Methotrexate

30

Joel R. Rosh

Introduction

In treating inflammatory bowel disease (IBD), the short-term goal remains the relief of clinical symptoms, while the long-term goal is to improve quality of life, as well as changing the natural history of the disease by decreasing the incidence of adverse outcomes, such as the need for hospitalization and surgical intervention. The long-term goals have undergone a paradigm shift over the last decade, embracing a model that emphasizes the induction and then maintenance of not only a clinical but also a biologic remission evidenced by mucosal healing [1, 2].

Glucocorticosteroids have both anti-inflammatory as well as immunomodulatory effects. As such, steroids have been the most commonly used immune-modifying agent in the treatment of pediatric IBD. Historically, it was recognized that when corticosteroids were started as an induction agent, more than 30% of pediatric patients with Crohn disease remained dependent on glucocorticosteroids 1 year after diagnosis, while almost 10% underwent surgery, thereby demonstrating steroids' inability to alter the course of Crohn disease [3]. In addition to this lack of long-term efficacy, chronic corticosteroid use is associated with a legion of side effects. As a result, approximately 60% of pediatric patients are placed on immune-modifying therapy within the first year of diagnosis [4].

The thiopurines, 6-mercaptopurine (6MP) and azathioprine (AZA), were shown to be effective as well as steroid sparing in the first pediatric IBD prospective multi-center trial which was led by Markowitz, et al. [5]. In addition to bone marrow suppression, pancreatitis, and idiosyncratic reactions, including fever and gastrointestinal toxicity, concerns with regard to hemophagocytic lymphohistiocytosis (HLH) and lymphoma, especially hepatosplenic T-cell lymphoma (HSTCL), drove clinicians to look for other potential immune-modifying agents [6, 7].

Methotrexate has emerged as an effective and overall well-tolerated alternative for the treatment of adults with Crohn disease [8–10]. While a prospective pediatric trial has not yet been performed, there are now ample published data regarding the efficacy of this agent in pediatric Crohn disease as well [11]. Notably, the clinical trial data in ulcerative colitis have not been positive [12].

Mechanism of Action

Methotrexate is a folic acid derivative originally designed as an analog of dihydrofolic acid. As a competitive antagonist of folic acid, methotrexate inhibits folate-dependent enzymes, such as dihydrofolate reductase (DHFR), which is critical to both purine and pyrimidine synthesis. In relatively high doses, methotrexate inhibits DNA production and exerts anti-proliferative as well as cytotoxic effects and has been used for many years in this manner as a cancer treatment [13].

When given for immune-mediated diseases, low-dose methotrexate is used. At these doses, methotrexate does not exert such a profound anti-metabolite effect. This is an important clinical distinction since at low dose, there is a relative absence of otherwise common side effects, such as hair loss and folate supplementation, may decrease the toxicity but not the apparent of efficacy of low-dose methotrexate [14].

The mechanism of action of low-dose methotrexate still needs to be fully elaborated. While not anti-proliferative, low-dose methotrexate may induce T-cell apoptosis [15, 16] although there are studies that do not agree with this finding [17]. Other potential mechanisms of action include methotrexate's effect on intra-cellular and extra-cellular concentrations of adenosine and the effects of adenosine on the adaptive immune response [18] (See Table 30.1). Methotrexate has also been shown to have a more direct effect on a variety of regulatory cytokines [19, 20]. Therefore,

Table 30.1 Effects of adenosine-related pathways on adaptive immune response

Increased interleukin (IL)-10
Increased IL-2
Inhibition of neutrophil chemotaxis
Decreased leukotriene B_4 (LTB_4)
Decreased tumor necrosis factor alpha
Decreased IL-6
Decreased IL-8
Decreased selective adhesion molecules (SAMs)

there are multiple effects of low-dose methotrexate and it should be considered as a nontargeted, nonspecific, immune-modulating agent.

Improved understanding of methotrexate's mechanism of action and pharmacokinetics may also affect the recommended dosing. As has become appreciated with the thiopurines, metabolites of the parent drug may be the more clinically important compounds. There is now evidence that intra-cellular methotrexate polyglutamates are the active immune-modifying compounds [19] and that there are genetic polymorphisms that have been shown to affect intracellular methotrexate polyglutamate levels. Therefore, pharmacokinetics and pharmacogenetics may play a large role in the efficacy and potential toxicity of methotrexate in any individual [20]. The importance of methotrexate polyglutamate levels in IBD patients has not yet been fully studied.

Efficacy

In 1995, Feagan et al. published their 16-week placebo-controlled induction study demonstrating that 25 mg of intra-muscular methotrexate delivered weekly is an effective, steroid-sparing, induction strategy in adult patients with active Crohn disease with a number needed to treat of five [9]. Those who achieved remission with methotrexate were then offered enrollment in a 40-week double-blind placebo-controlled maintenance trial of 15 mg of methotrexate administered intra-muscularly on a weekly basis. Seventy-six patients participated and demonstrated a methotrexate remission rate of 65% compared to 39% with placebo. No serious adverse events were noted [10]. In addition, there have been head-to-head trials suggesting that the effect of methotrexate is similar to that seen with thiopurines [21, 22].

There is now a true published experience with methotrexate in pediatric Crohn disease [23–33]. Mack et al. first reported on 14 patients with a mean age of 10.6 years who had active Crohn disease and received subcutaneous (SQ) administration of methotrexate and showed clinical improvement by as early as 4 weeks [25]. Steroid sparing was also demonstrated. Another single center experience [27] demonstrated a 12-month steroid-free remission rate of about 33% which is similar to that seen in reports of adult patients with Crohn disease. Good tolerance of the methotrexate therapy was reported. Two larger, multi-center retrospective reports [17, 26] demonstrated a 40–45% one-year steroid-free clinical remission rate with methotrexate. Again, overall good drug tolerance was demonstrated as were a steroid-sparing effect and a positive effect on linear growth [24]. Similar retrospective reports have been published from several European countries showing a 12-month remission rate of 25–52% and these studies are well summarized elsewhere [28]. Along with this growing evidence of the efficacy of methotrexate as monotherapy in treating pediatric Crohn disease, the concern regarding the potential toxicities of thiopurine therapy, especially in the pediatric population likely led to a much higher rate of methotrexate use in treating pediatric Crohn disease. In fact, a multi-center report from the Pediatric IBD Collaborative Research Group demonstrated that the number of patients exposed to methotrexate quadrupled from 2002 to 2010 (14% to 60%) [32].

Two prospective studies in ulcerative colitis (UC) investigated whether methotrexate was effective in adult UC. METEOR [34] was a randomized placebo-controlled trial that showed parenteral methotrexate to not be superior to placebo for the induction of steroid-free remission in adults with UC. Additionally, the multi-center MERIT-UC trial, a 48-week, double-blind, placebo-controlled trial demonstrated that methotrexate was both numerically and statistically inferior to placebo at preventing clinical relapse. Taken together, the METEOR and MERIT-UC studies have demonstrated a lack of efficacy for methotrexate in the treatment of adult UC [12, 35]. There are very limited published data on the use of methotrexate in pediatric UC and consensus guidelines state that this can be considered in rare cases [36, 37]. However, updated guidelines that consider the evidence from both METEOR and MERIT-UC are awaited.

In addition to its use as monotherapy, the use of methotrexate in combination with monoclonal antibodies directed against tumor necrosis factor alpha (TNF) has been explored. While the prospective COMMIT trial did not show improved efficacy of infliximab dosed in combination with methotrexate compared to infliximab monotherapy in adults with Crohn disease [38], many factors, including high rates of corticosteroid use at baseline, may have been critically confounding [39]. Notably, there were significantly higher infliximab levels and lower rates of antibodies to infliximab in patients who received methotrexate. Thus, a one-year trial may not have been long enough to see clinical difference between the two arms. Retrospective data from the Pediatric IBD Collaborative Research Group demonstrated improved infliximab durability when administered in combination with methotrexate [40]. It has been shown that the methotrexate dose may be critical to fully achieve this effect and a weekly dose of 12.5–15 mg weekly may be optimal when methotrexate is used as a concomitant agent [41, 42].

Dose and Administration

Methotrexate is administered once a week. The route of administration can be parenteral (subcutaneous or intramuscular) or oral. For parenteral dosing, the SQ route is better tolerated and, therefore, preferred. Since there are no head-to-head prospective trials comparing the efficacy of oral and parenteral methotrexate for IBD, it remains controversial whether there is a preferred route of administration. Retrospective reports have provided some data related to this question. Two uncontrolled, observational studies published within a year of each other differed in their conclusions with one showing no difference between oral and parenteral methotrexate [43] and the other showing clear advantage to the parenteral route [44]. Pharmacokinetic studies have been performed to see if there is a clinically significant difference in absorption between the two routes as it is recognized that oral absorption is individually variable and subject to a saturation effect with decreasing rates of absorption at higher doses, especially above 15 mg per dose [45].

In IBD, studies of adult [43] as well as pediatric patients [44] have demonstrated a wide individual range of methotrexate bioavailability. Interestingly, a study in adult patients showed the oral route to provide about 73% of the bioavailability that was seen with the parenteral route, while no such difference was seen in the pediatric study. Both of these pharmacokinetic studies were performed on subjects who were clinically stable on methotrexate maintenance therapy. Therefore, neither provides bioavailability data on patients being induced with methotrexate and there are retrospective data to suggest the parenteral route may induce a more rapid remission [45]. Additionally, it has recently been pointed out that any difference in bioavailability between these two routes of administration still falls within the FDA's definition of bioequivalence [46].

The question as to whether there is a clinically important difference in efficacy based upon the route of administration was investigated in a more direct, albeit retrospective manner, in the 2015 study by Turner et al. who used a propensity score analysis to look at outcomes in pediatric CD patients treated with oral vs. parenteral (subcutaneous) methotrexate [24]. This study demonstrated that any superiority of SQ over an oral route of administration was quite modest and the authors suggest that a change to oral MTX can be considered in those patients successfully induced with parenteral MTX. It is notable that a recent meta-analysis of the use of MTX in rheumatoid arthritis patients offered a different approach. This study demonstrated that efficacy and toxicity are related to an individual's absorbed dose rather than route of administration and the authors concluded that it is best to start patients on a relatively high oral dose and convert to the parenteral route in those who fail to respond [26].

In addition to the ongoing questions with regard to the optimal route of administration, the actual ideal dose of methotrexate for pediatric IBD patients has not been studied. The usual recommended dose is 15 mg/m^2 once weekly to a maximum weekly dose of 25 mg [47]. All patients are supplemented daily with folic acid 1 mg orally to avoid the development of medication-related nausea and subsequent anticipatory intolerance [28]. It has also been shown to be beneficial to recommend oral ondansetron as pre-medication before each of the first 8 doses to prevent drug-associated nausea [29]. In our Center, we often continue pre-medication with oral ondansetron indefinitely.

Toxicity and Monitoring

In patients with inflammatory bowel disease, low-dose methotrexate has been shown to be a well-tolerated agent with more than 90% of clinical trial patients able to complete study drug [20]. Reported side effects are usually transient or respond to dose reduction and, less commonly, drug withdrawal (the potential side effects of low-dose methotrexate are summarized in Table 30.2).

Table 30.2 Side effects and toxicities of low-dose methotrexate

- Teratogenicity:
  - Contraindicated in women of child-bearing potential
  - Contraindicated in breastfeeding women
- Gastrointestinal—folate related
  - Nausea and behavioral/anticipatory intolerance—most common
  - Abdominal pain, diarrhea
  - Stomatitis, including esophagitis
- Bone Marrow Suppression
  - Monitor with CBC (Table 30.3 for schedule)
  - Increased with trimethoprim–sulfamethoxazole
- Hepatic
  - Monitor with routine liver chemistries (Table 30.3 for schedule)
  - Increased risk with obesity, concomitant hepatotoxic medications
  - Routine liver biopsy not recommended
  - Possible role for elastography
- Infections
  - Upper respiratory most common
  - Rarely herpetic as well
  - Rarely clinically serious
- Pneumonitis
  - Immune mediated
  - Rare
  - Suspect if prolonged non-productive cough
  - Preliminary evaluation = chest radiograph and pulmonary function tests
- Dermatologic
  - Hypersensitivity reactions
- Renal excretion
  - Avoid in the face of renal impairment

There were early reports from the rheumatology literature that pediatric patients may have fewer methotrexate induced side effects compared to adult patients [48]. An exception to this may be the development of learned associations and anticipatory intolerance to the medication [49]. Nausea has been correlated with inhibition of folate-dependent enzymes. As a result, folic acid supplementation may help limit this side effect, which has been reported in more than 20% of the adult patients who participated in clinical IBD trials [50]. Use of ondansetron as a pre-medication for the first 4–8 weeks can effectively mitigate against the development of nausea [49]. Other gastrointestinal side effects include abdominal pain, diarrhea, and stomatitis that may even evolve into mucositis involving the esophagus [51].

In light of the potential for hepatic toxicity with high-dose methotrexate, liver-related complications have been well studied with low-dose methotrexate. There may be a disease-related rate of liver complications following therapy with low-dose methotrexate. Patients with psoriasis were shown to have a 7% rate of hepatic fibrosis [52] as compared to the 1% rate in rheumatoid arthritis [53]. The low rate of hepatic fibrosis and cirrhosis in RA has led to the official recommendation of the American College of Rheumatology that routine, surveillance liver biopsies not be performed [53]. Studies in juvenile idiopathic arthritis (JIA) patients have shown at least as good hepatic tolerance [50]. Similarly, negligible rates of drug-related hepatotoxicity have been seen in adult patients with IBD treated with prolonged low-dose methotrexate [54]. This may actually occur at a higher rate in pediatric patients with a meta-analysis demonstrating a rate of elevated liver chemistries as high as 10% with 6% requiring dose reduction [55].

Rather than biopsy, routine liver chemistry monitoring should be performed as shown in Table 30.3. Elastography is a promising tool to noninvasively monitor for drug-induced hepatic fibrosis and it may be more sensitive than measuring liver chemistries. More recent data using elastography have been quite reassuring as liver fibrosis was not seen in Crohn disease patients on low-dose methotrexate therapy [56].

Due to the risk of liver toxicity, it seems prudent to avoid methotrexate use in significantly overweight and obese patients as the risk of therapy is increased in the presence of fatty liver disease. In addition, since it is renally excreted, methotrexate should also be avoided in patients with known kidney disease.

Bone marrow suppression leading to leukopenia or thrombocytopenia occurs in about 1% of low-dose methotrexate treated patients [20]. This is usually transient and responds to dose reduction or holding of the drug. Routine monitoring of complete blood counts should be performed to look for bone marrow suppression (Table 30.3). Concomitant medications, especially anti-folate agents, such as trimethoprim–sulfamethoxazole should be avoided with methotrexate therapy as these can exacerbate potential bone marrow suppression. Theoretically, this may be true of sulfasalazine as well although the combination of low-dose methotrexate and sulfasalazine has been utilized without increased toxicity [57].

Table 30.3 Methotrexate (MTX)—dosing and Monitoring

- **Supplemental oral folic acid 1 mg/day to be given to all patients**
- **Consider pretreatment with ondansetron at least for first 4–8 doses of MTX**
- **Dose** (subcutaneous injection on a weekly basis)
  - 15 mg/m^2 (body surface area) to a maximum dose of 25 mg once a week
- **Maintenance**
  - Consider conversion to oral dosing if stable >3 months
  - If clinical remission for >3–6 months consider decreasing dose to 10 mg/m^2 to a maximum of 15 mg once a week
- **Patient monitoring**
  - Complete blood count (CBC) with differential and platelets, Erythrocyte Sedimentation Rate (ESR) and/or C-reactive protein (CRP), and liver chemistries weekly for the first month and then every 2–3 months if stable.
  - The dose should be reduced by 50% for elevation in alanine aminotransferase (ALT) >twice baseline
  - The dose should be reduced by 50% for white blood count (WBC) <4000, absolute neutrophil count (ANC) <1500, or platelet <120,000 and held for 2 weeks for WBC <3000, ANC <1000, or platelets <100,000.

MTX should be held for 2 weeks for nonproductive cough >1 week and discontinued for pneumonitis or serious infections

An immunologically mediated pneumonitis can also rarely be seen with methotrexate therapy. Screening asymptomatic pediatric patients does not seem warranted and in fact, the rarity of this condition when methotrexate is used for inflammatory disease has recently been further characterized [58]. Clinically, a persistent cough or other symptoms should prompt a chest radiograph and pulmonary function studies with suspension of methotrexate therapy until clarification of the clinical picture is achieved.

The most important toxicity of methotrexate is related to its teratogenicity. Methotrexate is completely contraindicated in pregnancy as well as during breastfeeding. All patients and their families must be educated about this prior to starting methotrexate therapy. Previous concerns about the use of methotrexate for males considering conception have recently been called into question [59].

Infliximab Therapy for Pediatric Crohn Disease and Ulcerative Colitis

31

Ruben J. Colman, Dana M. H. Dykes, Ana Catalina Arce-Clachar, Shehzad A. Saeed, and Phillip Minar

Introduction

Both Crohn disease (CD) and ulcerative colitis (UC) are chronic inflammatory conditions of the gastrointestinal tract characterized by a relapsing and remitting course that requires treatment to prevent disease-related complications. The goal of therapy in pediatric inflammatory bowel disease (IBD) should be to induce and maintain clinical remission, prevent delays in growth and puberty, and improve quality of life while minimizing the adverse effects of medications [1]. Since the onset of IBD peaks in early adolescence in children, there exists a very narrow therapeutic window before growth retardation and developmental deficiencies may become permanent. These goals are often not achieved with previous (historic) therapeutic strategies (sulfasalazine, 5-aminosalicylates, immunomodulators [IMMs], and corticosteroids [CSs]). Prior to use of biologics, the short-term clinical response with historic management strategies was only 60% with CS resistance seen in 17% and CS dependency noted in 30–45% of children with IBD with an overall unfavorable safety profile [2–5]. For maintenance of remission, IMM, including thiopurines (TPs) and methotrexate (MTX), had long been the mainstay of therapy for pediatric IBD. Historically, IMMs were considered first to second-line therapy despite an overall poor long-term response rate, ranging from 49 to 80% for TPs and 27% for MTX [6–9]. In addition to a high incidence of side effects [10], the IMMs are often paired with CS given the slow onset of action of IMM.

Additional therapeutic options prior to the development of biologics also included dietary therapy, specifically exclusive enteral nutrition, which is associated with response rates >80% [11]. Exclusive enteral nutrition has an important role in the management of IBD, especially in CD, including prevention and correction of malnutrition, prevention of osteoporosis, and the promotion of optimal growth and development with long-term non-adherence as the leading cause of treatment failure [12, 13].

With homage to historic approaches to manage IBD, it is clear that the advent of biologic therapies has revolutionized the treatment landscape for both adult and pediatric IBD. Infliximab was the first anti-TNF medication approved for use in children in 2006 followed by approval of adalimumab for treatment of moderate to severe pediatric IBD (discussed in Chap. 32). Infliximab is a chimeric monoclonal IgG1 antibody to tumor necrosis factor (TNF)-α. It is composed of a (±75%) human constant and (±25%) murine variable region. TNF is a prominent pro-inflammatory cytokine with the number of TNF-producing immune cells significantly increased in the lamina propria of the bowel of patients with IBD and increased concentrations of TNF have been found in the stool of children with IBD [14–16]. Infliximab binds to both soluble and bound TNFα to neutralize TNF, inhibit leukocyte migration and induce apoptosis of T lymphocytes and monocytes [17–21]. An additional mechanism of action for infliximab to neutralize TNF includes complement-dependent cytotoxicity (CDC) and antibody-dependent cellular cytotoxicity (ADCC) [22].

In this chapter, we will review the current evidence for the role of infliximab as a first-line biologic in pediatric CD and as second-line for moderate to severe UC, including review-

ing the current evidence for combination therapy vs. monotherapy and a review the role of therapeutic drug monitoring (TDM) to optimize dosing strategies to improve drug durability.

Crohn Disease

Current evidence suggests CD develops as the result of a dysregulated immune response to the intestinal microbial flora in a genetically susceptible host [23]. Targan et al. showed that more than 80% of adult CD patients had a clinical response 4 weeks after a single infusion (5 mg/kg) of infliximab [24]. This study was followed by the randomized ACCENT 1 clinical trial in which 58% of adult CD patients (335/573) had a clinical response after the first infusion and were randomized to either placebo or infliximab (dosed as 5 or 10 mg/kg) [25]. Both doses of infliximab were more effective in achieving clinical remission at week 54 compared to placebo, while there was no statistical difference in clinical response or remission between the 5 and 10 mg/kg groups. Early pediatric studies [26, 27] also demonstrated high clinical response (94%) and remission (48%) rates after a single dose of infliximab. These small clinical reports along with the landmark adult clinical trials paved the way for the first randomized clinical trial with infliximab in children with CD.

Infliximab Is Within REACH for Pediatric CD

The Randomized, Multicenter, Open-Label Study to Evaluate the Safety and Efficacy of Anti-TNF Chimeric Monoclonal Antibody in Pediatric Subjects with Moderate to Severe Crohn Disease (REACH) enrolled pediatric CD (PCD) patients with a Pediatric CD Activity Index (PCDAI) >30 [28]. Notably, all children enrolled were receiving concurrent, stable doses of an IMM (TP or MTX). All subjects received the same induction regimen of 5 mg/kg at 0, 2, and 6 weeks with clinical response (defined by a decrease in the PCDAI by 15 points from baseline) evaluated at week 10. Subjects meeting clinical response criteria were then randomized to receive infliximab either every 8 or 12 weeks. Overall, 112 children were enrolled and 103 (92%) were randomized. Hyams et al. found that 88.4% had a clinical response by week 10 and 55% in clinical remission (PCDAI ≤10). At week 54, 63.5% of subjects allocated to every eight-week infusions had a clinical response with 55.8% in clinical remission compared to a clinical remission rate of 23.5% for those who received infliximab every 12 weeks ($p < 0.001$). Not only did the subjects receiving infusions every 8 weeks have improvement in gastrointestinal symptoms, but they also had significant improvements in their mean height *z*-score by week 54 as well [28].

While REACH established infliximab efficacy and set the precedent for maintenance dosing in PCD, this landmark study may not reflect current practices in PCD treatment algorithm with infliximab. As discussed, all children in REACH were receiving and continued concomitant IMM therapy throughout the trial. While REACH demonstrated efficacy of combination therapy with infliximab (predominantly TP) [28], there is a serious safety concern with this dual therapy approach given the association of hepatosplenic T-cell lymphoma (HSTCL) in patients receiving this specific combination (infliximab and TP), especially in young (<35 years old) males [29]. Recent data from an Inflammatory Bowel Disease Multicenter, Prospective, Long-term Registry of Pediatric Patients (the DEVELOP Registry) confirmed that both malignancies and hemophagocytic lymphohistiocytosis (HLH) were associated with TP either used as monotherapy or in combination with biologic therapy and not with infliximab monotherapy itself [30]. While we await the results of the comparative effectiveness clinical trial of ant-TNF monotherapy vs. combination therapy with lose-dose MTX in PCD (The COMBINE Study, ClinicalTrials.gov, NCT02772965), Feagan et al. found that infliximab in combination with MTX was safe but no more effective (similar treatment failure rate, 30.6% vs. 29.8%) than infliximab monotherapy in a 50-week double-blind, placebo-controlled trial of 126 adults with CD [31].

Early Use of Infliximab

In contrast to UC, CD-specific phenotypes (severe growth failure, stricture, and/or fistula formation) and a poor overall response to 5-aminosalicylates [32] combine to present unique challenges toward the successful management of this progressive disease. The pivotal studies by Markowitz et al. [7]. showed that early induction with TP improved rates of sustained clinical remission and reduced CS use compared to placebo in PCD. Unfortunately, TP showed no effect on linear growth and subsequent studies have not been able to replicate these early results [7]. With the success of REACH in PCD, and the Study of Biological and Immunomodulator Naïve Patients in Crohn Disease (SONIC) [33] in adult CD, many pediatric gastroenterologists started to adopt early introduction of anti-TNF therapy with or without an IMM in a select group of patients who were judged by their physicians to be at increased risk of disease complications. The speculation was that early anti-TNF would improve rates of intestinal healing and result in less structural damage leading to fewer complications (strictures or fistula) and subsequently, a decrease in rates of CD-related abdominal surgery.

In order to better evaluate if early anti-TNF was associated with improved outcomes, Walters et al. [34]. evaluated early anti-TNF therapy in a well-defined inception cohort of PCD subjects who were enrolled in the RISK Stratification study (RISK; Risk Stratification and Identification of Immunogenetic and Microbial Markers of Rapid Disease Progression in Children with Crohn Disease). RISK is the largest prospective inception cohort of PCD and enrolled their first patient in 2008 and overall included 913 children <17 years of age with newly diagnosed, inflammatory (non-penetrating and non-stricturing) CD from 28 centers in the USA and Canada [35]. In the Walters et al. study, which included a subset of the RISK cohort (552/913), the authors separated the cohort into triads (those who initiated anti-TNF therapy within the first 3 months of diagnosis, subjects who received an IMM within 3 months, and a group who did not receive either an IMM or anti-TNF therapy within the first 3 months of diagnosis) and evaluated the one-year clinical outcomes. The physician global assessment (PGA) and PCDAI were used to document response. Patients receiving a combination of anti-TNF and IMM (n = 12) were not included in the analysis. Sixty-eight of the 552 subjects received anti-TNF within the first 3 months of the initial diagnosis which led to a propensity score analysis to match the subjects in each triad and reduce the risk of selection bias. In this study, 67/68 early anti-TNF subjects received infliximab. The IMM group (n = 68) included 14/68 patients on azathioprine, 40/68 on 6-mercaptopurine, and 14/68 on MTX. Overall, there was no difference in complete response (as defined by the PGA) at 3 months (50% on anti-TNF, 45.5% on IMM, 42.5% on IMM/anti-TNF). However, at 1 year, 85.3% of those receiving early anti-TNF were in remission compared to 60.3% receiving an IMM (P = 0.0003) and 54.4% in the no IMM/anti-TNF group [34]. The authors did not find any patient-specific characteristics (age, gender, albumin, or C-reactive protein) or disease phenotype (deep ulcerations at diagnostic colonoscopy) that affected the probability of surgery-free remission. Similar to REACH, they found the mean height z-score increased by 0.14 in the early anti-TNF triad compared to the other two triads [36].

Early infliximab therapy in treatment-naïve CD patients was also compared in a head-to-head trial versus CS or exclusive enteral nutrition (EEN) in an open-label, parallel-arm RCT [37]. In this Top-down Infliximab Study in Kids with Crohn disease (TISKids) trial, the biosimilar infliximab-dyyb was administered for the first 5 infusions as a modified induction to the first group and CS or EEN was given as an induction regimen in the second group of newly diagnosed, treatment-naïve moderate–severe (PCDAI >40) PCD patients. In this European trial, subjects also received azathioprine in combination from the start of treatment in both groups and continued throughout maintenance therapy. The primary endpoint was clinical remission (PCDAI <12.5) without the need for additional treatment escalation beyond TP maintenance therapy or surgery by 52 weeks. Among the top-down group, 41% (19/46) were in clinical remission at week 52, while only 15% (7/48) were in remission in the step-up group (P = 0.004) [38]. In a secondary analysis, top-down patients had a higher rate of mucosal healing than step-up patients at week 10 [38].

Combination Therapy Versus Infliximab Monotherapy

As noted, the hallmark studies of infliximab in PCD and adult CD, (REACH and SONIC), demonstrated efficacy of infliximab in combination with an IMM. In the SONIC trial, 56.8% of subjects receiving the combination of infliximab and TP achieved CS-free clinical remission at week 26 compared to 44.4% of those receiving infliximab monotherapy (P < 0.02). Although combination therapy was associated with higher rates of clinical remission compared to infliximab monotherapy in SONIC, there was a trend but not statistically significant difference in mucosal healing at week 26 between the two groups (43.9% vs. 30.1%, p = 0.06). With a growing, concerning list of IBD patients diagnosed with HSTCL, especially in young, male patients who had received combination TP and anti-TNF therapy, many pediatric gastroenterologists are hesitant to prescribe this combination [39].

With additional studies suggesting the benefit of combination infliximab therapy is secondary to improved pharmacokinetics (PK), Colombel et al. performed a post hoc analysis of the SONIC cohort in those who had infliximab trough concentrations available at week 30 [40]. When they re-evaluated the rates of CS-free clinical remission at week 26 by quartiles of infliximab concentrations, they found there was no difference in rates of remission between combination therapy and monotherapy [40]. These results led Colombel et al. to conclude that the benefit of combination therapy was likely secondary to the improvement in infliximab PK properties and to suggest future studies to evaluate whether sustaining therapeutic drug concentrations with biologic monotherapy could achieve the same desired clinical outcomes as combination therapy [40].

Grossi et al. [41] evaluated the real-world experience of concomitant use of IMM and infliximab in PCD. The study population included 502 PCD patients in the Pediatric Inflammatory Bowel Disease Collaborative Research Group Registry who had received infliximab. They included all children with CD younger than 15 years old who had received a minimum of three induction doses of infliximab. The primary outcome was continuation of infliximab after initiation of therapy. The probability of remaining on infliximab was evaluated using the Kaplan–Meier curve analysis. They

found 84% of patients remained on infliximab at 1 year, 76% at 2 years, 69% at 3 years, and 60% at 5 years. Overall, they found that clinical factors, including disease extent, age at diagnosis, perirectal involvement, or starting infliximab within 2 years of diagnosis, did not affect durability of infliximab response. They further showed that patients receiving concomitant IMM for >6 months were much more likely to remain on infliximab over time as compared to both no IMM exposure and IMM use <6 months. Overall, 47% of patients receiving infliximab required an intensification (increased dose or frequency), which was delayed if infliximab was combined with IMM for greater than 6 months ($P < 0.05$).

An additional significant finding from the Grossi et al. registry is that male patients receiving MTX for more than 6 months demonstrated a significant greater likelihood of remaining on infliximab (similar for females but a smaller cohort size) [41]. Furthermore, they showed that a combination of MTX and infliximab durability was superior to TP/infliximab. For comparison, in an RCT with adult-onset CD patients, Feagan et al. failed to show any differences in one-year clinical outcomes between combination infliximab and MTX compared to infliximab monotherapy. However, the combination group had a lower likelihood of developing immunogenicity (4% vs. 20%, $p = 0.01$) and had a higher median serum trough infliximab concentration (6.35 μg/mL) compared to those on infliximab monotherapy (3.75 μg/mL, $P = 0.08$) [31]. In addition, an analysis of pediatric data found that when IMMs were added following the development of anti-drug antibodies, patients receiving combination MTX had improved outcomes compared to those who were maintained on monotherapy [42].

As noted, a prospective pediatric RCT, the Low-Dose Oral Methotrexate in Pediatric Crohn Disease Patients Initiating Anti-Tumor Necrosis Factor Therapy (COMBINE) trial, is currently testing the long-term efficacy of combination MTX in comparison to anti-TNF monotherapy (NCT02772965).

Proactive Therapeutic Drug Monitoring and Treat-to-Target in CD

The defining feature of CD is its relapsing and remitting course. The overarching treatment goal is to induce and sustain remission while minimizing secondary complications. SONIC and other studies have shown that infliximab heals the gut lining (absence of ulcerations) with intestinal healing evolving as a "target" of CD management [33, 43]. Although the United States Food and Drug Administration (FDA) will continue to mandate documentation of intestinal healing in future drug trials, there has been an increased interest in evaluating patient reported outcome (PRO) measures and pharmacodynamic biomarkers, such as C-reactive protein and fecal calprotectin to inform biologic dosing [44]. In clinical practice, pediatric gastroenterologists are left to debate the safety and utility of repeat endoscopy to document intestinal healing versus using surrogate biomarkers or disease activity scores to guide treatment strategies. Until surrogate markers are further validated and cutoff values are better established (such as for fecal calprotectin) in those receiving infliximab, pediatric gastroenterologists will need to develop best practices to utilize therapeutic drug monitoring (TDM) as multiple studies have found that a detectable serum trough concentration correlates with clinical response and mucosal healing [45–48], while loss of response to infliximab largely results from increased clearance of the drug (high inflammatory burden, diarrhea) and/or presence of antibodies to the drug [49, 50].

Similar to TDM for TP metabolite concentrations, regular monitoring of infliximab serum concentrations is predicted to improve drug efficacy by tailoring dosing regimens to an individual's PK [51, 52]. An initial retrospective study suggested that proactive TDM, as an alternative to reactive TDM (testing with clinical symptoms), may be associated with improved clinical outcomes as proactive TDM allows for dosing adjustments to a target range when the patient is asymptomatic [53]. While future clinical trials of proactive TDM are needed for infliximab, Assa et al. found that proactive monitoring of adalimumab trough concentrations and subsequent dose optimizations were associated with an increase in clinical remission compared to the strategy of reactive TDM [54].

While the therapeutic target range for infliximab maintenance has been controversial, Ungar et al. showed in adults that an infliximab trough of 6–10 μg/mL was associated with mucosal healing [55]. More recent evidence suggests a target range of 10–15 μg/mL may be required for complicated CD as the median infliximab trough for perianal fistula healing was 12.7 μg/mL (IQR, 6.6–15.5) [56]. Finally, in a large adult and pediatric cohort study (PANTS), a subtherapeutic drug concentration prior to the start of infliximab maintenance was the only independent factor associated with both primary non-response and year-one non-remission [57]. The group found post-induction concentrations >7 μg/mL were associated with lower fecal calprotectin and protective against immunogenicity [57].

Despite a high clinical response rate during infliximab induction, the use of the as-labeled (5 mg/kg) infliximab dosing regimens in children with IBD has been associated with a high rate of subtherapeutic trough concentrations during induction as well [58]. These observations have led to renewed interest in achieving therapeutic targets at the start of treatment with higher infliximab doses guided by disease severity [59] and biomarkers of increased infliximab clearance [60].

As suggested by the findings in the post hoc analysis of the SONIC trial [40], anti-TNF monotherapy in combination with proactive TDM may minimize the need for combination therapy with IMM and infliximab [61]. Arguments for proactive TDM include preventing undetectable or subtherapeutic trough concentration (consequently also decreasing the risk of immunogenicity) and potentially preventing future morbidity by using dose intensifications prior to the development of symptoms or CD-related complications. In their retrospective review, Vaughn et al. showed that in adult CD patients, a strategy of proactive TDM vs. a standard of care group (where drug level monitoring was symptom based), achieving an infliximab trough of ≥5 μg/mL resulted in >90% probability of maintaining infliximab over 5 years. Importantly, they found with proactive monitoring only 29% of the cohorts were within the target range of 5–10 μg/mL, which is similar to a PCD study that found 24% had undetectable levels and 38% were <3 μg/mL following reactive TDM [46, 53]. Interestingly, Vaughn et al. found that small-dose adjustments (median escalation of 100 mg, range 50–250 mg) were enough to improve the trough levels in contrast to common methods of infliximab intensification in clinical practice of doubling from 5 to 10 mg/kg or decreasing the frequency of infusions from 8 to 6 weeks [53]. An analysis of a real-world practice change from reactive to proactive TDM among pediatric IBD patients demonstrated that proactive TDM was associated with a higher odds of achieving CS-free remission (clinical and biochemical) and decreased infliximab failure due to immunogenicity (Fig. 31.1) [62].

Two adult trials have attempted to study proactive monitoring prospectively; however, they did not find any clinical benefit when they studied this for the maintenance phase. In the Trough Concentration Adapted Infliximab Treatment (TAXIT) RCT, subjects with sub- or supratherapeutic doses were initially dose optimized to achieve levels between 3 and 7 μg/mL. Following dose optimization, subjects were then randomized into a reactive versus a proactive TDM group to maintain 3–7 μg/mL. While there were no differences in rates of achieving remission, the proactive group had fewer disease flares [48]. In a second study, a randomized controlled trial investigating tailored treatment with infliximab for luminal Crohn disease (TAILORIX), patients were randomized to different strategies of maintenance dose escalation based on a combination of clinical, biochemical, and trough level targets also using the 3 μg/mL cutoff [63]. At 1 year, the combination of strategies was no more effective in achieving remission than dose escalation based on symptoms alone. More recent evidence suggests that the cutoffs in these studies may have been suboptimal. A post hoc analysis of TAILORIX subsequently identified that a week-14 level of 7.8 μg/mL was associated with radiologic remission at 1 year [64], while a week-2 level >23 μg/mL and a week-6 level >10 μg/mL were associated with endoscopic remission at week 12 (which was prior to the randomization phase) [65]. In fact, a recent PCD study identified that an induction infusion level of ≥26.7 μg/mL at week-2 and a level of ≥15.9 μg/mL at week-6 were associated with clinical response [66]. Moreover, to achieve a higher week-14 level of >5 μg/mL, levels ≥29 μg/mL and ≥18 μg/mL should be targeted at week-2 and 6, respectively, and has been endorsed in the 2020 ECCO/ESPGHAN CD guidance on TDM [67].

There is an accumulating body of literature that has furthermore demonstrated that proactively monitoring trough levels as a proxy for exposure is important as there are several PK factors that can lower drug exposure, including weight <30 kg, younger patients, lower serum albumin, more extensive disease, immunogenicity, and possibly additional

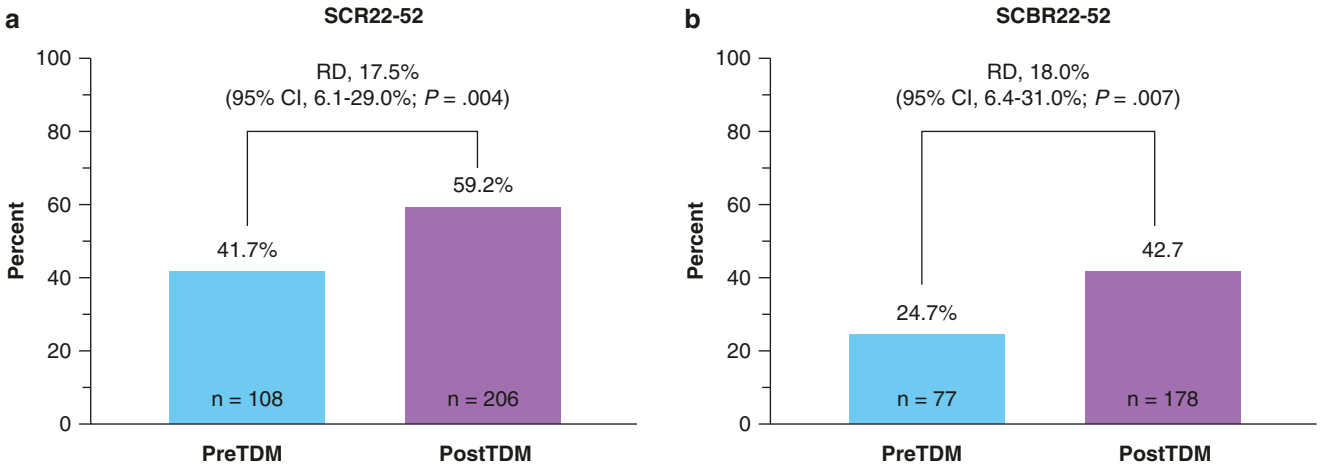

Fig. 31.1 Bar graphs comparing percentage of patients in (**a**) sustained clinical remission between 22 and 52 weeks (SCR22-52) and (**b**) sustained clinical and biochemical remission between 22 and 52 weeks (SCBR22-52) between pre-TDM and post-TDM groups. Used with Permission [62]

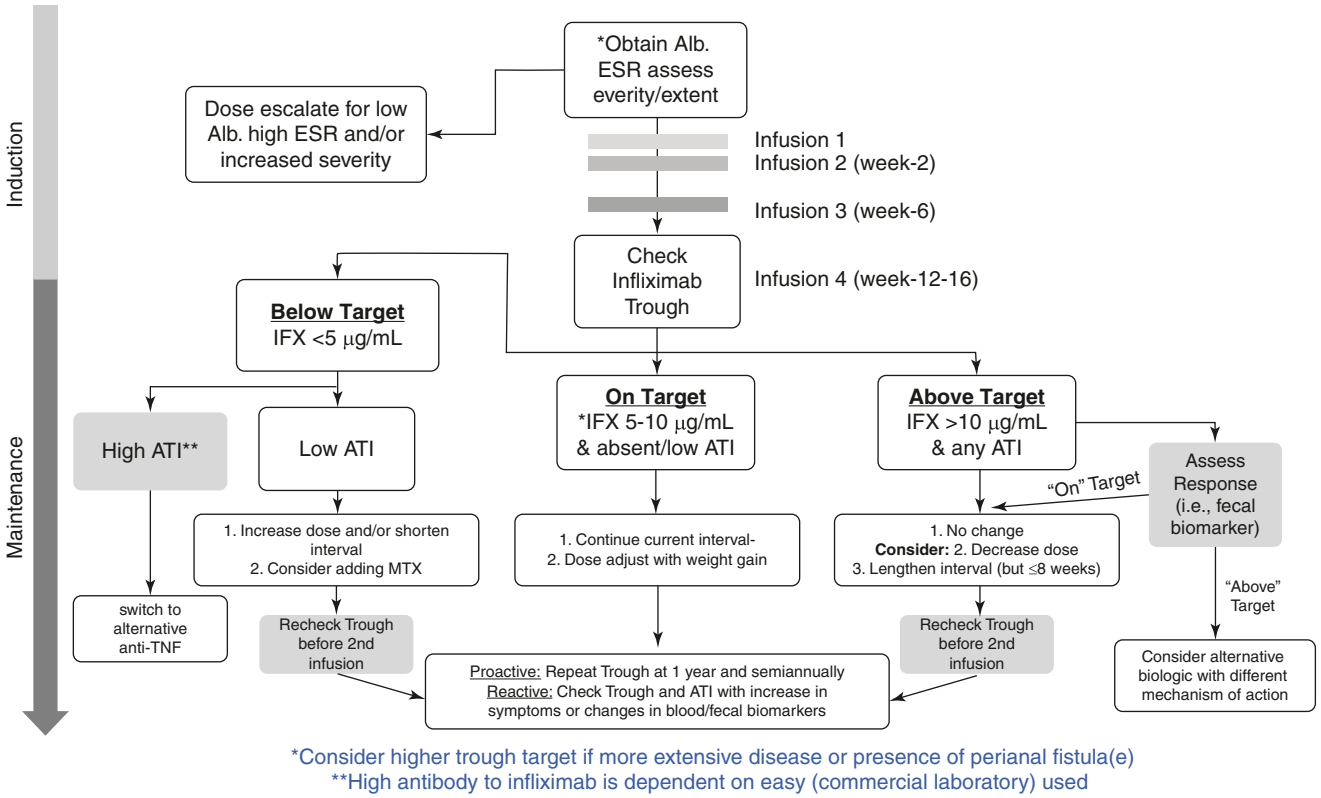

Fig. 31.2 Proposed Algorithm for Proactive Therapeutic Drug Monitoring in Children with IBD. The first infliximab trough concentration is to be obtained at the end of induction (prior to first maintenance dose). For patients predicted to have accelerated drug clearance during induction (high inflammatory burden, severe colitis, and/or low serum albumin), a higher dose (>5 mg/kg) should be considered as well as checking a trough concentration at infusion-3 (week-6) to guide future maintenance dosing. Alb, serum albumin; ATI, antibody to infliximab; ESR, erythrocyte sedimentation rate; IFX, infliximab; MOA, mechanism of action; MTX, methotrexate

composite markers of inflammation, such as erythrocyte sedimentation rate (ESR) and neutrophil CD64 surface expression. There is a need for a more systematic approach to biologic dosing and proactive TDM (Fig. 31.2) [60, 68–73]. Based on these observations, precision dosing guided by PK dashboards may be a more accurate way for clinicians to account for these individual factors in the real world [60, 69, 74, 75]. Preliminary data from a prospective adult trial found that dashboard-guided dosing was more effective in preventing relapse than labeled dosing, even when a target trough level of 3 μg/mL was used [76].

In addition to monitoring of PK factors, a better understanding of how infliximab exposure leads to mucosal healing and improvement in composite pharmacodynamic (PD) biomarkers is warranted. As close monitoring with serial endoscopies is impractical for adult-onset and PCD, the 2020 ECCO/ESPGHAN CD guideline recommends serial PD monitoring with fecal calprotectin to monitor biochemical response [77]. Moreover, a recent pediatric study demonstrated that higher exposure to infliximab was associated with a better improvement in fecal calprotectin and blood biomarkers [78].

Infliximab Concentration Detection Methods

Multiple assays have been developed to improve the monitoring for circulating infliximab levels, including the enzyme-linked immunosorbent assay (ELISA), the radioimmunoassay (RIA), a drug neutralizing (activity) assay (ARUP Laboratories, Salt Lake City, UT), and the homogenous mobility shift assay (HMSA) offered by Prometheus® (Prometheus Laboratories Inc., San Diego CA) [79–81]. Infliximab serum concentrations can be determined quickly and at low cost with the ELISA technique. However, due to infliximab drug interference, certain ELISA may not detect the presence of antibodies to infliximab (ATI) if circulating drug is present. Newer technologies have permitted commercial laboratories to offer novel assays that are drug tolerant and can detect both infliximab concentration and ATI in the presence of a detectable infliximab concentration using the HMSA or the electrochemiluminescence immunoassay (ECLIA, offered by LabCorp, Esoterix, Calabasas, CA and Mayo Clinic Laboratories, Rochester, MN). Moreover, it should be noted, that while infliximab levels are often comparable between these assays, there may be more disagree-

ment between ATI measurements (either in the reported unit of measure and whether total [neutralizing and non-neutralizing] or neutralizing ATI are reported) [82]. While these previously described techniques may be cost prohibitive and may take up to several weeks to result, with the increase use of proactive TDM and PK dashboard-assisted dosing, it is important to identify more rapid patient-centered and cost-effective methods optimized dosing and concentration monitoring [75]. Reliable point-of-care tests with instant turnaround times and more patient friendly methods (such as dried blood sampling by finger sticks at home) may revolutionize the current TDM practice [83].

Incidence of Primary and Repeat Abdominal Surgeries in the Infliximab Era

The cumulative incidence of surgery 10 years after diagnosis in CD ranges from 40 to 70% in adults [84, 85]. In a large pediatric cohort of 989 CD patients, Gupta et al. noted that 13% of children required intestinal resection after a median of 2.8 years, with 17% at 5 years and 28% at 10 years [86]. In a univariate regression analysis, infliximab use was associated with decreased risk of surgery (hazard ratio = 0.42, 95% confidence interval [CI] 0.23–0.76, $p < 0.004$). Park et al. [87] reported a similar decrease in risk of abdominal surgery in children receiving anti-TNF therapy (OR 0.57, 95% CI 0.46–0.7) in a large utilization review of anti-TNF therapy. The RISK study found patients who received early anti-TNFα were less likely to have a penetrating complication (hazard ratio 0.30, 95% CI 0.1–0.89) but no difference in stricturing complications (hazard ratio 1.13, 95% CI 0.51–2.51) [35]. It is important to note that only 21% of the RISK cohort received an anti-TNF within 90 days while drug levels and use of proactive TDM were not reported.

The postoperative recurrence of endoscopic inflammation following intestinal resection in PCD has been shown to be as high as 50%, 73%, and 77% at 1, 5, and 10 years, respectively [88]. The ECCO–ESPGHAN 2020 guidelines advocate for use of anti-TNF in high-risk patients to prevent recurrence [67].

Two adult RCTs described prophylactic anti-TNF use following intestinal resection. Regueiro et al., in a proof of concept randomized, double-blind, placebo-controlled trial, found that the 11 patients who were randomized to receive infliximab within 4 weeks of ileal resection had a significant reduction in endoscopic recurrence at 12 months compared to the 13 patients assigned to placebo (9% recurrence in infliximab treated vs. 85% in placebo group) [89]. In a subsequent multicenter randomized controlled trial, this group demonstrated that if infliximab was started within 45 days after ileocolonic resection, patients had 30% endoscopic recurrence compared to 60% in the group that was not treated postoperatively with infliximab [90]. The established risk factors for subsequent intestinal resection are a history of penetrating disease, cigarette smoking, and postoperative endoscopic recurrence of intestinal inflammation. Postoperative surveillance and prophylaxis are discussed in more detail in Chap. 43.

Ulcerative Colitis

In UC, the Active Ulcerative Colitis Trials 1 and 2 (ACT 1 and ACT 2) were the first multicenter trials that evaluated efficacy of infliximab in adult UC patients [91, 92]. These studies showed that infliximab was superior to placebo in achieving induction and remission in patients with moderate to severe UC and further supported several single-center and retrospective studies in pediatric UC.

Infliximab in Moderate to Severe UC

Since the initial use of infliximab in the treatment of moderate to severe UC in adults with the ACT1 and ACT2 studies, six studies have been conducted in children, four retrospectively and two prospectively [93–96]. Hyams et al. published the first prospective study in 2010 [97]. A total of 52 children with UC were treated with infliximab. Of these, 63% were CS refractory and 35% were CS dependent. At the initiation of therapy with infliximab, 51% of patients were receiving a 5-aminosalicylates, 63% were on IMM, and 87% were on CS. The study showed that 38% of the patients had CS-free inactive disease at 1 year and 21% at 2 years, while 61% were colectomy free at 2 years [97]. Turner et al. evaluated the short-term response (clinical improvement based on the pediatric UC activity index [PUCAI] and laboratory parameters, including ESR, C-reactive protein, and serum albumin at days 3 and 5 of admission) to intravenous CS in 128 children hospitalized with acute severe UC (ASUC). Based on the PUCAI, they found that 29% (37 patients) did not respond to CS treatment. Of these 37 patients, 33 received infliximab with 55% maintaining clinical response at 12 months. Finally, the efficacy and safety of infliximab for inducing and maintaining response in children with moderate–severe UC was studied in a clinical trial of 60 patients with a similar study design as the REACH trial. At week 8, 73.3% had a clinical response. For the maintenance study, 44 patients were randomized to receive infusions either at 8- or 12-week intervals. Among these 44 responders, they found twice as many (8/21 vs. 4/22) were in clinical remission at week 54 ($P = 0.146$) with every eight-week infusions [98].

Infliximab in Refractory UC

Even though treatment with infliximab in moderate to severe UC has been widely proven, there are still many patients who fail to respond to conventional doses (5 mg/kg) or who are unable to maintain remission. These patients represent a therapeutic challenge. In the prospective study conducted by Turner et al., of CS refractory patients treated with infliximab, 12% still remained CS dependent at 12-month follow-up and 52% of the cohort studied required a colectomy [99].

The initial poor response rates to the as-labeled dosing (5 mg/kg) has led to clinicians and researches to alternatively treat ASUC with an escalated doses of infliximab (up to 10 mg/kg) to better maintain therapeutic exposure and overcome rapid drug clearance seen with a high inflammatory burden and/or significant infliximab stool losses. Driven by favorable data from adult-onset UC [100], Falaiye et al. reported a single-center retrospective experience in 29 patients who required hospitalization for active IBD and were treated with infliximab [91, 101]. Of the 29 patients in the study, 15 had UC, 12 CD, and 2 IBD unspecified (IBD-U) and all of the patients were anti-TNF naïve at the initiation of the treatment. Their results showed that 62% (18/29) needed infliximab dose escalation, while 41% (12/29) went on to a colectomy [101]. Importantly, the study identified an association between the need for dose escalation and lower body mass index (BMI) z-score, low serum albumin (median of 3.0 g/dL), and an elevated ESR (median of 53 mm/h) from baseline. More importantly, in a retrospective analysis, Church et al. found that in 73 patients who received standard infliximab induction (5 mg/kg) and 52 patients who received intensified infliximab induction (mean induction dose >7 mg/kg or interval ≤5 weeks between doses 1 and 3) for either CS-refractory or CS-dependent UC, the intensified regimen was associated with a higher chance of remission (hazard ratio 3.2, $P = 0.02$) and a lower chance of colectomy (hazard ratio 0.4, $P = 0.05$) [36].

Therapeutic Drug Monitoring and UC

Several studies in adults have demonstrated that fecal calprotectin, infliximab trough concentration, and clinical symptoms should be used to inform dose optimization in pediatric UC. Huang et al. concluded in their study of adults with UC that fecal calprotectin <250 μg/g was associated with a favorable infliximab response and concluded dose escalation could be considered for fecal calprotectin >250 μg/g [102]. They also demonstrated that infliximab trough levels of 3–7 μg/mL were indicative of good drug response, while levels <3 μg/mL should trigger a dose escalation and levels >7 μg/mL may require a dose de-escalation. Similar results were published by Vande Casteele et al. where they found that an infliximab trough level between 3 and 7 μg/mL was associated with improved drug efficacy [48]. Very few studies of proactive TDM in children with only UC have been published [52, 103], while multiple studies that include both adult and PCD and UC have found that proactive TDM improves clinical outcomes in comparison to reactive TDM [61, 62]. Similar to the induction targets established for PCD [58], Papamichael et al. found that short-term mucosal healing had higher median infliximab concentrations at weeks 2, 6, and 14 than those who did not achieve mucosal healing [104]. More specifically, using a receiver operating characteristic analysis, the infliximab thresholds associated with short-term mucosal healing at weeks 2, 6, and 14 were 28.3 μg/mL, 15 μg/mL, and 2.1 μg/mL, respectively [104].

Infliximab and the Incidence of Surgery in Pediatric UC

The long-term effect of infliximab and the incidence on colectomy in children with UC is not clear at this time. In adult-onset UC, the ACT1 and 2 studies showed a colectomy rate of 10% in patients treated with infliximab at 54 weeks compared to 17% in the placebo group [97]. In pediatric UC, Hyams et al. found 72% of the patients studied avoided a colectomy at 1 year and 61% at 2 years with infliximab use [98]. Colombel et al. also demonstrated that patients being treated with infliximab and achieved mucosal healing were more likely to achieve CS-free and colectomy-free remission at 54 weeks [105]. While early use of infliximab in CS-dependent patients is promising, a recent meta-analysis from the biologic era identified that a cumulative rate of colectomy was 12.9% at 5 years [106]. These data along with the accelerated infliximab drug clearance associated with ASUC [107] suggest the critical need for use of precision dosing (based on individual predicted drug clearance) to reduce the rates of colectomy in children.

Infliximab Biosimilars

Since the expiration of the infliximab reference product patent in Europe in 2015 and the US in 2018, several infliximab biosimilars have entered the market. While the exact definitions slightly differ between the EU and US, a biosimilar is a highly similar product of a biological reference product with no clinically meaningful differences and high similarity in physiochemical characteristics, efficacy (and potency), purity, and safety [108]. Biosimilars could potentially reduce the cost of the therapy, but currently there are limited data regarding real-world efficacy, safety, and immunogenicity

among the different products. Approval of the infliximab biosimilars has been based on adult data from non-IBD indications. More recently, however, an adult trial also included IBD patients and showed that the biosimilar CT-P13 (infliximab-dyyb, Celltrion Inc.) was non-inferior to the infliximab originator [109]. Since then, several real-world studies have reported the safety and efficacy of starting a biosimilar or switching from the originator to a biosimilar in their respective pediatric IBD cohorts [110–113]. There are a limited amount of data available with regard to PK, such as immunogenicity; however, current rates of anti-drug antibody formation are similar to the infliximab originator different [114–116]. At this time, no biosimilar has yet received the label of interchangeability, and thus switching between the currently available infliximab biosimilars more than once or reverse-switching is not recommended.

Infliximab Safety Profile

Infusion Reactions

Although relatively rare, an infusion reaction is a side effect of infliximab therapy which may limit longer-term use of the medication for some patients. *Acute infusion reactions* may resemble anaphylaxis with urticaria, blood pressure changes, respiratory symptoms, and chest pain. While a portion of acute infusion reactions may occur in the absence of anti-drug antibodies, prevention of anti-drug antibodies with proactive TDM protocols, avoidance of episodic infliximab therapy, and concomitant IMM appear to have a role in prevention of some of these reactions [10, 25, 117–119]. In pediatrics, infusion reactions have been reported in 5–16% of patients receiving infliximab, but it is not currently known if proactive TDM and early dose escalation in patients with greater disease extent or severity may improve durability of infliximab therapy by reducing subtherapeutic exposure and therefore lowering the rates of immunogenicity [28, 120–122]. Although controversial, some acute infusions reactions may be prevented in part by pretreatment with antihistamines or CS and has led to a wide variation of pretreatment use across centers [123, 124].

Management of an acute infusion reaction may vary based on the type of reaction and could include CS, antihistamines, slowing, or even stopping the infusion. It has been generally accepted that if an infusion reaction is severe, a change to alternative medication with the same mechanism of action is advised.

Autoimmune phenomena may occur as an additional side effect of infliximab therapy. *Delayed reactions* may happen days after an infliximab infusion and mimic a serum sickness reaction [123]. These reactions are more typical in patients with high antibody levels or in patients who have not had infliximab exposure for an extended period of time (i.e., episodic therapy or attempted resumption of infliximab after a period of time off the drug). These reactions are thought to result from deposition of ATI-induced immune complexes being deposited in the tissues and blood vessels and present with myalgia, arthralgia, and other systemic symptoms requiring treatment with CS and/or switching to an alternative biologic [123]. Autoantibody formation has been described in patients with IBD and other conditions receiving infliximab therapy, with up to half of patients with infusion reactions developing antinuclear antibodies (ANA) and about one-third developing antibodies to double-stranded DNA (anti-dsDNA) [125, 126]. Fortunately, only about 1% of patients with ANA or dsDNA develop drug-induced lupus, whether being treated for IBD or other conditions [125–127]. Development of coombs negative anemias, demyelinating lesions, and optic neuritis has also been described with infliximab use, but fortunately, these are rare phenomena and typically improve with CS or withdrawal of infliximab [127, 128].

Skin-related side effects have also been associated with infliximab therapy and may warrant discussion prior to initiating infliximab therapy. Development of new psoriasis or other skin conditions can occur in up to 30% of patients receiving infliximab [129]. In most instances, these conditions are not associated with ATI and may be treated with topical and sometimes oral therapy without necessitating discontinuation of the anti-TNF.

Rapid (One-Hour) Infusions

Time burden and costs associated with prolonged infliximab infusions have resulted in investigations of decreasing infusion time. Most infusions are given over a period of 2–4 h, but shorter one-hour infusions appear to be safe in adults, with no increased risk of infusion reactions even for those receiving larger drug doses up to 10 mg/kg [130, 131]. These shorter infusions have been shown to correlate with improvement in overall, social, and job-related quality of life as well [132]. More recent pediatric data have shown that that rapid (1-h) infusions are likely safe for pediatric patients if they have demonstrated repeated tolerance of several standard (long) infusions in the past [130, 133, 134]. The selection of which patients qualify and timing (induction or maintenance) of rapid infliximab infusions should be at the discretion of the treating physician with careful consideration of presence of anti-infliximab antibodies along with the personnel present and resources at the infusion facility (i.e., hospital center, infusion clinic at a satellite, home infusions or private infusion center) to manage a possible infusion reaction.

Infections

As with other immunosuppressive therapy, infections may occur more commonly in patients receiving anti-TNF. In the REACH study, 80% of reported serious infections (pneumonia, herpes zoster, and abscess) occurred in patients receiving infliximab every 8 weeks compared to the 20% that occurred in patients receiving infliximab every 12 weeks [28]. As a whole, many infections were respiratory in nature, but severe infections included sepsis and fever, pneumonia, colitis, and skin infections, such as MRSA adenitis or furunculosis. Ultimately, the rate of serious infections associated with both infliximab and adalimumab in pediatrics has been reported to be 352 per 10,000 patient years and is similar between both anti-TNF agents as well as the expected rate of infections associated with IMM use (estimated at 333 per 10,000 patient years) [139]. Systemic CS in use is associated with a significantly higher risk infections with about 730 infections per 10,000 patient years compared to infliximab [127, 139]. Moreover, pooled analyses of adults receiving long-term infliximab did not demonstrate a significant risk of infections or serious infections for infliximab monotherapy, and data from the adult "TREAT" registry (Crohn's Therapy, Resource, Evaluation, and Assessment Tool) suggest that active moderate to severe disease and the use of CS are much more likely to be associated with infection compared to infliximab alone [135, 136].

Although there are limited pediatric data, opportunistic infections remain a significant risk as described in the adult "TREAT" registry and may occur in 1.81 of 1000 patients [135, 137]. While respiratory infections remain the most commonly reported infection in pediatrics, opportunistic infections, such as *Candida albicans*, *Listeria monocytogenes*, *herpes simplex virus* (HSV), *cytomegalovirus* (CMV), and *Epstein-Barr virus* (EBV) have been reported and present a higher risk to elderly IBD patients in comparison to the pediatric IBD patient [135, 138]. Clinician awareness of regional opportunistic infections, such as histoplasmosis (Ohio and Mississippi river valley), blastomycosis (Ohio and Mississippi river valley), or coccidioidomycosis (Southwestern US), may warrant additional screening and treatment prior to initiating therapy [140].

Rare, but serious infections, such as tuberculosis (TB) reactivation, have been associated with anti-TNF therapy as well [141]. Although first described in the setting of infliximab, reactivation of TB is a concern for all anti-TNF therapies and has led to standard screening guidelines for latent TB prior to initiation of anti-TNF therapy and yearly screening during maintenance treatment [142–145]. Most recently, during the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2, COVID-19) pandemic, there has been some concern from the community about contracting COVID-19 while receiving any immunosuppression. Preliminary data from the SECURE-IBD registry reported that among 1439 IBD patients with a confirmed COVID-19 infection, anti-TNF monotherapy was not associated with a more severe disease course. However, TP monotherapy and combination therapy with an anti-TNF and a TP were both associated with a four times increased risk of severe COVID-19 course [146].

Vaccination

Live attenuated vaccines are contraindicated for patients receiving anti-TNF therapy while all inactivated, attenuated viruses should be offered, particularly the annual influenza vaccine [142, 144]. Additional vaccinations that are important for those receiving immunosuppressant therapies include vaccinations for Hepatitis B and pneumococcal since these infections may pose serious health risks if reactivated or contracted during anti-TNF therapy. It is generally recommended that the patients serologic response to Hepatitis B be checked at diagnosis prior to initiating any immunosuppressive therapy, including anti-TNF biologics [143, 145, 147]. The Hepatitis B (if inadequate serologic response documented) and pneumococcal vaccines can be administered once infliximab has started. Additionally, protection against human papilloma virus (HPV) is indicated due to increased risk of cervical dysplasia in IBD patients on immunosuppression [148]. It is important to note that response to vaccines may be suboptimal in patients on biologic therapies, such as infliximab, or receiving CS.

In contrast, the varicella vaccines (Varivax®, the single-antigen varicella vaccine and ProQuad®, a combination measles, mumps, rubella, and varicella vaccine) contain live, attenuated varicella-zoster virus, and are *contraindicated* once a patient starts anti-TNF therapy or any immunosuppression. For patients found to be truly non-immune to varicella, the clinician must weigh the risks and benefits of delaying anti-TNF therapy to provide vaccination for a patient based on previously published guidelines [149].

Malignancy

Cancers, such as colorectal cancer, remain a risk for patients with IBD who have continued, active inflammation regardless of medication exposure [150, 151]. The additional risk of malignancy related to anti-TNF treatment remains a consideration for most patients and families starting a biologic. One of the most significant concerns has been for HSTCL, a rare malignancy associated with therapy for IBD and often universally fatal in most cases. In a recent systematic review (2020), Shah et al. found there have been 62 HSTCL reported cases in the literature. The median age of affected patient was 28 years (range 12–81), 83.6% were male and 84.7% had CD [152]. Only 5/62 of the cases had no prior (reported) TP exposure. They found 87.8% (43/49) of those patients

with a known (reported) outcome died with a median survival of 5 months [152]. Given the association between HSTCL and combination anti-TNF with a TP in the pediatric IBD population, it is recommended that a patient-centered (shared-decision) discussion be initiated before starting anti-TNF therapy in this demographic. A recent review found that combination therapy with anti-TNF and TP is declining and is not recommended in any male patient [153, 154].

Regarding other types of cancers, Lichtenstein et al. in a long-term safety registry of CD patients (TREAT registry), reported similar crude cancer incidences between infliximab and "other treatments only" exposed patients [155]. Furthermore, data from An IBD Multicenter, Prospective, Long-Term Registry of Pediatric Patients (the DEVELOP registry), found that infliximab exposure was not associated with an increased risk of malignancy or HLH when data were compared to the Surveillance, Epidemiology and End Results Program (SEER) database [30]. In contrast, pediatric IBD patients exposed to TP with or without infliximab do have an increased risk of malignancy compared to the reference population of the SEER database [30].

Other forms of malignancies, such as skin cancers, have been described during longer-term follow-up of patients on infliximab therapy, but the highest risk seems to be from older age and longer IBD duration rather than cumulative exposure to just infliximab [127]. Infliximab does not appear to increase risk for non-melanoma skin cancer after adjusting for TP therapy, but patients receiving infliximab may have an increased risk of melanoma skin cancer related to the disease itself and potentially related to anti-TNF therapy [156]. Cervical cancer remains a risk for women with IBD which may be unrelated to treatment but warrants appropriate vaccination for HPV in this high-risk population [157].

The discussion of malignancy risk for patients undergoing anti-TNF therapy represents a unique opportunity to include families in a shared decision-making approach to medical treatment. There is no single consensus about approach to anti-TNF monotherapy or combination therapy for young patients, so this particular aspect of treatment may call for a more customized approach to care, discussion of medications with presumed lower risk of cancers, such as MTX, and a clear communication between the patient (family) and the clinician about the potential benefits and side effects associated with starting infliximab.

Mortality

Mortality associated with anti-TNF use, particularly in pediatrics, is not common. Dulai et al. described seven deaths for patients on anti-TNFs, but two of these were felt to be unrelated to medication [139]. The five patient deaths receiving anti-TNF totaled a rate of 5.3 per 10,000 patient years during follow-up. Of the three patients who died on infliximab therapy, the cause of death was attributed to bone marrow transplant complication, cardiac complication (in the setting of a previously described arrhythmia), or azathioprine-induced neutropenia which led to sepsis [139]. Deaths due to lymphoma, particularly HSTCL, have also been described following infliximab use [127, 158].

Summary

The arrival of infliximab has revolutionized the treatment of moderate to severe IBD in both children and adults. It has shown to be effective in inducing and maintaining remission, is CS sparing, and restores growth. Varying practices in infliximab use has shown that scheduled dosing, rather than episodic, is not only more efficacious but also prevents ATI formation and thereby results in a more durable and sustained response. Newer data suggest that proactive TDM is more effective than reactive TDM in maintaining therapeutic trough concentrations, reduces IBD flares, and improves drug durability. The safety profile of infliximab is overall favorable although continued vigilance remains necessary for the occurrence of infrequent but serious events, including opportunistic infections and malignancies, especially in patients receiving concomitant immunosuppressive treatment. With more novel anti-cytokine and anti-integrin biologics available to the pediatric clinician (both on and off FDA label), it will be key to develop a multiomic approach to begin pairing the right drug (biologic or small molecule) for the right patient (based molecular, genetic, and/or IBD-specific phenotype). Once the right drug is selected, it is vital for clinicians to become familiar with precision dosing strategies and use of innovative PK dashboards that can quickly synthesize the predicted drug clearance and model individual PK profiles to simulate an optimized dose and dosing regimen for the individual patient.

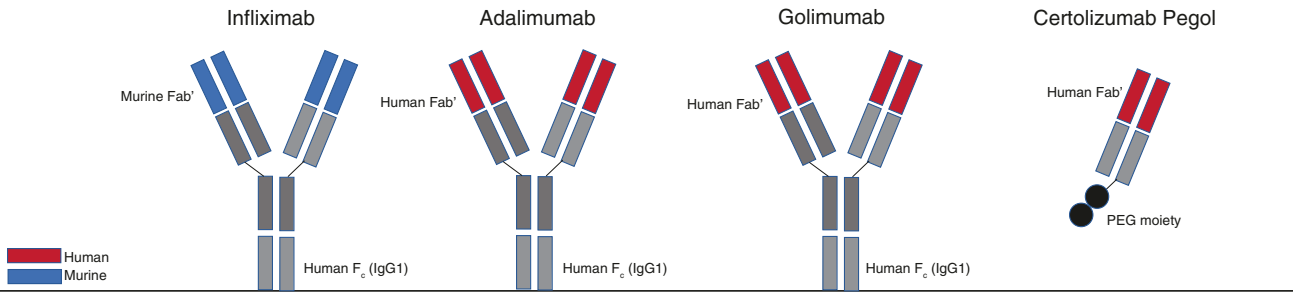
Anti-TNF Therapies Other Than Infliximab for the Treatment of Pediatric Inflammatory Bowel Disease

32

Stephanie Gold and Louis Cohen

Introduction

The cornerstone of inflammatory bowel disease (IBD) therapy for the last 20 years has revolved around biologic agents targeting tumor necrosis factor alpha (TNFα). Since the approval of infliximab as the first anti-TNFα agent to treat Crohn disease (CD) and ulcerative colitis (UC), other agents also targeting TNFα have come to market including adalimumab, certolizumab, and golimumab. These agents differ in their route of administration, pharmacokinetics, mechanism of action, as well as antibody structure (Fig. 32.1). In this chapter we will review the clinical efficacy, safety, and future directions for this class of drugs. While all of these agents have been used to treat pediatric IBD, only infliximab and adalimumab are FDA as well as EMA approved [1]. To date, a number of randomized controlled trials evaluating the use of adalimumab, certolizumab pegol, and golimumab are quite low in pediatric patients; therefore, the majority of the recommendations supporting their use in pediatric CD and UC come from observational studies or extrapolation from the adult literature.



- Binds Soluble TNF	Yes	Yes	Yes	Yes
- Binds Membrane TNF	Yes	Yes	Yes	Yes
- FcR Binding	Yes	Yes	Yes	No
- ADCC (Fc mediated)	Yes	Yes	Yes	No
- FDA Approval: Pediatric IBD	Yes	Yes	No	No
- FDA Approved: Adult IBD	Yes(UC/CD)	Yes (UC/CD)	Yes (UC)	Yes (CD)
- Method of Delivery	IV q 4-8 wks	S.C. Injection q1-2 wks	S.C. Injection q4 wks	S.C Injection q2-4 wks

TNF: Tumor Necrosis Factor, ADCC: Antibody Dependent Cell Mediated cytotoxicity, IV: intravenous, S.C: subcutaneous, wks: weeks, IBD: inflammatory bowel disease, CD: Crohn disease, UC: ulcerative colitis

Therapeutic Efficacy and Pivotal Trials

Adalimumab

Adalimumab is a fully humanized monoclonal antibody against TNFα, which, after infliximab, is one of the most commonly used biologics in pediatric patients with IBD [2]. Adalimumab was engineered using phase display technology and is indistinguishable in both structure and function from human immunoglobulin (IgG1) with no murine or other non-human components [3]. In adults and pediatrics adalimumab has been FDA approved for the treatment of CD and UC. In pediatrics, it is approved for CD ages 6–17 and UC approval was granted in February 2021 for ages 5–17. Adalimumab was the first anti-TNFα agent on the market after infliximab and offered an alternative route of administration as a subcutaneous injection. The recommended dosing of adalimumab in children with Crohn disease weighing more than 40 kg is 160 mg followed by 80 mg 2 weeks apart and then 40 mg every 2 weeks thereafter for maintenance. In children under 40 kg, the induction dosing is 80 mg and then 40 mg 2 weeks later, followed by 20 mg every 2 weeks for maintenance [4]. The pharmacologic half-life of adalimumab is 10–20 days. Although the exact mechanism of action is still incomplete the clinical efficacy of binding TNFα is believed to be secondary to decreased TNFα signaling as well as complement and antibody dependent cytotoxicity to TNFα-positive cells [5]. While there are no studies to date demonstrating a clear difference in the mechanism of action between adalimumab and infliximab, some researchers have suggested that structural differences in the molecules result in adalimumab's increased affinity for binding TNFα and that its recognition of a larger epitope compared to infliximab improves its ability to fully bind to the TNFα surface (Table 32.1) [6].

