Nutritional issues relating to therapy may arise. The use of steroids often leads to increased appetite and commonly alters fluid balance with initial fluid retention and weight gain that only partially reflects improvements in underlying nutritional status. Steroids are clearly linked with impaired bone mineralization, with enhanced resorption, and with decreased new bone formation [72, 73]. Adequacy of calcium and vitamin D intake must be reviewed regularly. Inhibition of linear growth and altered final height, due to suppression of insulin-like growth factor-1 (IGF-1), is also a feature of daily corticosteroid therapy [74].

Other medications may interfere with the absorption of specific micronutrients. Sulfasalazine may interfere with folate metabolism by reducing absorption; however, daily supplementation does not appear necessary [75]. In con-

trast, folate supplementation is required when the immunosuppressive drug methotrexate is used, as this drug acts to inhibit the conversion of folate to the active moiety tetrahydrofolate [76].

Questions related to nutrition and which foods to avoid are among the commonest raised by families both at diagnosis and in routine follow-up. The current consensus from the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) is that diets of children with CD should be well balanced, based on the Food Guide Pyramid, and follow dietary reference intakes [19]. Brown et al. [77] created a "global practice guideline," which attempted to consolidate the existing information regarding diet and IBD proposed by medical societies or dietary guidelines from patient-centered, IBD-related organizations. The dietary suggestions included nutritional deficiency screening, avoiding foods that worsen symptoms, eating smaller meals at more frequent intervals, eliminating dairy if lactose intolerant, limiting excess fat, reducing carbohydrates, and reducing high-fiber foods during flares. Enteral nutrition was recognized as being recommended for CD in some parts of the world more often than others (e.g., more in Japan than in the USA). According to the most recent ESPEN guidelines [54, 55], no specific diet needs to be followed during remission phases of IBD. Dietician counseling as part of the multidisciplinary care is recommended to improve nutritional status and avoid malnutrition and nutrition-related disorders [54, 55]. General advice on healthy eating can be given to patients with UC and Crohn, aiming for a Mediterranean-style diet is supported by recent studies [78].

Overall, CD, in contrast to UC, can have a tremendous and long-lasting impact upon nutritional status but can also be successfully treated with nutritional therapy. Minimal evidence exists for the treatment of UC with enteral nutrition. Wedrychowicz et al. [79] evaluated the effect of EEN on vascular endothelial growth factor (VEGF) and transforming growth factor beta 1 (TGF-β1) in both UC and CD. However, due to the concomitant use of antibiotics and 5ASA in this study, the role of EEN in UC is impossible to determine from this study. Although there is not yet definitive data illustrating a role for EEN in the management of active UC, there are several lines of evidence that suggest a potential benefit for dietary interventions, including the effects on the microbiome in CD that are likely also relevant to UC. Furthermore, the use of EEN in children with UC may improve bone health [80]. Prospective studies are needed to evaluate the role of EEN and other dietary interventions in UC in children. However, given the current paucity of data, the remainder of this chapter will focus on the nutritional impact and management of CD.

History of the Use of EEN in CD

The effectiveness of elemental diets was originally identified in 1973 by Voitk [81] when it was used in adults with CD to provide preoperative nutritional support. The first controlled study of an elemental diet in adults with CD determined that an elemental diet was equally effective in the induction of remission as corticosteroids [82]. The role of EEN in pediatrics, where EEN had the important additional benefit of supporting growth, was first reported by Sanderson and colleagues in 1987 [83].

The type of EEN utilized has evolved from the initial use of elemental feeds by nasogastric tube toward using polymeric feeds, which have better palatability, lower cost, and the option of oral administration. Although still the subject of some debate, practice has moved toward the use of EEN for any disease location in the gastrointestinal tract. Ongoing research continues to explore the mechanism of action of EEN and strategies to optimize acceptance and utility of nutritional therapy.

Postulated Mechanisms of Action of EEN in CD

Our understanding of the mechanisms by which the beneficial effects of EEN are achieved in active CD remains incomplete. Various mechanisms have been proposed over time, including relative gut rest, avoidance of allergenic elements, nutritional mechanisms, alteration of the intestinal microflora, and specific anti-inflammatory effects. Gut rest does not appear to be a complete explanation as complete gut rest, with total parenteral nutrition and nil by mouth, does not lead to enhanced rates of remission. Avoidance of dietary protein allergens also does not seem to explain the effects of EEN fully as the benefits of EEN are shown to the same whether an elemental or polymeric formula is utilized. Recent studies have focused upon changes in the intestinal microbiota, direct anti-inflammatory activities, and effects upon gut barrier function.

The Intestinal Microbiota

The intestinal microbiota plays a central role in the pathogenesis of IBD, although current data does not indicate any one species as being causative on its own. The impact of EEN upon the intestinal microbiota has been examined in human settings and in an animal model of IBD.

Two early studies used molecular techniques to examine the impact of EEN upon the flora in the context of IBD [84, 85]. These reports illustrated changes in the flora consequent

to the introduction of the enteral formula. A more recent study employed a more comprehensive molecular approach (denaturing gel gradient electrophoresis or DGGE) with a wider selection of probes, enabling a broader profile of the changes [86]. This study showed a reduction in the diversity of the bacterial species and changes within all the main bacterial groupings. These changes were sustained, with effects well beyond the period of EEN alone.

A subsequent study utilized 16S rRNA and whole genome high-throughput sequencing to ascertain additional understanding of the impact of EEN upon the microbiota [87]. All five children included in this study had dysbiosis at diagnosis of CD. EEN resulted in a prompt reduction of the number of operational taxonomic units (OTUs), which correlated with induction of disease remission. Subsequent exacerbation of disease leads to an increase in the number of OTU. Furthermore, six specific *Firmicutes* families were shown to correlate closely with disease activity during and after exposure to EEN [87]. Further studies from the UK [88] and the USA [89] have utilized advanced molecular tools to further define changes in the intestinal microbiota consequent to EEN.

These reports (and others) were further summarized in a recent systematic review [90] . In addition, Pigneur and colleagues [91] demonstrated that EEN induced high rates of mucosal healing and that this was associated with a particular change in the microbiome. Although each of these reports indicates the impact of EEN, they do not yet fully illustrate whether these changes result solely from the difference in the nutrients supplied in the formulae or how these changes then influence mucosal inflammation.

Data from an animal model of CD complements these human data. Using an IL-10 knockout model of gut inflammation, a Japanese group assessed changes after the administration of elemental formula [92]. The bacterial diversity and bacterial number were both reduced in those animals given the formula compared to a control group with normal mouse diet.

Two studies have also assessed patterns of the intestinal flora consequent to enteral feeding in non-IBD contexts. Smith et al. [93] assessed changes in bacterial composition in the stomach and duodenum of adults receiving enteral formulae via a gastrostomy for various non-inflammatory indications. Higher levels of bacterial DNA were found in the upper gut after enteral feeding. The fecal flora was not examined in this patient group. A second study examined the fecal microflora in a small group of adults requiring exclusive nasogastric feeding for a variety of medical indications [94]. Individuals with IBD were excluded from this study. The subjects provided stools at the start of, during, and at the end of a 14-day period of enteral feeds. Molecular methodology was employed to assess the flora (fluorescence in situ hybridization). Overall the investigators did not observe consistent changes in the microflora during this short period. However, they did note changes in particular groups of organisms in the individuals who developed diarrhea secondary to the enteral feeds. However, these effects differed to those seen consistently in individuals with IBD.

Anti-Inflammatory Activities of Enteral Formulae

Meister et al. [95] demonstrated in vitro anti-inflammatory activities of formulae in a series of experiments using explants (short-term culture of colonic tissue samples obtained endoscopically). These samples were incubated directly with an elemental formula or maintained in a control situation. The production of interleukin (IL)-1-β, IL-1-receptor antagonist (RA), and IL-10 was used as an indicator of cell responses. The cells incubated with formula lead to an increase in the ratio between IL-1RA and IL-1-β, compared to the control cells ($P < 0.05$). These changes were also evident when full protein-based formulae were employed. Further, these changes were not observed in biopsies taken from individuals with UC or with non-inflamed IBD tissue.

An in vitro model of intestinal cells has been used extensively to elucidate the anti-inflammatory effects of formulae [96]. These experiments utilized established colonic epithelial cells lines, which were stimulated with one or more pro-inflammatory cytokines to replicate intestinal inflammatory events. Polymeric formulae (PFs) were then used to rescue or to prevent the cellular response to this inflammatory insult, with interleukin (IL)-8 utilized as an indicator of epithelial response. The effect of adding PF to this model was assessed in a series of different ways, with particular use of a two-compartment model, whereby the PF was separated from the inflammatory cytokine. Experiments using this model demonstrated that PF leads to alteration of the inflammatory effects of TNF-α (reduced levels of IL-8) and suggested alteration of cellular signal transduction pathways as a mechanism for this finding [96].

A similar model was utilized to show that the application of PF resulted in modulation of nuclear factor (NF)-κB activity, thereby modulating the production of pro-inflammatory cytokines [97]. Subsequent studies showed that vitamin D and two specific amino acids (arginine and glutamine) mediated the effects of PF in this setting [98]. These findings suggest that active components within the nutritional products used for EEN may explain the anti-inflammatory effects seen in vivo. More recently, an animal model has again shown that EEN mediated reduced gut inflammation via inhibition of NF-κB activation, in conjunction with regulation of the p38/MSK1 pathway [99].

Other investigators have examined the impact of EEN upon other mucosal responses. Teng et al. [100] demonstrated that EEN utilized in an animal model of gut inflammation contributed to decreased expression of IL-17A along with concomitant reduction of IL-17A protein production. Variable patterns of mucosal cytokines were noted in a small group of six children managed with EEN [101]. Together, these data indicate mucosal anti-inflammatory effects consequent to EEN.

Epithelial Barrier Function

Disruptions to barrier function, measured as altered intestinal permeability, are demonstrated in individuals with CD [102]. It is unclear whether these are primary events or are consequent to inflammation. Data showing similar alterations in permeability in asymptomatic first-degree relatives of people with IBD suggest that these could be primary changes, which could thereby predispose to the development of inflammatory changes in some individuals [103]. Intestinal permeability improves with resolution of inflammation [104], including following EEN [105].

In vitro studies have explored these mechanisms further [106] . These studies employed an in vitro model of inflammation similar to that described above, whereby intestinal epithelial cell monolayers were stimulated with pro-inflammatory stimuli and then rescued with PF. Using an Using chamber, these experiments demonstrated that PF leads to complete reversal of cytokine-induced changes in transepithelial resistance, short-circuit current, and horseradish peroxidase flux. In addition, PF was shown to correct cytokine-induced changes in tight junction proteins and key mediators of tight junction function. A subsequent series of confirmatory experiments were conducted using an animal model of colitis. Colitis induced in interleukin-10 knockout mice resulted in altered barrier function. These changes were reversed by the administration of a PF to the affected animals. PF in this setting also had reversal of mucosal inflammatory changes [107].

Further support for nutritional modulation of barrier dysfunction comes from another animal study [108]. The administration of a multi-fiber mix to the mice in these experiments enhanced barrier function and ameliorated inflammatory changes.

Although the molecular mechanisms of these observations are not yet defined, these findings provide significant clues to the activity of EEN in vivo. More work is required to clearly define the molecular events behind these important observations and also to translate these findings to the in vivo situation.

Effectiveness of Exclusive Enteral Nutrition Therapy in Crohn Disease

Induction of Remission

Multiple pediatric studies have indicated that approximately 60–90% of children fed an exclusive liquid diet will enter clinical remission. As shown in several studies and a meta-analysis [109] updated with the most recent randomized study [110], high remission rates with EEN are achieved irrespective of the type of enteral feed (14/15 93% achieved remission with elemental diet vs. 15/19 73% on polymeric diet, n.s.). In addition, a number of pediatric retrospective studies have found that EEN is more effective than corticosteroids in improving disease severity and growth deficiency. Among these is a large retrospective study from Canada, including 229 patients, where EEN has been commonly used as induction therapy [111]. In addition, a recent retrospective study from China where the incidence of CD is much lower, EEN was also found to more effective than corticosteroids (90% vs. 50% $P < 0.05$) [112]. Another large Canadian cohort found equal efficacy to corticosteroids [113].

In addition, there have been numerous open and comparative studies evaluating the use of EEN versus corticosteroids in adults [114–117] (and children [83, 118, 119] with CD. Recently, patients enrolled at diagnosis into the growth relapse and outcomes with therapy in Crohn disease (GROWTH CD) study were evaluated for disease activity, CRP, and fecal calprotectin for 1 year. Clinical remission at 12 weeks with EEN was superior to corticosteroids both when considering remission by PCDAI (OR, 2.07; 95% CI, 1.8–18.3) or combined normal PCDAI and CRP (OR 3.4; 95% CI, 1.3–9) [120]. The latest studies continue to show the effectiveness of EEN either in comparison to medications or partial enteral nutrition (PEN) combined with novel dietary approaches.

In the original meta-analyses investigating the use of EEN in CD, including both pediatric and adult studies, steroids were found to be more effective in the induction of remission [121–124]. However, these analyses involved predominantly adult studies of varying quality and many confounding factors. There have now been four pediatric meta-analyses combining data from studies with EEN [124–127] showing no difference between steroids and EEN. Swaminath et al. [124] included 8 studies and 451 patients and demonstrated no difference between corticosteroids and EEN (OR 1.26, 95% CI 0.77–2.05). When only those patients who completed the treatment were compared by per-protocol analysis, a slightly [but statistically significant] larger proportion of patients on EEN reached clinical remission. Most recently, Yu et al. [127] analyzed 13 stud-

ies, including 349 patients treated with exclusive elemental diet and 311 pediatric patients treated with corticosteroids and also found no difference in remission rates between groups. Additional subgroup meta-analysis of only RCTs showed that EEN was more effective than corticosteroids (OR 2.62 90%CI 0.86–7.94; $p = 0.09$). In addition, the most recent meta-analyses examined mucosal healing and found that patients who received EEN were more likely to achieve both endoscopic and histologic mucosal healing than those who received corticosteroids [124, 127].