Efficacy of Adalimumab in Pediatric CD Patients

The pivotal trial supporting the efficacy of adalimumab induction therapy in pediatric CD patients was the IMAGINE 1 study published in 2012 [7]. This trial was an open-label induction trial of 188 patients aged 6–17 years with moderate to severe CD. All patients were given adalimumab at week 0 and 2 with either 160 mg and then 80 mg (weight ≥40 kg) or 80 mg and then 40 mg (weight <40 kg). After induction patients were randomized at week 4 to treatment with high-dose adalimumab (40 mg if ≥40 kg, or 20 mg if <40 kg every 2 weeks) or low-dose adalimumab (20 mg if ≥40 kg, or 10 mg if <40 kg every 2 weeks) and followed for 52 weeks. The primary endpoint of this study was clinical remission (defined as a decrease in Pediatric Crohn Disease Activity Index [PCDAI] of ≤10) at week 26. As a secondary endpoint, the trial looked at remission rates at week 52 as well as clinical response rates and steroid-free remission at weeks 26 and 52. At week 4 after induction 82.4% of patients had a clinical response and 27.7% were in clinical remission per PCDAI scores. The high-dose adalimumab group had a higher rate of clinical remission (38.7%) compared to the low-dose group (28.4%) at week 26, but this difference did not reach significance ($p = 0.075$). At week 52 there was again no significant difference in the percentage of patients who achieved clinical remission between high- and low-dose adalimumab ($p = 0.100$) though there was a significant difference in clinical response rates ($p = 0.038$). The study also compared the response to adalimumab in patients who were infliximab naïve and those who had previous infliximab exposure. Patients who were infliximab naïve had significantly higher rates of clinical remission compared to those with previous infliximab exposure at week 52 (45% vs. 19%, p value <0.001) [4, 7]. Of note, one of the limitations of the IMAGINE 1 trial was that there was no placebo comparison group for analysis.

As part of IMAGINE 1, patients who did not achieve a clinical response or those with loss of response by week 12 were allowed to dose escalate to weekly dosing. As part of this protocol, patients were continued on the blinded dose initially started in IMAGINE 1. After a minimum of 8 weeks of blinded weekly dosing, patients with ongoing flare symptoms or no response were allowed to enter into open-label weekly high-dose adalimumab (40 mg weekly if ≥40 kg and 20 mg weekly if <40 kg). 83 patients from IMAGINE 1 underwent dose escalation at week 12 [7, 8]. Among patients who received low-dose weekly adalimumab, 18.8% were in clinical remission at week 52 and 47.9% had a clinical response. Similarly, among patients on high-dose weekly adalimumab 31.4% of patients were in clinical remission and 57.1% had a clinical response. While the response and remission rates were higher among those on the high-dose weekly adalimumab, this difference did not achieve statistical significance ($p = 0.19$ for remission, $p = 0.41$ for response).

To understand the long-term efficacy and safety of adalimumab in pediatric patients with CD, the IMAGINE 2 study followed patients from the conclusion of IMAGINE 1 at week 52 through to week 240 [9]. In this open-label extension study, including 31 sites, 100 patients were included. Enrollment in IMAGINE 2 required successful completion of IMAGINE 1 and having achieved clinical response at any time point during the initial study. For the duration of the IMAGINE 2 trial, patients continued their original, blinded dosing from IMAGINE 1 (high- or low-dose adalimumab based on weight and either every other week or weekly injections). In this study, 41% of patients were in remission at week 240 and 48% had a clinical response. In a sub-analysis evaluating patients in clinical remission at the end of IMAGINE 1 (and therefore beginning of IMAGINE 2), 45% maintained this remission through week 240.

Table 32.1 Pivotal trials on the efficacy of adalimumab in pediatric and adult patients with inflammatory bowel disease

Study	Year	Study Type	Patients	Disease	Pediatric	Findings
IMAGINE 1 [7]	2012	Open label	188	CD	Yes	At week 4, 82.4% of patients had a clinical response and 27.7% were in clinical remission. At week 26, 33.5% were in clinical remission
IMAGINE 2 [9]	2016	Open-label extension	100	CD	Yes	At week 240, 48% of patients had a clinical response and 41% of patients were in clinical remission
Nobile et al. [11]	2014	Retrospective	48	CD	Yes	At 12 months, 50% of patients had endoscopic improvement and 25% had mucosal healing. 48% of patients had a clinical response and 36% in clinical remission
CLASSIC I [20]	2006	RCT	299	CD	No	At week 4, 12% of patients in placebo group in clinical remission compared to 18%, 24%, and 36%, respectively, for adalimumab dosed 40 mg/20 mg, 80 mg/40 mg, and 160/80 mg (week zero/week two doses)
CLASSIC II [21]	2007	RCT	276	CD	No	At week 56, 79% of patients who received adalimumab 40 mg every other week, 83% of patients who received adalimumab 40 mg weekly and 44% of those who received the placebo were in clinical remission
CHARM [22]	2007	RCT	854	CD	No	At week 26, 40% receiving every other week adalimumab, 47% receiving weekly adalimumab and 17% receiving placebo were in clinical remission
EXTEND [24]	2012	RCT	135	CD	No	At week 12, 27% of patients receiving adalimumab had mucosal healing compared to 13% receiving placebo. At week 52, 24% of patients treated with adalimumab had mucosal healing compared to 0% who received placebo
GAIN [25]	2007	RCT	301	CD	No	All patients infliximab exposed. At week 4, 21% of patients in the adalimumab group compared to 7% in the placebo group achieved clinical remission
ULTRA 1 [26]	2011	RCT	390	UC	No	At week 8, 16.5% of patients treated with adalimumab were in remission compared to 9.2% of placebo
ULTRA 2 [27]	2012	RCT	494	UC	No	At week 52, 17.3% of patients in the treatment group and 8.4% of patients in the placebo group were in clinical remission
Sandborn et al. [28]	2013	Post hoc analysis	248	UC	No	At week 52, 30.9%, 49.6%, and 43.1% achieved clinical remission, clinical response, and mucosal healing, respectively
ULTRA 3 [29]	2014	Open-label extension	199	UC	No	60% of the patients who had achieved remission as well as mucosal healing by year 1 were able to maintain these endpoints at year 4

CD Crohn disease, *UC* Ulcerative colitis, *RCT* Randomized controlled trial

The largest systematic review of clinical remission rates in pediatric CD patients treated with adalimumab included 14 studies (one randomized trial and 13 case series) and 664 patients. In this review the pooled clinical remission rates were 30% at 4 weeks, 54% at 3 months, 42% at 6 months, and 44% at 12 months [10]. In this study only 6% of patients were deemed primary non-responders to adalimumab.

To date there is only a single study evaluating endoscopic remission in pediatric patients with CD treated with adalimumab [11]. In this retrospective cohort study of 48 patients 7–18 years of age, 19 patients were treated with adalimumab and observed for a mean of 38.5 months (range 1–116 months). Adalimumab dosing in this study was 160 mg at week 0 and 80 mg at week 2 for induction in 84% of patients and 80 mg at week 0 and 40 mg at week 2 for induction in the remaining patients. All patients then received 40 mg every other week. Endoscopic remission in this study was defined as disappearance of lesions, whereas endoscopic response as defined as a significant reduction, but not disappearance of lesions. After 12 months of therapy 50% of patients on adalimumab had endoscopic improvement and 25% had endoscopic remission. In those who responded endoscopically to adalimumab the response was sustained for an average of 22.2 months. Likewise, in this study, clinical remission and response were seen in 36% and 48% of patients, respectively, after 12 months of therapy.

Efficacy of Adalimumab in Pediatric UC Patients

Only small retrospective studies have evaluated the use of adalimumab in pediatric UC. In one retrospective case series of 11 pediatric patients with UC treated with standard-dose adalimumab, 55% of patients achieved and maintained clinical remission after a median of 25 weeks [12]. All of the patients in this study had prior exposure to infliximab. Similarly, in a larger retrospective study of 31 pediatric patients with UC refractory to infliximab, 83% of those who transitioned to adalimumab had a clinical response and remained on adalimumab for the duration of the study [13, 14]. In the largest retrospective study to date utilizing data from a national registry, pediatric patients with UC who had previously failed infliximab were treated with standard-dose adalimumab (160 mg at week 0, 80 mg at week 2, and 40 mg thereafter every other week) for a median follow-up of 16 months. The primary endpoint of this study was corticosteroid-free clinical remission at week 52 (PUCAI <10). Of the 32 patients included, 41% achieved corticosteroid-free clinical remission after 1 year. Mucosal healing was evaluated as a secondary endpoint at month 0 and 12 using the Mayo Score. Mucosal healing in this study was seen in 28% of patients at 52 weeks [15].

Efficacy of Adalimumab in Pediatric Patients Exposed to Infliximab

While some of the studies described above included patients who were previously treated with infliximab and subsequently given adalimumab, there are studies that specifically aimed to understand the response to adalimumab after infliximab exposure. A nationwide observational cohort study from the Netherlands evaluated 53 pediatric patients with CD who were previously exposed to infliximab and subsequently treated with adalimumab [16]. Adalimumab induction dosing regimens varied in this study with 74% of patients receiving an induction doses prior to maintenance dosing which was weight based: 20–40 mg for patients <40 kg and 40–80 mg for patients >40 kg. 25% of patients required dose escalation which included shortening the interval of dosing and increasing the dose at the discretion of the treating physician. In this study, the primary endpoint was clinical remission and this was achieved in 64% of patients after a median of 3.3 months of therapy. Among patients who responded to adalimumab this response was maintained in 50% of patients for an average 2 years. 34% of patients were considered 'adalimumab failures' due to non-response (n = 4), loss of response (n = 11) or adverse events requiring termination of the drug (n = 3). Patients who were primary non-responders to infliximab tended to be less likely to achieve clinical remission with adalimumab (33%) compared to those who were secondary non-responders to infliximab (71%), however this difference did not achieve statistical significance (p = 0.24). Furthermore, patients with antibodies to infliximab had higher remission rates with adalimumab compared to those without antibodies (81% vs. 53%, p = 0.09). Of note, there was no difference in response rates to adalimumab based on concomitant immunomodulator use. A similar, however smaller, retrospective case series of 27 pediatric patients treated with adalimumab after infliximab loss of response or intolerance was published utilizing data from a population based registry [17]. In this study, treatment response was measured using the Physician Global Assessment (PGA); clinical remission was defined as a PGA of 1 and clinical response was defined as a decrease of at least 2 points in PGA score after 6 months of adalimumab therapy. After a median follow-up of 16 months, clinical response was seen in 70% of patients and was maintained in 52% of patients at 26 months. Primary adalimumab failure was seen in 30% of patients and loss of response in 19% of patients. While all patients initially received adalimumab subcutaneously every other week, 52% of patients in this study required 'dose optimization' which included dose escalation in 6 patients, a reduced dosing interval in 1 patient and a combination of the two techniques in 7 additional patients. Among these patients [10], 71% had a clinical response after dose optimization.

One of the first studies to demonstrate the efficacy of adalimumab in pediatric CD patients previously exposed to infliximab was the Retrospective Evaluation of the Safety and Effect of Adalimumab Therapy (RESEAT) study. This was a retrospective multicenter study at 12 sites as part of a pediatric IBD collaborative research group [18]. This study included 115 patients with pediatric CD who received at least one dose of adalimumab and were evaluated for clinical response as measured by the Physician Global Assessment (PGA). 95% of the patients in this study had prior exposure to infliximab with the majority of patients discontinuing the infliximab due to loss of response or infliximab intolerance (secondary non-responders). In this study clinical remission rates at months 3, 6, and 12 were 65%, 71%, and 70%. Steroid-free remission was seen in 22%, 33% and 42% of patients at months 3, 6 and 12.

Efficacy of Adalimumab in Adult Patients

Clinical trial data focusing on the use of adalimumab in pediatric IBD are somewhat limited, especially for patients with UC; however, there is extensive research in the adult IBD population. These data are often used as an adjunct to the limited pediatric data, although whether the efficacy and safety data can be extrapolated to patients under the age of 18 remains unclear. Adalimumab was first approved for the treatment of moderate to severe adult CD in 2007 and subsequently for UC in 2012. Unlike in the pediatric population, dosing of adalimumab in adults is not weight based; induc-

tion dosing is 160 mg at week 0, 80 mg at week 2 and 40 mg every other week thereafter. Escalation to weekly dosing has been demonstrated to be both safe and effective [19].

The first randomized placebo-controlled trial evaluating the use of adalimumab as an induction treatment for moderate to severe ileocolonic CD naïve to anti-TNFα therapy was the CLASSIC I trial [20]. This study included 299 patients and investigated the efficacy of 3 dosing regimens to induce clinical remission at week 4. In this study, clinical remission at week 4 was seen in 12% of the placebo group and 18%, 24% and 36% respectively for adalimumab dosed 40 mg/20 mg, 80 mg/40 mg and 160/80 mg (week zero/week two doses). The CLASSIC II trial sought to evaluate the long-term efficacy of adalimumab maintenance therapy utilizing patients from the CLASSIC I trial [21]. 276 patients from CLASSIC I were enrolled in CLASSIC II and these patients received open-label adalimumab 40 mg at week 0 (week 4 of CLASSIC I) then at week 4 were randomized to maintenance with adalimumab based on response. 55 patients in remission at week 4 of CLASSIC II were then randomized to either placebo, adalimumab 40 mg every other week or adalimumab 40 mg weekly for a total follow-up of 56 weeks. Those not in remission after 4 weeks of CLASSIC II were enrolled in a separate, open-label arm of the study and received adalimumab 40 mg every other week. The primary endpoint of CLASSIC II was maintenance of remission, which was defined as a CDAI score <150 at week 56. In this study, among the 55 patients who entered the randomization arm at week 4, 79% of patients who received adalimumab 40 mg every other week, 83% of patients who received adalimumab 40 mg weekly and 44% of those who received the placebo were in remission at week 56. In the open-label group (those not in remission at week 4), which included 93 patients, 46% were in clinical remission at week 56.

The CHARM trial was a randomized, double-blind, multicenter placebo-controlled trial that enrolled 854 patients with moderate to severe CD to study maintenance of remission using adalimumab [22]. Patients received induction therapy with 80 mg of adalimumab at week 0 and 40 mg at week 2 then were randomized at week 4 to receive placebo, adalimumab 40 mg every other week or adalimumab 40 mg weekly. Primary endpoints were clinical remission at week 26 and 52. Remission rates were significantly greater at 26 weeks in both adalimumab treatment groups compared to placebo (40% every other week adalimumab, 47% weekly adalimumab and 17% placebo, $p < 0.001$). At week 56, there was again a significant difference in clinical remission rates for patients taking adalimumab every other week or every week compared to placebo (36%, 41%, and 12%, $p < 0.001$). Patients in both treatment groups had a significant clinical response as early as 6 weeks into therapy. A secondary endpoint analysis for quality of life using the IBDQ also was significantly improved in patients receiving adalimumab. In this trial the most durable maintenance of remission was observed in patients with a shorter duration of disease prior to initiation of therapy (<3 years) [23].

The EXTEND trial was the first randomized, double-blind, multicenter placebo-controlled trial that evaluated the use of adalimumab in the induction and maintenance of mucosal healing in patients with moderate to severe CD [24]. A total of 135 patients were enrolled in this study with a baseline endoscopic evaluation followed by induction with adalimumab 160 mg/80 mg at weeks 0/2. The patients were then randomized to adalimumab 40 mg every other week or placebo and monitored for 52 weeks. Mucosal healing was assessed at weeks 12 and 52. In this study, 27% of patients treated with adalimumab had mucosal healing at week 12 compared to 13% in the placebo group. At week 52, 24% of patients treated with adalimumab had mucosal healing compared to 0 who received placebo ($p < 0.001$). At week 12 the rate of clinical remission was higher in patients treated with adalimumab compared to placebo but this difference was not significant (47% vs. 28%, $p = 0.21$). At week 52 there was a significant difference between treatment and placebo groups for maintenance of clinical remission (33% vs. 9%, $p = 0.001$).

The GAIN trial was a randomized, double-blind placebo-controlled trial of maintenance adalimumab in patients with CD who had previously been intolerant to infliximab or had a secondary loss of response [25]. In this study, 301 patients were assigned to adalimumab (160 mg/80 mg at weeks 0/2) or placebo and evaluated for clinical response at week 4. 21% of patients in the adalimumab group compared to 7% in the placebo group achieved clinical remission at week 4 ($p < 0.001$). A subgroup analysis of the GAIN trial demonstrated that adalimumab had improved efficacy compared with placebo regardless of concomitant immunosuppressive therapy, previous intolerance or loss of response to infliximab, or presence of antibodies against infliximab.

The efficacy of adalimumab in inducing and maintaining clinical remission in adult patients with UC was initially demonstrated in the ULTRA trials. In ULTRA-1390 patients with moderate to severe UC were randomized to adalimumab with standard dosing (160 mg/80 mg then 40 mg q2 weeks) or placebo [26]. The primary endpoint of the study was clinical remission (Mayo score ≤2) after 8 weeks of therapy. 16.5% of patients treated with adalimumab were in remission compared to 9.2% of placebo ($p = 0.019$). The study was later amended to include a third treatment arm with an adalimumab dose regimen of 80 mg/40 mg induction and 40 mg q2week maintenance. This low-dose adalimumab group had a remission rate of 10.0% after 8 weeks of therapy. In follow-up, ULTRA-2 studied the long-term maintenance of remission with adalimumab in patients with moderate to

severe UC [27]. 494 patients were randomized to adalimumab therapy (160 mg/80 mg at weeks 0/2 and then 40 mg q2 weeks) or placebo and followed through week 52. At week 8, 16.5% in the adalimumab group and 9.3% in the placebo group were in clinical remission ($p = 0.19$). At week 52, 17.3% of patients in the treatment group and 8.4% of patients in the placebo group were in clinical remission ($p = 0.004$). A second study was subsequently published as a post hoc analysis of the ULTRA I and 2 data, assessing the efficacy of adalimumab at week 52 in patients with UC who failed prior TNFα therapy and achieved clinical response at week 8 of ULTRA 2. Of the 248 patients evaluated in this study, 49.6% achieved clinical response at week 8. Of these patients, 30.9%, 49.6% and 43.1% achieved clinical remission, clinical response and mucosal healing respectively by week 52. Of those who entered ULTRA 2 on corticosteroids, ($n = 90$), 21.1% achieved steroid-free remission and 37.8% were steroid free by week 52 [28]. To evaluate longer-term remission rates in patients with moderate to severe UC, an open-label extension trial was performed (ULTRA-3) [29]. Roughly 60% of the 199 patients who entered ULTRA-3 and had achieved remission as well as mucosal healing by year 1 were able to maintain these endpoints at year 4. While patients who had previous TNFα exposure had lower rates of remission and mucosal healing throughout ULTRA-1 and -2, some of these differences diminished at the later time points in ULTRA-3 [29].

Certolizumab

Certolizumab is a monoclonal antibody against TNFα where the Fc portion of the antibody has been replaced with a polyethylene glycol moiety (Fig. 32.1). The lack of Fc portion and subsequent pegylation makes certolizumab unique among other TNFα inhibitors including infliximab, adalimumab and golimumab. The pegylation with a 40 kDa polyethylene glycol (PEG) moiety attached to the monoclonal antibody increases the effective half-life of the Fab molecule and thereby reduces the dosing frequency [30]. While certolizumab binds and neutralizes both soluble and transmembrane TNFα, exchanging the Fc region for a PEG moiety limits its ability to induce complement dependent cytotoxicity and antibody dependent cell mediated cytotoxicity, both of which are induced by the other anti- TNFα agents. The PEG moiety however does make certolizumab unique among anti-TNFα agents in that it does not cross the placenta during pregnancy [30]. Certolizumab was approved for the treatment of adults with moderate to severe CD in 2008 and is under investigation in adults with UC. Certolizumab is not approved for the treatment of pediatric IBD or any other condition in patients under the age of 18. The dosing regimens for children are extrapolated from the adult literature. In adults, certolizumab pegol is given subcutaneously; standard induction dosing is 400 mg at weeks 0, 2, and 4 and then 400 mg every 4 weeks thereafter.

Efficacy of Certolizumab in Pediatric Patients

To date, there are no randomized controlled trials evaluating the use of certolizumab in the treatment of pediatric IBD; in fact, there are no peer-reviewed articles evaluating this drug in the treatment of pediatric CD or UC at the current time. Despite the lack of studies on certolizumab, pediatric IBD specialists have extrapolated data from the adult IBD publications as well as pediatric rheumatologic studies (Table 32.2). Interestingly, there was a preliminary phase II

Table 32.2 Pivotal trials on the efficacy of certolizumab pegol in pediatric and adult patients with inflammatory bowel disease

Study	Year	Study Type	Patients	Disease	Pediatric	Findings
Winter et al. [32]	2004	RCT	92	CD	No	At week 2, 47.1% in the 10 mg/kg treatment group achieved clinical remission compared to 16% in the placebo group
Schreiber et al. [33]	2005	RCT	292	CD	No	At week 2,- 52.8% of patients receiving 400 mg CZP had a clinical response compared to 35.6% placebo
PRECiSE 1 [34]	2007	RCT	662	CD	No	At week 6, 35% in treatment group had clinical response compared to 27% placebo. At week 26, 23% had a clinical response compared to 16% placebo
PRECiSE 2 [35]	2007	RCT	688	CD	No	At week 26, 62% of responders maintained their clinical response in the treatment group compared to 34% in the placebo group
PRECiSE 3 [36]	2010	Open-label extension	595	CD	No	At week 80, 66% of patients in the treatment group maintained their clinical response
MUSIC [38]	2010	Open label	89	CD	No	At week 10, 62% had an endoscopic response and 42% were in endoscopic remission. At week 54 week, 62% had an endoscopic response and 28% endoscopic remission
WELCOME [39]	2010	RCT	539	CD	No	All patients infliximab exposed. At week 6, 62% of patients had a clinical response and 39.3% of patients were in clinical remission

CZP Certolizumab pegol, *CD* Crohn disease, *UC* Ulcerative colitis, *RCT* randomized controlled trial.

open-label prospective study entitled "The Use of Certolizumab Pegol for Treatment of Active Crohn Disease in Children and Adolescence (NURTURE)" that enrolled roughly 160 patients in 2013. As per the clinical trial information, this study was designed to evaluate the safety, pharmacokinetics, efficacy, and immunogenicity of certolizumab and planned to evaluate inflammatory markers, clinical disease activity, and growth scores at the end of 62 weeks of therapy. Unfortunately, this study was terminated prior to completion due to "higher than projected discontinuation rate during the maintenance phase." However, prior to the study termination, preliminary data were presented at the Digestive Disease Week Meeting in 2011, simply suggesting that after induction with 400 mg of certolizumab pegol at weeks 0,2, and 4, (if patients were ≥40 kg) or 200 mg at the same intervals (in patients 20–40 kg), patients had similar serum levels compared with adults [31].

Efficacy of Certolizumab in Adult Patients

In 2004, the first randomized, placebo-controlled trial with certolizumab was performed to evaluate the safety and efficacy of a single dose of intravenous certolizumab over 12 weeks [32]. In this study, 92 adult patients with CD were included and randomized to placebo or 10–20 mg/kg of certolizumab. The primary endpoint of this study was clinical response (decrease in CDAI ≥100 points) or remission (CDAI ≤150) after 4 weeks. A statistically significant improvement in clinical remission was seen at week 2 in 47.1% of those in the 10 mg/kg treatment group compared to 16% remission in the placebo group ($p = 0.041$). A subsequent randomized placebo-controlled trial was published in 2005 evaluating the use of certolizumab administered subcutaneously to induce remission in adult patients with CD [33]. 292 patients were randomized to 100 mg, 200 mg or 400 mg of certolizumab pegol or placebo given at weeks 0, 4, and 8. All of the certolizumab pegol doses produced significant clinical improvement compared to the placebo at 2 weeks, ($p = 0.033$, $p = 0.026$, $p = 0.010$, respectively). The improvement in clinical disease activity was greatest in patients who received 400 mg of certolizumab pegol (52.8% response) compared to placebo (35.6%), although this difference did not reach significance.

The PRECiSE 1 trial evaluated the efficacy of certolizumab in the induction of remission in adult patients with moderate to severe CD [34]. This trial enrolled 662 patients with moderate to severe CD and randomly assigned them to receive 400 mg of certolizumab or placebo at weeks 0,2, and 4 and then 400 mg every 4 weeks after that. The primary endpoints were the induction of clinical response at week 6 and maintenance of this response at week 26. Significantly more patients treated with certolizumab pegol compared to those treated with placebo had a clinical response at week 6 (35% vs. 27%, $p = 0.02$) and 26 (23% vs. 16%, $p = 0.02$). A comparison of clinical remission rates in both groups at weeks 6 and 26 did not differ significantly ($p = 0.17$) [34].

Following this study, PRECiSE 2 was a randomized, double-blind, placebo-controlled trial designed to evaluate the efficacy of certolizumab pegol for maintenance therapy in adults with CD [35]. In this study, 668 patients were enrolled and given induction dosing of 400 mg of certolizumab pegol subcutaneously at weeks 0, 2, and 4. Patients who had a clinical response at week 6 were then randomized to 400 mg of certolizumab every 4 weeks or placebo and followed for 24 weeks. 62% of patients in the treatment group maintained their clinical response at week 26 compared to 34% in the placebo group ($p < 0.001$). In the treatment group, clinical remission was achieved independent of corticosteroid use, concurrent immunosuppressants, or prior infliximab exposure.

As a follow-up, the PRECiSE 3 trial was an open-label extension to PRECiSE 2 to understand the efficacy of certolizumab for long-term maintenance in 595 patients who previously responded to certolizumab [36, 37]. At week 80, 66.1% of patients maintained a clinical response and 62.1% of patients were in clinical remission. Patients who received a placebo during weeks 6–26 as part of the PRECiSE 2 trial and started back on certolizumab as part of the open-label extension (drug interruption group) had higher levels of antibodies against certolizumab compared to the group who received continuous treatment. This study was extended further to look at the long-term safety and efficacy data of certolizumab in 117 patients over 7 years. Clinical remission rates by last observation carried forward and non-responder imputation were 58% and 45% at year 1, 56% and 26% at year 3, and 55% and 13% at year 7, respectively.

The MUSIC trial was the first study to evaluate the efficacy of certolizumab in patients with CD using mucosal healing as a primary endpoint [38]. In this prospective, open-label single arm study performed over 54 weeks, 89 patients with moderate to severe CD were treated with certolizumab pegol 400 mg subcutaneously at weeks 0, 2, 4, and then every 4 weeks thereafter. Endoscopic response was evaluated with the Crohn Disease Endoscopic Index of Severity (CDEIS). After 10 weeks, 62% had an endoscopic response and 42% were in endoscopic remission. After 54 weeks of therapy, endoscopic response and remission rates were 62% and 28% respectively.

To date there are no studies published on the efficacy of certolizumab for the treatment of adult UC.

Efficacy of Certolizumab in Adult Patients with Previous Infliximab Exposure

Similar to the studies on adalimumab, many of the randomized trials and smaller case series included patients who were previously exposed to infliximab; however, these studies did not focus on this population as their primary endpoint. The

WELCOME study was a prospective, randomized, double-blinded trial looking at the efficacy of certolizumab pegol in adults with moderate to severe CD who were secondary non-responders to infliximab [39]. This study included an open-label induction phase of treatment with certolizumab pegol 400 mg at weeks 0, 2, and 4; patients who responded were then randomized to receive placebo or certolizumab pegol 400 mg every 2 weeks or every 4 weeks. At week 6, 62% of patients in the treatment group had a clinical response to certolizumab and 39.3% of patients were in clinical remission. After 26 weeks of therapy, there was no significant difference in the rates of clinical remission or response between those who received certolizumab pegol 400 mg every 2 weeks and those who received 400 mg every 4 weeks.

Golimumab

Golimumab is a fully humanized monoclonal antibody against TNFα and is FDA approved for the treatment of adults with UC. Similar to adalimumab and certolizumab, golimumab is administered subcutaneously with an induction dose of 200 mg at week 0, 100 mg at week 2, and then 100 mg every 4 weeks. Golimumab's structure and mechanism of action are more similar to adalimumab and infliximab binding both soluble and membrane bound TNFα [40]. Golimumab is not currently approved for the treatment of pediatric IBD or any other inflammatory conditions in patients under 18 years of age.

Efficacy of Golimumab in Pediatric Patients

There are no randomized controlled studies of golimumab in pediatric patients with IBD. In 2017 a multicenter open-label study of golimumab in 35 pediatric patients with moderate to severe UC was published [41]. Patients received golimumab induction at weeks 0 and 2 based on weight (90/45 mg/m^2 if <45 kg and 200/100 mg if ≥45 kg). At week 6, 60% of patients had a clinical response, 34% where in clinical remission and 54% had mucosal healing (Mayo Score, PUCAI). In addition, serum levels of golimumab were lower in those <45 kg compared to those >45 kg. In a subsequent study looking at the pharmacokinetics of golimumab in adult and pediatric patients with UC, golimumab clearance increased with increased body weight, lower serum albumin, lack of concurrent methotrexate use, and positive antibodies to golimumab [42]. After controlling for weight, age did not influence golimumab clearance suggesting that the pharmacokinetics of the drug are likely similar in pediatric and adult patients. The PURSUIT PEDS PK Long-Term study published data on the use of golimumab for maintenance therapy in moderate to severe pediatric UC [43]. In this multicenter open-label study, patients who were responders (at week 6) to induction therapy were allowed to continue receiving open-label golimumab maintenance therapy (subcutaneous injection, 100 mg every 4 weeks) with a follow-up of 2 years. Thirty-five children entered the trial and 60% had a clinical response at week 6, resulting in a total of 20 children entering the open-label extension. Of these patients, 50% were in clinical remission (Pediatric Ulcerative Colitis Activity Index <10) at week 110. (Table 32.3).

Although golimumab is not approved for the treatment of CD, a small case series of 6 patients from Finland was published to understand the efficacy of golimumab in pediatric CD patients refractory to infliximab and adalimumab [44]. 83% of patients exposed to infliximab were secondary non-responders. Among these 6 patients, inflammatory markers and fecal calprotectin all decreased initially with golimumab induction; however, the improvement was not maintained and all needed dose escalation to 50 mg every 2 weeks (from 50 mg every 4 weeks) to maintain the improvement. Only two patients in this study continued past 1 year on golimumab both which received higher dosages of golimumab

Table 32.3 Pivotal trials on the efficacy of golimumab in pediatric and adult patients with inflammatory bowel disease

Study	Year	Study Type	Patients	Disease	Pediatric	Findings
Hyams et al. [41]	2017	Open label	35	UC	Yes	At week 6, 60% of patients had a clinical response, 34% where in clinical remission, and 54% had mucosal healing
PURSUIT -PK [43]	2020	Open-label extension	35	UC	Yes	At week 6, 60% of patients had a clinical response at week 6 and 50% were in clinical remission
PURSUIT -SC [46]	2014	RCT	1030	UC	No	At week 6, clinical response was seen in 51% and 54.9% of patients receiving 200 mg/100 mg and 400 mg/200 mg, respectively, compared to the 30.3% who were treated with the placebo
PURSUIT M [47]	2014	RCT	464	UC	No	Clinical response was maintained in 47% (50 mg dose) and 49.7% (100 mg dose) of patients receiving golimumab compared to 31.2% of those on placebo
GO OBSERVE [49]	2019	Observational	102	UC	No	Clinical response was achieved in 36.4%, 39.1%, and 26.3% of patients at weeks 6, 10, and 14, respectively

CZP Certolizumab pegol, *CD* Crohn disease, *UC* Ulcerative colitis, *RCT* randomized controlled trial

(100 mg every 3 weeks and 50 mg every 2 weeks). In another small case series of 7 patients with refractory CD treated with golimumab a clinical response was seen in 71% of patients with 28% achieving clinical remission based on PCDAI [45].

Efficacy of Golimumab in Adult Patients

The PURSUIT trial was the initial study supporting the approval of golimumab for the treatment of adults with moderate to severe UC [46–48]. This study was divided into two phases: the induction phase (PURSUIT-SC) and the maintenance phase (PURSUIT-M). PURSUIT-SC, a multicenter randomized placebo-controlled trial, evaluated the efficacy of golimumab in inducing remission in anti-TNFα-naïve patients with moderate to severe UC [46]. The PURSUIT-SC study had two parts: a phase 2 dose escalation study for induction and a phase 3 dose confirmation study to look at efficacy and safety of the selected induction regimen. In this second section, the primary endpoint was clinical response at week 6. In total, 1030 patients were included in this study; in the phase 2 portion of this study, the largest improvement in Mayo score was seen with 400/200 mg golimumab given at weeks 0 and 2. In the phase 3 part of the study, clinical response at week 6 was seen in 51% and 54.9% of patients receiving 200 mg/100 mg and 400 mg/200 mg respectively compared to the 30.3% who were treated with the placebo. Rates of clinical remission were significantly higher when comparing golimumab 400 mg/200 mg (17.9%) and golimumab 200 mg/100 mg (17.8%) to the placebo (6.4%), ($p < 0.001$ for both comparisons). Likewise, mucosal healing was seen in 42.3% and 45.1% of those receiving golimumab 200 mg/100 mg and 400 mg/200 mg, respectively, which were significantly higher than the rate in those who received the placebo (28.7%), ($p < 0.0014$ for both comparisons.) Finally, looking at change from baseline in IBDQ scores, those who received 400/200 mg and 200/100 mg had improved IBDQ scores compared to those who received the placebo ($p < 0.001$ for both comparisons) [46, 48]. Of note, a separate study evaluating the use of intravenous golimumab for induction of remission was conducted (PURSUIT-IV); however, the clinical response and remission rates were low and the study was abandoned [48].

The maintenance phase of the PURSUIT studies (PURSUIT-M) was a multicenter randomized, placebo-controlled study in which patients who had a positive response to induction with golimumab were randomized to receive golimumab (50 mg or 100 mg) subcutaneously or placebo every 4 weeks through 52 weeks [47]. In this study, a clinical response was maintained in 47% (50 mg dose) and 49.7% (100 mg dose) of patients receiving golimumab compared to 31.2% of those on placebo, $p = 0.010$ and $p < 0.001$ (golimumab vs. placebo respectively). At week 54, clinical response was maintained in more patients treated with 100 mg golimumab (49.7%) and 50 mg golimumab (47%) compared to placebo (31.2%, $p < 0.001$ and $p = 0.01$ respectively). Among those who responded to golimumab induction, clinical remission rates were significantly higher at both 30 weeks and 54 weeks in those who received golimumab 100 mg (27.8%) compared to placebo (15.6%, $p = 0.004$).

A post hoc analysis of the PURSUIT data was performed to better understand the longer-term outcomes of those who had a delayed response to golimumab (patients who had a clinical response at week 14 but had not previously responded at week 6) [48]. In these patients, 35.7% and 30.4% achieved clinical remission at weeks 30 and 54, respectively, which is similar to the rates of clinical response among those who were initial responders by week 6 (39.7% and 33.8% at weeks 30 and 54). Similar results were seen with mucosal healing suggesting that perhaps some patients have a delayed response with equal long-term outcomes at 1 year. A long-term three-year follow-up study of 195 patients in PURSUIT-M demonstrated that 86% of patients continued to have inactive or mild disease at week 104 and 69% remained on golimumab through week 216. Of note, this study only evaluated disease activity using the PGA.

Currently, an international multicenter trial evaluating the use of golimumab in patients with moderate to severe UC is underway [49]. The GO OBSERVE trial included patients naïve to and previously exposed to biologic therapy and treated them with standard-dose subcutaneous golimumab induction, followed by maintenance therapy with either 50 mg or 100 mg of golimumab every 4 weeks. Preliminary data from this study showed that among 102 patients, clinical response was achieved in 36.4%, 39.1%, and 26.3% of patients at weeks 6, 10, and 14 respectively [49].

Numerous case series and retrospective studies have evaluated the use of golimumab in patients with UC [50]. These studies range in size from 21 patients to 205 patients, and follow patients anywhere from 6 weeks to 54 weeks. Clinical response rates in these studies are quite variable, ranging from 14% to 69% [51, 52]. Four of these studies looked at endoscopic healing as well as clinical response and remission [50]. The largest of these studies that evaluated mucosal healing was a case series of 93 patients [53]. The primary endpoint in this study was induction and maintenance of clinical remission, defined as a Mayo score ≤ 2 after 6 months of therapy. In this study, remission was obtained in 36.5% of patients and clinical response was seen in 64.5% of the cohort. Mucosal healing was only seen in 19.3% of patients.

Additional Clinical Endpoints

Growth and Bone Health

The presence of systemic inflammation in IBD appears to play a significant role in growth failure, pubertal delay and poor bone health. Given this, researchers have focused on the restoration of growth and bone health as outcomes of interest for treatments, such as TNFα inhibitors. To date there are only studies of infliximab or adalimumab on growth velocity or bone health in children. Future studies will hopefully report on whether this effect can be extended to other TNFα inhibitors, including golimumab and certolizumab.

A retrospective study of 49 children used growth failure as a primary outcome in patients who received infliximab or adalimumab [54]. The study concluded that use of TNFα inhibitors to improve linear growth and pubertal delay is most effective when used early in childhood and when patients are treated to clinical remission. A smaller retrospective case series in Europe studied the effect of adalimumab on growth, bone mineral density, and bone metabolism among 18 pediatric patients with IBD [55]. In this study 61% of patients had improved growth velocity after the initiation of adalimumab. There was, however, no significant improvement in weight, height, and BMI after adalimumab ($p > 0.05$ for all) or an influence on markers of bone metabolism or bone mineral density.

In the IMAGINE 1 trial linear growth was measured as a secondary endpoint [56]. Adalimumab resulted in significantly improved and normalized growth rates at week 26 ($p < 0.001$) and 52 ($p < 0.001$). Interestingly, improvement in Z-scores was significantly greater in those who received low-dose (80 mg/40 mg) adalimumab (vs. placebo) compared to high-dose (160 mg/80 mg) adalimumab (vs. placebo).

In a retrospective case series focused on changes in growth velocity with adalimumab use, 36 pediatric patients were included and growth data were collected at three time points: 6 months prior to adalimumab, at the initiation of adalimumab therapy, and 6 months after drug initiation [57]. In this study 42% of children had "catch up growth" which was associated with clinical remission ($p = 0.007$), concomitant immunosuppression ($p = 0.03$), and use of adalimumab in a secondary non-responder to infliximab ($p = 0.02$). Controlling for steroid use, the improvement in growth velocity was still present suggesting the effect of adalimumab is independent of a steroid sparing effect.

Finally, a prospective single-center open-label study in patients with moderate to severe CD who failed prior immunomodulator therapy was published evaluating the effect of adalimumab on bone metabolism utilizing in vivo and in vitro systems [58]. This study analyzed healthy patients and patients with CD on adalimumab. A variety of markers of bone health were measured, including parathyroid hormone, vitamin d, bone formation serum markers, inflammatory and anti-inflammatory cytokines, as well as osteoprotegerin and sRANKL. In the in vitro studies, patient serum was plated onto osteoblast cells obtained from human fetal tissue and monitored for viability as well as hormone production. Bone mineral density was measured with DEXA scans. This study demonstrated that adalimumab use was associated with a significant increase in osteocalcin ($p < 0.05$) and procollagen type 1 N terminal propeptide ($p < 0.01$) after 1 and 3 months of therapy. Adalimumab also resulted in a numeric although not statistically significant drop in a bone resorption marker (C-telopeptide of type 1 collagen). Serum from patients who had been treated with adalimumab showed increased osteoblast differentiation compared to controls ($p = 0.001$) which the authors suggest is a sign of new bone growth.

Quality of Life

Quality of life in pediatric IBD has been evaluated as a secondary endpoint in certain randomized controlled trials for anti-TNFα therapy. In the IMAGINE 2 trial evaluating the use of adalimumab in pediatric CD health-related quality of life was assessed using the IMPACT III questionnaire [9]. At enrollment in the trial, the mean IMPACT III score was 116.9 indicating substantial impairment in quality of life. At week 52 IMPACT III scores were significantly improved with sustained improvements through week 240 ($p = 0.001$).

While there are somewhat limited data on quality-of-life metrics in the setting of anti-TNFα therapy (other than infliximab) among pediatric patients, there are additional studies published in this field in adults with IBD [59]. The InspirADA study was a multicenter prospective study evaluating the effect of adalimumab on quality-of-life measures in patients with moderate to severe UC. Quality of life was assessed using the Short Inflammatory Bowel Disease Questionnaire (SIBDQ) and European Quality of Life 5 Dimensions 5 Level (EQ5D5L) questionnaire. In this study, treatment with adalimumab resulted in improvement in work productivity (11% absolute decrease in absenteeism, 25% absolute decrease in impairment while working) and improvement in ability to perform daily activities (27% decrease in impairment of ability to perform daily activities). In addition, this study looked at medical costs (all cause and IBD specific) and found that both general medical costs and UC-specific medical costs were significantly reduced by 59% ($p < 0.001$) and 77% ($p < 0.001$), respectively, when comparing costs 6 months prior to initiation of adalimumab to costs 6 months after initiation of adalimumab.

In addition, utilizing data from the CHARM study, a phase III randomized, double-blind trial of patients with moderate to severe CD treated with adalimumab, health-related quality-of-life outcomes were compared between the treatment groups (adalimumab maintenance weekly, adalimumab maintenance every other week, and adalimumab induction only) [60]. This study utilized the Zung Self-Rating Depression Scale, the Function Assessment of Chronic Illness Therapy (FACIT) Fatigue Score, visual analog pain scales, the IBDQ, and the SF-36. Compared to patients who received the placebo after induction (no maintenance adalimumab), patients treated with maintenance adalimumab reported less depression ($p < 0.01$), less fatigue ($p < 0.001$), improved IBDQ scores (<0.05), and greater SF-36 scores ($p < 0.05$) at week 12 and through week 56.

In a sub-analysis of the PRECiSE 2 cohort, patients receiving continuous certolizumab therapy compared with those in the placebo group had improved Inflammatory Bowel Disease Questionnaire (IBDQ) scores (60% vs. 43%, $p < 0.001$), significantly higher Short Form 36 (SF-36) scores (60% vs. 43%, $p < 0.001$) and improved mental health (44% vs. 32%, $p = 0.016$) responses [61]. In this same analysis, treatment with certolizumab was associated with a greater gain in quality adjusted life years than placebo ($p = 0.001$). Moreover, after 26 weeks of therapy with certolizumab 21% of patients compared to 13% of those in the placebo group reported living a normal life ($p = 0.019$) [61, 62]. Improvements in work productivity, success in school and employment status were seen after induction and maintenance with certolizumab pegol [62]. These improvements in productivity, ability to perform daily activities, and increased health related quality of life were also demonstrated in patients who were treated with certolizumab pegol who previously lost response or could not tolerate infliximab [62, 63].

Postoperative Prophylaxis

In patients with CD who undergo a "curative" surgical resection of inflamed or strictured bowel a decision must be made as to whether to start a biologic in the postoperative period to prevent recurrence of disease. In 2017, NASPHGHAN released a clinical report on postoperative recurrence of CD, suggesting that a decision to initiate postoperative prophylactic treatment should be made individually, weighing the risk of disease recurrence with the overall goal of avoiding any unnecessary immunosuppression. This report noted that of all medication classes, TNFα inhibitors have the best efficacy in preventing disease recurrence, concluding that based on adult studies, postoperative prophylaxis should be considered in pediatric patients with moderate to high risk of recurrence.

There are few studies evaluating the effectiveness of postoperative prophylactic treatment in children with CD. One is a retrospective cohort study of 122 children looking at postoperative prophylaxis (mesalamine, thiopurines, methotrexate, or TNFα inhibitors) within 30 days [64]. The study unfortunately did not break down the results by class of drug or specific agent; however, it concluded that immediate postoperative therapy with any of the above agents reduced the risk of both clinical (HR 0.3, 95%CI 0.1–0.6, $p = 0.001$) and surgical (HR 0.5, 95%CI 0.1–0.9, p = 0.035) recurrence.

Data from the adult IBD literature can again be used to extrapolate in the pediatric population given the limited literature available. In a randomized controlled trial of 51 adult patients, postoperative prophylaxis with adalimumab was compared to azathioprine or mesalamine [65]. In this study, the rate of endoscopic recurrence was significantly lower in the adalimumab treated group (6.3%) compared with the azathioprine (64.7%, OR 0.036, 95%CI 0.004–0.347) and mesalamine (83.3%, OR 0.013, 95%CI 0.001–0.143) groups. In addition, significantly fewer patients had clinical recurrence in the adalimumab group (12.5%) compared with the azathioprine group (64.7%, OR 0.078, 95%CI 0.013–0.464) and mesalamine group (50%, OR 0.143, 95%CI 0.025–0.819). Finally, a multicenter prospective observational study evaluated the effectiveness of adalimumab in preventing postoperative recurrence in 29 adult CD patients [66]. All of the patients in this study had undergone an ileal or ileocolonic resection and were defined as high risk for recurrence based on having 2 or more of the following characteristics: smoking, penetrating disease, or a prior resection. Subcutaneous adalimumab (160 mg/80 mg and then 40 mg thereafter) was administered 2 weeks after surgery. In this study, despite adalimumab therapy, 13.7% developed clinical recurrence and 20.7% had endoscopic recurrence.

There are no studies specifically focused on the use of certolizumab pegol or golimumab as an agent for postoperative prophylaxis; however, future studies may elucidate their role in preventing CD recurrence.

Optimizing the Use of Adalimumab, Certolizumab Pegol, and Golimumab

Treat to Target

The conventional approach to treatment of IBD has focused on improving symptoms and escalating therapeutic interventions based on progression of clinical disease. However, it has become increasingly clear that treatment strategies aimed purely at controlling symptoms are failing to improve the overall trajectory of the disease and prevent long-term com-

plications. More recently a treat-to-target approach has been widely adopted by the IBD community, in which the focus has shifted to understanding additional goals of therapy, including endoscopic remission and using biomarkers to guide therapies. Interestingly, this treat-to-target approach is not unique to IBD and has been described in numerous chronic conditions including rheumatoid arthritis and diabetes.

The "Selecting Therapeutic Targets in Inflammatory Bowel Disease" (STRIDE) group released an expert consensus on the best strategies for a treat–to-target approach in patients with UC and CD [67]. Within these recommendations, the primary goal was to achieve both clinical/patient reported remission and endoscopic remission. Clinical or patient reported remission was defined as a resolution of symptoms and endoscopic remission was defined as a Mayo score of 0–1 in patients with UC and resolution of ulceration on ileoscopy/colonoscopy or resolution of inflammatory findings on cross-sectional imaging in CD. This committee recommended that clinical remission should be assessed every 3 months in patients with active UC and every 6 months in those with active CD. Other targets, including histologic remission on pathology and biomarker remission, such as calprotectin or C-reactive protein, were not recommended due to lack of evidence. The STRIDE recommendations were supported by evidence suggesting that patients who used a treat-to-target approach had improved clinical disease activity scores, fewer surgeries, fewer hospitalizations, and faster steroid tapering [67, 68].

The majority of the data supporting the use of a treat-to-target approach come from retrospective studies, few of which include pediatric patients. In a study of 67 adults with active CD, mucosal healing was associated with early endoscopic evaluation after initiation of therapy (defined in this study as within 26 weeks of initiation of treatment) (HR 2.35, 95%CI 1.15–4.97, $p = 0.019$) and adjustment of medical therapy (adding a medication or switching to a different medication) if mucosal healing was not observed on the endoscopy (HR: 4.28, 95%CI 1.9–11.5, $p = 0.003$) [69]. In this study of the 72 adjustments made in therapy, 12.5% were done in the absence of clinical symptoms. A similar retrospective study was performed in adults with UC where 60 patients were evaluated for endoscopic and histologic healing as a means to guide therapy [70]. Only patients who had a minimum of two endoscopic evaluations performed during the study period were included. At the time of each endoscopy, the chart was reviewed for endoscopic and histologic findings as well as any adjustments in medical therapy as a result of the endoscopy (within 3–6 months of the procedure). In patients with active disease on endoscopy regardless of symptoms, subsequent mucosal healing on the next endoscopy was associated with an adjustment in the medical therapy (HR 9.8, 95%CI 3.6–34.5, $p < 0.0001$) as was histologic healing (HR 9.2, 95%CI 3.4–31.9, $p < 0.001$). In this study 51 adjustments to the medical regimen were made, 15.6% of which were done in the absence of symptoms.

While these data certainly support a clinical benefit with repeated endoscopic evaluation, this practice is costly and not always practical. Therefore, researchers have looked to serum and stool biomarkers as a way to frequently and non-invasively evaluate the degree of inflammation and subsequently use this information to guide management decisions. In the CALM study, an open-label randomized controlled phase 3 trial, adults with active CD (Crohn Disease Endoscopic Score >6) and no prior biologic use were randomized into two groups: tight clinical control using biomarkers or standard clinical management [71]. In both groups, treatment was escalated in a stepwise manner, from no biologic to adalimumab induction with maintenance injections every other week, then further escalated to weekly if necessary, with or without the addition of azathioprine. In the tight control group, treatment escalation occurred for a C-reactive protein ≥5, fecal calprotectin ≥250, CDAI ≥150, or any prednisone use in the prior week. In the standard management group, treatment escalation occurred based on symptoms (using changes in CDAI score as a marker) as well as any prednisone use in the prior week. The primary endpoint in this study was mucosal healing (CDEIS <4) at endoscopy at 48 weeks. Of the 244 patients enrolled in this study, a significantly higher number achieved mucosal healing at week 48 in the tight control group (46%) compared to the standard management group (30%), $p = 0.01$. This study demonstrated that timely dose escalation with adalimumab on the basis of biomarkers and not just clinical symptoms results in improved clinical and endoscopic outcomes.

Combination Therapy

The landmark SONIC trial was the first major publication to demonstrate that combination therapy with infliximab and azathioprine was superior to infliximab alone [72]. After this paper, subsequent studies designed to understand what the mechanism of this effect was and whether it can be extended to other anti-TNFα therapies were published. While some of these data have been published in the pediatric literature, much of it focuses on adults with IBD.

To date, only one randomized controlled trial has been published evaluating the use of combination therapy vs. monotherapy in pediatric patients with IBD; however, this study was in patients treated with infliximab. A post hoc analysis of IMAGINE 1 was presented at Digestive Disease Week (DDW) in 2014 and demonstrated that remission and response rates were similar among those treated with adali-

mumab plus an immunomodulator and adalimumab alone over 26 weeks [73]. A few retrospective studies have been published evaluating the use of combination therapy with adalimumab in pediatric patients; however, the results are quite variable. In one case series from Britain, including 72 children with IBD from 19 different pediatric centers, clinical remission (defined with the PCDAI) was seen in 61% of patients [74]. Remission rates in this study were higher in those on concomitant immunomodulators (74% vs. 37%, $p = 0.003$). Conversely, a retrospective observational study of 78 CD patients treated with either infliximab or adalimumab concluded that there was no change in outcomes when comparing use of concomitant immunomodulators and anti-TNFα therapy vs. anti-TNFα monotherapy [75].

In adults with IBD, the literature on the efficacy of combination vs. monotherapy with adalimumab has also demonstrated significant variability. One study evaluated the effect of concomitant immunomodulators on the pharmacokinetics, efficacy, and safety of adalimumab in patients included in the major randomized, placebo-controlled trials (CLASSIC-1, GAIN, CHARM, EXTEND, ULTRA 1, and ULTRA 2) [76]. A total of 1382 patients with CD and 754 patients with UC were included. None of the trials had a significant difference comparing those on adalimumab monotherapy and those on combination therapy for induction of clinical remission (CLASSIC-1: p = 0.700, GAIN: $p = 0.862$, CHARM weekly $p = 0.233$, CHARM every other week $p = 0.670$, EXTEND: $p = 0.228$). Similarly, an open-label prospective study was performed evaluating the efficacy of adalimumab with azathioprine compared to adalimumab alone among adults with CD who were biologic naïve. In this study, the clinical efficacy of combination therapy (adalimumab plus azathioprine) was not significantly different at week 26 compared to monotherapy [77]. In a retrospective observational study, including 123 adult patients, a greater rate of clinical remission was seen at week 12 in those who were treated with a concomitant immunomodulator (81%) compared to those on monotherapy (60%), $p = 0.0001$ [78]. Multivariate analysis suggested that therapeutic 6TGN levels were a strong predictor of induction response (OR 4.3, $p = 0.01$). Another retrospective study evaluating thiopurine use in adalimumab induction and maintenance demonstrated that thiopurines dosed to therapeutic 6TGN levels were significantly more likely to be associated with CD remission than subtherapeutic doses ($p = 0.004$) when used in combination therapy [79]. Given concerns of increased side effects with combination therapy compared to monotherapy (specifically concern for increased lymphoma risk), if combination therapy is used, the goal should be to taper off the immunomodulator once clinical remission is induced and the patient is stable on the TNF inhibitor to reduce the risk of complications [80].

Therapeutic Drug Monitoring

Proactive monitoring of serum drug and antibody levels in order to optimize drug dosing is an area of great interest given the relatively high rates of loss of response to anti-TNFα agents in patients with IBD. To date, the use of therapeutic drug monitoring and the impact of anti-drug antibodies have been most extensively studied in patients on infliximab and adalimumab; however, a few studies have been published looking at these relationships in patients on certolizumab and golimumab. Therapeutic drug monitoring is covered extensively in a separate chapter in this book.

Comparative Effectiveness

Once a decision is made start a biologic it remains unclear how to choose among the anti-TNFα agents. There are certain considerations that may lead to choosing one medication over the other in terms of ease of administration, need for concurrent immunomodulator, or potential pregnancy. There are no head-to-head trials comparing anti-TNFα agents at this time. While the TNFα inhibitors have the most data available, newer biologics have emerged, including vedolizumab and ustekinumab, adding to the difficulty of selecting a first line agent. Certainly, the clinical context in which the biologic is being prescribed may impact the choice of agent, as infliximab is the only biologic studied in hospitalized patients.

Given the very limited head-to-head comparisons of biologic therapy, the majority of the comparative effectiveness data come from large, retrospective analyses and meta-analyses. In a meta-analysis from 2016, 3205 biologic naïve patients with CD were identified and included for analysis [81]. The primary outcomes were all cause and CD-related hospitalization, abdominal surgery, steroid use, and serious infections. This study suggested that infliximab was superior to adalimumab and certolizumab pegol for all outcomes studied. In 2018, the same research group published a network meta-analysis evaluating the comparative effectiveness of various biologics in adults with CD [82]. Ranking was assessed using surface under the cumulative ranking (SUCRA) probabilities. In this study infliximab (SUCRA 0.93) and adalimumab (SUCRA 0.75) were ranked highest for induction of clinical remission among patients who were biologic naïve. In patients with prior anti-TNF exposure, adalimumab (SUCRA 0.91) and ustekinumab (SUCRA 0.71) were ranked highest for induction of clinical response, although with a low quality of evidence. Finally, among patients who had a response to induction, infliximab (SUCRA 0.68) and adalimumab (SUCRA 0.97) were the highest ranked for maintenance of remission. Interestingly, in a sepa-

rate systematic review with network meta-analysis evaluating the effectiveness of various biologics for the treatment of adults with UC, infliximab (SUCRA 0.85) and vedolizumab (SUCRA 0.82) were the highest ranking for induction of clinical remission and mucosal healing in biologic naïve patients [83]. Looking at mucosal healing as an endpoint of various biologics, a subsequent systematic review with meta-analysis compared data from 12 randomized controlled trials [84]. This study demonstrated that anti-TNFα therapy (infliximab or adalimumab) was superior to placebo for maintenance of mucosal healing (28% vs. 1%, OR 19.71, 95%CI 3.51–110.84) in patients with CD. Similar results were found in patients with UC; anti-integrins and anti-TNFs (adalimumab and infliximab) were more effective than placebo at inducing (45% vs. 30% and maintaining mucosal healing (33% vs. 18%) compared to placebo. In the network analysis, adalimumab therapy was found to be inferior to infliximab use (OR 0.45, 95%CI 0.25–0.82) for inducing mucosal healing in adults with UC. This study concluded that infliximab and adalimumab had similar efficacy in CD for induction of mucosal healing while both infliximab and anti-integrin agents are similarly effective in UC and superior to adalimumab.

Finally, in the first head-to-head trial comparing two biologics, the VARISTY trial evaluated the use of adalimumab and vedolizumab for the treatment of moderate to severe UC [85]. In this double-blind, double-dummy, randomized study conducted at 245 centers in 34 countries, 769 patients were randomized to vedolizumab or adalimumab. At 52 weeks clinical remission (31.3% vs. 22.5%, $P = 0.006$) and endoscopic improvement (39.7% vs. 27.7%, $P < 0.001$) were significantly higher in patients treated with vedolizumab.

Safety Data

When infliximab was approved it was on the leading edge of a new class of medications, biologics, and as such there was significant concern from patients and providers over the safety of this unknown class of drugs and specifically the risk with blocking tumor necrosis factor α signaling. With time it has become clear that anti-TNFα therapy is safe and tumor necrosis factor α is not critical to tumor surveillance. Studies, however, continue to show persistent concerns from patients when adopting this therapy [86].

General adverse events will be reviewed here and certain serious adverse events will be reviewed more in detail in specific sections. In the IMAGINE I trial of adalimumab induction in pediatric patients, the most common adverse events reported included non-serious infectious events and injection site reactions [7]. In the open-label induction period, 101 (52.6%) patients reported treatment-related adverse events, including two serious infections (one Yersinia infection and one viral infection, both of which resolved without significant morbidity or mortality). Adverse events reported during the double-blind maintenance period were very similar in terms of number and type comparing the low-dose to high-dose adalimumab groups. More rare events included opportunistic infections (such as tuberculosis), allergic reactions, hepatic- and hematologic-related adverse events, as well as malignancy. No deaths were reported. The IMAGINE 2 trial had a similar rate of adverse events with the most common being headache and nasopharyngitis [9]. A systematic review of 664 patients exposed to adalimumab reported adverse events in 49% of patients, including headache, abdominal pain, and rash [10].

While there are no data on the safety of certolizumab in pediatric patients the PRECiSE studies included follow-up to 7 years for reporting of adverse events [37]. Over 7 years of treatment with certolizumab 88.2% of patients experienced one or more adverse events, including worsening of the patient's underlying CD and infectious complications, such as nasopharyngitis and urinary tract infections. In this trial the majority of adverse events (71.8%) were considered "unrelated" to the study drug.

In a multicenter open-label study of 33 pediatric patients exposed to golimumab, 94.3% reported one or more adverse events through 14 weeks of follow-up [41]. The most common adverse events with golimumab were worsening UC symptoms (37%), abdominal pain (26%), and headache (26%). In the PURSUIT PEDS PK Long-Term Results study, pediatric patients with IBD treated with golimumab were observed for the development of any adverse events over 126 weeks [43]. Among patients in this study, 95% reported one or more adverse events, including worsening of underlying disease, headache, abdominal pain, and upper respiratory tract infections.

Malignancy

TNFα was originally discovered in 1975 by a tumor immunologist who was seeking a serum factor which led to tumor necrosis in response to an antigen challenge with endotoxin [87]. Despite its origin of discovery, its role in the immune surveillance of tumors is believed to be less significant and studies have demonstrated little risk for the development or recurrence of malignancy. A large population-based study demonstrated that children with IBD (regardless of treatment regimen) had a three-fold increase in mortality risk secondary to a malignancy (HR of 6.6 95%CI 5.3–8.2) [1]. These cancers included colorectal carcinoma, cholangiocarcinoma as well as lymphoma. To understand if the increase in malignancy was secondary to therapy, especially anti-TNFα, there

have been a number of prospective and retrospective studies. Here we will focus on the relationship between anti-TNFα therapies (other than infliximab) and malignancy risk.

The majority of the data on risk of malignancy with TNFα inhibitor use are related to adalimumab exposure. A Swedish group evaluated outcomes in 9405 pediatric IBD patients and did not find an association between cancer risk and drug exposure, including anti-TNFα [1, 88]. A systematic review to understand the risk of malignancy in IBD patients included 65 publications with a total of 5528 patients and 9516 patient-years of follow-up in the final analysis [89]. Among the patients included in this study, the majority had CD (84%) and were treated with infliximab while 10% of the patients included were treated with adalimumab. Two patients developed lymphoma both of whom were previously treated with infliximab. This study concluded that the risk of lymphoma was similar to that in children with IBD treated with non-anti-TNFα therapies and similar to the rate seen in the adult IBD population. A second systematic review looking specifically at patients exposed to adalimumab included 14 studies and a total of 664 patients [10]. In this study there was a single case of medulloblastoma identified; however, no cases of lymphoma were reported. In the IMAGINE I trial and the IMAGINE II trial there were no reported malignancies (including solid tumors and lymphomas) in follow-up [7, 9].

While there are no data on the development of malignancy in pediatric patients on certolizumab, the PRECiSE studies included seven-year follow-up to monitor for malignancy [37]. The rate of malignancy in the PRECISE studies was 0.84 cases/100 patient-years. A total of 20 malignancies were reported the most common of which was basal cell carcinoma. No cases of lymphoma were reported. The studies of golimumab exposure in children are short term, though the PURSUIT PEDS PK study observed patients through 126 weeks with no reported malignancies [43].

The development of hepatosplenic T cell lymphoma which is a devastating and often fatal outcome in pediatric IBD was initially found to be associated with infliximab and led to a large level of concern [1, 90, 91]. It was subsequently determined though that this fatal lymphoma was associated with combination use of infliximab and an immunomodulator (azathioprine or 6 mercaptopurine) and not anti-TNFα use alone [1, 90, 91].

Infection

Studies on the risk of infection using adalimumab are the most common. Two large systematic reviews have been published evaluating the risk of infection in pediatric IBD treated with TNFα inhibitors. One systematic review previously discussed included 65 publications with a total of 5528 patients and 9516 patient-years of follow-up in the final analysis [89]. Among patients treated with adalimumab 5.4% developed a serious infection requiring termination of the drug which was similar to the rate seen in patients treated with infliximab. Seven deaths were reported in this study two of which were while on adalimumab therapy. Both of these deaths resulted from a central line infection while on total parenteral nutrition. The rate of serious infection was lower in children treated with anti-TNFα therapy compared to pediatric patients on corticosteroids as well as adults on TNFα inhibitors. In the IMAGINE I trial, eight serious infections were observed including two opportunistic infections (one non-serious aeromonas infection and disseminated histoplasmosis infection) [7]. In the IMAGINE 2 trial non-serious opportunistic infections, including oral candidiasis ($n = 7$), aeromonas infection ($n = 1$), fungal esophagitis ($n = 1$), and esophageal candidiasis ($n = 1$), were seen. One case of disseminated histoplasmosis was seen and no active tuberculosis cases were reported [9].

While there are no data on the safety of certolizumab in pediatric patients, the PRECISE studies again provide insight into potential infectious complications [37]. In the PRECISE studies nasopharyngitis was the most reported infectious complication in 15.3% of patients. Patients treated with concomitant corticosteroids were more likely to have a serious infection compared to those on TNFα therapy without steroids. Three cases of disseminated tuberculosis were reported (0.5%).

In a multicenter open-label study of 33 pediatric patients with UC treated with golimumab, 94.3% reported one or more adverse events through there were no serious infections [41]. Similarly, in a small case series evaluating the use of golimumab in 6 children with CD, no serious infections were reported [44]. In the PURSUIT PEDS PK Long-Term Results study of golimumab, upper respiratory tract infections were among the most common adverse event reported (25% of patients) and only 1 patient experienced a serious infection [43].

Postoperative Infections

With the introduction of biologics and their use in hospitalized patients with severe IBD came concerns over the safety of these agents in the perioperative period. To date, the majority of the literature in this field comes from adult patients treated with infliximab, though a few studies did include adalimumab or other biologics in their data. In a meta-analysis of 22 observational studies evaluating postoperative complications, including infections, were evaluated in 4251 patients who received perioperative biologics [92].

The pooled prevalence of infectious postoperative complications was 16% and 17% in CD and UC, respectively. In this study, the prevalence of infectious complications was slightly increased in patients who received perioperative TNFα inhibitor use (OR 1.45, 95%CI 1.03–2.05). Conversely, numerous studies have suggested that perioperative infliximab, adalimumab, and certolizumab pegol do not increase postoperative infectious complications. In an analysis of a national database of 2068 IBD patients, the incidence of postoperative complications after perioperative exposure to anti-TNFα (infliximab, adalimumab, and certolizumab) was no different from patients who were not exposed (33.3% vs. 37.1%, $p = 0.7969$) [93]. In a case matched retrospective observational study of 123 adult patients with CD, the effect of adalimumab on postoperative complications was again analyzed and did not demonstrate a difference in overall surgical complications (36% vs. 12%, $p = 0.095$) [94].

Novel Viral Infections

Today, in the setting of the recent Coronavirus (COVID-19) pandemic, new concerns have surfaced regarding the safety of TNF inhibitors and specifically the impact that systemic immunosuppression may have on susceptibility to COVID-19 and severity of disease course. Surveillance Epidemiology of Coronavirus Under Research Exclusion (SECURE-IBD) is the largest cohort to date evaluating outcomes of patients with IBD and confirmed COVID-19 [95]. 294 pediatric patients were included in this dataset (ages 19 and under) which suggests that patients on TNFα inhibitor monotherapy are at no increased risk of becoming infected with COVID-19 or having a worse outcome if infected (hospitalization, intubation, or death).

Immune Reactions (TNFα-Induced Psoriasis, Drug-Induced Lupus, Auto-Immune Hepatitis)

Biologics targeting TNFα, including infliximab, adalimumab, certolizumab, and golimumab, have been associated with paradoxical inflammatory reactions, including psoriasis, drug-induced lupus, and auto-immune hepatitis (AIH). The histopathology of TNFα-induced psoriasis is not well understood; however, it is thought to involve a spectrum of cutaneous pathology, including psoriasis, like inflammatory patterns, eosinophilic hypersensitivity reactions, or sterile pustular folliculitis [96]. TNFα-induced psoriasis is thought to affect roughly 1.6%–2.7% of IBD patients. Currently, infliximab is thought to be the most common TNFα inhibitor to cause psoriasis; however, this paradoxical reaction has been documented in patients on adalimumab, certolizumab, and golimumab. In a prospective Spanish cohort of IBD patients treated with infliximab and adalimumab patients were monitored and the development of psoriasis [97]. In this study of 7415 patients, 1.7% of patients developed TNFα-induced psoriasis with an incidence rate of 0.5% per patient-year. In a multivariate analysis, female sex (HR 1.9, 95%CI 1.3–2.9) and being an active or former smoker (HR 2.1, 95%CI 1.4–3.3) were associated with increased risk of psoriasis. In this study, topical steroids were effective in the majority of patients (78%) for treatment. Interestingly, among patients who switched to another TNFα inhibitor, 60% had recurrence of psoriasis with a different agent, and 37% required switching to a different biologic class. For psoriasis refractory to topical steroids, switching to ustekinumab can help treat the skin disease as well as the underlying IBD [98].

Anti-TNFα-induced lupus is poorly understood and continues to be a diagnostic and therapeutic challenge for physicians. The majority of cases of TNFα inhibitor-induced lupus have been reported secondary to infliximab use; however, adalimumab and other TNFα inhibitors, including etanercept have been associated with this rare paradoxical side effect. Symptoms of drug-induced lupus can range from mild cutaneous lesions to more serious coagulopathies, including deep venous thrombosis as well as pleural or pericardial effusions. Differentiating between primary systemic lupus erythematosus and TNFα inhibitor-induced lupus is usually based on timing of symptoms in relation to TNFα initiation and the development of serum markers, such as anti-histone antibodies (although this can be seen in de novo cases of lupus as well as in drug-induced lupus) [99]. The pathogenesis of anti-TNFα-induced lupus is not well understood, however several mechanisms have been proposed, including a possible "cytokine shift," from Th1 cytokine to Th2 cytokines, leading to the production of autoantibodies. Other suggested mechanisms include a reduction in apoptosis from decreased CD44 expression, impairing the ability of the body to clear nuclear debris and promoting autoantibody production against nuclear antigens and possible inhibition of cytotoxic T cells which regulate auto-antibody producing B cells [99]. While there are little data on the incidence of adalimumab-induced lupus in patients with IBD, a post-marketing surveillance study in patients with rheumatoid arthritis demonstrated that this adverse event is very rare, with four cases reported after 4870 patient-years of adalimumab exposure [100]. In this study, the majority of cases reported cutaneous lesions, photosensitivity, and serositis; however, no significant internal organ involvement was documented.

Auto-immune hepatitis has been reported as a complication of biologic use, specifically with TNFα inhibitors. AIH is a chronic inflammatory condition that can unfortunately progress into end stage liver disease. Numerous medications have been associated with the development of AIH, most recently biologics, including infliximab and adalimumab.

Adalimumab-induced AIH was first described in 2010 in a patient being treated for psoriatic arthritis [101]. The majority of the literature on adalimumab-induced AIH stems from case reports in adults with various inflammatory conditions. The first two reports of adalimumab-induced AIH were in women in their 40s who did not have any underlying liver pathology prior to initiating adalimumab [102]. In both of these women, symptoms of AIH started within months of initiation of the adalimumab and both had liver biopsies consistent with a diagnosis of AIH. In a retrospective cohort study of 659 pediatric patients with IBD, an index case of AIH secondary to infliximab use was identified [103]. This patient developed abnormal liver enzymes and features of AIH 23 weeks after initiating infliximab. There are no data on the incidence of adalimumab-induced AIH in pediatric patients with IBD.