Day et al. [128] have identified poor compliance resulting in inadequate volume of EEN received as a major reason why some patients did not achieve remission. The effect of compliance was explored in a recently updated Cochrane meta-analysis by performing a sub-analysis of the data on a per-protocol basis, excluding patients who withdrew due to lack of acceptability of nasogastric tube feeding or palatability of the enteral feed. When comparing those who completed EEN therapy to the corticosteroid group, efficacy was equivalent for induction of clinical remission [109]. Since the effectiveness of EEN in inducing remission in CD is now well established, but is felt to be poorly accepted over a prolonged period as the sole source of nutrition, Levine et al. [129] chose tolerance as the primary endpoint of a novel study comparing PEN with the Crohn disease exclusion diet (CDED). They defined the patient's tolerance to the diet by week 6 by withdrawal from the study because of patient's refusal to continue the diet. Four patients randomized to EEN withdrew within 48 hours with refusal to continue to take Modulen orally. The primary endpoint of tolerance was significantly different, favoring CDED+PEN over EEN: 39 of 40 (97.5%) vs. 28 of 38 (73.7%), $P = 0.002$ (Delta 23.8%; 95% Confidence Interval [CI] 9.0%–38.6%); odds ratio (OR) 13.92 (95% CI 1.68–115.14). Compliance with both regimens showed no significant difference (CDED+PEN 82.5%, EEN 76.5% $p = 0.52$) indicating that the majority of children have very good adherence to the different types of nutritional therapy.

In summary, existing studies and meta-analyses demonstrate high remission rates with EEN therapy depending on adherence. With efficacy to corticosteroids being similar, the advantages in mucosal healing, lack of corticosteroid side effects, and improvements in nutritional status strongly support the use of exclusive enteral nutrition over corticosteroid therapy for induction of remission. Current guidelines support EEN as the first-line therapy to induce remission in children with active CD [4, 130].

Comparative Effectiveness of Nutritional and Biological Therapy

In a recent prospective study of 90 children with CD, clinical outcomes of disease activity, quality of life, and mucosal healing estimated by fecal calprotectin were compared between PEN ($n = 16$), EEN ($n = 22$), and anti-TNF therapy ($n = 52$). Clinical response (PCDAI reduction ≥15 or final PCDAI ≤10) was achieved by 64% on PEN, 88% EEN, and 84% anti-TNF (test for trend $P = 0.08$). FCP ≤250 μg/g was achieved with PEN in 14%, EEN 45%, and anti-TNF 62% (test for trend $P = 0.001$). Improvement in overall quality of life was not statistically significantly different between the three groups [131]. Further clinical and cost-effective studies are required to aid in the therapeutic decision pathway of pediatric CD.

Adult studies [132] also suggest a role for EEN for anti-TNF refractory Crohn disease.

Maintenance of Remission

Following the induction of remission, the use of EN as maintenance therapy may have additional benefits to prolonging remission, including delaying the requirement for further therapy (i.e., corticosteroids) and optimizing growth and nutrition. Most often maintenance EN is practiced in combination with maintenance medical therapy, but limitations of adherence may similarly impact enteral therapy as it does medical therapy.

To date the majority of the literature on maintenance of remission of CD with EN therapy has been in adult patients, mostly arising from multiple centers in Japan. A recent meta-analyses [133] to assess the remission maintenance effect of EN ($n = 857$) included 8 studies. The remission or response maintenance effect in the EN group was 203/288 (70.5%), which was higher than 306/569 (53.8%) in the non-EN group. The odds ratio for long-term remission or response using fixed effects model and random effects model were 2.23 (95% CI 1.60–3.10) and 2.19 (95% CI 1.49–3.22), respectively. There is a smaller and older body of work in pediatrics.

While EEN is often used as an adjunct to medical and surgical therapy in complex pediatric Crohn disease, further study is required to better define its indications, efficacy, and mechanism of action in complex clinical phenotypes or disease complications.

Maintenance of Remission with EN in Adults

Akobeng and Thomas [134] conducted a Cochrane review of enteral nutrition for maintenance of remission in CD. They identified only two maintenance studies in adult patients which were randomized controlled studies, one where the comparison groups were two types of formula (elemental vs. polymeric) [135] and another where a maintenance EN regimen was compared with regular diet [136]. Verma and colleagues [135] studied 33 adult steroid-dependent patients

with CD in remission, who were randomized to elemental ($n = 19$) versus polymeric ($n = 14$) formula, and followed for maximum of 12 months. Fourteen or 43% of the total population remained in remission and off corticosteroid at 12 months, with no significant difference in relapse rates noted between the two formula groups. They did not identify any disease- or patient-related factors that predicted response to enteral nutrition; however, their sample size was small limiting their ability to make meaningful comparisons. Although no "toxicity" was encountered per se, 6 (18%) of patients withdrew within 2 weeks of study start due to intolerance to feeds related to smell or taste problems.

Takagi [136] studied 51 adult patients in remission who were randomized to receive a half-elemental diet ($n = 26$) or a free diet group ($n = 25$). The half-elemental diet group was required to take half the daily caloric allowance as an elemental formula (either orally or via a nasogastric tube). While there were some restrictions placed on the caloric intake of the other "half" of their diet (aided through use of semi-weighed food diaries), there were no specifications for its composition. This was one of many Japanese studies which has looked at the question of maintenance EN, however, and as such, the unrestricted free diet is likely different from the equivalent Western diet. The authors in the Takagi study chose a primary outcome of relapse over a two-year period [136]. The study was stopped before achieving the two-year follow-up for all participants because the relapse rate in the half-elemental diet group was significantly lower than that in the free diet group (34.6% vs. 64%) after a mean follow-up of 11.9 months.

Yamamoto [137] carried out a systematic review examining EN for the maintenance of remission in CD. They included studies where EN was compared with another therapy; thus, the study by Takagi [136] was included, but not the study by Verma and colleagues [135]. They did not limit their review to RCTs, so three prospective non-randomized trials [138–140] and six retrospective studies [141–145] were included. The number of patients included in most of these studies was small. One of the ten studies included pediatric patients alone [142]. Eight of ten studies were conducted in Japan. Knowledge of the country of origin for a study is important when interpreting the results and assessing generalizability. In Japan, EN has a central role in the management of CD. In all but one of the eight Japanese studies included in the systematic review, an elemental formula was used, and also in a majority of studies, the oral component of the diet was a low-fat diet. The impact of this dietary approach, compared with a maintenance PF and/or traditional Western diet, has not been directly studied. The contribution of the low-fat diet, and elemental formula with a relative low-fat component, may be a relevant factor in light of the work by Bamba et al. [146] who suggested that a lower-fat diet may be an important factor related to the efficacy of EN in CD. Another factor, when reviewing EN studies from Japan, is that virtually all participants with CD are on a 5ASA preparation, as this is viewed as a standard of care for maintenance [137]. Because all participants are exposed to this intervention, it would not be expected to bias the findings relative to the EN outcomes. Additionally azathioprine was used by a number of study participants, but as is the case with 5ASA, overall its use seemed to be balanced between the treatment and comparison groups in the studies, thereby limiting the bias this concomitant therapy might have introduced.

In the systematic review by Yamamoto [137], the authors broke down the studies by whether the patients had achieved a medically or surgically induced remission. Interestingly, different from what would be seen in studies conducted in North America, for those studies with patients who entered from a medically induced remission, the majority of patients went into remission with total parenteral nutrition or EEN. Regardless of the method of induction of remission (medical or surgical), the outcomes for the ten included studies showed benefit of EN for maintenance of remission (48–95%) over the non-EN comparison groups (21–65%) [137]. In four studies the impact of dose of EN on remission rates was evaluated [141, 143, 145]. They found that higher amounts of enteral formula were associated with higher clinical remission rates. Another interpretation of these findings could be that patients with less active disease tolerated the enteral feeding better and, therefore, reached greater intakes than those with more active disease. Thus, patients with milder disease may tolerate the nutrition better, rather than the higher intake being a predictor of maintenance of remission. As well, because there was no standard approach to "dosing" used in these studies, at this time no clear recommendations can be made regarding the minimum dose of EN required to optimally maintain remission.

Maintenance of Remission with EN in Pediatrics

Maintenance EN programs have been provided in various forms: overnight NG feeds in conjunction with normal daytime eating, short intervals of exclusive NG feeds every few months interspersed with regular diet, or as oral supplements in addition to oral eating through the day. Two Canadian groups have considered the first two approaches [142, 147]. Researchers from Toronto, Canada, reported on 28 children who after entering remission with EEN had subsequently continued overnight supplementary NG feeds in addition to normal diet in the daytime [142]. They were compared with 19 children in whom EEN successfully induced remission but who opted to discontinue nocturnal elemental feeding. At 12 months, 43% (12/28) of those receiving nocturnal EN had

relapsed compared with 79% (15/19) who had discontinued supplemental elemental feedings ($P < 0.02$). A second group, from Montreal, Quebec, published a report utilizing a different approach to EN feeds, with intermittent intensive periods of nutritional therapy (EEN) [147]. This small study included eight children with CD and associated growth failure who were given intensive exclusive periods of formula for 1 month out of every 4 months. Disease activity markers fell in this group over time and in comparison to a control group who did not receive this intensive therapy. These eight children managed with intensive nutritional therapy also had significant catch-up growth [147].

EN in Combination with Medical Therapy

Thus far, the majority of studies investigating the role of EN with medical therapy have focused on concomitant use with infliximab. A meta-analysis of four adult studies, which were all from Japan, showed that specialized enteral nutrition therapy with infliximab resulted in 109 of 157 (69.4%) patients reaching clinical remission compared with 84 of 185 (45.4% with infliximab monotherapy [OR 2.73; 95% confidence interval 1.73–4.31, $P < 0.01$]. Maintenance of remission was also achieved in the combination treatment group [148].

In children, there have been minimal studies conducted to examine the use of immunomodulators and EEN in children with newly diagnosed CD, but Buchanan et al. reported that patients found it difficult to continue supplemental nutrition as maintenance or remission and therefore used a strategy of early introduction of azathioprine for maintenance of EEN-induced remission [149]. The relative importance of choice of initial induction therapy on two-year outcomes in the setting of early thiopurine use was recently evaluated. In the setting of early thiopurine commencement, choice of EEN over corticosteroid induction was associated with reduced linear growth failure (7 vs. 26%, $P = 0/02$), steroid dependency (7 vs. 43%, $P = 0.002$), and improved primary sustained response to infliximab (86 vs. 68%, $P = 0.02$) [150].

The effect of supportive short-term partial enteral nutrition (SPEN) on the treatment of children with severe CD along with unspecified conventional therapy was recently explored in a Korean cohort [151]. Patients with active CD were divided into mild, moderate, and severe categories according to PCDAI. The severe group was given the option of receiving SPEN, and 17 of 34 patients opted in. The remaining 17 patients were considered to be the non-SPEN group. Changes in nutritional status and PCDAI were significantly higher in the SPEN group ($P < 0.05$).

Further long-term study of the combination and synergistic effects of enteral nutrition and medical therapy particularly for maintenance of remission and mucosal healing is needed.

Repeated EEN and Long-Term Outcomes of Therapy

Despite the convincing results regarding immediate benefits of nutritional treatment, the efficacy of EEN for disease exacerbation and duration of remission is poorly studied.

The efficacy of repeated EEN therapy as a treatment for flares of disease tends to decrease with the second course. In a recent retrospective study, 26/52 patients received a second EEN course. The first compared to the second EEN tended to a higher remission rate (92% remission for the first course vs. 77% n.s.). Duration of the second EEN therapy was shorter compared to the first (mean days 50 vs. 43, $P < 0.05$). It was possible that non-adherence increased with the second course of EEN and contributed to the lower effectiveness. Disease activity measured by the mathematically weighted PCDAI (wPCDAI) was higher for the first course of EEN therapy (59 vs. 40, $P < 0.0001$) [152]. Remission rates ranging from 57 to 80% have been reported by other retrospective studies evaluating a consecutive course of EEN [128, 153, 154].

In terms of 1–2-year outcomes, approximately half to two-thirds of patients will relapse [152, 154, 155]. Predictors of higher relapse rates include the type of induction therapy (corticosteroids have higher relapse rates than EEN induction) [154, 155] and the type of NOD2 genotypes (92% R702W or G908R vs. 50% 1007 fs vs. 60% wild type, $P < 0.01$) [152].

Further data on the impact of induction therapy on clinical course from Grover et al. [150] demonstrated superiority of EEN over corticosteroids as initial induction therapy when comparing two-year corticosteroid-dependency (EEN, 7% vs. CS, 43%) and primary response to anti-TNF therapy (EEN, 86% vs. CS, 68%) in a retrospective study. Similarly, Connors et al. [156] demonstrated that the choice of EEN over CS for induction was associated with avoidance of corticosteroids over a six-year follow-up period which was most pronounced at 2 and 4 years post-diagnosis with 47.3% and 39.6% of EEN patients remaining steroid naive, respectively. Cohen-Dolev et al. [157] prospectively evaluated the outcomes of patients with mild to moderate disease in an inception cohort from the GROWTH CD study, treated with either EEN or CS at presentation, in order to evaluate if early use of EEN might reduce early complication rates and improve growth. A total of 147 children, treated by EEN [$n = 60$] or CS [$n = 87$] were included. They found similar relapse and complication rates in new-onset mild to moderate pediatric CD. However, the use of EEN was associated with higher remission rates (41/87 [47%] in CS and 38/60 [63%] EEN, $p = 0.036$) and a trend toward better growth (mean height Z scores decreased from Week 0 to Week 78 with CS [-0.34 ± 1.1 to -0.51 ± 1.2, $p = 0.01$], but not with EEN [-0.32 ± 1.1 to -0.22 ± 0.9, $p = 0.56$] [157].