Biosimilars

Biosimilars are biologic therapies that are very similar to the previously approved reference or originator biologic drug in terms of efficacy, makeup, and safety. As drugs, such as adalimumab, come off of patent, biosimilars are increasingly being used worldwide as alternative therapies to reduce treatment cost [104]. To date, six biosimilars have been approved in the US for the treatment of adult IBD. Three of these approved medications are biosimilars to the originator adalimumab. Of note, there are very limited data on the use of these drugs in pediatric patients with IBD although utilization rates are increasing. While these agents are rather new in the United States, biosimilars have been approved for use in Europe and Canada for over a decade. Biosimilars undergo different testing and have different regulatory requirements as compared to their originator drug [105]. All biosimilars undergo extensive structural and functional analyses to confirm that the biosimilar has a high degree of similarity to the originator drug. Animal studies are also conducted to demonstrate pharmacokinetics, immunogenicity and toxicity. Finally, the biosimilar must be evaluated in at least one clinical study to demonstrate similar efficacy and safety as compared to the originator drug. Of note, some regulatory agencies, including the U.S Food and Drug Association (FDA), reserve the right to waive the requirement of a clinical study [105]. Once a biosimilar is approved for a single indication, it is subsequently approved for the other indications of the originator drug without further studies [106, 107]. One of the first position papers on the use of biosimilars in patients with pediatric IBD is from the Porto IBD working group of ESPGHAN in 2015 [106, 108]. With very limited data on the use of these novel agents in pediatric IBD, the group concluded that extrapolation to children with IBD should be done with caution. This group pointed to the fact that all of the studies were done in adults and that the dosing can be different from the originator drugs to argue against the generalized acceptance of biosimilars for pediatric patients [106].

Two major areas for research in biosimilars is the efficacy, safety and comparability of these drugs to their originators and the interchangeability of these drugs with the originators. The early studies on biosimilars in pediatric patients all focus on infliximab and its biosimilars; no similar studies have been published with adalimumab. However, these early studies suggested that the biosimilars did in fact have similar efficacy compared to infliximab and patients were able to maintain clinical remission despite changing from infliximab to the biosimilar [106, 109–111]. Perhaps similar data will be published in the near future evaluating adalimumab biosimilars in pediatric IBD patients. In adults a phase I randomized trial of safety, pharmacokinetics and immunogenicity were conducted comparing the adalimumab biosimilar BI 695501 to the originator (VOLTAIRE-PK) [112]. In this trial there were no differences in any outcomes between BI 695501 and adalimumab in healthy adults. ABP-501 and SB5, two other adalimumab biosimilars, showed no immunogenicity concerns in healthy adults and were comparative to adalimumab in efficacy in patients with plaque psoriasis in double-blind placebo-controlled trials [106, 113, 114].

Looking forward, there are over ten new adalimumab biosimilars awaiting approval from the FDA. Moreover, the patent on certolizumab is set to expire in Europe in 2021 and in the US in 2024. Biosimilars to certolizumab are already being investigated and likely will be approved in the future. Likewise, the patent on golimumab is set to expire globally in 2024 and numerous biosimilars have been described in the literature that are awaiting future use.

Future Directions

While novel biologic targets and new small molecule therapies have been studied and brought to the market, the cornerstone of IBD therapy in the past decade has certainly focused on biologics targeting TNFα. Although infliximab is the most commonly used drug in this category, adalimumab, certolizumab, and golimumab have been used in the treatment of moderate to severe CD and UC. To date, adalimumab is the only one of these agents approved specifically for the treatment of pediatric IBD; looking forward, randomized controlled trials evaluating the efficacy and safety of these agents in children with CD and UC will help elucidate their role in the treatment algorithm.

Novel biologics targeting TNFα are also in the pipeline including oral antibody formulations, which could certainly change the landscape of IBD therapy going forward. AVX-470 is an orally administered bovine polyclonal antibody against TNFα that is being studied in adults with UC. V565

is an engineered Vorabody which is resistant to proteases and facilitates delivery to the intestine with the hope of reducing systemic absorption. There is currently an ongoing an international phase II trial looking at the efficacy of this agent in the treatment of CD. In addition to traditional methods for delivering anti-TNFα therapy a Belgium-based biopharmaceutical company has reported positive results from a Phase I trial of AG014, a strain of genetically modified Lactococcus lactis bacteria that is being studied for oral administration of certolizumab directly to the gastrointestinal tract.

It is likely that anti-TNFα therapy will continue to be a mainstay in the treatment of IBD for years to come. As more is understood about the specific mechanisms that underlie this therapy and innovations are made to deliver these therapies in a safe and cost-effective manner, it is likely we will continue to see new products pushing the limits of what this class of therapies can do for patients with IBD.

Therapeutic Drug Monitoring in Pediatric Inflammatory Bowel Disease

33

Namita Singh and Marla C. Dubinsky

Introduction

A key management strategy in the care of IBD patients includes maximizing the efficacy of IBD medications while minimizing their toxicity. The recognition of factors leading to a therapeutic response and remission allows for individualized dosing regimens to meet these goals. Standard dosing of immunomodulator and anti-TNF therapy is often insufficient giving inter-patient variability with regard to response and tolerability. Therapeutic drug monitoring (TDM) is a concept worth understanding in order to optimize drug efficacy with the goal of achieving a sustained and durable remission. The concept of dose optimization initially started over a decade ago with the use of thiopurines and is now utilized in anti-TNF therapies. With the additional classes of biologics introduced in the past several years, including antibodies to alpha4beta7 integrin and IL12/IL23, the use of TDM may broaden to these classes of medications, although sparse supporting data exist currently. Given the limited approved medications available for young patients with IBD and the need for durable treatment strategies, TDM can be an invaluable tool to guide treatment decisions. This chapter will review the historical and current utilization of TDM, as well as the accompanying challenges, in treating pediatric patients with IBD.

Thiopurine Monitoring

TPMT and thiopurine metabolite levels are used in current clinical practice to manage IBD patients receiving thiopurines, including 6-mercaptopurine (6-MP) and azathioprine (AZA). 6-MP and its prodrug, AZA, undergo intestinal and hepatic metabolism by numerous enzymes, including hypoxanthine phosphoribosyltransferase (HPRT), TPMT, xanthine oxidase (XO), and inosine monophosphate dehydrogenase (IMPDH), to produce the active metabolites, 6-thioguanine nucleotides (6-TGNs), and 6-methylmercaptopurine ribonucleotides (6-MMPs) [1] (Fig. 33.1). Through the study of these enzymes and metabolites, the mechanisms of drug efficacy and toxicity have been well described [2].

Prior to initiating a thiopurine, obtaining a TPMT level is considered standard practice, as this determines the starting dose for an individual patient. For the majority (89%) of patients with a normal TPMT level, standard initial dosing is 2.5 mg/kg/day of AZA or 1.5 mg/kg/day of 6-MP. For the 10% of patients who are heterozygote for the TPMT gene, known as intermediate metabolizers, the clinician should prescribe half the standard dose to minimize high 6-TGN levels and the associated risks, including leukopenia. In patients who are homozygote for the TPMT gene (1 in 300), thiopurines are contraindicated given the risk of life-threatening leukopenia [3]. TPMT guided dosing avoids sub-therapeutic use, as knowledge of TPMT activity identifies the variability in metabolism, improving clinician confidence in dosing selection.

TPMT levels drive initial dosing, yet 6-TGN and 6-MMP metabolites influence the subsequent efficacy and safety. Cuffari et al. showed in 1996 that higher 6-TGN metabolite concentrations correlate with clinical remission in pediatric Crohn disease (CD) patients [4]. Subsequent pediatric studies demonstrated that the therapeutic response doubled in patients whose 6-TGN levels were >235 pmol/8 × 10(8) RBC (78% vs. 41%, $p < 0.001$) [5]. The odds of responding to thiopurines was 5 times higher in patients with 6-TGN

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_33

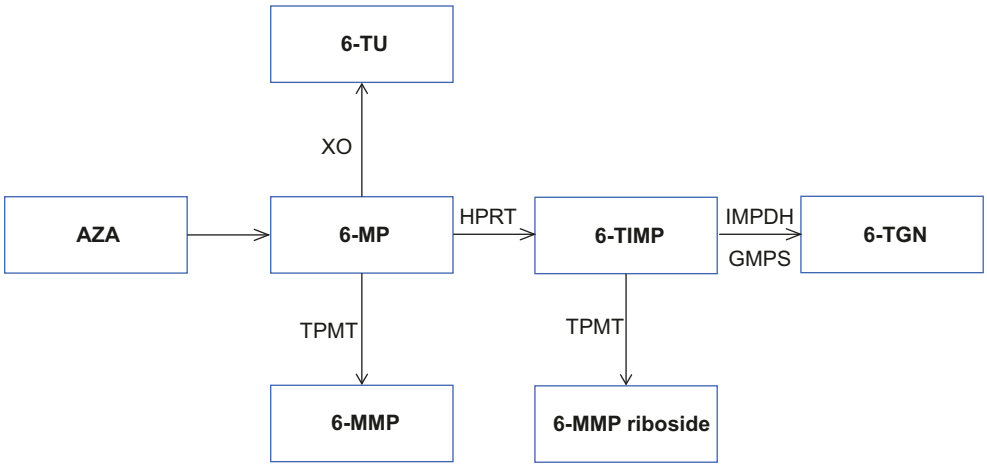

Fig. 33.1 Azathioprine/6-mercaptopurine metabolism pathways. *AZA* Azathioprine, *GMPS* Guanosine monophosphate synthetase, *HPRT* Hypoxanthine phosphoribosyltransferase, *IMPDH* Inosine monophosphate dehydrogenase, *6-MMP* 6-Methylmercaptopurine, *6-MP* 6-Mercaptopurine, *6-TG* 6-Thioguanine, *6-TIMP* 6-Thioinosine monophosphate, *TPMT* Thiopurine *S*-methyltransferase, *6-TU* 6-Thiouric acid, *XO* Xanthine oxidase

levels >235 pmol/8 × 10(8) RBC, as compared to those below this therapeutic threshold [5]. A 6-TGN level of 235 pmol/8 × 10(8) RBC has been supported as a cut point in other pediatric and adult studies, and a meta-analysis also reported that patients with 6-TGN concentrations above this threshold had a three-fold increased odds of being in remission than those below this threshold (62% vs. 36%; pooled odds ratio 3.3, 95% confidence interval, 1.7–6.3; $p < 0.001$) [6–9]. In a patient not responding clinically to standard thiopurine dosing, obtaining a 6-TGN and 6-MMP level would be clinically useful to ensure therapeutic dosing. If 6-TGN levels are <235 pmol/8 × 10(8) RBC, dose escalation is warranted; yet if therapeutic (235–400 pmol/8 × 10(8) RBC), switching to a non-thiopurine therapy would be reasonable.

Leukopenia is the most concerning toxicity associated with the use of thiopurines. This is most commonly attributable to high 6-TGN metabolite levels. Patients that are homozygous deficient for TPMT polymorphisms are most at risk of thiopurine-related myelosuppression. Colombel et al., however, reported that only one-third of myelosuppression cases were secondary to a low TPMT activity, indicating other factors contributing to leukopenia, such as effects of concomitant medications and secondary viral infections (EBV, CMV, parvovirus) [10]. It is unclear what 6-TGN level is considered "too high"; however, a level >400 pmol/8 × 10(8) RBC has been suggested as the cut point which clinicians should avoid [11].

Hepatotoxicity is another risk with thiopurine use, with some studies associating it with 6-MMP concentrations above 5700 pmol/8 × 10(8) RBC ($p < 0.05$) [5, 11]. If a patient has a therapeutic 6-TGN level with a 6-MMP level >5700 pmol/8 × 10(8) RBC and normal liver enzymes, more frequent clinical monitoring of liver enzymes is indicated, rather than a reflexive thiopurine dose decrease. If a patient, however, has both a high 6-TGN level (>400 pmol/8 × 10(8) RBC) *and* 6-MMP level (>5700 pmol/8 × 10(8) RBC), then dose de-escalation is warranted in order to minimize the risk of leukopenia and hepatotoxicity. Perhaps the most important application of high 6-MMP levels is in the patient who also has a low 6-TGN level, with subsequent dose-escalation resulting in decreasing 6-TGN and increasing 6-MMP [12]. This group has been defined as being "thiopurine-resistant," or "6-MMP preferential metabolizers," and such patients would benefit from changing to another class of medications, such as methotrexate (MTX) or biologic therapy. The proposed use of allopurinol in these patients to reverse the metabolism to favor more 6-TGN and less 6-MMP may carry additional toxicity risks with relation to leukopenia but has been shown to be an effective strategy [13]. The understanding of the importance of thiopurine drug monitoring paved the way for applying the TDM concept to other IBD therapies and more specifically, anti-TNF therapies.

Anti-TNF Drug Concentrations

Only recently studies have examined the durability of anti-TNF agents and their pharmacokinetic profiles, despite being approved since 1998 in adults and 2006 in pediatric patients. Most studies have examined infliximab (IFX), with evolving literature for the other anti-TNF agents, including adalimumab, certolizumab pegol (CZP), and a paucity of data with golimumab.

Although the response to IFX induction is highly successful in 75–90% of pediatric IBD patients, more challenging is the maintenance of a sustained and durable remission [14, 15]. In the REACH trial, only 60% of pediatric CD patients who responded to induction were in remission at 1 year, and half of these patients required dose modification after losing response [14]. In a meta-analysis of adult IBD patients on

IFX, 23–46% required dose escalation and 5–13% discontinued the drug at 1 year [16]. Using TDM, one can better understand the etiology of primary non-response and secondary loss of response, and TDM may be used in clinical management with the goals of a sustained response to therapy.

In 2003, initial studies found higher serum IFX concentrations to be correlated with longer duration of response [17]. It was reported in 2006 that detectable serum IFX concentrations were associated with a higher rate of clinical remission, endoscopic improvement, and lower CRP values in CD patients [18]. Other studies also support the findings that detectable IFX concentrations were predictive of a sustained response in CD patients [19]. In UC, the data are just as strong, with detectable IFX concentrations associated with higher remission rates, endoscopic improvement, and a significant decrease in colectomy risk (55% vs. 7%, OR 9.3; 95% CI 2.9–29.9; $p < 0.001$) [20]. In the post hoc analysis of the ACT trials, higher IFX concentrations in UC patients were associated with an increased likelihood of achieving clinical remission and mucosal healing with increasing quartiles of IFX levels [21]. Patients with drug levels in the third or fourth quartile had remission rates at week 30 closer to 60% as compared to those in the second quartile whose remission rates were 25%. In the recent UK PANTS study consisting of 955 CD patients, low drug concentration at week 14 for both infliximab and adalimumab was the only factor independently associated with primary non-response in a multivariable analysis [22]. Other studies have found that higher adalimumab concentrations correspond to mucosal healing and clinical remission; higher CZP concentrations in CD patients are associated with endoscopic remission and response; and higher golimumab concentrations were associated with clinical remission [23–25].

The minimum anti-TNF trough concentration associated with improved outcomes remains debatable and may vary depending on the outcome measured (clinical/biochemical/endoscopic/histologic remission). Murthy et al. demonstrated that an IFX concentration of >2 μg/mL in UC patients was associated with a higher rate of corticosteroid-free remission, compared to a trough concentration of <2 μg/mL (69% vs. 16%; $p < 0.001$) [26]. A trough concentration >3 μg/mL during IFX maintenance therapy has been shown by Vande Casteele et al. to be independently associated with a lower CRP and has been proposed as a cut-off to improve outcomes [27]. Recent studies suggest that yet even higher IFX trough drug concentrations at week 14, the time of the first maintenance dose, are associated with better one-year efficacy outcomes [28, 29]. In one study, a ≥3.5 μg/mL post-induction serum infliximab concentration level and a ≥60% CRP decrease from baseline to week 14 significantly predicted durable sustained response to infliximab in patients with raised baseline CRP [29]. In the PANTS study, week 14 infliximab drug concentration of 7 μg/mL was associated with remission at both week 14 and week 54 [22]. Fistula healing with IFX in CD has been associated with even higher concentrations (>15 μg/mL) [30].

In a pediatric IBD study, median IFX trough levels were significantly higher when children achieved clinical remission (5.4 μg/mL vs. 4.2 μg/mL), biological remission (5.2 μg/mL vs. 4.2 μg/mL), combined clinical and biological remission (5.7 μg/mL vs. 4.4 μg/mL), and endoscopic remission (6.5 μg/mL vs. 3.2 μg/mL) compared with not meeting these criteria [all $p \leq 0.001$] [31]. In an Israeli study, pediatric IBD patients in clinical remission were found to have higher IFX concentrations than those with active disease (4 vs. 2.25 μg/mL, $P < 0.0001$). In this study, a week 2 IFX level >9.2 μg/mL predicted clinical remission by week 14 (AUC 0.72, $p = 0.02$); at week 6 IFX level >2.2 μg/mL predicted IFX durability beyond 1 year of treatment (AUC 0.974, $p < 0.0001$) [32]. Another pediatric study reported that the median IFX pre-fourth dose level in responders was significantly higher at 12.7 μg/mL, compared with 5.4 μg/mL in the active perianal disease group [33]. In further examining earlier IFX trough levels, Buhl et al. found that the optimal IFX thresholds early in treatment associated with response to IFX was 22.9 μg/mL at week 2 (sensitivity 51%, specificity 80%, AUCROC 0.67, $p < 0.05$) [34]. Another study revealed IFX concentration below 6.8 μg/mL at week 2 are associated with primary non-response in Crohn disease patients. Clarkson et al. found that infusion 2 (≥29 μg/mL) and infusion 3 (≥18 μg/mL) infliximab concentrations were strongly associated with improved early outcomes and higher first maintenance dose levels [35].

Differing cut-offs have also been suggested for adalimumab concentrations. Velayos et al. found that an adalimumab concentration of >5 μg/mL was associated with decreased CRP level; Yarur et al. confirmed this association [36, 37]. Karmaris et al. suggested a higher therapeutic threshold of >8 mg/mL [38]. In the PANTS study examining adult CD patients, an adalimumab trough concentration of 12 μg/mL was associated with remission at 1 year [22].

For CZP, in the post hoc analysis of the WELCOME trial, evaluating induction therapy of CZP in 203 patients, remission rates were higher among patients whose CZP concentration fell within the two highest quartiles during induction at weeks 0, 2, 4, and 6 (27.5–33.8 μg/mL and ≥33.8 μg/mL, respectively); thus, a CZP concentration of >27.5 μg/mL has been proposed for clinical use [39]. For golimumab, patients with drug concentrations in the highest quartile with a concentration of >3.1 μg/mL had higher rates of clinical remission at 30 and 54 weeks when compared to lower quartiles [25].

The importance of optimized anti-TNF levels is exemplified by recent expert consensus that reactive TDM should be used for all biologics for both primary non-response and sec-

ondary loss of response. It was recommended that treatment discontinuation should not be considered for infliximab or adalimumab until a drug concentration of at least 10–15 μg/mL was achieved [40].

Anti-TNF Drug Antibodies and Outcomes

Despite a high primary response rate to the anti-TNF agents, two-thirds of patients losing response do so within the first year [16]. The loss of response to anti-TNF agents is most often due to an individual's unique physiologic profile driven by drug clearance, with factors that influence drug clearance, including low serum albumin concentration, high baseline CRP levels, large body size, male sex, and a high degree of systemic inflammation [41]. In children younger than 10 years, the clearance of IFX has been estimated to be more rapid, with higher likelihood of developing anti-drug antibodies (ADAs) and these young children often require higher and more frequent doses of IFX [42]. The development of ADAs in all patients, referred to as immunogenicity, remains a significant driver of loss of response. It should be noted that non-chimeric anti-TNF therapies have the same issues with ADA formation as chimeric anti-TNF agents [43]. The presence of ADA increases the clearance of the drug, resulting in lower drug concentrations. This, in turn, results in shorter duration of response, which has been demonstrated in multiple studies [17, 18, 22, 23, 41, 44–47]. Other factors may be responsible for ADA development, including the presence of specific genetic alleles. Recent data reveal that the HLA-DQA1*05 gene allele is associated with development of antibodies to anti-TNF agents (hazard ratio [HR], 1.90; 95% confidence interval [CI], 1.60–2.25; $P = 5.88 \times 10^{-1}$) [48].

In a prospective study of patients receiving IFX therapy, ADA development preceded clinical loss of response in over half of patients [49]. Similar results have been reported with adalimumab, with 20% of patients developing anti-adalimumab antibodies which predicted biochemical and clinical loss of response [50]. Another study also confirmed the association of anti-adalimumab antibodies with increased markers of inflammation and with clinical indices, indicating increased disease activity [51]. Antibodies to certolizumab were also found to be associated with reduced remission rates through week 26 in the PRECISE 2 trial (71 vs. 62%), and similarly found in the WELCOME trial [52, 53]. In addition to the negative effect ADAs have on efficacy, they also increase toxicity, with the example of anti-infliximab antibodies (ATIs) being associated with infusion reactions [45]. Additionally, a 2015 pediatric study found that the presence of ATIs was a predictor of lower IFX concentrations, and a higher risk of surgery [54].

Additionally, ATIs may be transient. Vande Casteele et al. retrospectively found that in 28% of patients' ATIs disappeared over time, whereas they were sustained in 72% of patients [47]. They also suggested that ATI concentrations of >9.1 U/mL were less likely to be overcome with a likelihood ratio of 3.6 of failure [47], and thus, such patients should be changed to another anti-TNF therapy.

The knowledge of the presence of ADA is also important in the setting of reintroduction of anti-TNF therapies after a prolonged interruption, or "drug holiday". Baert et al. reported that the presence of ATI 2 weeks after the first re-induction dose of IFX was associated with lower response rates and higher rates of infusion reactions [55]. The data suggest that if a patient has discontinued IFX for at least 6 months, it is important to check for the presence of ATIs prior to administering the second induction dose. It remains unclear whether, following a drug holiday, a patient should be re-induced with the standard initial induction regimen (0, 2, 6 weeks) or forego re-induction and resume with every eight-week interval.

The reported rates of ADA are entirely dependent on the specific assay used to measure ADA. Several techniques are available for measuring anti-TNF concentrations and ADA. Thus, comparison of results from different assays should be performed with caution, as there remains no standardization between different assays. Drug concentrations are generally detected sensitively between assay types, yet the detection and accurate quantification of ADAs have been more challenging. First-generation assays, such as the enzyme-linked immunosorbent assay (ELISA), have less clinical utility, given the lower sensitivity for measuring ADAs. Using the ELISA assay, serum anti-TNF drug competes with the ADA detection moiety so when drug is detected in the sample, ADA is unable to be accurately measured. Radioimmunoassay (RIA) is sensitive and specific for drug and ADA detection, yet disadvantages include the complexity of the test, prolonged incubation time, expense, and the handling of radioactive materials [56, 57]. The homogeneous mobility shift assay (HMSA), using high-performance liquid chromatography, has the advantage of separating and quantifying the drug and antibody concentrations independently, making it feasible to detect ADAs in the presence of anti-TNF drug. ELISA and ELISA-like assays (LabCorp, Esoterix Inc) as well as HMSA assays (Prometheus labs) are currently commercially available for IFX and adalimumab.

Immunomodulator Use with Anti-TNF Agents

Given the negative effects of ADA on therapeutic efficacy, durability, and association with infusion reactions, attempts should be made to reduce the likelihood of ADA formation. Various strategies have been recommended in order to do so,

such as the addition of an immunomodulator and even proactive optimization of drug concentrations.

In the ACCENT 1 trial, concomitant immunomodulator use with IFX was associated with lower rates of ATI formation [58]. In another prospective CD cohort, patients who received concomitant immunomodulator therapy had higher IFX concentrations and less likelihood of ATI formation than those not receiving a concomitant immunomodulator (43% vs. 75%; $p < 0.01$) [17]. A logistic regression analysis further demonstrated that the only significant variable predictive of IFX concentrations was the use of a concomitant immunosuppressive agent ($p < 0.001$) [17]. The SONIC trial demonstrated that combination therapy of IFX with AZA is superior to IFX monotherapy in achieving clinical remission and mucosal healing [46]. This is potentially due to less formation of antibodies and higher trough levels associated with combination therapy. A study of Danish registries found that combination therapy, without use of TDM, improved two-year clinical outcomes in pediatric CD patients treated with IFX [59]. In the UC SUCCESS trial, combination therapy with IFX was also superior to monotherapy after 16 weeks [60]. In a recent study, Lega et al. proposed utilizing IFX monotherapy with a proactive TDM approach, after finding that IFX durability in young IBD patients did not differ between those receiving IFX monotherapy with proactive TDM and those receiving combination therapy [61]. Additionally, with golimumab therapy, patients receiving a concomitant immunomodulator had a lower incidence of antibody formation (1.1% vs. 3.8% $p = 0.01$) [25].

Data regarding the utility of combination therapy with adalimumab are mixed. Patients receiving an immunomodulator in combination with adalimumab have been noted to have higher drug concentrations than those on monotherapy [37]. In the DIAMOND trial, Crohn's patients treated with adalimumab and immunomodulator therapy had increased adalimumab trough levels, which in turn were associated with endoscopic response and mucosal healing at 6 and 12 months [62]. Recent data further reveal that combination therapy with an immunomodulator and adalimumab decreases the risk of developing ADAs (hazard ratio; 0·44 [0·31–0·64] $p < 0·0001$) [22]. However, the post hoc analysis of the randomized control PAILOT trial revealed no significant difference in outcomes between pediatric CD patients on adalimumab and immunomodulator therapy and those on adalimumab monotherapy with regard to clinical and biochemical remission. Furthermore, adalimumab trough concentrations and immunogenicity were not significantly different between groups [63]. In a recent post hoc analysis of the IMAgINE 1 study, immunomodulator therapy with adalimumab in pediatric CD did not lead to improvement of response, remission or increased serum adalimumab trough levels, when compared to those on adalimumab monotherapy [64]. An observational study revealed that concomitant immunomodulators decreased immunogenicity in patients receiving infliximab but not adalimumab, further confounding the role of combination therapy on immunogenicity [65].

Studies suggest that concomitant immunomodulator use may be used to recapture response in patience with low drug concentrations. Ben Horin et al. reported in a small case series that the addition of an immunomodulator to maintenance infliximab monotherapy increased IFX concentrations and lowered antibody concentrations, improving patient outcomes by restoring clinical response [66]. Other small studies have shown that the addition of a thiopurine in patients losing response to anti-TNF monotherapy was an effective strategy to recapture response [67]. Overall, these studies suggest that not only does concomitant immunomodulator use decrease immunogenicity preemptively as suggested by SONIC, but its use may also recapture response in patients with low drug concentrations.

In pediatric patients, particularly in males, the substitution of MTX for thiopurines may provide a safety advantage, given the rare yet positive association between combination therapy of IFX with thiopurines and malignancy, including hepatosplenic T-cell lymphoma in this age group. The efficacy of combining an anti-TNF agent with MTX has been examined as well. In the rheumatoid arthritis literature, a low dose of 7.5 mg weekly was associated with lower rates of ATI development in IFX treated patients [68]. However, no clinical benefit in IFX durability or efficacy was found when using very low-dose oral MTX (<10 mg/week) as concomitant therapy in pediatric IBD patients [69]. It has been proposed that a dose of at least 12.5 mg of oral MTX is needed to avoid immunogenicity [70]. The COMMIT trial found that patients on IFX combination therapy with 25 mg of weekly subcutaneous MTX were significantly less likely to develop ATIs and had higher IFX concentrations, yet no clear benefit was found in inducing and maintaining clinical remission [71]. A German group found that concomitant use of MTX with infliximab had a positive effect in the treatment of refractory CD adult patients, using a MTX dose of 20 mg weekly, both parenterally and orally administered [72].

Proactive Dose Optimization

Perhaps most the most important utilization of TDM is proactively preventing the loss of response, rather than awaiting a treatment failure. This can be accomplished by dose adjusting early in the treatment course. Researchers have attempted to determine whether a drug concentration obtained early in maintenance is a predictor of a more durable response. Bortlik et al. found that, on retrospective evaluation, an IFX threshold of greater than 3 μg/mL at either the week 14 or week 22 dose was predictive of a sustained response [19]. Vande Casteele et al. described that low IFX concentrations

at 14 weeks (<2.2 μg/mL) predicted IFX discontinuation due to persistent loss of response and was associated with increased incidence of ATIs [47]. In a recent post hoc analysis of ACCENT1, patients with post-induction week 14 IFX concentrations of ≥3.5 μg/mL and a ≥ 60% CRP decrease were significantly associated with durable sustained response at week 54 [29]. Using a cohort of pediatric IBD patients, Singh et al. was the first to prospectively determine the optimal cut point for a week 14 IFX trough concentration in predicting one-year durable remission. In this study a concentration of at least 5.5 μg/mL was described as optimal ($p = 0.01$) [28]. Using a cohort of pediatric IBD patients on IFX therapy, Stein et al. found that IFX concentrations of ≥9.1 μg/mL at week 10 was found to be predictive of continuing on IFX at 12 months, with a sensitivity of 80% and specificity of 60% [73].

Given the growing body of literature supporting the role of TDM, prospective trials using TDM-based dose adjustment have been performed. The TAXIT trial showed that proactive dose adjustments, maintaining an IFX concentration between 3 and 7 μg/mL, resulted in improved disease activity in CD patients, even though the primary outcome at 1 year was not achieved. Additionally, up to 30% of the TAXIT patients may be able to have their IFX dose de-escalated, again suggesting a cost-saving potential of proactive, individualized TDM [74]. In TAILORIX, IFX dosing intensification beyond week 14 based on symptoms, biomarkers and IFX drug concentrations did not lead to improved outcome of steroid-free remission. It is possible that the target IFX goal of >3 μg/mL in both TAXIT and TAILORIX was too low to achieve primary endpoints. Another study demonstrated that proactive dose adjustment using TDM, keeping IFX drug concentrations between 5 and 10 μg/mL, was associated with sustained remission as compared to those with concentrations lower than 5 μg/mL or without TDM monitoring [75].

Pediatric-specific studies also demonstrate the utility of proactive drug monitoring for anti-TNF therapy. In the PAILOT trial utilizing a pediatric CD cohort, adjusting adalimumab dosing to achieve a trough concentration of 5 μg/mL was associated with sustained corticosteroid-free clinical and biochemical remission through week 72 compared to a reactive monitoring (82% vs. 48%, $p = 0.002$) [76]. Lyles et al. demonstrated higher rates of achieving a sustained clinical steroid-free remission by utilizing proactive drug monitoring, with goal IFX or adalimumab concentration of >5 μg/mL in pediatric IBD patients treated with anti-TNF therapy [77].

Although societal guidelines have not yet adopted recommendations to use TDM proactively, expert IBD consensus is to utilize proactive TDM. This has been associated with decreased cost up to 34% when using TDM algorithm as opposed to routine IFX dose intensification, without affecting rates of clinical response [78]. Proactive TDM of IFX has been associated with higher rates of mucosal healing, as well as decreased rates of unfavorable outcomes (surgery, hospitalization, treatment failure, lack of mucosal healing) compared with non-TDM-based treatment [79]. Another multi-center study also revealed fewer treatment failures, hospitalizations, surgeries, infusion reactions, and antibodies to IFX compared to reactive TDM [80]. The long-awaited Norwegian randomized trial of standard of care dosing versus proactive TDM revealed that among patients with immune-mediated inflammatory diseases undergoing maintenance therapy with infliximab, proactive TDM was more effective than treatment without TDM in sustaining disease control without disease worsening [81]. A recent expert consensus panel recommends to perform proactive TDM, after induction, at least once during maintenance while on anti-TNF therapies [40]. More advanced methods may be used, such as the application of a pharmacokinetic dashboard, which takes into account factors that influence anti-TNF clearance; using such a dashboard early during induction may render proactive TDM even more effective, as it has been shown to improve IFX durability and immunogenicity [82].

Practical Use of TDM with Anti-TNF Agents

TDM is integral to treating IBD patients on anti-TNF therapy. It may more readily establish the mechanism for loss of response or lack of response and allow the clinician to appropriately tailor therapy for the individual patient. It is important that anti-TNF drug concentration and ADA be evaluated in the context of each other and thus that a drug-tolerant assay is used. Our suggested guideline for TDM in a patient on IFX therapy is outlined in Fig. 33.2.

In a patient with a therapeutic drug concentration and no ADA present, ongoing therapy should continue if in remission; if not in clinical and mucosal remission despite therapeutic drug concentrations and lack of ADA, that patient is likely a non-responder to the anti-TNF class of medications and should be changed to another class of medications. If a patient is in deep remission and therapeutic drug concentrations with low ADA is present (i.e., IFX ATI <9.1 μg/mL [47]), attempt should be made to overcome the low ADA and stay on drug. Options include adding an immunomodulator as previously mentioned or escalating the dose and or shorten the interval.

In a patient with low or undetectable drug concentrations without ADA, optimizing drug dose by escalating therapy is warranted and may prevent development of ADA. In a patient with low/undetectable drug concentrations and high ADA, if that patient has responded prior to anti-TNF mechanism then switching to another anti-TNF agent is indicated. However,

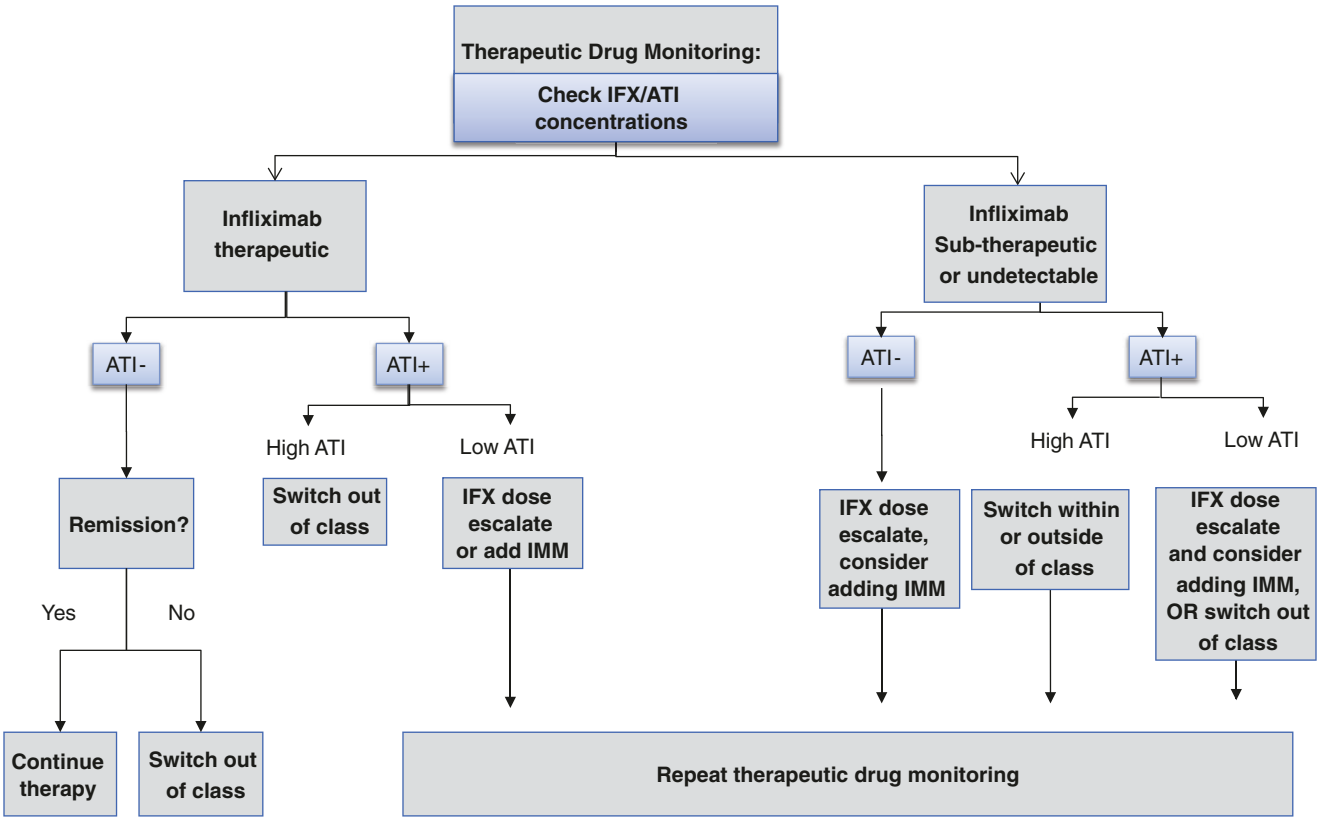

Fig. 33.2 Utilizing therapeutic drug monitoring (IFX). *ATI* Anti-infliximab antibody, *IFX* Infliximab, *IMM* Immunomodulator

if no response to anti-TNF therapy had been evidenced, switching out of class would best serve the patient. With low/undetectable drug concentration and low ADA, options would be to dose escalate and add an immunomodulator to overcome low ADA, or to entirely switch out of class. With each change, if staying within class, TDM should be repeated in next 2–3 infusions, once reaching a drug steady state.

TDM with Vedolizumab and Ustekinumab

Vedolizumab

Since its approval in 2016 for adult patients with CD and ulcerative colitis, vedolizumab has been used in this population as well as in the pediatric populations, albeit off-label. The safety profile of vedolizumab and its gut specificity has made it an appealing agent to use in some pediatric IBD patients. Although not yet FDA approved in pediatrics, several studies have found it to be safe and efficacious in this population [83–86]. Clear consensus on goal trough concentrations is not yet present, yet there are data associating higher trough levels with improved clinical responses. Post hoc analysis of the registration studies of vedolizumab (GEMINI) revealed that higher vedolizumab concentrations at week 6 were associated with higher rates of clinical remission at week 14. Increases in trough concentrations resulted in increased remission rates [87]. Using data from GEMINI 1, vedolizumab serum concentrations of 37.1 at week 6, 18.4 at week 14, and 12.7 μg/mL in maintenance were associated with improved 1 year clinical outcomes [88]. In a pooled analysis of five cohort studies, proposed cut-off vedolizumab concentrations of >20 μg/mL at week 6 and >12 μg/mL during maintenance was associated with improved outcomes [89]. Similarly, in a study encompassing pediatric IBD patients, Ungaro et al. demonstrated that IBD patients were 2.4 times more likely to be in a corticosteroid-free clinical and biochemical remission with a vedolizumab trough concentration >11.5 μg/mL [90].

Dose escalation of vedolizumab may help to restore or gain response. A French study found that patients with lower week 2 and 6 vedolizumab trough levels necessitated dose escalation within 6 months. In a systemic review of adult cohorts, dose intensification restored response to vedolizumab in 53.8% of patients who were found to be secondary non-responders [91].

Registration studies have found low incidence of persistent antibodies (<1%), and the use of a concomitant immu-

nomodulator has not been found to be beneficial [92–94]. In fact, real-world studies have reported a wide range of ADAs to vedolizumab of 0–17%, without notable effects on efficacy. Immunogenicity has not been found to be the cause of vedolizumab treatment failure, with only 8% of patients with transient ADAs at time of discontinuation of vedolizumab [95]. A pediatric study examining trough and antibody concentrations similarly found no association between anti-drug antibodies and efficacy [96]. Thus, in using TDM, one may consider optimizing dose of vedolizumab regardless of presence of antibodies. In secondary loss of response, clinicians may consider measuring vedolizumab drug serum concentrations and dose escalating. However, prospective trials are further required before recommending a widespread approach to proactive TDM with vedolizumab.

Ustekinumab

Ustekinumab (UST) is a fully human IgG1 monoclonal antibody targeting the IL-12p40 subunit of IL-23 and IL-12 and was approved for adult IBD patients in 2016, with an evolving body of literature demonstrating efficacy in pediatric IBD, although not yet FDA approved in this population [97–99]. In patients with CD, ustekinumab clearance is affected by body weight, serum albumin concentration, C-reactive protein (CRP), TNF antagonist failure status, sex, race, and antibody to UST status [100].

In examining the phase 3 registration Crohn disease UNITI studies (UNITI-1,2, IM-UNITI), serum UST concentrations were positively associated with clinical remission at 8 weeks [101, 102]. There was a significant association between clinical remission, endoscopic response, and CRP normalization [102]. Overall, receiver operating characteristic (ROC) analysis demonstrated an area under curve (AUC) of 0.64 ($P < 0.003$) for clinical remission and UST concentrations, with an optimal cut-off being approximately 1 μg/mL. In addition, UST concentrations greater than 1.1 μg/mL were associated with CRP normalization at week 24 (52% vs. 25%, $P < 0.0001$). In a smaller subset of patients, UST concentrations greater than 0.5 μg/mL were associated with increased endoscopic response at week 44 (40% vs. 8%, $P < 0.003$). Serum UST concentrations during maintenance treatment (q4/8week dosing) above 4.5 μg/mL were associated with endoscopic response and biomarker reduction and also associated with a composite outcome of steroid-free clinical remission and endoscopic response (75.9% for >4.5 μg/mL vs. 40.7% if below; $P = 0.008$) [102]. In UNIFI, a UST concentration of 3.7 μg/mL at week 8 was identified by ROC analysis to be associated with clinical response, and 1.3 μg/mL at week 44, in UC patients [103]. In the only pediatric study to date, Dayan et al. revealed no significant difference in UST drug concentrations in pediatric IBD patients in remission compared to those not [98].

In IM-UNITI, patients with a clinical loss of response during maintenance period were successful in recapturing response by UST dose escalation [104]. In clinical experience, several studies have demonstrated the ability to recapture response with dose escalation in patients who have not responded or lost response, with varying degrees of success (61%,73%) [105, 106]. One pediatric study also revealed that 62% of patients required dose escalation [98]. Unlike anti-TNF therapies, concomitant immunomodulator therapy does not seem to have a significant impact on ustekinumab concentrations in adult and small pediatric studies [98, 102, 107]. Immunogenicity also appears to be low, with rates up to 2.3% at 1 year, and 4.6% through the three-year UM-UNITI extension study [101–103]. At this time, further studies are required before recommending utilizing a TDM approach with ustekinumab in pediatric IBD patients.

Conclusion

The body of evidence correlating serum anti-TNF drug and ADA concentrations to clinical outcomes is growing, and the value of TDM is well recognized. The use of TDM allows clinicians to gain insight into the etiology of loss of response and enables the optimization of therapy for an individual patient. With increasing prospective studies on TDM of anti-TNF therapies, new algorithms are being developed with the goal of achieving a sustained, durable remission on these therapies. Future TDM may evolve with point-of-care anti-TNF drug concentration assays, identification, and testing of other genetic alleles impacting response to anti-TNF therapy and use of dashboards. Already, data modeling and use of dashboards to individualize IFX dosing have been shown to be improve outcomes in IBD patients of all ages [108–112]. Issues related to TDM, including clearance and immunogenicity, are not unique to anti-TNF therapies and these concepts will be applicable to other biologics used in IBD patients. As more data are obtained, there may be an evolving role of TDM in vedolizumab and ustekinumab. In this era of personalized medicine, TDM allows for optimized, individualized dosing, and improved care for IBD patients of all ages.

New Non-anti-TNF-α Biological Therapies for the Treatment of Inflammatory Bowel Disease

34

Bhavana Bhagya Rao, Abhik Bhattacharya, and Gary R. Lichtenstein

Introduction

Blockade of the tumor necrosis factor-alpha (TNF-α) pathway has been a major advancement for the treatment of inflammatory bowel disease (IBD). However, 20–40% of patients with moderate to severe disease do not have a response to treatment with TNFα antagonists (primary nonresponse), and 23–46% lose response within the first 12 months of treatment (secondary nonresponders) [1]. As a result, there is an ongoing need to develop new medidations with different mechanisms of action. This chapter will discuss the major non-anti-TNF-α agents in the pipeline that are currently undergoing evaluation to effectively and safely treat patients with IBD. This chapter discusses the major non-anti-TNF-α agents in the pipeline that are currently undergoing evaluation in order to effectively and safely treat patients with IBD. Figure 34.1 illustrates the drugs currently in the pipeline, and Table 34.1 is a summary of the treatments that is discussed in this chapter.

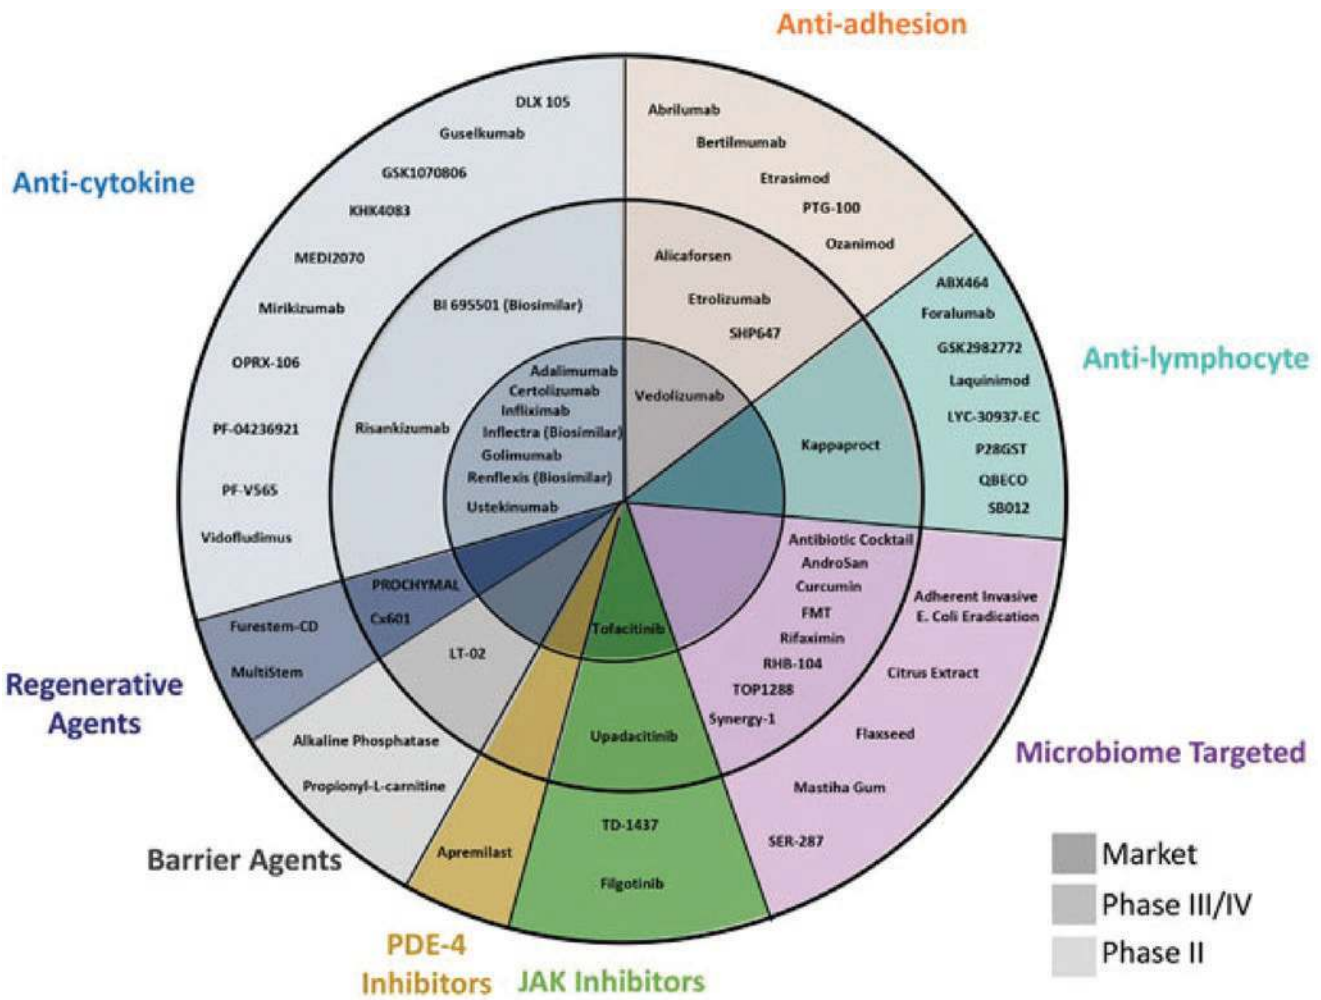

Fig. 34.1 Drugs in pipeline for IBD [2]

Table 34.1 Treatments discussed in this chapter

Target	Name	Development in IBD	Mechanism of action
Cytokines			
IL-12/IL-23	Ustekinumab Briakinumab	Approved (CD,UC) Phase II (CD)	Inhibits p40 subunit of IL12/23 Inhibits p40 subunit of IL12/23
IL-23 selective	Brazikumab	Phase II (CD)	Inhibits p19 subunit of IL23
	Risankizumab	Phase II (CD)	Inhibits p19 subunit of IL23
	Mirikizumab	Phase II (CD,UC)	Inhibits p19 subunit of IL23
	Guselkumab	Phase II (CD,UC)	
IL-6	PF-04236921	Phase II (CD)	IL-6 inhibitor
IL-13	Tralokinumab QAX576 Bertilimumab	Phase II (UC) Phase II (CD) Phase II (CD, UC)	IL-13 receptor antagonist Inhibits of IL-13 Blocks the activity of eotaxin-1
IL-17	Vidofludimus	Phase II (CD,UC)	Inhibits IL-17 secretion
IL-21	ATR107 NNC0114-0006	Phase I Phase II (CD)	Anti-IL-21 receptor antibody IL-21 inhibitor
Signaling pathways mediated by cytokines			
JAK/STAT	Tofacitinib	Approved (UC)	Inhibits JAK1 and JAK3, and mildly JAK 2
	Filgotinib	Phase II (CD,UC)	JAK1 inhibitor
	Upadicitinib	Phase II (CD,UC)	JAK1 inhibitor

Table 34.1 (continued)

Target	Name	Development in IBD	Mechanism of action
	Peficitinib	Phase II (UC)	Non-selective JAK inibitor
	TD-1473	Phase I (UC)	Non-selective JAK inibitor
TGF-b	GED0301 (Mongersen)	Phase III/II (CD/UC)	SMAD7 antisense oligonucleotide
Chemokines			
Anti CXCR2/CXCL10	BMS936557 (Eldelumab)	Phase II (CD, UC) Phase I/III	CXCL-10 inhibitor
Anti CCR9/CCL25	CCX282-B (Vercirnon)	(UC/CD)	CCR9 antagonist
Antiadhesion molecules	Natalizumab	Approved (CD), phase I (UC)	α4 integrin antaogmist
	Vedolizumab	Approved (CD, UC)	α4β7 integrin antagonist
	Etrolizumab (rhuMAb β7)	Phase III (CD, UC)	Blocks β7 subunit of α4β7 and αEβ7 integrins
	Ontamalimab (PF-00547659, SHP647)	Phase II (CD, UC)	MAdCAM-1 protein inhibitor
	AJM300	Phase III (UC)	α4 integrin antagonist
	Alicaforsen (ISIS 2302)	Phase II/III (CD/UC)	Targets intercellular adhesion molecule 1 (ICAM-1)
	AMG181 (abrilumab)	Phase II (CD/UC)	α4β7 integrin antagonist
	Firategrast (SB 683699)	Phase II (CD)	α4 integrin antagonist
	GLPG0974	Phase II (UC)	Against FFA2
	TRK-170	Phase II (CD)	α4β1/α4β7 integrin antagonist
Anti-inflammatory cytokine	IL-10 (rhu-IL-10)	Phase III (CD)	IL-10 replacement
T-cell stimulation and induction of apoptosis blockades	Laquinimod	Phase II (CD)	Modulation of immune cells
	Cobitolimod (DIMS0150)	Phase III (UC)	Activates TLR9
	Monarsen (BL 7040)	Phase II (UC)	TLR9 modulator
Spingosine-1-phosphate receptor modulators	Etrasimod (APD334)	Phase II (CD/UC)	S1P receptor 1 modulator
	Ozanimod (RPC1063)	Approved	Agonist for S1P receptors 1 and 5
Antisense oligonucleotides	GATA3 DNAzyme	Phase II (UC)	Modulate production of Th2, Th9 related cytokines
	STNM01	Phase I/II (CD/UC)	Blocks carbohydrate sulfotransferase 15 mRNA
Miscellaneous	Apremilast (CC-10004)	Phase II (UC)	Inhibitor of phosphodiesterase 4 enzyme
	RDP58 (delmitide acetate)		
	LT02	Phase II (UC)	Mitogen-activated protein kinase inhibitor
	LYC-30937-EC	Phase III (UC)	Modified release phosphatidylcholine
	TOP-1288	Phase II (UC) Phase II (UC)	Gut-directed ATPase modulator Narrow spectrum protein kinase inhibitor
	GSK2982772	Phase II (UC)	Receptor Interacting Protein 1 Kinase inhibitor
	Rosiglitazone	Phase II (UC)	Peroxisome proliferator-activated receptor agonist
	VB-201	Phase II (UC)	Oxidised phospholipid molecule

Cytokine Targets

IL-12/IL-23

Interleukin (IL)-12 and IL-23 have been shown to have a central role in the inflammatory pathway in Crohn disease, psoriasis and multiple sclerosis [3]. The risk for a patient to develop CD and UC has been demonstrated through genome-wide association studies studying variants of the gene encoding the IL-23 receptor and the locus for the gene encoding the p40 chain [4].

IL-23 is a heterodimer of the same p40 subunit and a p19 subunit which induces naïve CD4+ T cells into T helper 17 cells, which then induce the production of proinflammatory cytokines such as IL-17, IL-6, and TNF-α [5].

Ustekinumab

Ustekinumab is a human monoclonal antibody (IgG1) that targets the IL-12/23 shared p40 subunit. The result is the inhibition of IL-12 and IL-23 binding to their receptor on the surface of T cells, natural killer cells, and antigen-presenting cells (see Fig. 34.2).

Ustekinumab (UST) has been shown to be clinically effective in the treatment of moderate to severe CD and UC in phase III studies. Both UNITI 1, UNITI 2 and IM-UNITI, proved the efficacy for UST in the treatment of CD over placebo [7]. In UNITI 1 trial included 741 patients who were primary or secondary non responders to TNFα antagonists or had unaccepatable side effects, whereas UNITI 2 included 628 patients who had failed conventional therapies or experienced unacceptable side effects. These two were induction trials where patients in the test arm received 130 mg or 6 mg/kg UST intravenously, as opposed to placebo. Patients who responded in the induction arms were randomly assigned to the IM-UNITI or maintenance arm of the trial. In the maintenance study, 397 patients were randomly assigned to receive either 90 mg of UST every 8 weeks or 12 weeks versus placebo. The primary end point for the induction trial was clinical response at 6 weeks as defined by reduction in Crohns Disease Activity Index (CDAI) score of ≥100 points

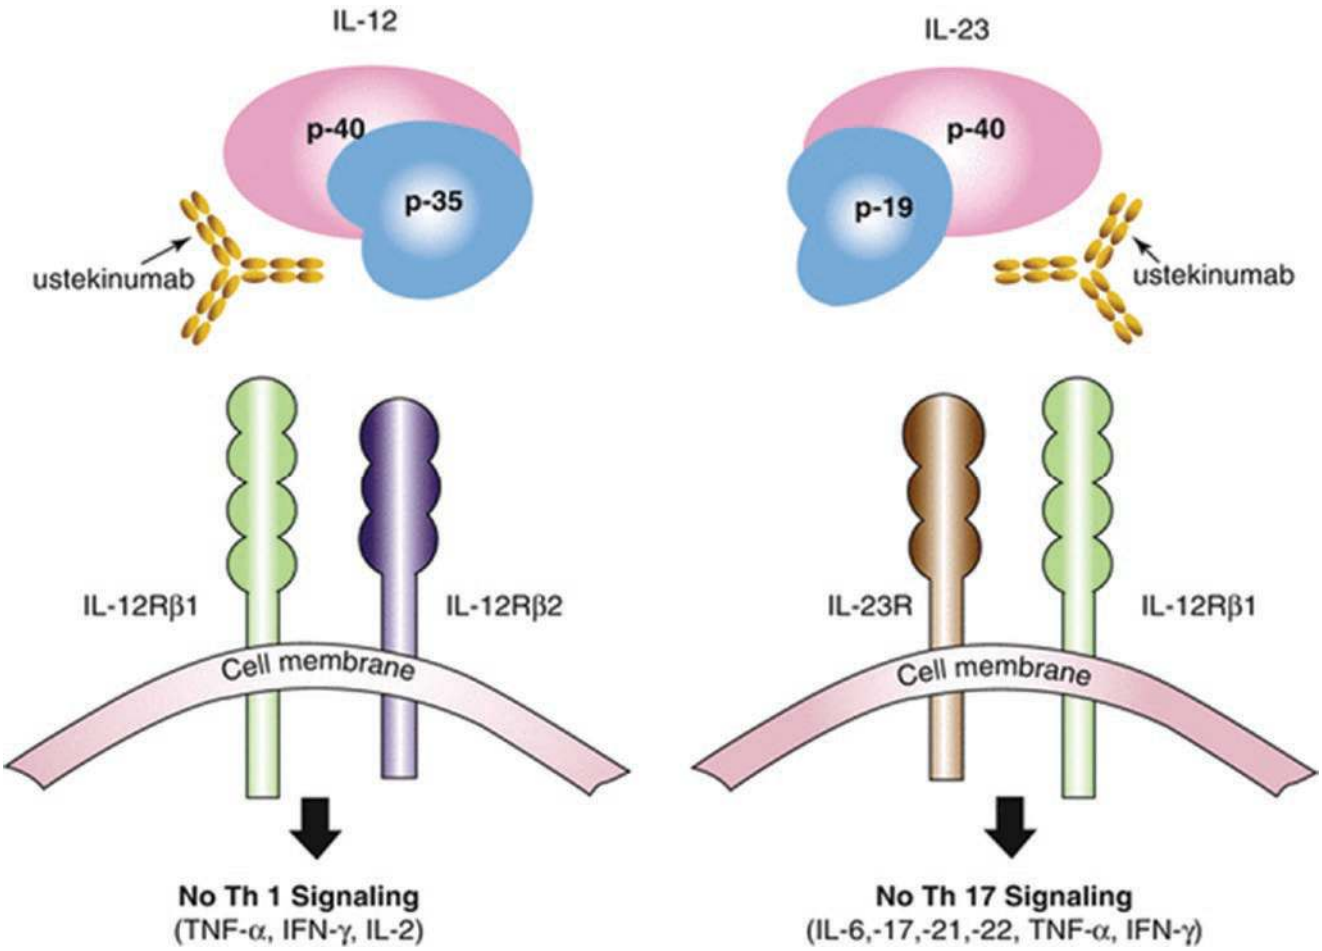

Fig. 34.2 Ustekinumab mechanism of action (Onuora [6])

or CDAI score <150, whereas primary end point for the maintenance arm was remission at week 44 defined as CDAI score <150. In the induction arms, remission rates were significantly higher in the UST receiving patients, either at 130 mg or 6 mg/kg intravenously as compared to placebo (UNITI I: 34.3%, 33.7%, versus 21.5%, $P \leq 0.003$ for both comparisons with placebo; UNITI-2, 51.7%, 55.5%, and 28.7%, $P < 0.001$ for both doses). Similarly in the in the IM-UNITI arm, patients receiving UST 90 mg every 8 weeks or 12 weeks had significantly higher remission rates as compared to placebo (53.1%, 48.8%, respectively, versus 35.9%, $P = 0.005$ and $P = 0.04$, respectively).

The UNIFI study proved the efficacy of UST for use in UC [8]. It had an 8-week induction and 44-week maintenance arm. In the induction arm, 961 patients were assigned to receive either UST 130 mg or 6 mg/kg intravenously as compared to placebo, and those who had response to treatment were included in the maintenance arm to receive UST 90 mg either every 8 or 12 weeks versus placebo. The primary end point was clinical remission defined as total Mayo Score ≤2 and no sub-score >1 on any of the four Mayo scale components. At the end of 8 weeks, significantly higher number of patients receiving UST as 130 mg or 6 mg/kg intravenously were in remission compared to placebo (15.6%, 15.5% vs 5.3%, $P < 0.001$ for both comparisons). At the end of maintenance at 44 weeks, significantly higher number of patients receiving UST as 90 mg at 8 weks or 12 weeks were in remission compared to placebo (43.8%, 38.4% versus 24%, $P < 0.001$ and $P = 0.002$, respectively).

Another study looking at 334 patients with moderate to severe CD from three-phase three randomized controlled trials showed significantly higher endoscopic response as defined by reduction in change in the Simplified Endoscopic Activity Score for Crohn Disease (SES-CD), from baseline, at week 8 for patients given ustekinumab when compared to placebo (reduction of 2.8 versus a reduction of 0.7 points, $P = 0.012$) [9].

Pediatric Data

Data regarding the efficacy of ustekinumab in pediatric CD are not as robust as that in adults. The best data comes from a multicenter retrospective analysis of 44 pediatric patients who failed at least one biologic treatment and received open-labelled subcutaneous UST. Primary outcome was changes in mean abbreviated Pediatric Crohn Disease Activity Index (aPCDAI) and rate of clinical remission at 3 and 12 months. UST was shown to significantly lower aPCDAI at 3 months and 12 months (16 and 19.6 at 3 and 12 months respectively), and also shown to achieve 47.8% clinical response and 38.6% clinical remission [10]. However additional larger studies are awaited.

Safety

In a 3-year extension study of IM-UNITI evaluating the safety of UST in patients who were selected for a 5 year long term extension trial, 69.5% of patients who responded to Q8 week treatment and 61.9% of patients who responded to Q12 week treatment at the end of 44 weeks continued to be in remission at 3 years. The overall safety was similar for patients receiving UST versus placebo (389.7 versus 444.17 adverse events per 100 patient-years, P = NS) [11].

In both UNITI 1 and 2, the rates of adverse events for patients receiving 130 mg and 6 mg/kg intravenously were similar to placebo (UNITI 1: 64.6%, 65.9%, and 64.9%, respectively; in UNITI 2: 50.0%, 55.6%, and 54.3%, respectively). At the end of 1 year there were no deaths, three opportunistic infections in those receiving UST and no cases of reversible posterior leukoencephalopathy syndrome [9].

Similarly in the UNIFI study for UC, rates of adverse events for patients receiving 130 mg and 6 mg/kg intravenously were similar to placebo (41.4%, 50.6%, and 48.0%, respectively) in the induction phase. Even in the maintenance phase rates of adverse events for patients receiving 90 mg every 8 weeks or 12 weeks subcutaneously were similar to placebo (77.3%, 69.2% and 78.9%, respectively). Overall there were 3 deaths, 7/825 cancers and four opportunistic infections in those receiving UST [8].

Briakinumab

In a phase 2b multicenter, double-blind, parallel group study, 246 patients with CD who had failed prior TNFα antagonists were randomised to induction treatment with briakinumab vs. placebo, with responders entering the maintenance arm [12]. The study did not meet primary outcome, but patients in the treatment arm had numerically higher response and remission rates at 6, 12 and 24 weeks.No additional studies are currently in progress.

Selective IL23 Inhibition

In contrast to IL-12/23 inhibition, selective IL-23 inhibition has been previously shown to be associated with a decreased incidence of tumor formation and incidence of serious infections and major adverse cardiovascular events [13]. Therefore, IL-23-specific antagonism may provide similar or greater efficacy than blocking IL-12/23p40 and without the potential risks associated with blocking IL-12.

Brazikumab

This is a monoclonal antibody that targets the p19 sub-unit of IL-23. In a phase 2a double-blind, placebo-controlled study of adults with moderate to severe CD, with prior anti-TNF

therapy failure, 119 patients were randomly assigned 1:1 to Brazikumab (700 mg) or placebo intravenously at weeks 0 and 4. Patients received open-label 210 mg subcutaneously every 4 weeks from weeks 12 to 112. Clinical response was defined as 100-point decrease in CDAI score from baseline and clinical remission defined as CDAI score <150 at week 8. Patients receiving Brazikumab compared with placebo had significantly higher rates of clinical response (49.2% versus 26.7%, $P = 0.01$). There was a tendency to higher likelihood of response in patients with higher baseline serum concentrations of IL22, a cytokine whose expression is induced by IL23 [14].

There are current phase 2 studies to assess the efficacy and safety of brazikumab in patients with moderate to severe UC and long term data via open label extension (OLE) studies in CD patients is being collected [15]. Additionally, Phase 2b/3 assessment is ongoing. (https://clinicaltrials.gov/ct2/show/NCT03759288).

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Brazikumab in children or adolescents with IBD.

Safety

Data from phase 2a trial referred to earlier showed that the most common adverse events were headache and nasopharyngitis. A similar proportion of treatment-related adverse events and serious adverse events of > Grade 3 severity occurred in both induction and maintenance study arms. Placebo patients had higher rates of treatment-related adverse events compared to treatment arms (21.7% versus 10.2%) [14].

Risankizumab

Risankizumab (BI 655066) is another monoclonal antibody that targets the p19 sub-unit of IL-23. In a randomised, double-blind, placebo-controlled phase 2 study conducted across 36 referral sites in North America, Europe, and southeast Asia, 121 adult patients (79% of whom had failed prior anti-TNF therapy) with moderate-severe CD, Risankizumab induced clinical remission in 31% patients versus 15% with placebo ($P = 0.048$) [16].

Additional larger studies to further assess the efficacy and safety of risankizumab in subjects with moderately to severely active CD and UC who failed prior biologic therapy are currently ongoing [17–19].

Recently, the results of ADVANCE (NCT03105128), a double-blind randomized phase 3 study evaluating efficacy and safety of Risankizumab as induction therapy in patients with moderate to severe CD was reported (**Reference:** D'Haens GD et al. DDW 2021, Abstract 775a). Eligible patients had a demonstrated inadequate response (IR) or intolerance to biologic therapy (bio-IR) and/or to conventional therapy (non-bio-IR), CD Activity Index (CDAI) 220-450, average (avg) daily(liquid/very soft) stool frequency (SF) ≥4 and/or avg. daily abdominal pain (AP) score ≥2, and Simple Endoscopic Score for CD (SES-CD) ≥6 (≥4 for isolated ileal disease) excluding the narrowing component. Patients were randomized 2:2:1 to receive IV Risankizumab 600 mg, 1200 mg, or placebo (PBO) at Weeks 0, 4, and 8. Randomization was stratified by number of prior biologics failed, baseline (BL) corticosteroid use, and BL SES-CD. Co-primary endpoints were clinical remission (per US protocol, CDAI <150; per ex-US protocol, avg. daily SF ≤2.8 and avg. daily AP score ≤1, not worse than BL for both) and endoscopic response (decrease in SES-CD >50% from BL [or for patients with isolated ileal disease and a BL SES-CD of 4, ≥2-point reduction from BL])at Week 12. Safety was assessed in patients receiving ≥1 dose of study drug. Risankizumab 600 mg and 1200 mg was found to be more effective than placebo at inducing clinical remission and endoscopic response at Week 12 in patients with moderate-to-severe CD. Both Risankizumab doses were generally well-tolerated and AEs were consistent with the known safety profile of Risankizumab.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of BI 655066 in children or adolescents with IBD.

Safety

Safety data from phase 2 trial showed that the most common adverse event was nausea and most common serious adverse event was worsening of underlying Crohn disease. No deaths were reported, and serious infections occurred in 3 patients in placebo and one patient in the treatment arm [16].

Mirikizumab

A phase 2 trial to study the efficacy and safety of Mirikizumab for patients with moderate to severely active UC from 14 countries with primary outcome of clinical remission (defined as Mayo subscores of 0 for rectal bleeding, with 1-point decrease from baseline for stool frequency, and 0 or 1 for endoscopy) at 12 weeks was conducted [20]. Patients ($n = 188$) were randomized to receive intravenous placebo versus 50 mg, 200 mg or 600 mg of Mirikizumb at induction, with responders (decrease in 9-point Mayo score, including ≥2 points and ≥35% from baseline with either a decrease of rectal bleeding subscore of ≥1 or a rectal bleeding subscore of 0 or 1) being randomized to receive 200 mg subcutaneously at Q4 weeks or Q12 weeks. At week 12, only the 200 mg group showed significantly higher remission and when compared to placebo

(22.6% versus 4.8%, $P = 0.004$). At week 52, 46.8% of patients given subcutaneous mirikizumab 200 mg every 4 weeks and 37.0% given subcutaneous mirikizumab 200 mg every 12 weeks were in clinical remission.

At DDW 2019, phase 2 study of Mirikizimab for moderate to severely active CD was presented. Primary outcome was assessing for endoscopic response defined as a 50% reduction from baseline in SES-CD score, at Week 12 [21]. Patients were randomized to receive either intravenous placebo versus 200 mg, 600 mg or 1000 mg of Mirikizumab. Significantly higher endoscopic response was seen compared to placebo for all Mirikizumab groups (25.8%, $P = 0.079$, 37.5%, $P = 0.003$, 43.8%, $P < 0.001$ for 200 mg,600 mg and 100 mg respectively, versus 10.9% for placebo).

At DDW 2021 phase 2 maintenance of the SERENITY trial was presented (Reference: Sands BE et al. DDW 2021, Abstract 132) (NCT02891226). Patients with moderate-to-severe CD were randomized 2:1:1:2 across 4 treatment arms (PBO, 200, 600, 1000 mg Mirikizumab, administered intravenously (IV) every 4 weeks (Q4W) at Weeks 0, 4, and 8. Patients who received miri and achieved ≥1 point improvement at Week 12 in Simple Endoscopic Score for Crohn Disease (SES-CD) were re-randomized 1:1 into double-blind maintenance to continue IV treatment assignment Q4W (IV-C; $N = 41$) or to 300 mg miri SC Q4W (SC; $N = 46$). Due to small sample sizes and lack of an apparent trend across doses at Week 52, all IV and all SC arms were pooled. Clinical and endoscopic endpoints at Week 52 were evaluated. Missing data were imputed as nonresponse.

Endoscopic (SES-CD) response rates at Week 52 were 58.5% (24/41) and 58.7% (27/46) in the IV-C and SC groups, respectively. PRO remission rates were 46.3% (19/41) and 45.7% (21/46) in the IV-C and SC groups, respectively. Among those with endoscopic response (50% reduction from baseline in SES-CD) at Week 12, 69.6% (16/23) and 66.7% (16/24) in the IV-C and SC groups, respectively, also had endoscopic response at Week 52. Among those with endoscopic remission at Week 12, 50.0% (3/6) and 64.3% (9/14) in the IV-C and SC groups, respectively, also had endoscopic remission at Week 52. One patient in each group discontinued due to an adverse event (AE), and similar frequencies of treatment-emergent AEs and serious AEs were reported in IV-C and SC groups.

The findings of this study demonstrated that Mirikizumab demonstrated sustained efficacy to 52 weeks by multiple measures, with few discontinuations due to AEs during the maintenance period. These Phase 2 data supported continued characterization of Mirikizumab efficacy and safety in Crohn disease in the ongoing VIVID Phase 3 program. Tne safety findings were consistent with the anti-IL-23 p19 class with few discontinuations in the re-randomized maintenance group due to AEs.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Mirikizumab in children or adolescents with IBD. But there is a multicenter open labelled clinical trial ongoing for pediatric patients with UC [22].

Safety

In the phase 2 study for UC the most frequent treatment-emergent adverse events were nasopharyngitis, worsening of UC, anemia, headache, nausea, cough, and worsening of gastroenteritis during induction and worsening of UC, nasopharyngitis, headache, upper respiratory tract infection, arthralgia, hypertension, and influenza during maintenance. No deaths or hypersensitivity reactions were reported at the end of 1 year [20].

Similarly in the phase 2 study for CD the frequencies of serious adverse events and treatment-emergent adverse events across treatment groups were similar to placebo [21].

Guselkumab

This is another anti p19 sub-unit antibody specific to IL23. Guselkumab is currently undergoing phase 2/3 clinical trials for both CD (estimated completion in 2028) [23]and UC (estimated completion in 2025) [24].

Recent data was presented at DDW 2021 (reference: Sands BE et al. DDW 2021, Abstract Fr532 and D'Haens GD et al. DDW 2021, Abstract 455) The GALAXI 1 study was presented. GALAXI 1 is a phase 2, double-blind, placebo-controlled, multicenter study of guselkumab (GUS) in patients (pts) with moderately to severely active Crohn disease (CD) who had inadequate response or intolerance to conventional therapies (corticosteroid, immunosuppressant) and/or biologics (TNF antagonist, vedolizumab). Endoscopic improvement at Week (Wk) 12 following induction treatment was presented and the influence on biomarkers was also presented.

The GALAXI 1 study is a 5-arm Phase 2 double-blind placebo-controlled multicenter study of Guselkumab with Ustekinumab and Placebo. This represented a report on the interim pooled analysis of 3 Guselkumab arms versus placebo. Patients were randomized 1:1:1:1:1 into 5 arms: Guselkumab 200 mg, 600 mg, or 1200 mg IV at Wks 0, 4, 8; ustekinumab (UST) ~6 mg/kg IV at Wk 0 and 90 mg SC at Wk 8; or placebo (PBO) IV. Video ileocolonoscopies performed during screening and at Wk 12 were assessed by blinded central read. Interim analyses at Wk 12 evaluated SES-CD change from baseline and endoscopic response, healing, and remission (as defined in Table 34.1) in pts. treated with GUS vs PBO. Endoscopic outcomes were assessed by serum Guselkumab concentration quartiles. UST was a reference arm.

250 pts were evaluated; approximately 50% had failed biologic therapy. Baseline demographics and disease characteristics were generally similar among treatment groups (mean CD duration, 8.8 year; mean CDAI, 306.2; median SES-CD, 11.0). Per central endoscopy read, 29.6% of pts. had isolated ileal disease, 42.8% had colonic disease, and 27.6% had ileocolonic disease. At Wk 12, the mean reduction in SES-CD from baseline was greater in the Guselkumab combined group than in the PBO group (LS mean −4.6 vs −0.5, respectively) and was greater across all 3 Guselkumab induction dose groups vs PBO (Table 34.1). Across all Guselkumab induction doses, in the overall population, as well as biologic- and conventional-failure subgroups, a greater proportion of Guselkumab-treated pts. achieved endoscopic response vs PBO-treated pts. In the Guselkumab combined group, a greater proportion of pts. achieved endoscopic healing and remission vs PBO (17.3% and 14.0% vs 3.9% and 3.9%, respectively). Among conventional therapy failures, in the Guselkumab combined group vs the PBO group, 44.6% vs 10.7% achieved endoscopic response, 23.0% vs 0% achieved endoscopic healing, and 17.6% vs 0% achieved endoscopic remission, respectively. Neither a dose-response nor a consistent exposure-response relationship was observed with respect to endoscopic outcomes with GUS.

Thus, in pts. with moderate to severely active CD, the mean reduction in SES-CD from baseline was greater with GUS than with PBO. Endoscopic response, healing, and remission were seen in a greater proportion of Guselkumab-treated pts. vs PBO. Higher rates of endoscopic response, healing and remission occurred with Guselkumab in the conventional therapy failure sub-population compared with PBO, but small sample sizes limit conclusions. A dose-response relationship with GUS was not demonstrated for endoscopic outcomes within the induction dose-range evaluated. This data looks promising, but final results are awaited.

IL-6

Interleukin-6 (IL-6) is a cytokine with central roles in immune regulation, inflammation, hematopoiesis, and oncogenesis. It is a contributor of Th-17 differentiation [25]. Increased levels of IL-6 and soluble IL-6 receptor have been demonstrated in both serum and intestinal tissues of the patients with active Crohn disease, especially in those with more severe disease phenotypes [26].

PF-04236921 is a monoclonal antibody against IL-6. A phase II placebo-controlled study has been completed to evaluate the safety and efficacy of this subcutaneously administrated antibody in patients with active CD (the ANDANTE study) [27]. There were limitations of the study including early termination which led to small numbers of participants and technical problems with measurement resulting in unreliable or uninterpretable data.

A parallel-group, dose-ranging, double-blind trial with 4-week screening and 12-week treatment periods (ADVANTE I) was conducted in adults with CD who had prior inadequate response to anti-TNF therapy. They randomized 247 patients (1:1:1:1) to placebo, PF-04236921 10, 50 or 200 mg by subcutaneous injection on days 1 and 28 and 191 subjects were enrolled in the OLE and received PF-04236921 50 mg every 8 weeks up to six doses followed by 28-week follow-up (ADVANTE II). During the study the 200 mg dose was discontinued due to safety findings in another trial. Response rates as gauged by Crohn Disease Activity Index (CDAI)-70 with PF-04236921 50 mg were significantly greater than placebo at weeks 8 (49.3% vs 30.6%, $P < 0.05$) and 12 (47.4% vs 28.6%, $P < 0.05$). Week 12 CDAI remission rates were also higher with PF-04236921 50 mg than placebo (27.4% vs. 10.9%, $P < 0.05$) [28].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of PF-04236921 in children or adolescents with IBD.

Safety

Adverse effects noted in both studies included a worsening of disease activity, abdominal pain (including events of gastrointestinal perforation and abscess) and nasopharyngitis [28].

IL-13

Interleukin-13 (IL-13) is a central cytokine in the T helper 2 immune response [29–31]. IL-13 has effects on many cell types including B cells, monocytes, macrophages, epithelial cells, smooth muscle cells and neurons and has been indicated in the pathogenesis of many diseases including asthma and scleroderma in addition to IBD [32]. Its upregulation has been proposed to be a key driver of mucosal inflammation—specifically in UC.

Tralokinumab

Tralokinumab (CAT-354, Adtralza®) is an IL-13-specific human immunoglobulin G4 monoclonal antibody that binds to and neutralizes IL-13 [33, 34].

In a phase IIa, randomized, double-blind, placebo-controlled, parallel-group, multicenter trial, 111 patients with UC (total Mayo score ≥6) were randomized to

tralokinumab 300 mg subcutaneous or placebo [35]. The primary endpoint of clinical response at week 8 was 38% (21/56) for tralokinumab vs. 33% (18/55) for placebo (P = 0.406). Clinical remission rate at week 8 was 18% (10/56) vs. 6% (3/55) (P = 0.033) and mucosal healing rate was 32% (18/56) vs. 20% (11/55) (P = 0.104) for tralokinumab vs. placebo.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of tralokinumab in children or adolescents with IBD.

Safety

Tralokinumab had an acceptable safety profile in the only phase IIa study to date [35]. The median duration of exposure was 84 days. The number of patients who experienced adverse events was similar in the tralokinumab and placebo groups. The most frequently reported adverse events were symptoms of UC and headache. The number of patients discontinuing treatment because of adverse events was similar in both groups and the most common adverse event leading to discontinuation was symptoms of UC.

Dectrekumab

Dectrekumab (QAX576) is a highly potent and specific inhibitor of human IL-13 activity in cell-based in vitro assays. A phase II study to assess the safety and efficacy of intravenously administered QAX576 in patients with fistulizing Crohn disease has been completed [36]. Another phase II study to test the safety and efficacy of the drug in the treatment of perianal fistulas has also been completed. Results are not available in either of the studies [37]. The study sponsor noted: " In this study, QAX576 was well tolerated. As expected IFX was a powerful agent to induce fistula closure. Blockade of IL-13 may be effective, too, as compared to historical placebo rates, although the very low patient number does not allow a formal assessment." (https://oak.novartis.com/21363/).

Pediatric Data

At the time of writing this chapter, there are no published data on the use of QAX576 in children or adolescents with IBD.

Bertilimumab

Bertilimumab is a fully human, IgG_4-type monoclonal antibody that blocks the activity of a protein called eotaxin-1. Eotaxin-1 plays an important role in inflammation and causes eosinophils to migrate towards sites of inflammation where they become activated and release substances that result in tissue damage and enhance inflammation.

A randomized, double-blind, placebo-controlled, parallel-group, multicenter study in adult patients with active moderate to severe UC is ongoing. Patients are currently being enrolled and eligible patients will be randomly assigned in a 2:1 ratio to one of two treatment groups, bertilimumab 10 mg/kg intravenously or matching placebo, respectively [38].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Bertilimumab in children or adolescents with IBD.

IL-17

Vidofludimus

Vidofludimus (4SC-101, IMU-838) is a novel oral immunomodulatory drug that inhibits dihydro-orotate dehydrogenase and lymphocyte proliferation in vitro and inhibits interleukin (IL)-17 secretion in vitro, independently of effects on lymphocyte proliferation [39].

A phase IIa open-label, single-arm trial with vidofludimus (ENTRANCE trial) in IBD was performed [40]. The primary outcome was to assess remission-maintenance potential in steroid-dependent IBD patients upon steroid weaning (ECCO 2011). There were 26 CD and UC patients. Complete, partial and non response was seen in 53.9% (14/26), 34.6% (9/26) and 11.5% (3/26) of patients. There was no difference in response rates between CD (85.7%) and UC (91.7%). In addition, the average prednisolone consumption dramatically dropped during treatment with the drug.

Currently, a phase 2, multicenter, randomized, double-blind, placebo-controlled, dose-finding study is actively recruiting patients with moderate-to-severe UC (CALDOSE-1) to evaluate the efficacy and safety of vidofludimus calcium for induction and maintenance therapy [41].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of vidofludimus in children or adolescents with IBD.

Safety

Vidofludimus was safe and well tolerated by all patients in the ENTRANCE trial [40]. A total of 75 adverse events were reported (53 mild, 18 moderate, and 4 severe) of which 19 adverse events were judged as possibly or probably drug-related and included nasopharyngitis, abdominal pain, fatigue, insomnia, glucosuria, leucocyturia, microhematuria, musculoskeletal pain, myalgia, tachycardia, and dyspepsia. No drug-related serious adverse events were reported.

IL-21

ATR-107

ATR-107 is a fully human anti-IL-21 receptor (IL-21R) monoclonal antibody designed to block IL-21 from binding and activating the receptor, as a novel approach to the treatment of systemic lupus erythematosus and other autoimmune diseases [42–44].

The first human ascending single-dose study was terminated in 2011, due to the development of anti-drug antibodies in 70% of the subjects and other factors. No other trials are currently planned for this agent.

NNC0114-0006

NNC0114-0006 is an anti-IL-21-antibody. A randomized, double-blind, placebo-controlled, parallel-group trial phase II study to assess the clinical efficacy and safety of NNC0114-0006 in subjects with active Crohn disease has been completed. Results are not yet known [45].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of NNC0114-0006 in children or adolescents with IBD.

Blockade of the Downstream Signaling Pathways Mediated by Cytokines

JAK/STAT Pathway

Janus kinases (JAK) 1, 2 and 3 and Tyk2 are extremely important in cytokine signaling that is involved in lymphocyte survival, proliferation, differentiation and apoptosis [45]. JAK3 is found only in hematopoietic cells and is part of the signaling pathway activated by IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 which is crucial in the activation, function and proliferation of lymphocytes [46] (see Fig. 34.3). As an important component of the JAK-STAT signaling pathway, Tyk2 regulates IL12, INFα and IL23. Selective Tyk2 inhibition has the potential to achieve benefit in the treatment of several disease states including psoriasis, systemic lupus erythematosus (SLE), inflammatory bowel disease (IBD), rheumatoid arthritis (RA), cancer, and diabetes mellitus.

Tofacitinib

Tofacitinib (CP-690,550) is an oral small molecule inhibitor of JAK 1 and 3. In vitro studies have shown that it interferes with Th2 and Th17 cell differentiation and blocks the production of IL-17 and IL-22 [48].

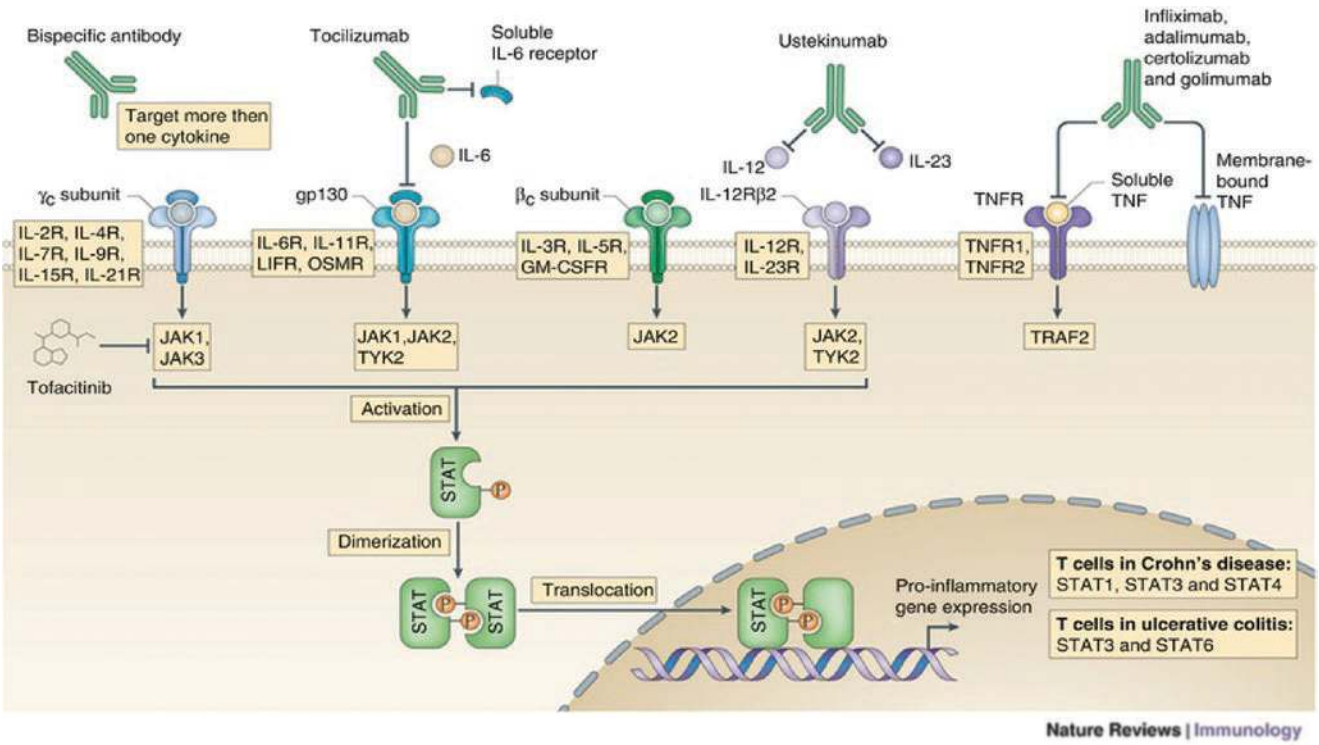

Fig. 34.3 JAK pathway inhibitors (Neurath [47])

Three phase 3, randomized, double-blind, placebo-controlled trials of tofacitinib therapy in adults with UC were conducted [49]. The OCTAVE Induction 1 and 2 trials included 598 and 541 patients with moderate to severely active UC and randomly assigned them to receive induction therapy with tofacitinib (10 mg twice daily) or placebo for 8 weeks. The OCTAVE Sustain trial re-randomised [1:1:1] clinical responders [$N = 593$] from induction studies to placebo, tofacitinib 5 mg BID, or 10 mg BID, for 52 weeks. Remission with tofacitinib vs. placebo at 8 weeks was 18.5% vs. 8.2% ($p = 0.007$) in OCTAVE 1 and 16.6 vs. 3.6% ($p < 0.001$) in OCTAVE 2. Remission at 52 weeks in the OCTAVE Sustain trial was achieved in 34.3% of the patients in the 5-mg tofacitinib group and 40.6% in the 10-mg tofacitinib group versus 11.1% in the placebo group ($P < 0.001$ for both comparisons with placebo).

Tofacitinib was also evaluated in patients with moderate to severely active CD. Patients were randomized to receive tofacitinib twice daily for 4 weeks at doses of 1 mg, 5 mg, 15 mg, or placebo [50]. The primary endpoint was not met in this phase II trial in CD patients receiving tofacitinib, but the placebo response rate was high. The primary endpoint was clinical response at week 4 and the rates were as follows: 36% ($P = 0.467$), 58% ($P = 0.466$), and 46% ($P \geq 0.999$) in those patients given 1, 5, or 15 mg tofacitinib twice daily versus 47% given placebo. As the clinical response was not significant, the trial was negative. However, the placebo response and remission rates were unexpectedly high and in addition, the reduction in fecal calprotectin and C-reactive protein levels among patients receiving 15 mg tofacitinib twice daily suggested biological activity of the drug.

Two additional randomised, double-blind, placebo-controlled, multicentre phase IIb studies were pursued. Adult patients ($n = 280$) with moderate-to-severe CD were randomised to tofacitinib 5 or 10 mg twice daily or placebo for 8 weeks [51]. Clinical responders ($n = 180$) were re-randomised to maintenance treatment with placebo, tofacitinib 5 or 10 mg twice daily for 26 weeks. Rate of clinical remission at 8 weeks was 43% vs. 43.5% vs, 36.7% with tofacitinib 10 mg twice daily, 5 mg twice daily and placebo respectively, which failed to meet statistical significance. At week 26, rates of clinical response or remission were 55.8% vs. 39.5% vs, 38.1% with tofacitinib 10 mg twice daily, 5 mg twice daily and placebo respectively, which again failed to meet statistical significance.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of tofacitinib in children or adolescents with IBD. There is an ongoing study evaluating Oral Tofacitinib in Children Aged 2–17 Years Old Suffering From Moderate to Severe Ulcerative Colitis (NCT04624230). This study is "designed to evaluate the efficacy, safety and pharmacokinetics (PK) of tofacitinib in pediatric participants with moderately to severely active UC. In the US patients with prior TNFi failure or intolerance will be enrolled. Outside of the US, TNFi naïve and TNFi experienced patients will be enrolled. All eligible participants will initially receive open label tofacitinib at a dose expected to produce equivalent systemic exposure to that observed in adults receiving 5 mg BID with the option for an individual dose increase to 10 mg BID adult dose equivalent if dose escalation criteria are met. The primary objective of this study is to evaluate the efficacy of tofacitinib based on remission in pediatric participants with moderately to severely active UC. The primary endpoint is remission by central read Mayo score following 44 weeks in the maintenance phase. Remission is defined by a Mayo score of 2 points or lower, with no individual subscore exceeding 1 point and a rectal bleeding subscore of 0. The study Design is an open-label Phase 3 study that includes a screening period of up to 4-weeks duration, an 8-week or 16-week induction phase, a 44-week maintenance phase, and a 24-month extension phase for pediatric participants with moderately to severely active UC. Participants will have a follow-up visit 4 weeks after the last dose of study intervention and telephone contact 8 weeks later to assess for any adverse events (AEs)/serious adverse events (SAEs). The total maximum duration of this study will be up to 180 weeks." (reference: https://clinicaltrials.gov/ct2/show/NCT04624230).

Safety

In OCTAVE 1 adverse events occurred in 56.5% patients in 10 mg group and 59.8% in placebo. OCATVE-2 had adverse event rates of 54.1% in 10 mg and 52.7% in placebo [49]. In OCTAVE sustain, adverse events occurred in 72.2% in 5 mg group, 79.6% in the 10 mg group and 75.3% in placebo. In OCTAVE 1 and 2 rates of infections were higher for 10 mg group versus placebo 23.3% and 18.2% versus 15.6% and 15.2%, respectively for OCTAVE 1 and 2). In the SUSTAIN trial infections occurred at rates of 35.9% in 5 mg group, 39.8% in 10 mg group and 24.2% in the placebo arm. Most infections were mild to mkoderate in severity. In OCTAVE 1 and 2 herpes zoster infection occurred in 3 patients (0.6%) and 2 patients (0.5%), respectively, in tofacitinib groups and in 1 (0.8%) patient and no patients in the placebo groups. In the sustain trial, herpes zoster infection occurred in 3 patients (1.5%) in the 5 mg group, 10 (5.1%) in the 10 mg group, and 1 (0.5%) in the placebo group. Two non-melanoma skin cancers occurred in the induction trials and four occurred in the sustain trial. Of note, patients in induction and maintenance trials had high lipids (total cholesterol, high density lipoproteins and low-density lipoproteins) which plateaued at 4 weeks. This effect is of unknown significance. Three patients treated with tofacitinib (one at dose of 10 mg twice daily and two at dose of 15 mg twice daily) had an absolute neutrophil count of less than 1500 (with none being <1000).

In a composite assessment of all tofacitinib-treated UC, patients enrolled in phases 2,3, open label, long-term extension trials, the rates of herpes zoster were found to be increased compared to placebo at 5.6% [52]. These rates are higher in older and Asian patients and those with prior anti-TNF failure [53]. The overall risks of infections and mortality with tofacitinib seem to be similar to those observed with other biologic agents [54].

Based on interim analysis results from a post-marketing trial in rheumatoid arthritis, the tofacitinib package insert now contains a boxed warning describing the increased risk of thrombosis and mortality with a dosage of 10 mg twice daily [55].

However, in UC, Sandborn et al. performed a post hoc analysis of data from induction, maintenance and overall patients receiving ≥1 dose of tofacitinib 5 or 10 mg b.d. in any phase 2, 3 or open label extension study cohorts [56]. Of the 1157 patients (2404 patient-years exposure; ≤6.1 years' tofacitinib treatment); one patient had deep vein thrombosis and four had pulmonary embolism, all during the OLE study, on a predominant dose 10 mg b.d. (83% of overall cohort patients received predominant dose 10 mg b.d.), and in the presence of venous thromboembolism risk factors.

Filgotinib

Filgotinib (GLPG0634) [brand name: Jyseleca] selectively inhibits JAK1 receptors. The FITZROY study was a randomized, double-blind, placebo-controlled phase 2 trial that studied the efficacy and safety of filgotinib for the treatment of moderate-to-severe Crohn disease [57]. From 52 European centers, 175 patients were randomly assigned (3:1) to receive filgotinib 200 mg once a day or placebo for 10 weeks. The primary endpoint was clinical remission, defined as CDAI less than 150 at week 10. After week 10, patients were assigned based on responder status to filgotinib 100 mg once a day, filgotinib 200 mg once a day, or placebo for additional 10 weeks., At week 10, 47% patients in the filgotinib group achieved clinical remission versus 23% patients in the placebo group ($p = 0.007$). In TNF naïve patients this effect was even larger at 60% clinical remission for Filgotinib group versus 13% for placebo.

Phase-III studies, which include CD patients with the perianal fistulizing disease and isolated small bowel disease are still ongoing and will help decide whether Filgotinib will be a worthwhile drug in the treatment of CD [58]. A combined phase 2b/3 study for the efficacy and safety of filgotinib in the induction and maintenance of remission in subjects with moderately to severely active UC was completed in May 2020 and the results have been presented recently [59]. Data from the SELECTION trial were presented at DDW 2021.

The SELECTION induction studies aimed to evaluate the efficacy and safety of FIL as a therapy for patients with moderate to severely active UC. This phase 2b/3, double-blind, randomized, placebo-controlled trial included two induction studies and one maintenance study. Eligible patients were aged 18–75 years with moderately to severely active ulcerative colitis for at least 6 months before enrollment (induction study A: inadequate clinical response, loss of response to or intolerance to corticosteroids or immunosuppressants, naive to tumour necrosis factor [TNF] antagonists and vedolizumab [biologic-naive]; induction study B: inadequate clinical response, loss of response to or intolerance to any TNF antagonist or vedolizumab, no TNF antagonist or vedolizumab use within 8 weeks before screening [biologic-experienced]). Patients were randomly assigned 2:2:1 to receive oral filgotinib 200 mg, filgotinib 100 mg, or placebo once per day for 11 weeks. Patients who had either clinical remission or a Mayo Clinic Score response at week 10 in either induction study entered the maintenance study. Patients who received induction filgotinib were rerandomized 2:1 to continue their induction filgotinib regimen or to placebo. Patients who received induction placebo continued receiving placebo. The primary endpoint was clinical remission by Mayo endoscopic, rectal bleeding, and stool frequency subscores at weeks 10 and 58.

The results of this study demonstrated Filgotinib 200 mg was well tolerated, and efficacious in inducing and maintaining clinical remission compared with placebo in patients with moderately to severely active ulcerative colitis [60].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of filgotinib (GLPG0634) in children or adolescents with IBD.

Safety

Adverse events in the FITZROY trial were combined, and the pooled analysis of adverse events was similar between Filgotinib and placebo groups (75% versus 67%) [57]. Serious adverse events were encountered in 9% of patients in Filgotinib group versus 4% in the placebo group. Serious infections were reported in 3% of patients in the Filgotinib group versus none in the placebo group. There was a 11% increase in HDL and 12% increase in LDL seen in patients treated with Filgotinib for 20 weeks.

Upadicitinib

Upatacitinib (ABT-494) is an oral JAK 1 selective inhibitor. Sanborn et al. evaluated the safety and efficacy of a JAK 1 inhibitor upadacitinib in CD patients who had inadequate

response or intolerance of immunomodulators or anti-TNF therapy in phase II, multicenter, randomized, double-blind placebo-controlled trial [61]. This trial included 220 patients with moderate-to-severe CD (CDAI 220-450), where patients were randomised to upadacitinib 3, 6, 12, 24 mg twice a day, 24 mg once a day or placebo for 16 weeks. The primary endpoints were clinical remission at week 16 (stool frequency [SF] ≤1.5 or abdominal pain [AP] ≤1, and both no worst from baseline) and endoscopic remission at week 12/16 SES-CD score ≤4 and ≥2 point reduction from baseline, no subscore >1). Significantly more patients achieved clinical remission with 6 mg twice-a-day dose when compared with placebo (27% vs 11% $P \leq 0.05$). There was a significant dose relationship for endoscopic remission when doses of 12 mg, 24 mg twice a day and 24 mg once a day compared to placebo (8% $P \leq 0.05$, 22% $P \leq 0.001$, 14% $P \leq 0.01$ and 0% respectively). This study demonstrated both clinical and endoscopic benefits with 6 mg doses and above. Upadacitinib use also results in a significant and sustainable reduction in markers of inflammation.

Another double-blind, phase 2 trial in adults with moderate to severe UC was conducted by Sandborn et al. [62]. Patient were randomly assigned to receive placebo versus or 7.5 mg, 15 mg, 30 mg, or 45 mg, extended release once daily for 8 weeks. Primary end points were clinical remission as per adapted Mayo score at week 8. At week 8 there was higher rates of clinical remission in Upadicitnib groups versus placebo (8.5% $P = 0.052$, 7.5 mg; 14.3% $P = 0.013$, 15 mg; 13.5% $P = 0.011$, 30 mg; and 19.6% $P = 0.002$, 45 mg versus 0%, placebo). Similarly significantly higher endoscopic improvement was achieved in 14.9%, 30.6%, 26.9% and 35.7% of Upadicitnib 7.5 mg, 15 mg, 30 mg, or 45 mg, respectively, when compared to 2.2% receiving placebo ($P = 0.033$, $P < 0.001$, $P < 0.001$, and $P < 0.001$ compared with placebo, respectively).

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Upadicitinib in children or adolescents with IBD.

Safety

In the phase-2 CD trial higher rates of adverse events were observed during induction with a higher Updaicitinib dose (>12 mg twice daily) [61]. Similarly, the highest serious adverse event rates were also seen in >12 mg twice daily group (28%). The most frequently observed adverse events were headache, worsening of CD, fatigue, upper respiratory tract infection, urinary tract infection, nausea, vomiting, and acne. During induction and maintenance periods 9 patients and 5 patients, respectively developed serious infections in the Upadicitnib group. Herpes zoster was encountered in 1 and 2 patients receiving upadicitnib in the induction and maintenance arm, respectively. There was 1 acute myocardial infarction, 1 non melanoma skin cancer, 1 Hodgkins lymphoma and 1 thymus cancer reported. Elevations in total cholesterol, LDL, HDL and CPK levels and decreases in triglyceride levels were observed in the upadacitinib 24-mg twice-daily arm compared with the placebo at week 16; total cholesterol and LDL levels were also significantly elevated in the 12-mg twice-daily group vs placebo.

In the phase-2 UC trial, a higher incidence of adverse events was seen in the treatment group as compared to placebo (0%, 4.1%, 5.8%, and 5.4%, 10.9%, for upadacitinib 7.5 mg, 15 mg, 30 mg, and 45 mg once daily and placebo, respectively) [62]. One herpes zoster event was noted in the Upadicitinib group at 45 mg once daily. One participant on 45 mg once daily had an acute pulmonary embolism and mild acute deep venous thrombosis, but this was seen 26 days after discontinuing drug and with worsening of underlying UC. Similar to CD study, elevations of cholesterol, LDL, HDL and CPK levels were noted in all groups on Upadicitinib.

Peficitinib

Peficitinib [Smyraf® (Astellas Pharma)] is a Janus kinase (JAK)1, JAK2, JAK3 and tyrosine kinase (Tyk)2 (pan-JAK) inhibitor recently approved in Japan for the treatment of rheumatoid arthritis. A Phase IIb multi-center randomized, double-blind, placebo-controlled, parallel group, dose-response trial evaluating the safety and efficacy of peficitinib (ASP015) a nonselective JAK inhibitor was done in patients with moderate-to-severe active UC [63]. Patients received either placebo versus 25 mg once daily, 75 mg once daily, 150 mg once daily., and 75 mg twice daily of study drug. The primary outcome was Mayo score change from baseline at week 8, which did not meet statistical significance, but was met by numerically higher proportion of patients receiving 75 mg twice daily peficitnib.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Peficitinib in children or adolescents with IBD.

Safety

Adverse, serious adverse events, and serious infection rates in the patients receiving Peficitinib were similar to placebo (45.5% versus 34.9%; 4.7% versus 3.4%; 12.5% versus 14% for Peficitinib versus placebo,respectively) [63]. Elevations in total cholesterol, LDL, HDL and CPK levels were also observed with Peficitinib, especially at higher doses.

TD-1473

TD-1473-an oral gut-selective pan-JAK inhibitor-TD-1473 is an orally administered nonselective JAK inhibitor that has been evaluated in a phase I trial in patients with

moderate-to-severe UC showing significant endoscopic improvement in patients receiving 20 mg, 80 mg or 270 mg daily versus placebo (20%, 30%, 18% versus 0% for TD-1473 versus placebo) [64]. TD-1473 is a gut-selective treatment specifically designed to distribute adequately and predominantly to the tissues of the intestinal tract, treating inflammation in those tissues while minimizing its systemic exposure.

TGF-β

One mechanism by which Crohn disease develops involves transforming growth factor (TGF)-b which is a suppressive cytokine [65, 66]. SMAD7 is an endogenous inhibitor of the immunosuppressive cytokine transforming growth factor-β1. In CD, TGF-b1 activity is inhibited by high Smad7, an intracellular protein that binds to the TGF-b1 receptor and prevents TGF-b1-driven signaling [67, 68].Studies in mice have consistently shown that the induction of experimental CD-like colitis is associated with enhanced expression of Smad7 and reduced TGF-b1 activity [67]. The inhibition of Smad7 in CD mucosal cells with a specific antisense oligonucleotide has been demonstrated to restore TGF-b1 activity which therefore down-regulates the production of inflammatory cytokines [69].

Mongersen

GED0301 is an antisense oligonucleotide targeting SMAD7 and is an oral gastro-resistant compound with a pH-dependent, delayed-release of the oligonucleotide in the terminal ileum and right colon.

A phase I clinical trial was performed which showed that GED0301 in active, steroid-dependent/resistant CD patients resulted in a clinical benefit in all patients [70, 71]. In a placebo-controlled phase II study (IGONI) in patients with active CD, patients were randomized to receive induction treatment with different doses of Mongersen or placebo for 2 weeks [72]. The primary endpoint was clinical remission and this was seen in 55, 65, and 9.5% of patients receiving Mongersen 40 mg/day, 160 mg/day, or placebo ($p < 0.0001$, for both comparisons) at 15 days and maintained for ≥2 weeks. A post hoc analysis of the IGONI study noted that CD patients with higher CDAI scores achieved clinical remission most frequently with the highest mongersen dose, without any significant impact of disease duration and baseline CRP level [73].

A subsequent trial randomly assigned 63 CD patients to 4-, 8-, or 12-week course of mongersen 160 mg/day and found that at week 12, 32% (4 weeks), 35% (8 weeks), and 48% (12 weeks) of patients receiving mongersen were in clinical remission (CDAI < 150) and endoscopic improvement occurred in 37% of all participants [74].

Based on the above promising results, a phase 3, blinded study was pursued where patients were randomized (1:1:1:1) to placebo, mongerson 160 mg for 12 weeks followed by 40 mg continuously, or alternating placebo with 40 or 160 mg every 4 weeks through week [75]. This study was prematurely terminated based on its concerning results where rates of 52 week clinical remission were similar among individuals in mongersen groups and placebo. At week 12 more patients who received placebo had achieved endoscopic response and at week 12 and 52 endoscopic endpoints were similar across groups. Several study design flaws have been suggested to be responsible for the negative results and the premature termination of the study [76]. However, since then subsequent studies exploring the role of mongersen in CD therapy have been terminated or withdrawn based on the sponsor's decision.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of GED0301 in children or adolescents with IBD.

Safety

A phase I clinical trial using GED0301 in active, steroid-dependent/resistant CD patients was safe and well tolerated [70]. Adverse events were similar across the treatment groups in two phase II clinical trials [72, 74].

However in the phase 3 trial similar rates of treatment-associated adverse events were reported for the treatment group versus placebo (70.2% versus 71.3%, GED-0301 versus placebo) [75]. Most frequently reported events were arthralgia, exacerbation of CD, abdominal pain, upper respiratory tract infection, pyrexia, headache, nausea, and diarrhea. Adverse events were predominantly secondary to poorly controlled CD from poor treatment response, and also two deaths in the mongersen group (due to small intestinal obstruction and pneumonia) occurred.

Targeting Chemokines

Chemokines are cytokine proteins expressed in lymphoid and nonlymphoid tissue, thought to be involved in leukocyte trafficking. Persistent, aberrant leukocyte chemotaxis to inflamed mucosa is thought to play a role in the pathogenesis of IBD. Increased expression of several chemokines has been reported in patients with UC and Crohn disease.

Anti CXCR3/CXCL10

Interferon-γ-inducible protein-10 (IP-10 or CXCL10) is a chemokine that plays an important role in the migration of cells into sites of inflammation by influencing the activation and migration of activated T-cells, monocytes, eosinophils, natural killer, epithelial and endothelial cells [77, 78].

CXCL10 has been found to be expressed in higher levels in the colonic tissue and plasma of patients with UC [79, 80].

BMS936557 (MDX-1100, Eldelumab)

Mayer and colleagues in 2014 published data from an 8-week phase II, double-blind, multicenter, randomized study in patients with active UC [77]. Patients with moderately to severely active UC were given either BMS-936557 (10 mg/kg) or placebo intravenously every other week. The primary endpoint was the rate of clinical response at day 57. Primary and secondary endpoints were not met. However, what was found was that with higher steady-state trough levels of BMS-936557 (108–235 μg/mL), there was an increased clinical response (87.5% vs. 37% $p < 0.001$) and histological improvement (73% vs. 41% $P = 0.004$) compared to placebo.

In a phase IIb study of patients with CD patients ($n = 121$) with CDAI ≥220 and ≤450 were randomly assigned 1:1:1 to placebo or intravenous eldelumab 10 or 20 mg/kg given on days 1 and 8 and then every other week [81]. Patients with a score of 2–3 on the ulcerated surface subscore of SES-CD in at least 1 of 5 segments had a follow up endoscopy at 11 weeks. Primary outcome was defined as a reduction in CDAI 100 points from baseline or an absolute CDAI score <150 (clinical remission) and endoscopic improvement. There was a trend towards efficacy as remission and response rates at week 11 for the 10 mg/kg dose, 20 mg/kg and placebo groups were 22.5 and 47.5%, 29.3 and 41.5%, vs. 20 and 35% and were higher in anti-TNF-naive patients versus those patients who experienced anti-TNF failures. Both drug groups achieved a greater reduction from baseline in mean endoscopy scores compared to placebo and were similar in the eldelumab-treated groups across the anti-TNF-naive and anti-TNF failure subgroups.

In a 11-week Phase IIb study, 252 adult patients with active UC were randomised 1:1:1 to placebo or eldelumab 15 or 25 mg/kg intravenously on Days 1 and 8, and alternate weeks thereafter [82].Primary outcome was clincal remission defined as Mayo score ≤2; no individual subscale score >1. Results showed numerically higher remission and response rates with eldelumab 25 mg/kg [17.6% and 47.1%, respectively] and 15 mg/kg [13.1% and 44%] versus placebo [9.6% and 31.3%].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of BMS936557 in children or adolescents with IBD.

Safety

In the UC phase II study infusion reactions occurred in 19%, 14%, and 5% in the 25 mg/kg, 15 mg/kg, and placebo groups, respectively, without any detectable anti-drug antibodies [77]. The CD phase 2 study also noted higher infusion reactions in the study drug group (10% and 27% of patients receiving 10 mg/kg and 20 mg/kg arms), with 3 cases being considered serious [81]. Rates of infections in the UC phase 2 trial were 26% (25 mg/kg), 17.9% (15 mg/kg) and 18% (placebo) with the most common type of infection being nasopharyngitis [82].

Anti CCR9/CCL25

The chemokine CCL25 and its receptor CCR9 are essential for optimal mucosal immune development and function, with the latter being expressed by 58–97% of lymphocytes imprinted with guttropism [83]. Elevated serum levels of CCL25 are found to be present in patients with UC [84] and, most significantly, a strong positive correlation between CCL25 gene expression in the colonic mucosa and both the Mayo endoscopic sub-score and mucosal TNFα levels in UC patients has been noted [85].

Vercirnon (CCX282-B)

This is an orally bioavailable CCR9 antagonist, which is a potent inhibitor of CCR9+ T cell-mediated chemotaxis in vitro, and shows near complete protection against ileitis and attenuation of colitis in animal models [86].

The PROTECT-1 phase IIb trial randomly allocated patients with CD to placebo or one of three treatment dosages, organized into: an induction phase (induction of clinical response at Weeks 8 and 12); an active, open-label study phase (4 weeks) in which all eligible participants received CCX282-B at 250 mg twice daily; and a maintenance period in which patients who showed clinical response during the active phase were re-randomised to receive placebo or CCX282-B at a dose of 250 mg twice daily [87]. The induction phase of PROTECT-1 failed to attain its primary endpoint of a significant reduction in the CDAI of 70 points at Week 8. During the maintenance phase, remission was

achieved in 47% of patients on CCX282-B treatment compared with 31% of those on placebo ($P = 0.012$).

In a phase III double-blind randomised placebo-controlled trial (SHIELD-1) conducted over 162 centres in 23 countries, CD patients with active disease, who had failed corticosteroid or immunosuppressive therapy were enrolled [88]. In the 608 participants, the placebo, 500 mg od and 500 mg twice daily vercirnon arms showed no significant difference in remission rates. Clinical trial design flaws and higher rate of anti-TNF exposed patients in the SHIELD-1 study have been hypothesized as possible explanations to address the discrepancy in results between PROTECT-1 and SHIELD-1.

In the SHIELD-4 study, patients with moderate-to-severe Crohn disease were randomized for a double blind 12 week induction study with 500 mg once daily or twice daily vercirnon or placebo, followed by a phase 3 maintenance trial (SHIELD-2) [89]. An incremental increase in response and remission rates with the higher dose of vercirnon, similar to PROTECT-1 was noted, however primary endpoints of CDAI ≥100-point response at week 12 were not met.

In UC a first-in-human, double-blind, randomized, placebo-controlled trial was performed to evaluate safety, tolerability, and immunological response of selective removal of circulating CCR9-expressing monocytes by leukapheresis in patients with moderate to severe disease [90]. Patients received five sessions of leukapheresis every other day, with a C-C chemokine ligand 25 [CCL25; CCR9 ligand] column or a placebo column. Pro-inflammatory HLA-DRhi cells ($p = 0.039$) and Mayo score ($p = 0.016$) decreased significantly in the active treatment group whereas no statistically significant change was seen in the placebo group ($p = 0.469$ and $p = 0.125$ respectively). A dose-response correlation was observed between the blood volume processed and clinical outcome. No major safety concerns were raised and the procedure was well tolerated.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of CCX282-B in children or adolescents with IBD.

Safety Data

While the phase 2 study noted no specific safety concerns [87], in the phase 3 trial, patients in the vercirnon group, especially with higher treatment doses, showed greater incidence of gastrointestinal adverse events (30%, 37%, and 48% for placebo, Vercirnon once daily, and Vercirnon twice daily respectively [$P < 0.001$, 500 mg twice daily vs placebo] [88].The most common adverse effects were abdominal pain, nausea, dyspepsia and CD worsening.

Antiadhesion Molecules

Natalizumab

Natalizumab is a humanized IgG_4 monoclonal antibody against the adhesion molecule α4 integrin, which is involved in migration of leukocytes across the endothelium, and is upregulated in sites of inflamed endothelium. Six randomized, double-blind, placebo-controlled trials assessed the efficacy in patients with Crohn disease, whereas only one uncontrolled pilot study has been conducted in patients with UC.

Three Phase III trials have been conducted in CD. In Efficacy of Natalizumab as Active Crohn Therapy (ENACT-1), 905 patients with moderate to severe Crohn disease were randomly assigned to receive induction therapy at weeks 0, 4, and 8 with either natalizumab 300 mg or placebo [91]. The primary endpoint in the induction trial was clinical response defined as at least 70-point decrease in baseline CDAI score at week 10 and it was achieved in 56% and 49% of natalizumab and placebo recipients, respectively ($P = 0.05$) [80]. In ENACT-2, 339 patients who had a response to natalizumab in induction ENACT-1 trial at both week 10 and 12 were randomly reassigned to receive 300 mg of natalizumab or placebo every 4 weeks from week 12 through week 56 [91]. The primary endpoint in ENACT-2 trial was a sustained response through week 36. Patients with at least 70-point increase in CDAI score after week 12 with an absolute CDAI score of at least 220 or needed therapeutic intervention after week 12 were considered to lose response. Rates of sustained response at week 36 were 61% in patients receiving maintenance treatment with natalizumab and 28% in those receiving placebo maintenance ($P < 0.001$). Patients who maintained remission on natalizumab over 12 months in the ENACT-2 trial were enrolled into a subsequent phase III, open-label, 2-year open-label extension trial designed to assess long-term efficacy and safety of natalizumab [92]. This open-label trial comprised of 146 patients who received 12 natalizumab infusions over 12 months. The proportion of patients who maintained remission after 6 (week 24) and 12 (week 48) additional infusions of natalizumab was 89% and 84%, respectively. This open-label extension trial supported data from ENACT-2 trial that natalizumab maintains remission over additional 12 months in patients with sustained remission on natalizumab in the preceding 12 months.

In the ENCORE trial, 509 patients with moderate to severe Crohn disease were randomized to receive natalizumab 300 mg or placebo at weeks 0, 4, and 8 [93]. Natalizumab was significantly superior over placebo in

inducing remission at week 8 that was sustained through week 12 (primary endpoint defined as at least 70-point decrease in CDAI score) with respective proportions of patients of 48% vs. 32% ($P < 0.001$).

Finally, Sands et al. performed a placebo-controlled trial in which 79 patients with active Crohn disease during ongoing treatment with infliximab 5 mg/kg every 8 weeks for at least 10 weeks before initiation of randomization were randomly assigned to receive three intravenous infusions of either natalizumab 300 mg or placebo every 4 weeks while continuing their initial infliximab regimen during the duration of the trial [94]. At week 6 patients treated with natalizumab plus infliximab experienced mean decrease in their CDAI score of 37.7 points, while those treated with placebo plus infliximab experienced small increase in CDAI score of a mean of 3.5 points ($P = 0.084$). A trend towards greater efficacy of combined treatment with natalizumab and infliximab over infliximab alone was shown in patients with active Crohn disease not responding to infliximab therapy.

Gordon et al. published results of one small open-label study of 10 patients with active UC who were treated with a single infusion of natalizumab 3 mg/kg [95]. All patients had their disease activity evaluated using Powell-Tuck score 2 weeks after infusion. Treatment with natalizumab resulted in significant decrease in median disease activity score from 10 at baseline to 6 at 2 weeks postinfusion ($P = 0.004$). It was suggested that future randomized, placebo-controlled trials are warranted to further assess the efficacy of natalizumab in UC.

Overall, natalizumab, was the first non-anti-TNF biological drug to be approved for treatment of CD patients and is an effective option for patients with refractory CD. However, the association with the serious adverse event, PML and the current availability of more specific anti-integrin drugs with a more favorable safety profile, has limited further studies of natalizumab. However, its use in select patients, may be considered after a risk-benefit consideration.

Pediatric Data

There was only one open-label study conducted on 38 pediatric patients (ages 12–17 years) with active Crohn disease that assessed the efficacy of natalizumab in a pediatric population [96]. Among 38 enrolled patients 31 of them received three intravenous infusions of natalizumab 3 mg/kg at weeks 0, 4, and 8. Disease activity was measured using Pediatric Crohn disease Activity Index (PCDAI) at baseline and then every 2 weeks through week 12. There was a significant decrease observed in PCDAI score from baseline at every time point ($P < 0.001$) with the greatest decrease observed at week 10 with 55% of patients achieving clinical response (>15-point decrease from baseline) and 29% of patients achieving clinical remission (PCDAI <10). These promising findings however need to be validated in large randomized controlled trials.

Safety

In one study in patients with Crohn disease, 7% of patients given one or two induction doses of natalizumab (at weeks 0 and 4) had formed anti-natalizumab antibodies at 12 weeks [91]. Patients in the ENACT-2 trial who received concomitant immunosuppressants did not develop persistent anti-natalizumab antibodies, compared to 7.5% of patients who received natalizumab alone [97].

The largest ENACT-1 ($n = 905$) and ENACT-2 ($n = 339$) trials of natalizumab observed that serious adverse events occurred in similar proportion of patients in both trials (7% in natalizumab and placebo arms in induction ENACT-1 trial and 8% in natalizumab arm and 10% in placebo arm in maintenance trial) [97, 98]. However, one patient died (three doses of natalizumab combined with azathioprine during ENACT-1, placebo with azathioprine during ENACT-2 and -5 doses of natalizumab alone after completion of ENACT-2 trial) from progressive multifocal leukoencephalopathy, associated with the JC virus was observed [99]. In the other large induction trial ENCORE (n=509) a similar proportion of adverse events was observed between natalizumab (85%) and placebo (82%) without any deaths [93]. The most common adverse events that were observed in at least 10% among either treatment arms were headache, nausea, abdominal pain, nasopharyngitis, dizziness, fatigue, and exacerbation of Crohn disease. There was a significant greater proportion of patients in natalizumab group versus placebo that experienced nasopharyngitis (11% vs. 6%, $p < 0.05$), headache (29% vs. 21%, $p < 0.05$) and hypersensitivity reaction (4% vs. 0.8%, $p < 0.05$). On the other hand, exacerbation of Crohn disease was observed in greater proportion of placebo treated patients when compared to natalizumab (13% vs. 7%, $P < 0.05$).

A placebo-controlled trial by Sands et al. assessed primarily safety of concurrent therapy with natalizumab in 79 patients with Crohn disease already receiving infliximab [94]. The observed incidence of adverse events was similar in the treatment groups (natalizumab plus infliximab vs. infliximab plus placebo). The most frequent adverse events in both groups were headache, Crohn disease exacerbation, nausea, and nasopharyngitis. No one experienced a hypersensitivity-like reaction to natalizumab, whilst 4 patients (5%) experienced such reactions to infliximab. The development of antibodies to natalizumab was reported in 4% of patients whereas antibodies to infliximab were detected in 14% of patients.

Data from pediatric open-label study showed that the most common adverse events were headache (26%), pyrexia

(21%) and exacerbation of Crohn disease (24%) [96]. Anti-natalizumab antibodies were detected in 8% of patients.

Clinical trials and marketing of natalizumab were suspended in February 2005 after two patients with multiple sclerosis treated with natalizumab and interferon beta-1A developed progressive multifocal leukoencephalopathy (PML) from reactivation of the latent human Jacob Creutzfeldt polyoma virus [100, 101]. A third patient treated with natalizumab and prior exposure to azathioprine was reclassified from malignant astrocytoma to PML [102]. An independent adjudication committee performed a safety evaluation in all patients who had recently been treated with natalizumab in clinical trials. Evaluation consisted of a referral to a neurologist, brain magnetic resonance imaging, and polymerase chain reaction analysis of cerebral spinal fluid and serum for JC virus. Of 3826 initial patients enrolled in clinical trials of natalizumab, safety evaluation included 87% (1275), 91% (2248), and 92% (296) of patients with Crohn disease, multiple sclerosis, and rheumatoid arthritis patients. No additional cases of PML were identified. The median duration of treatment for all patients was 17.9 months, while that of patients with Crohn disease was 7 months. The absolute risk of developing PML during treatment with natalizumab was 1:1000 (0.1%) with 95% confidence intervals of 1:200–1:2800 [103]. The FDA reapproved natalizumab for multiple sclerosis in September 2006, with the requirement of mandatory participation in a risk management and registry program called the TOUCH program [99].

In the meta-analysis encompassing 1771 participants they noted rates of adverse effects after 1, 2 and 3 infusions of natalizumab as 74%, 86% and 86% (compared to 81%, 81% and 83% among the placebo participants) [104]. The corresponding rates of serious adverse effects after 1, 2 and 3 infusions were 10%, 9% and 7% with natalizumab (versus 11%, 11% and 8% with the placebo). Withdrawal due to an adverse effect at these time points occurred in 1%, 3% and 8% of those treated with natalizumab (versus 3%, 3% and 10% of those treated with placebo). Hence overall the rates of AEs (moderate quality evidence), withdrawals due to AEs (low-quality evidence) and serious AEs (low-quality evidence) were similar across the groups at 10 weeks. The adverse events included headache, exacerbation of CD, nausea, and nasopharyngitis. Although natalizumab is asoosicated with the development of PML, the studies included in the meta-analysis were not powered to detect it.

Vedolizumab (MLN-002, MLN-02, Entyvio®)

Vedolizumab (also known as MLN-002 and MLN-02) is a recombinant IgG1 humanized monoclonal antibody against the adhesion molecule α4β7 integrin and is the first gut-selective humanized monoclonal antibody. In contrast to natalizumab, vedolizumab specifically targets α4β7 integrins that are exclusively present on gut homing T cells and as a result the interaction between α4β7 and antimucosal vascular addressin cell adhesion molecule (MAdCAM)-1 is blocked.

GEMINI I was a double-blind, phase III trial in patients with moderate to severe UC [105]. Patients were randomized to receive vedolizumab (300 mg intravenously) or placebo on day 1 and day 15. The primary endpoint of the induction trial was clinical response at week 6 and this was achieved in 47% vs. 26% of patients receiving vedolizumab and placebo, respectively ($P < 0.0001$). Clinical remission at week 6 was seen in 17% versus 5% on vedolizumab vs. placebo ($P = 0.0009$) and mucosal healing was seen in 41 and 25% in the vedolizumab versus placebo groups ($P = 0.0012$). Patients who achieved a clinical response after induction therapy were randomized to receive placebo or further intravenous vedolizumab at 300 mg at 4- or 8-week dosing intervals up to 46 weeks. Clinical remission rates at week 52 were 42 and 45% in the vedolizumab 8- and 4-weekly groups, respectively, versus 16% in the placebo arm; $P < 0.0001$. Mucosal healing rates were also significantly higher in the vedolizumab group—52 and 56% in the vedolizumab 8- and 4-weekly group versus 20% in the placebo group; $P < 0.0001$. The overall clinical efficacy was higher with vedolizumab in those patients naive to anti-TNF-naïve compared to those who had a prior failure or intolerance to anti-TNF therapy.

GEMINI II was a clinical trial evaluating vedolizumab in patients with moderate to severe CD [106]. Week 6 clinical remission rates were 13.3 vs. 9.7% ($P = 0.157$) and 22.7 vs. 10.6% ($P = 0.005$) in patients who had failed anti-TNF therapy vs. those who were naive to anti-TNF therapy compared to placebo. Week 10 clinical remission rates were 21.7 versus 11% ($P = 0.0008$) and 24.7 versus 15.4% ($P = 0.044$) in patients who had failed anti-TNF therapy and anti-TNF naive patients compared to placebo, respectively. Week 52 clinical remission rates were 52 and 27% in vedolizumab vs. placebo groups naive to anti-TNF but in those patients who had failed anti-TNF therapy, the clinical response rate was lower (28 versus 13% in the vedolizumab and placebo groups, respectively).

GEMINI III is a placebo-controlled phase III induction trial evaluating the efficacy and safety of vedolizumab in CD patients who had failed anti-TNF therapy [107]. At week 6, clinical remission rates were not found to be superior in vedolizumab vs. placebo groups (15.2 and 12.1% ($P = 0.433$)). However, at week 10 the therapeutic efficacy of vedolizumab was detected and vedolizumab was statistically superior to placebo for inducing clinical remission at week 10 (26.6% versus 12.1% in the vedolizumab vs. placebo groups, respectively ($P = 0.001$).

Overall, the results with vedolizumab seem to be somewhat better in UC compared to CD and the 6-week time

point in CD was thought to have been set too early to appreciate optimal efficacy given the mode of action of this agent. In the open-label long-term extension study (GEMINI LTS) there was a suggestion that certain patients with both UC and CD benefited from an increase in vedolizumab dosing frequency from every 8 weeks to every 4 weeks [108].

This drug was approved in 2014 by the FDA and EMA for both UC and CD, refractory to standard therapy and/or anti-TNF agents. In one of the only head-to-head trials of therapies done to date, a phase 3b, double-blind, double-dummy, randomized trial conducted at 245 centers in 34 countries, compared vedolizumab ($n = 383$) with adalimumab ($n = 386$) in adults with moderately to severely active UC [109]. The patients were assigned to receive infusions of 300 mg of vedolizumab on day 1 and at weeks 2, 6, 14, 22, 30, 38, and 46 (plus injections of placebo) or subcutaneous injections of 40 mg of adalimumab, with a total dose of 160 mg at week 1, 80 mg at week 2, and 40 mg every 2 weeks thereafter until week 50 (plus infusions of placebo). Dose escalation was not permitted in either group. At week 52, the vedolizumab group showed higher rates of clinical remission (defined as total score of ≤2 on the Mayo scale, and no subscore >1) (31.3% vs. 22.5%; $P = 0.006$) and endoscopic improvement (subscore of 0 to 1 on the Mayo endoscopic component) (39.7% vs. 27.7%; $P < 0.001$) than the adalimumab group. Interestingly, rates of corticosteroid-free clinical remission were higher with adalimumab compared to vedolizumab (21.8% vs. 12.6%). Safety data was favorable to vedolizumab with exposure-adjusted incidence rates of infection being 23.4 with vedolizumab and 34.6 events per 100 patient-years with adalimumab. The corresponding rates for serious infection were 1.6 and 2.2 events per 100 patient-years. These above results will likely influence the positioning of vedolizumab in the treatment armamentarium for UC patients, and possibly make it the first choice biologic for those with moderate to severe disease.

Pediatric Data

A small observational prospective cohort study of 21 pediatric patients with refractory IBD (16 with CD and 5 with UC) and prior anti-TNF therapy failure suggested notable response rates with vedolizumab therapy within the first 6 weeks, which increased further by week 22 [110]. In an Australian case series, 12 IBD patients (CD = 7 and UC = 5), aged 8–17 years, with prior anti-TNF exposure were then administered vedolizumab [111].While CD activity scores did not significantly change from baseline to week 38 (median 47.5 vs. 40 points, $p = 1.0$), the median UC activity scores changed from 70 to 5 points ($p < 0{,}001$), thus suggesting the utility of vedolizumab, especially in pediatric UC patients.

In a 3 center restrospective review of 52 pediatric IBD patients (58% CD and 42% UC) with median age, 14.9 years and 90% having prior failure to ≥1 anti-TNF agent, week 14 remission rates for UC and CD were 76% and 42%, respectively ($P < 0.05$) [112]. Eighty percent of anti-TNF-naive patients experienced week 14 remission and at week 22, anti-TNF-naive patients had higher remission rates than TNF-exposed patients (100% versus 45%, $P = 0.04$). No infusion reactions or serious adverse events/infections were noted.

Another retrospective study pooled 54 children [aged 2-18 years] treated with vedolizumab after prior anti-TNF exposure, from 19 centres affiliated with the Paediatric IBD Porto group of ESPGHAN (UC/IBD-unclassified = 41, CD = 23) and assessed corticosteroid-free remission [CFR] at 14 weeks [113]. Week 14 CFR was 37% in UC, and 14% in CD [$P = 0.06$] and mucosal healing rate among the 16 endoscopically evaluated was 19%. Concomitant immunomodulatory drugs did not affect remission rate [42% vs 35%; $p = 0.35$]. Only minor drug related events ($n = 3$) were noted. Thus this study further corroborated the safety and efficacy of vedolizumab in pediatric IBD patients, particularly pediatric UC.

Safety

Patients with UC (GEMINI I) and CD (GEMINI II) who completed 52 weeks of vedolizumab treatment were enrolled in GEMINI LTS for an additional 52 weeks [105, 106]. The 2-year efficacy data of vedolizumab in CD and in UC showed the safety of vedolizumab in the GEMINI program [108, 114].To date, there have been no cases of PML. Furthermore, Milch and colleagues conducted a study to determine whether vedolizumab alters T cell subpopulations in cerebrospinal fluid and no significant changes in T cell populations were observed [115]. Also, the incidence of systemic and gastrointestinal infections was similar among patients on vedolizumab or placebo [115].

Furthermore, safety data (May 2009–June 2013) from six trials of vedolizumab were integrated and treatment with vedolizumab for up to 5 years demonstrated a favorable safety profile. In total, 2830 patients had 4811 person-years of vedolizumab. No increased risk of any infection or serious infection was associated with vedolizumab exposure. No cases of progressive multifocal leucoencephalopathy were observed. Infusion-related reactions as defined by the investigator were reported for ≤5% of patients in each study. Eighteen vedolizumab-exposed patients (<1%) were diagnosed with a malignancy [116]. Thus vedolizumab has emerged as a safe alternative in IBD, especially for patients for whom systemic immunosuppression is preferred to be avoided, such as the elderly, or those at increased risk for infection or malignancy.

Etrolizumab (rhuMAb β7)

Etrolizumab is a humanized monoclonal antibody that selectively targets the β7 subunit of α4β7 and αEβ7 integrins and as a result blocks leucocyte migration.

In a placebo-controlled, randomized phase II trial, patients with moderate to severe UC received subcutaneous etrolizumab (100 mg at weeks 0, 4, and 8, with placebo at week 2 or 420 mg at week 0 and 300 mg etrolizumab at weeks 2, 4, and 8) or placebo [117]. At week 10, etrolizumab was found to be more effective in achieving clinical remission (primary endpoint) as compared to placebo - 21% and 10% of patients in the 100 mg or 300 mg etrolizumab group, respectively, and in 0% of patients receiving placebo; the low placebo rate was thought to be a result of very careful patient selection. Subsequently, higher levels of granzyme A and Integrin αE ITGAE mRNAs in the colonic tissue have been highlighted as potential biomarkers to identify UC patients that are most likely to benefit from etrolizumab treatment [118].

A meta-analysis of 7 trials to pool data for etrolizumab and infliximab in moderate to severe UC to perform an indirect comparison found no significant differences in clinical remission between etrolizumab and infliximab, however larger studies to assess clinical response and mucosal healing of etrolizumab vs. infliximab, especially in anti-TNF alpha naïve patients would be necessary to understand the utility of each drug better [119].

The etrolizumab phase 3 clinical program is the largest and most comprehensive in IBD, enrolling more than 3000 patients for six randomized controlled trials (RCTs; UC: HIBISCUS I and II, GARDENIA, LAUREL, HICKORY; Crohn disease: BERGAMOT) and two open-label extension trials (OLEs; UC: COTTONWOOD; Crohn disease: JUNIPER) evaluating patients with moderately to severely active UC or Crohn disease [120]. In the UC RCTs, patients are randomly assigned according to each protocol to receive etrolizumab, adalimumab, infliximab, or placebo. In BERGAMOT, patients are randomly assigned to receive etrolizumab 105 mg, etrolizumab 210 mg, or placebo. This program with the various trials are underway or have been completed to explore both induction and maintenance regimens and the OLEs will primarily provide long-term efficacy and safety data.

Pediatric Data

A phase I, open-label, randomized, pharmacokinetic, pharmacodynamic, and safety study of etrolizumab followed by open-label extension and safety monitoring in pediatric patients from 4 years to less than 18 years of age with moderate to severe UC or moderate to severe CD is currently recruiting patients.

Safety

In the UC phase 2 trial adverse events occurred in 25/41 patients (61%) in the etrolizumab 100 mg group (12% regarded as serious), 19/40 patients (48%) in the etrolizumab 300 mg plus loading dose group (5% serious), and 31/43 patients (72%) in the placebo group (12% serious) [117]. The indirect comparison of infliximab and etrolizumab in the meta-analysis showed higher odds for adverse events with the former (OR: 3.04, p = 0.003), however serious adverse events were comparable [119].

Ontamalimab

Ontamalimab (SHP647, PF-00547659) is a fully human monoclonal antibody that binds specifically to human MAdCAM-1 which is involved in leukocyte recruitment to the site of inflammation has been explored as a therapeutic target in IBD due to its overexpression in the inflamed mucosa and successful intervention based on this ligand in preclinical animal models [121].

In a randomized, placebo-controlled trial evaluating the safety and efficacy of PF-00547659 in patients with active UC, 80 patients received a single or three doses of PF-00547659 (0.03–10 mg/kg, intravenously or subcutaneously administered) or placebo at 4-week dosing intervals [122]. No statistical differences were found between patients given the drug compared to placebo although some benefits were seen in the actively treated group in terms of clinical and endoscopic improvements. Clinical response at week 4 was seen in 32 and 52% of patients on placebo or PF-0054659 (all doses) ($P = 0.102$) and clinical response at week 12 was 21 versus 42% in the placebo and PF-00547659 groups, respectively ($P = 0.156$).

Larger clinical trials evaluating efficacy of PF-00547659 in UC and CD were completed in 2015. The TURANDOT study was a phase II trial evaluating the safety and efficacy of PF-00547659 in patients with UC [123]. Three hundred and fifty-seven adults with UC (with disease extending more than 15 cm beyond the rectum and with a total Mayo Score at least 6 and endoscopic subscore of at least 2) who had failed at least one prior therapy were randomized to receive 7.5, 22.5, 75, or 225 mg of PF-00547659 or placebo every 4 weeks for three doses. Clinical remission at week 12 was the primary endpoint defined as total Mayo score 2 or less with no subscore more than 1. Clinical remission at week 12 was significantly greater in the 7.5, 22.5, and 75 mg dose groups compared with placebo.

OPERA was a randomized, multicenter double-blind, placebo-controlled study that evaluated the safety and efficacy of PF-00547659 in patients with Crohn disease [124]. Two hundred and sixty-seven adults with moderate to severe

Crohn disease (CDAI 220–450), who had failed or did not tolerate other therapy (anti-TNF and/or immunosuppressant drugs), had C-reactive protein (CRP) more than 3.0 mg/L and ulcers on colonoscopy were randomized to placebo or PF-00547659 at the dose of 22.5 mg, 75 mg, or 225 mg. The primary endpoint was CDAI-70 response at week 8 or 12. The CDAI-70 response was not significantly different between any of PF-00547659 doses and placebo but in patients who had a baseline CRP level more than 18 remission at week 12 was higher in the drug groups compared to placebo (37%, 24 and 39% with increasing doses vs. 14% placebo). At week 2, soluble MAdCAM-1 decreased significantly in a dose-dependent manner and remained low during the study in patients who received drug.

However, in a subpopulation analyses of the OPERA study for Asian subjects (n = 21), efficacy of PF-00547659 could not be demonstrated using any clinical endpoints compared with placebo and larger analysis were called for [125].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of PF-00547659 in children or adolescents with IBD.

Safety

While the concern for PML arises with the use of anti-integrin drugs that inhibit lymphocyte translocation from bloodstream to tissue, an analysis of cerebrospinal fluid in 39 patients with active CD and previous immunosuppression over 12 weeks of PF-00547659-induction therapy showed no reduction of cerebrospinal fluid lymphocytes, T-lymphocyte subsets, or CD4:CD8 ratio, thus suggesting that the compound does not affect immune surveillance in the central nervous system [126]. Treatment-related adverse events, none serious, were reported in 23/49 [47%] patients and even in the TURANDOT and OPERA studies, adverse events were mild, comparable to the placebo group and most often related to the underlying disease [123, 124].

AJM300

AJM300 is an orally active small molecule with antagonistic properties to α4-integrin (both $\alpha_4\beta_7$ and $\alpha_4\beta_1$) . A randomized trial involving 71 patients with active Crohn disease compared oral treatment with either AJM300 (40 mg tid, 120 mg tid, or 240 mg tid) to placebo for 8 weeks [127]. The primary endpoint was the decrease of CDAI score from baseline to final evaluation at week 4 or later, while the secondary efficacy endpoint was clinical response (≥70 point decrease in CDAI). There was no significant difference in clinical response was observed between active treatment and placebo arms. Among patients with high CDAI at baseline a significant decrease from baseline CDAI score (mean decrease 41.5 points, P = 0.0485) was observed in those treated with AJM300 at the dose of 120 mg tid and mean 41.6 point decrease from baseline CDAI in those treated with AJM300 at the dose of 240 mg tid (p-value not reported). In addition, patients treated with AJM at the dose of 240 mg tid had significant twofold decrease in C-reactive protein from baseline over 8 weeks (P = 0.0220). The investigators suggested that AJM300 at dose 120 mg tid and 240 mg tid showed clinical efficacy in treating patients with active Crohn disease.

A double-blind, placebo-controlled, phase 2a study, recruited 102 patients with moderately active UC with inadequate response or intolerance to mesalamine or corticosteroids, and randomly assigned them to receive AJM300 (960 mg) or placebo 3 times daily for 8 weeks [128]. Clinical response (decrease in Mayo Clinic score of at least 3 points and a decrease of at least 30% from baseline, with a decrease in the rectal bleeding subscore of at least 1 point or an absolute rectal bleeding subscore of 0 or 1) rates were 62.7% and 25.5% at week 8 in the AJM300 group vs. placebo group (p = 0.0002), clinical remission rates (Mayo Clinic score ≤2 and no subscore >1) were 23.5% and 3.9% in the AJM300 group vs. placebo groups (p = 0.0099), and rates of mucosal healing (endoscopic subscores of 0 or 1) were 58.8% and 29.4% (p = 0.0014) respectively. No serious adverse events, including PML were observed.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of AJM300 in children or adolescents with IBD.

Safety

AJM300 was tolerated well with incidence of adverse events that was not dose-dependent (0.0%, 23.5%, and 22.2% for AJM300 40 mg, 120 mg and 240 mg treated patients, respectively, vs. 16.7% for placebo-treated patients, p-value not reported) [127]. In the UC trial, the incidence of drug-related adverse events was 21.6% (11 of 51 patients) in the active treatment group and 7.8% (4 of 51 patients) in the placebo group, all of which were mild. The most common adverse events were nasopharyngitis and related to the underlying UC. Adverse events leading to discontinuation of the study drug included exacerbation of UC (1 patient in the active treatment group and 8 in the placebo group) and abnormality

of liver function (1 patient in the placebo group). Overall, infection, neurologic symptoms, or onset of PML was not observed in the study.

Alicaforsen

Alicaforsen (ISIS 2302) is a oligodeoxy-nucleotide that can downregulate intercellular adhesion molecule 1 (ICAM-1) expression in an RNAse H-dependent manner and thus hinder leukocyte migration and trafficking to the site of inflammation [129].

There have been three randomized, placebo-controlled trials that assessed the efficacy of alicaforsen administered intravenously [130–132] and one randomized, placebo-controlled trial that evaluated the efficacy of this agent administered subcutaneously [133] in patients with active CD.

A phase IIA, double-blind, randomized, placebo-controlled trial of 20 patients with active Crohn disease suggested the efficacy of intravenously administered alicaforsen [132]. Patients were randomly assigned to be treated with 13 infusions of either alicaforsen (0.5, 1, or 2 mg/kg, $n = 15$) or placebo ($n = 5$) over the period of 26 days with subsequent 6-month follow-up. The rates of clinical remission (CDAI <150) at the end of treatment were 47% and 20% in active drug and placebo arms, respectively (p-value not reported). ISIS 2302 showed corticosteroid sparing effect with significantly lower dose of corticosteroids over time when compared to placebo ($p = 0.0001$). Data from subsequent dose ranging pharmacokinetic trial of high-dose alicaforsen administered intravenously at the dose of 300 or 350 mg three times a week for 4 weeks in 22 patients with active Crohn disease demonstrated that 41% of patients achieved clinical remission indicating that this agent might be efficacious in treating Crohn disease. Unfortunately, large randomized, placebo-controlled trials with intravenous alicaforsen did not support these preliminary findings.

In the subsequent large clinical trial that comprised of 299 patients with active steroid dependent (prednisone 10–40 mg) Crohn disease patients were randomly assigned to intravenous treatment three times a week with either ISIS 2302 (2 mg/kg) or placebo for 2 or 4 weeks and the regimen was then repeated after 1 month without treatment [130]. The corticosteroid-free remission (CDAI <150) at week 14 (primary endpoint) was comparable between combined ISIS 2302 and placebo arms (20.2% vs. 18.8%, p-value not reported). On the other hand, a significantly greater proportion of patients receiving ISIS 2302 than placebo had successful corticosteroids withdrawal at week 14 (78% vs. 64%; $P = 0.032$). According to pharmacodynamic analysis, statistically significant results for clinical remission, improvement in CDAI and quality of life based on IBD questionnaire were observed in the highest area under the curve subgroup of ISIS 2302 arm when compared to placebo. Finally, data from two double-masked, placebo-controlled trials of patients with Crohn disease who received intravenous treatment with either alicaforsen ($n = 221$) or placebo ($n = 110$) three times a week for 4 weeks did not show any benefit of alicaforsen over placebo in achieving clinical remission at week 12 with respective remission rates of 33.9% and 34.5% ($P = 0.89$) [131]. Subcutaneous administration of alicaforsen also did not demonstrate any superiority over placebo in achieving clinical remission in patients with Crohn disease. Schreiber et al. randomized 75 patients with corticosteroid-refractory Crohn disease to subcutaneous treatment with either ISIS 2302 or placebo [133]. The primary endpoint, corticosteroid-free remission at week 14 (CDAI <150) was observed in 3.3% of ISIS-2302-treated and 0% of placebo treated patients. On the other hand, there was a trend towards efficacy of ISIS 2302 in achieving one of the secondary endpoints, namely corticosteroid-free remission at week 26 (13.3% vs. 6.7%, p-value not reported). Similarly, a greater proportion of patients receiving active drug when compared to placebo achieved a corticosteroid dose <10 mg/day at week 14 (48.3% vs. 33.3%) and week 26 (55.0% vs. 40.0%) and a prednisone equivalent dose of 0 mg at week 26 [23.3% vs. 6.7%, respectively].