Additional Effects and Proof of Efficacy of EEN

EEN and Mucosal Healing

For some time the treatment goals for the management of active CD have focused on the induction of remission, judged clinically (resolution of symptoms) and biochemically (normalization of altered inflammatory markers). More recently it has become clear that the goal of treatment should be the achievement of mucosal healing. Mucosal healing in both CD and UC is clearly associated with improved long-term outcomes [158]. Persisting inflammatory changes are likely to contribute to poor growth in children and are also associated with an increased risk of subsequent disease relapse [159]. Mucosal healing may also influence disease progression and extraintestinal disease patterns.

Both EEN and infliximab lead to high rates of mucosal healing in CD: more so than other therapies used to induce remission (such as corticosteroids) [160].

At the turn of the century, Fell and colleagues [161] undertook a prospective assessment of mucosal healing in a group of children treated with EEN. These 29 children with active CD were treated with a PF. In addition to baseline endoscopic assessment, repeat colonoscopy was completed after 6–8 weeks time in order to judge endoscopic and histologic changes. EEN leads to clinical remission in 79% of these children. Overall there was significant endoscopic improvement in these children. A one-point improvement in the colonoscopy grading score was seen in the ileum and colon ($P < 0.0001$ and $P < 0.001$, respectively). Eight of the children achieved mucosal healing in the ileal region, while eight also had colonic mucosal healing.

More recently the results of two prospective Italian studies and an Australian study show the enhanced rates of mucosal healing following EEN comparing to corticosteroids [162–164]. Berni-Canani and colleagues [162] evaluated the responses in children managed with EEN or corticosteroids. Thirty-seven children were treated nutritionally for 8 weeks with various different formulae (polymeric, semi-elemental, and elemental), while ten received corticosteroids. Clinical remission rates were similar in the two groups (86.5% vs. 90%, respectively), but mucosal healing rates were quite different. Twenty six of the 37 children treated nutritionally had mucosal improvements, and seven of them had complete mucosal healing. In contrast, just four of the steroid group had improvement noted, and none had mucosal healing.

In a second Italian study, children with active CD were allocated to receive either EEN (PF) or corticosteroids. Baseline colonoscopic assessment was followed by repeat colonoscopy at 10 weeks. Fourteen (74%) of the 19 children treated with EEN had mucosal healing. In contrast, mucosal healing was achieved in just six (33%) of the 18 children treated with corticosteroids ($P < 0.05$) [163]. Grover et al. evaluated the effects of 6 weeks of EEN in a cohort of 26 children. Paired endoscopic assessments showed that 58% of the group had complete or near-complete MH following EEN [164]. Subsequent work by this group in a larger group of children demonstrated that complete MH (seen in 18 of 54 children) after EEN resulted in sustained remission for up to 3 years [165]. A further recent report showed MH in 89% of a small group of 13 French children with CD managed with 8 weeks of EEN [91]. In comparison, only one of the six children treated with corticosteroids for the same duration was noted to have achieved MH.

Data from adult patients also clearly demonstrate high rates of mucosal healing consequent to EEN. Yamamoto et al. [166] assessed the mucosal changes following an elemental formula in 28 adults with active CD. In this series of patients treated with EEN, clinical remission was seen in 71%. Furthermore, endoscopic healing or improvements were documented in 44% and 78% of patients, respectively. Chen et al. [167] noted a MH rate of 79% in a group of patients of average age of 28.9 years managed with EEN. Despite this, however, only 17% of the group were noted to have transmural healing (noted sonographically).

Mucosal healing with EEN does not appear to be dependent on the type of formula utilized. Benefits have been documented with elemental [162, 166, 168] or polymeric formulae [161, 163].

Coincident with promoting healing of the inflamed mucosa, EEN is also shown to lead to changes in levels of inflammatory mediators. Several reports published in the final decade of the last century demonstrated that EEN lead to reduced mucosal production of pro-inflammatory cytokines (especially TNF-α and interleukin-2) [168, 169] and prompted downregulation of pro-inflammatory genes measured within the intestinal mucosa [161, 170]. In addition, Fell et al. [161] also demonstrated increased levels of TGF-β mRNA, consistent with increased production of this anti-inflammatory cytokine. Yamamoto and colleagues [166] also showed that the mucosal levels of multiple pro-inflammatory cytokines fell to control levels consequent to treatment with an elemental formula. The ratio between IL-1β and IL-1ra within the mucosa was also normalized.

Overall these data clearly show alterations in levels of inflammatory mediators within the mucosa following treatment with EEN. The full implications of achieving mucosal healing with EEN in children are not yet well defined. Maintenance EN may have a role in maintaining the levels of mucosal healing. It is also not clear if mucosal healing with one therapy (such as EEN) is different to that achieved by another agent (e.g., steroids). Furthermore, treatment protocols have not yet evolved to stratify maintenance therapy upon the level of mucosal healing.

EEN and Changes in Fecal Markers of Inflammation

Various proteins measured in the stool are valid markers of the level and extent of gut inflammation [171]. The most well-known markers are calprotectin and lactoferrin, but others include S100A12 and osteoprotegerin.

In a study by Gerasimidis et al., [172] fecal calprotectin (FC) levels were measured on multiple occasions during and following a course of EEN in 15 children. The children received a PF, and clinical disease activity was defined by determination of PCDAI scores, with a score of 10 or less being judged as clinical remission. FC levels fell only in the children who were in clinical remission by the end of the period of EEN, but FC levels were normalized in only one child. Interestingly, the FC level after 1 month of EEN was associated with clinical response at the end of EEN, suggesting a predictive value at this time. In contrast, a subsequent study evaluated serial measurement of FC in a group of 38 children with CD [173]. An early reduction in FC at week 2 of EEN did not predict clinical response. The authors suggested that a lack of reduction in FC at week 2 should not be seen as a signal to cease EEN. A composite of CRP, FC, and PCDAI was suggested in an Australian study as a non-invasive end point for assessment of the response to treatment [174].

Logan et al. [175] demonstrated reductions in FC after 4 and 8 weeks of EEN in a group of 66 children with CD. This work also noted a subsequent rise in FC levels within 17 days of food reintroduction following the end of the course of EEN. Interestingly, the use of ongoing maintenance enteral nutrition provided some protection against this increase in FC.

The levels of S100A12 (a protein related to calprotectin) were evaluated in a small group of Australian children managed with EEN for active CD [176]. Levels fell in the subset of children who achieved clinical remission and normal CRP.

Recent work showed that EEN treatment also led to reductions in levels of another fecal inflammatory marker, osteoprotegerin (OPG) [177]. Levels of OPG fell to around 25% in response to 6–8 weeks of EEN (1994 ± 2289 pg/g at baseline to 406 ± 551 pg/g after EEN: $P = 0.002$). The value of this marker in predicting response to EEN or in correlating with mucosal healing has not yet been determined.

EEN: Nutritional Status and Growth

Along with improvements in disease activity, weight and growth improvements are also commonly seen with EEN. Numerous studies show improved weight gains, while some have illustrated changes in specific nutritional markers. Several studies have suggested that nutritional improvements occur at different times to changes in specific inflammatory markers. These studies demonstrate that improvements in nutrition do not correlate with the timing of normalizing inflammatory markers [66, 178]. It is not clear whether the nutritional changes are essential to achieve anti-inflammatory improvements. However, satisfactory weight gains are associated with response to EEN, illustrating the importance of these events [128].

Insulin-like growth factor (IGF)-1 is a key mediator of growth hormone signaling. Alterations in this protein occur due to the effects of cytokines (reduced hepatic production secondary to interleukin-6) and are commonly observed in active CD. A number of studies illustrate early increases in IGF-1 and its related binding protein (IGF-BP3) after commencement of EEN [179]; unpublished data, Day et al. [128]. IGF-1 levels rose after just 7 days of EEN in a small group of 12 children [178].

Detailed nutritional assessments, including body composition analysis, have been conducted in individuals receiving EEN. One key study evaluated body composition using multiple direct methods to define fat, water, total body protein, and potassium [180]. A group of 30 individuals with CD were assessed before and after 3 weeks of EEN. Within this short time, increased weight was linked with proportionate increases in body fat, protein, and water. Another study documented changes in body compartments in a group of Canadian children [25]. Body water, lean body mass, and height increases were observed in the children who had received EEN, but not in a comparison group treated with corticosteroids. EEN has been shown by other authors to promote anabolism consequent to suppression of proteolysis and enhanced protein synthesis [18, 39].

These changes in nutrition manifest in weight gains during EEN. The average weight gain in a group of Australian children treated with 6–8 weeks of EEN was 4.7 ± 3.5 kg [128]. In addition, weight Z scores increased over the duration of EEN from −0.2767 ± 0.9707 to 0.1866 ± 0.8024 ($P = 0.0016$). Weight standard deviation scores increased after 8 and 16 weeks ($P < 0.05$) in a small cohort of 14 UK children with a mean age of 12.5 years [179]. However, studies do report variable weight gains [163, 181].

EEN is also noted to have a positive benefit upon linear growth, with improved height velocity even within a short period of time [17, 83]. In a meta-analysis, Newby and colleagues [182] illustrated a significant improvement in height velocity Z scores with EEN compared to outcomes after treatment with corticosteroids. In the aforementioned Australian study, children receiving EEN gained up to 3 cm during the eight-week course of EEN; however, there was no change in height Z scores across the whole group [128].

EEN and Bone Health

CD is associated with reductions in bone mineral density, which can lead to osteopenia and increased fracture risk. EEN appears to have benefits upon bone health. Whitten et al. [183] evaluated serum markers of bone turnover in a group of children with active newly diagnosed CD who were treated with PF as sole therapy to induce remission. Serum levels of bone resorption and bone production were measured at baseline and then again after 6–8 weeks of EEN. Control data were obtained from a group of children without IBD with normal growth patterns. Serum levels of C-terminal telopeptides of type-1 collagen (CTX), a marker of bone resorption, were elevated at baseline and fell during therapy ($P = 0.002$). In addition, levels of bone-specific alkaline phosphatase (BAP), a marker of new bone formation, were low at baseline but rose significantly during therapy ($P = 0.02$). This study did not include evaluation of other aspects of bone health or bone densitometry.

Other work has evaluated the impact of EEN upon vitamin D, an important factor involved in bone health [41]. This study retrospectively evaluated levels of vitamin D in 78 children with CD. A subgroup ($n = 38$) had been treated with EEN at diagnosis. These children treated with EEN had higher levels of vitamin D than a comparison group of 17 children treated with corticosteroids after diagnosis ($P = 0.04$), suggesting that EEN provided a protective effect for this aspect of bone health.

Further information supporting the role of EEN in bone health was shown in a small German study. In this report, ten children with CD managed with EEN had repeated assessments of bone densitometry. The administration of EEN lead to improved trabecular and cortical density by 3 months after starting EEN, although further improvements were not seen subsequently [184]. Strisciuglio et al. [185] assessed bone mineral density (BMD) in 18 children before and after 8 weeks of EEN. BMD scores at week 52 were improved from baseline. A more recent assessment of bone health evaluated markers of bone formation, bone resorption and bone mineral density in children before and after nutritional interventions [186] A serum marker of bone formation increased with nutritional therapy at week 12; however, BMD at week 26 was no different to baseline. This study included some subjects managed with EEN for 6 weeks and others managed with CDED and PEN. In addition, the timing of follow-up assessments differed. Another recent study assessed the impact of PEN alone upon bone health [187]. Bone health did not improve in the group of 22 children managed with PEN for 12 months: however, the children's growth was enhanced.

Together, these data clearly demonstrate that EEN provides significant beneficial effects upon bone metabolism in children with CD.

EEN and Quality of Life

Impaired QOL is well recognized in children with CD. The IMPACT questionnaire was developed and validated as a disease-specific tool to measure QOL in pediatric IBD [188]. Given the importance of eating and food in many cultures and the disruption of these usual patterns during treatment with EEN, there has been some concern that EEN could further impair QOL in these children. The influence of EEN upon QOL has been examined in just a small number of studies in children and adults.

An initial report on the effects of EEN upon QOL and functioning was published by a French group [189]. This study involved 30 children with active CD: half of the group was treated with EEN via an NG tube, while the other half of the group was given corticosteroids. The children were assessed by an adaptation of the IBD Questionnaire and underwent a series of psychological assessments, including a psychological interview. A disease-specific pediatric scoring tool was not utilized in this cohort. The authors showed that the children managed with EEN overall had improvements in their well-being. Several reported concerns about feeling different, disruptions to family routines, and the cosmetic effects of the NG tube itself. The children managed with EEN had better scores of anxiety and depression measures than those treated with corticosteroids. Both groups had disruptions to daily activities, such as school absences. A study from the UK looked specifically at QOL in a group of 26 children with active CD who were all managed with EEN [190]. This study reported remission rates and measured QOL using the IMPACT II questionnaire. Almost 90% of these children entered remission with EEN. Overall, 24 of the 26 children had improved QOL scores during this therapy. In this group of English children, the use of NG tubes to provide the formula did not impact adversely upon QOL.