There have been three randomized, placebo-controlled trials assessing the efficacy of alicaforsen enemas in patients with active left-side UC [134–136].Van Deventer et al. performed a randomized, placebo-controlled trial of alicaforsen enema in 40 patients with mild to moderately active distal UC who received 60 mL of alicaforsen enema (0.1, 0.5, 2, or 4 mg/mL) or placebo once daily for 28 consecutive days [136]. There was observed a significant dose-dependent reduction in disease activity index in patients treated with active drug than placebo at day 29 that was observed for alicaforsen given at the highest dose 4 mg/mL (70% vs. 28%, $P = 0.004$). After 3 months alicaforsen 2 mg/mL and 4 mg/mL caused significant reduction in disease activity index when compared to placebo by 72% and 68%, respectively (vs. 11.5% for placebo, $P = 0.016$ and 0.021, respectively). In the subsequent phase II dose ranging, double-blind, placebo-controlled study of alicaforsen enema (120 mg daily for 10 days, then every other day; 240 mg every other day; 240 mg daily for 10 days, then every other day; 240 mg daily) given daily for 6 weeks in 112 patients presenting with acute exacerbation of mild to moderate left-sided UC there was no significant difference observed between active drug and placebo in reduction of disease activity index at week 6 [134]. However, a greater proportion of patients receiving alicaforsen 240 mg daily had prolonged clinical improvement at week 18 (51% vs. 18%) and week 30 (50% vs. 11%) when compared to placebo. Finally, Miner et al. compared two dose formulations of alicaforsen enema (120 mg or

240 mg) with 4 g mesalamine enema given for 6 weeks in 159 patients with mild to moderate left-sided UC [135]. There was no difference observed between treatment arms in reduction of disease activity index at week 6 with reduction in mean disease activity index when compared to baseline of 50% for the mesalamine arm and 40% and 41% for the 120 and 240 mg alicaforsen groups (P = 0.27 and 0.32, respectively). However, higher dose of alicaforsen enema was significantly more efficacious than mesalamine in achieving clinical remission at week 18 (20% vs. 6%, P = 0.03).

An open-label study of alicaforsen enema given at daily dose of 240 mg for 6 weeks to 15 patients with active UC showed a 46% reduction in mean disease activity index and 33% rate of complete mucosal healing at the end of treatment [137]. In addition, alicaforsen concentrations were greater in mucosal colonic tissue biopsies than those observed in plasma suggesting that alicaforsen enemas allow for achieving high local concentrations with little systemic exposure. Another open-label study of 12 patients with chronic pouchitis following an ileal pouch-anal anastomosis for UC showed that alicaforsen enemas given at dose of 240 mg daily for 6 weeks resulted in significant reduction in the mean pouchitis disease activity index from baseline value of 11.42 points to 6.83 points at 6 weeks (P = 0.001) [138].

In summary, clinical trials of an intravenous formulation in Crohn disease showed no significant treatment effect with alicaforsen compared to placebo. After 6 weeks of treatment, topical alicaforsen has significantly more effective than placebo in inducing remission in patients with moderate-severe distal UC, with treatment effects lasting up to 30 weeks. No difference has been seen in head-head comparison with mesalamine topical enema, although alicaforsen appears to have more durable treatment effect. An open-label trial in alicaforsen for pouchitis demonstrated encouraging results, and it is now being assessed in a multi-national phase 3 trial. No major safety signals have been observed in UC patients treated with alicaforsen enemas. Its promising signals as a novel therapy, have led to a Fast-Track and orphan designation for this indication by the Food and Drug Administration and European Medicines Agency [139].

Pediatric Data

At the time of writing this chapter there are no published data on the use of alicaforsen in children or adolescents with IBD.

Safety

Data from a large trial of 331 patients treated with intravenous alicaforsen or placebo showed that the only adverse events that occurred in greater proportion of patients treated with alicaforsen were symptoms related to infusion reactions such as fever (22.6% vs. 14.7%, p-not significant), chills (14% vs. 1.8%, P = 0.0005), and myalgia (5.4% vs. 0.92%) [131]. Data from the second largest trial of 299 patients with Crohn disease receiving alicaforsen or placebo intravenously showed that the only adverse events that occurred in significantly greater proportion of patients treated with active drug than placebo were infusion reactions described as transient facial flushing or a feeling of warmth during infusion (11.6% vs. 4%, P = 0.03) [130]. There was a significantly greater average transient aPTT increase without bleeding sequelae (8.66 s vs. 0.8 s, P + 0.0001) after alicaforsen than placebo infusion. Safety analysis of alicaforsen administered subcutaneously in the largest trial of 75 patients determined that injection site reactions, headache, pain, fever, rash, arthritis, asthenia, and flu-like symptoms injection site reactions occurred in greater proportion of patients treated with active drug than placebo with injection site reactions demonstrating the largest difference (23.3% vs. 0%, p-value not reported) [133].

Gastrointestinal complaints were associated with the alicaforsen enemas in a dose-dependent fashion. Community-acquired pneumonia and sinusitis were also reported and were associated with the study drug [134, 136–138].

Abrilumab

Abrilumab (AMG181) is a human monoclonal IgG2 antibody that specifically binds to α4β7 heterodimers.

In a phase 2b, placebo-controlled, double-blind study that evaluated the efficacy and safety of the anti-$\alpha_4\beta_7$ antibody abrilumab in patients with moderate-to-severe UC despite treatment with conventional therapies, 354 patients were randomized to receive subcutaneous abrilumab (7, 21, or 70 mg) on day 1, weeks 2 and 4, and every 4 weeks; abrilumab 210 mg on day 1; or placebo [140]. Those who received ≥1 dose of investigational product (placebo, n = 116; 7 mg, n = 21; 21 mg, n = 40; 70 mg, n = 98; 210 mg, n = 79), non-adjusted rates of remission (total Mayo Score ≤2 points, no individual sub-score >1 point) at week 8 were 4.3%, 13.3%, and 12.7% for the placebo and abrilumab 70-mg and 210-mg groups, respectively (P < 0.05 for 70 and 210 mg vs placebo). Response and mucosal healing rates with these dosages also were significantly greater than with placebo and while higher baseline $\alpha_4\beta_7$ levels on naïve $CD4^+$ T cells were a prognostic indicator for overall outcome, it was not a predictive biomarker of abrilumab response.

In a Japanese study, 45 UC patients were randomized to abrilumab 21 mg (n = 11), 70 mg (n = 12), 210 mg (n = 9), or placebo (n = 13) via subcutaneous (SC) injection for 12 weeks. The double-blind period was followed by a 36-week open-label period, in which all patients received

abrilumab 210 mg SC every 12 weeks, and a 28-week safety follow-up period [141]. Week 8 clinical remission rates were 10%, 16.7% and 11.1% for abrilumab 21 mg, 70 mg and 210 mg groups vs. 0 in the placebo arm.

A phase 2b, randomised, multi-centre, double-blind, placebo controlled study enrolled 249 patients with moderate to severe CD and biochemical/endoscopic evidence of active inflammation, with prior failure with anti-TNF therapy or corticosteroids and data was presented at the ECCO meeting [140]. Patients were randomised to receive placebo or abrilumab (21 or 70 mg) SC on day 1, weeks 2 and 4, and every 4 weeks (Q4W) for up to 24 weeks, or one dose of abrilumab 210 mg SC on day 1. The results were impacted by a systematic misalignment in investigational product, however the study blind and randomisation remained intact. Statistically significant improvement was not achieved between the abrilumab 70 mg Q4W and placebo arms for the primary endpoint of CDAI remission (score <150) at week 8 ($p = 0.76$). However, higher rates of remission and response were observed in the active treatment arms at week 12, particularly in patients with prior failure of TNF antagonists assigned to the 210 mg abrilumab group. Abrilumab induced a significant post-dose increase in α4β7-high central memory CD4+ T cell counts between baseline and week 8. Adverse events were similar among treatment groups through week 24, with no cases of PML or deaths. No No neutralizing antibodies to abrilumab were detected.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Abrilumab in children or adolescents with IBD.

Firategrast

Firategrast (SB 683699) is an orally bioavailable small molecule α4β1 and α4β7 integrin antagonist [142]. A phase II study evaluating the effectiveness and safety of Firategrast in treating subjects with moderately to severely active CD has been completed. Results are not available [143].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of Firategrast in children or adolescents with IBD.

TRK-170

TRK-170 is a novel orally active α4β1 and α4β7 integrin antagonist [144]. A study evaluated the effect of TRK-170, as compared to an anti-alpha4 antibody and prednisolone, on 2, 4, 6-trinitrobenzene sulfonic acid (TNBS)-induced colitis. Oral administration of TRK-170 significantly inhibited the increase of macroscopic damage scores. TRK-170 also reduced the elevation of myeloperoxidase activity in colons, and the increase in colon weight. Efficacy of TRK-170 is almost comparable to the anti-alpha4 antibody and prednisolone at this dosage and dose regimen. Detailed mechanisms of action of TRK-170, such as potential effects on immune cells, are being characterized. These results indicate that TRK-170 is expected to provide an attractive approach for the future therapy of IBD. Because TRK-170 is orally active unlike anti-alpha4 antibody, TRK-170 may be more beneficial than the antibody.

A 2 part, multi-centre, randomized, placebo-controlled, double-blind study to evaluate the efficiacy, safety and pharmacokinetics of TRK-170 in CD has been completed and the results are awaited.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of TRK-170 in children or adolescents with IBD.

GLPG0974

Free fatty acids (FFA) act as inflammatory signaling molecules through receptors such as FFA2, which is activated by short chain fatty acids (SCFA). Through FFA2, SCFAs induce neutrophil activation and migration. In IBD patients, FFA2 expression is up-regulated in the colon. GLPG0974 is a potent and selective antagonist of FFA2, inhibiting SCFA-induced neutrophil migration and activation in vitro.

In a 4-week, first-in-UC study with GLPG0974 in patients with mild to moderate UC, GLPG0974 was well tolerated and safe. Biomarkers (MPO and FC) indicate that GLPG0974 reduces neutrophil activation and influx, suggesting a role for FFA2 in neutrophil migration in UC. The reduction in neutrophil influx is not sufficient to induce a measurable clinical difference between GLPG0974 treated patients and placebo within 4 weeks [145]. An exploratory, phase II, randomized, double-blind, placebo-controlled, proof-of-concept study to evaluate the safety, tolerability, efficacy, pharmaco-

kinetics and pharmacodynamics of GLPG0974 in subjects with mild to moderate UC has been completed, but the results are yet to be released [146].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of GLPG0974 in children or adolescents with IBD.

Administration of Anti-Inflammatory Cytokine

Interleukin-10 (IL-10)

Interleukin-10 is secreted by T helper cells, B cells, monocytes, macrophages, dendritic cells and keratinocytes. It suppresses inflammation by reducing HLA class I expression decreasing secretion of IL-2 and diminishing production of IL-1α, Il-1β, IL-6, IL-8, and TNF-α. The recombinant human rHuIL-10 may be administered subcutaneously, intravenously, or orally via a genetically modified *Lactococcus lactis* (LL-Thy12).

A randomized, double-blind, placebo-controlled phase IIa trial by Van Deventer et al. suggested that intravenous bolus of recombinant human IL-10 once daily for 7 consecutive days (rhu-IL-10) might be efficacious for the treatment of active Crohn disease [147]. Among 46 patients with active steroid-resistant Crohn disease who were treated with rhu-IL-10 (0.5, 1, 5, 10, or 25 μg/kg) or placebo 50% treated with active drug and 23 who received placebo achieved a complete remission (decrease in baseline CDAI <150 and >100-point decrease in CDAI when compared to baseline) at any time during 3-week follow-up (*p*-value not reported). The second randomized, placebo-controlled trial of subcutaneous rhuIL-10 (1, 5, 10, or 20 μ/kg) given for 28 consecutive days with subsequent 20-week follow-up in 95 patients with active Crohn disease observed that only rhu-IL-10 administered at dose 5 μg/kg showed benefit over placebo with 23.5% (CI, 6.8–49.9%) and 0% (CI, 0–14.8%) rates of complete remission (CDAI <150 and at ≥100 point decrease in CDAI from baseline with improvement or resolution in on endoscopy) measured on day 29 [147].

A double-blind, placebo-controlled phase III trial of 329 patients with chronic, active and refractory to corticosteroids Crohn disease randomly allocated patients to receive subcutaneous injections with either rhu_IL-10 (1, 4, 8, or 20 μ/kg) or placebo daily for 28 days [148]. There was no significant difference between any of rhu-IL-10 dose and placebo in inducing primary endpoint, clinical remission (CDAI ≤150 with concomitant decrease in CDAI ≥100 points from baseline) with rates of 18% for dose 1 μg/kg ($P = 0.79$ vs. placebo), 20% for dose 4 μg/kg ($P = 0.76$), 20% for dose 8 μg/kg ($P = 0.76$), 28% for dose 20 μg/kg ($P = 0.17$) when compared to 18% for placebo-treated patients. There was a significant superiority in achieving clinical improvement (decrease in CDAI ≥100 points when compared to baseline) in patients who received rhu-IL-10 at the dose 8 μg/kg when compared to placebo (46% vs. 27%, $P = 0.034$).

A subsequent randomized, double-blind, placebo-controlled phase III trial (published only in an abstract form) assessed the efficacy of rhu-IL-10 in 373 patients with corticosteroid-dependent Crohn disease who received once daily subcutaneously for 2 weeks then 3 times per week for 26 weeks either rhu-IL-10 (4 μg/kg or 8 μg/kg) or placebo [149]. Rhu-IL-10 4 μg/kg or 8 μg/kg was not statistically significant more efficacious than placebo in achieving the ability to discontinue corticosteroids by 16 weeks and to maintain clinical remission (CDAI<150) by week 28 with respective rates of 25%, 32%, and 29% (*p*-value not reported).

Colombel et al. analyzed 65 patients with Crohn disease after curative ileal or ileocolonic resection and primary anastomosis who were randomized within 2 weeks after surgery to subcutaneous injections of either rhu-IL-10 4 μg/kg once daily, rhu-IL-10 8 μg/kg twice weekly or placebo and were followed-up for 12 weeks [150]. Of 65 patients 58 underwent endoscopy at the end of follow-up that showed that 46% of patients treated with active drug and 52% of placebo recipients had recurrent lesions (*p* not significant).

Successful treatment of a murine model of colitis with *L. lactis* secreting interleukin-10 has been reported [131]. A pilot Phase Ia study has demonstrated the potential of a genetically modified *L. lactis* (LL-Thy12) given orally at the dose of 10 capsules with 1 × 10 [10] colony-forming units (CFU) of LLThy12 twice daily for 7 days to 10 patients with active Crohn disease [151]. Clinical benefit was observed in 8 of 10 patients with 5 patients achieving complete remission (CDAI <150) and 3 patients experiencing clinical response (decrease in CDAI >70). Future clinical trials are needed to validate these preliminary findings.

Pediatric Data

At the time of writing this chapter, there is no published data on the use of rhu-IL-10 in children or adolescents with IBD.

Safety

The only clinical trial that assessed safety of intravenously administered rhu-IL-10 observed similar proportion of

adverse events between active drug and placebo arms [147]. The only exception was the abdominal pain that was reported in 9% of patients receiving rhu-IL-10 and 31% of placebo recipients. Data from 329 patients with Crohn disease who were treated with either rhu-IL-10 (n = 262) or placebo (n = 66) provided the largest population of patients that was assessed for safety of rhu-IL-10 and showed that both active drug and placebo arms had comparable proportion of adverse events (95% vs. 94%) [148]. The only events that occurred in greater proportion of patients treated with rhu-IL-10 than placebo were headache (P = 0.02), fever (P = 0.02), back pain (P = 0.01), decrease in hemoglobin concentration (P = 0.0007), dizziness (P = 0.005), and thrombocytopenia (P = 0.0006) [127]. Severe adverse events were observed in 28% 17% of patients treated with rhu-IL-10 and placebo, respectively (P = 0.057). A dose-dependent decrease in hemoglobin of unknown mechanism occurred in 33% of patients treated with rhuIL-10 at the dose of 20 μg/kg when compared to 8% of placebo patients (P = 0.0003). Thrombocytopenia of unknown mechanism was also observed in greater proportion of patients receiving rhuIL-10 at the dose 8 μg/kg (6, P = 0.04) and rhuIL-10 at the dose 20 μg/kg (27%, P < 0.0001) when compared to 0% among placebo recipients. All hematologic abnormalities were reversible upon cessation of study medication. Reversible anemia and thrombocytopenia are common, as are mild to moderate headaches, fever, back pain, diarrhea, arthralgias, and dizziness. Antibodies to IL-10 have not been detected [147, 150].

Blockade of T Cell Stimulation and Induction of Apoptosis

Laquinimod

Laquinimod is an oral agent that produces anti-inflammatory effects by modulating immune cells with result of reduced synthesis of several cytokines.

A phase IIa trial was performed using different doses of laquinimod (0.5, 1, 1.5, or 2 mg/day) for 8 weeks in patients with active Crohn disease [152]. Clinical remission rates at week 8 were as follows: 48.3, 26.7, 13.8, and 17.2% of patients receiving 0.5, 1, 1.5, and 2 mg laquinimod versus 15.9% placebo. This may be an effective treatment of Crohn disease and further studies are needed.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of laquinimod in children or adolescents with IBD.

Safety

Overall, induction treatment with laquinimod was tolerated and the most common adverse effects were headache, abdominal pain, nausea, vomiting, and musculoskeletal pain [152].

Cobitolimod (DIMS0150)

DNA-based immunomodulatory sequence (DIMS0150) is a single-stranded partially modified synthetic oligonucleotide of 19 bases in length and activates the Toll-Like Receptor 9 (TLR9) present in immune cells such as T and B cells, macrophages and plasmacytoid dendritic cells (pDCs) that are found in abundance on mucosal surfaces such as the colonic mucosa. In experimental colitis models, administration of DIMS0150 has resulted in marked suppression of colitis, with microarray analysis showing mucosal IL10 upregulation and suppression of IL17 pathways via activation of TLR9 [153]. The drug has also interestingly been shown to increase steroid sensitivity in steroid resistant UC patients and human monocytes [154]. Administration of DIMS0150 in the form of an enema in steroid-refractory subjects with UC allows the drug to come into direct contact with a large number of target cells harboring the TLR9 receptor and has been shown to be beneficial in steroid refractory patients with UC.

In a study where a single dose of DIMS0150 was given to steroid unresponsive IBD patients on concomitant steroid therapies, single doses of 3 and 30 mg were effective in inducing a clinical response [155]. Five of seven patients (70%) that received active treatment had a clinical response 1 week after therapy and after more than 8 years, two remained in glucocorticoid free remission.

In a phase II study, 151 patients with mild or moderately active UC were given DIMS0150 as a single rectal dose at one of four dose levels (0.3, 3, 30, and 100 mg) with the hopes of inducing clinical remission. No significant benefit was demonstrated at any dose level.

In a randomized, double-blind, placebo-controlled trial (COLLECT study) conducted in 131 patients with moderate to severe UC, patients were randomized to receive two topical endoscopic administrations of cobitolimod at a dosage of 30 mg at baseline and week 4, or placebo [156]. There was no statistical difference in clinical remission, (44.4% of cobitolimod treated patients vs. 46.5% of those treated with placebo). More patients treated with cobitolimod compared to placebo had mucosal healing [34.6% vs. 18.6%; p = 0.09] and histological improvement (defined by the Geboes score of 0–2) [30.9% vs. 9.3%; p = 0.0073] at Week 4. Overall the drug showed no safety signals compared with placebo and was well tolerated.

Currently, a phase 2 study (CONDUCT) comparing different doses and different administration intervals of cobito-

limod in an enema formulation over 12 weeks is being conducted in moderate to severe UC patients [157].

Safety Data

Altogether, agonists of the Toll-like receptor-9 appeared safe and well-tolerated in moderate to severe UC patients and could represent a novel promising therapeutic option for the management of UC patients.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of DIMS0150 in children or adolescents with IBD.

Monarsen

Monarsen (BL 7040) is a TLR9 modulator that is orally administered and in a prospective multicenter phase 2a study in patients with moderately active UC it was investigated at doses of 12 mg once daily for 3 weeks followed by 40 mg once daily for 2 weeks [158]. Clinical remission was seen in 12.5% patients (2/16). Clinical response as well as mucosal healing were achieved in 50% of the patients.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of BL7040 in children or adolescents with IBD.

Safety

Total of 29 adverse events were reported in 16 patients (72.7%) in the phase 2a study discussed above, of which 10 were considered drug related [158]. Most common AEs were exacerbation of UC and influenzalike illness.

Sphingosine-1-Phosphate Receptor Modulators

S1P (sphingosine-1-phosphate) is a bioactive sphingolipid and its concentration gradient (between tissues and blood) regulates lymphocyte recirculation [159]. In order for lymphocytes to leave lymph nodes, the S1P receptors on the surface of the lymphocyte must bind to S1P and S1P modulators cause the S1P receptors on the surface of lymphocytes to be internalized and degraded, blocking lymphocyte egress from lymph nodes. As a result lymphocytes are trapped in lymph nodes resulting in a reduction of the peripheral lymphocyte count and circulating effector T cells making fewer immune cells available in the circulating blood to effect tissue damage. S1P receptor agonism is a novel strategy for the treatment of inflammatory conditions and success in clinical trials led to the approval of the non-selective S1P modulator, fingolimod, for relapsing forms of multiple sclerosis. However, given the association of this non-selective S1P modulator with serious adverse events, the development of more selective S1P receptor modulators has since gained focus, including etrasimod (APD334), ozanimod (RPC1063) and amiselimod (MT-1303). The development of amiselimod has since been discontinued by the developer to focus on other drugs in their portfolio. The S1P receptor agonists offer the advantage of being orally administered and might avoid triggering the formation of anti-drug antibodies [160].

Etrasimod

Etrasimod (APD334), an orally available $S1P_1$ receptor modulator, discovered by Arena Paramaceuticals, has therapeutic potential in autoimmune diseases such as UC.

In a phase 2, proof-of-concept, double-blind, parallel-group study, conducted across 87 centers in 17 countries, adult outpatients with moderately to severely active UC were randomly assigned to groups given once-daily etrasimod 1 mg (n = 52), etrasimod 2 mg (n = 50), or placebo (n = 54) for 12 weeks [161]. The primary endpoint was an increase in the mean improvement in modified Mayo clinical score (MCS) from baseline to week 12. Secondary endpoints included the proportion of patients with endoscopic improvement (subscores of 1 or less) from baseline to week 12. At week 12, the etrasimod 2 mg group met the primary and all secondary endpoints. Etrasimod 2 mg led to a significantly greater increase in mean improvement in modified MCS from baseline than placebo, while the 1 mg dose showed no significant difference. Endoscopic improvement occurred in 41.8% of patients receiving etrasimod 2 mg vs 17.8% receiving placebo (P = 0.003). Currently, 3 phase 3 trials ranging from 12 to 52 weeks for evaluating the efficacy of etrasimod for moderate to severely active UC [162–164] and a phase 2b trial to assess the efficacy and safety of etrasimod as induction therapy for moderate to severely active CD are actively ongoing [165].

Pediatric Data

At the time of writing this chapter, there are no published data on the use of etrasimid in children or adolescents with IBD.

Safety

In the phase 2 UC study, among the 102 patients who received etrasimod, three patients experienced asymptom-

atic, low-grade atrioventricular block which was tranisent and resolved spontaneously [165]. These patients also had evidence of atrioventricular block prior to etrasimod exposure. All other reported adverse events were mild to moderate.

Ozanimod

Ozanimod (RPC1063) is an oral selective agonist for S1P receptors 1 and 5 and has been shown in phase II studies to be effective for the treatment of both multiple sclerosis and UC [166]. The US Food and Drug Administration (FDA) has approved ozanimod (Zeposia) for adults with moderately to severely active ulcerative colitis (UC). (Reference: https://www.accessdata.fda.gov/drugsatfda_docs/label/2021/209899s001lbl.pdf).

The UC TOUCHSTONE phase II study evaluated the safety and efficacy of 0.5 and 1 mg RPC1063 compared to placebo and after the 8-week induction period, there was a continuing maintenance period for responders [167]. One hundred and ninety-seven patients with moderate to severe UC (Mayo score of 6–12 with an endoscopic subscore 2). The primary endpoint of clinical remission (Mayo score 2, no subscore >1) at week 8 was 16.4% for high dose ($P = 0.048$ versus placebo), 13.8% for low dose ($P = 0.14$), and 6.2% for placebo. Ninety-five percent of patients completed the induction portion of the study. Clinical response (reduction in Mayo score of 3 and 30% with a decrease in the rectal bleeding score of 1 or a rectal bleeding score 1) was 56.7% for high dose ($P = 0.01$), 53.8% for low dose ($P = 0.06$), and 36.9% for placebo. Mucosal improvement (endoscopy score 1) was 34.3% for high dose ($P = 0.002$), 27.7% for low dose ($P = 0.03$), and 12.3% for placebo. The improvement in Mayo score from baseline was 3.3 points for high dose ($P = 0.003$), 2.6 points for low dose ($P = 0.098$), and 1.9 for placebo. The trial was thought to be not large enough or of sufficiently long duration to establish clinical efficacy or assess safety.

In the STEPSTONE phase 2 uncontrolled, multicenter clinical trial in adults with moderate to severely active CD recruited from 28 hospitals across North America and Europe, where 69 patients began treatment with a 7-day dose escalation (4 days on ozanimod 0·25 mg daily followed by 3 days at 0·5 mg daily), followed by 1 mg oral capsule daily for a further 11 weeks, for a 12-week induction period, and finally a 100-week extension. The primary endpoint was a change in Simple SES-CD from baseline to week 12 [168]. At week 12, the mean change from baseline in SES-CD was -2·2 and 16 (23·2%) patients experienced endoscopic response.

Currently, there is a Phase 2/3 trial to evaluate the efficacy and long-term safety of ozanimod in Japanese subjects with moderate to severe UC [169] and multiple ongoing phase 3 studies in patients with moderate to severe CD [170–172].

Recently, data was presented on the TRUE NORTH data. [173].

There were two components of the trial reported, the induction phase and the maintenance phase of the trial. The 10-week induction period findings from this phase 3, randomized, double-blind study in patients with moderate-to-severely active ulcerative colitis (True North; NCT02435992) were enrolled. Results from the maintenance period were remarkable and are reviewed separately below.

In the TRUE NORTH study adult patients with moderate-to-severely active ulcerative colitis (total Mayo score 6-12 with a Mayo endscopy score ≥2 on oral aminosalicylates or corticosteroids) were randomized 2:1 to receive ozanimod HCl 1 mg (equivalent to ozanimod 0.92 mg) or placebo once daily (stratified by prior tumor necrosis factor inhibitor [TNFi] and corticosteroid use at screening) during a 10-week induction period. The primary endpoint was the proportion of patients in clinical remission per the 3-component Mayo score at week 10. Ranked secondary endpoints were the proportions of patients with a clinical response, endoscopic improvement, and mucosal healing.

This trial enrolled a total of 645 patients to receive ozanimod ($n = 429$) or placebo ($n = 216$), of whom 94% and 89%, respectively, completed the induction period. All primary and key secondary efficacy endpoints showed statistically significant improvements with ozanimod vs placebo at week 10. For the primary endpoint, 18.4% and 6.0% of patients in the ozanimod and placebo groups, respectively, achieved clinical remission at week 10 (absolute difference 12.4% [95% CI, 7.5-17.2]; $P < 0.0001$). Key secondary endpoints of clinical response ($P < 0.0001$), endoscopic improvement ($P < 0.0001$), and mucosal healing ($P < 0.001$) were also statistically significant for ozanimod vs placebo. In patients with prior TNF-inhibitor exposure, clinical remission results favored ozanimod over placebo but this was not statistically significant, while a nominally statistically significant difference was observed for clinical response. The most common treatment-emergent adverse events (TEAEs) for patients who received ozanimod vs placebo, respectively, were anemia (4.2% vs 5.6%), nasopharyngitis (3.5% vs 1.4%) and headache (3.3% vs 1.9%). Cardiovascular events were infrequent and included bradycardia (0.5% vs 0%) and hypertension (1.4% vs 0%). The frequency of serious TEAEs were 4.0% vs 3.2%, respectively, and serious infections occurred in <1% in each group. No cases of progressive multifocal leukoencephalopathy were reported in the trials. Thus the overall conclusion from the induction phase of the trial was that Ozanimod treatment for 10 weeks in patients with

moderate-to-severe UC led to statistically significant improvements in clinical remission, clinical response, endoscopic improvement, and mucosal healing. Safety findings were consistent with ozanimod's known profile and in a moderate-to-severe UC study population; no new safety signals were observed with ozanimod in this study.

In this trial, patients who had demonstrated the presence of a clinical response after 10 weeks to treatment with ozanimod induction therapy were enrolled in a maintenance arm. These patients were offered and followed as double-blind and open-label cohorts to be re-randomized 1:1 to double-blind maintenance treatment with ozanimod HCl 1 mg/day (equal to ozanimod 0.92 mg) or matching placebo. The efficacy and safety of ozanimod vs placebo at week 52 in the maintenance period of a randomized, double-blind, phase 3 study in patients with moderate-to-severe UC (True North; NCT02435992) will now be reviewed [174].

Patients were stratified by clinical remission status and corticosteroid use at week 10. Endpoints were assessed at week 52 and tested sequentially via closed hierarchical procedure. The primary endpoint was the proportion of patients in clinical remission per 3-component Mayo score. Ranked key secondary endpoints were assessment of the proportions of patients with clinical response, endoscopic improvement, maintenance of clinical remission, corticosteroid-free remission, mucosal healing (both endoscopy and histology), and durable clinical remission. Data were also analyzed by prior tumor necrosis factor inhibitor (TNFi) use.

Overall, a total of 457 patients were re-randomized to maintenance treatment with either ozanimod ($n = 230$) or placebo ($n = 227$). Of these, 80% and 54.6% of patients who received ozanimod and placebo, respectively, completed the study. In this study disease relapse (13.5% ozanimod, 33.9% placebo) was the most common reason for discontinuation of ozanimod. All primary and key secondary efficacy endpoints showed statistically significant improvements with ozanimod vs placebo at week 52 . Ozanimod resulted in a significantly higher clinical remission rate vs placebo (37.0% vs 18.5%; difference: 18.6% [95% CI, 10.8-26.4]; $P < 0.0001$). Significant results were also observed in all key secondary endpoints; clinical response ($P < 0.0001$), endoscopic improvement ($P < 0.001$), maintenance of remission ($P < 0.0047$), corticosteroid-free remission ($P < 0.001$), mucosal healing ($P < 0.001$), and durable remission ($P = 0.003$). Clinical remission and response also improved with ozanimod regardless of previous TNF inhibitor use. The most common treatment-emergent adverse events (TEAEs) for ozanimod vs placebo, respectively, were alanine aminotransferase increase (4.8% vs 0.4%; no serious events), and headache (3.5% vs 0.4%). Frequency of possible, probable, or related serious TEAEs was low (≤1% in both groups). The autors of this study thus concluded that patients with moderate-to-severe UC treated with ozanimod for up to 52 weeks in this study demonstrated clinically relevant and statistically significant benefits on clinical, endoscopic, and mucosal healing endpoints. No new safety signals were observed for ozanimod.

Pediatric Data

At the time of writing this chapter, there are no published data on the use of ozanimod in children or adolescents with IBD.

Safety

In the UC Touchstone study no differences in adverse events were observed between the treatment and placebo groups [167]. Four patients in ozanimod group had an elevated alanine aminotransferase >3 times upper limit of normal. In the STEPSTONE trial, the most commonly reported serious treatment-related adverse events were Crohn disease (9%) and abdominal abscess (3%) [168].

Oligonucloetides

Antisense oligonucleotides (ASOs) or synthetic oligonucleotides comprise novel drugs which could act as therapies against precise pro-inflammatory molecular targets to avoid unwanted systemic side effects [175, 176]. Their molecular action spans a range and includes inhibition of the translational process of mRNA transcripts of pro-inflammatory molecules, to mimicking bacterial DNA which can activate cellular targets for immunomodulation. A few of these agents have been discussed already (Alicaforsen: selectively targets ICAM-1 mRNA, Mongersen: against SMAD7 mRNA, cobitolimod: mimics bacterial DNA by activiating Toll-like receptor 9 on different immune cells). Two additional agents under investigation are discussed below.

GATA3 DNAzyme

Th17 cells are a subset of lymphocytes which play a major role in intestinal inflammation in both CD and UC [177]. The GATA3 specific DNAzyme (SB010) is an oligonucleotide which can mediate the cleavage of the mRNA of the transcription factor GATA3 and a study conducted with intestinal biopsies of UC patients as well as murine models of colitis showed a correlation between the expression of the transcription factor GATA3 and the production of inflammatory Th2 and Th9 related cytokines. Conditional GATA3 deficiency in T cells prevented experimental colitis in mice [178]. Intrarectal administration of a GATA3 specific DNAzyme (hgd40) significantly ameliorated colitis in murine colitis models.

A phase 2a study of this novel drug as an enema formulation (SECURE study) in patients with moderate to severe UC has recently been completed and the results are awaited [179].

STNM01

Nearly one-third of patients with CD and 5% of UC patients are diagnosed with fibrotic stenosis during their clinical course [180]. Carbohydrate sulfotransferase 15 (CHST15) is an intracellular enzyme that mediates the biosynthesis of sulfated matrix glycosaminoglycans which can induce fibrotic reactions in IBD patients. STNM01 is a novel double-strand RNA oligonucleotide that selectively blocks the expression of CHST15 mRNA and can inhibit the excessive production of glycosaminoglycans in the colon by fibroblasts [181].

A subsequent phase 1 placebo-controlled trial recruited 18 CD patients, with mucosal ulcerative lesions refractory to conventional therapy and randomized them to receive a single endoscopic submucosal injection of STNM01 (2.5, 25, or 250 nM) or placebo, administered at 8 sites directly surrounding the bigger ulcer [182].STNM01 was able to reduce day 30 segmental SES-CD score and induce a reduced extension of fibrosis per histologic analysis, compared to placebo, along with a good safety profile.

Miscellaneous Agents

Apremilast (CC-10004)

Phosphodiesterase 4 (PDE4) enzyme is responsible for lysis of cyclic adenosine monophosphate (cAMP) in inflammatory cells and thereby regulates the inflammatory response by increasing production of proinflammatory mediators (eg TNF-α and IL-23) and decreasing production of anti-inflammatory mediators (eg IL-10) in IBD patients [183]. Apremilast is an oral small-molecule inhibitor of PDE4 and dose of 30 mg twice daily is approved for treatment of patients with active psoriatic arthritis, moderate to severe plaque psoriasis, or oral ulcers associated with Behçet's disease.

A double-blind, phase 2 trial recruited UC patients from 14 countries and randomized them to apremilast 30 mg ($n = 57$), apremilast 40 mg ($n = 55$), or placebo ($n = 58$) twice daily for 12 weeks, followed by random assignment to groups that received apremilast, 30 or 40 mg twice daily, for an additional 40 weeks [184]. Clinical remission at 12 weeks was achieved in 31.6%, 21.8% and 12.6% of patients in the apremilast 30 mg, 40 mg and placebo arms (p = 0.01 for placebo vs. 30 mg and $p = 0.27$ for placebo vs. 40 mg). At week 52, clinical remission was achieved by 40.4% of patients initially assigned to the apremilast 30 mg group and 32.7% of patients initially assigned to the apremilast 40 mg group. The most frequent apremilast-associated adverse events were headache and nausea.

No additional pediatric or adult studies of apremilast for IBD patients are currently in progress.

RDP58 (Delmitide Acetate)

RDP58 also known as delmitide acetate, is a drug that disrupts cell signaling responsible for production of pro-inflammatory cytokines via the mitogen-activated protein kinase superfamily, which have been shown to be significantly activated in the inflamed colonic mucosa of IBD patients [185]. In two phase 2 studies that enrolled patients with mild to moderate UC and compared varied doses of RDP58 100 mg, 200 mg, 300 mg vs. placebo; while primary and secondary endpoints were not met with the 100 mg dose, treatment success was noted with increasing doses 71% and 72% for the 200 mg and the 300 mg dose respectively when compared to 43% for placebo ($P = 0.016$) and the study drug was well tolerated [186].No further clinical trials evaluating RDP58 in IBD are currently planned.

LT02

One hypothesis for explain the increased susceptibility to inflammation and ulcers in UC patients has been the low intrinsic phosphatidylcholine content that reduces intestinal mucus barrier function [187]. LT02 is a modified release phosphatidylcholine, administered as an oral agent to stabilize the gut barrier. In a phase 2 trial of 156 UC patients with prior inadequate response to mesalazine, randomization to placebo, 0.8, 1.6 or 3.2 g of phosphatidylcholine was done [188]. Simple clinical colitis activity index score change for placebo, 0.8, 1.6 and 3.2 g was 33.3%, 44.3% and 51.7% respectively and The 3.2 g dose was statistically superior when compared to placebo at 51.7% compared to 33.3% ($P = 0.03$). Histological remission for placebo and all phosphatidylcholine doses was 20% compared to 40.5% ($P = 0.016$). LT02 was also found to be well tolerated. However, since then two phase III trials have been terminated; one due to failure to induce remission and the second for reasons unknown. Another phase III trial comparing phosphatidylcholine to placebo and mesalamine for maintenance of remission in UC has been completed and results are awaited [189].

LYC-30937-EC

This is a first-in-class, oral, gut-directed ATPase modulator, that selectively targets and induces apoptosis in pro-inflammatory T-lymphocytes. A randomized, double-blind, placebo-controlled, parallel group study to assess the efficacy and safety of induction therapy with LYC-30937-EC was undertaken in subjects with active UC. Patients were randomized to receive LYC-30937-EC 25 mg od or placebo for 8 weeks [190]. Clinical remission at 8 weeks was the primary endpoint and since it was not met, the OLE trial has been discontinued and no additional trials are currently planned.

TOP-1288

This is a first in narrow spectrum protein kinase inhibitor, which when given rectally, has shown local anti-inflammatory action in experimental models of UC. A Phase I placebo-controlled, single and multiple ascending dose study of TOP1288 conducted in 61 healthy volunteers demonstrated that rectal administration of TOP1288 at doses up to 200 mg BID for 4 days was safe and well tolerated, with minimal systemic absorption [191]. A Phase 2a proof-of-concept study evaluated the efficacy and safety of daily administration of 200 mg of TOP1288 rectal solution, compared with placebo solution, for 4 consecutive weeks and the results are still awaited [192].

GSK2982772

Receptor Interacting Protein 1 (RIP1) Kinase is a critical driver of inflammation via various pathways [193]. GSK2982772 is a RIP1 kinase inhibitor that has shown excellent activity in blocking many TNF-dependent cellular responses and in reducing the spontaneous production of cytokines from human UC explants. A multicentre, randomised, double-blind, placebo-controlled study with OLE to investigate the safety and tolerability, pharmacokinetics, pharmacodynamics, and efficacy of GSK2982772 in subjects with active UC has been completed and the results are awaited [194].

Rosiglitazone

Thiazolidinedione ligands for the gamma subtype of peroxisome proliferator-activated receptors (PPARgamma), widely used to treat type 2 diabetes mellitus, have also been found to attenuate inflammatory cell proliferation, expression of selected adhesion molecules, inflammatory cytokine production (e.g. interleukin-1β and TNF-α), and reduce colonic inflammation in murine colitis models [195]. A multicenter, randomized, double-blind, placebo-controlled clinical trial compared the efficacy of rosiglitazone 4 mg orally twice daily vs placebo twice daily for 12 weeks in 105 patients with mild to moderately active UC vs. placebo [196]. At week 12, rates of clinical response (44% vs. 23%, $p = 0.04$ and clinical remission (17% vs. 2%, $p = 0.01$) were higher with rosiglitazone vs. placebo. Endoscopic remission was uncommon in both groups (8% rosiglitazone vs 2% placebo; $P = 0.34$).

New concerns related to increased risk of heart disease in patients taking rosiglitazone for diabetes has since emerged and currently no further studies for rosiglitazone for IBD are in process.

VB-201

This is a small oxidised phospholipid molecule that was explored in UC at a dose of 160 mg daily for 24 weeks, via a randomised, cross over placebo-controlled phase II trial [197]. However no statistically significant effect of VB-201 was observed compared to placebo on the primary or secondary endpoints (disease remission at 12 and 24 weeks) and hence further drug development is not planned.

Summary

Blockade of the TNF-a pathway has provided significant strides in the treatment of IBD. However, still a substantial proportion of patients with IBD, specifically those with moderate to severe Crohn disease, do not have a response to treatment with TNF antagonists and are primary or secondary nonresponders or they develop side effects or intolerances leading to discontinuation of medical therapy. As discussed in this chapter, several new biologic treatments utilizing different mechanisms of action are currently in the pipeline and are promising new treatments for IBD.

Medical Treatment of Perianal Crohn Disease

35

Jan-Michael A. Klapproth and Gary R. Lichtenstein

Background

Case

The patient is an 18-year-old female with a recent diagnosis of mild to moderate ileo-colonic Crohn disease, confirmed by endoscopy, histology, and radiography. Her initial fecal calprotectin concertation was determined at 59 micrograms per gram of stool and treatment with a combination of mesalamine and Budesonide 9 mg by mouth per day was initiated. Six months after her initial visit, she is seen in follow up, now complaining of recurrent malaise, fever, and dull right lower quadrant abdominal discomfort. Repeat fecal calprotectin was found to be 450 micrograms per gram stool and a pelvic magnetic resonance imaging scan revealed a complex inter-sphincteric fistula with a 3 cm pelvic abscess.

The patient underwent percutaneous drainage of the pelvic abscess in interventional radiology, and placement of a central venous access port for intravenous antibiotics and parenteral nutrition. Antibiotics were stopped after 2 weeks and a follow up magnetic resonance imaging study 4 weeks later revealed complete resolution of the pelvic abscess. Induction and maintenance of remission were achieved with Infliximab at 5 mg per kg body weight, currently given every 6 weeks. Her test for trough and antibody levels were negative antibodies and 12.45 microgram per ml. She continues to be asymptomatic.

Classification

In a position statement and technical review, the American Gastroenterological Association has stratified perianal fistulae into two groups, simple and complex [1, 2]. Anatomically, simple fistulae develop below the dentate line, and are of either superficial, low inter-sphincteric, or low trans-sphincteric origin. Simple fistulae usually have a single opening, without evidence of abscess formation, anorectal stricture, or genitourinary involvement. In contrast, complex fistulae are classified as high in origin (high inter-sphincteric, high trans-sphincteric, or supra-sphincteric), with possibly multiple external openings, pain or evidence of abscess formation. Complex fistulae are likely to extend into vagina, rectum, or contributing to the development of a rectal stricture. Precise classification of fistulas is mandatory for successful treatment, as well as prognosis, as simple fistulae have a high degree of healing, whereas complex fistulae have a lower rate of achieving remission i.e., cessation of discharge [3–6].

Pathogenesis

As opposed to ulcerative colitis, the transmural nature of the inflammation that typifies CD predisposes patients to fistula formation. This process is initiated by epithelial to mesenchymal transition, characterized by increased epithelial mobility and cells spreading. During this transformation, epithelium-specific barrier proteins, such as E-cadherin and claudin-4, are down-regulated, whereas mesenchymal proteins, such as vimentin, are up-regulated [7]. This process is driven by increased expression of tumor necrosis factor α and transforming growth factor β [8], leading to activation of transcription factors, namely SNAIL1 and SLUG. SNAIL1 and SLUG have also been found to be induced by interleukin-13, a molecule that favors fibrosis, itself up-regulated by transforming growth factor β. Interestingly, cell wall component muramyl dipeptide, found in Gram-positive and Gram-negative bacteria, stimulates expression of SNAIL1, SLUG, interleukin-13, tumor necrosis factor α and transforming growth factor β. The inability to neutralize muramyl dipeptide due to a C-terminal mutation in nucleotide oligomerization domain, has been described in up to 50% of patients with ileo-colonic CD [9]. Eventually, immune acti-

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_35

vation as described above, leads to the expression of β6-integrin, a molecule associated with cell invasion and matrix remodeling.

Natural History

The reported incidence of fistulae in patients with CD ranges from 17% to 43% in referral-center-based case series [10–19]. Early studies examined 176 patients diagnosed with CD in Olmsted County, Minnesota, from 1970 to 1993 and found a cumulative incidence of at least one fistula (at any site) of 21% at 1 year, 26% at 5 years, 33% at 10 years, and 50% at 20 years [20]. The corresponding cumulative incidences of at least one perianal fistula were 12% at 1 year, 15% at 5 years, 21% at 10 years, and 26% at 20 years. An updated and more recent population-based cohort study from this cohort found out of 414 participants 20.5% had at least one rectovaginal or perianal fistula with a 1:1 female-to-male ratio [9]. The cumulative incidence of rectovaginal fistulae increased over time: 18% at 10 years, 23% at 20 years, and 24% at 30–40 years following the diagnosis of Crohn disease. Interestingly, the incidence of fistulae was significantly lower in the patient population diagnosed after 1998 in comparison to before 1998 (14.5% vs. 25.8%, respectively; $p = 0.03$) with a 10-year risk reduction of 12%. This time frame appears to coincide with the introduction of biologic therapy for fistulizing CD [21]

Population-based studies have also examined the natural history of CD fistulae [17–19]. A study from Stockholm County with 826 patients, diagnosed between 1955 and 1974, observed a 23% cumulative incidence of perianal fistulae [19]. Interestingly, while the frequency of perianal fistulae formation increased, the incidence of inflammation increased from proximal to distal: 12% ileum, 15% ileocolonic, 41% colonic without rectal involvement, and 92% rectum. As opposed to inflammation, this study identified fistulae in the following locations: 54% perianal, 24% enteroenteric, 9% rectovaginal, 6% enterocutaneous, 3% enterovesical, and 3% entero-intraabdominal. Remarkably, 45% of patients developed a perianal fistula before or at the time of diagnosis of CD, first described by Gray et al in 1965 [22] and followed up by Hellers et al [17–19]. This observation highlights the frequent difficulties encountered in attempting to diagnose CD in patients with isolated perianal disease.

At this point it is worthwhile discussing the characteristics and long-term outcomes of pediatric patients. In a recent study, out of 234 included patients (mean age 14.2 ± 2.4 years; 8), 56% were male participants, and 24% had evidence of perianal disease, but only 9% had fistulae. Interestingly, children with perianal disease had significantly lower body weight, z scores for height, serum albumin concentrations, but a higher pediatric CD activity index, Magnet Resonance Enterography Global Inflammatory Score, rectal and jejunal involvement, and a high prevalence of granulomas in biopsy material. These data were interpreted that children with fistulizing disease display a distinctly different phenotype with a predisposition to greater inflammatory burden. In a related study [23] it was found that male pediatric patients with inflammation from CD are at increased risk for the development of fistulizing disease over time, similar to adults. In contrast, female sex was associated with a higher incidence of perianal involvement. In a more recent study, involving 2406 children, perianal disease was present at time of diagnosis in 5.5% of participants, with 80.9% being male. During the follow-up period of 2 years, an additional 4.3% of patients developed perianal disease, steroids being potential risk factors for the development of perianal disease.

The clinical course of perianal fistulae depends on their complexity. Simple fistulae may heal spontaneously in up to 50% of cases [24] whereas complex fistulae rarely heal spontaneously [25]. A number of studies have demonstrated that simple perianal fistulae tend to heal more completely and recur less frequently than complex fistulae [4, 6, 26–28].

Diagnosis

Since healing rates seem to decrease when fistulae transform from simple to complex, it is tantamount to recognize and treat perianal CD fistulae as soon as symptoms or abnormal imaging raise suspicion for penetrating CD. Thus, fistula location and extent must be accurately ascertained prior to commencing therapy. Unfortunately, digital rectal examination alone is not sufficient in this capacity, with accuracy as low as 62% [29] Similarly, fistulography and CT are of limited use, given their low diagnostic accuracy of 16–50% and 24–60%, respectively [30–41]

Magnetic resonance imaging is currently the gold standard for the assessment of perianal fistulae. MRI scanning is free of ionizing radiation, but is more costly than convention CT radiography. Cross-sectional imaging by MRI is superior to barium studies for detecting fistulizing disease, and equally accurate as CT in assessing luminal disease activity and bowel damage in Crohn disease. Diagnostic accuracy has been reported at a range of 76–100% [42–50]. A related study, investigating 219 MRI studies comparing images from an adult and pediatric population, identified an increased prevalence of perianal disease in children (34.% vs. 16.1%. (OR = 2.8, $p = 0.0017$;12. The pediatric population had a high incidence of rectal involvement (29.7% vs, 13.5%, OR = 2.7, $p = 0.0045$).

Equally accurate in characterizing perianal fistulae is endoscopic ultrasound (EUS) with a diagnostic accuracy ranging from 56–100% [41, 46, 51–57]. Ultrasound can be

further enhanced with hydrogen peroxide fistulography, originally described in 1993 [58]. With this method the external opening of the fistula is located, cannulated and injected with hydrogen peroxide, allowing for exact delineation of the fistulous tract. Although initially described, this is not performed in clinical practice. An additional enhanced technique is three dimensional endo-anal sonography, in which multiple parallel two dimensional ultrasound images are synthesized into a three dimensional data set [57]. Diagnostic accuracy consistently exceeds 96%, defined as an agreement among operators with a consensus of equal to or more than 85% of patient findings. Combining two investigations of either EUS, MRI, or examination under anesthesia provides the most accurate tests for determining fistula anatomy patients with perianal Crohn disease, reaching 100% [59].

When assessed in a prospective trial evaluating patients with perianal Crohn disease use of both pelvic MRI or anorectal EUS has been found to change surgical management in 10–15% of cases [44–50, 56].

EUA performed by an experienced colorectal surgeon has long been considered the gold standard for diagnosis of perianal fistulae in CD. However, this view has recently been challenged by Schwartz et al who compared EUA, MRI, and EUS in a prospective blinded study of 34 patients with suspected CD perianal fistulae [49]. In this study, a consensus gold standard was determined for each patient. The authors observed a diagnostic accuracy exceeding 85% for all three modalities, specifically 91% for EUA and EUS and 87% for MRI. Of note, when any two of the tests were combined, diagnostic accuracy increased to 100%.

Medical Therapy of Fistulas

5-Aminosalicylic Acid Derivatives

5-Aminosalicylic acid and derivatives have not been shown to be efficacious in inducing remission in luminal CD and also have never been studied for the treatment of CD fistulae in controlled trials. Thus, they cannot be recommended for the treatment of fistulizing CD.

Corticosteroids

There have been no controlled studies evaluating the use of steroids in the management of CD fistulae. Unfortunately, neither the National Cooperative Crohn Disease trial, nor the European Cooperative Crohn Disease trial provided data on response in the subgroup of patients with fistulae. However, two large uncontrolled studies have shown that corticosteroid use may actually be detrimental to patients with fistulizing CD, as it was associated with higher rates of surgical intervention [60, 61]. A retrospective case-control study of 432 patients with CD studied the risk of intra-abdominal or pelvic abscess with systemic corticosteroid use during the previous 3 months [62]. The authors found a significant nine-fold increased risk of intra-abdominal or pelvic abscess in patients with perforating CD who had received systemic corticosteroids during the prior 3 months (adjusted OR = 9.03, 95% CI = 2.40–33.98). In patients with relapsed active disease, they also reported a significant nine-fold increased risk of abscess in patients receiving systemic steroids in the 3 months prior to presentation (unadjusted OR = 9.31, 95% CI = 1.03–83.91). For these reasons, corticosteroids should be avoided in patients with fistulizing CD.

Antibiotics

There is increased evidence to suggest that the intestinal microbiome actively contributes to the pathogenesis of CD. Although antibiotics are the most commonly used medication for the treatment of fistulae in CD, there are limited controlled data indicating that these agents are effective in this regard. The use of antibiotics in fistulizing CD is largely based upon a number of uncontrolled case series, each with a small number of patients [63–72]

A randomized and controlled study investigating ciprofloxacin, metronidazole, or placebo involving 25 patients was recently completed [73]. In this study, remission was defined as closure of all fistulae and response was defined as closure of at least 50% of all fistulae that were draining at baseline. Among the 25 patients who completed the study, remission and response rates for the ciprofloxacin (n = 10), metronidazole (n = 7), and placebo (n = 8) groups were 30% and 40%, 0% and 14%, and 13% and 13%, respectively. It is worth noting, that in a separate study 21 therapy refractory patients with perianal Crohn disease were treated with 6.5 months of metronidazole. In this uncontrolled trial, fistula drainage, erythema, and induration decreased in all patients, with complete healing of fistulous tracts observed in 10/18 patients, chronically treated with this antibiotic. Of concern is the fact that half the patient population experienced neuropathy, requiring reduction or even discontinuation of this medication. Discontinuation of maintenance therapy with metronidazole was associated with relapse in all patients [66] However, rapid healing was noted in all patients upon re-administration of metronidazole. Thus, while efficacious in the induction of improvement, metronidazole is limited in that maintenance therapy is often required. Three other small, uncontrolled studies have also observed efficacy with metronidazole in fistulizing CD with fistula closure rates of 40–50%, but a high rate of relapse after cessation of therapy was seen in one of these studies

[65, 67, 68] The typical dose of metronidazole in the treatment of fistulizing CD ranges from 750–1500 mg/day. Adverse events caused by metronidazole are quite common, often leading to intolerance and discontinuation of the drug, and include a distal sensory neuropathy with paresthesias, nausea, dyspepsia, fatigue, glossitis, metallic taste, and a disulfiram-like reaction to alcohol ingestion [74].

Given that adverse events are commonly encountered with the use of with metronidazole, ciprofloxacin began to be used in the late 1980s to treat CD fistulae [69–72]. A meta-analysis, originally published in 2015, discussing three trials with ciprofloxacin to treat perianal fistulas, revealed a significant increase in clinical response and remission in the treatment group, versus placebo (18C; RR = 1.54, 95%CI: 1.16–2.32, p = 0.0005). Other, significantly smaller trials with ciprofloxacin have been performed. This includes an investigation with eight metronidazole-refractory CD patients who were subjected to 1000–1500 mg/day ciprofloxacin for 3–12 months [69]. The initial response was favorable, but almost all patients developed recurrent and persistent fistula drainage, requiring surgical intervention. And even a small study with 5 patients noted clinical improvement in 4/5 participants, following 5 weeks of therapy [70].

Ciprofloxacin and metronidazole have been used in combination therapy in a retrospective study with 14 patients [71] Their group observed improvement in 9 patients and fistula closure in 3 patients within 12 weeks, but like previous antibiotic studies, they also reported that relapse was the norm following discontinuation of therapy. The typical dose of ciprofloxacin in the treatment of fistulizing CD ranges from 1000 to 1500 mg/day. Adverse events with ciprofloxacin are uncommon and include headache, nausea, diarrhea, rash, and spontaneous tendon rupture [74, 75]. Recently, neuropathy [76] and aortic aneurysm or aortic dissection [77] have been described to occur in patients using fluoroquinolones.

Azathioprine/6-Mercaptopurine/Methotrexate

Early investigations into the effect of azathioprine and 6-MP on active perianal CD showed that after 3 years, cumulative probabilities of remaining free of perianal complications and achieving a clear anatomic improvement were 0.47 (95% CI 0.36–0.58) and 0.4 (95% CI 0.29–0.53) [78]. In this study, a total of 29% responded azathioprine or 6-mercaptopurine. The absence of fistulae, perianal disease duration shorter than 22 months, and age 40 years and older, were independent factors associated with a response to immunomodulatory therapy. Interestingly, there was no correlation between the resolution of perianal disease and intestinal remission.

The study by Present et al observed a 31% rate of complete closure of the fistulae in the group receiving 6MP versus 6% for the placebo group [79]. A meta-analysis of these five trials reported an overall response rate (defined as improvement or complete healing) in 54% of patients treated with azathioprine or 6MP compared to 21% in patients treated with placebo [80]. The corresponding pooled odds ratio for fistula healing with azathioprine or 6MP was 4.44 (95% CI = 1.50–13.20). In the pediatric population, represented by 15 CD subjects and treated for 6 months (25), 67% had an improvement in drainage, 73% in tenderness, 60% in induration, and 40% in fistula closure. The authors also concluded, that immunomodulators are warranted for healing perianal CD.

Given the favorable response on perianal disease, a total of 16 patients, mean age 37 years, 13 subjects with perianal fistulas, were treated with a combination of infliximab and 6-mercaptopurine or azathioprine [81]. Interestingly, 75% of patients develop complete closure of fistulae, persisting for more than 6 months, with the median time to closure of about 14 days (range 2–36 days). The authors speculated that immunomodulator therapy could prolong the effect of initial infliximab therapy, leading to fistula closure in patients with CD.

In a prospective, open label study with 31 patients, the effect of ciprofloxacin 500–1000 mg/day and/or metronidazole 1000–1500 mg/day in combination with azathioprine were tested [77]. Endpoint was reduction in fistula drainage assessment and the perianal disease activity index at week 8 and 20. Approximately 50% of participants responded to antibiotic therapy and 25% achieved complete healing by week 8. The perianal disease activity index decreased from 8.4 to 6.0 (p = 0.0001). By week 20, the response was achieved in 35% of patients, and complete healing was achieved in 18% of patients. Interestingly, participants receiving combination therapy with azathioprine and antibiotics were more likely to achieve a response, leading the authors to conclude that antibiotics play a role in bridging the time until immunomodulators become active.

Over the past few years, Methotrexate has secured a role in the management of inflammatory CD. Its role in fistulizing disease was investigated by recruiting 33 adult patients with luminal and or fistulizing Crohn disease. In 16 patients with fistulae, 25% experienced complete closure, 31% had partial closure and an overall response to methotrexate therapy of 62% was observed. It is worth noting that 6% of patients had significant adverse events.

In a follow-up study, 12 patients with fistulizing Crohn disease, having failed azathioprine, were subjected to combination therapy with infliximab at 5 mg/kg and long-term methotrexate, 20 mg per week [82]. The primary endpoint in this trial was sustained closure of fistulas for greater or equal

to 6 months after fistula closure. In 4/12 patients the primary endpoint was reached, with additional partial closure in 3 patients. Unfortunately, 5 patients did not achieve closure, or experienced side effects from the medication.

Finally, 34 CD patients with complex perianal fistulae were subjected to infliximab infusions [83] as well as maintenance therapy with methotrexate in combination with at least removal of one seton between the second and third infliximab infusion. At week 14, the overall response rate was 85%, with 74% of patient's showing a complete response. At 12 months, 50% of patients still responded with recurrent luminal inflammation as the major cause of relapse.

Thus, methotrexate may represent a reasonable alternative to patients who fail or cannot tolerate azathioprine or 6MP, and long-term maintenance therapy is likely necessary; however, prospective randomized placebo-controlled trials are still needed to evaluate formally the efficacy of methotrexate for fistulizing CD. The initial dose of methotrexate suggested is 25 mg intramuscularly every week. Interestingly, concurrent and mandatory administration of folate is advocated to lessen nausea. Adverse events are common and include hepatic fibrosis, bone marrow suppression, pneumonitis and pulmonary fibrosis, nausea, and teratogenicity [84, 85].

In addition, two uncontrolled case series, one in adults and one in children, have been published [86, 87]. The adult series, by Korelitz et al, treated 34 patients with 6MP at a dose of 1.5 mg/kg/day with various types of fistulae, including perianal (18 patients), abdominal wall (8 patients), enteroenteric (7 patients), rectovaginal (6 patients), and vulvar (2 patients) [86]. Complete fistula closure was achieved in 39% of patients, with an additional 26% showing improvement. This study also underscored the importance of maintenance therapy. Fistulae remained closed for 1–5 years in 46% of patients (6 out of 13) who remained on 6MP, and relapses tended to occur within 2 weeks to 9 months after discontinuation of the drug. Healing was once again achieved upon re-administration of 6MP. Furthermore, the authors noted that although all types of fistulae responded to 6MP, abdominal wall and entero-enteric fistulae responded particularly well.

Typical doses of immunomodulators azathioprine and 6MP are 1–1.5 mg/kg/day and 2–3 mg/kg/day, respectively. A meta-analysis has demonstrated that higher 6-thioguanine nucleotide levels (especially ≥230–260 pmol/10^8 red blood cells) were associated with a higher likelihood of clinical remission [88]. Adverse events are common with azathioprine and 6MP, occurring in 9–15% of patients, and include allergic reactions, bone marrow suppression (especially leukopenia), pancreatitis, infection, hepatotoxicity, non-Hodgkin's lymphoma, and other gastrointestinal side effects (nausea, vomiting, and abdominal pain) [80, 89, 90].

Tacrolimus

Few studies have been performed with tacrolimus for fistulizing CD. Previously, a randomized, double-blind, placebo-controlled, multi-center clinical trial involved 48 patients with Crohn disease and actively draining perianal and enterocutaneous fistulas [91]. The subject received oral tacrolimus at 0.2 mg/kg and day, or placebo, for a total of 10 weeks. The primary outcome in this study was the closure of more than 50% of particular fistulas that were actively draining at baseline and maintained closure for at least 4 weeks. The secondary outcome was remission as defined by closure of all fistulas and maintenance of that closure for at least 4 weeks. At 4 weeks, 43% of tacrolimus-treated subjects displayed fistula improvement, compared to 8% of placebo-treated patients ($p = 0.004$). Unfortunately, only 10% of tacrolimus treated patient's experienced remission of fistulae, compared with 8% of placebo-treated patients, leading the authors to speculate that oral tacrolimus is effective for fistula improvement, but not remission.

A pilot study, investigating oral tacrolimus for infliximab-refractory fistulizing CD, enrolled 10 patients [92]. The subjects were resistant to azathioprine, antibiotics, 6 mercaptopurine and infliximab. The patient has received tacrolimus at 0.05 mg/kg every 12 h. Clinical response was determined by the perianal Crohn Disease Activity Index and MRI. Follow-ups at 6 and 24 months revealed 4 patients who achieved a complete and 5 patients a partial response. It is worth noting, that all steroid-dependent patient's stopped therapy with prednisone and concomitant immunomodulatory therapy being tapered. However, despite the interpretation that tacrolimus appears to be effective and safe for therapy refractory CD patient's, results were obtained from a rather heterogeneous cohort with a broad variety of fistulizing disease and no controls. Tacrolimus is not widely used for patients and is not a maintenance medication for treating fistulizing Crohn disease.

Cyclosporin A

Results for clinical trials investigating the efficacy of cyclosporin A in fistulizing CD are limited have been published as case series [93–101]. In an older series, a total of 16 patients were investigated with symptomatic perianal, rectovaginal, and enterocutaneous fistulae receiving cyclosporine A intravenously. Cyclosporin A at 4 mg/kg/day resulted in clinical improvement an 88% of subjects with complete fistula closure in 44% [97]. However, within a week's time 36% of patients experienced recurrent symptoms when converted to oral cyclosporine A. Unfortunately, fistula recurrence after discontinuation of cyclosporin A was 62%.

Therefore, cyclosporin A functions as a temporizing measure for immunomodulatory therapy (azathioprine, 6-MP or a biologic). The recommended initiation intravenous dose of cyclosporine is 4 mg/kg/day for 1 week, followed by oral formulation, typically 6–8 mg/kg/day, all dosed by levels. Adverse events are common and include paresthesias, hirsutism, hypertension, tremor, renal insufficiency, headache, opportunistic infections, gingival hyperplasia, seizures, and hepatotoxicity [84, 102].

Infliximab

In the management of perianal fistulizing CD, neutralizing Tumor Necrosis Factor α plays a key role in controlling penetrating disease. Infliximab, a chimeric (75% human, 25% murine) IgG1 monoclonal antibody directed against Tumor Necrosis Factor α, is the prototype anti-tumor necrosis factor α agent and has now become the cornerstone in medical therapy of fistulizing CD. The efficacy of infliximab in controlling fistulae was first established in a randomized, double blind, placebo controlled trial, involving 94 patients with fistulizing disease [103, 104]. This cohort consisted of 10% of patients with draining abdominal (10% of patients) or perianal (90% of patients) fistulae. Infliximab was given at 5 mg/kg, or 10 mg/kg intravenously at week 0, 2, and 6 [103]. The primary endpoint was a reduction in the number of draining fistulae by ≥50%, maintained for at least 4 weeks, with a secondary end point being closure of all fistulae. The primary goal was achieved in 68% of patients receiving infliximab at 5 mg/kg and 56% of patients who received infliximab at 10 mg/kg, compared to 26% of patients who received placebo ($p = 0.002$ and $p = 0.02$, respectively). Closure of all fistulae was achieved in 55% of patients who received infliximab at 5 mg/kg and 38% of patients who received infliximab at 10 mg/kg, compared to only 13% of patients who received placebo ($p = 0.001$ and $p = 0.04$, respectively). The median time to response was 14 days for infliximab-treated patients vs. 42 days for patients assigned to placebo. The majority of infliximab-treated patients achieved fistula closure prior to the third infusion and 6 weeks. Eleven patients experienced at least 1 fistula closure in infliximab-treated subjects developed a perianal abscess, possibly resulting from premature closure of the cutaneous end before closure of the rest of the fistula tract. However, the overall rates of infection did not differ between the infliximab and placebo groups. The median duration of response was 3 months, suggesting that maintenance therapy may be required.

Subsequently, the long-term efficacy of infliximab in the treatment of fistulizing Crohn disease was investigated in the ACCENT II trial (A Crohn's Disease Clinical Trial Evaluating Infliximab in a New Long-Term Treatment Regimen in Patients with Fistulizing Crohn Disease). This study recruited 282 patients with draining perianal, abdominal, and rectovaginal fistulae [104]. All patients received infliximab at 5 mg/kg at weeks 0, 2, and 6, followed by assessment of reduction in the number of draining fistulae by ≥50% for at least 4 weeks. This primary endpoint was achieved in 195 patients (69%). At week 14, the 195 responders were then randomly assigned to receive infusions of either infliximab 5 mg/kg or placebo every 8 weeks until week 54. The primary endpoint was time to loss of response. The authors observed a median time to loss of response of 40 weeks in infliximab-maintained patients vs. 14 weeks in placebo-assigned patients ($p = 0.001$). Overall, 42% of patients in the infliximab group had a loss of response, compared to 62% in the placebo group. At week 54, 46% of patients treated with infliximab still had a response, versus 23% of patients treated with placebo ($p = 0.001$). In addition, at week 54, 36% of patients in the infliximab group had a complete absence of draining fistulae, compared to 19% in the placebo group ($p = 0.009$). A post-hoc analysis of the ACCENT II data looked at efficacy of infliximab induction and maintenance in a subset of women with rectovaginal fistulae [104]. Twenty-five of the original 138 women had a total of 27 draining rectovaginal fistulae at baseline. At week 14, 64% of these 25 women had responded and were then randomized to receive infliximab or placebo maintenance therapy. The authors reported a median time to loss of response of 46 weeks for the infliximab group vs. 33 weeks in the placebo group.

The social impact of infliximab in patients with active fistulizing CD has also been investigated in two recent studies. Cadahia et al were interested in the effect of infliximab induction treatment on health-related quality of life, and thus, they conducted a prospective observational study of 25 patients who received three-dose induction infliximab therapy for single or multiple draining abdominal or perianal fistulae [105]. The authors found that health-related quality of life, as measured by the SF-36, demonstrated significant improvement in the physical domain after 4 and 10 weeks. In addition, a significant increase in IBDQ score was seen after 4 weeks. Lichtenstein et al evaluated the impact of infliximab maintenance therapy on the number of hospitalizations, surgeries, and procedures in patients with fistulizing CD [106]. Using data from the ACCENT II trial, they revealed that compared to patients who received placebo, patients who received maintenance infliximab had significantly fewer number of mean hospitalization days (0.5 vs. 2.5 days), hospitalizations (0.11 vs. 0.31), total surgeries and procedures (65 vs. 126), inpatient surgeries and procedures (7 vs. 41), and major surgeries (2 vs. 11).

A retrospective survey performed with 66 patient's suffering perianal disease [107], determined that trough concentrations were significantly higher in patients with closed fistulae as opposed to patients with actively draining fistulae (6 μg/

mL [5.4–6.9] vs. 2.3 μg/mL [1.1–4.0], respectively). From this study, it was concluded that serum concentrations of equal to or greater 5.0 μg/mL were associated with fistula closure.

Similar findings have been reported for the pediatric population suffering from fistulizing Crohn disease. An analysis of 50 children with perianal fistulizing Crohn disease, age range 9–18 years, received induction therapy with infliximab at 5 mg/kg at week 0, 2, and 6 [108]. Maintenance therapy was given at 5 milligrams/kilogram every 8 weeks. The results revealed that 76% of children after induction therapy with infliximab and 71.8% after maintenance therapy achieved and maintained closure of fistulae, respectively. A multi-center inception cohort study investigated 667 consecutive children younger than age 17 years with fistulizing perianal Crohn disease to further characterize the serum infliximab concentration required fistula closure. The authors determined that the median infliximab concentration in responders was 12.7 μg/mL vs. 5.4 μg/mL in those with active fistulizing disease, which is significantly higher than in the adult population.

The effectiveness of infliximab in combination with other medical therapies for fistulizing CD has also been investigated in several studies [81, 109, 110]. West et al conducted a double-blind, placebo-controlled trial of ciprofloxacin overlapping with infliximab in patients with perianal CD fistulae [109]. In this study, 24 patients were randomized to receive either ciprofloxacin at 1000 mg/day or placebo for 12 weeks in addition to infliximab at 5 mg/kg at weeks 6, 8, and 12. Patients were followed for 18 weeks, and the primary endpoint was reduction in the number of draining fistulae by ≥50%. The authors reported that 73% of the ciprofloxacin-treated patients responded, compared to 39% in the placebo group. One caveat is that the response rate to infliximab alone was much less than in other infliximab studies, in which at least 60% of patients responded.

Infliximab has also been evaluated in combination with immunomodulator therapy. Ochsenkühn et al performed an uncontrolled pilot study of long-term azathioprine (at 2–2.5 mg/kg/day) or 6MP (at 1 mg/kg/day) in combination with induction infliximab in 16 patients [81]. They found that 75% of patients achieved complete fistula closure, which persisted for more than 6 months (median time of 10 months). As seen previously, the median time to fistula closure was 14 days. A similar uncontrolled pilot study by Schröder et al followed 12 consecutive patients with CD fistulae intolerant or resistant to azathioprine [110]. Patients were treated with induction infliximab and long-term methotrexate at 20 mg/week (intravenously for 6 weeks, followed by oral thereafter). The authors observed that 33% of patients experienced complete fistula closure for at least 6 months (median 13 months), and 25% had a partial response. While providing a suggestion of efficacy of combination therapy for the treatment of fistulizing CD, controlled trials have yet to be performed.