In contrast to these findings, Hill et al. [191] found that the use of EEN was associated with lower QOL scores in their evaluation of children in their Australian center. This study involved the repeated assessment of various variables, including QOL and disease activity, at diagnosis and then six monthly in 41 children (with 186 assessments in total). Nine children had assessments while receiving EEN: these children were noted to have lower QOL scores than other children on no treatments or those on other medical therapies. However, the group treated with EEN was also those with the highest disease activity scores and lowest nutritional parameters. Furthermore, multiple regression analyses showed that the only independent factor for prediction of QOL in the overall group was disease activity.

These data relate to the use of EEN as therapy for active disease. The ongoing influence of maintenance EN upon QOL has also been assessed in a large group of Japanese adults with known CD [192]. Ninety five of the 126 patients

included were receiving EN as maintenance therapy at the time of the assessment. The investigators used the adult IBD Questionnaire to assess QOL scores. In addition to QOL, other parameters were evaluated. Overall, this study showed that disease activity affected QOL, while nutritional treatment improved QOL. Overall scores and sub-scores for bowel and systemic symptoms were better in the patients with long-standing disease who were receiving maintenance EN. In a pediatric study, Wall et al. (2019) showed in a small cohort that the effects of EEN on improving HRQOL could be seen quite quickly, with significant improvements in HRQOL ($p < 0.0001$) and anxiety scores ($p = 0.002$) observed after 2 weeks of EEN. These were sustained such that at 6 months significant improvements in HRQOL, as well as anxiety and depression measures were observed in this cohort, while a comparator cohort from the same center with standard of care induction at diagnosis noted an improved HRQOL at 6 months, but not with anxiety or depression outcomes [193].

In the PLEASE study discussed above, comparing anti-TNF therapy, EEN, and PEN, with assessment of outcomes at 8 week of therapy, a secondary outcome of QOL was assessed [131]. While clinical response (PCDAI reduction ≥15 or final PCDAI ≤10) was obtained in 64% of PEN, 88% EEN, and 84% anti-TNF, improvement in overall QOL was not statistically different between the three groups ($P = 0.86$). However, QOL improvement in the body image domain was greatest in the EEN group ($P = 0.03$) and with anti-TNF in the emotional functioning domain ($P = 0.04$).

At present, the overall impression of the available data is that the net benefits of EEN upon QOL are positive, likely consequent to improved energy and improved disease control. However, these data are not yet comprehensive, and further study is required to more fully understand the relationships between nutritional therapies and QOL in children with CD.

Pre-/Postoperative Effects

Grass et al. [194] conducted a systematic review on preoperative nutritional support in adult CD patients. They found that EEN prior to surgery may improve preoperative nutritional status and reduce inflammation (CRP) and reduce the risk of postoperative complications and infections. Two recent adult studies from China have examined the role of EEN in the preoperative setting. Li et al. [195] retrospectively reviewed the influence of preoperative three-month EEN on the incidence of intra-abdominal septic complications (IASCs) after bowel resections for enterocutaneous fistulas (ECFs). The EEN group had a significantly higher serum albumin level and lower CRP at operation and suffered a lower risk of IASCs (3.6% vs. 17.6%, $P < 0.05$). In addition, another Chinese report. Demonstrated that preoperative optimization of CD following immunosuppressive therapy by EEN prolongs the immunosuppressant-free interval, reduces the risk of urgent surgery and reoperation, and decreases complications after abdominal surgery [196]. Both these studies by Li et al. were included in a meta-analysis of five studies by Brennan and colleagues examining whether preoperative enteral or parenteral nutrition reduce postoperative complications in CD patients [197]. The remaining three studies looked at use of TPN, and found that postoperative complications occurred in 15.0% of patient receiving preoperative TPN compared with 24.4% in the group who did not ($P = 0.43$). In this meta-analysis preoperative EN was superior to preoperative TPN in reducing postoperative complications. Supporting these findings, a recent case-matched study from Yamamoto et al. [198] showed that an elemental diet (1800–2400 kcal/day) for at least 2 weeks prior to surgery, compared with a group who did not receive preoperative EN or parenteral nutrition, did reduce postoperative complications. The incidence of postoperative septic complications was significantly lower in the EN group (4%) compared with the control group (25%, $p = 0.04$). The occurrence rate of overall complications was lower in the EN group (21% vs. 29%, $P = 0.51$), but this difference did not achieve statistical significance.

In an adult case–control study of 51 patients, EEN was found to down stage the need for surgery in patients presenting with stricturing or penetrating complications of CD with 25% [13/51] patients treated with EEN avoiding surgery. It was also associated with a reduction in systemic inflammation, operative times, and the incidence of postoperative abscess or anastomotic leak [OR 9.1; 95% CI (1.2–71.2), $P = 0.04$] [199].

There is limited data from Japan on the impact of enteral nutrition on postoperative recurrence of CD. Initial intraoperative enteroscopic evaluation suggested prophylactic effects of enteral nutrition on postoperative recurrence of small intestinal CD [145]. Yamamoto et al. [140] studied the impact of long-term enteral nutrition on the clinical and endoscopic recurrence rates in a prospective, non-randomized, parallel, controlled study of 40 adults who underwent resection for ileal or ileocolonic CD. Twenty patients continuously received enteral nutritional therapy (EN group) overnight via nasogastric tube and had a low-fat diet during the day. The 20 controls had neither nutritional therapy nor food restriction (non-EN group). Six months after operation, five patients (25%) in the EN group, and eight (40%) in the non-EN group developed endoscopic recurrence, but the difference did not achieve significance. At 1 year a significant difference was found in both clinical recurrence (5% in the EN group vs. 35% in the non-EN group) and endoscopic recurrence rates (30% in the EN group vs. 70% in the non-EN group). The authors subse-

quently published the five-year extension of this prospective cohort study [200]. Using an intention to treat analysis the end point selected for the five-year follow-up study was recurrence requiring biologic therapy or reoperation. In the EN group, 4/20 could not continue with the elemental diet long term. Two patients (10%) in the EN group and nine patients (45%) in the non-EN group developed recurrence requiring infliximab therapy ($P = 0.03$). One patient (5%) in the EN group and five patients (25%) in the non-EN control group required reoperation for recurrence, but this difference was not statistically significant ($P = 0.18$). This preliminary work in the postoperative setting supports the effectiveness of enteral nutrition, but additional studies are required to replicate this effect or determine regimens of postoperative EN use that would optimize long-term compliance and outcomes.

Adverse Effects of Enteral Nutrition

There are very few adverse effects associated with the use of EN. Loose stools may be reported, particularly in those with predominantly colonic disease distribution. Nausea and constipation are less commonly reported [161].

A cross-sectional Japanese study in adults has reported a risk of selenium deficiency in patients with CD being treated with EN. Selenium concentrations were measured and compared in 29 patients with CD treated by EN, 24 patients with CD who were not being treated with EN, and 21 healthy controls. Selenium levels were only decreased in patients with CD receiving EN and were inversely correlated to the duration and daily dose of EN. Clinical manifestations of selenium deficiency were only found in one patient [201]. A European study examining the effect of exclusive EN on antioxidant concentrations in childhood CD reported conflicting results with respect to selenium. Mean selenium concentrations of the cohort increased significantly from 0.82 μmol/l to 1.14 mmol/L ($P < 0.001$). There were, however, significant reductions in mean concentrations of vitamins C and E [202]. A recent study on the impact of EEN on circulating micronutrients resulted in improved concentration for several nutrients, but interestingly, more than 90% of patients had depleted concentrations of all carotenoids, which later improved on normal diet [47]. Multiple factors, including differences in age groups, disease activity, nutritional status, and EN formulae, may all impact on vitamin and antioxidant levels and the disparate results of the above studies. Further investigation of potential adverse effects at the micronutrient level is required.

Another potential biochemical side effect reported to occur with EEN is transient elevation of transaminase enzymes. Schatorje et al. [203] performed prospective follow-up of liver enzymes in 11 new consecutive children who were primarily treated with total enteral nutrition (TEN) for 6 weeks. Liver enzymes were measured before starting TEN and after 3, 6, and 12 weeks. Overall, nine of 11 patients developed a marked elevation of aspartate transaminase (AST), and ten had an elevated alanine transaminase (ALT) peaking at 3 and 6 weeks. GGT was slightly elevated in three patients during therapy, including two boys with either pre-existing or persistent raised transaminases. Alkaline phosphatase and bilirubin remained normal. The mean follow-up period was 2.1 years (1.0–3.5 years). None of the patients developed liver disease during follow-up, and liver biopsy was therefore not performed [203]. However, subsequent to this publication, a letter to the editor by Lemberg et al. [204] reviewing transaminase results in their published cohort of 12 children with newly diagnosed CD managed with 8 weeks of EEN showed conflicting data. ALT levels were borderline elevated in only two of their patients at 3 weeks of EEN and one patient at 8 weeks of EEN therapy. At diagnosis, all of the markers were within normal ranges. After 2–3 weeks of EEN, the average AST levels were 26.2. Subsequent means were 25 at 8 weeks and 16.8 at 1–2 months after EEN. Average ALT levels rose initially to 21.9 U/L and were subsequently 21.2 at 8 weeks and 14.2 at 1–2 months after EEN. ALT levels were above the upper range of normal (45 U/L) at 2–3 weeks in only two children (51 and 48, respectively) and at 8 weeks in one child (48 U/L). GGT levels did not change and liver disease did not develop in any of the patients.

In a retrospective study exploring liver enzyme elevation in pediatric IBD, EEN therapy was strongly associated with the first episode of abnormal LEs in patients with IBD without PSC/ASC (hazard ratio [HR] 4.2; 95% confidence interval [CI], 1.6–11.3). The effect of EEN on the liver is unclear from existing data. Further prospective investigation is required to clarify the effects of EEN on transaminase levels.

Severe adverse events related to EN are rare. To date there are three case reports of refeeding syndrome consequent to the use of EEN in CD [205, 206]. The two cases reported by Akobeng et al. occurred within days of starting EEN in severely malnourished children [206]. Although rare, it is important for clinicians to be aware of refeeding syndrome and to identify and monitor patients at risk [207].

Factors Affecting Response to EEN

Disease-Related Factors

Disease Duration

Several studies suggest higher efficacy of EEN in children with newly diagnosed CD over those with established disease duration. A multicenter North American study using a semi-elemental formula showed a remission rate of 83% in children newly diagnosed with CD [208], compared to a response rate of 50% in children with previously diagnosed

CD. An Australian retrospective study found 12 of 15 (80%) children with newly diagnosed CD entered remission, defined by PCDAI, compared to 7 of 12 (58%) children, who had been diagnosed with CD for a mean of 3.2 years [128]. The latter study also showed that although some children in this group did not enter remission, each had reductions in PCDAI scores and each had nutritional improvements. The recent meta-analysis by Swaminath did not show a difference in efficacy based on newly diagnosed versus relapsing disease [124].

As previously discussed, the efficacy of repeated EEN therapy as a treatment for flares of disease tends to decrease with the second course [152], but the contribution of non-adherence in this setting versus disease duration is unclear.

Disease Location

Disease location has often been considered to potentially influence the effectiveness of EEN. Several early reports suggested increased efficacy when there is small bowel involvement [143, 153] and a trend toward earlier relapse in those with isolated colonic involvement [153]. Yet, Afzal et al. [181] demonstrated, in a prospective study of 65 children with acute intestinal CD treated with exclusive polymeric diet, that even the patients with disease limited to the colon had remission rates of 50%, albeit much lower than those with ileocolonic (82% remission rate) or ileal disease (91.7% remission rate).

Buchanan and colleagues [149], using carefully defined phenotypic classification in 110 patients on EEN, found no significant differences in the remission rates based on disease location. This is supported by a retrospective study by Rubio et al. who recently compared remission rates according to route of administration and found that the site of disease activity had no impact on response to nutritional therapy [209]. Disease location could not be examined by the meta-analysis by Narula and Zachos et al. due to insufficient data [109, 123]. The most recent randomized trial evaluating elemental versus PF also did not identify any difference in remission rates based on disease location [110]. Additional studies exploring EEN in the last 5 years have included all disease locations but do not report on response according to disease location. Thus, until the influence of disease location on response to EEN is more clearly delineated, it is reasonable to recommend it for all patients with CD regardless of disease site.

EEN-Related Factors

Polymeric Versus Elemental/Semi-Elemental Diets

Nutritional therapy is classified by the nitrogen source derived from the amino acid or protein component of the formula. Elemental diets are created by mixing of single amino acids and are entirely antigen free. Oligopeptide or semi-elemental diets are made by protein hydrolysis and have a mean peptide chain length of four or five amino acids, which is too short for antigen recognition or presentation. Polymeric diets contain whole protein from sources, such as milk, meat, egg, or soy. They can be classified more simply as elemental (amino acid based), semi-elemental (oligopeptide), and polymeric (whole-protein) diets.

Although elemental diets were used in the initial studies focusing upon the nutritional treatment of CD, subsequent studies in both children and adults have compared these elemental diets to polymeric diets [110, 161, 210, 211] Comparisons between any combination of the different protein sources when combined in meta-analysis [109, 123] have shown no significant difference in effectiveness. Similarly, one study comparing polymeric diets differing in glutamine enrichment showed no difference in remission rates [212].

Fat Composition

Several trials have been conducted to investigate the importance of fat composition [146, 213–215], building on the hypothesis that the proportion or type of fat in an enteral feed could affect the production of pro- or anti-inflammatory mediators. Two trials, Leiper et al. [214] and Sakurai et al. [215], investigated the effect of low versus high long-chain triglyceride (LCT) content and differing amounts of medium-chain triglycerides, respectively, in adult patients and showed no difference in effect. Another study by Bamba et al. [146] comparing diets of low-fat (3.06 g/day), medium-fat (16.56 g/day), or high-fat (30.06 g/day) contents showed higher remission rates in the lowest fat group. By intention to treat analysis, remission was achieved in eight of 11 patients (72.7%) of the low-fat group, four of 13 (30.8%) in the medium-fat group, and two of 12 (16.7%) of the high-fat group. However, all of these studies were flawed by either small sample sizes, high dropout rates, or unvalidated activity indices used to define remission. When studies evaluating fat composition were combined by meta-analysis [109, 123], a non-significant trend favoring very low-fat and low LCT content has been demonstrated. However, these results should be interpreted with caution due to statistically significant heterogeneity and small size, which may have lacked statistical power to show differences should they exist. In addition, subgroup analyses could not be performed based on the n6 or n9 fatty acid composition in the feeds due to significant heterogeneity. Ajabnoor et al. [216] recently conducted a systematic review attempting to assess the effects of individual dietary oils and their fatty acids. Their results suggest trends supporting diets with a high n-6 to n-3 ratio and perhaps from avoidance of monounsaturated fatty acids (MUFA). However, definitive conclusions once again were

not possible due to incomplete comparative information and a lack of robust clinical trials in this area.

The possibility that fat composition influences immunomodulatory or anti-inflammatory effect in active CD warrants further exploration with larger trials. In summary, no specific formula composition of EN diets has been conclusively shown to influence induction of remission in active CD.

Exclusive Versus Partial EN (PEN)

The question of whether supplementary EN could be considered instead of EEN was explored in a randomized controlled pediatric trial by Johnson et al. [217]. This study showed that the combination of partial EN (50% of energy requirements) with normal diet leads to a substantially lower rate of remission compared to the use of EEN (100% of energy requirements) (15% in PEN vs. 42% in EEN; $P < 0.035$).

Gupta et al. [218] retrospectively examined a novel protocol providing patients with 80–90% of caloric needs by EN and allowing consumption of remaining calories from a normal diet. Fifteen of twenty three (65%) of the patients receiving the novel partial EN protocol achieved remission [218]. However, subsequent work from this group, as part of the PLEASE study [131], would suggest that although patients/families are instructed to consume 10–20% of calories from a normal diet, it would seem that in many patients, the overall caloric consumption is increased. Close monitoring of intake by dietitians revealed that the PEN group consumed 150.8% ± 36.2 of their estimated energy requirement from a combination of formula (77.7% ± 14.2) and food (72.9% ± 25.5) so that 47.0% ± 13.5 of their caloric intake was from food. While PEN plus ad lib diet improved clinical symptoms in this study, EEN and anti-TNF therapies were superior for inducing remission. Overall, data suggest that EEN is effective due to the exclusion or at least a significant reduction of certain components of normal diets. In the past decade, emerging data and further efforts have been underway to study the effect of restricted table food-based diets (e.g., AID, CDED, specific carbohydrate diet (SCD), CD-TREAT) on CD, often in conjunction with PEN. These specialized diets will be addressed in another chapter.

Duration of Therapy

The duration of EEN therapy ranges from 2 to 12 weeks but the majority of studies use EEN for 6–8 weeks [219]. The early effects of EEN on the microbiome have been achieved over the first 4 weeks of therapy. Additional later effects in the fourth to eighth weeks of therapy may include further anti-inflammatory and nutritional benefits [128].

Predicting the Response to EEN

Several reports have focused on early indicators of the likely success of a course of EEN in children with active CD. Moriczi et al. [220] examined predictors of better response to EEN in 22 children treated with EEN. Ileal location and several markers of disease activity at diagnosis (including FC <500 or a weighted PCDAI score less than or equal to 57.5) were associated with superior outcome. A recent report further highlighted changes in the microbiome in the prediction of remission with EEN [221] Modeling that included microbial abundances, disease location, and bacterial species richness provided a strong association with sustained remission in a group of children managed with EEN. Although not yet assessed in a pediatric cohort, Xu et al. [222] recently developed and validated a nomogram to predict the response to EEN with ROC curve of 0.906. This tool included colonic involvement, the pattern of colonic ulceration, endoscopic severity score, BMI, and CRP value.

Delivery of EEN

Route of Administration of EEN

EEN can be administered by various different routes, such as oral and nasogastric (NG), or via a gastrostomy tube. The choice of route of administration will often be dependent on clinical judgment and reflects local practice, tolerance of formulae, and patient choice [223]. An international survey of pediatric practitioners found that oral administration was the preferred route, with 66% of respondents always starting oral, and switching to NG only if oral route not tolerated [219]. Nine percent of respondents always start NG and switch to oral only if the patient is unwilling/unable to tolerate NG route, while 24% of respondents present both routes and let patient/family decide [219]. Elemental or semi-elemental formulae may be more difficult to take orally. Since PFs have the same clinical benefits, lower cost, and better palatability (allowing for oral administration), they may be associated with increased interest, tolerance, and adherence of EN therapy, which remains the greatest challenge of this form of therapy. However, while generally, children will accept the oral route more than the NG route, oral feeding may lead to greater difficulties over time as the child tries to maintain sufficient volume over a longer period of time. Rubio et al. [209] retrospectively reviewed 106 patients treated with either fractionated oral or continuous enteral feedings and found that both routes were efficacious in inducing remission and mucosal healing. After 8 weeks of EEN, 34/45 (75%) achieved remission in the oral group and 52/61 (85%) in the enteral nutrition (via NG) group ($P = 0.157$). All patients showed a significant decrease in disease severity assessed by PCDAI and significant improvements in anthropometric measures and inflammatory indices. Weight gain was greater in the enteral group ($P = 0.041$) [209]. Similarly a Croatian group reporting their single center retrospective cohort results noted no significant differ-

ence in terms of efficacy (induction of remission) in either the oral or NG routes of administration of EEN [224].

Some reports refer to the practice of routine placement of a NG tube at the start of the course of EEN and then encouragement of oral intake so that children end up with removal of the tube and ongoing oral feeds [110, 219]. On the other hand, children who struggle with tolerance soon after commencing a period of EEN orally can subsequently be switched to NG administration [149].

Approach to Reintroduction of Normal Diet

Following the completion of the course of EEN, the next step will be the recommencement of normal regular diet. An international review of protocols in different units illustrated the range of approaches [225]. Overall, the time taken to reintroduce a normal diet (following a 6–8-week period of EEN) at these pediatric units varied from 1 to 12 weeks.

One of the most accepted approaches to reintroduce normal diet is a gradual introduction of food quantity, while formula volume is progressively decreased [225]. This approach entails the introduction of a meal every 2–3 days while reducing the volume of formula with the introduction of each meal, so that the adjustment takes place over 7–10 days time [128, 149]. Although not formally evaluated in this setting, this approach has been well accepted with very few children having disruptions to the reintroduction of normal diet [personal observations, A. Day].

One group has reported the immediate introduction of food, while formula volume is decreased to overnight feeds [226]. A further approach has involved the use of a low-allergen diet, with new low-allergen foods (initially lamb, potato, chicken, or rice) introduced every 2 or 3 days, followed by the progressive reintroduction of other foods and food groups [227]. This method of returning to a normal diet was evaluated by Shergill-Bonner et al. in 100 patients, and no clear benefits were demonstrated [228]. Similarly Faiman et al. reported a retrospective cohort study where 20 patients had reintroduction of food using the low-allergen approach, while a comparison group (n = 19) followed a low-residue diet for 3 days before reestablishing their usual unrestricted diet, with their EEN being weaned over a 2-week period. As with other studies which have looked at this issue, no significant differences were noted between the two groups with respect to relapse rate and duration of remission [229].

Geographic Variability and Barriers to Utilization of EEN

There is significant geographic variation in the practice and recommendations for EEN as primary therapy in the management of children with CD [77]. In Europe and Japan, guidelines recommend EEN as the first-line therapy for induction of remission in children with CD [230, 231]. The variation in use is noted between and within different countries across the world [5, 232–234]. In an early study by Levine et al. [5], significant variations in the use of EEN were reported in a trans-Atlantic survey of 167 physicians from the USA, Canada, Western Europe, and Israel. In that study, while 4% of North American pediatric gastroenterologists used EEN regularly, 62% of European practitioners reported regular use. These European numbers were echoed in a report from a survey of Swedish pediatric GI units, which showed that 65% of the units used EEN as their primary therapy in newly diagnosed CD [233]. The variation in practice among North American pediatric gastroenterologists was revisited in a survey of 326 NASPGHAN members from North America (86% USA, 14% Canada) [234]. They reported that 31% of respondents never used EN, 55% reported sparse use, and 12% reported regular use. Physicians in Canada reported significantly more use than in America ($P < 0.001$). Variations in EN use within a country were also demonstrated in a study of Australian pediatric gastroenterologists by Day et al. [232]. In both the North American and Australian studies, currently working and previously working in a center where EEN was used were important factors for both the perceived appropriateness of EEN and the regularity of its use. North American pediatric gastroenterologists reported that concerns about adherence were the main disadvantage of EEN and provided a barrier to wider usage. Australian respondents also commented that adherence was a concern but cited other issues, including cost and resource demands. Both of these surveys noted that experience with EEN during gastroenterology training related to current use and confidence with EEN.

While this preliminary work has attempted to explore physician factors to explain the use of EEN, currently only one pilot study has been published which assesses factors influencing patient or parent acceptance [235]. Individual qualitative interviews were conducted with 11 pediatric CD patients and their parents from various clinics across Canada to explore the experience of choosing (or not choosing) a treatment option. Of the 11 patients, seven had received some form of EN as part of their initial treatment. Issues raised during the qualitative interviews were grouped into six themes, and for each of these themes, considerations and impacts on practice were derived (see Table 27.2). Patient, family, and societal/cultural factors undoubtedly play a role in the acceptance and use of EEN. The fear of corticosteroid-related side effects, the cost of EEN (which is rarely covered by insurance plans in many countries), concerns over giving up conventional foods, poor palatability of formulae, and fear of tube feedings are some of the reasons patients and/or parents give for not choosing EEN [236].

Another potential barrier to the incorporation of EN as a realistic therapeutic option is adequate resources to support an EN program. There are no published studies which have delineated the optimal resources required. A recent clinical

Table 27.2 Thematic summary of patient and family interviews

Factor/themes (with examples)	Considerations and impact on practice after discussion in workshop
Messaging from healthcare team	
"Pharmacist said incidence of most side effects from steroids was 10% or lower" Family opted for the steroid because they did not feel the efficacy of the EEN was explained	Need for multidisciplinary education and conviction; ensure accurate and consistent messaging Written information to ensure accurate recall by families
Parental assumptions and expectations	
"At 14, no way would she do that" "12 is a difficult, in-between age. Maybe if he was younger or older, he would (been convinced to) have tried the [formula]."	Importance of connecting parents with experienced parents Involve social work or health psychology
Social concerns	
Integration into school, activities, not eating "EEN would be socially isolating" "Patient became emotional about not eating (worried about missing the food he like, being different from his friends)"	Importance of connecting patients to youth with EEN experience; use available resources (videos, camp/social experience)
Guilt	
Parents felt that he had already been through so much that they did not want to upset him further "At 10 or 11, it was hard to imagine that he could only drink, when his friends were eating"	Focus on benefits of EEN, not only challenges Importance of connecting parents with experienced parents Involve social work or health psychology
Child as the decision maker	
"Parents have to respect the wishes of their children (even very young children). The option of a steroid was the only one our son wanted to look at, so we had to go with his wishes." (patient was 10 years old when EEN was offered) "You can't make your teen do what they don't want to do"	Be sure child is present and actively engaged in discussions regarding treatment The child is a key player in the decision making, but they are not the only player—parental involvement is also important; it is a difficult decision to make alone Engage supports—such as peers—and connect with patient who has been on EEN
Adaptation	
"It seems so traumatic at first, but you have to look ahead. There are so many possibilities for a good outcome." "It is hard, but it will get a lot better" "Nervous but relieved [at decision to place NG tube]." "The tube was in for 10½ weeks, stayed in, and was changed three times. Very successful. She gained weight."	Have families share their experiences and strategies

Taken from Johan Van Limbergen et al. [235]
EEN Exclusive enteral nutrition, *NG* Nasogastric

report on EN as primary therapy in pediatric CD from the NASPGHAN highlighted several issues of importance [236]. Attitudes among the healthcare staff that promote the use of EN and the center's experience appear to play a large role [234]. Dedicated dieticians are fundamental to an EN program, determining appropriate nutrient intake, and in administration of the program. Nursing support with experience in administering and teaching care of tube feedings and use of the feeding pumps is necessary for those who are unable to tolerate oral formula. Formula cost is also an important consideration, particularly when semi-elemental or elemental formulae are chosen, and they are providing sole source of nutrition during the period of exclusive EN feeding. Also, formula costs may not be covered by the relevant health system or drug insurance plans. In some jurisdictions, coverage may be obtained if formula is delivered by a tube, either NG or gastrostomy tube. The high cost is likely to be a barrier to utilization of this therapy.

Conclusion

Nutrition is an important component of the management of IBD in children and adolescents. Successful use of EEN as a form of therapy, specifically for CD, requires a dedicated multidisciplinary team of nurses, dieticians, social workers, and medical staff to support children and families during therapy. Pediatric gastroenterologists must consider EEN in the therapeutic decision process since it yields all of the target outcomes of interest in the management of CD, including alleviation of symptoms, mucosal healing, correction of nutritional deficiencies, optimization of growth, and normalization of quality of life, without adverse effects encountered with most pharmacologic therapies.