In order to increase the rate of fistula closure a recent study evaluated if there was added benefit for concurrent seton placement. In this study, 156 patients were treated with infliximab and 62% received additional therapy with placement of a seton [111]. Follow-up at 250 weeks revealed 69% of patients had at least one fistula closure. Among patients who experienced fistula closure, the probabilities of fistulae recurrence where 16.6% and 40.1% at 1 and 5 years, respectively. Interestingly, 28.9% developed abscesses during follow-up, with the number of infliximab infusions greater than 19 to be associated with less abscess recurrence. In conclusion, two-thirds of patients experienced fistula closure, and one third of patients had recurrence after infliximab initiation. It appears that combination therapy, duration of seton drainage less than 34 weeks and long-term treatment with infliximab were associated with better outcomes including combination with an examination under anesthesia [112].

Despite all of its reported success, the use of infliximab may not obviate the need for surgical management of CD fistulae in many cases. Poritz et al retrospectively examined surgical rates in patients treated with infliximab for fistulizing CD at a single institution [113]. Among the 26 patients with various types of fistulae, 46% experienced a partial response to infliximab, and an additional 23% had fistula closure. However, 54% of patients overall still required surgery after infliximab therapy and another 23% continued to open fistulous drainage but refused surgery. Of note, none of the patients with either enterocutaneous or peristomal fistulae were healed with infliximab treatment.

The combination of infliximab with surgical intervention (i.e. seton placement) in the treatment of CD perianal fistulae has been assessed in a several studies [4, 5, 114–116]. Three single-center retrospective case series, from Calgary, Leeds, and Oxford, each of which included 21 patients, have documented favorable rates of fistula healing with seton placement followed by induction and maintenance therapy with infliximab, with complete and partial healing rates of 67% and 19%, 47% and 53%, and 21% and 42%, respectively [5, 114, 115]. Two studies were able to compare the outcomes of patients treated with infliximab and seton placement to those treated with infliximab and/or seton placement alone [6, 120]. The first, by Regueiro and Mardini, retrospectively analyzed 32 consecutive patients with perianal CD fistulae, all of whom had received at least 3 induction doses of infliximab and some of whom had additionally undergone an EUA with seton placement prior to infliximab treatment [4]. Response was defined as complete closure and cessation of drainage from the fistula. They found that compared to patients treated with infliximab alone ($n = 23$), patients who had a pre-infusional EUA with seton placement ($n = 9$) had a significantly higher rate of initial response (100% vs. 83%,

$p = 0.014$), lower rate of recurrence (44% vs. 79%, $p = 0.001$), and longer time to recurrence (13.5 months vs. 3.6 months, $p = 0.0001$). The second study, by Scaudione et al, prospectively subdivided 35 consecutive patients with complex perianal fistulae into 3 different interventional groups: infliximab with seton placement ($n = 14$), infliximab alone ($n = 11$), and seton placement alone ($n = 10$) [116]. The authors reported that patients in the combination group had a non-significantly higher rate of complete response, defined as closure of all draining fistulae and cessation of drainage for 3 months, of 79% vs. 64% and 70%, respectively, and a significantly longer time to recurrence of 10.1 months vs. 2.6 and 3.6 months, respectively ($p < 0.02$).

The combination of infliximab with immunomodulators and seton placement has also been investigated more recently. A prospective open-label study of 34 patients from three hospitals in France, by Roumeguere et al., had patients undergo seton placement 3 months prior to start of medical therapy, followed by initiation of methotrexate 25 mg per week, followed by induction infliximab, after which patients were maintained on methotrexate alone [117]. At 14 weeks, 74% of patients had a complete response and another 11% had a partial response. Of patients with the initial response, 90% had maintained at least a partial response after 56 weeks. A prospective study of 41 patients from St. Mark's Hospital in London, by Tozer et al., assessed long-term fistula response and remission rates after treatment with infliximab (or adalimumab in 9 patients who lost response to infliximab) combined with thiopurines in which 73% of patients had seton placement which was removed after 2–6 weeks [118]. They reported rates of fistula response and remission at 2 years of 35% and 29%, respectively, and at 3 years of 37% and 21%, respectively. A large retrospective study from two referral centers in France, by Bouguen et al., assessed long-term rates of initial and sustained fistula closure in 156 patients treated with infliximab and immunomodulators (in 58%) and seton placement (in 62%) [111]. They observed rates of initial fistula closure of 59%, 73%, and 88% at 3, 5, and 10 years, respectively, and rates of sustained fistula closure of 22%, 43%, and 57% at 3, 5, and 10 years, respectively. Interestingly, the use of infliximab for more than 118 weeks and the use of combination therapy were associated with significantly higher rates of initial fistula closure. [Discontinuation of infliximab for any reason can result in severe relapses of fistulizing disease] [119]. Median follow-up of 62 months revealed 24/45 patient is experiencing recurrent perianal disease, with 79% of patients requiring surgical drainage. The cumulative probabilities perianal relapse at 1 and 5 years was determined at 24 in 55%, respectively associated with perianal relapse were external fistula opening, second line anti TNF alpha use, or lack of dose optimization. Reintroduction of infliximab resulted in remission in 96% of patients.

Adverse events with infliximab treatment are common and include infusion reactions, delayed-type hypersensitivity reactions, formation of human anti-chimeric antibodies, formation of antinuclear and anti-double-stranded DNA antibodies, and drug-induced lupus-like reactions [120]. In addition, infectious complications seem to be increased, but serious infections, such as pneumonia, sepsis, tuberculosis, and opportunistic infections, including listeriosis, aspergillosis, histoplasmosis, coccidiomycosis, and *Pneumocystis carinii* pneumonia, occur only rarely [121–127]. Finally, there have been isolated case reports of hepatic necrosis and non-Hodgkin's lymphoma in patients treated with infliximab, although it has not been determined whether these events were the direct consequence of infliximab therapy.

Adalimumab and Certolizumab Pegol

Similar to infliximab, the other commonly used anti-TNF-α medications for CD treatment, adalimumab and certolizumab pegol, have shown efficacy in the treatment of fistulizing disease. Although data focusing on patients with fistulae for both adalimumab and certolizumab pegol were obtained from randomized placebo-controlled studies, the data assessed on fistula healing was not a primary endpoint in these studies. Adalimumab, a fully human IgG1 monoclonal antibody, was found to be efficacious for maintenance of remission in The Crohn's Trial of the Fully Human Antibody Adalimumab for Remission Maintenance (CHARM), in which 854 patients received open-label induction treatment with subcutaneous adalimumab 80 mg at week 0 and 40 mg at week 2, followed by randomized maintenance treatment with adalimumab 40 mg every week or every other week or placebo up to week 56, with a co-primary endpoint of clinical remission at weeks 26 and 56 [128]. In this study, 117 patients had draining fistulae and 113 of these had perianal fistulae. A subgroup analysis of these patients, in which complete fistula healing was defined as the absence of draining fistulae at the last two consecutive post-baseline evaluations, reported complete fistula healing rates of 30% for the combined adalimumab groups versus 13% for the placebo group at week 26 ($p < 0.05$), and 33% for the combined adalimumab groups versus 13% for the placebo group at week 56 ($p < 0.05$) [129]. The authors also observed that these rates of fistula healing were largely maintained for up to 2 years of follow-up in a long-term extension study of CHARM called ADHERE [130]. Similar findings have been described for the pediatric population where 36 children/adolescent with moderately to severely active Crohn disease were treated with Adalimumab induction therapy, resulting in fistula closure and improvement at 44.4% and 52.8%, comparing week 0–52 and week 240, respectively [131].

Analogous to infliximab, combination therapy with Adalimumab and Ciprofloxacin is more effective than monotherapy to achieve fistula closure in Crohn disease. In a randomized, double blind, placebo-controlled trial, conducted at multiple sites, 76 patients received Adalimumab induction therapy in combination with ciprofloxacin 500 mg twice a day versus placebo, for a total of 12 weeks. Ciprofloxacin was discontinued after 3 months. The primary endpoint was defined at a 50% reduction of fistulae from baseline to week 12. Secondary end points include remission, defined by the perianal Crohn disease activity index, Crohn disease activity index, and inflammatory bowel disease questionnaire. A clinical response was achieved in 71% of patients receiving adalimumab plus ciprofloxacin, and 47% in patients treated with adalimumab plus placebo. Rate of remission at 12 weeks was significantly higher for the combination group vs. monotherapy with Adalimumab (65% vs. 33%, $p = 0.0005$). Mean improvement in IBDQ and CDAI scores were significantly higher in the combination group at 12 weeks, but not at 24 weeks. Therefore, combination therapy with Adalimumab plus Cipro is more efficacious in fistula closure than Adalimumab alone.

Certolizumab pegol, a pegylated humanized Fab fragment of an anti-TNF-α monoclonal antibody, was shown to have efficacy in the maintenance of remission in active Crohn disease in the Pegylated Antibody Fragment Evaluation in Crohn Disease: Safety and Efficacy 2 (PRECISE 2) randomized placebo-controlled trial, in which 668 patients received open-label induction treatment with subcutaneous certolizumab pegol 400 mg at weeks 0, 2, and 4, followed by randomized maintenance treatment with certolizumab pegol 400 mg or placebo every 4 weeks through week 24 and followed to week 26 [132]. In this study, 58 patients had draining fistulae and 55 of these had perianal fistulae. A subgroup analysis of these patients, in which complete and partial fistula closure was defined as closure of 100% and at least 50%, respectively, of all draining fistulae at two consecutive post-baseline evaluations at least 3 weeks apart, reported complete fistula healing rates of 36% for the certolizumab pegol group versus 17% for the placebo group ($p = 0.038$) and partial fistula healing rates of 54% for the certolizumab pegol group versus 43% for the placebo group (p = NS) at week 26 [133]. Rates of adverse events associated with the use of adalimumab and certolizumab pegol were similar to those seen with infliximab.

Other Anti-TNF-α Agents

Other anti-TNF-α medications, including CDP571 and thalidomide, have also been preliminarily investigated for the treatment of fistulizing CD. Of note, golimumab has not been studied for the treatment of CD fistulae. CDP571, a humanized (95% human, 5% murine) IgG4 monoclonal antibody, has been assessed for efficacy in the treatment of CD fistulae in two multicenter, randomized, double-blind, placebo-controlled trials [134, 135]. The first study, by Feagan et al, published only in abstract form, treated 71 patients with steroid-dependent CD with intravenous CDP571 at 20 mg/kg or placebo at week 0, followed by a second infusion of CDP571 at 10 mg/kg or placebo at week 8 [134]. At week 16, among the subgroup of patients with draining perianal fistulae, fistula closure was achieved in 25% of patients who received CDP571, compared to none in the placebo group. The other study, by Sandborn et al, followed 169 patients for 24 weeks, during which patients received an initial infusion of CDP571 at either 10 mg/kg or 20 mg/kg or placebo, followed by CDP571 at 10 mg/kg or placebo every 8–12 weeks [135]. This study included 37 patients with open perianal or enterocutaneous fistulae and reported that 50% of patients treated with CDP571 achieved fistula closure vs. 15% of patients who received placebo. Adverse events due to CDP571 include infusion reactions, formation of anti-idiotype antibodies, development of new antinuclear or anti-double-stranded DNA antibodies, insomnia, pruritus, and rash [134, 135].

Thalidomide has also been preliminarily evaluated in the treatment of fistulizing CD in two open-label pilot studies [136, 137]. The first study, by Ehrenpreis et al, enrolled 22 patients with refractory CD to receive oral thalidomide at 200 or 300 mg/day for 12 weeks [136]. At week 4, of the 13 patients with fistulae, 9 patients (69%) responded, 3 patients (23%) achieved remission, and 2 patients (15%) had closure of all fistulae. Nine patients with fistulizing disease completed the 12 weeks of treatment. Of these 9 patients, all (69%) were responders, 6 patients (46%) achieved remission, and 5 patients (38%) had complete closure of all fistulae. The other pilot study, by Vasiliauskas et al, treated 12 patients with steroid-dependent CD with 50 or 100 mg/day of thalidomide for 12 weeks [140]. Of the 6 patients with active perianal fistulae at the time of entry into the study, five (83%) had improvement in symptoms after 4 weeks. Four of these 6 patients with fistulizing disease completed 12 weeks of treatment. Fistula closure was achieved in 1 patient (17%) at week 12, with improvement in another 2 patients (33%). Adverse events are common with thalidomide therapy and include severe somnolence, peripheral neuropathy, teratogenicity, peripheral edema, constipation, seborrheic dermatitis, hypertension, muscle spasm, and diffuse rash [136, 137].

Vedolizumab

Anti-integrin therapy has been used more recently in the treatment of CD as a means to target reduction of lymphocyte trafficking to the gut. The α4β7 integrin, a cell surface glycoprotein

expressed on lymphocytes, helps to regulate lymphocyte migration into inflamed intestinal tissue via interaction with mucosal addressin-cell adhesion molecule 1 (MAdCAM-1) on intestinal blood vessels [138]. Natalizumab, which is not gut-specific as it binds both α4β7 and α4β1 integrins (the latter which are located in the central nervous system), was shown to be effective for the treatment of CD in a large randomized controlled trial but patients with draining fistulae were excluded [139]. However, the use of Natalizumab is associated with an increased risk of progressive multifocal leukoencephalopathy [140], and thus Vedolizumab was developed as a purely gut-selective blocker of α4β7. Vedolizumab was shown to be efficacious for the treatment of moderate-to-severe active Crohn disease in the GEMINI 2 double-blind randomized placebo-controlled trial [141]. Although fistula treatment was not the primary endpoint in this trial, 57 patients had actively draining fistulae at baseline. Treatment with Vedolizumab 300 mg every 8 weeks was associated with a significantly higher rate of fistula closure than treatment with placebo after 52 weeks (41% vs. 18%, $p = 0.03$).

Recently, a nationwide multi-center cohort study was conducted in a population of 151 patients, investigating the role of Vedolizumab in perianal Crohn disease [65]. Demographics include mean disease duration of 14.6 years, mean age 39.8 years, and 32.4% male patients, with the majority of having received at least one anti TNF alpha medication prior to receiving Vedolizumab. Primary endpoint was defined by absence of draining fistula at clinical examination and no anal ulcers at 6 months without medical or surgical treatment. Unfortunately, 68% of patients discontinued therapy after median time of 33 weeks, only 22.5% of patients who finished this study achieved the primary endpoint, and almost 1/3 of patients with inactive disease had perianal recurrence.

Other Therapies

A variety of other therapies for fistulizing CD have been suggested to be of possible benefit in uncontrolled case series or anecdotally. These include elemental diets, bowel rest with total parental nutrition, mycophenolate mofetil, granulocyte-colony stimulating factor, hyperbaric oxygen, local mesenchymal cell injection, and coagulation factor XIII [142–162]. However, controlled trials are required before any of these modalities can be recommended for routine use. Other novel therapies are also currently under investigation (refer to www.clinicaltrials.gov).

Conclusions

The treatment of perianal fistulizing CD has evolved greatly in the last two decades, due largely to improvements in medical therapy. Tables 35.1 and 35.2 summarize all published controlled and uncontrolled trials of immunomodulator and anti-TNF-α therapy for the treatment of CD. The advent of immunomodulators and biologic agents has transformed the treatment of CD from almost exclusively surgical to placing a much larger emphasis on medical therapy, either as initial therapy alone, with surgery reserved for refractory cases, or in combination with surgery from the start. For this reason, gastroenterologists and surgeons must work in concert in order to provide the best care for each patient. Proper fistula management also relies heavily on accurate diagnosis, especially defining the anatomy of the fistula, ascertaining whether abscess formation is present, and determining the location and extent of intestinal inflammation.

Treatment of Acute Severe Ulcerative Colitis

36

Jess L. Kaplan and Harland S. Winter

Case

A 13-year-old boy was previously well until he acutely developed non-bloody diarrhea while on a skiing vacation. The following day he continued to have nausea, vomiting, and diarrhea, and started a clear liquid diet. On day 3 of this acute illness, he continued to pass 6–8 liquid stools daily and began to notice red blood in the stool. He was treated in the local emergency room with intravenous fluids and discharged. Stool cultures for enteric pathogens, including *Escherichia coli* 0157, ova, parasites, and *Clostridium difficile* were all negative. His white blood cell count (WBC) was 15,900, hemoglobin 13 g/dL, and hematocrit 37%. Liver function tests, amylase, and lipase were all normal. C-reactive protein (CRP) was elevated at 25 mg/dL.

On day 6 of the illness, he noted increased bloody diarrhea and was admitted to the local hospital. Despite being kept nil per os (NPO), he continued to pass 3–4 loose, grossly bloody stools daily. On the seventh day of the illness, he became febrile to 39 °C and continued to pass 5–6 bloody stools daily. His albumin was decreased at 2.2 g/dL. He was transferred to a tertiary care facility.

On transfer, his vital signs were stable and he was afebrile. His weight was 46 kg. He appeared pale but was resting comfortably. He had no oral ulcers. His chest and cardiac examinations were normal. His abdomen was soft with diffuse but mild tenderness without guarding or rebound tenderness. He had no organomegaly. Upon admission, an upper endoscopy was normal, but the ileocolonoscopy revealed pancolitis (Fig. 36.1) with normal-appearing terminal ileum, consistent with ulcerative colitis. His Pediatric Ulcerative Colitis Activity Index (PUCAI) score was 65. He was made NPO, given intravenous fluids at 1.5 times maintenance, and started on intravenous methylprednisolone sodium succinate 20 mg every 12 h. Repeat stool analysis was negative for enteric pathogens. Biopsies of the colon showed moderate-to-severe chronic pancolitis without evidence of granulomas, and biopsies of the terminal ileum were normal. Electrolytes were monitored daily and corrected as necessary; hematocrit was maintained over 30% with packed red blood cell transfusions; albumin was replaced with salt-poor albumin (1 g/kg) when below 3.0 g/dL. After 3 days of intravenous corticosteroids, his PUCAI was 55. Because of ongoing diarrhea and bleeding, a peripherally inserted central catheter (PICC) was placed for nutritional support and total parenteral nutrition was started. His PUCAI score on day 5 of intravenous corticosteroids was 60. Options for rescue therapy were discussed with the patient and family, and the pediatric surgery team was consulted. On hospital day 6, he was given 10 mg/kg of infliximab intravenously. Over the next 2 days, stool output decreased; he was restarted on oral feedings and was dis-

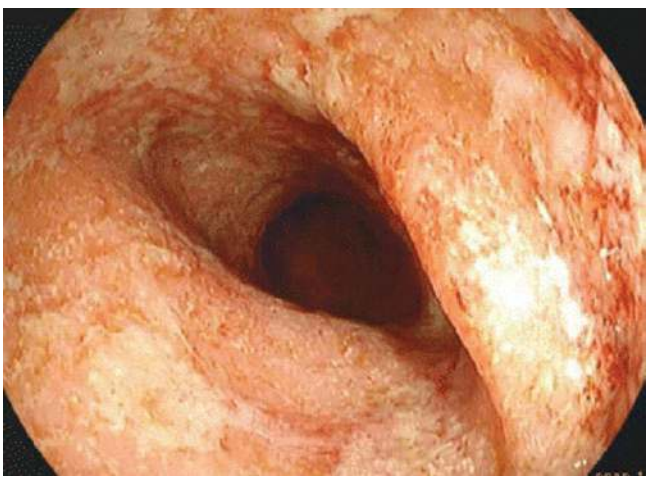

Fig. 36.1 Sigmoid colon: Diffuse inflammation with loss of vascular pattern and ulceration, typical of the pattern seen in ulcerative colitis

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_36

charged on day 10. He returned in 2 weeks for his second infliximab infusion, passing formed stools without visible blood, and a prednisone taper was started.

He continued to do well, and maintenance infliximab therapy was continued after induction therapy was complete. Approximately 7 months later, hematochezia and abdominal cramping returned 6 weeks following an infliximab dose. The infliximab trough concentration was 9 μg/mL, and the presence of anti-infliximab antibodies could not be determined. Stool cultures were negative for enteric pathogens, and *Clostridium difficile* testing was also negative. Oral prednisone was started, but symptoms did not improve. He was passing 10–12 grossly bloody liquid stools daily, with three nocturnal stools with peridefecatory cramping and fecal urgency. He was admitted to the hospital, made NPO, and started on intravenous methylprednisolone sodium succinate 20 mg every 12 h. On day 3, his PUCAI score was 60. A sigmoidoscopy was performed that revealed severe proctitis. Rectal biopsy showed severely active chronic colitis without evidence of granulomas, and immunohistochemistry for cytomegalovirus (CMV) was negative. A 10 mg/kg dose of infliximab was given (6.5 weeks following the previous dose) without clinical improvement. He developed a fever of 38.5 °C, and intravenous ampicillin, gentamicin, and metronidazole were started. Total parenteral nutrition was started on day 4. On day 6 of intravenous steroids, his stool output was >2 L, and he required a blood transfusion for symptomatic anemia. His C-reactive protein was 10 times the upper limit of normal. On day 9 of the hospitalization, he underwent a total abdominal colectomy and ileostomy. He was discharged 6 days later and subsequently returned for completion of the colectomy, creation of a J-pouch with ileostomy reversal, and ileal pouch-anal anastomosis (IPAA).

Introduction

The clinical course of ulcerative colitis (UC) in children is unpredictable. Compared to patients with adult-onset disease, children with UC have more extensive disease and often a more severe course, characterized by higher rates of corticosteroid use and shorter time to surgery [1, 2].

Severe exacerbations of UC are common in both children and adults and cause significant morbidity. These exacerbations can occur both at disease onset and as relapse in patients with established disease.

In 2008, the European Crohn's and Colitis Organization (ECCO) defined acute severe colitis (ASC) in adults as an exacerbation with more than six bloody stools per day with at least one of the following: tachycardia (>90 b/min), temperature >37.8 °C, anemia (hemoglobin <10.5 g/dL), or an erythrocyte sedimentation rate (ESR) >30 mm/h [3]. In children, ASC is generally defined by a Pediatric Ulcerative Colitis Activity Index (PUCAI) score ≥ 65 [4], a cutoff that has been validated in independent cohorts and has predictive value with regard to response to intravenous corticosteroid (IVCS) therapy [5, 6] (see Chap. 46, Appendix 3.2 for more details regarding PUCAI scoring). In adults, fulminant colitis has been defined by >10 stools per day with continuous bleeding, abdominal tenderness and distension, systemic toxic symptoms such as fever and anorexia, and blood transfusion requirement; this can progress to toxic megacolon with severe colonic distension (>6 cm), hypotension, altered mental status, and high mortality [7]. While colonic dilation is a hallmark of current or impending toxic megacolon (TMC), precise criteria for TMC in children have not been established. One study showed that in children ≥10 years of age, a transverse colon diameter ≥ 5.6 cm was suggestive of TMC [8], while in children younger than 10 years of age, a diameter > 4 cm is concerning for toxic megacolon [9].

The frequency of ASC in children with UC is not fully known, but it is suggested that rates are as or even higher than the rates in adults. For example, over a 3-year period, in the greater Toronto area, it was estimated that 28% of all children with UC developed a severe exacerbation requiring hospitalization for intravenous corticosteroids before the age of 15 [10]. Colectomy rates have decreased significantly since the introduction of biological agents to treat ulcerative colitis [11]. A retrospective European and North American study of 5-year outcomes in children with ASC demonstrated that about one-third of patients had colectomy. Children with new-onset disease who had oral corticosteroids within 3 months of admission, elevated ESR and hypoalbuminemia were more likely to have a colectomy. These data were obtained prior to therapeutic drug monitoring which could change outcomes [12].

The remainder of this chapter addresses the management and ASC in children.

Initial Management

ASC is a serious and potentially life-threatening exacerbation of pediatric UC. As such, care for patients with ASC should be in the hospital setting so that frequent monitoring of clinical status, disease progression, and potential complications can take place. The goals of management are medical stabilization, treating exacerbating factors such as certain infections and implementing a stepwise active treatment approach typically beginning with intravenous corticosteroids (IVCS) in order to control gastrointestinal hemorrhage while avoiding/limiting complications from the disease and/or therapy. Response to therapy should be frequently reassessed by a multidisciplinary team of providers, including, in many cases surgeons with experience in IBD, in order to help guide plans for subsequent treatment.

The initial management of ASC includes a complete history and physical examination, beginning with the assessment of vital signs and general appearance which may reveal signs of systemic toxicity such as hypotension, fever, significant tachycardia, or altered mental status. Abdominal tenderness should be assessed, keeping in mind that tenderness and even colonic perforation and peritoneal signs may be masked in patients on high-dose corticosteroids. The absence of bowel sounds is an ominous prognostic indicator. Frequent reassessment is necessary as progression to fulminant disease may be rapid. A PUCAI score should be calculated at the onset of symptoms and then daily during the exacerbation until improvement and disposition. A PUCAI score over 65 correlates with severe disease. This validated scoring system not only gives the provider an idea of the general well-being of the child but also predicts response to IVCS and helps guide the timing of subsequent "rescue" therapy [6].

Hospitalized patients with ASC should have intravenous access and be fluid-resuscitated to assure adequate hydration. Laboratory studies including a complete blood count, serum electrolytes, albumin, ESR, and CRP should be obtained and repeated frequently. Despite the lack of randomized controlled clinical trials to provide evidence-based guidance for optimal therapy, expert opinion suggests that mucosal healing is best achieved by keeping the hematocrit over 30%, the albumin over 3 g/dL, and the electrolytes in the normal range. Although not evidence-based, in theory, avoiding anemia and hypoalbuminemia may enhance the delivery of oxygen to the intestinal tissues and improve mucosal blood flow. Hypoalbuminemia was identified as a predictor of long-term colectomy [12]. Normal electrolytes decrease the likelihood of stasis related to poor motility. Measurement of fecal calprotectin or lactoferrin may be a useful baseline as repeated assessment can help define response to medical therapy.

Patients with IBD are at higher risk of being diagnosed with *Clostridium difficile* infection (CDI). In one single-center study, 18.4% of children with UC had a positive polymerase chain reaction (PCR) for the toxin B gene of *C. difficile* [13]. The percentages may be even higher in hospitalized children with IBD [14]. CDI is implicated in disease exacerbation and increases the risk for complications such as colectomy in adults with UC [15, 16]. Although there is not yet direct evidence that treating CDI in children with ASC improves outcomes, testing for and treatment of CDI is current standard practice and was recommended in the joint ECCO/European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) ASC guidelines [9]. Stools should be screened for both toxins A and B. Stools should also be cultured for other potentially treatable bacterial pathogens.

Plain films of the abdomen are recommended as part of the initial evaluation of severe colitis if there are any signs of systemic toxicity that may suggest fulminant disease or TMC [9]. However, since examination findings can be masked by corticosteroid therapy, our practice is to obtain a baseline KUB on every hospitalized patient with ASC. As previously mentioned, transverse colon dilation ≥56 mm and ≥40 mm is suggestive of TMC in children ≥10 and <10 years of age, respectively. Colonic dilation has also been shown to predict response to IVCS therapy in this setting [17].

Although children with ASC may not wish to eat or drink due to their physical symptoms, unless surgery is imminent, they should be allowed to do so, since available evidence from the adult literature shows that while bowel rest may decrease stool frequency and volume, it does not improve outcomes and may worsen nutritional status [18]. If a regular diet cannot be tolerated by the third or fourth day, then enteral or parenteral nutrition should be considered, as malnutrition may impair healing and delay clinical improvement. The risks of parenteral nutrition, including complications from central venous catheters (e.g., infection, thrombus) and electrolyte abnormalities, need to be balanced with potential benefits. There is no evidence to support any particular oral diet or dietary restrictions in ASC.

Unlike in Crohn disease, antibiotics are generally not indicated in ulcerative colitis, unless there is evidence of toxicity or infection. Since bowel perforations may be silent in patients on high doses of corticosteroids, any clinical signs of infection should be investigated and treated. In well-controlled trials in adults with ASC, intravenous (IV) antibiotics including ciprofloxacin [19] and metronidazole [20] have not been shown to improve ASC outcomes when used as adjunctive therapy to corticosteroids. No large or controlled pediatric studies directly address the efficacy of antibiotics in ASC; however, the recommendations are to treat with IV antibiotics if the infection is suspected or while awaiting confirmatory testing [9]. ASC patients with fulminant disease or suspicion or diagnosis of TMC should be treated with IV antibiotics. The antibiotic agent(s) used should target enteric bacteria, including anaerobes.

In a small series of 28 children with ASC who were randomized to receive quadruple antibiotics (amoxicillin, vancomycin, metronidazole, doxycycline/ciprofloxacin) plus corticosteroids or corticosteroids alone for 14 days, the PUCAI on day 5 was lower in the antibiotic group, but five children underwent colectomy by 1 year—3 who received antibiotics and 2 who received only corticosteroids [21]. A group of adults with ASC were randomized to intravenous placebo or ceftriaxone and metronidazole along with standard care. Patients in the antibiotic group had similar CRP, partial Mayo score and fecal calprotectin and were as likely to have complete remission on day three as the placebo group. There were no differences in the likelihood of requiring a colectomy [22]. These studies, albeit with a small num-

ber of subjects raise doubts about the short-term and long-term benefit of antibiotic therapy in ASC.

Adults who are hospitalized with ASC are routinely treated with anticoagulants for venous thromboembolism (VTE) prophylaxis. Hospitalized children with IBD are also at increased risk for VTE [23]. The prothrombotic tendency in IBD is thought to be attributable to many different factors including an increase in procoagulants, a decrease in anticoagulants, thrombocytosis, as well as endothelial and immunologic factors [24]. VTE is more common in children with active IBD than in those who have the quiescent disease [25]. This risk may be augmented by the relative immobility of sick, hospitalized IBD patients. In one study, risk factors for VTE in hospitalized children with IBD included older age, central venous catheters, parenteral nutrition, and the presence of a hypercoagulable condition [23]. Children with colonic IBD appear to be at higher risk for VTE [26]. Despite this, the overall incidence of VTE in hospitalized children remains low (11.8/1000 hospitalizations) [23], and there have been no pediatric studies assessing the benefits and risks of prophylactic anticoagulation in ASC or in IBD in general. As such, the routine use of anticoagulation in children with ASC is not currently recommended [9]. However, non-invasive methods of VTE prophylaxis like frequent mobilization, adequate hydration, and pneumatic/mechanical devices are advised, as they are of low risk, even if not well supported by current evidence. It is reasonable to consider anticoagulation in patients with other risk factors for VTE, including known hereditary causes of thrombophilia, smoking, and the use of oral contraceptives. When used, anticoagulation does not seem to worsen bleeding during IBD flares.

Intravenous corticosteroids (IVCS) are the recommended first-line treatment for ASC in children. IVCS have been used for acute exacerbations of UC for more than 60 years and have been shown to reduce mortality in adults [27]. There are no randomized trials evaluating the comparative efficacy of various CS doses in children. The current recommendations for CS dosing are for 1–1.5 mg/kg/day of methylprednisolone up to 40–60 mg/day [9]. The daily dose is often divided over two daily doses. Doses above 60 mg/day have not been found to be more effective in adults with ASC [28]. More recently, a prospective pediatric cohort study which followed 283 children with ASC for 1 year concluded that an IVCS dose of 2 mg/kg/day was not more effective than doses of 1–1.25 mg/kg/day in preventing the need for salvage therapy during the hospitalization or by 1 year, although day 5 PUCAI scores were improved in the high-dose CS group before sensitivity analysis [29]. In this study, IVCS dosing was at the discretion of the provider (not randomized), but propensity matching was performed to limit bias. Interestingly, glucocorticoid bioactivity in serum did not predict response to IVCS in a study of children with ASC [30].

Not all children with ASC improve with IVCS. A systematic review found a 34% (range 9–47%) IVCS failure rate in a pooled analysis of five studies of children with ASC [31]. In the one prospective study included in the analysis, 37 of 128 children (29%) failed to respond to IVCS and required second-line treatment [6]. Multiple predictors for poor response to IVCS in children have been identified. A multicenter prospective study that followed 128 children with ASC found a response to IVCS less likely in older patients and in patients with the established disease [6]. The same study showed that after multivariate analysis, additional day 3 and day 5 predictors of IVCS failure included high stool frequency and a large amount of blood in the stool. A high CRP on day 5 also predicted CS failure. The PUCAI score outperformed other clinical indices in predicting IVCS failure on both days 3 and 5. A PUCAI score >45 on day 3 predicted CS failure with a sensitivity of 92% and a negative predictive value (NPV) of 94%, indicating a high likelihood of response if the PUCAI score is ≤45. On day 5, a PUCAI score of >70 had a specificity and positive predictive value (PPV) of 100% for CS failure, while a score of >65 has specificity and PPV of 96% and 82%, respectively. The addition of fecal calprotectin or CRP to the model did not improve the accuracy of the PUCAI score. The findings from this study and others have formed the basis of recommendations for disease monitoring and for the timing of second-line/rescue therapy in children with ASC. Additional predictors of poor response to IVCS have also been identified. A prior single-center study found that a high number of nocturnal stools and high CRP were predictive of CS failure on days 3 and 5 [10]. The presence of a megacolon, defined as a transverse colon diameter >40 mm and >60 mm in children <12 and >12 years of age, respectively, and ulceration on abdominal x-ray may also predict IVCS failure [17]. A separate study showed that day 3 interleukin (IL)-6 levels predicted IVCS failure, although this did not hold true after multivariate analysis [32]. Finally, there is limited evidence that IVCS nonresponders have decreased fecal microbial richness/diversity compared to responders, though this is not yet clinically applicable [33].

Monitoring Response to Corticosteroids

In general, monitoring for response to initial therapy begins with a careful and frequent reassessment of vital signs, stool frequency, volume, blood loss, and abdominal pain as well as changes in the abdominal examination. The validation of the PUCAI score in predicting IVCS failure has led to a suggested algorithm and the following recommendations for disease monitoring and for the timing of second-line, also referred to as "rescue" or "salvage", therapy [9]. A PUCAI score > 45 on day 3 of IVCS should initiate preparation for

second-line therapy, including discussion of potential risks and benefits with patients and families and inclusion of a surgeon with experience in IBD. A PUCAI score > 65 on day 5 should prompt initiation of second-line therapy. Patients with PUCAI scores between 35 and 65 on day 5 can continue IVCS for an additional 2–5 days, at which point further recommendations are based on the PUCAI score at that time. Patients who improve on IVCS and have a PUCAI score <35 on day 5 are unlikely to require rescue therapy before discharge [9]. Thiopurines can be considered in IVCS responders, particularly in those who were previously naive, but the therapeutic benefit is often delayed for 2–3 months; so, they have little role in the acute setting.

There is no current evidence to support the value of repeat colonoscopic evaluation in ASC patients who are improving on IVCS in the clinical setting. However, repeat sigmoidoscopy is suggested if the day 3 PUCAI score is >45 in order to search for evidence of Crohn disease such as granulomas and to exclude cytomegalovirus (CMV) colitis, which can complicate ASC and may alter therapy. While the prevalence of CMV colitis in children with ASC is not known, it is relatively common in adults with UC, particularly in those with steroid-refractory disease [34]. Mucosal biopsies should be obtained and evaluated for signs of CMV disease (deep ulcerations and viral inclusions) as well as immunohistochemistry [9]. CMV colitis should prompt an infectious disease consultation, and antiviral treatment should be considered [35]. In a small study pediatric patients who were found to be CMV-positive during hospitalization for ASC did not have an increased incidence of colectomy during admission when compared to children with ASC who were CMV-negative [36].

Medical Rescue Therapy

Patients with ASC with poor response to IVCS require rescue therapy. About one-third of children with ASC require rescue therapy before discharge from the hospital. In adults, the earlier use of rescue therapy appears to decrease mortality [37], and extending IVCS without rescue treatment beyond 14 days is unlikely to provide benefit and may increase the risk for complications, including, but not limited to, opportunistic infections, metabolic and electrolyte abnormalities, osteopenia/porosis, and psychiatric disturbance. The goals of rescue therapy are to improve symptoms and allow for the eventual discontinuation of CS. Current rescue therapy options for children with ASC include infliximab, calcineurin inhibitors (cyclosporine and tacrolimus), and colectomy. Although the data supporting these rescue therapies are primarily in CS refractory patients, these treatments are also used without IVCS in patients with contraindications or prior lack of response to CS.

Infliximab (IFX) is a monoclonal antibody against TNF-α that can induce and maintain remission in pediatric UC [37]. Pooled data from six pediatric case series (n = 126) of ASC patients treated with IFX showed a 75% (67–83%, 95% CI) response rate by the time of hospital discharge and a 64% colectomy-free rate during follow-up which ranged from a few months to a few years [31]. In one prospective study, 76% (25/33) of children with ASC refractory to IVCS had short-term responses to IFX [6]. The remaining 24% underwent colectomy. At 1 year, 55% had sustained response to IFX and 45% had CS-free sustained response, while an additional 28% required colectomy by 1 year. In a more recent retrospective study from a single center in Italy, 80% of ASC patients had short-term responses to IFX, but 50% of these patients went on to colectomy by 24 months [38]. Predictors of IFX failure may include shorter disease duration and more active disease at the time of admission and day 3 of IVCS [6]. IFX is typically dosed at 5 mg/kg at baseline and then repeated at 2 and 6 weeks following the initial dose. The pharmacokinetics of IFX in children with moderate-to-severe UC appears to be similar to that in adults [39]. However, many pediatric centers use higher doses (10 mg/kg) and/or shorter dosing intervals of IFX in ASC. The introduction of therapeutic drug monitoring has resulted in the clinical practice of adding additional doses if the IFX level is below 10. Since IFX is bound to albumin, patients who have serum protein loss in the stool are more likely to also lose IFX. While there is currently a lack of direct evidence to support this practice, some have suggested that IFX clearance may be higher in patients with acute severe disease leading to a requirement for higher dosing [40]. A recent retrospective study of children with IBD (CD and UC) showed that patients with a larger colonic inflammatory burden were more likely to require IFX dose escalation by 12 months than patients with limited or moderate disease and that 43% of patients who started at 5 mg/kg dosing did not improve with dose escalation [41]. Although this study was not limited to ASC patients, it does provide some indirect evidence that children with more extensive disease may benefit from higher IFX doses at the start of treatment. ECCO/ESPGHAN guidelines recommend IFX as the preferred rescue therapy in patients with previous thiopurine failure as IFX can also be effective as a maintenance agent in UC [9]. Prior to starting IFX, tuberculosis and Hepatitis B status should be documented.

Cyclosporine (CsA) is a calcineurin inhibitor that has been shown to be effective at inducing remission in adults with ASC [42, 43]. Support for the use of CsA in children with ASC comes from eight retrospective case series (n = 94) [31]. Pooled short-term response rates were 81% (76–86%, 95% CI), but long-term colectomy-free rates dropped to 39% (29–49%, 95% CI) in patients treated with CsA. There is heterogeneity in the eight studies with regard to CsA dose, route of administration, and duration of follow-up, which makes

interpretation difficult. CsA is generally used for 3–6 months as a bridge to maintenance therapy, often thiopurine treatment, which can take 2–3 months to become effective. CsA has not been studied as a long-term maintenance agent at UC. More prolonged use of CsA is limited by serious potential side effects such as hypertension, gingival hyperplasia, electrolyte disturbance, and renal and neurologic toxicity. Dosing is generally started intravenously and then transitioned to oral dosing (4–8 mg/kg/day) once the response is achieved [9]. Trough levels should be monitored frequently with preferred levels starting in the range of 150–300 ng/mL. Clinical response is generally seen in 5–7 days. Adult guidelines suggest that *Pneumocystis jiroveci* prophylaxis should be routinely given to patients treated with CsA, who are also treated with other immunosuppressive agents [44].

Tacrolimus, another calcineurin inhibitor, also appears effective as short-term rescue therapy for children with CS-resistant ASC. Retrospective studies report short-term response rates between 50 and 89% with long-term colectomy-free rates ranging from 0 to 40% [45–47]. The largest of these studies reported a 40% colectomy-free rate at 26 months, with most patients having been bridged to either thiopurines or IFX [45]. Hypertension (52%), tremor (46%), and hyperglycemia (35%) were common side effects of tacrolimus treatment. Initial dosing is typically 0.1 mg/kg/dose twice daily (0.2 mg/kg/day), and the dose is adjusted to reach levels of 10–15 ng/mL during induction and 5–10 ng/mL during maintenance therapy [45]. Tacrolimus may have more reliable oral absorption and may be better tolerated than CsA. Otherwise, time to response and side effects are similar to those of CsA, as is the need for *P. jiroveci* prophylaxis when used with other immunosuppressive agents.

There are no pediatric studies that directly compare the efficacy of medical rescue options in ASC. A prospective, multicenter, randomized open-label trial in adults with ASC refractory to IVCS found no difference in the efficacy of CsA and IFX [48]. A recent meta-analysis confirmed that these two treatments were equally successful in randomized trials but concluded that IFX appeared slightly more effective than CsA in nonrandomized trials [49]. Adverse events, postoperative complications, and mortality were similar with both treatments. Two small retrospective studies have compared tacrolimus and IFX rescue in adults with ACS [50, 51]. Neither study showed a difference in short-term efficacy, but the larger of the two studies showed that IFX was more effective than a tacrolimus bridge to thiopurine strategy in the longer term [51].

There is limited evidence from retrospective adult studies that a second medical rescue therapy (IFX following calcineurin inhibitor or vice versa) can prevent colectomy in ~30–70% of ASC patients following failure of a first rescue agent [52–54]. However, due to the high risk for serious toxicity with this approach, the use of a second rescue agent is not currently recommended for children with ASC until additional data on efficacy and safety can be obtained [9].

Surgery

The indications for surgical treatment in ASC are perforation, toxic megacolon, massive hemorrhage, or failure to respond to maximal medical management. However, in rare circumstances in which there are contraindications to medical rescue therapy, surgery may be considered first. The details of surgical options for UC are detailed in Chap. 41. The current surgical standard of care for UC is a restorative proctocolectomy consisting of a total colectomy, and rectal mucosectomy with ileal pouch-anal anastomosis (IPAA). This procedure can be done in one, two, or three steps. The first step in a three-step procedure includes a subtotal colectomy with ileostomy and Hartmann's pouch creation. This is followed by completion of the colectomy, rectal mucosectomy, and restorative IPAA with diverting ileostomy (step 2), and finally by ileostomy takedown reversal (step 3). In a typical two-step procedure, bowel continuity is immediately restored when the ileal pouch is formed (step 2), without a diverting ileostomy. Alternatively, the abdominal colectomy and mucosectomy may be performed with IPAA and diverting ileostomy in step 1 followed by ileostomy takedown (step 2). At some centers, abdominal colectomy and mucosectomy with IPAA may be done as a single operation [55]. The decision on which operation(s) to select is highly dependent on the experience and expertise of the surgical team.

High-dose corticosteroids have been shown to increase short-term complications such as postoperative infection [56]. Additionally, adult studies show a lower risk of IPAA leak in patients with a temporary protective ileostomy [57]. For these reasons, it is recommended that a two- or three-step procedure be considered in more complicated patients including those requiring emergent surgery, those treated with high-dose corticosteroids, or for those with significant malnutrition [9]. In a retrospective pediatric study, preoperative exposure to calcineurin inhibitors or thiopurines within 30 days of surgery or to IFX within 90 days of surgery was not associated with an increase in postoperative complications [58]. Whenever possible, efforts should be made to maximize nutritional status before surgery. Postoperative risks as well as typical outcomes should be discussed with patients and families to help form realistic goals. Additional issues that need to be discussed prior to surgery include the risk for pouchitis and potential issues with future fertility in female patients [59]. Patients also need to be aware that the risk for an eventual diagnosis of Crohn disease following restorative proctocolectomy for UC is 5–10% [60]. In addition to medical and surgical management, stress management and support for the patient and family are essential

components of the multidisciplinary approach needed to optimally care for children with ASC. Speaking with other patients/parents and a mental health evaluation should be part of the care of patients with ASC in whom surgical treatment is being considered.

Future Directions/Conclusions

Recommendations for the management of ASC in children are somewhat limited by the lack of pediatric data. Important questions remain unanswered and the rarity of ASC in children makes prospective interventional trials challenging to complete. Large, multicenter collaborative studies may be best positioned to answer some of these questions. Specific gaps in knowledge include longer-term outcomes of children with ASC, the most effective dosing regimens for rescue medications like IFX and calcineurin inhibitors, and the role of CMV in pediatric ASC. There needs to be an improved understanding of predictors of response to first-line rescue therapy which can help personalize care going forward. The role of established UC treatments like adalimumab, which has recently been approved by the FDA for ASC, and vedolizumab need to be elucidated. Despite recent improvements in medical treatment, many patients continue to require surgical intervention before discharge, and still more within the following 12 months.

Dietary Therapies for Inflammatory Bowel Disease

37

Natalie Stoner and Ronen Stein

Abbreviations

AIP	Autoimmune protocol
CD	Crohn disease
CDED	Crohn disease exclusion diet
CD-TREAT	Crohn disease treatment with eating diet
DHA	Docosahexaenoic acid
EDIP	Empirical dietary inflammation pattern
EEN	Exclusive enteral nutrition
ESPEN	European Society for Clinical Nutrition and Metabolism
FODMAP	Fermentable oligosaccharides, disaccharides, monosaccharides, and polyols
GAPS	Gut and Psychology Syndrome
HBI	Harvey Bradshaw Index
IBD	Inflammatory bowel disease
IBD-AID	Inflammatory Bowel Disease Anti-Inflammatory Diet
IL-10	Interleukin 10
n-3	Omega-3
n-6	Omega-6
PEN	Partial enteral nutrition
PUFA	Polyunsaturated fatty acids
SCD	Specific carbohydrate diet
TNFα	Tumor necrosis factor-alpha
UC	Ulcerative colitis

Introduction

Inflammatory bowel diseases (IBD) Crohn disease (CD) and ulcerative colitis (UC), are chronic, relapsing, and remitting inflammatory conditions of the gastrointestinal tract. They are complex disorders with genetics, environmental influences, and the immune system all involved in disease development and progression [1]. To date, over 200 genetic polymorphisms have been associated with the development of IBD [2]. However, data from twin studies have demonstrated that genetics alone cannot entirely explain the etiology of IBD as the concordance rates for CD and UC among monozygotic twins are only 45% and 15%, respectively [3]. This indicates that environmental factors play a large role in the development of IBD. The current understanding of the etiology of IBD is that in a genetically susceptible host, environmental factors may trigger dysregulation of the innate and adaptive immune response and lead to chronic inflammation in the gastrointestinal tract [4].

The two largest environmental exposures for the gastrointestinal tract are the microbiota and dietary intake, although cigarette smoking, antibiotics, nonsteroidal anti-inflammatory drugs, and infectious agents are among the other environmental exposures associated with IBD [5]. As mentioned in Chap. 4, there is strong evidence from multiple studies that the gut microbiota is involved in the pathogenesis of IBD, as many of the genetic polymorphisms associated with IBD regulate the body's interactions with microbes [6]. As we will describe later in the chapter, there have been multiple studies showing that dietary intake itself plays an important role in the composition and function of the gut microbiota. Therefore, diet is likely involved in the pathogenesis of IBD and may be a potential therapeutic target.

In this chapter, we will summarize epidemiological data supporting the role of diet in IBD, show that the composition of the gut microbiota is heavily influenced by diet, and describe the relationship between macronutrients, food

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_37

additives, oral supplements, and IBD. We will also review the literature on a number of structured diets proposed to treat IBD.

Diet and Worldwide Trends in IBD

The incidence and prevalence of IBD vary by region, with the highest rates in developed nations, particularly in North America and Northern Europe. The overall global incidence of IBD is rapidly increasing worldwide, not only in westernized societies but also in developing countries with historically low rates [7, 8]. The influences of globalization and industrialization in countries such as China, India, Japan, and South Korea have resulted in increased urbanization, improved sanitation, increased antibiotic use, sedentary lifestyles, and refrigeration [9, 10]. However, this has also resulted in the adaptation of a westernized diet, which is associated with the development of CD in a newly industrialized population [11].

Population migration studies also suggest that westernization may be a risk factor for the development of IBD. Children who immigrate to western countries from developing nations have a higher risk of IBD than their counterparts from their country of origin, but lower risk than children in their new country [12, 13]. The younger the child is at the time of immigration, the higher the risk of IBD [12]. However, second-generation immigrants have an even higher risk of developing IBD and, in fact, assume the same incidence of IBD as their peers in their new country [9, 12]. This may indicate that environmental exposures, such as a westernized diet, particularly early in life, impact the development of IBD.

Diet and the Gut Microbiota

Multiple studies have shown that the composition of the gut microbiota differs between healthy controls and individuals with IBD [14–17]. There is decreased microbial diversity in IBD with an increased proportion of bacteria in the phyla *Actinobacteria* and *Proteobacteria*, including *Escherichia coli*, and a decrease in *Firmicutes*, specifically in the group *Clostridia* [18, 19]. This dysbiosis, or alteration in the balance between commensal and pathogenic microorganisms, has been hypothesized to be involved in the pathogenesis of IBD. *Clostridia*, including *Faecalibacterium prausnitzii*, produce butyrate, a short-chain fatty acid that is an important energy source associated with colonic epithelial health. Conversely, adherent invasive *E. coli*, which are able to cross across ileal epithelium and can be found within granulomas in CD patients, may be linked to the development of IBD [20].

Dietary patterns can alter the composition of the gut microbiota starting in infancy. The composition of the gut microbiota differs between breastfed and formula-fed infants. The intestinal tract of formula-fed infants is colonized with increased numbers of *E. coli*, whereas in breastfed infants, *Bifidobacterium* species predominate and account for approximately 75% of microorganisms in the intestinal tract [21]. The human milk oligosaccharides contained in breast milk are felt to selectively promote the growth of *Bifidobacterium* species [22], which may have anti-inflammatory properties [23]. A decrease in *Bifidobacterium* species has been found among CD patients [15]. The effect of breastfeeding on *Bifidobacterium* species may help explain why breastfeeding has been shown to have a protective effect against the development of pediatric CD [24].

Long-term dietary patterns also affect the microbiome. Individuals on a westernized diet, high in animal fat and low in fiber, have high levels of *Bacteroides* species, whereas, in those on a high-carbohydrate, low-fat diet, *Prevotella* species predominate [25]. Likewise, another study compared the microbiome of healthy children from a village in rural Africa on a low-fat, high-fiber diet to counterparts in Europe on a westernized diet. The African children had a high proportion of *Prevotella* species compared to the European children [26].

Mounting evidence shows that the composition of the gut microbiota is heavily influenced by diet. However, in addition to changing the makeup of the microbiome, animal models have shown that dietary intake can also affect its function [27]. A diet high in milk fat was found to induce colitis in interleukin 10 (IL-10) knockout mice by facilitating the growth of *Bilophila wadsworthia*. Sulfur is an important nutrient necessary for *B. wadsworthia* to thrive. Milk fat was found to stimulate the secretion of sulfur-containing taurine-conjugated bile acids thereby creating an environment that preferentially promoted the growth of *B. wadsworthia.* Increased populations of *B. wadsworthia* were associated with greater inflammatory cytokine burden and the development of colitis in IL-10 knockout mice. *B. wadsworthia* may also have exerted its effect by the production of hydrogen sulfide leading to disruption of the intestinal epithelial barrier [28]. This indicates that by affecting the composition and function of the microbiome, dietary intake can stimulate immune responses in genetically susceptible hosts, leading to the development of chronic inflammation [29].

Dietary Components and IBD

The typical westernized diet contains high amounts of saturated fats, refined sugars, red meat, and processed foods with limited fresh fruits, vegetables, and fiber [30]. Many studies have investigated the dietary risk factors associated with new-onset IBD and have identified many components of a westernized diet [31]. In particular, a diet high in animal fats, omega-6 (n-6) fatty acids, and refined sugars has been associated with an increased risk of IBD. Conversely, high vegetable intake has been associated with a decreased UC risk and a diet high in fruits and fiber has been associated with a decreased CD risk [32]. The increase in food processing in the western diet has also significantly decreased the amount of microbiota-accessible carbohydrates content—indigestible polysaccharides that provide value and shaping to the microorganisms found within the gut [33]. In a study observing the effects of diet on microbiota changes, a semi-vegetarian diet high in fiber (>30 g/day), low in saturated fat, and low in sulfites that eliminated added sugar, processed foods, carrageenan, and polysorbate 80 was found to provide a significant increase in the microbial diversity in healthy individuals [33]. In a recent analysis of three prospective cohorts, empirical dietary inflammation pattern (EDIP) scores were calculated after collecting data and examining food frequency questionnaires completed by 166,903 women and 41,931 men from the Nurses Health Study, Nurses Health Study II, and Health Professional Follow-up Study. The scores were based on the sums of 18 foods identified within the questionnaires. The analysis found that dietary patterns associated with high inflammatory potential were associated with an increased risk of CD but not UC. Foods associated with a higher EDIP score included processed meats, red meat, organ meat, some fish and seafood, certain vegetables, refined grains, tomatoes, and regular/diet sodas [35]. Below, we review the literature on the relationship between different dietary components and IBD based on in vitro studies, animal models, and epidemiological data (summarized in Table 37.1).

Table 37.1 Dietary components and IBD

Dietary component	Dietary sources	Association with IBD
Saturated fat	Animal fat, milk fat	Increased risk of CD with high intake of saturated fat [32] Milk fat-induced colitis in IL-10 knockout mice [28]
Omega-3-polyunsaturated fatty acid (n-3 PUFA)	Fish, flaxseed	Decreased risk of CD and UC with high intake of n-3 PUFA [36] Decreased risk of CD and UC with high docosahexaenoic acid intake [37, 38] Supplementation with n-3 PUFA not shown to have benefit as maintenance therapy in UC or CD [39, 40]
Omega-6-polyunsaturated fatty acid (n-6 PUFA) Monounsatruated Fatty Acids (MUFAs)	Avocado, egg, nuts, poultry, red meat, vegetable oils Vegetable oils	Increased risk of CD and UC with high intake of n-6 PUFA [32] High ratio of n-6 PUFA to n-3 PUFA associated with an increased risk of CD [36] Conflicting reports for therapeutic potential in IBD Dietary oleic acid intake is inversely associated with UC development [40]
Simple carbohydrates	Candy, refined sugars, sweetened drinks	Increased risk of CD and UC with high intake of simple carbohydrates [32]
Complex carbohydrates/fiber	Fruits, legumes, vegetables, whole grains	High fiber, fruit, and vegetable intake is associated with decreased CD risk [36] and high vegetable intake is associated with lower UC risk [32]
Maltodextrin	Artificial sweeteners, breakfast cereals (selected), candy, infant formulas, processed snack foods	Maltodextrin promoted adhesion of adherent invasive *E. coli* based on in vitro studies [41] Consumption may be a risk factor for the IBD-prone population and a factor promoting low-grade intestinal inflammation leading to metabolic abnormalities [42]
Emulsifiers (e.g., carboxymethylcellulose, polysorbate-80, carrageenan) Sulfites	Bread, coffee creamers, dressings, ice cream, margarine, mayonnaise, processed cheeses, sauces Dried fruits, deli meats, hot dogs, sausages, canned fruits and vegetables	Positive correlation between emulsifier intake and CD incidence [43] Emulsifiers induced mild colitis in wild-type mice and severe colitis in IL-10 knockout mice [44] Carrageenan consumption resulted in the loss of tight junction competence [45] Polysorbate 80 increased bacterial translocation across the intestinal epithelium [43] Sulfites damaged beneficial bacteria, Lactobacillus and S. thermophilus in-vitro [46]
Curcumin	Turmeric, oral supplementation	Supplementation with pure curcumin was superior to placebo for induction of remission [47] and maintenance of remission [48] in UC
Iron	Heme iron (fish, red meat, poultry), non-heme iron (fortified cereals, fruits, vegetables), oral supplementation	Increased risk of CD and UC with high meat intake [32] Increased risk of UC flares with red meat consumption [49] Oral iron supplementation worsened colitis by generating oxidative stress in animal models [50]

Macronutrients

Fat

High total fat intake, a component of the westernized diet, is associated with the development of IBD [32]. Even among healthy subjects, a high-fat diet has been shown to increase markers of systemic inflammation [51]. A study of dietary intake among the Japanese population annually from 1966 to 1985 found that total fat intake was strongly correlated with the development of CD [11].

Although increased total fat intake is associated with IBD, the specific type of fat consumed may be a more important risk factor. Fatty acids are comprised of saturated fats, polyunsaturated fatty acids (PUFA), and monounsaturated fats [31]. Products with animal and milk fat contain a high proportion of saturated fat [28]. In a study completed on mice, a high-fat diet was found to alter the spatial distribution of microbiota in the duodenum, jejunum, and ileum [52]. Multiple studies have found a high intake of saturated fat to be a risk factor for the development of IBD [32]. Likewise, milk fat has been shown to induce colitis in susceptible hosts in other animal models [28]. Moreover, among subjects with known UC, studies have found increased red meat consumption to be a risk factor for disease flares [49]. In a recent cross-over study in 17 UC patients in remission or with mild disease, a low-fat diet resulted in decreased markers of inflammation and reduced intestinal dysbiosis in fecal samples [53]. Conversely, among patients with CD in remission, the Food and Crohn Disease Exacerbation Study trial found that the level of red meat and processed meat consumption was not associated with time to symptomatic relapse [54].

Similar to fat, alcohol is calorie-dense. Alcohol consumption among IBD patients is similar to the general population and is known to be pro-inflammatory and harmful to gut barrier function [55]. Several studies reveal the worsening of IBD symptoms among patients who consume alcohol. However, more studies are needed to identify the exact association between alcohol intake and IBD disease activity and to determine if there is a specific quantity of alcohol that can be safely consumed [55].

Increased intake of PUFA has also been linked to IBD [32, 40]. PUFA are comprised of n-6 and omega-3 (n-3), and it is the relative ratio of these fatty acids that is important [36]. The westernized diet contains an unbalanced ratio of n-6 to n-3 PUFA, which is a risk factor for IBD [30]. In animal and in vitro models, n-3 PUFA has been found to have anti-inflammatory properties, including inhibition of macrophage tumor necrosis factor-alpha (TNFα) production, while n-6 PUFA is broken down into byproducts that are pro-inflammatory [56, 57]. Foods higher in n-3 PUFA include fish and flaxseed [58]. Vegetable oils, poultry, and red meats are high in n-6 PUFA [30]. Among the n-3 PUFAs, docosahexaenoic acid (DHA) may have the strongest anti-inflammatory effects, as several studies have found an inverse association between DHA intake and risk of developing UC and CD, although no association was found with eicosapentaenoic acid, another n-3 PUFA [37, 38]. Despite these promising epidemiological results, systematic reviews of n-3 PUFA supplementation have not shown any benefit as a maintenance therapy of remission for patients already diagnosed with UC or CD [39, 59]. A 2014 Cochrane review found n-3 PUFA supplementation to be ineffective for the maintenance of IBD [59]. Interestingly, a large cohort of women from the high school diet study completed validated dietary questionnaires to further investigate dietary factors that may influence the pathogenesis of CD and UC. This prospective study documented 70 incident cases of CD and 103 cases of UC and found an association between greater fiber and fish intake during high school with a reduced risk of CD. While the study also investigated other specific food groups of an adolescent diet, those with fish intake <10 g/day compared to those with >30 g/day had a 57% lower risk of CD [60].

Carbohydrates

Carbohydrates are comprised of monosaccharides, disaccharides, oligosaccharides, and polysaccharides. Monosaccharides (e.g., glucose and fructose) and disaccharides (e.g., lactose and sucrose) are also called simple carbohydrates, whereas oligosaccharides and polysaccharides are complex carbohydrates [31]. Processed simple sugars are known as refined sugars. There is no association between total carbohydrate intake and the risk of developing IBD. There are also no studies that demonstrate a difference in carbohydrate requirements in pediatric patients with IBD compared to the healthy population [61]. However, studies have found increased consumption of simple carbohydrates to be associated with a higher risk of both CD and UC [32].

Dietary fibers are nondigestible oligosaccharides and polysaccharides and are comprised of insoluble and soluble fiber. Insoluble fibers pass through the gastrointestinal tract mostly undigested, adding bulk and reducing transit time for stool. Cellulose is an important insoluble fiber found in fruits, vegetables, flaxseed, and quinoa. Soluble fibers, such as inulin and pectin, are found in grains and nuts. They are digested via fermentation by the gut microbiota producing short-chain fatty acids, such as acetate, butyrate, and propionate [58]. Not only is butyrate a critical energy source for colonocytes, but it is also felt to help maintain gastrointestinal homeostasis [31, 58]. In vitro studies have shown that fiber can enhance epithelial barrier function [58, 62]. Additionally, multiple epidemiological

studies have associated increased fiber intake with a decreased risk of developing CD and UC [32, 36].

The clinical efficacy of prebiotics in IBD is limited. Prebiotics are types of dietary fiber that promote favorable bacteria in the gut that can benefit the host. Prebiotics include fructans, galacto-oligosaccharides, and can be found in foods such as asparagus, beets, garlic, and lentils [63]. Evolving evidence suggests that prebiotic fibers may be useful in maintenance of remission in patients with UC. Yet, fiber in the form of fructo-oligosaccharide is not effective in CD treatment [64]. A significant increase in colonic butyrate production was found in a study investigating clinical symptom improvement in UC patients who were provided inulin, a soluble fiber found naturally in chicory root [63]. Another study investigating the effect of inulin on inflammation of the ileal reservoir evaluated 20 patients who were provided with dietary supplementation (24 g) of inulin for 3 weeks. Results found those that were provided with supplementation had increased butyrate concentrations, lowered stool pH, decreased numbers of *Bacteroides fragilis*, and diminished concentrations of secondary bile acids in the feces. This was endoscopically and histologically associated with a reduction of inflammation of the mucosa in the ileal reservoir [65].

A low-residue, low-fiber diet has been the historical recommendation for patients with active IBD, including those without stricturing disease [58]. However, there has been no proven benefit to this dietary therapy in non-stricturing diseases. A study comparing a low-residue diet to an unlimited diet among CD patients with a non-stricturing disease phenotype showed no difference in symptoms, hospitalizations, or complications, including the need for surgery [66]. Additionally, a semi-vegetarian diet, high in fiber, has been shown to improve clinical outcomes in a small cohort of adult CD patients [67].

Micronutrients and Trace Minerals

Patients with IBD are prone to micronutrient deficits, especially those with active small bowel disease or previous resections. Vitamin D deficiency is highly prevalent in pediatric patients with IBD due to a number of factors including self-exclusion of dairy products, impaired absorption, bile salt malabsorption, medical advice to limit and protect against sun exposure, seasonal changes, and geographical variation—as IBD is more common at northern latitudes [68]. In a retrospective longitudinal study evaluating vitamin D levels, inflammatory markers, and clinical disease activity in IBD patients, low vitamin D levels were associated with higher fecal calprotectin in UC and CD [63, 69, 70]. A deficiency of vitamin D was correlated with an increase in disease flares, hospitalizations, and steroid use [63]. The findings of a prospective cohort study of 72,719 women enrolled in the Nurses' Health study found a significant inverse association between dietary and supplementary vitamin D and the risk of developing UC and a non-significant reduction in CD risk [69].

Dietary zinc is thought to potentially influence the risk of IBD through effects of autophagy and maintenance of the intestinal barrier [69]. Additional new data suggests that a diet rich in vitamin D and zinc may protect against CD, but not UC [71]. In another study involving two large prospective cohorts from the Nurses Health Data, intake of zinc was inversely associated with risk of CD, but not UC [69].

Several other micronutrient deficiencies have been studied in IBD patients and animal models with varying measures of clinical significance and are featured in Table 37.2. Although these results are promising, large human studies are needed to determine if vitamin and mineral supplementation might offer a therapeutic role in IBD.

Table 37.2 Micronutrient and vitamin deficits in IBD

Micronutrient	Sources	Association with IBD
Biotin	Liver, smaller amounts in fruits and vegetables[a]	Deficiency associated with an IBD-like state in mouse model associated with failure to thrive, microcephaly, alopecia, dermatitis, and conjunctivitis [72] Biotin therapy led to delayed onset and severity of colitis and accelerated healing in mice challenged with dextran sodium sulfate. Oral biotin supplementation (1 mmol/L) was found to prevent the production of inflammatory cytokines and maintain the integrity of the intestinal barrier [72]
Folate	Dark green leafy vegetables, fortified cereals[a]	Folate deficiency hindered the conversion of homocysteine to methionine, which increases oxidative stress in the body. Studies in mice demonstrated a susceptibility towards intestinal inflammation in mice fed diets deficient in folate [70]
Selenium Vitamin D	Fish, meats (organ), eggs, milk, shellfish[a] Fatty fish, fortified milk, cod liver, sunlight[a]	Selenium deficiency worsened experimental colitis by affecting multiple pathways involved in inflammation, oxidative stress, and alteration of the gut microbiota [70 Low vitamin D levels are associated with higher fecal calprotectin in UC and CD [63] Deficiency correlated with an increase in disease flares, hospitalizations, and steroid use [63]
Zinc	Seafood, meats, greens, whole grains[a]	Intake of zinc is inversely associated with risk of CD, but not UC [69] Thought to potentially influence the risk of IBD through the effects of autophagy and maintenance of the intestinal barrier [69]

[a]ASPEN Core Curriculum [73]

Food Additives

Maltodextrin is a polysaccharide food additive commonly found in infant formula, breakfast cereals, candy, artificial sweeteners, and processed snack foods [74]. In animal studies, maltodextrin has been found to interfere with the integrity of the gastrointestinal epithelial barrier [75]. Recently, Laudisis et al., found consumption of foods with maltodextrin leads to the advancement of intestinal inflammation and that maltodextrin adversely affects the intestinal environment by promoting depletion of the protective mucus layer [42]. Adherent invasive *E. coli* exposed to maltodextrin have enhanced biofilm formation and improved adhesion to intestinal epithelial cells. Additionally, in vitro, maltodextrin promotes adhesion of adherent invasive *E. coli* [41].

Emulsifiers are common food additives that have both hydrophilic and lipophilic properties, which allow for the mixture of otherwise immiscible substances. Common emulsifiers include carboxymethylcellulose, carrageenan, and polysorbate-80 [31, 44]. Emulsifiers are found in processed foods, including store-bought bread, processed cheeses, ice cream, dressings, margarine, mayonnaise, sauces, and coffee creamers [76–81]. Carrageenan refers to high molecular weight sulfated polysaccharides extracted from seaweeds that are used to thicken and emulsify foods. In vitro studies have shown that carrageenan decreases gastrointestinal epithelial integrity [82]. Increased intake of emulsifiers has been positively correlated with CD incidence [43]. Consumption of carboxymethylcellulose and polysorbate-80 in wild-type and IL-10 knockout mice was studied over 12 weeks [44]. Emulsifier consumption resulted in low-grade chronic colitis in wild-type mice and severe colitis in IL-10 knockout mice. Intestinal permeability increased as a result of emulsifier intake with bacterial-epithelial distance inversely correlated with severity of inflammation. This suggests that emulsifier exposure is associated with translocation of bacteria, confirming the findings of a previous in vitro study [62]. The importance of host-microbiota interactions was further supported by the observation that colitis did not occur in germ-free mice exposed to emulsifiers. However, when the microbiota from emulsifier-exposed mice was transferred to emulsifier-naïve mice, inflammation resulted [44]. Human intervention studies investigating emulsifier consumption and IBD are needed to better understand the association between emulsifiers and IBD.

Oral Supplements

Curcumin

Curcumin is the major yellow pigment found in turmeric and has historically been used in traditional Chinese medicine to treat a variety of inflammatory conditions [47]. In vitro studies have shown curcumin to have antioxidant and anti-inflammatory properties, while in mice, curcumin has been found to improve colitis via downregulation of TNFα and nuclear transcription factor kappa B [83]. A pilot study of five patients with ulcerative proctitis and five patients with CD who received an oral pure curcumin preparation for 2–3 months found improvement in inflammatory markers and disease activity scores [84]. A multicenter, double-blind placebo trial of 82 subjects with quiescent UC on mesalamine or sulfasalazine therapy showed that curcumin was superior to placebo for maintenance of remission [48]. Another multicenter, double-blind, clinical trial of 50 patients with active mild-to-moderate UC found that the addition of a 95% pure curcumin preparation to mesalamine therapy was superior to combination therapy with placebo in inducing clinical and endoscopic remission [47]. After 1 month of therapy, 14/26 (53.8%) subjects receiving curcumin were in clinical remission compared to none in the placebo group. Likewise, 8/22 (36.3%) subjects who underwent endoscopic evaluation were found to be in endoscopic remission compared to 0/16 subjects receiving placebo. Despite these promising results, the quantity of curcumin used in these studies was much higher than the amount that can be consumed exclusively through diet. In fact, a large trial with 300 patients with mild-to-moderate UC with low-dose curcumin did not find a significant clinical benefit when provided with 450 mg/day [63]. Additional larger clinical trials are needed to confirm these findings in UC and to investigate whether curcumin has a therapeutic role in CD.

Iron

Iron deficiency anemia is a common complication of IBD, and oral iron supplementation is often used for treatment [85]. Iron is a catalyst for reactions that generate reactive oxygen species. In animal models of IBD, oral iron supplementation has been shown to worsen colitis by generating oxidative stress [53]. It is unclear if oral iron can generate oxidative stress and worsen disease activity in IBD patients, as there is conflicting evidence in the literature. A small study of ten CD patients receiving 1 week of ferrous fumarate supplementation showed a rise in oxidative stress and disease activity scores [86]. However, another study of 33 IBD patients supplemented with ferrous sulfate for 4 weeks did not show an increase in reactive oxygen species. Clinical disease activity scores worsened for the UC subjects, but there was no difference in rectosigmoid endoscopic activity or laboratory parameters [87]. As the adverse effects of oral iron supplementation include gastrointestinal symptoms such as abdominal pain, it is unclear if the increases in clinical disease activity scores truly reflect the inflammatory activity.

In terms of dietary sources of iron, heme iron, which is found in red meat, has been found to worsen colitis in animal models [88]. Studies have also found increased red meat consumption to be a risk factor for disease flares in UC [49]. There are no published studies on the effects of non-heme iron sources, such as those found in fruits, vegetables, or iron-fortified cereals, on disease activity in IBD. Avoidance of aggravating, iron-rich foods including beans, red meat, spinach, and seeds among IBD patients may lead to limited oral intake of dietary iron sources.

Probiotics

The use of probiotics in IBD is not a newly-studied concept. Probiotics, live organisms that provide positive health effects in a host, are popular dietary supplements that have been used and studied in a variety of gastrointestinal diseases including IBD. Despite their popularity, there is limited evidence in favor of recommending probiotics in IBD. The strongest data supporting the use of probiotics are among patients with mild UC or among UC patients who have undergone a colectomy and have an ileal pouch-anal anastomosis [69, 89]. In a small study of 40 patients with UC, VSL #3 was found to be more effective than placebo for the prevention of acute pouchitis and improved quality of life [69]. For the treatment of chronic pouchitis, two double-blind placebo-controlled trials in adults demonstrated the effectiveness of VSL#3 in maintaining remission [69]. According to the European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines, *Escherichia coli* Nissle 1917, or VSL #3, can be considered for use in patients with mild-to-moderate UC for the induction of remission [69]. It should be noted that the VSL #3 used in previous clinical studies is the original formulation of the product and that this formulation may now be sold under a different brand name. Probiotics have no clear role in the induction or maintenance of remission in CD [63, 89]. Probiotics should be used with caution for patients with central venous catheters [61].