With a renewed interest in the role of nutrition in the treatment of IBD, a remaining challenge is the difficulty in maintaining remission as many patients do not welcome repeated restrictions on normal eating. The combination of enteral

and drug therapy with immunomodulators, or other therapies, to maintain remission requires further study. Avenues of investigation will likely include further exploration of specific oral diets and nutrients that have anti-inflammatory and pharmacologic properties, such as the ability to induce immunomodulation. Although the influence of nutrition on the pathogenesis of IBD and the role of nutrition in the therapy of IBD remain unclear, future investigation of the potential interactions among nutrition and the genome, microbiome, and immune system will enhance our understanding of pathogenesis and have an important clinical impact on the treatment of pediatric IBD.

2021 Corticosteroids

28

Charles M. Samson and Johanna C. Escher

Introduction

Glucocorticosteroids (GCs) have been used since about 60 years ago as a first-line treatment to induce remission in Crohn disease and ulcerative colitis in children and adults. The first randomized trial demonstrating their efficacy in active IBD was conducted in 1965 by Truelove et al. [1]. Systemic corticosteroid treatment causes disfiguring cosmetic side effects during short-term use and bone demineralization as well as growth failure in long-term treatment, therefore limiting its use in children and adolescents. In addition to the side effects, corticosteroid resistance and dependence are common. The current trend is to minimize or even avoid corticosteroid use in pediatric as well as adult inflammatory bowel disease (IBD). In mild pediatric Crohn disease, enteral nutrition as primary therapy is a safe and effective alternative to prednisolone in mild disease. In moderate-to-severe pediatric Crohn disease, specifically in patients that are at risk of complicated disease, first-line anti-TNF treatment is preferred over corticosteroids [2]. In this chapter, the working mechanism, efficacy, side effects and pharmacokinetics of "classic" (systemic) as well as topical corticosteroids, such as budesonide, will be reviewed.

The Working Mechanism of Corticosteroids

Under homeostatic conditions, activation of the innate and adaptive immune system is counteracted by endogenous glucocorticoids [3, 4]. At lower dosages, steroids may well follow these physiological pathways, whereas at higher concentrations other mechanisms may be involved.

Upon binding of the high affinity glucocorticoid receptor, a cascade of events takes place starting with the dissociation of molecular chaperones followed by nuclear translocation. At this location, specific DNA sequences in the promoter region of steroid-responsive genes (glucocorticoid response elements) are bound leading to suppression of the genes encoding for the transcription of inflammatory proteins, such as those involved in the mitogen-activated protein kinase (MAPK) pathway. Subsequently, the production of inflammatory mediators, such as prostaglandins, is reduced. The major anti-inflammatory effects of glucocorticoids appear to be due largely to interaction between the activated glucocorticoid receptor and transcription factors, notably nuclear factor-kappa B (NF-kappaB) and activator protein-1 (AP-1), that mediate the expression of inflammatory genes [5]. Inflammation may also become suppressed by increasing the synthesis of the anti-inflammatory mediators, such as interleukin-10, and of Inhibitor of kappa Ba (IκBα), which is regarded as an inhibitor of the key inflammatory transcription factor NFκB. Inhibition of non-genomic mechanisms may also be involved. An example is the activation of endothelial nitric oxide synthase by glucocorticoids leading to the production of nitric oxide (NO). NO is an important modulator of the inflammatory cascade in IBD by affecting leukocyte–endothelial interactions, leukocyte infiltration, and vasodilatation. In summary, it has become clear that glucocorticoids interact with wide range of molecules and therefore exert their immunosuppression by affecting various inflammatory pathways.

Systemic Corticosteroids

Placebo-controlled trials on the safety and efficacy of prednisolone have not been performed in children with Crohn disease or ulcerative colitis. Multiple studies, however, as reviewed by Heuschkel et al. [6], have compared the results of enteral nutrition versus a course of steroids in the treatment of active Crohn disease in children and reported clinical remission in 85% of children treated with predniso(lo)ne. However, it has long been known that corticosteroids do not heal the mucosa in IBD [7] and are not effective for the maintenance of remission [8–10]. From recent excellent data, drawn from a multicenter observational registry in the USA, we are now informed about the natural history of corticosteroid therapy in children with Crohn disease [11] as well as ulcerative colitis [12]. Despite the use of immunomodulators, 31% of children with CD and 45% of children with UC were found to be corticosteroid dependent at 1 year after diagnosis [11, 12]. This is in accordance with data from adults [13–15]. A recent randomized controlled trial in children with moderate-to-severe Crohn disease showed that first-line infliximab induction treatment combined with azathioprine (AZA) was more effective to achieve and maintain clinical remission without treatment escalation at week 52 compared to conventional induction treatment (by predniso(lo)ne or exclusive enteral nutrition) combined with AZA [13]. Furthermore, propensity score-matched analysis of the RISK study suggested that early anti-TNF monotherapy had higher corticosteroid- and surgery-free remission rates at 1 year than induction with predniso(lo)ne or exclusive enteral nutrition followed by immunomodulator therapy [14]. These and other studies have resulted more and more in corticosteroids being a less preferable first choice in the treatment of pediatric Crohn disease, specifically in children with high risk of complicated disease, where first-line anti-TNF is recommended [2].

In children with severe acute ulcerative colitis, current guidelines recommend intravenous methylprednisolone as first-line treatment [16], with response rates of 71% as reported from a prospective trial in this group of patients [17].

One of the major drawbacks of corticosteroids is the range of side effects that may emerge during treatment, being cosmetic (acne, moonface, weight gain), psychological (mood swings, insomnia, depression), metabolic (bone demineralization, diabetes) or a risk of infections as a result of immune suppression. In children, the effect of systemic corticosteroids on growth is a special concern [18].

Topical Corticosteroids

For targeting local and systemic inflammatory processes in IBD therapeutic agents of first choice (e.g., aminosalicylates, corticosteroids) have been developed in special galenic forms to accomplish the topical delivery of the active compounds to the terminal ileum (Crohn disease) and/or the colon (Crohn disease and ulcerative colitis).

For over 10 years, non-systemic corticosteroids, such as budesonide, beclomethasone dipropionate, fluticasone, and hydrocortisone thiopivalate, have been of interest for the targeted therapy of IBD. Budesonide is a GC with a weak mineralocorticosteroid activity. It has a favorable ratio between anti-inflammatory activity and systemic GC effect. This is explained by a high local GC activity and an extensive first-pass hepatic degradation to metabolites with very low GC activity. Due to these circumstances the well-known GC adverse effects are less frequent than with the conventional corticosteroids.

Pharmacokinetics

The absolute bioavailability of budesonide is very low, which results from gastrointestinal afflux mediated by P-glycoprotein, the product of the multidrug resistance 1 (MDR1) gene, and from biotransformation via cytochrome p450 3A (CYP3A) in gut and liver. After this extensive first-pass metabolism, the metabolites 6β-hydroxybudesonide and 16α-hydroxyprednisolone are formed. Glucocorticoid activity of these metabolites amounts to only 1–10% of the parent drug.

Two pharmacokinetic studies have been performed in children with Crohn disease [19, 20]. Absolute bioavailability of budesonide (Entocort®) was found to be similar in children (9 ± 5%) compared to healthy adults (11 ± 7%) [20]. Consistently, overall systemic elimination of budesonide (Budenofalk®) reflected by clearance and half-life was not different in children and adults [19]. Conversion to 6β-hydroxybudesonide was shown to be 1.5-fold higher in children than in adults, suggesting enhanced biotransformation via CYP3A enzymes in children [19]. Corrections in dosing of budesonide based on body weight or body surface may not adequately reflect differences in pharmacodynamics. Therefore, the dose of budesonide (9 mg, once daily) decided on in both pediatric clinical trials [21, 22] was the same as used in adults with Crohn disease.

Topical Steroid Formulations

There are two oral formulations of budesonide used for treatment of Crohn disease: controlled ileal release (Entocort®) and pH-dependent release (Budenofalk®). The controlled ileal release capsules contain 3 mg of budesonide distributed in approximately 100 pellets that have an outer coating of Eudragit L100-55 that dissolves at pH of 5.5 or higher.

Absorption of Entocort® in the ileocaecal region ranges from 52 to 79 percent. The pH-dependent Budenofalk® capsules also contain 3 mg of budesonide in 400 pellets of a 1 mm diameter and are coated with eudragit, resistant to pH below 6.

For rectal treatment of left-sided ulcerative colitis, budesonide is available as enemas containing 2 mg per 100 mL of enema (Entocort® enema) and a foam containing 2 mg per dose of enema (Uceris® foam or Budenofalk® foam) has been developed with a goal of optimizing drug retention and providing uniform drug delivery to the rectum and distal colon with a mean spread of 25 cm [23]. Also, an oral controlled release system, MMX® extended-release budesonide 9 mg tablets (Uceris®; Cortiment®), characterized by a multimatrix structure, has been developed. This new formulation has a gastro-resistant outer layer that dissolves as the luminal pH increases over 7.0 [24, 25]. It aims at a homogeneous distribution of budesonide through the ascending, transverse, and descending colon, in order to treat colonic IBD, more specifically ulcerative colitis.

Efficacy of Oral Budesonide Treatment in Crohn Disease

Two randomized clinical trials have been performed comparing safety and efficacy of budesonide versus prednisolone in children with active ileocecal Crohn disease [21, 22]. In the non-blinded study by Levine et al., 33 patients (mean age 14.3 years) with active mild-to-moderate pediatric Crohn disease were randomized to 12 weeks of treatment with pH modified release budesonide (Budenofalk® 9 mg, once daily) or prednisone (40 mg, once daily) [26]. The groups treated with budesonide and prednisone did not differ by age, onset of disease, location of disease, or disease activity. Remission (defined as Pediatric Crohn Disease Activity Index PCDAI ≤10) at 12 weeks was reported in 9/19 patients (47%) of the budesonide treatment group and in 7/14 patients (50%) of the prednisone treatment group (difference not statistically significant). Side effects occurred in 32% and 71% of patients treated with budesonide and prednisone, respectively ($p < 0.05$). Severity of cosmetic side effects was significantly lower in patients treated with budesonide ($p < 0.01$).

The study by Escher et al. was a randomized, double-blinded, double-dummy, controlled multicenter clinical trial. In a joined effort by the IBD working group of the European Society of Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN), 36 centers located in eight European countries took part [22]. Planned sample size was 120, but the study was terminated prematurely due to low enrolment numbers, with 48 patients (mostly new patients) with active Crohn disease involving ileum and/or ascending colon completing the 12-week study. Patients (mean age 13 years) were randomized to budesonide (Entocort 9 mg, once daily for 8 weeks, tapered to 6 mg for 4 weeks) or prednisolone (1 mg per kg bodyweight, once daily for 4 weeks, followed by 4 week tapering down to a 2.5 mg daily dose). Primary outcome parameter was clinical remission (modified Crohn Disease Activity Index CDAI ≤150) at 8 weeks. Clinical remission was reported within 2 weeks of treatment in about 50% of the patients in both groups. At week 8, 12/22 patients in the budesonide group (55%) and 17/24 patients in the prednisolone group (71%) were in clinical remission ($p = 0.25$). The observed 16% difference in remission rate in favor of prednisone was statistically not significant. In case of planned enrolment of 120 patients, the extrapolated difference in remission rates would still not have reached significance. Mean CDAI of the patients was 239 (budesonide group) and 268 (prednisolone), representing mild to moderate disease. It is unknown whether prednisolone may be more effective than budesonide in patients with severe disease. Data from the North American prospective Pediatric IBD Collaborative Research Group Registry show that oral budesonide was used in 13% of children with newly diagnosed Crohn disease, mostly combined with 5-ASA (in 77%) or immunomodulators (43%). Despite the fact that oral budesonide is designed for controlled ileal release, less than 50% of these patients had disease located in the terminal ileum and/or ascending colon [27].

In adults, a Cochrane systematic review demonstrated that budesonide is more effective than placebo and although inferior to conventional corticosteroids in mild to moderately active Crohn disease in the terminal ileum and/or ascending colon, the likelihood of adverse events and adrenal suppression with budesonide is lower [28]. Four trials comparing budesonide versus prednisolone in adults showed less corticosteroid-related adverse events in the budesonide group [29–32]. Based on the above evidence, ECCO guidelines state that oral budesonide (9 mg once daily) for mild-to-moderate ileocaecal Crohn disease is an alternative to systemic corticosteroids for induction of remission in children [2].

Side Effects of Budesonide in Children

Glucocorticosteroid-associated side effects, such as moon face and acne were shown to occur significantly less in children treated with budesonide compared to prednisolone [22]. In the randomized clinical trial by Escher et al., moon face was almost three times as common in the prednisolone group. All short-term GC-associated side effects of budesonide versus prednisolone are listed in Table 28.1. Adrenal suppression, expressed as a decrease in mean morning plasma cortisol levels, was evident during budesonide remission induction while being significantly less compared to prednisolone treatment. Headache was reported in both treatment groups in

Table 28.1 Glucocorticosteroid-associated side effects of budesonide versus prednisolone in children with ileocaecal Crohn disease

	Budesonide $n = 22$	Prednisolone $n=26$[a]	p-value

RCT by Escher, et al. [20], with permission
NS Not statistically significant
[a]One of these had no on-treatment data regarding possible glucocorticosteroid side effects
[b]Some patients had more than one sign

4/22 (budesonide group) and 4/26 patients (prednisolone group) and may be associated with benign intracranial hypertension as reported by Levine et al. [33].

A retrospective review of 6 prepubertal children with Crohn disease showed linear growth to be subnormal (2 cm/year) during budesonide maintenance treatment [34]. It remains unclear, however, whether impaired growth in these children (with PCDAI's of 15–27.5, indicating active disease) was due only to budesonide treatment or to ongoing mucosal inflammation.

Maintenance Treatment in Crohn Disease

Maintenance treatment with budesonide has not been studied prospectively in children. Systemic corticosteroids, however, have not been shown to be effective in prolonging clinical remission. A Cochrane review based on four placebo-controlled randomized trials in adults with Crohn disease [31, 35–37] concluded that maintenance treatment with oral budesonide at 6 mg/day is not effective in preventing relapses of Crohn disease in adults [38]. In view of this evidence, and the concerns on longitudinal growth in children, maintenance treatment with budesonide should not be recommended.

Budesonide in Ulcerative Colitis

In children, no studies have been performed on the efficacy of budesonide enemas. In adults, topical steroid treatment with budesonide foam enemas is more efficacious than placebo in inducing remission in patients with mild to moderate left-sided colitis as demonstrated in two randomized, double-blinded studies and has demonstrated a favorable safety profile [39, 40]. However, budesonide enema was less effective in left-sided UC compared to 5-ASA [41]. In adults with mild–moderate active mesalazine-refractory ulcerative colitis, two recent studies have each shown a modest effect of budesonide MMX formulation for inducing remission compared to placebo and is well tolerated [42, 43]. In children with active ulcerative pancolitis, budesonide MMX was reported not be effective though side effects were not observed during a median treatment time of 5.2 months [44]. The role of these medications in maintenance of remission in ulcerative colitis has not been studied.

Conclusion

Corticosteroids have been primary induction treatment in Crohn disease for many years, but early, first-line biological treatment is now preferred in most pediatric patients due to their high risk of complicated disease. The inability to heal mucosa and disfiguring acute and serious long-term side effects, such as growth retardation and bone demineralization, further limit their use. The current trend in pediatric as well as adult Crohn disease is to minimize and avoid repeated corticosteroid use by introducing immunomodulators and biological treatment early in the course of disease. In mild active Crohn disease, primary treatment by a 6–8-week course of enteral nutrition is favored over remission induction by prednisolone. Systemic or topical corticosteroids are not effective as maintenance treatment.

Adrenal suppression is less during budesonide treatment compared to prednisolone, and GC-associated side effects, such as acne and moon face, occur less frequently.

Corticosteroids do not heal the mucosa, prevent relapse, and alter the course of disease. In the current era, confidence with early immunomodulator and biological treatment is growing, with a tendency towards top-down instead of step-up treatment. It is now clear that corticosteroids are losing their position as first-line treatment of pediatric IBD.

Mercaptopurine Therapy

29

Darja Urlep and Erasmo Miele

Introduction

Thiopurines (azathioprine and its prodrug 6-mercaptopurine (6-MP)) have been widely used as the first-line immunosuppressive drugs for maintenance of remission in patients with Crohn disease (CD) and ulcerative colitis (UC) [1]. Their role in combination therapy with anti-tumor necrosis factor (anti-TNF)-alpha agents is also established [2, 3]. However, their use is limited, mainly due to toxicity and the increased risk of lymphoproliferative disorders (LPDs) [4, 5]. Withdrawal of thiopurines associated with adverse events has been reported in about a quarter of patients with IBD [6]. Given the aforementioned increased risk for adverse events and malignancy, some pediatric gastroenterologists avoid using thiopurines in their everyday clinical practice. Recently, differences in use of thiopurines between the North American and European clinical practice have been reported [7]. In North America, anti-TNF drugs are frequently used as first-line treatment, while in Europe, they are more commonly used as second-line treatment in patients who do not respond adequately after at least 3 months of treatment with an immunomodulator [7]. These differences are reflected in the current European [8] and Canadian [9] guidelines on medical management of pediatric CD.

Currently, the prognostic factors for thiopurine effectiveness and their side effects mostly remain unknown. This is in part due to large interindividual pharmacokinetic differences and differences in genetic polymorphisms of enzymes involved in the complex thiopurine metabolism [10].

In this chapter, we review the metabolism of thiopurines and mechanisms of their action, their effectiveness in pediatric CD and UC, current clinical indications, the use of thiopurine methyltransferase (TPMT) enzyme testing and monitoring of thiopurine metabolites, thiopurines' toxicity, and adverse events, including the risk of malignancy.

6-Mercaptopurine Metabolism

Thiopurines are prodrugs and must be converted intracellularly to 6-thioguanine nucleotides (6-TGNs) to exert their therapeutic effect. After oral intake, azathioprine (AZA) is rapidly converted, predominantly by glutathione-S-transferase, to 6-MP. 6-MP can then be metabolized via three competing pathways: xanthine oxidase (XO), TPMT, and hypoxanthine-guanine phosphoribosyltransferase (HGPRT). In the first pathway, thiopurine metabolism via the XO pathway leads to production of 6-thiouric acid, an inactive metabolite excreted in urine. In the second pathway, TPMT converts 6-MP to 6-methylmercaptopurine (6-MMP) and 6-methyl-mercaptopurine ribonucleotides (6-MMPRs), which are inactive metabolites. Finally, metabolism via HPRT followed by inosine monophosphate dehydrogenase and guanosine monophosphate synthase leads to the production of 6TGNs, which are thought to be the active metabolites [11]). The complete metabolism of thiopurines leading to the production of 6TGNs and their mechanism of action are illustrated in (Fig. 29.1).

Thiopurines modulate immune responses through several mechanisms, which ultimately lead to apoptosis and inactivation of T-lymphocytes [12]. Firstly, 6TGN is incorporated into DNA replacing guanine and adenosine, leading to strand breakage and cell cycle arrest. Secondly, 6TGNs that are incorporated into DNA show reduced stability, leading to changes in DNA structure and activation of the mismatch repair system. Thirdly, the GTPase Ras-related C3 botulinum toxin substrate 1 (*Rac1*) bound to 6TGN (instead of guanosine-5′-triphosphate) blocks the *Rac1* activation pathway. The suppression of *Rac1*-target genes, such as mitogen-activated protein kinase, *NF*-k*B* and *bcl-x(L)*, causes a mitochondrial apoptosis [13]. Further mechanisms of action

include inhibition of several genes involved in intestinal inflammation and trafficking of leukocytes to the gut, such as tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL), TNF receptor superfamily member 7 (TNFRS7), and alpha-4-integrin in the presence of T-cell activation [14]. Similarly, anti-TNF-alpha therapy was also shown to suppress activation of Rac1-GTP. This may contribute to the synergistic effects of thiopurines and anti-TNFα agents [15].

Efficacy of Thiopurines in Crohn Disease

6-MP was shown to be an effective immunomodulator (IM) agent in the management of CD as early as in the 1980s. In a randomized controlled trial (RCT) published in 1980, 6-MP was more effective than placebo in stopping or reducing steroid therapy [16].

In a landmark pediatric RCT by Markowitz et al., early use of 6-MP was shown to be highly effective in pediatric CD patients with newly diagnosed moderate to severe CD. Fifty-five children, initially placed on a prednisone weaning therapy, were randomized into 6-MP or placebo groups. After 18 months of follow-up, 91% and 47% of patients in the 6-MP and placebo groups maintained clinical remission, respectively ($p = 0.007$) [17]. This is the only pediatric RCT on 6-MP effectiveness that has been published; however, subsequent observational pediatric studies did not confirm such high efficacy of early thiopurine use [18–21]. In a retrospective pediatric French study, steroid-free remission (SFR) was maintained in only 40% of CD patients at 12 months, and in 33% and 31% at 18 and 24 months of AZA monotherapy, respectively [21]. Lower success rates were also implied by Boyle et al., in a prospective multicenter study on thiopurine effectiveness in maintaining clinical remission based on real-life clinical practice. The observed rate of SFR was 47% at 6 and 23% at 12 months [22].

A large meta-analysis of AZA/6-MP effectiveness, a 2015 Cochrane review of nine studies, comparing AZA/6-MP with placebo, showed only modest superiority over placebo for maintenance of remission (relative risk (RR) 1.28) [23].

Until recently, no pediatric studies on use of dose optimization via therapeutic drug monitoring to bolster thiopurine efficacy have been published. In the first such study, published by Atia et al., interestingly, SFR at 12 months was comparable to those previously reported, with SFR found in 39% (37/96) of patients with CD. The study also underlined the importance of the normalization of inflammatory markers (C-reactive protein, erythrocyte sedimentation rate) as an outcome of treatment. At 12 months, SFR with a normalization of inflammatory markers was found only in 21% (20/96) of CD patients [24]. Further larger studies, preferably of RCT design, using optimized thiopurine therapy via monitoring of metabolites, are needed in the future.

Efficacy of Thiopurines in Ulcerative Colitis

The evidence for thiopurine use in UC is not as robust as in CD. In 2006, an adult open-label study in patients with UC demonstrated significant superiority of AZA over 5-aminosalycilic acid (5-ASA) in achieving clinical and endoscopic SFR [25]. A further 2016 meta-analysis showed thiopurine to be significantly superior to placebo in maintaining remission [26]. In pediatrics, an important prospective multicenter study by Hyams et al. found that 49% (65/133) of patients were in SFR, without the need for biologics or calcineurin inhibitors 1 year after initiating thiopurine therapy [27].

A multicenter Italian study compared SFR between early (0–6 months) and late (6–24 months) AZA initiation, with no statistically significant difference observed. At year 1, SFR was found in 50% and 57% of UC pediatric patients in the early and late groups [28].

In the previously mentioned study by Atia et al. with optimization of thiopurine treatment, in the UC arm, SFR was achieved in 39% (13/33) and SFR with a normalization of inflammatory markers in 27% (9/33) of UC patients at 12 months [24].

Thiopurines and Mucosal Healing

Thiopurines have also been shown to induce mucosal healing (MH), which has recently been put in the foreground as a main goal of treatment. An adult CD study by D′ Haens et al. demonstrated complete endoscopic healing of the colon in 70% and ileum in 54% of patients with CD after at least 9 months (24 ± 14 months) of AZA monotherapy [29]. However, the SONIC study reported that only 15% of adult CD patients treated with AZA monotherapy achieved MH at week 26 [2]. In another adult study by Qiu et al., MH was reported in 38% and 46% of CD patients on thiopurine monotherapy, after 12 and 36 months of thiopurine initiation [30].

A recent Italian pediatric multicenter study reported endoscopic healing in 77% of UC and 48% of CD patients after 52 weeks of AZA monotherapy; however, no association between histologic and endoscopic scores was observed [31].

Interestingly, in a recent observational study of 269 CD patients receiving anti-TNF biologics, combination therapy with thiopurines resulted in higher rates of MH at 12 months, compared to methotrexate co-therapy (58% vs. 17%, $p < 0.01$), while there were no significant differences in adverse events [32].

Clinical Indication

According to the current European pediatric clinical guidelines on CD, in patients who have reached remission, thiopurines can be used as maintenance therapy. Instead of thiopurines, methotrexate can also be used to maintain clinical remission as a first choice IM, or after thiopurine failure or intolerance [8]. The European pediatric guidelines on UC recommend thiopurines as first-line maintenance therapy, precisely in children with moderate-severe UC, who are steroid dependent or relapsing (≥ 2 relapses per year) despite optimal 5-ASA treatment and in UC children who are intolerant to 5-ASA [33]. However, in the Canadian recommendations on management of pediatric luminal CD, thiopurine use to maintain remission is recommended only in females, while the consensus group did not issue a recommendation regarding its use in male patients [9]. Reasons behind this decision were the concerns regarding increased conferred risk of LPDs [4, 5]. However, larger RCTs, comparing the effectiveness of thiopurines and methotrexate head to head are currently lacking. A smaller RCT comparing the effectiveness of these drugs in adult CD did not find any statistical differences in remission rates after 6 months (methotrexate 56%, azathioprine 63%; $p = 0.39$) [34]. However, in children, no RCTs on methotrexate effectiveness exist, and in almost all existing observational studies on methotrexate effectiveness, children mostly received methotrexate after thiopurine failure [35]; therefore, comparing the efficacy of thiopurines and methotrexate in children is difficult. Given the differences in recommendations, each pediatric gastroenterologist should consider the benefits and risks of prescribing thiopurines in each individual patient, considering their characteristics, and disease severity.

Thiopurines in Combination with Anti-TNF

Thiopurines, when used concomitantly with anti-TNF drugs, have been shown to decrease the likelihood of development of anti-drug-antibodies (ADAs) [2, 3].

In the SONIC study, the adult double-blind RCT, significantly more anti-TNF and AZA naïve CD patients on combination therapy (AZA + IFX) achieved SFR at week 26 (57%) in comparison with patients receiving IFX (44%; $p = 0.02$) or AZA alone (30%; $p < 0.001$) [2]. Using AZA with IFX improved serum IFX trough titers and decreased prevalence of ADA [2]. Similarly, in the UC SUCCESS study, superior efficacy of IFX in combination with AZA was shown in patients with steroid-refractory UC [3]. Quite surprisingly, in the DIAMOND study, no differences in clinical efficacy were found when AZA was used in combination with adalimumab or as monotherapy [36].

In pediatrics, most of available data are based on retrospective studies. A retrospective pediatric study which included 195 patients, treated for ≥30 weeks with IFX (monotherapy or combination with IM), showed a significant decrease in loss of response in patients who were treated with combination therapy [37]. Additionally, in a prospective observational study by Grossi et al., patients on combination therapy had a greater likelihood of remaining on IFX over time [38]. In agreement with these data, a recent systematic review of pediatric real-world observational studies (with an observation period of >1 year) reported that combination therapy with an IM improves the durability of IFX therapy [39].

A lot of uncertainty remains regarding the optimal duration of combination therapy. In an open-label pediatric trial by Kierkus et al., patients with CD who had achieved clinical response after induction treatment with IFX were randomized to groups, receiving either combination therapy for 54 weeks or 26 weeks, followed by 26 weeks of IFX monotherapy in case of the latter. At the end of year 1, there were no differences in terms of the clinical response loss rates, and clinical and endoscopic scores [40].