Structured Diets

A number of structured diets have been proposed for the treatment of IBD (Tables 37.3 and 37.4). These diets are based on the exclusion of dietary components felt to be pro-inflammatory. However, with the exception of enteral nutrition therapy, there is currently a lack of robust data to support the efficacy of any structured diet in IBD. This partially reflects the challenges of performing prospective trials of dietary therapies. Because patients in diet trials are often on concurrent medical therapies, the efficacy of the dietary

Table 37.3 Supporting evidence for proposed IBD structured diets

Diet	Description	Supporting evidence
Exclusive enteral nutrition (EEN)	Polymeric, semi-elemental, or elemental formula taken as the sole source of nutrition	Multiple prospective studies support the use of EEN for induction of remission, mucosal healing, and growth impairment in pediatric CD
Partial enteral nutrition (PEN)	Same as EEN except formula is the nonexclusive source of nutrition	Retrospective and prospective studies support the use of PEN for induction of remission and maintenance therapy in pediatric CD
Specific carbohydrate diet	Consumption of monosaccharides is allowed, but disaccharides, oligosaccharides, and polysaccharides are eliminated	Limited evidence. Small, uncontrolled studies that demonstrated clinical improvement and microbiome shifts prospectively
IBD anti-inflammatory diet	Multiple-phase diet derived from the SCD. Certain carbohydrates and fats are restricted and intake of pre- and probiotics is encouraged	Limited evidence. Small retrospective case series of adult IBD subjects demonstrated improvement in disease activity scores
Crohn disease exclusion diet (CDED)	Structured diet that reduces or eliminates exposure to animal fats, dairy products, gluten, and processed foods	Randomized, controlled pediatric trial with mild-to-moderate CD demonstrated CDED plus PEN was better tolerated and equally effective compared to EEN
CD-TREAT	Whole food based diet used to replicate the nutrient composition of EEN	Limited evidence. Three small studies evaluating the effects on the gut microbiome, inflammation, and clinical response in a rat model, healthy adults, and children with relapsing CD
Semi-vegetarian diet	Diet containing fruits, vegetables, dairy, and eggs with limited fish and meat	Limited evidence. A prospective study showed improvement in symptom-based remission compared to a free diet
Low-FODMAP diet	Diet low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols	Small studies revealing patients with IBD with functional-like gastrointestinal symptoms may have symptomatic benefit
Gluten-free diet	Gluten (found in rice, barley, and wheat) is completely excluded	No published data on the effect of the diet on disease activity in IBD
Paleolithic diet	Exclusion diet allowing foods presumed to be available in prehistoric times, including most fruits, vegetables, and game meat	No published scientific literature

Table 37.4 Allowed and restricted foods in proposed IBD structured diets

Structured diet	Allowed foods	Restricted foods
Specific carbohydrate diet[a,b]	Fresh or frozen meat, poultry, fish, eggs Most fruits (fresh or dried), vegetables (fresh or frozen), and certain legumes Certain cheeses (cheddar, Colby, Swiss, farmers); fully fermented yogurt Oats, flax; nut and legume flours Honey Unsweetened fruit juices	Processed or smoked meats/fish Canned fruits and vegetables, potatoes, chickpeas, soybeans Most forms of dairy Wheat, barley, rye, corn, rice Refined sugars Maple syrup, mayonnaise
IBD anti-inflammatory diet[c]	Lean meat, poultry, fish, omega-3 eggs Most fruits, vegetables, and legumes Certain cheeses (aged, cheddar, farmers), fresh-cultured yogurt, kefir Oats, flax, nuts; legume and nut flours Honey, maple syrup, mayonnaise Unsweetened fruit juices	Non-lean cuts of meat Fruits with seeds and vegetables with stems (depending on diet phase) Most forms of dairy Wheat, barley, rye, corn, rice Hydrogenated oils Refined sugars
Crohn disease exclusion diet (CDED)[d,e]	Fresh fish and chicken breast; eggs; limited fresh beef Select fruits and vegetables (i.e. potato, apple, banana) White rice; rice noodles, rice flour Honey; sugar for cooking Freshly squeezed orange juice	Processed or smoked meats/fish Canned fruits and vegetables, soy Dairy products Wheat, cereals, breads, baked goodsRefined sugars Packaged snacks
CD-TREAT[f]	Macronutrients, vitamins, minerals, and fiber comparable to EEN Full fat milk, rice-based cereals, juices, chicken, salmon, cod, mashed potato All dairy products are lactose-free All cereal products are gluten-free	Gluten, lactose, maltodextrin, and alcohol
Low-FODMAP diet7	Meat, poultry, fish, eggs Low-FODMAP fruits (e.g., banana, orange, strawberry) and vegetables (carrot, celery, potato) Lactose-free dairy, hard cheeses Rice, quinoa, corn, peanut Maple syrup	High-FODMAP fruits (e.g., apple, pear, watermelon), vegetables (e.g., asparagus, cauliflower, garlic, onion), and legumes (e.g., beans, chickpeas, lentils) Most forms of dairy Wheat, barley, rye High-fructose corn syrup, honey, agave nectar

intervention is more difficult to interpret. Accurately assessing dietary intake and adherence is another challenge for diet studies. Moreover, as opposed to scientifically rigorous pharmaceutical trials, clinical trials involving dietary interventions cannot be double-blinded or have a placebo arm [9]. Whereas many study drugs are only available by enrolling in a clinical trial, structured diets are often well known and can be followed outside the confines of a clinical trial, rendering recruitment difficult.

Exclusive Enteral Nutrition

Exclusive enteral nutrition (EEN) has been extensively studied in pediatric IBD and is an effective treatment modality for induction of remission [95–97]. The formula is the sole source of nutrition in EEN, and the duration of treatment can range from 3 to 12 weeks. There is insufficient evidence for a food reintroduction pattern during the weaning of formula after the induction phase [61]. The formula can be taken orally or through a nasogastric tube with equal efficacy; with nasogastric tube feedings, the formula can be administered while asleep [98]. Additionally, there is no difference in efficacy between polymeric, semi-elemental, or elemental formulas. Polymeric formulas may be more palatable and increase compliance with oral EEN [96, 98]. EEN is widely used in Europe, yet is used by fewer than 4% of gastroenterologists in North America [99]. The exact mechanism of action of EEN is unknown, yet EEN is known to have a profound impact on the gut microbiome [100]. Although early studies had indicated that response to EEN was strongest among CD patients with small bowel disease, more recent

studies have not shown any difference in efficacy based on disease location in CD [101]. Data showing efficacy in UC is lacking.

Meta-analyses have shown that 73% of pediatric CD patients treated with EEN achieve clinical remission [96]. In children with CD, EEN is as effective as corticosteroids for induction therapy [102]. Additionally, EEN is significantly better than corticosteroids at achieving mucosal healing [100, 103]. Whereas corticosteroids are known to impair growth, EEN has been shown to improve growth, bone mass, and lean mass accrual among children with IBD [104, 105]. Based on these data, the latest pediatric CD treatment guidelines by ESPEN and The European Crohn's and Colitis Organization recommend EEN as first-line therapy for the induction of remission in children with active luminal CD [96]. Enteral nutrition has also been studied in CD patients with intestinal strictures. In a prospective observational study, 59 adult CD patients with inflammatory bowel strictures were treated with 12 weeks of EEN. EEN was found to relieve inflammatory strictures with 81.4% of patients achieving symptomatic remission, 53.8% patients achieving radiologic remission, and 64.6% patients achieving clinical remission [106]. Additional studies are warranted to see if EEN can be successfully resued to prevent future relapses, as a study completed by Frivolt et al. found decreased efficacy with a second course of EEN [107].

Partial Enteral Nutrition

Although EEN is an effective therapy for induction of remission in pediatric IBD, it may be too restrictive for many children, as it requires avoidance of all foods. Even among children who do elect to use EEN for induction, it may not be a feasible long-term treatment modality for maintenance therapy. Partial enteral nutrition (PEN) refers to the nonexclusive use of formula for the treatment of IBD with typically at least 50% of calories from formula. Studies have shown that PEN may also be effective for the induction of remission among children with CD [108, 109]. The use of a diet providing 80–90% of caloric needs from formula, with the remainder of calories coming from a free diet, was found to induce remission in 65% of children with CD [108].

In pediatric CD, PEN has also been shown to be an effective maintenance therapy. Children who received PEN that provided 50–60% of caloric needs for 4–5 nights per week were less likely to relapse compared to those on a free diet over a 1-year follow-up period after induction of remission [110]. PEN is also effective as maintenance therapy in adult CD. Patients with CD who received 50% of calories through formula and the remainder of calories via table foods were more likely than those on a free diet to be in clinical and endoscopic remission after 1–2 years [111, 112]. Among adult CD patients, PEN has been found to be as effective as 6-mercaptopurine in maintaining long-term remission [113].

Head-to-head comparisons of PEN and EEN have found EEN to be a more efficacious treatment for pediatric CD [109, 114]. In a prospective study, 90 children with active CD received either infliximab, EEN, or PEN with a regular diet (80% of caloric feeds from formula) and found that infliximab and EEN were superior to PEN in terms of mucosal healing and improvement to quality-of-life [115]. Clinical response was found in 88% of children receiving EEN, 84% of children receiving anti-TNF therapy, and 64% in the PEN group [109]. The PEN and EEN groups were similar in the amount of calories received from formula. However, the amount of table food consumed was significantly higher among the PEN group. This suggests that the mechanism of action of EEN may result from the elimination of table food rather than from any intrinsic therapeutic properties of the formula. Another dietary therapy, known as the Crohn Disease Exclusion Diet (CDED), uses PEN coupled with an exclusion diet and will be discussed later in the chapter.

Parenteral Nutrition

According to ESPEN Guidelines for Surgery 2016, the enteral route should always be favored for supportive nutritional therapy [69]. Parenteral nutrition should not be used as a means to induce remission in pediatric CD [61]. Parenteral nutrition may be indicated if enteral nutrition has failed or if the following contraindications exist: intestinal obstructions or ileus, severe shock, intestinal ischemia, high output fistula, or severe intestinal hemorrhage [69]. In IBD, parenteral nutrition is often a temporary measure provided to severely malnourished patients awaiting surgery. It can also be used to prevent weight loss when calories cannot be consumed orally or enteral nutrition cannot be provided. The risks of parenteral nutrition in IBD patients include line infections when infused in a central venous catheter, catheter-related venous thrombosis, hyperglycemia for patients on steroids, and electrolyte abnormalities among those at risk for refeeding syndrome [115].

Exclusion Diets

Whole food based exclusion dietary therapies to possibly treat IBD includes the Crohn Disease Treatment with Eating Diet (CD-TREAT), Specific Carbohydrate Diet (SCD), the Inflammatory Bowel Disease Anti Inflammatory Diet (IBD-AID), and the Crohn Disease Exclusion Diet (CDED). Restriction diets involving regular food have shown promise, yet shared decision-making is critical for success. Throughout dietary therapy, it is important to assess for improvement in

the clinical and biological condition, as well as adherence to the diet. Completing a nutrition assessment can help determine if the patient is meeting nutritional needs and help identify risks for nutrient deficiencies in restricted diets. The goals of these dietary therapies are to induce and maintain remission, as well as to decrease gastrointestinal symptoms.

CD-TREAT: Crohn Disease Treatment-with-EATing

The CD-TREAT is an exclusion diet designed to replicate the nutrient composition of EEN with the use of ordinary foods for the treatment of CD. This whole foods-based diet was created to see if similar therapeutic results of EEN can be achieved by using ordinary foods compared to a formula-based diet with EEN. The proposed mechanism of action is to mimic the effect that EEN has on the microbiome. The diet eliminates gluten, lactose, maltodextrin, and alcohol, while imitating the macronutrient distribution, vitamins, minerals, and fiber of EEN feeds [93]. The composition of the diet was based on Modulen®formula. CD-TREAT is an individualized dietary plan tailored to the participant's daily energy requirements and also considers food preferences.

The study published by Svolos et al., had three parts including a randomized controlled trial in 25 healthy adult volunteers that investigated the microbial alterations of the prescribed diet, animal experiments that focused on gut inflammation and the microbiome in a disease state, and an open-label trial in five pediatric patients with active CD to test the efficacy of the diet [93]. Results from the 25 healthy adult volunteers found the CD-TREAT to be more satisfying compared to EEN and similar changes to the metabolome and microbiome were identified. Among these findings, participants on both EEN and CD-TREAT were found to consume more total and saturated fat, but less fiber and carbohydrate intake compared to their habitual diets [93]. Among the five children receiving CD-TREAT, four had a clinical response and three entered remission with significant decreases in fecal calprotectin after 8 weeks. In animal studies, similar changes in bacterial load, short-chain fatty acids, microbiome, and ileitis severity scores were similar between CD-TREAT and EEN [93]. Restriction diets involving regular food, such as the CD-TREAT, have shown promise, yet there is a need for additional larger clinical trials.

Specific Carbohydrate Diet

The specific carbohydrate diet (SCD) was developed in the 1920s as a treatment for celiac disease and proposed as a treatment for IBD in the 1990s. The diet allows for the consumption of monosaccharides, but not disaccharides, oligosaccharides, or polysaccharides, which are felt to be poorly absorbed and felt to influence the composition of the microbiota [30]. Fruits, fresh meat and fish, eggs, fully fermented yogurt, and most vegetables are allowed, although potatoes, corn, and some legumes and lentils are not. Grains, including wheat, barley, and rice, as well as most forms of dairy are excluded. Processed foods and refined sugars are also eliminated. Soy is not permitted. Nut flours can be used as substitutes to make baked goods. Because the diet is restrictive and weight loss is common, close follow-up with a dietician is warranted [116].

To examine the nutritional adequacy of the SCD, a small study was performed in eight pediatric patients and found that the majority of participants had nutrient intake comparable to a peer reference group. However, inadequate weight gain was seen in two patients. SCD patients met or exceeded the Recommended Daily Allowance (RDA) for vitamins A, B2, B3, B5, B6, B7, B12, C, and E. Conversely, all patients following the SCD did not meet the RDA for vitamin D and 75% did not meet the Recommended Daily Allowance for calcium [117].

There have been several small studies investigating the use of the SCD in pediatric IBD. Several prospective case series in children have shown improvement in clinical and inflammatory markers in mild-to moderate-disease. A retrospective study of 20 CD and 6 UC subjects on the SCD demonstrated improved clinical disease activity scores and serum inflammatory markers on the diet. Importantly, the authors noted that weight loss occurred in nine subjects (35%) [116]. A prospective study of ten pediatric subjects with active CD starting the SCD showed improvement in disease activity scores after 12 weeks of therapy. Video capsule endoscopy demonstrated mucosal healing in 4/10 (40%) subjects. Seven subjects were followed for 52 weeks with mucosal healing seen in 2/7 (29%) subjects [90]. Another prospective study of 12 patients with mild-to-moderate IBD showed a decrease in mean Pediatric Crohn Disease Activity Index/Pediatric Ulceartive Colitis Activity Index, a decrease in mean C-reactive protein, and significant changes in microbial composition after following the diet. However, diet therapy was found to be ineffective for two patients and another two patients were unable to maintain the diet [118]. In another small study, seven subjects were identified with a modified SCD (SCD plus addition of "illegal foods") and found that complete macroscopic healing of both the ileocolon and upper gastrointestinal tract was not achieved in any patient [119]. In a larger patient survey study, 417 participants perceived clinical benefit with the SCD [120].

The Gut and Psychology Syndrome (GAPS) diet, derived from the SCD, also focuses on the mechanism of removing foods that are considered to be difficult to digest and cause damage to gut flora. The GAPS diet may be popular among

patients, yet there is no published data on the efficacy of this diet in IBD [121].

Larger cohort prospective studies, with a control group, are needed to further study the efficacy of the SCD in pediatric IBD and several larger trials are currently underway.

IBD Anti-inflammatory Diet

The IBD anti-inflammatory diet (IBD-AID) is another structured diet derived from the SCD and was modified to increase the diversity of bacteria that produce short-chain fatty acids [122]. There are four phases to the diet based on disease activity. The diet restricts certain carbohydrates, including lactose and refined sugars. Most grains, with the exception of oats, are also eliminated. The diet encourages the consumption of foods that are prebiotics and probiotics, including fermented foods and those high in soluble fiber. Allowed foods are high in n-3 PUFA and low in saturated fats. In conjunction with a dietician, food intolerances and nutritional deficiencies are identified. Food textures are modified based on clinical disease activity.

There has only been a single retrospective case series reporting experience with the IBD-AID among 27 adult participants with IBD [122]. Self-reported symptoms improved in 24/27 (89%) of subjects. More extensive chart reviews, including disease activity scores, were reported for only 11 subjects (8 CD and 3 UC) among whom all reported improved symptoms and were able to de-escalate medication therapies. All 11 subjects were in clinical remission as defined by the Harvey Bradshaw Index (HBI) and the Modified Truelove and Witts Severity Index for the CD and UC subjects, respectively. Large, randomized, clinical trials with the assessment of disease activity and mucosal healing are needed to define the therapeutic role of the IBD-AID.

Crohn Disease Exclusion Diet

The Crohn Disease Exclusion Diet (CDED) is a structured diet that reduces or eliminates exposures to foods that are thought to aggrevate intestinal permeability and induce dysbiosis. These items include animal fats, certain types and cuts of meats, gluten, maltodextrin, xanthum gum, emulsifiers (carrageenan), sulfites, certain monosaccharides, and several processed westernized foods [123]. The diet, coupled with Modulen® formula, is comprised of allowed, mandatory, and disallowed foods. It was developed for the treatment of pediatric and adult CD, as well as in patients with secondary loss of response to TNFα therapy [92]. Mandatory and allowed foods in the diet provide sources of resistant starch, fiber, pectin, and substrates required to produce short-chain fatty acids. Specific sources of animal protein are considered mandatory [123]. The diet consists of three phases and requires full compliance. Phase 1, the strictest phase, occurs from weeks 0 to 6 with 50% of calorie needs to be provided from formula with the remainder of nutritional needs met from mandatory and allowed foods. Phase 2 occurs from weeks 7 to 12 with 25% of calorie needs provided from formula with the remainder of nutritional needs met from mandatory and additional allowed foods. Phase 3 is considered a maintenance phase which continues with 25% of calorie needs to be met from formula and allows for two free days off from formula consumption plus "cheat" meals that can include restaurant meals [92].

A randomized control trial with two arms comparing CDED with PEN (50%) and EEN (100%) administered orally over 12 weeks in 78 pediatric patients with mild-to-moderate active luminal CD found that the CDED with PEN was better tolerated than EEN alone. The intervention for the CDED arm consisted of 6 weeks of CDED with 50% PEN followed by a Stage 2 CDED with 25% PEN. The EEN arm followed EEN for 6 weeks and then transitioned to 25% PEN with a free diet. Both diets were found to induce remission by week 6. While there was no mucosal healing endpoint, the CDED with PEN protocol was found to induce sustained remission compared to the EEN group and produced changes in the fecal microbiome associated with remission [92].

In an earlier retrospective case series, patients with loss of response to biologics, despite dose escalation or combination therapy, were treated with PEN + CDED for 12 weeks. Twenty one pediatric and adult subjects met study criteria with 81% identified as using combination therapy and 47% had failed a second biologic. Dose escalation failed in 62% of patients. A 62% remission rate was seen in patients in response to diet by physician global assessment and HBI after 6 weeks and 90% displayed clinical response. Improvement in inflammatory markers, including a decrease in mean CRP and an increase in albumin, were observed [123].

Another published study with a small cohort of 47 children and young adults with active CD also followed this diet [91]. Most subjects also received PEN and consumed 50% of calories from formula. Subjects were allowed to be on concomitant immunomodulator therapy, as the primary endpoint was at 6 weeks, prior to the expected full onset of action of such medications. At 6 weeks, clinical remission was achieved in 70% of patients with significant improvements in inflammatory markers and serum albumin. Among the seven subjects who consumed all calories from table food and did not receive PEN, six were in clinical remission at 6 weeks, suggesting that the exclusion diet without PEN may also be efficacious. Fifteen subjects in clinical remission practicing the diet for at least 6 months were assessed for mucosal healing, with 73% found to have evidence of healing based on endoscopy or the combination of imaging and fecal calprotectin. Despite these encouraging results, randomized studies

with a larger cohort, currently underway, are needed to further evaluate the efficacy of the CDED for both induction and maintenance therapy in pediatric CD.

Semi-Vegetarian Diet

There has been one published study on the use of a semi-vegetarian diet for maintenance of remission among 22 adults with CD [67]. This cohort was instructed to consume a diet containing brown rice, vegetables, fruits, yogurt, eggs, and milk. Fish was limited to once a week and meat to once every 2 weeks. During the study period, subjects were treated with either mesalamine or sulfasalazine. The cohort was followed for 2 years with 16 subjects remaining on the diet and six subjects consuming an omnivorous diet. Of the subjects on the semi-vegetarian diet, 15/16 (94%) were in remission compared to 2/6 (33%) subjects on free diet. This study is limited by the small sample size and the definition of remission based on clinical symptoms rather than biochemical or endoscopic parameters. Additionally, all patients were offered this diet, with the treatment group including those who were compliant while the control group was comprised of those who were non-compliant. A study with a larger cohort using established clinical endpoints is needed to assess the efficacy of this dietary intervention.

Low-FODMAP Diet

A diet low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAP) has been shown to reduce clinical symptoms in irritable bowel syndrome [125], but the data are limited in IBD. FODMAPs contain food products that are poorly absorbed by the human body, which leads to an influx of luminal water via osmosis. Additionally, FODMAPs are easily fermentable by the gastrointestinal microbiota into hydrogen byproducts. Together, luminal water and hydrogen production lead to luminal distention and clinical discomfort in patients with functional gastrointestinal disorders [94]. Typically, the fermentable carbohydrates of the FODMAP diet are reintroduced and the patient monitors his/her tolerance in order to expand the diet.

Functional abdominal pain is common in childhood with 13% of pediatric CD patients in remission meeting criteria [125]. About one-third of patients with IBD develop functional gastrointestinal symptoms [126]. Therefore, it is possible that a low-FODMAP diet may have some benefits among IBD patients with overlap functional gastrointestinal disorders. Moreover, since the prevalence of lactose malabsorption is high among patients with small bowel CD [58], a diet low in lactose, such as the low-FODMAP diet, may improve clinical symptoms.

There have been small studies that have investigated the use of a low-FODMAP diet in IBD. A cohort of eight UC patients who had undergone colectomy and started on a low-FODMAP diet was retrospectively found to have decreased stool frequency on the diet. However, a prospective arm of five subjects did not show a dietary effect [127]. A retrospective study of 52 CD and 20 UC patients started on a low-FOMAP diet demonstrated improvement in overall gastrointestinal symptoms in 56% and 55% of CD and UC patients, respectively. Patient-reported improvements in abdominal pain, diarrhea, and bloating were the most common [128]. However, the study had no control group, and disease activity was not objectively measured. Another study among 88 patients with IBD who were referred for low FODMAP diet education found a significant increase in patients having relief of symptoms and improvements in stool consistency and urgency [129]. This study suggests that patients with IBD and functional–like gastrointestinal symptoms (FGS) following a low FODMAP diet may benefit depending upon severity of FGS symptoms. Likewise, among patients with quiescent IBD based on physician global assessment and objective serological markers of remission, but with ongoing gastrointestinal symptoms, a single-blind trial found more patients felt relief (52%) and had a higher quality of life with a low FODMAP diet compared to the control group (16%). Since the patients all had quiescent IBD these results suggest that the clinical improvements were independent of inflammation [130].

Taken together, these studies show that a subset of IBD patients may have symptomatic improvements on a low-FODMAP diet, but it is unclear if these improvements are related to a placebo effect, an underlying functional gastrointestinal disorder, or true improvements in IBD clinical activity. As such, there is currently no data to support the use of a low-FODMAP diet for induction of remission or maintenance therapy in IBD.

Gluten-Free Diet

Adherence to a gluten-free diet is common among IBD patients with a cross-sectional questionnaire study finding that approximately 19% of patients had previously followed the diet. Approximately two-thirds of patients on a gluten-free diet reported improvement in gastrointestinal symptoms [131]. Self-reported non-celiac gluten sensitivity is common in IBD and possibly associated with active disease activity in CD [132]. Gliadin has been shown to increase intestinal permeability even among individuals without celiac disease [133], suggesting that gluten restriction could be a logical dietary target in IBD. Currently, there is no evidence to support the use of a gluten-free diet for induction of remission or maintenance therapy in IBD. Prospective studies are needed to study the effect of a gluten-free diet on clinical disease activity and mucosal healing in IBD.

The Paleolithic Diet

The theory behind the Paleolithic diet is that the increased prevalence of diseases like IBD is due to a change in the human diet from foods obtained by hunting and gathering to agricultural-based foods. Therefore, the diet excludes farm-based foods, such as grains, legumes, and meats from domesticated animals, and allows fruits, most vegetables, and game meat [30, 58]. Although the Paleolithic diet has been promoted in the lay literature, there have been no published studies regarding its use in IBD except for case reports [126]. The autoimmune protocol (AIP) diet is considered an extension of the Paleolithic diet, which removes grains, legumes, nightshades, eggs, dairy, nuts and seeds, coffee, alcohol, refined/processed sugars, food additives, and industrial seed oils. The diet is a phased approach which does allow individuals to identify foods that may be associated with increased symptoms during a reintroduction phase [134]. Recently, a small, uncontrolled clinical trial was conducted in order to examine the efficacy of the AIP among 15 adults with active IBD on concurrent pharmacological therapy. The AIP diet was found to improve quality of life during the elimination and maintenance phases of the diet. Similar to other elimination diets, the AIP diet may have the potential to be an effective adjunct therapy in IBD, but larger, randomized trials, are needed [134].

Conclusion

The westernized diet, consisting of high amounts of animal fat, refined sugars, and processed foods with limited amounts of fresh fruits, vegetables, and fiber, has been associated with the rise in worldwide IBD. Patients with CD typically consume a hypocaloric low-fiber diet. UC patients commonly avoid fiber, especially vegetables, and consume more fat compared to control populations [69]. Patients and families with IBD commonly seek dietary guidance from their medical providers. Unfortunately, there is currently no strong evidence to support the use of any structured diet, with the exception of enteral nutrition, for the long-term treatment of pediatric IBD. Compared to the other structured diets, CDED might have the best data to support a role in the treatment of mild-to-moderate CD. More research is needed and there are several trials underway to study a variety of structured exclusion diets. Until a structured diet is developed that is proven to maintain long-term remission in IBD, clinicians can use data from the epidemiological, microbiome, and animal-model studies to provide general dietary guidelines to their patients. Clinicians can collaborate with a registered dietitian to help educate patients about nutritional therapy, prevent malnutrition and nutrient deficiencies, and assist with individualized diets tailored to the patient's nutritional needs. Pending additional data, a recommendation of a well-balanced diet high in fresh fruits, fresh vegetables, and whole grains with limited processed foods, red meat, and saturated fat may be warranted for pediatric IBD patients.

Integrative Health Therapies for Pediatric IBD

38

Srisindu Vellanki, Jennifer Panganiban, Jessi Erlichman, and Maria Mascarenhas

Introduction

Integrative health is an umbrella term encompassing a broad range of modalities, healing philosophies, and approaches. These therapies are often classified into one of the five domains: (1) whole medical systems, (2) mind-body medicine, (3) biologically based practices, (4) manipulative and body-based practices, and (5) energy medicine. Whole medical systems represent the theories and practices of traditional Chinese medicine, Ayurvedic medicine and homeopathy, for example. Mind-body interventions involve modalities such as prayer and meditation and are meant to facilitate the connection between the mind and body. Herbal products, dietary supplements, and diets comprise the category of biologically based therapies. Body-based practices employ human touch to manipulate the physical body, such as massage or craniosacral therapy. Finally, the domain of energy therapies harnesses the body's energy fields to promote health and healing. Examples include tai chi and reiki. These classification entities encompass a wide range of diverse therapies and may have disparate, but interrelated therapeutic targets.

In the United States, the National Center for Complementary and Integrative Health has moved toward a two-subgroup classification system: mind and body practices or natural products. Furthermore, the identification that most Americans use nonmainstream practices in conjunction with, not as an alternative to, conventional treatments has to lead the development of the term integrative medicine or health. Integrative health (IH) refers to the incorporation and integration of complementary approaches into mainstream healthcare practices.

The use of IH practices is common. The most recent national survey data in the United States suggest that 33.2% of adults and 11.6% of children use complementary and integrative health approaches. The rates of IH use in chronic disease populations frequently exceed those in the general population. The prevalence of IH use in pediatric chronic disease populations also exceeds that of the general pediatric population [1]. In this chapter, we explore the interest, utilization, and efficacy of a subset of IH modalities for the adjuvant treatment of IBD in pediatrics.

Integrative Health Use in IBD

Multiple studies confirm IH use is common among children with IBD, with prevalence estimates ranging between 6.7 and 84% [2]. Pediatric prevalence rates are comparable with or exceed IH use in adults IBD [3–7]. Surveys also suggest that high proportions of IBD patients who do not use IH modalities would consider using them in the future [8]. These surveys indicate that biologically based therapies, including dietary interventions, are the most common IH domain utilized in pediatric IBD populations [6, 7, 9, 10]. The use of IH in conjunction with prescribed medications is also common. In a study by Wong et al., 43.6% of all patients with IBD used both prescription medications and IH therapies in the treatment of their disease [6].

Across surveys, however, the prevalence of IH and predictors of use vary and are inconsistent. Variation in prevalence rates may be attributed to methodologic differences in survey instruments and sampling approaches, regional and

geographic differences, and ethnic, cultural, and other demographic influences [11]. The high degree of variability in use estimates may also be due to how IH is defined. For example, in surveys where prayer, specifically for health reasons, is included as a mind-body modality, 62% of US adults used IH in the past 12 months. Whereas when prayer was excluded, utilization estimates decreased to 36% [12]. In a survey of IH use among pediatric IBD patients from a mid-Western tertiary care center, 100% of respondents used IH modalities when defined broadly. Yet, when a more narrow definition of IH was applied, removing modalities such as prayer and multi-vitamin use, prevalence decreased to 84% [2].

There are myriad factors associated with the use of IH in pediatric IBD populations. These factors can be categorized into sociodemographic characteristics or disease-related characteristics. Parents' own use of IH, parental education level, parental age, and age of the child may predict IH use in children with IBD [6, 9, 13, 14]. Disease-related attributes associated with IH use may include dissatisfaction with traditional treatment, low self-reported health-related quality of life (HRQOL), desire to have more control over child's condition, symptom management, and to avoid side effects of medicine, the extent of out-of-pocket expenditures on prescription medication, and CD vs. UC [7, 9, 14].

However, disease-related characteristics do not consistently predict IH use. In part, this may be due to how disease severity or activity is defined across studies. In several studies, low HRQOL, increased school absences, greater out-of-pocket spending, and frequency of use of certain conventionally prescribed medications were associated with pediatric IH use [7, 9, 13]. Yet in other studies, school absences, hospital admissions, and prescription medication were not associated with or predictive of IH use [9, 15–19].

Irrespective of whether the child used any IH modalities, parental receptivity toward IH use remains high [14]. Many IH modalities may confer a sense of control over the child's disease as the parent voluntarily chooses which modalities to use, whereas the clinician prescribes a treatment. Interestingly, when parents perceive conventional medical treatment as effective or if they worry about IH interactions, they are unlikely to recommend IH for their child [20].

The remainder of this chapter will focus on the available literature as it pertains to the safety and efficacy of two common IH domains: biologically-based IH modalities (defined as natural herbal remedies and dietary supplements) and mind and body interventions.

Biologically Based Therapies for the Treatment of IBD

The specific role of Integrative Health therapies in the treatment of IBD has not yet been established. Products that have been evaluated in clinical studies for the treatment of IBD include biologically based therapies (herbs and dietary supplements) and mind-body medicine. The use of herbal remedies or nutritional supplements in pediatric IBD has been reported to be high at ~20% and ~36%, respectively. Although research has explored many of these products, scientific evidence regarding their efficacy or safety has not been adequate. The most common biologically based therapies in the treatment of IBD are those stated below (Table 38.1):

Table 38.1 Biologically based therapies in the treatment of inflammatory bowel disease

Biologically based therapy	Year	Indication	Number of subjects	Comparator	Study duration	Response rate (%)	Response on comparator (%)	Author, ref

Herbal Therapies

Aloe Vera

Aloe Vera (Xanthorrhoeaceae) is a stemless, drought-resisting succulent plant of the lily family. It is indigenous to hot countries and has been shown to have anti-inflammatory and antioxidant properties. *Aloe vera* gel is the mucilaginous aqueous extract of the leaf pulp of Aloe barbadensis and can act as a barrier such as in patients with colitis. *Aloe vera* contains an abundance of phytochemical substances such as mannans and anthraquinone. Its immunomodulating activity is thought to work through the induction of maturation of dendritic cells and in vitro inhibition of prostaglandin E2 and IL-8. Topical administration of aloe gel is considered safe but if taken orally has been found to cause abdominal cramps, diarrhea, and dehydration. This has also been linked to thyroid dysfunction, acute hepatitis, and perioperative bleeding.

Aloe vera gel has been used in the treatment of mild-to-moderate ulcerative colitis. A randomized double-blind controlled trial from the United Kingdom by Langmead et al. showed that oral aloe vera gel when administered to patients with mild to moderately active ulcerative colitis for 4 weeks, was superior to placebo. Thirty patients were given 100 mL of oral *Aloe vera* gel twice daily and fourteen patients were given 100 mL of placebo twice daily. The primary outcome measures were clinical remission (Simple Clinical Colitis Activity Index < 2), sigmoidoscopic remission (Baron score < 1), and histological remission (Saverymuttu score < 1). Aloe vera gel taken for 4 weeks appeared to be safe, produced a clinical response ($p < 0.05$), reduction in median SSCAI ($p < 0.01$), and reduction in histological disease activity ($p < 0.03$) in comparison to placebo [21].

Triticum aestivium

Triticum aestivum (Poaceae) or better known as **wheat grass** is prepared by sprouting wheat seeds in water for 7–10 days before harvesting the leaves. It has antioxidant properties and is a natural source of vitamins and minerals. It contains agropyrene that has antibiotic activity and apigenin, which has anti-inflammatory properties by inhibiting the adhesion of leucocytes to endothelial cells. It is relatively safe but can cause nausea, anorexia, and constipation.

Wheat grass has shown significant benefit as single or adjuvant treatment for active distal ulcerative colitis. In a randomized, double-blind, multicenter study from Israel, 23 patients with active distal UC were given either daily wheat grass juice or a placebo for 4 weeks. Patients were found to have clinical improvement (reduction in rectal bleeding, abdominal pain, physical global assessment score) in 10/11 patients on wheat grass (91%) vs. 5/12 on placebo (42%). Gross improvement was also seen on sigmoidoscopy in 78% or 7/9 patients on wheat grass vs. 30% or 3/10 on placebo [22].

Andrographis paniculata

Andrographis paniculata (Acanthaceae) is a bitter-tasting annual plant in Asia. This has been marketed in China as Kan Jang, Kold Kare, KalmCold, and Paractin. *Andrographis* has been found to have antibacterial, antioxidant, anti-inflammatory, anticancer, and immune-stimulating properties. Its active constituents are diterpenoid lactones known as andrographolides. Its anti-inflammatory activity works by inhibiting nitric oxide production, cyclooxygenase-2 expression, and TNF-alpha, IL-1b, and NF-kB. Side effects include headache, fatigue, hypersensitivity, lymphadenopathy, nausea, diarrhea, altered taste, elevated hepatic transaminases, and acute kidney injury. *Andrographis* extract may inhibit 1A2, 2C9, and 3A4 and induce CYP1A1. These two properties can affect the intracellular concentration of drugs metabolized by these enzymes.

Andrographis has been found to be an efficacious alternative to mesalamine in the treatment of active UC. A multicenter randomized double-blind, 8-week parallel-group pilot study showed that *Andrographis paniculata* (HMPL-004) was as efficacious as mesalamine in clinical response (76% vs. 82%; clinical response defined as total improvement in clinical symptom scores) in the treatment of mild-to-moderate ulcerative colitis. Furthermore, about 21% of those treated with *Andrographis paniculata* (HMPL-004) achieved complete clinical remission vs. 16% treated with mesalamine (clinical remission defined as 100% improvement in clinical symptom scores). However, there was no difference in endoscopic remission rates at 8 weeks between the two groups, 28% vs. 24% [23]. This was followed up by a larger randomized, double-blind controlled trial in 224 adults with mild-to-moderate ulcerative colitis. HMPL-004 given at a higher dose (1800 mg daily) was associated with a greater clinical response than placebo (60% vs. 40%; $P = 0.018$) although remission rates at 8 weeks were not different between both groups, 38% vs. 34%; $P = 0.101$ [24]. In both trials, the most common adverse events were abdominal pain, diarrhea, and headache. However, the frequency of adverse events was similar in both the treatment and control groups.

Jian Pi Ling

Jian Pi Ling (JPL) tablet and *Yukui tang* tablets are herbal therapies that have been studied in China in the treatment for ulcerative colitis [25, 26, 51, 52]. In a randomized controlled

trial, 153 patients with UC were randomly assigned to three groups: group I, Jian Pi Ling (JPL) tablet with retention enema of *Radix Sophorae Flavescentis* and Flos Sophora decoction; group II, sulfasalazine and retention enema of dexamethasone; and group III, placebo and retention enema of decoction. Remission rates at 3 months in group 1 were significantly higher (53%) than those in the other two groups (28 and 19%, respectively) [25, 26]. Another study evaluated 118 patients with active UC who were treated with oral Yukui tang tablets and herbal decoction enemas, in addition to oral prednisolone 15 mg daily, neomycin, and vitamin B for 40 days. Eighty-six control patients who received only low-dose prednisolone, neomycin, and vitamin B were used for comparison. The remission rates and response rates were 33 and 51%, respectively, in the active group, compared with 17 and 43%, in the control group [25, 26].

Oenothera biennis

Oenothera biennis also known as **evening primrose oil**, night willow herb, fever plant, and king's cure-all. Evening primrose oil is rich in omega-6 gamma-linolenic acid (GLA), which can be converted directly to the prostaglandin precursor dihomo-GLA (DGLA). It has been demonstrated to have anti-inflammatory activity and inhibits platelet aggregation. Administration of the oil may benefit individuals unable to metabolize cis-linolenic acid to GLA, producing subsequent intermediates of metabolic significance including prostaglandins. Side effects include abdominal pain, indigestion, nausea, softening of stools, and headaches. This may cause increased bleeding when taken with anticoagulants or antiplatelet medication. Although there are no interactions reported with antihypertensive medications, evening primrose oil was identified to increase both systolic and diastolic blood pressures, with a clinically meaningful difference for systolic blood pressure in a large population-based study.

Primrose oil has been used in the treatment of ulcerative colitis. In a placebo-controlled study, 43 patients with stable ulcerative colitis were randomized to receive MaxEPA (Omega 3 FFA) ($n = 16$), super evening primrose oil ($n = 19$), or olive oil as placebo ($n = 8$) for 6 months, in addition to their normal treatment. Super evening primrose oil significantly improved stool consistency, and the difference was maintained even after treatment was discontinued. There was no difference in stool frequency, rectal bleeding, disease relapse, sigmoidoscopic appearance, or histology in the three treatment groups [53].

Curcumin

Curcumin is the major phytochemical active ingredient of the **spice turmeric**. It is a herb derived from the ginger family (*Zingiberaceae*) native to India and Southeast Asia. Curcumin is commonly used in Indian traditional cuisine and medicine. It has been found to have anti-inflammatory, antioxidant, and antitumor effects. Curcumin is thought to cause the suppression of the nuclear factor kappa-light chain enhancer of activated B cells (NF-KB). Furthermore, curcumin activity includes suppression of interleukin-1 (IL-1) and tumor necrosis factor-alpha (TNF α), two main cytokines that play important roles in the regulation of inflammatory responses. Side effects include dyspepsia, diarrhea, distension, reflux, gassiness, nausea, and vomiting. It also has been found to interact with anticoagulants, hypoglycemic medications, and iron and can increase sulfasalazine levels. Thus, this must be discontinued at least 2 weeks prior to any surgery.

Curcumin has been used in the treatment of both ulcerative colitis and Crohn disease. A 2012 Cochrane review found curcumin is safe and effective therapy for the maintenance of remission in quiescent UC when given as adjunctive therapy along with mesalamine or sulfasalazine. A multicenter randomized double-blind Japanese study evaluated 89 patients who were randomized to receive either curcumin (1 g twice daily) or placebo, in addition to sulfasalazine or mesalamine, for 6 months. The relapse rate was significantly lower in the curcumin group, 4.7% compared to the placebo 20.5%, $p = 0.04$ [27]. This was reinforced by a multicenter double-blind randomized control trial, which evaluated 50 patients with active mild-moderate UC on 5-ASA, who did not respond to 2 weeks of max 5-ASA oral and topical therapy. Patients were randomly assigned to curcumin 3 g/day ($n = 26$) or placebo ($n = 24$) × 4 weeks. Clinical response (reduction of ≥3 points in SCCAI) was achieved by 17 patients (65.3%) in the curcumin group vs. three patients (12.5%) in the placebo group ($P < 0.001$). Endoscopic remission (partial Mayo score ≤ 1) was observed in 8 of the 22 patients evaluated in the curcumin group (38%), compared with 0 of 16 patients evaluated in the placebo group $p = 0.04$ [28]. One study evaluated the efficacy of topical curcumin therapy in the form of an enema. They evaluated 45 patients with mild-to-moderate distal UC who were randomized to oral 5-ASA plus either curcumin enema or a placebo enema for 8 weeks. Curcumin compared with the placebo group showed a superior clinical response (92.9% versus 50%, $p = 0.01$), clinical remission (71.4% versus 31.3%, $p = 0.03$), and endoscopic improvement (85.7% versus 50%, $p = 0.04$) [50, 54].

Curcumin has been also evaluated in Crohn disease. An open label pilot study of five patients with UC proctitis/proctosigmoiditis and five patients with Crohn disease were evaluated. Those with Crohn disease were treated with curcumin, 360 mg (1 capsule) three times daily for 1 month and then 360 mg (4 capsules) four times daily for the remaining 2 months demonstrated a mean reduction in CDAI of 55 points, ESR reduction of 10 mm/h, and CRP reduction of

0.1 mg/dL in 4 out of the 5 patients. All of the proctitis patients improved, with reductions in concomitant medications in four [30]. Despite previously reported results, an RCT done in 2003–2005 showed the failure of low-dose curcumin to induce remission in mild-to-moderate UC using a combination of oral mesalamine and curcumin. Forty-one patients were randomized, either to oral mesalamine 2.4 g daily with curcumin at 150 mg three times a day (16 patients) or oral mesalamine 2.4 g daily with placebo (25 patients). There was no significant difference between the two groups in terms of clinical response, clinical remission or mucosal healing after 8 weeks of therapy [29].

A pilot pediatric tolerability study was performed in 11 patients with mild UC or CD. This had shown overall good tolerability of the drug with only 2 out of the 11 patients exhibiting gassiness. All participants in this pilot study received 500 mg of curcumin twice a day for 3 weeks, and with the use of a forced dose titration design, doses were increased up to 1 g twice a day at Week 3 for a total of 3 weeks and titrated again to 2 g twice a day at Week 6 for an additional 3 weeks. By using the Pediatric Ulcerative Colitis Activity Index (PUCAI) and Pediatric Crohn Disease Activity Index (PCDAI), which are validated measures of disease activity, scores were obtained at Weeks 3, 6 and 9. Three patients had a decrease in their PUCAI or PCDAI scores and none had a relapse or worsening of symptoms [31].

Boswellia

Boswellia (Burseraceae), also known as **Indian frankincense,** is a tree prevalent in India, the Middle East, and North Africa. The gummy exudate or the resin obtained by peeling away the bark is commonly known as "frankincense" or "olibanum." Boswellic acids act as an anti-inflammatory by noncompetitive inhibition of 5-lipoxygenase and decrease in pro-inflammatory makers such as TNF-α. Side effects include gastric irritation and nausea. It has been shown to interact with cytochrome P450 substrates and immunosuppressants and decrease the inflammatory effects of NSAIDs. In addition, this may accelerate menstrual flow and may induce miscarriage in pregnant women.

Boswellia has been used in the treatment of ulcerative colitis and Crohn disease. Two studies had compared the efficacy of herbal therapy to mesalamine. In the first study, 30 patients with chronic active UC were randomized to gum resin of *Boswellia serrata* (900 mg daily in three doses; $n = 20$) or sulfasalazine (3 g daily in three doses; $n = 10$) for 6 weeks. Fourteen of the twenty patients treated with *Boswellia* gum resin and four of the ten treated with sulfasalazine achieved remission. Eighteen of 20 patients treated with *Boswellia* gum resin and 6 of 10 patients on sulfasalazine showed an improvement in one or more of the parameters including stool properties, histopathology, and scanning electron microscopy [32].

In a randomized, double-blind, non-inferiority, parallel-group control trial done in Germany, 102 patients with Crohn disease were randomized. Forty-four patients were treated with *Boswellia* extract (H15) and thirty-nine with mesalamine. CDAI decreased by 90 in the *Boswellia* group and 53 in the mesalamine group [33]. A subsequent double-blind, placebo-controlled, randomized, parallel study from 22 centers in Germany evaluated the long-term efficacy and safety of *Boswellia serrata* extract (Boswelan, PS0201Bo) in maintaining remission in 108 patients with Crohn disease. At 52 weeks, there was no significant difference in the proportion of patients in clinical remission between those who were actively treated or in the placebo group (59.9% vs. 55.3%). The mean time to relapse was also not different between the two groups [34].

Artemisia absinthium

Artemisia absinthium (Asteraceae) is commonly known as **wormwood or sweet sagewort** and has been used in traditional Chinese medicine. Dihydroartemisinin (DHA) is a semisynthetic derivative of artemisinin and has been found to have anti-inflammatory properties. It is believed to attenuate COX-2 production via downregulation of serine/threonine kinase (AKT) and mitogen-activated protein kinase (MAPK) pathways and decrease TNF-α. Side effects include hepatitis and patients with a history of ulcers should not take *Artemisia*. *Artemisia* can also induce seizures resulting from decreased efficacy of antiseizure medications. Extracts from *Artemisia* induce CYP2B6 and CYP3A4 and may affect the serum concentration of drugs metabolized by these enzymes.

Wormwood has been used in the treatment of Crohn disease. A double-blind study carried out at five sites in Germany evaluated 40 patients suffering from Crohn disease receiving a stable daily dose of steroids at an equivalent of 40 mg or less of prednisone for at least 3 weeks. They were randomized to receive either a herbal blend containing wormwood herb (3 × 500 mg/day) or a placebo for 10 weeks. There was a steady improvement in CD symptoms in 18 patients (90%) who received wormwood in spite of tapering of steroids as shown by Crohn Disease Activity Index (CDAI) questionnaire, Inflammatory Bowel Disease Questionnaire (IBDQ), Hamilton Depression Scale (HAMD), and Visual Analogue Scale (VA-Scale). After 8 weeks of treatment with wormwood, there was almost complete remission of symptoms in 13 (65%) patients in this group as compared to none in the placebo group. This remission persisted till the end of the observation period which was week 20, and the addition of steroids was not necessary. This study strongly suggests that wormwood has a steroid-sparing effect on the improvement

of mood and quality of life-based on the HAMD scale, which is not achieved by other standard medications [35].

In a separate controlled trial, 20 patients with active CD were given either dried powdered wormwood or a placebo, in addition to their existing CD therapy. At 6 weeks, 8 of 10 patients (80%) on wormwood and 2 of 10 patients (20%) on placebo achieved clinical remission defined as a Crohn disease activity index (CDAI) below 170 or a reduction in CDAI by 70 points. Six of ten patients on wormwood had a clinical response compared to none on placebo [36].

Tripterygium wilfordii Hook F (TWHF)

Tripterygium wilfordii Hook F (TWHF) known by its mandarin name "léi gōng téng," sometimes called thunder god vine, is a vine used in traditional Chinese medicine that has both immunomodulatory and anti-inflammatory activities. It is a dipterpene tripoxide from an extract obtained from *Tripterygium wilfordii*. Side effects include amenorrhea and nonspecific gastrointestinal symptoms. *Tripterygium* is used in the treatment and in prevention of postoperative recurrence of Crohn disease. A study evaluated 20 adult patients with active Crohn disease who were treated with *Tripterygium* pills for 12 weeks. CDAI scores dropped during the first 8 weeks, and endoscopic improvements were observed at week 12. Furthermore, a significant decrease in serum levels of C-reactive protein and pro-inflammatory cytokines was reported [37].

Two placebo-controlled studies assessed the role of *Tripterygium wilfordii* (GTW) in preventing postoperative recurrence of CD. Forty-five patients with CD were randomly assigned to receive GTW or mesalamine after their operation. No clinical recurrence occurred in both groups at 3 months. There were no significant differences in clinical relapse at 6 months (18% vs. 22%) or 12 months (32% vs. 39%) between the GTW and mesalamine groups. Endoscopic recurrence at 12 months was also similar in the two groups, 46% vs. 61% [38]. This was followed by a subsequent study, which randomized 39 CD patients to GTW ($n = 21$) or sulfasalazine ($n = 18$) 2 weeks after resection for Crohn disease. Clinical recurrence was reported in 6% on GTW and 25% on sulfasalazine, and endoscopic recurrence was reported in 22% on GTW and 56% on sulfasalazine. GTW appeared to be as effective, if not more effective, than mesalamine in preventing recurrence of postoperative Crohn disease [39].

Belladonna

Belladonna (Tincture of belladonna) *Atropa belladonna* or *Atropa bella-donna*, commonly known as belladonna or **deadly nightshade**, is a perennial herbaceous plant in the tomato family Solanaceae. This is native to Europe, North Africa, Western Asia, and some parts of Canada and the United States. The active agents in belladonna include atropine, hyoscine, and hyoscyamine which have anticholinergic properties. Side effects include dilated pupils, sensitivity to light, blurred vision, tachycardia, loss of balance, staggering, headache, rash, flushing, severely dry mouth, urinary retention, constipation, confusion, hallucinations, delirium, and convulsions. This has been used for its anticholinergic properties and symptomatic treatment of pain in inflammatory bowel disease. Its side effect is suppression of gastrointestinal motility and thus can precipitate toxic megacolon. Thus, use is not recommended.

Cannabis

Cannabis is a genus of flowering plants that includes three species *sativa*, *indica*, and *ruderalis*. The plant is indigenous to Central Asia and the Indian subcontinent. D9-tetrahydrocannabinol (THC) and cannabidiol (CBD) seem to be the most active cannabinoids. Two cannabinoid receptors in the gut have been identified, cannabinoid receptors CB1 and CB2. They act mainly through cannabinoid receptor 2 which causes downregulation of cytokines, specifically tumor necrosis factor (TNF)-α and interleukin-1. They also act by suppressing cell-mediated immunity and enhancing humoral immunity. Cannabinoid exposure antagonizes the release of prostaglandins, histamine, and matrix-active proteases from mast cells. Side effects can include dry mouth, drowsiness, palpitations, paranoia, anxiety, memory loss [55], altered state of consciousness, distorted perceptions of time and space, bloodshot eyes, dilated pupils, increased appetite, and impaired coordination and concentration.

Cannabinoids have been used within gastroenterology to treat anorexia, emesis, abdominal pain, gastroenteritis, diarrhea, intestinal inflammation, and diabetic gastroparesis [56]. Endogenous endocannabinoids have been discovered which may modulate intestinal inflammation [57], and animal models suggest cannabis plays a role in the treatment of colitis [58]. THC has been used in the symptomatic relief of inflammatory bowel disease in adults.

Observational data have indicated that marijuana use by patients with CD generally improves their overall perception of health, ability to work, and social function and reduces physical pain and depression, with an increase in weight [59]. This was also echoed in a retrospective study, wherein 21 out of 30 patients with CD had clinical improvement ($p < 0.001$) based upon Harvey-Bradshaw Index and a decreased need for escalation of therapy and surgery after cannabis treatment [60]. A double-blinded prospective study evaluated 21 patients with Crohn Disease Activity Index (CDAI) scores greater than 200 who did not respond to ther-

apy with steroids, immunomodulators, or antitumor necrosis factor-α agents. Patients were randomized to receive cigarettes containing 115 mg of D9 tetrahydrocannabinol (THC) or a placebo containing cannabis flowers from which the THC had been extracted twice daily for 8 weeks. Complete remission (CDAI score, <150) was achieved by 5 of 11 subjects in the cannabis group and 1 of 10 in the placebo group (p 0.43), and clinical response (decrease in CDAI score of >100) was observed in 90% the cannabis group vs 40% in the placebo group ($p = 0.028$). THC-rich cannabis produced significant clinical, steroid-free benefits with active Crohn disease, compared with placebo, without side effects [40].

The most recent trial by Naftali et al., was a small RCT evaluating 20 patients with moderately active CD on various therapies who were randomized to receive cannabidiol 20 mg/day or placebo. No significant difference in CDAI score was noted between the 2 groups after 8 weeks [41]. CBD was noted to be safe but had no beneficial effects. Lastly, a study by Irving, showed that among patients with left-sided or extensive UC stable on 5-ASAs (Mayo scores of 4–10 (endoscopy scores ≥ 1), a cannabidiol-rich botanical extract was superior to placebo in improving QOL outcomes and may be beneficial for symptomatic treatment of UC although remission rates at 10 weeks were similar between the two groups [42].

Indigo naturalis

Indigo naturalis (IN) also known as Qing-Dai is a herbal medicine extracted from indigo plants (*Indigofera tinctoria*) predominantly used in China. IN contains ligands for the aryl hydrocarbon receptor and promotes regeneration of the mucosa by inducing the production of interleukin 22. It has anti-inflammatory properties secondary to the inhibition of TNF-α, interleukin 1, 6, and NF-κB. It has been used as an antipyretic and hemostatic agent. Side effects include diarrhea, abdominal pain, nausea, vomiting, transaminitis, and headaches [61].

In rat models, this has also been seen to reduce myeloperoxidase activity and expression of inflammatory cytokines while increasing the expression of colonic mucosal repair–related cytokines and proteins. A multicenter RCT evaluated the benefit of Indigo in 86 patients with active UC (Mayo score ≥ 6) refractory to conventional treatments. Patients were randomized to receive a daily dose of Indigo at doses of 0.5 g, 1.0 g, or 2.0 g for 8 weeks. The primary endpoint was the rate of clinical response at week 8, defined as a 3-point decrease in the Mayo score and a decrease of at least 30% from baseline, with a decrease of at least 1 point for the rectal bleeding subscore or absolute rectal bleeding score of 0–1. The trial was terminated because of an external reason: a report of pulmonary arterial hypertension in a patient who used self-purchased IN for 6 months. Patients on IN demonstrated significantly higher rates of clinical response, remission, and mucosal healing vs patients in the placebo group. IN should not yet be used because of the potential for adverse effects, including pulmonary arterial hypertension [62].

Non-herbal Therapies

Fatty Acids

Fish Oil (Omega-3 FFA)

Fish oil (omega-3 FFA) is a type of polyunsaturated fatty acid (PUFA) derived mainly from fish oil. It has been found to have anti-inflammatory and immunomodulatory properties. The main components behind its potential therapeutic effects include omega-3 polyunsaturated fatty acids (n-3 PUFAs), docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA), the latter 2 being the main bioactive forms synthesized from the precursor n-3 PUFA α-linolenic acid. Recently, n-3 PUFAs have been implicated in favorable shifts in the gut microbiota, including decreases in *Faecalibacterium* and an increase in *Bacteroidetes*.

Fish oil suppresses mediators of immune function by reducing cytokine production (IL-1, IL-2, IL-6 TNF-α), suppressing T and B cell proliferation and decreasing antibody production. Omega-3 fatty acids may also reduce inflammation in patients with ulcerative colitis by reducing rectal dialysate leukotriene β4. This is generally safe but side effects include fishy after taste, nausea, diarrhea, and heartburn. Fish oil can have additive anticoagulant/antiplatelet effects and interact with NSAIDS. This may also potentiate some of the adverse effects of glucocorticoids.

Fish oil has been used in the treatment of both ulcerative colitis and Crohn disease. Despite its generally accepted use, results in clinical studies have been inconsistent. A 2014 Cochrane review of six studies with 1039 patients demonstrated the marginal benefit of therapy for maintenance of remission. The overall quality of evidence was very low, and the two best quality studies showed no benefit. In two systematic reviews, omega-3 fatty acids are not effective for the maintenance of remission in Crohn disease [63]. However, an RCT performed in 2018 examined a cohort of patients in clinical remission (partial Mayo score < 2) but with fecal calprotectin at least 150 μg/g. Patients were randomized to receive EPA (1 g twice daily) or placebo. They found that 63.3% of patients receiving EPA vs 13.3% of patients receiving placebo had at least a 100-point reduction in fecal calprotectin ($P < 0.001$) and 76.7% of patients receiving EPA (vs 50% of patients receiving placebo) maintained remission (odds ratio, 3.29; 95% CI, 1.08–9.95) [64, 65].

Although there is evidence that PUFAs can benefit IBD ex vivo and in animal models, a systematic review and meta-analyses by Turner et al. in 2011 concluded that there are insufficient data to recommend the use of omega-3 fatty acids for the maintenance of remission in CD and UC [66]. Furthermore, a systematic review in 2012 concluded that there is insufficient evidence to recommend n-3 PUFA in IBD [67].

A pediatric study by Romano et al. assessed the use of long-chain omega-3 FFA supplementation, in addition to 5-ASA in pediatric patients with CD. This study included 38 patients 5–16 years of age with CD in remission, randomized to two groups, either receiving 5-ASA and omega-3 FFA or receiving 5-ASA and olive oil placebo capsules for a period of 12 months. Relapse rates were significantly lower in the group receiving omega-3 FFAs, 61% (11/18) compared to placebo, 95% (19/20) ($P < 0.001$) [43].

Blond psyllium

Blond psyllium comes from the husk surrounding the seeds of a herb called ***Plantago ovata*** (Plantaginaceae). When exposed to water, psyllium swells and forms a gel-like mass called mucilage. The colonic fermentation of psyllium in the gastrointestinal tract produces butyrate. Butyrate has an anti-inflammatory effect and inhibits cytokine production. Side effects include transient flatulence, abdominal pain, diarrhea, constipation, dyspepsia, and nausea. Contraindications for its use in IBD include fecal impaction, GI tract narrowing, obstruction, swallowing disorders, and treatment within 2 weeks of surgery.

Blond psyllium has been used to prevent relapse and improve associated ulcerative colitis symptoms. Blond psyllium has been used as a butyrate enema and is effective for the treatment of diversion colitis. In an open-label, parallel-group, multicenter, randomized clinical trial, 105 patients with UC in remission were randomized into groups to receive *Plantago ovata* seeds (10 g twice daily), mesalamine (500 mg three times daily), and *Plantago ovata* seeds plus mesalamine at the same doses. The primary outcome was the maintenance of remission for 1 year. Relapse rates at 12 months were similar in the three groups, psyllium 40% vs. mesalamine 35% vs. combination 30%. There was a significant increase in fecal butyrate with psyllium. Side effects were mild and included constipation and/or flatulence [44].

N-Acetyl Glucosamine (NAG)

N-acetyl glucosamine (NAG) is a chemical that comes from the outer shells of shellfish. It is an amino sugar form of glucosamine. NAG is thought to restore the gastrointestinal protective glycoprotein layer that is broken down with mucosal inflammation. It has been shown to block adherence of *Candida* to gastrointestinal mucosa and stimulates the growth of beneficial *Bifidobacteria*. Side effects include gastrointestinal upset and it is not advised in patients with shellfish allergy. It may interact with acetaminophen, hypoglycemic medication, and warfarin and is contraindicated in asthmatics.

NAG has been used in the treatment of both ulcerative colitis and Crohn disease. A pediatric pilot study evaluated 12 children with severe treatment-resistant bowel disease (10 CD, 2 UC). Seven of the twelve patients had symptomatic strictures. Patients were given 3–6 g of NAG orally as adjunctive therapy. Similar doses were given rectally as monotherapy to nine children with distal UC or proctitis resistant to steroids and antibiotics. Eight of the twelve children who were given oral treatment improved but four required resections. Two of the nine children given rectal therapy achieved remission and three improved, and there was no effect seen in the remaining two patients. Histological improvement was seen in all nine cases biopsied [45].

Chitosan

Chitosan is the N-deacetylated form of chitin extracted from shells of crustaceans and has a structure similar to cellulose. It is a water-insoluble dietary fiber that helps improve bowel habits and prevents colon cancer. Evidence suggests positively charged chitosan polymers bind to negatively charged bile acids in the intestines. This is generally safe but side effects include gastrointestinal upset, nausea, flatulence, increased stool bulk, constipation, and shellfish allergy. It has also been shown to reduce the absorption of calcium, magnesium, selenium, fat-soluble vitamins, and warfarin. This has been studied in the treatment of Crohn disease. A pilot trial of 11 patients with Crohn's was given chitosan and ascorbic acid mixture (1.05 g/day) for 8 weeks. Patients continued their regular therapy. They found that bowel movements slightly increased but nutritional, inflammatory markers, and CDAI did not change. There have been no studies on children. Based on data, this is not recommended in the treatment of IBD [68].

Bromelain

Bromelain (*Ananas comosus*) is a proteolytic enzyme derived from the pineapple stem. It can decrease the expression of mRNAs encoding pro-inflammatory cytokines by human leukocytes in vitro. It has also been shown to decrease the secretion of granulocyte-macrophage colony-stimulating factor, IFN-gamma, and TNF-α in ulcerative colitis and Crohn disease colon biopsies in vitro [53]. Side effects include mild nausea and vomiting, diarrhea, and excessive menstrual bleeding, and it has been seen to interact with anticoagulants, sedatives, and antibiotics. It has been used in refractory ulcerative colitis. There has been a case report of two patients who entered and remained in clinical and endoscopic remission after self-treatment [69].

Rutin

Rutin is a flavonoid with antioxidant properties. It is found in buckwheat, Japanese pagoda tree, eucalyptus, lime tree flowers, elder flowers, hawthorn leaves, St John's wort, *Ginkgo biloba*, and apples. It is safe in small amounts such as present in fruits and vegetables. Side effects include headache, flushing, rashes, and gastrointestinal disturbance. This has shown some benefit in improving inflammatory bowel disease in rats, yet there are no human studies.

Rectal Enema Therapies

Kui Jie Qing (KJQ)

Kui jie qing (KJQ) is a traditional Chinese remedy that has been used as an enema in the treatment of active ulcerative colitis. A randomized controlled trial from China evaluated 95 patients with active UC who were treated with Kui jie qing enemas four times a day. This form of treatment was compared with conventional anti-IBD drugs, including sulfasalazine (1.5 g 3 times daily), oral prednisolone (30 mg once daily), and prednisone enemas (20 mg 4 times daily). After 20 days of treatment, the authors reported a 95% effectiveness rate for KJQ and 62% for conventional drugs, based on the comparison of cure and improvement between the groups. Effective "cure" was shown in 72% of KJQ-treated patients but only in 9% of controls although the definition of "cure" or "improvement" in this study was not clear [46].

Xilei-San

Xilei-san is used in traditional Chinese herbal medicine for its anti-inflammatory properties. This has been used in the treatment of ulcerative proctitis. In an 8-week double-blind randomized study, Xilei-san enema was compared with dexamethasone enemas in 35 subjects with mild-to-moderate active ulcerative proctitis. Subjects were followed up for 12 weeks. Both treatments showed significant improvement in clinical, endoscopic, and histological scores compared to baseline [47].

In another randomized control trial, Xilei-san was used to induce remission in 30 patients with intractable ulcerative proctitis. Subjects were treated with topical mesalamine or corticosteroids for 4 weeks and then randomized into Xilei-san suppositories or placebo for 2 weeks. In the Xilei-san-treated group, significantly more patients achieved remission on day 14 (clinical disease index ≤ 4) compared with placebo ($P < 0.04$). 81.8% of patients on Xilei-san suppositories were without relapse versus 16.7% in placebo ($P < 0.001$) on Day 180. Furthermore, significant endoscopic ($P < 0.01$), histological ($P < 0.02$) and inflammatory bowel disease questionnaire ($P < 0.04$) improvements were observed in the Xilei-san-treated group [48].

Bovine Colostrum

Bovine colostrum is cow's milk secreted during the first few days following calving. It is rich in immunoglobulins, growth factors, and cytokines and confers immune protection to the newborn calf from opportunistic infections. Bovine colostrum is postulated to enhance the immune response. Although the high concentration of immunoglobulins may account for bovine colostrum's effects, the exact mechanism is not known. This may not be used in patients who have cow's milk allergy. Bovine colostrum has been used as an enema in the treatment of ulcerative proctitis. Fourteen patients with mild-to-moderate active UC were treated with bovine colostrum enemas or a placebo containing albumin solution twice daily for 4 weeks in addition to mesalamine. Only the colostrum group showed a mean reduction in symptom score in 7 out of 8 patients and an improvement in the histological score in 5/8 patients vs. 2/6 in the placebo group [49].

Dietary Therapy and Probiotics

Please see separate chapter for this discussion.

Mind Body Therapies for Pediatric IBD

There is an emerging body of literature focused on the use of mind-body therapies to mitigate psychosocial stress and improve HRQOL among IBD patients. Considering that stressful event experiences are perceived as possible triggers for relapse and increased disease activity, the application of mind-body interventions to enhance stress coping skills may enhance the durability of remission [70, 71]. Furthermore, the known association between stress and physical symptom exacerbation and the prevalence of comorbid affective disorders in patients with GI conditions suggest that mind-body therapies may be effective in symptom amelioration [72].

Patients with low-stress levels and those who engage in distraction have shown fewer relapses of disease [73]. Stress has been linked to altering gut permeability, modulating the immune system, and in mice models changing the gut-microbiota leads to a dysregulated colonic inflammatory response by affecting epithelial barrier function [74–76]. In regards to human studies, Mackner et al. showed in a small pilot study that pediatric patients with Crohn disease with high perceived stress had a significantly different composition of their microbiome and metabolome than those with lower perceived stress [77].

Mind-body interventions (MBI) aim to "employ a variety of techniques to facilitate the mind's capacity to affect bodily function" [78]. MBI therapies target stress by affecting the autonomic nervous system and engaging the relaxation response to affect physical symptoms. Mind-body interventions include modalities such as meditation, yoga, and deep breathing, for example, and may be a useful adjuvant treatment for pediatric IBD patients. These MBI modalities are relatively inexpensive, safe, easily integrated, and readily accessible and available. However, there is the paucity of literature in studying these interventions in children with IBD. This section will outline the current body of literature on various mind-body modalities for IBD, focusing on pediatric studies when available, but highlighting adult literature when there are no relevant pediatric studies.

Yoga

Yoga stems from the Indian subcontinent and is a set of practices of physical postures and breathing exercises aimed to promote health. Yoga has been demonstrated to decrease physiologic stress, inflammation, and improve regulation of the sympathetic nervous system and hypothalamic-pituitary-adrenal axis by affecting various physiologic parameters [79]. Furthermore, the European Crohn's and Colitis Organization's recent review on complementary medicine and psychotherapy in IBD concludes that yoga improves QOL in adults with IBD [80].

Cramer et al. published that when comparing written self-care advice to a 12-week supervised weekly yoga program in adults with UC in clinical remission, those in the yoga group had significantly higher QOL and lower disease activity scores compared to the self-care advice group in both study outcome time points of week 12 and 24 of the study [81]. In 2015, Sharma et al., compared an 8-week yoga intervention to a control group with standard medical care in both adults with UC (n = 60) and CD (n = 40) [82]. They found that those in the UC yoga group had decreased arthralgias, decreased pain, and significantly reduced anxiety levels in comparison to the UC control group. However, no significant changes were observed in the CD yoga group nor in objective markers such as heart rate variability and immune markers (soluble IL-2 receptor level and serum eosinophilic cationic protein) in either the UC or CD groups in comparison to controls [82].

In pediatrics, to date, there is only one pilot study that assessed the acceptability and feasibility of a combination 8-week in-person and video yoga program for youth with IBD. Arruda et al. recruited nine adolescents with IBD (both UC and CD) who did not have severe disease (as characterized by exclusion criteria of PUCAI <65, starting a recent biologic therapy, and recent hospitalization or surgery in the last two and one months, respectively [83]. The study was well accepted and feasible as both in-person and video yoga sessions had good attendance (all 9 participants attended 2 out of the 3 in-person sessions and 6 completed at least 2 of 3 online sessions weekly) [83]. Qualitative focus group themes from the study revealed that yoga had a calming effect on participants, increased their emotional self-awareness, reduced stress, helped identify and manage their physical symptoms, and was accessible [83]. However, the study was not adequately powered to detect any statistically significant changes in PUCAI, calprotectin, or PROMIS-37 (Patient Reported Outcomes Measurement Information System, which is a validated form assessing six domains of pediatric wellness) [83].

There is more robust literature studying the effect of yoga in both children and adults with Irritable Bowel Syndrome (IBS). Several systematic reviews and randomized control trials have shown that yoga is feasible and safe, helped with the overall reduction in pain and led to global symptom improvement in patients with IBS [84–86]. And, because the report of IBS-type symptoms is as high as 39% in patients with IBD, yoga can be considered as a helpful adjuvant therapy for patients with IBD [87, 88]. However, further robust well-designed research studies are needed to understand the effect yoga may have on objective inflammatory markers, calprotectin, disease activity, etc. in patients with IBD.

Mindfulness and Meditation

The goal of mindfulness and meditation therapies is to increase non-judgmental, purposeful, moment-to-moment awareness of one's thoughts, feelings, bodily sensations and surrounding environment, often practiced via breathing, movement, and meditation exercises [89]. The two most commonly studied mindfulness modalities in IBD are Mindfulness-based stress reduction (MBSR) and Mindfulness-based cognitive therapy (MBCT). MBSR was developed by John Kabat-Zinn at the University of Massachusetts Medical Center in 1970 and consists of an 8-week evidence-based group program taught by a certified teacher. Mindfulness-based cognitive therapy is similar to MBSR and developed by Zindel Segal and colleagues; it is also in 8-week group program that integrates mindfulness and techniques from cognitive therapy [90].

MBSR is beneficial in children with anxiety, depression, and other chronic disease states [89]. Jedel et al. conducted one of the first randomized controlled trials in 2014 examining MBSR in comparison with a mind-body course designed by the study group in 55 adults with UC in remission [91]. The study showed that MBSR was feasible and acceptable but did not impact psychological or disease outcomes, including calprotectin and inflammatory cytokines, compared to the control course. However, among those who flared during the study period, those assigned to the MBSR

group reported a significantly higher quality of life than the control group ($p = 0.0010$) [91]. Feasibility and acceptability of MBSR were again demonstrated in a 2016 randomized trial of 60 adults with IBD conducted by Nielson et al. Significant improvements in anxiety ($p < 0.05$), depression ($p < 0.05$), quality of life ($p < 0.01$), and mindfulness ($p < 0.01$) were reported in comparison to the control group of usual standard medical care immediately post-intervention and significant reductions in depression and improvements in quality of life and mindfulness were sustained at 6 months post intervention [92]. MBCT was studied by Schoultz et al., in a wait-list control study in 44 adults with IBD and found that there were significant improvements in depression, anxiety, and dispositional mindfulness among those who underwent MBCT as opposed to those in the wait-list control group [93, 94].