Contribution of thiopurines to the superiority of combination therapy with IFX is linked partially to their impact on IFX pharmacokinetics (formation of antibodies) [2]; however, thiopurines have also been shown to exert the additional synergistic effect with anti-TNF agents [41]. It was also demonstrated that the addition of a thiopurine in some patients who have lost response to anti-TNF monotherapy was an effective strategy to recapture anti-TNF response [42].

The European guidelines on pediatric CD recommend combination therapy with an IM (thiopurines or methotrexate) in patients starting with IFX [8]. The guidelines suggest stopping concomitant immunomodulator therapy after 6–12 months of combination therapy in cases when drug through levels are within the target levels and both endoscopic and transmural healing have been achieved [8]. The European recommendations on pediatric UC state that discontinuation of AZA may be considered after 6 months of combination therapy if satisfactory trough IFX levels are ensured (>5 μg/mL). The use of thiopurines with adalimumab, golimumab, and vedolizumab remains controversial due to a lack of randomized studies [33].

Contrary to the European guidelines on pediatric CD, the Canadian guidelines suggest against using infliximab or adalimumab in combination with thiopurines in males [9], but for females, the consensus group has not issued a recommendation [9]. Indeed, in a meta-analysis by Kotylar et al., assessing relative risk of lymphoma in patients with IBD exposed to thiopurines, the risk was lower in women compared with men, with the highest risk in younger men (<35 years) [4].

As it has become clear that combination therapy is associated with increased risk of lymphoproliferative disease, the risk of combination therapy must be always weighed against its benefits [43]. The risks of combination therapy may perhaps be lowered by a reduction in the dose of AZA, a strategy that has been shown not to affect immunogenicity [44]. Another strategy is to shorten the period of combination therapy, as it was shown that most immunogenicity develops in the beginning of biologic treatment [45].

Postoperative Prophylaxis

Studies from referral centers reported that symptomatic postoperative recurrence (POR) occurred in 20–37% of CD patients, whereas endoscopic lesions (Rutgeerts' endoscopic score ≥1) were found in 48–93% of patients within one year after surgery [46]. Risk factors for POR include extensive disease, short disease duration from diagnosis to surgery, recurrent surgery, long resected segment, surgery for fistulizing disease, disease complications, impaired growth, pubertal delay, perianal disease, or smoking habits [46, 47]. The current European guidelines on surgical management of pediatric CD state that thiopurines may be used for prevention of POR in children with moderate risk of CD recurrence. However, when thiopurines have failed preoperatively, careful risk–benefit analysis prior their postoperative use is recommended [47]. The use of thiopurines for prevention of POR in pediatric CD remains controversial, as all existing data come from adult studies [47]. The RCT by Hanauer et al. showed benefit of 6-MP (50 mg/day) over placebo (hazard ratio (HR) 0.52; $p = 0.045$) [48]. A RCT on 142 adult CD patients receiving AZA (2 mg/kg/day) or mesalazine (3 g/day) for 24 months did not find any difference in clinical

and surgical POR. Nevertheless, a subgroup analysis showed a favorable effect of AZA for patients with previous intestinal resections [49]. In a RCT by D'Haens et al., patients at high risk of POR received metronidazole (250 mg three times daily for 3 months) and additional AZA or placebo for 12 months. The endoscopic recurrence rate at 12 months was significantly lower in those receiving concurrent AZA (44%) compared to placebo (69%) [50].

Reinisch et al. randomized 78 CD patients with postoperative CD and moderate to severe endoscopic recurrence to receive AZA (2–2.5 mg/kg) or mesalazine (4 g/ day). Even if AZA treatment was associated with a significant decrease in the endoscopic score (decrease Rutgeerts' score ≥1) and lower rates of severe endoscopic lesions (Rutgeerts' score ≥i3), no difference in treatment failure between the two groups was observed [51]. However, three meta-analyses showed that thiopurines, although with more adverse events, were more effective than 5-ASA in preventing endoscopic POR at 12 months, but not severe recurrence or clinical recurrence at 12 or 24 months [52–54]. Nevertheless, evaluating only studies with a placebo arm, they demonstrated that thiopurines reduced clinical and severe endoscopic recurrence at 12 months [48, 50].

Finally, three RCTs comparing thiopurines and anti-TNF (adalimumab) also showed conflicting results. The first randomized study by Savarino et al., evaluating CD patients with ileocolonic resection receiving adalimumab, AZA, or mesalazine, starting 2 weeks after surgery, with follow-up for 2 years, demonstrated that the rate of endoscopic recurrence was significantly lower in adalimumab (6.3%) compared with AZA (64.7%) or mesalazine groups (83.3%). Furthermore, there was a significantly lower proportion of patients with clinical recurrence in the adalimumab group (12.5%) compared with AZA (64.7%) or mesalazine group (50%) [55]. In agreement with these data, the POCER study reported superiority of adalimumab over azathioprine [56]. However, the more recent APPRECIA trial demonstrated equivalent efficacy of the two drugs in terms of clinical, combined endoscopic/magnetic resonance enterography and surgical rates of recurrence [57].

Testing for TPMT Deficiency

Testing for TPMT deficiency has an important role in determining a safe initial dose of thiopurines [58]. The recommended pediatric AZA dose is 2–2.5 mg/kg once daily. The dose for its prodrug 6-MP is 1.0–1.5 mg/kg once daily [8]. Children aged six and younger may require higher doses of 6-MP/AZA per body weight to achieve clinical remission [59]. Dose reduction is necessary in patients who are heterozygous in the S-methyltransferase (TPMT) gene or with intermediate enzyme activity. Thiopurines are contraindicated in patients who are TPMT homozygotes, with extremely low enzymatic activity, as these patients are at increased risk of developing severe and even life-threatening myelotoxicity [58]. European clinical guidelines both on CD and UC and Canadian guidelines on pediatric CD recommend TPMT activity testing (phenotype or genotype) prior to thiopurine treatment [8, 9, 33]. However, as normal TPMT activity does not fully eliminate the risk of thiopurine toxicity, monitoring of complete blood count (CBC) and liver enzymes is mandatory. The aforementioned tests should be initially preformed once every 1–2 weeks during the first month of thiopurine treatment and later at least once every 3 months [8, 9, 33].

TPMT polymorphisms account for only 10–25% of overall thiopurine toxicity [10]. In 2014, Yang et al. discovered a missense variant in the NUDT15 gene (encoding p.Arg139Cys), strongly associated with thiopurine-induced early leukopenia in patients with CD. Although more common in Asians, the missense variant in the NUDT15 gene was also associated with thiopurine-induced leukopenia in patients with IBD of European descent [60]. Subsequent studies have reported several novel NUDT15 variants found in Asians (9.8%) and among Hispanics (3.9%), but rarely in Europeans (0.2%). Additionally, a NUDT R139C variant was shown to be significantly associated not only with early leukopenia but also with severe hair loss in patients with IBD [61]. Some authors have suggested to consider testing for NUDT15 variants, particularly in patients of Asian origin [62].

Monitoring of Thiopurine Metabolite Levels

Measurement of 6-TGN and 6-MMP levels during treatment with thiopurines has been suggested to facilitate safer and more effective thiopurine therapy. The correlation between 6-TGN levels and both clinical response and myelotoxicity was confirmed in several studies [63–67]. The adequate levels of 6-TGN to ensure efficiency while avoiding leukopenia are 230–450 pmol/8 × 108 RBC), and for 6-MMP <5700 pmol/8 × 108 RBC to avoid hepatotoxicity [43]. Interpreting the level of 6-TGN as low (<230) or high (>450) depends on the clinical features. In cases of active disease**,** a low or absent 6-TGN level may indicate underdosing or nonadherence [68]. A change in treatment should be considered in patients with active disease despite adequate 6-TGN levels after at least 12 weeks of thiopurine treatment [33]. In patients with hyperactive TPMT (hypermethylators) who present with low 6-TGN and high 6-MMP (often associated with elevated transaminases), concomitant use of allopurinol)50 mg once daily in patients <30 kg and 100 mg once

daily in patients ≥30 kg, maximum 5 mg/kg) with reduced dose of azathioprine (to approximately 25–30% of initial dose) may provide a valid therapeutic option [8, 33]. The current pediatric European clinical guidelines on CD [8] and UC [33] recommend measuring thiopurine metabolites (6-TGN and 6-MMP) in patients with suboptimal response, elevated liver enzymes, cytopenia, for compliance monitoring and for optimizing drug dosing.

Thiopurine Toxicity

Adverse reactions may occur in 10–28% of patients, including gastrointestinal intolerance, pancreatitis, hypersensitivity, and life-threatening bone marrow suppression, which often result in withdrawal of treatment [69–71]. Indeed, a thiopurine withdrawal rate due to adverse events has been observed in 2–30% of children [69]. Among dose-independent minor adverse events, rash, arthralgias, nausea, vomiting, diarrhea, and flu-like reactions represent common manifestations in patients receiving AZA or 6-MP; pancreatitis, neutropenia, hepatotoxicity, and malignancy represent major adverse events [69]. Pancreatitis has been reported in approximately 4% of patients treated with thiopurines, usually within weeks of beginning treatment, and is considered an idiosyncratic, dose-independent drug reaction [6]. Mild leukopenia ($3.0–4.0 \times 10^9$/L) is the most common hematological side effect occurring with standard doses of AZA. In children, leukopenia has been reported in about 10% of children receiving AZA or 6-MP and resolves either spontaneously or with dose reduction or drug discontinuation [72]. However, severe myelosuppression is the most common serious and occasionally fatal adverse event of treatment with AZA, more likely to occur in patients with absent or decreased TPMT activity [73]. An increased rate of serious infection, including opportunistic infections, has been described even in the absence of neutropenia [74].

As thiopurines prevent lymphocyte proliferation and increase apoptosis of activated lymphocytes, a primary infection with EBV or CMV may lead to development of hemophagocytic lymphohistiocytosis (HLH), a rare but life-threatening disorder of excessive macrophage activation and cytokine production [75]. A prospective registry of long-term outcomes in 5766 pediatric IBD patients identified five patients with HLH, all of whom were exposed to thiopurines [76].

Thiopurines may also cause mild elevations in transaminases that are transient or reversible with dose reduction, as well as, albeit rarely, nodular regenerative hyperplasia and portal hypertension, which can be progressive [77].

Thiopurines and Risk of Malignancy

In a large prospective observational French study that included 19,486 adult IBD patients, the multivariate-adjusted HR of LPDs between patients receiving thiopurines and those who had never been exposed to thiopurines was 5.28 [78]. Similarly, in a nationwide cohort study on 36,891 patients with UC, including 4734 UC patients treated with thiopurines, the adjusted HR of developing lymphoma for those treated with thiopurines was 4.2 [79]. Men with IBD taking thiopurines were found to be at higher risk for development of LPD, compared with women (SIR = 4.50 for men and 2.29 for women) [4]. Patients younger than 30 years had the highest relative risk (SIR = 6.99). Importantly, an elevated risk of lymphoma was found in current, but not former thiopurine users [4]. Interestingly, in a recent large cohort study, including 189,289 IBD patients, the risk of lymphoma did not differ between patients on thiopurine monotherapy (adjusted HR = 2.60), compared with patients on anti-TNF monotherapy (adjusted HR = 2.41). The risk was greatest in patients on combination therapy with thiopurines and anti-TNF agents (adjusted HR = 6.11) [5]. Similarly, in a recent systematic review and meta-analysis, using specific generalized linear mixed models appropriate for meta-analyses for rare events, the risk of lymphoma did not differ between exposure to thiopurine monotherapy and anti-TNF monotherapy, but was higher in those with combination therapy, as expected [80].

Among LPDs associated with thiopurines, the most concern is focused on hepatosplenic T-cell lymphoma (HSTC), a rare but mostly incurable form of non-Hodgkin lymphoma. The first cases of HSTCL were reported in 2007 in patients treated with thiopurines alone or with combination therapy with IFX [81]. In 2011, Kotylar et al. reported that the main risk factors for the development of HSTCL are male gender, age <35 years, and at least 2 years of thiopurine exposure [82]. In a recent systematic review that included data from the Food and Drug Administration (FDA) Adverse Event Reporting System, 62 patients with HSTCL were identified among IBD patients on biologic therapy (median age of 28 years; range 12–81) and only five of them did not have thiopurine exposure. All cases of HSTCL were exposed to anti-TNF, at least before exposure to other biologic agents. Eighty-four percent of them were male and 88 percent of them died, with a median survival of 5 months [83].

Due to higher risk of EBV-associated lymphoma in patients on thiopurines, the European Crohn's and Colitis Organisation stated that EBV IgG screening should always be considered before initiation of thiopurine therapy [84].

Thiopurine use has also been associated with risk of non-melanoma skin cancer, especially after several years of therapy [85]. European evidence-based consensus on malignancy in IBD recommends that patients being treated with thiopurines should be instructed on the lifelong use of sun protection measures and have regular full-body skin examinations [86].

Conclusion

Thiopurines have been proven to have a steroid-sparing effect, reduce likelihood of relapse, and improve efficacy of anti-TNF agents. However, their use should always be weighed against their potential risks, especially of LPDs. All current guidelines on pediatric IBD recommend TPMT enzyme activity or genetic testing prior to initiation of thiopurine therapy. Nevertheless, adverse effects may occur and pediatric IBD patients on thiopurine therapy should be carefully monitored. The purpose of thiopurine metabolite measurement (6-TGN and 6-MMP) is to achieve appropriate therapeutic response, assess for non-compliance or underdosing, and to minimize toxicity. Future discovery of new pharmacogenetic variants in the complex metabolism of thiopurines may elucidate the predictors of thiopurines effectiveness and help prevent their short-and long-term adverse events.