To date, there is only one pilot study in pediatrics published by Kohut et al., studying mindfulness in adolescents with IBD. They investigated the feasibility and acceptability of an 8-week mindfulness-based intervention, consisting of 2-h in-person group classes. The intervention, labeled MBI-A (mindfulness-based group intervention for adolescents), was developed by members of the study team initially for chronic pain patients and later adapted for youth with IBD and consisted of skill building and mindfulness meditations, exercises, and activities [95]. The mixed-methods study included three groups (16 total participants) studied over 18 months. Significant improvement was found in emotional functioning related to IBD pre- and post-intervention, but overall mean disease activity actually increased though the majority of the participants had mild disease activity [96]. The study did not have sufficient power to detect the statistical significance in their secondary outcomes, which consisted of various questionnaires measuring disease activity, HRQOL, anxiety, depression, self-efficacy, mindfulness, pain acceptance, and social support [96]. While the intervention was well accepted by participants, the authors suggested that feasibility could have been improved by an online delivery method, shorter class time (90 min versus 120 min), and timing of the class in relation to the academic school year [96].

It is important to note that many of the mindfulness studies in IBD are of small populations, so the efficacy is not generalizable. Further studies with more rigorous methodology with higher sample sizes and cohesive outcome measures are necessary in the future.

Acupuncture and Moxibustion

Acupuncture and moxibustion are two forms of Traditional Chinese Medicine (TCM) that have limited data in human studies, but are commonly used. Acupuncture is a modality used to stimulate certain points in the body based on the patient's symptoms as described by TCM, usually with the use of thin needles, to help activate various energy pathways in the body. Acupuncture has been shown to reduce various pro-inflammatory cytokines in murine models with colitis such as TNF-alpha, IL-6, IL-8 [28–30] and increased levels of anti-inflammatory cytokines such as IL-10 and IL-8 [97, 98] in various mouse models. However, the generalizability of this data is limited as the mechanisms used to induce colitis in these mouse models are heterogeneous.

Frequently, moxibustion is used in conjunction with acupuncture as a treatment modality in TCM. Moxibustion is performed by burning dried mugwort (moxa) root in cones or sticks and placing them at certain points on the body, depending on the patient's ailment, like in acupuncture [99]. Joos, et al., published randomized control trials in both UC and CD in comparing control interventions (sham acupuncture and moxibustion) to true acupuncture and moxibustion. For both the UC ($n = 29$, treatment group, $n = 15$) and CD ($n = 51$, treatment group, $n = 27$) populations, baseline disease activity was defined as mild to moderate [100, 101]. In both studies, the treatment groups had a significant mean reduction in disease activity scores as measured by CAI (colitis activity index) and CDAI (Crohn disease activity index), respectively, for UC and CD groups. However, it is important to note that while a difference between the mean reductions between treatment and control groups in both studies was statistically significant, there was also a mean reduction in disease activity in both control (or sham acupuncture/moxibustion) groups. This suggests that there was a large placebo effect in both the studies for these interventions [100, 101].

Exercise and Sleep

There is a growing body of evidence that physical exercise and sleep can positively impact mood, function, and quality of life in patients with IBD. While the quality of the studies looking at various exercise interventions for IBD is mixed and the duration of the interventions was short, the patients who participated in these studies showed an increase in fitness, a decrease in stress and anxiety induced by IBD, and an increased bone mineral density [102]. Long-term moderate-intensity exercise reduced inflammatory markers in patients with IBD [103], but on the other hand, there is some evidence that exercise can also transiently increase pro-inflammatory cytokines and cause mild systemic inflammation that could exacerbate gastrointestinal symptoms [104]. Sleep disturbance is a common occurrence in patients with IBD with one study finding that 67.5% of 166 patients with IBD suffered a sleep disturbance, not associated with active or inactive IBD but rather associated with their psychological state [105–107]. Overall, the importance

of a well-balanced lifestyle with good sleep hygiene and exercise should be encouraged in patients with IBD.

Conclusion

Conventional treatment for IBD focuses on induction or maintenance of remission and symptom management primarily through medication administration. No therapy is curative. The physical and psychological effects of this chronic disease have an enduring impact on HRQOL and may be refractory to treatment. Since conventional treatment may have untoward health effects, parents and patients may seek opportunities to gain a sense of control over the child's disease and therefore may seek out Integrative Health therapies.

Clinicians should be aware of the prevalence of complementary and Integrative Health modality utilization in the pediatric IBD population, parents' receptivity toward these modalities as adjuvant therapies, and the reticence to disclose utilization. Concurrent use of biologically based Integrative therapies, such as herbals and supplements, and prescription medication is common and may cause untoward drug interactions. While the survey literature on IBD IH therapy prevalence rates is robust, there is a dearth of high-quality studies assessing the safety and efficacy of these modalities. Randomized controlled trials are infrequently employed. The methodologic quality of small pilot studies limits the extrapolation of study conclusions. Evidence to support the use of biologically based therapies is still lacking. Stronger randomized control trials are needed in pediatrics to support their use.

Pediatric gastroenterologists should routinely inquire about complementary and integrative therapy use and maintain open, nonjudgmental channels of communication about modality use. The maintenance of a cursory level of understanding and awareness of Integrative Health modalities, including knowledge of efficacy, interactions, and contraindications, is essential to ensure patient safety.

Part V

Surgical Therapy

39 Management of Intraabdominal Complications of Inflammatory Bowel Disease

Elizabeth C. Maxwell, Peter Mattei, and Andrew B. Grossman

Introduction

While the initial phenotype of Crohn disease (CD) is most commonly inflammatory in pediatric patients, the pathogenesis is characterized by transmural inflammation, which can lead to complications such as fistulae, bowel perforation, and intra-abdominal and pelvic abscesses. This chapter will describe the evaluation for patients with suspected intraabdominal complications of CD and considerations for management, with a focus on intraabdominal and pelvic abscess resulting from internal penetrating disease. In particular, medical and surgical options for treatment will be compared. Surgical emergencies and elective procedures in CD for the indications of perforation, obstruction, and stricture are discussed in more detail in Chap. 41. The approach for managing the penetrating perianal disease is covered in Chap. 35. Surgical treatment of ulcerative colitis (UC) is the focus of Chap. 42, but the complication of toxic megacolon will also be described here.

Intraabdominal and Pelvic Abscess

It is estimated that 10–28% of patients with CD will develop intraabdominal or pelvic abscess, and in some patients, abscess is part of the initial disease presentation [1]. Once recognized, the key principles of treatment are source control of the infection and, if possible, drainage. Traditionally, intraabdominal and pelvic abscesses were treated with surgical drainage, often involving bowel resection and the creation of an ostomy (either temporary or permanent) in an acutely ill patient [1]. More recent evidence has shown that antibiotics and percutaneous drainage, if feasible, may have a more favorable outcome compared to surgery as initial therapy, though this issue continues to be debated. Other treatment considerations include the role of disease-specific medical therapies to control underlying inflammatory disease in the setting of active infection, and how to best optimize nutritional status in these patients.

Pathogenesis

Abscesses tend to form in dependent areas including the paracolic gutters, pelvis, subdiaphragmatic region, and in between loops of bowel [1]. Figure 39.1 illustrates the progression from mucosal ulceration to penetrating disease with abscess formation. Alternatively, abscesses can also be formed via hematologic seeding from a remote section of the diseased bowel or from contamination at the time of bowel surgery [1]. Approximately half of the CD-related abscesses are spontaneous and half result after bowel surgery [1]. Culture from pelvic and intraabdominal abscesses may not always be obtained, but one report found that at least 80% of abscesses are comprised of mixed bacterial pathogens [1]. They may also be sterile and may contain fungal organisms, particularly in the case of immunosuppressed patients and in the setting of chronic abscess [1].

Evaluation

The most common presenting symptoms and signs in patients with the internal penetrating disease include abdominal pain (84%), fever (49%), nausea and vomiting (41%), diarrhea (25%), and the presence of a fistula (14%) [2]. There may also be features of partial bowel obstruction, including a colicky nature of the pain, vomiting, abdominal distention, and/or intermittent constipation [3]. Additional symptoms may

be present depending on the nature and location of the abscess. The right lower quadrant is the most common location of an abscess, followed by the pelvis [4]. If an abscess is adjacent to the bladder, a patient may have urinary symptoms, while local irritation of the psoas muscle from an abscess in the distal ileal region can present as a refusal to walk or bear weight [2].

Physical examination may demonstrate localized tenderness and an abdominal mass may be palpable. Peritoneal signs such as rebound tenderness and involuntary guarding may also be present. Abscess in the right lower quadrant secondary to ileal disease can be difficult to distinguish from acute appendicitis on physical examination. A pelvic abscess may be palpable as a tender bulge on the rectal exam. In a patient with known CD, the development of intraabdominal abscess may also be coupled with other signs of active diseases, such as poor growth or weight loss, extraintestinal manifestations including oral ulcers or arthritis, or perianal findings such as tags or fistulae [2].

Laboratory evaluation will not be specific for an intraabdominal process, but there may be abnormalities in complete blood count (leukocytosis, anemia, thrombocytosis), complete metabolic panel (electrolyte disturbances, hypoalbuminemia), and elevation of C-reactive protein and/or erythrocyte sedimentation rate. It can be useful to compare these values to previous results to establish a trend or deterioration from a patient's baseline. In patients with abdominal pain and vomiting, liver and pancreatic enzymes should be investigated, and urinalysis and urine culture should be obtained in any patient with urinary symptoms. Blood cultures should be obtained in any febrile and acutely ill appearing patient [2].

Cross-sectional imaging is a key component in the evaluation of patients with a suspected intraabdominal complication of CD [2]. Magnetic resonance enterography (MRE) is often considered the optimal imaging modality in pediatrics because it is radiation-sparing (Fig. 39.2). However, in the acutely ill child, standard computed tomography (CT) may be the most readily available and appropriate option [5]. Cross-sectional imaging is able to demonstrate bowel wall thickening, bowel dilation, and mesenteric fat proliferation. Both CT and MR can detect the presence of fistulae, particularly if utilizing oral contrast and performing full MRE or CT enterography (CTE) [2]. Bowel ultrasound (US), which is also radiation-sparing, can be useful in certain clinical scenarios as well, particularly serial monitoring for improvement or disease progression as well as detection of phlegmon or an intra-abdominal abscess if performed and interpreted by an experienced team (Fig. 39.3) [5, 6]. The administration of enteral contrast may improve the quality of bowel US [7]. US can be limited by bowel gas, which is not an issue with CT or MR [2]. Lastly, magnetic resonance imaging (MRI) of the pelvis is usually the modality of choice to evaluate complicated perianal diseases [8]. One challenge is successfully being able to distinguish a phlegmon, which is an inflammatory mass, from a pus-filled abscess cavity, particularly in cases of extensive bowel inflammation. CT, MR, and ultrasound may allow for this differentiation using the presence of gas, fluid, and/or color Doppler signals, though, without these clear features, discerning abscess and phlegmon can be difficult in practice [9]. This can be a clinically critical delineation, as phlegmons cannot usually be drained, while drainage is a mainstay of abscess treatment, as described later in this chapter.

The role of endoscopy in the evaluation of intraabdominal abscess has not been well defined in the literature. In general, endoscopy can be useful to better define overall disease activity, assess for infectious complications of disease or immunosuppression, such as cytomegalovirus, and may provide guidance for overall disease management, particularly when surgery is being considered [2]. However, there is concern regarding the higher rate of complications of endoscopic assessment in the setting of an active abscess secondary to penetrating disease. The optimal timing of endoscopy following treatment of an intraabdominal abscess is also debated, with most sources citing a window of 4–6 weeks after therapy as the ideal interval [1].

Treatment

Management of intraabdominal or pelvic abscess as a result of internal penetrating CD involves antimicrobial coverage and drainage of the abscess if possible either by percutaneous or surgical approach [10].

Antimicrobial Therapy

Antimicrobial coverage is indicated in all cases of intraabdominal and pelvic abscess and is aimed at enteric gram-negative aerobic and facultative bacilli, enteric gram-positive *Streptococci*, and obligate anaerobic bacilli [1]. Coverage should also target nosocomial pathogens, as many patients with CD and abscess will have had multiple exposures to the health care system [2]. Initial broad spectrum options include a carbapenem, a B-lactam/B-lactamase-inhibitor combination, or an advanced generation cephalosporin, plus metronidazole [2]. Narrowing of coverage may be possible if abscess material is obtained for culture and sensitivity. Consulting with an infectious disease specialist can provide additional guidance related to local resistance patterns and other special considerations such as recent antibiotic exposure [2].

Route of administration of antimicrobials has not been directly compared in the literature, but the decision regarding parenteral versus oral antibiotics is usually determined based on the clinical course and severity [1]. Duration of therapy depends primarily on the ability to successfully drain the collection. Antibiotics are usually continued for 3–7 days after successful drainage [11]. Longer courses are required if the abscess cannot be drained adequately [1].

Some adult studies have shown that antibiotics alone, without percutaneous or operative drainage, can be successful in the treatment of some CD-related intraabdominal abscesses. Cases that may be more likely to respond to medical management alone include abscesses of small size (<3 cm), absence of associated fistula(e), and patients who are immunomodulator-naïve [12–15]. A recent single-center retrospective study of pediatric patients compared medical management vs percutaneous drainage and found that by 1 year follow-up, 67% of the medically managed group and 60% of those managed with percutaneous drainage went on to have surgery [16]. Despite these described associations in several studies, there are no clear indications for which patients will respond to this approach [1]. The recurrence rate after medical treatment for an intraabdominal abscess in CD ranges from 37 to 50% [1].

Percutaneous Interventional Drainage

Percutaneous abscess drainage is performed, most commonly by interventional radiologists, by positioning a catheter or drain into the abscess cavity guided by imaging techniques such as ultrasound or CT scan [12]. In the past, this technique was avoided because of the perceived risk of creating a post-drainage enterocutaneous fistula, but more recent studies have shown favorable results in certain clinical scenarios [2], particularly since the advent of biologic therapies to treat CD [1]. Percutaneous drainage is done in conjunction with antibiotics and can either serve as definitive therapy or as an intended bridge therapy prior to a surgical procedure [12]. There are also cases of failure of percutaneous drainage to fully treat the abscess where surgery is required [12].

Factors related to the success of percutaneous drainage have been described to include abscess size, number, etiology, location, presence of fistula, and proximity to vital structures [12], though studies have shown mixed results when analyzing these variables. In general, a unilocular, well-defined cavity, >2–3 cm in size, without direct contact with major vessels or organs, is most likely to be successfully drained [17]. The expectation is that clinical improvement should be seen within 3–5 days after drain placement, with decreasing volumes of drainage [12]. When drainage decreases to <10 mL/day (5 mL/day in neonates), and the patient is clinically improved, the drain can be removed [2, 18]. If clinical improvement is not seen, reimaging is indicated to reassess if abscess has been drained adequately. If it has not, repositioning of the drain or a plan for surgical intervention usually follows [12].

Persistent drainage raises the concern for fistula formation, in which case an abcessogram can be performed using injected contrast [2]. Studies examining continued treatment with the percutaneous drain combined with medical therapy, bowel rest, and parenteral nutrition have reported varying success in addressing these fistulae [19–21].

Rypens and colleagues published a retrospective series of 14 pediatric patients with CD and intraabdominal or pelvic abscess who underwent percutaneous abscess drainage as an initial intervention. All but two patients eventually had the affected bowel segment resected, though the authors indicated definitive surgical management was the preferred therapy at their institution, thus percutaneous drainage had not been intended to be definitive therapy. They concluded that following the percutaneous drainage, the patients had improved clinical status prior to surgery, which was thought to contribute to a less invasive and technically easier surgical procedure [22]. Another single center retrospective study of 25 pediatric patients with CD who underwent percutaneous drainage abscess drainage found 76% of cases to be clinically successful, defined as no surgery within 1 year of drainage OR surgical resection following drainage with no residual abscess at the time of surgery or on preoperative imaging [23]. Other studies, which were not designed to examine this exact question, have shown reduced postoperative complications in patients who have percutaneous drainage pre-operatively [24–26].

Percutaneous drainage is a relatively safe procedure [17]. Complications have been reported in approximately 5–11% of cases, and include sepsis, small bowel fistulae, colon perforation, and death [17, 22]. Minor complications such as bacteremia or infection at the catheter site have been reported in about 3% of cases [17].

Surgical Intervention

Traditionally, surgical drainage had been the primary treatment option for intraabdominal abscesses in CD [12]. Surgical drainage of intraabdominal or pelvic abscess involves exploration of the region, evacuation of all abscess contents, irrigation and debridement of the abscess cavity, and commonly resection of the affected bowel [1]. Importantly, surgical resection of diseased bowel is not considered curative in Crohn disease as post-operative recurrence of disease, particularly at the surgical anastomosis, is common. Surgical drainage can be associated with significant morbidity, particularly when it is performed in ill patients. Potential complications include wound infections, small bowel fistulae, and anastomotic leakage [12]. Often ostomy creation is indicated or cannot be avoided [12].

As will be discussed in more detail in the following section, surgical intervention may be necessary when medical and percutaneous drainage measures are unsuccessful in achieving abscess resolution, and in some cases, maybe the primary intervention selected along with antimicrobial therapy and CD-specific treatment, based on a variety of factors [2]. General principles of surgical management include preservation of intestinal length and resection with macroscopically disease-free margins [2]. Laparoscopy has become the preferred approach over time due to the benefits of shorter post-operative recovery time, decreased wound-related complications, formation of fewer intraabdominal adhesions, and better cosmesis when compared to an open approach [27]. Laparotomy, however, is still considered a safe and reasonable approach in patients who cannot tolerate or have too many adhesions from prior surgery to allow the insufflation of the abdomen with carbon dioxide needed for laparoscopy [2]. Diverting ileostomy or colostomy may be necessary when there is significant intraabdominal soilage, inflammatory thickening of the intestinal wall, and intraoperative instability precluding safe additional operating time to construct an anastomosis [2]. Ostomy creation may be temporary.

Complication rates vary in the literature but have been reported to be as high as 25% [28] and may be influenced by several factors, including preoperative percutaneous drainage, discussed in more detail in the next section. Otherwise, weight loss, the number of structures involved in the inflammatory mass, peritonitis and free air, smoking, and previous intestinal surgery have also been associated with post-operative complications [29]. Nutritional status and decreasing steroid dose may reduce surgical complication rates [2], and are discussed in more detail in later sections of this chapter.

Percutaneous Versus Surgical Drainage

Drainage in conjunction with antibiotic therapy should be considered for abscesses >3 cm or with other features associated with the likelihood of failing medical therapy alone with the percutaneous approach being regarded as the first line option if feasible [10]. Factors to consider when choosing drainage modality include patient stability, complexity, size, location, accessibility of the abscess, number of abscesses, as well as patient history including prior surgeries and therapies [10]. Abscesses under or near overlying organs or between loops of bowel may not be amenable to safe IR drainage therefore may require surgical drainage [10].

Several studies have indicated success with percutaneous drainage as definitive management of intraabdominal abscesses [19, 30–33], though a larger meta-analysis by He and colleagues found that over one-third of patients treated by percutaneous drainage as the intended definitive therapy did ultimately require surgery [34]. Even when eventual surgery is needed, several studies suggest preoperative percutaneous drainage is beneficial, contributing to less surgical technical difficulty and decreased risk of ostomy creation [1, 22].

Regarding safety, several studies have reported increased complication rates in patients undergoing surgical drainage compared to percutaneous drainage, specifically longer lengths of stay in the hospital [35] and increased need for ostomy creation [34, 36]. Another study noted fewer postoperative complications in patients who first underwent percutaneous abscess drainage, including anastomotic leaks, post-operative abscess formation, intestinal fistula, leaks of intestinal stumps, and leaks of sutured secondary internal fistulae, though these trends (25% vs 11% complication rates) did not reach statistical significance [29]. Again, there are potential biases in these analyses as more severe illness and disability may be present in the patients who were treated primarily surgically [35]. In the large recent meta-analysis by He and colleagues, the initial surgery was associated with a significantly higher overall complication rate compared to initial percutaneous drainage. However, there was no difference in rates of specific complications such as enterocutaneous fistula, wound infection, anastomotic leak, postoperative abscess, and recurrent abscess [34].

To date, randomized controlled trials comparing the two approaches are lacking [1, 12]. Several consensus guidelines including the North American Society for Pediatric

Gastroenterology, Hepatology, and Nutrition (NASPGHAN) [2] and the American College of Radiology [14, 15] have recommended percutaneous drainage as an initial step, provided it is technically feasible [12]. When abscesses are not amenable to percutaneous drainage because of size or location or persist despite percutaneous drainage and antimicrobial therapy, surgical drainage is warranted [12].

Treatment of Phlegmon (Inflammatory Mass)

A phlegmon is an ill-defined inflammatory mass that can form as a result of a sealed-off perforation. Phlegmons in CD typically involve the mesentery and adjacent loops of the bowel. Though it is known that penetrating disease affects 40% of CD patients within the first 5 years of diagnosis, there are no specific data related to the prevalence of phlegmons [37]. One review of about 350 adult patients with CD who had a median duration of disease of about 10 years reported penetrating disease in 20% and phlegmon in 3.4% using CTE [38]. Treatment has traditionally included antibiotics, bowel rest, drainage of an associated abscess collection if present, and eventually surgical resection of the mass. CD-specific medications may also play an important therapeutic role as described in the next section [37]. In the future, radiologic terminology may be moving away from the term "phlegmon," to more illustrative descriptions of findings, such as "inflammatory mass with or without abscess."

Crohn Disease-Specific Therapy

In addition to antimicrobials and drainage of abscess, CD-specific therapy should also be considered as part of the management plan. Aminosalicylates are not effective in the treatment of internal penetrating CD [2]. Corticosteroids should be avoided in the presence of known fistulizing disease because of the increased risk of abscess formation [39]. If a patient is already on steroids at the time an abscess is diagnosed, there does not seem to be additional morbidity associated with continuing the steroids if the abscess is otherwise being addressed [1]. Weaning steroids to a lower dose may reduce the risk of perioperative complications when surgical intervention is required [28, 40], with some recommending reduction to less than 20 mg daily [2, 24].

There are no randomized prospective clinical trials examining the efficacy and safety of biologic agents (infliximab, adalimumab, vedolizumab, ustikinumab), small molecules (tofacitinib) or immunomodulators (6-mercaptopurine, azathioprine, methotrexate) in the setting of acute abscess in CD. Post-hoc analysis of the ACCENT II study explored whether fistula-related abscess formation was impacted by exposure to infliximab; no increased formation of abscess was found in the group treated with infliximab compared to placebo [41]. Nguyen and colleagues examined the role of initiation of anti-TNFα therapy after initial management of intraabdominal abscess in 95 adult patients, 55 of whom underwent image-guided percutaneous drainage and 40 of whom had laparotomy. In the patients who underwent laparotomy as initial treatment of abscess, 30% were not on any therapy for CD at the time. After treatment for the abscess, treatment with an anti-TNFα agent either alone or in combination with a thiopurine was protective against abscess recurrence compared to no therapy [35]. The small retrospective pediatric study by Pugmire et al. also found early resumption of immunosuppressive therapy (within 8 weeks after drainage) to be associated with statistically significant clinical success [23]. There is also data in adults to suggest that 30% of fistulas are partially or completely closed on immunomodulator therapy (azathioprine, 6-mercaptopurine, methotrexate), but require ongoing treatment to maintain closure [39, 42]. Taken together, expert opinion based on this data indicates that immunomodulators and/or biologic agents can be given soon after drainage of the abscess and are beneficial [1].

Cullen et al. retrospectively described the initiation of anti-TNFα therapy following antibiotics in 13 adult patients with CD and abdominal phlegmon [37]. Abscess was detected by imaging in 12 patients initially, but had resolved or was drained prior to initiation of anti-TNFα in all but 5 patients who had small undrainable collections. At a mean of 2.3 years of follow-up, no patients developed an infection or new abscess. Two patients eventually had surgery after failure of anti-TNFα therapy, and 10 of the 11 patients who remained on anti-TNFα therapy were asymptomatic at the conclusion of the study. Although this was a small study in adult patients, the results suggest that initiation of anti-TNFα therapy after antibiotics in patients with intestinal phlegmon can be safe and successful [37].

Nutritional Considerations

Nutritional support and rehabilitation are important in all patients with CD, particularly those with complications of the disease and when surgery is being considered. Nutritional status is one of the few modifiable risk factors related to surgical outcomes and should be optimized whenever possible before proceeding to surgery [2]. Historical and daily weights should be obtained and compared, and serum albumin and prealbumin monitored. Bowel rest and support with total parental nutrition may be considered until drainage of the abscess can be achieved. Once the abscess is drained without evidence of reaccumulation, enteral feeds can be initiated and are usually tolerated [2]. The presence of an actively flowing fistula may be another indication to select

bowel rest over enteral feedings [2]. Some studies, however, have shown a benefit to nutritional rehabilitation with enteral feedings in the setting of internal penetrating disease [25], and exclusive enteral nutrition is a proven therapy to induce remission in CD [43].

Summary

Internal penetrating disease represents a complicated type of CD and leads to several possible complications, including fistulae, phlegmon, and abscess. There are many factors that determine the optimal management approach for each individual patient, including overall clinical status and risk for deterioration, the severity of underlying disease, nutritional status, and features of the collection including size and location. Source control of infection using antimicrobial agents and drainage of the abscess when possible are the mainstays of therapy. CD-specific therapy and nutritional optimization are also important aspects of management in these patients.

Other Complications from Internal Penetrating CD

Perforation

Spontaneous free perforation of the small intestine in CD is rare, with a quoted prevalence of 1–3% in adult patients with Crohn disease over their disease course [44]. One series of 1000 consecutive adult patients found 15 cases of perforation over the course of 20 years. Spontaneous free perforation was the presenting feature leading to CD diagnosis in 9 of those 15 patients (60%) [45]. An older case series in 1415 adult patients with CD over 23 years found a similar incidence of spontaneous free perforation in 21 (1.5%) patients; this series included 10 patients with small bowel perforation, 10 with colonic perforation, and one patient with perforation in both small bowel and colon [46]. There are no large series of pediatric patients with CD and spontaneous intestinal perforation but it has been described in case reports [47]. Perforation is managed operatively, which is urgent in the setting of peritonitis to prevent sepsis. Typically the diseased area of the bowel is resected and primary anastomosis is attempted if deemed safe, or a diverting ostomy, which is often temporary, is performed [45].

Small Bowel Obstruction

Fibrostenotic CD usually presents with obstructive symptoms. The most common location for stricture is the ileocecal region. Obstructive symptoms related to narrowing and stricture formation may be aggravated by superimposed edema from active inflammation [48]. Therefore, a trial of medical management with corticosteroids may be attempted to evaluate whether the obstruction can be relieved without surgery [49]. It was previously thought that pre-existing bowel stenosis was a contraindication for therapy with anti-TNFα agents, but further study has demonstrated that some patients with mixed strictures (both fibrotic and inflammatory components) can benefit from infliximab therapy [50–52].

If medical management is unsuccessful, balloon dilation, stricturoplasty, or surgical resection are considered [48]. One large meta-analysis of 13 studies of endoscopic balloon dilation of mostly post-surgical strictures reported a technical success rate of 86% [53]. In that study, long-term clinical efficacy was 58%, with a mean follow-up of 33 months and a major complication rate of 2%. Short strictures of ≤4 cm were most likely to avoid the need for surgery. Stricturoplasty is a surgical intervention which increases bowel diameter without any resection. It is technically feasible for short strictures [48]. Compared to resection, results are comparable when analyzing the resolution of obstructive symptoms, reoperation rate, and time to recurrence of symptoms [54]. Stricturoplasty may be performed in conjunction with a bowel resection [54]. Limited resection for stenotic CD is effective in relieving obstruction but multiple respective bowel surgeries are avoided if possible, to reduce the risk of short bowel syndrome [48].

Toxic Megacolon

Toxic megacolon is a serious complication of IBD and is a syndrome of systemic toxicity and colonic dilation (>6 cm) in the setting of active colitis with high morbidity and mortality. Toxic megacolon is most often seen in IBD patients with UC, though it has been described in Crohn colitis, as well as other non-IBD entities such as Hirschsprung disease and *Clostridium difficile* infection [55]. Toxic megacolon in pediatric IBD is rare, but the true incidence is not known. A small case-control study of ten pediatric IBD patients with toxic megacolon identified diagnostic features of fever, tachycardia, dehydration, and electrolyte abnormalities to be significantly more common in patients with toxic megacolon compared with hospitalized age-matched controls with UC. Also, a mean luminal transverse colon diameter of ≥56 mm was highly suggestive of toxic megacolon in children. Altered mental status and hypovolemic shock have been described more commonly in adults with toxic megacolon than in pediatric cases [56]. New narcotic requirements in a patient admitted with acute severe colitis can be a red flag sign of evolving toxic megacolon. This and other suggestive symptoms should prompt evaluation of toxic megacolon with an abdominal x-ray (Fig. 39.4).

The goal of the treatment of toxic megacolon is to reduce colitis and the likelihood of colonic perforation [55].

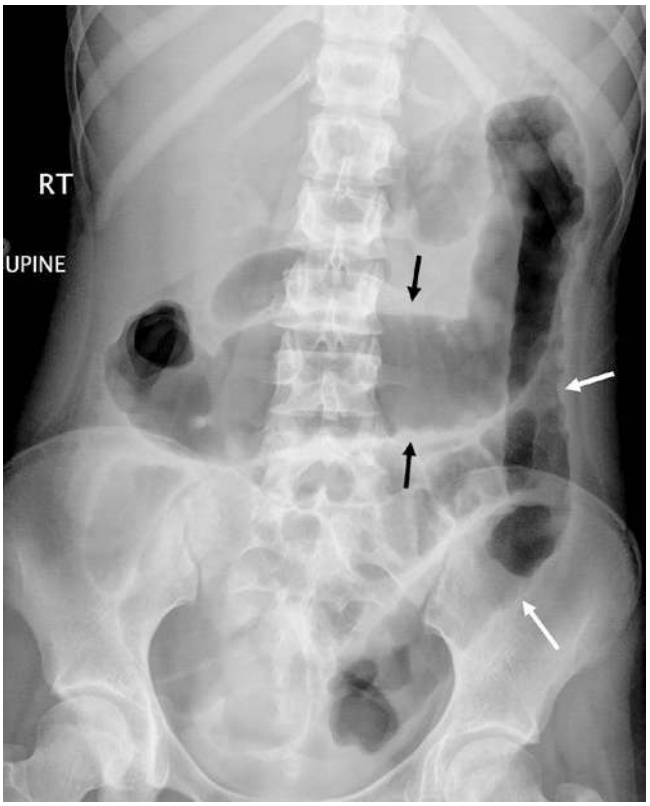

Fig. 39.4 15 year old female with ulcerative colitis: Supine radiograph of the abdomen shows dilated featureless, ahaustral transverse and left colon to sigmoid with thumb printing (white arrows) indicative of submucosal edema or hemorrhage. In addition the transverse colon is disproportionately dilated suggestive of toxic megacolon (black arrows). *Images courtesy of Sudha Anupindi MD, Children's Hospital of Philadelphia*

Immediate surgical consultation should be initiated at the time toxic megacolon is suspected. Medical therapy includes complete bowel rest and NG tube and/or rectal tube for decompression. Patients are frequently monitored in the ICU setting for serial exams and should have laboratory studies (complete blood count, electrolytes) and abdominal radiographs reviewed every 12 h, initially. IV corticosteroids can be used to reduce inflammation and broad-spectrum antibiotics are recommended to decrease the risk of septic complications. Anticholinergic and narcotic medications should be discontinued. Resolution of toxic appearance, decreased fluid and transfusion requirement, improvement in colonic dilation and abdominal distention, and improved laboratory derangements are signs that toxic megacolon is resolving. Absolute indications for surgery are free perforation, massive hemorrhage, increasing transfusion requirements, progression of colonic dilation, and/or worsening toxicity. Subtotal colectomy with end ileostomy is the surgical procedure of choice in urgent or emergent situations [55]. There is a paucity of data regarding the outcome of toxic megacolon for pediatric inflammatory bowel disease; 7 of 10 patients in the aforementioned case series underwent colectomy [56].

Surgical Management of Crohn Disease in Children

40

Amanda Jensen, Daniel von Allmen, and Jason Frischer

Introduction

Surgery plays an important role in the treatment of Crohn disease. Crohn disease has a major impact on the quality of life in the pediatric population, and, unfortunately, despite the dramatic improvements in medical therapies, 70–80% of patients who carry the diagnosis of Crohn disease undergo some type of surgical procedure at some point during the course of their disease [1–4]. The principles regarding surgical intervention are similar in the pediatric population with the caveat that 50% of patients who undergo an initial operative intervention will require additional surgery in the future. The indications for surgery have evolved over time with a trend toward less invasive procedures and fewer emergency surgery operations because of an acute complication of the disease [5]. Crohn disease cannot be cured in the operating room so procedures are primarily employed to treat complications of the disease including obstruction, perforation, abscess, fistulas, and medically refractory disease. Strategies are employed to preserve intestinal length and minimize scarring. The primary goals of management are aimed at (1) controlling mechanical complications or resecting refractory disease, (2) inducing and maintaining remission of disease, (3) promoting growth and development and (4) preventing short and long-term adverse events. Surgery is not a curative procedure, but, the resolution of disease manifestations can have a tremendous impact on the quality of life in these patients.

As with many diseases in children, studies specific to the pediatric population are not always available making it necessary to extrapolate the results of adult series when considering treatment options for younger patients. Although some differences between the patient populations exist, the philosophy remains the same. Surgical intervention is an integral part of the management of patients with Crohn disease but should be invoked judiciously with a collaborative approach with input from the surgeon, the gastroenterologist, radiologist and pathologist to promote informed discussions with the patient and their family to ultimately aim to avoid the potential for long-term consequences.

History of Surgical Therapy

When Crohn disease was first described in the early 1930s, the disease was thought to be isolated to the terminal ileum [6], and surgical therapy typically involved resection of the terminal ileum with an ileocolic anastomosis. In this era, before the development of antibiotics and sophisticated electrolyte replacement and nutritional support, the mortality for this operation was 25% [7]. In an effort to improve the surgical outcomes and reduce mortality, many surgeons moved to a two-stage approach in which the diseased segment of the bowel was bypassed with an ileocolostomy leaving the diseased segment of the terminal ileum as a blind pouch emptying into the cecum. Months later the patient was returned to the operating room for resection of the diseased segment. Although this approach required a second trip to the operating room to resect the bypassed segment, surgical mortality was substantially reduced. As experience with this approach increased, it became clear that the bypassed segment often improved and ceased causing problems. Many surgeons subsequently abandoned resection of the diseased segment altogether resulting in a dramatic improvement in surgical mortality. In one study mortality in 145 patients was 16% for one-stage operations, 12% for two-stage operations, and 0% in ileotransverse colostomy with exclusion [8]. Unfortunately, it became apparent that there were long-term consequences to bypassing the diseased segment and right side of the colon and leaving it in situ. The function of normal colonic tissue was sacrificed and increased risks of malignant changes in the small bowel were reported [9].

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_40

Fortunately, with improvements in perioperative surgical care, the risk of a primary definitive procedure has been reduced to the point where it has once again become the operation of the first choice and is associated with extremely low mortality rates.

Prognostic Indicators and Operative Indications

The indications for surgical intervention in Crohn disease are varied and often patient-specific, especially in children. However, the principles regarding surgical intervention are similar regardless of the age of the patient. The goal of an operation for Crohn disease is to control one of the many mechanical complications resulting from the inflammatory process in the intestine, and there are many clinical situations that warrant consideration of a surgical procedure during the course of a child's disease (Table 40.1). Surgery is not meant to be curative, but rather to relieve the symptoms or complications of Crohn disease. The timing, indications, and operative procedure performed vary considerably based on the segment of the intestine involved and the specific complication being addressed. The distribution of disease in pediatric patients has been examined in a large cohort of European children. In that study combined ileocolonic disease was found in 53% of patients followed by isolated colonic disease in 28% and limited ileocecal disease in 16% (Fig. 40.1) [10].

Isolated Crohn disease of the foregut is relatively rare [13] and seldom requires surgical intervention. In contrast, terminal ileal and colonic diseases account for the vast majority of surgical interventions in the pediatric patient. Some require an urgent operation, while most are more elective in nature. The most common complications leading to a surgical intervention are obstruction, abscesses, fistulas, and failure or intolerance of pharmacological treatment [14–16].

The indications for surgery have evolved somewhat as medical treatments have improved. A study examining surgical indications in the period from 1970 to 1990 compared to the period from 1991 to 1997 revealed that active disease as an indication for surgery decreased from 64 to 25% of cases, while chronic stricture increased from 9 to 50% of cases. In addition, the time from diagnosis to initial operation increased

Table 40.1 Operative indications in Crohn disease

Intestinal stricture or obstruction	Fistula (bowel to bowel, bowel to skin, bowel to adjacent organ)
Bowel perforation	Urologic complications
Massive intestinal bleeding	Growth failure
Complex perianal abscess or fistula	Fulminant disease refractory to medical management
Neoplastic changes	Intra-abdominal abscess

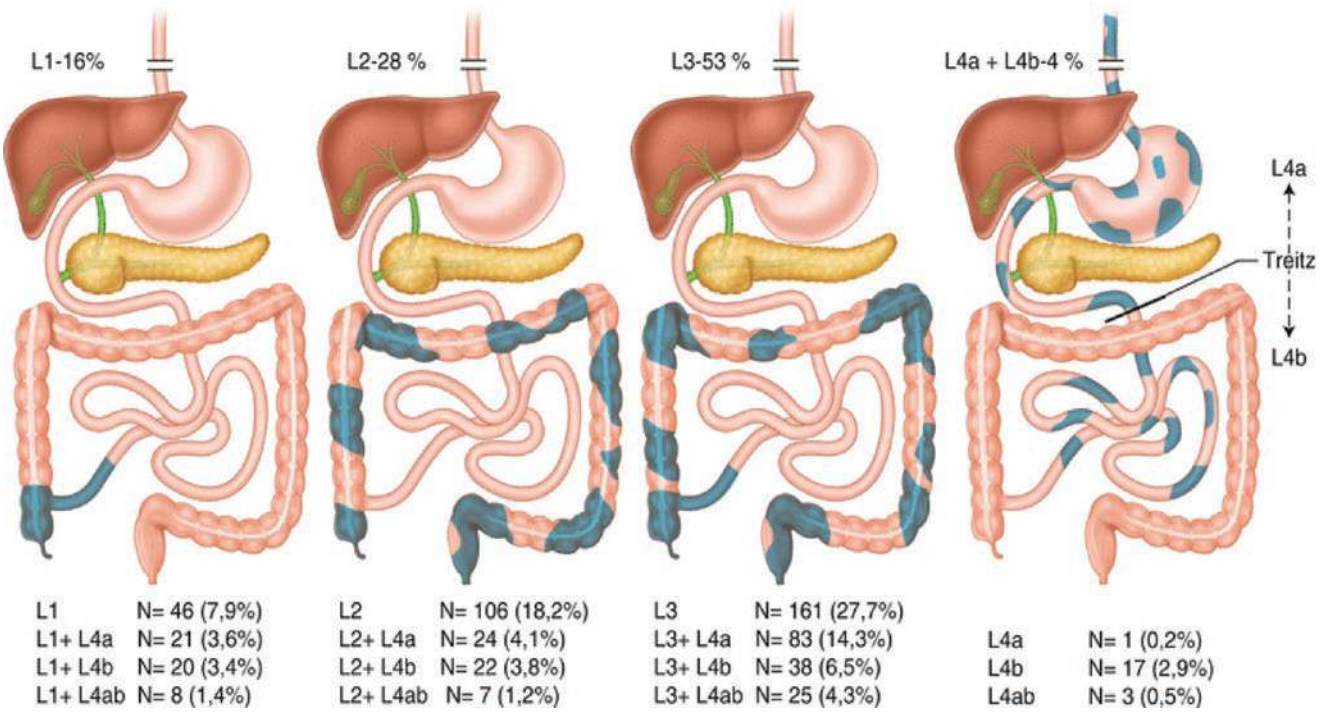

Fig. 40.1 Distribution of pediatric Crohn disease (de Bie et al. [10]) in newly diagnosed pediatric Crohn disease patients who underwent complete diagnostic work up according to Porto criteria [11]. L1: terminal ileal disease (± limited cecal disease). L2: colonic disease. L3: ileocolonic disease. L4: isolated upper gastrointestinal disease. L4A: esophagogastroduodenal disease. L4B: jejunal/proximal ileal disease

from 3.5 to 11.5 years [17] suggesting that medical therapy has been successful in altering the course of the disease but not necessarily preventing ultimate progression in many cases. Fortunately, the shift to less emergent operation likely reduces the morbidity associated with a surgical intervention.

Absolute indications for surgery are rare, and many patients present with multiple relative indications rather than an acute precipitating event. In a large cohort of adults with Crohn disease, the decision to proceed with surgery was distributed as follows: failure of medical management in 47%, obstruction in 20%, intestinal fistula in 15%, mass in 12%, abdominal abscess in 7%, hemorrhage in 2%, and peritonitis in 2% [18].

As our understanding of inflammatory bowel disease has increased, it has become clear that there are different variants of Crohn disease, and some phenotypes are more likely to require operative intervention. The age at diagnosis has an impact on disease characteristics and propensity to progress with younger patients having more extensive and more aggressive disease than adult-onset patients [19]. The complex associations of genetic and epigenetic alterations with specific phenotypes are beyond the scope of this chapter, but our ability to predict patterns of disease and response to therapy continues to improve. As our understanding of the relationship between genotype and phenotype grows in the future, it may be possible to target specific patient populations for specific types of surgical intervention based on response rates and disease characteristics.

In the refractory Crohn disease patient, prior to surgical intervention, nonadherence, inadequate dosing, duration of therapy and other features should be considered prior to surgical intervention as surgery is not curative for Crohn disease (Table 40.2). The indications for surgical intervention in the pediatric population differ from those in adults in many cases. The mechanical complications of obstruction and perforation are the same, but the impact of medical therapy on growth and development is unique to the pediatric population [20]. The indication for surgery may be the failure of medical therapy with growth impairment rather than obstruction or other mechanical complications [21]. Growth failure is observed in 15–40% of pediatric Crohn disease patients with malabsorption, suboptimal intake and increased energy needs leading to this malnutrition [22, 23]. In one study of children who had received extensive medical and/or nutritional treatment before surgery, 26 patients underwent intestinal resections. The indication for surgery was chronic intestinal obstruction in 13 cases and chronic intestinal disability leading to growth failure in 13 cases [24]. Furthermore, the timing of surgery for growth issues is critical in the adolescent. Surgical intervention must occur well before epiphyseal plates close to allow sufficient time for subsequent catch-up growth following the operation [25]. Surgical therapy is associated with significant catch-up growth in 6 months following operation in patients with the treatment-resistant disease [26].

Fortunately, surgical treatments have evolved along with medical therapy, and current surgical procedures are safer and less invasive than at any time in the past. Surgery has progressed from a treatment of last resort for life-threatening complications to therapy for use in conjunction with medical interventions to maximize the patient's quality of life. While the specter of short bowel syndrome must be kept in mind, elective procedures to treat the complications of Crohn disease can be accomplished safely and effectively [27]. While medical therapy may one day render surgical therapy unnecessary, at present, the surgeon remains an integral part of the treatment team for patients with inflammatory bowel disease and Crohn disease in particular.

Table 40.2 Considerations prior to surgical intervention

	Features to consider
CD phenotype	Paris classification: distribution, structuring or inflammatory or both, presence and location of fistulas
Disease severity	Number of affected bowel segments Number of fistulas and locations
Current medications	Compliant? Previous and current response? Effect on the risk of complications—do they need to be discontinued or decreased?
Previous medications	Reason for discontinuation: Loss of response? Nonadherence? Side-effects?
Nutritional status	BMI, deficiencies in micronutrients affecting the immune system and healing process
Growth potential	Age, pubertal status, bone age, height for age and grown velocity over the last 6–12 months
EEN	Previous use, compliance, response, duration of remission
Comorbidities	Infections, genetic immunodeficiencies, other chronic illness

Adapted from [2, 12]

Surgical Emergencies

The most common indication of emergency surgery in patients with Crohn disease is perforation (60.5%), followed by obstruction (22.6%), fistula or abscess (10.3%) and hemorrhage (6.6%) [28]. The operative goal with perforation is to control sepsis and decompress the intestine with as little risk to the patient as possible. In cases of perforation where the process is localized, percutaneous drainage and antibiotics may convert an acute situation into a more controllable elective intervention. When laparotomy is undertaken in the acute setting, the peritoneal cavity may be very hostile with inflammatory adhesions, fistulas, friable bowel, and diffuse peritonitis making extensive dissections and primary bowel anastomosis ill-advised. Rather than proceed with extensive surgery, often the most prudent approach is to divert the fecal

steam with a proximal ostomy [29]. Resection of the involved intestinal segment may be considered when technically possible, but proximal diversion without addressing the actual diseased bowel may be the safest option in severe cases. With emergency surgery, there is a risk of a longer small bowel resection (median length of small bowel resected 30.4 cm), with an additional 10 cm resected compared to an elective surgery for primary Crohn disease (median length of small bowel resected 19 cm, $p < 0.0001$) [30]. Additionally, the incidence of intra-abdominal septic complications with primary anastomosis compared to staged surgery is also higher (15.6% vs 7.5%; $p = 0.04$) [28]. In the setting of perforation, primary anastomosis should only be considered if peritonitis is localized, BMI <18.5 kg/m^2 and/or it was in the setting of iatrogenic perforation as these attributes are associated with a lower risk of post-operative intra-abdominal septic complications.

Proximal diversion with an ileostomy is not without risk. Morbidities most commonly described post-operatively include intra-abdominal fluid collection requiring radiological guided drainage, mechanical bowel obstruction, wound infection and high output stoma [30]. Ileostomies are associated with significant complications at the ileostomy site in addition to the accompanying challenging body image and social stigmata in teenagers [31]. The risk of a diverting ostomy becoming permanent is significant.

Once the intra-abdominal sepsis is controlled and the inflammatory adhesions are allowed to resolve for 6–8 weeks following emergent ileostomy, a more definitive procedure with ostomy closure can be considered. Although no one, especially teenagers and their parents, wants an ileostomy, attempting an extensive dissection or bowel anastomosis in the face of severe inflammation can result in life-threatening complications and potential loss of large segments of the small bowel.

A complete bowel obstruction without accompanying sepsis that does not respond to medical therapy may also require an acute surgical intervention [32]. In a stable patient, aggressive medical management should be attempted to resolve the obstruction before committing to taking a patient to the operating room. This is especially true in cases involving difficult-to-treat intestinal segments like the duodenum where avoiding any surgical intervention is desirable if possible [33]. Recently the pendulum has swung to the more aggressive style of treatment starting with biologics before other milder agents such as immunosuppressants or corticosteroids. In this aggressive medical management model, the MRE is key in helping to identify and differentiate between the inflammatory vs. fibrotic strictures so that we are able to differentiate who has the potential to respond appropriately to biologics and who will need an operation [34, 35].

If the obstruction fails to resolve or evidence of bowel compromise is present, an operation must be undertaken without the ability to prepare the bowel for primary anastomosis. At surgery, the bowel is often inflamed and friable, and although a definitive resection with reanastomosis may be possible, it is imperative that the patient and family be prepared for a diverting ileostomy to avoid the risks of a breakdown in an attempted primary bowel anastomosis.

Patients that have had multiple previous abdominal operations may be particularly challenging because of pre-existing adhesions. Studies suggest that as many as half of the patients undergoing reoperative surgery will require ileostomy formation [36]. In many pediatric patients, this is less of an issue because often patients are making their first trip to the operating room, but one should never hesitate to perform a temporary bowel diversion when primary anastomosis may be unsafe.

Elective Surgery

The indication for surgical intervention is more commonly not emergent, and the timing of the intervention requires the careful consideration of the surgeon, the gastroenterologist, and the family. The typical indications for surgery include failure of medical management, stricturing disease with obstructing lesions, fistulas, and complications related to the side effects of medical therapy.

The preoperative evaluation usually includes both endoscopic and imaging studies. Traditional imaging involves contrast enemas and/or upper gastrointestinal series with small bowel follow-through. More recently, magnetic resonance enterography has been utilized to provide a more complete assessment of the entire gastrointestinal tract [37]. Some recent evidence suggests that CT enterography may provide superior imaging [38] but the differences are not dramatic, and the experience of the radiologist is probably more important when deciding between the two studies. Whichever method is chosen, enterography offers the advantage of cross-sectional imaging of the entire bowel wall rather than being limited to assessing luminal disease (Fig. 40.2). This

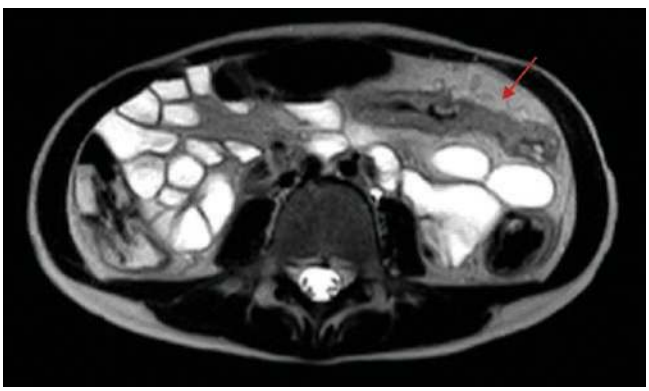

Fig. 40.2 MRE in patient with Crohn pancoltiis with active inflammation involving the entire colon and rectum with prominence at splenic flexure

allows for more accurate surgical planning and facilitates discussions with the patient and family regarding the operative approach.

Efforts should be made to control intra-abdominal sepsis through drainage of abscess and treatment with antibiotics prior to surgery along with supporting the nutritional status of the patient. Percutaneous abscess drainage with prompt resumption of immunotherapy has been associated with avoidance of bowel resection in the pediatric Crohn disease population [39].

Methods to reduce the risk of surgical site infections (SSI) including anastomotic leaks, intra-abdominal sepsis, and wound infections have been extensively studied and remain controversial. The use of intravenous antibiotics, enteral antibiotics, and mechanical bowel preparation have all been advocated for colorectal procedures. The evidence pertaining to the prevention of SSI has recently been evaluated and reported by the Outcomes Committee of the American Pediatric Surgical Association and as with many pediatric surgical procedures, most of the data comes from the adult surgical literature [40]. Parenteral antibiotic prophylaxis should include one of the Surgical Care Improvement Project (SCIP)-approved agents within 1 h of incision and should be discontinued within 24 h of the end of surgery. The use of mechanical bowel prep alone without enteral antibiotics for the indication of reducing infectious complications is not recommended as it provides no benefit over parenteral prophylaxis alone. Additionally, while the evidence for use of enteral antibiotics combined with mechanical bowel prep for reducing SSIs is strongly supported in adults, the data is much more limited in children. Decisions surrounding the use of parenteral antibiotics, mechanical bowel preparation and nonabsorbable antibiotics should be carefully considered within each specific clinical situation.

The presence of a stricture alone is not an indication of operation. Areas of diseased bowel that do not present a mechanical impediment to the flow of the intestinal contents do not require intervention. However, significant chronic obstruction is suggested by dilation of bowel loops proximal to the diseased area (Figs. 40.3 and 40.4). These changes signify a possible impending complete obstruction, and elective resection prior to that allows the opportunity for bowel preparation and resection with primary anastomosis rather than a two-stage procedure requiring temporary diversion with subsequent ileostomy closure. Entero-entero fistulas, chronic phlegmon, and enterocutaneous fistulas are other mechanical indications for operative intervention which can be dealt with after careful radiographic studies to delineate the anatomy and preoperative patient preparation.

Fistulas to the urinary tract with recurrent urinary tract infections may not constitute an urgent indication for operation, but continued soiling of the urinary tract could result in progressive renal dysfunction arguing for earlier rather than later intervention in these situations. Although some patients will respond to medical therapy, the vast majority of patients

Fig. 40.3 Barium contrast study demonstrating a segmental distal ileal stricture

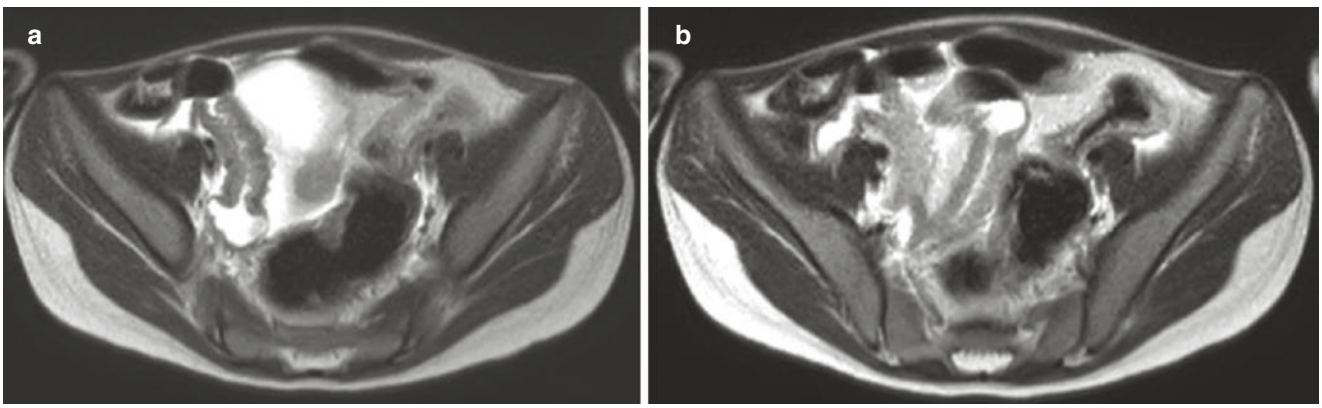

Fig. 40.4 MRE of Crohn disease distal ileum stricture (**a**) and proximal dilation (**b**)

will require surgical intervention [41–44]. Enterovesical fistulas are treated with takedown of the fistula and closure of the bladder, while ureteral fistulas may require resection with reanastomosis or reimplantation of the ureter.

Finally, the progression of the disease with persistent symptoms despite maximal medical therapy may also be the impetus for considering the surgical option. Regardless of the indication, the philosophy of therapy remains the same. The surgical procedure must be tailored to the individual patient with an eye toward preserving all possible small bowel length while providing the most effective palliation of the presenting complication of Crohn disease. Surgical intervention in patients with progressive or chronic symptoms related to stricturing or fistulizing disease in the abdomen is effective in relieving symptoms and can minimize absence from school and improve the overall quality of life when compared to nonoperative therapy [45].

Surgical Therapy

The procedure performed at the time of operation depends on the clinical situation and extent of the disease. As mentioned previously, in a patient that is acutely ill with sepsis or complete obstruction, simple diversion may be the most appropriate response. However, in most patients, a more definitive procedure is performed. In pediatric patients with stricturing disease, the terminal ileum is the most common site involved. Often the disease extends up to include the ileocecal valve, and the most common approach is bowel resection extending from the proximal extent of the disease in the ileum to the ascending colon, which is usually uninvolved. Bowel continuity is restored with a primary anastomosis.

In an effort to preserve as much bowel length as possible, only gross disease is resected since the recurrent disease may require additional surgery, and bowel length may be shorter than normal in patients with Crohn disease leaving less margin for resection before developing issues with poor absorption [46]. The actual technical aspects of the procedure vary somewhat by the surgeon and are largely a matter of training and experience. Bowel resection is carried out in the standard fashion with no need to obtain clear margins or mesenteric lymph nodes as might be required for a cancer operation. The only technical aspect of the procedure that may impact the outcome is the manner in which the bowel is anastomosed.

There are several techniques for reanastomosing bowel with the majority of surgeons performing either a hand-sewn end-to-end anastomosis or a side-to-side, functional end-to-end stapled anastomosis. There is some evidence to suggest that a stapled anastomosis may reduce the time to recurrence in patients with Crohn disease due to the wide lumen configuration and the nonreactive nature of the staples [47–55]. Alternatively, it may have more to do with the anatomic orientation of the anastomosis rather than the manner in which the bowel is re-approximated [56]. The other reported benefit of a stapled anastomosis stems from data to suggest that anastomotic leaks and intra-abdominal abscesses are less common with the stapled anastomosis in some series but not in others [51, 57–60]. Lastly, another anastomotic configuration that has been described is known as the Kono-S anastomosis which combines stapled and hand-sewn techniques with mesentery preservation combined with a supporting column to prevent anastomotic distortion, and an anti-mesenteric anastomosis. Systematic reviews assessing recurrence following Kono-S anastomosis with preservation of mesentery vs mesenteric resection and overall safety and efficacy have found that the Kono-S anastomosis is safe and may reduce endoscopic and surgical recurrence. However, the level of evidence remains poor [61, 62]. A more recent randomized controlled trial with 79 ileocolic Crohn disease patients randomized into Kono-S vs. conventional anastomosis found at 6 months endoscopic recurrence was significantly lower in the Kono group (22.2% vs. 62.8%; $p < 0.001$, OR 5.91) [63]. At 12 months, clinical recurrence was 8% vs. 18% (Kono-S vs. conventional respectively; $p = 0.2$) and at 24 months 18% vs. 30.2% (Kono-S vs. conventional respectively; $p = 0.04$, OR 3.47). There was no difference in surgical recurrence at 24 months (Kono-S 0% vs conventional 4.6%; $p = 0.3$) and no difference in post-operative outcomes [63].

Complications following bowel resection and anastomosis in patients with Crohn disease are common and most often infectious in nature. Wound infections are most common and occur in as many as 20% of patients, while more serious intra-abdominal infections related to anastomotic leaks occur in 3–10% [51, 64]. Wound complications are treated with local care, while anastomotic complications may require reoperation with revision or temporary diversion with an ostomy.

Small Intestinal or Ileo-colonic Disease

For patients with localized ileocecal Crohn disease but no significant evidence of active inflammation, surgical resection is the preferred option. Long-term studies in adults have demonstrated that there is a 50% chance that the patient will never require further operation [65]. With refractory obstructive symptoms after initial medical treatment of ileocecal Crohn disease, surgical resection should be considered as the first option.

Stricturoplasty

Diffuse small bowel disease with skip lesions or strictures that do not involve the ileocecal valve allows for some addi-

tional options in surgical treatment. Short segments are often resected with primary anastomosis when it represents the only area of disease. However, multiple short segments or longer segments up to 20 cm in length may be amenable to stricturoplasty rather than resection in an effort to preserve bowel length.

The most common technique used is the Heineke-Mikulicz stricturoplasty, this technique entails a longitudinal enterotomy through the strictured segment with closure in a transverse fashion to relieve the obstruction and is ideal for short strictures (Fig. 40.5a). For those strictures that are slightly longer (>10 cm but <25 cm), a Finney procedure is indicated and entails taking the strictured segment and folding it on itself. A "U"-shaped incision is made along the length of the stricture it is sutured together thus creating a large diverticulum (Fig. 40.5b). For those that are longer than 20 cm, a Michelassi is indicated and is performed by dividing both the strictured bowel and its mesentery in the

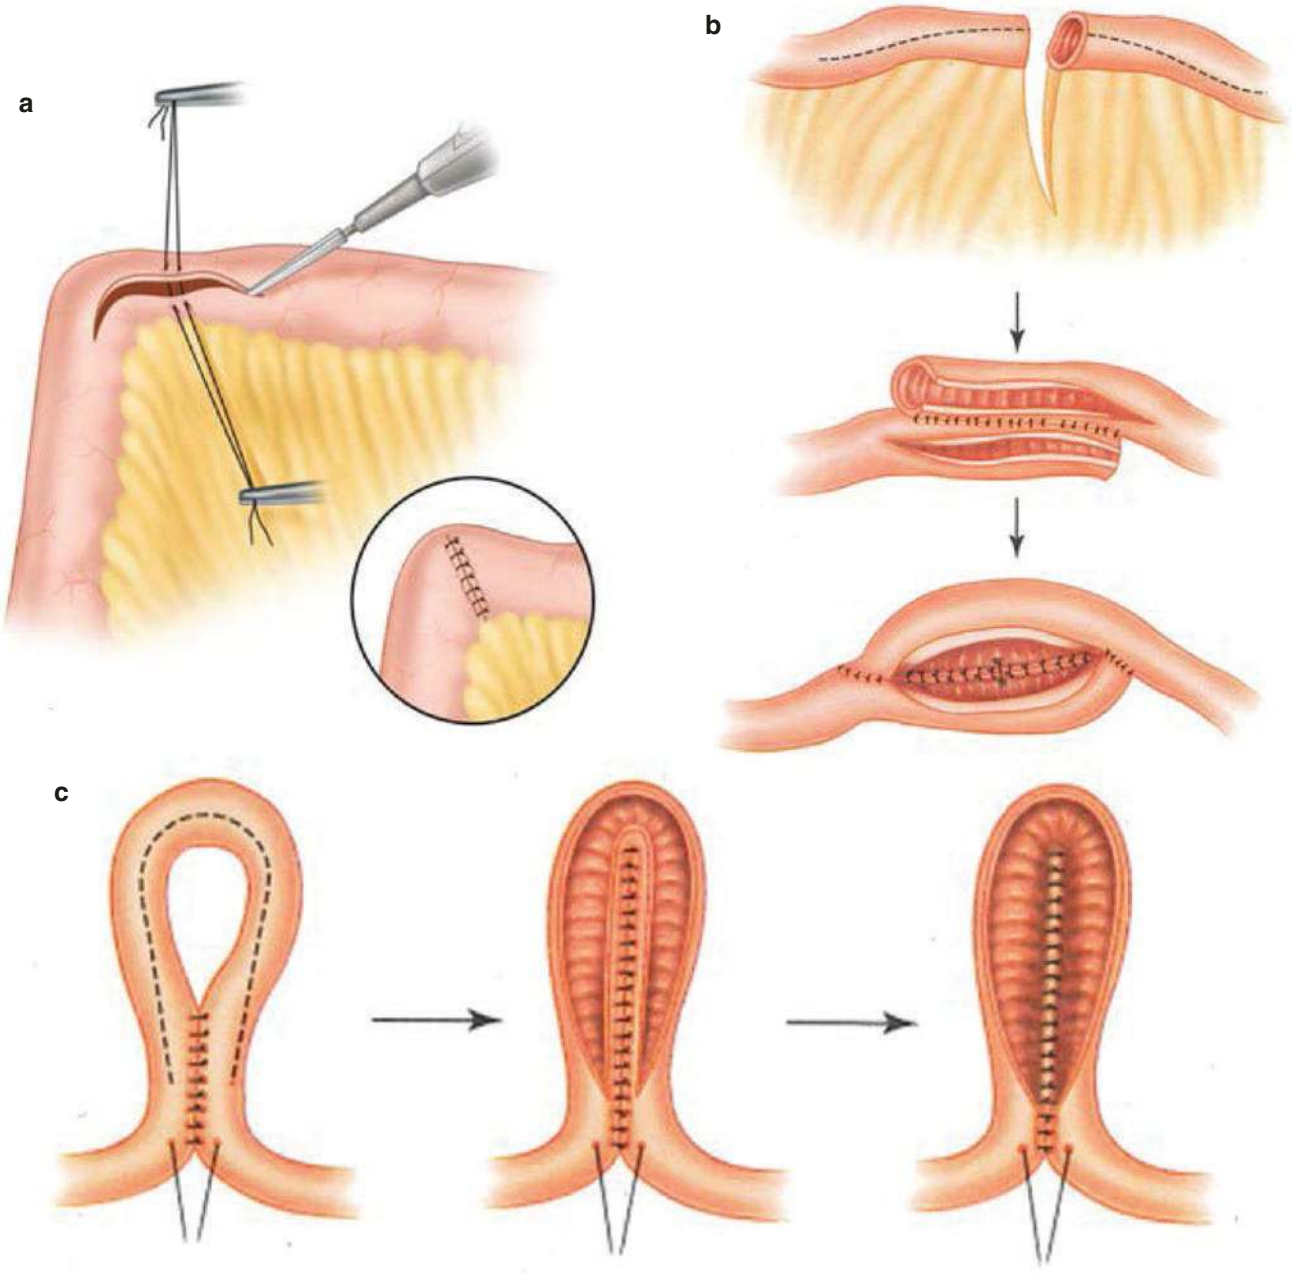

Fig. 40.5 Stricturoplasties: (**a**) Heineke-Mikulicz (**b**) Michelassi (**c**) Finney (Images **b** and **c** reproduced with permission from The ASCRS Textbook of Colon and Rectal Surgery 3rd ed.) [70]

center of the stricture. The bowel is then placed side-to-side and a longitudinal incision is made in both limbs and the stricture is sutured together in a side-to-side fashion (Fig. 40.5c).

While it seems somewhat counterintuitive to leave the diseased bowel in situ, the results following these operations are quite good even when applied to multiple strictures in the same patient [66]. Surprisingly, the rate at which recurrent disease occurs at the stricturoplasty site is low [67], and the technique has been used for many years with results from long-term follow-up studies supporting its use [68]. Recurrence rates following stricturoplasty are on the order of 15% at 2 years and 20% at 5 years [69].

There are a number of technical modifications of this technique that allow for longer segments to be preserved while relieving obstruction [71–75]. In a study of 102 patients undergoing a nonconventional stricturoplasty for a longer segment of the intestine, there were 48 ileoileal side-to-side isoperistaltic stricturoplasties, 41 widening ileocolic stricturoplasties, and 32 ileocolic side-to-side isoperistaltic stricturoplasties, which were associated with Heineke-Mikulicz stricturoplasties in 80 procedures or with short segmental bowel resections or both in 47 procedures. The post-operative complication rate was 5.7% which is consistent with the complication rate from the more common Heineke-Mikulicz stricturoplasty. The 10-year clinical recurrence rate was 43%, and the recurrence rate at the previously affected site was only 0.8% [73]. In another study, long-segment stricturoplasty (>20 cm) was reported to have recurrence rates that are not significantly different from that of shorter-segment disease. Recurrence rates were 20–35% at 3 years, 50% at 5 years, and 60% at 10 years with no difference in complications between the groups [73].

In some very difficult situations such as long duodenal strictures, other modifications of the stricturoplasty technique can be applied. In one such case, a jejunal patch was used to successfully relieve the obstruction and avoid intestinal bypass in a patient with a difficult duodenal stricture [76].

Laparoscopy

Laparoscopy used for Crohn disease was first described by Miller and colleagues in 1996 with the use for a diagnostic laparoscopy to detect the presence of abnormal mesenteric fat (“creeping fat”) in patients thought to have Crohn disease after other studies were inconclusive. Three of the seven suspected who underwent laparoscopy were found to have “creeping fat” and thus underwent resection and the diagnosis of Crohn disease was confirmed [77]. This early implementation of laparoscopy was beneficial and allowed for diagnosis when other studies were not diagnostic [78].

In 2002, Rothenberg was one of the first pediatric surgeons to describe his preliminary experience with laparoscopy for 15 segmental bowel resections in the treatment of Crohn demonstrating the feasibility of minimally invasive surgery for the treatment of inflammatory bowel disease in children [79]. As with many of the other conditions to which laparoscopic techniques have been applied, multiple studies have demonstrated a decrease in hospital length of stay, a more rapid return to regular activity, less postoperative opiod use, and improved cosmetic results. Similarly, multiple studies of laparoscopic techniques applied to surgery for Crohn disease in children and adults have also suggested shorter hospital stays, decreased need for parenteral opiods, and faster return to a regular diet [80–89]. However, a recent Cochrane analysis has shown no difference in length of stay or duration of ileus [90], and the morbidity of the laparoscopic approach is equivalent to open surgery [91]. Thus, although the benefits of the laparoscopic approach may be limited to improved cosmesis at the expense of longer operating time, there is a trend toward increased use of minimally invasive techniques, and the outcomes are at least equivalent to open surgery.

The techniques employed often use the laparoscopic exploration of the abdomen with mobilization of the diseased bowel segment. Various sealer/cutting devices facilitate taking the mesentery of involved segments without additional blood loss and stapling devices allow for dividing the bowel at the margins of disease. The anastomosis may be carried out extracorporeally after the diseased segment is delivered from the abdomen through a small incision or intracorporeally using the laparoscopic stapling devices. These techniques can also be incorporated into the single-site surgical approach to achieve “scarless” operations [92] although the benefit is purely cosmetic and the outcomes have not been tested. The use of the surgical robot has also been reported with the possible benefit of reducing conversions to an open operation but no difference in other surgical morbidities [93].

Although complicated disease involving fistulas or phlegmon was considered a relative contraindication to the laparoscopic approach, many cases are now handled by experienced surgeons without an increase in complication rate [94–99]. One potential benefit of the laparoscopic approach is a reduction in postoperative adhesion formation. This carries added importance in Crohn’s populations where disease recurrence is more the rule than the exception and reoperation is often necessary. Reduced adhesions facilitate subsequent operations [100] and theoretically lower the risk of injury to the bowel and ureters. Approaching recurrent disease laparoscopically is also feasible without an increased complication rate [101, 102].

In the long run, the patients’ quality of life does not appear to be impacted by the technique used at the time of surgery

[102, 103]. However, the advantage of the minimally invasive approach likely extends beyond quality-of-life measurements. Reduced intra-abdominal adhesion formation, possible faster resumption of full enteral nutrition, and perhaps less psychological trauma related to body image issues are all of particular significance to the pediatric patient population.

Colonic Disease

Isolated colonic disease is reported in approximately 27% of cases [10]. In patients with isolated colonic disease, there is a significantly lower risk of surgery (pooled HR, 0.57; 95% CI, 0.43–0.78; $p = 0.0003$; $n = 2289$) [104]. Additionally, this indicates that the presence of small bowel disease increases the risk of surgery. With colonic disease, often the inflammatory behavior, perianal disease and extra-intestinal manifestations are higher when compared to ileal/ileocolonic Crohn disease. However, the overall requirement for surgery is significantly lower in colonic Crohn disease (17.1% vs. 26.1%, $p = 0.032$) and patients with the colonic disease have a lower cumulative probability of first surgery in the first 10 years of follow-up [105].

Crohn colitis requires a different approach than for small bowel disease. The colonic disease is traditionally regarded as being more aggressive, and the colon is not necessary for the nutritional function of the intestinal tract, so some advocate subtotal colectomy rather than segmental resections when colonic involvement requires surgical intervention. However, segmental resection offers the opportunity to preserve colonic function and avoid or delay the potential for permanent ileostomy and has become the more common approach [17]. Fewer symptoms, fewer loose stools, and better anorectal function have been reported following segmental resection, and the re-resection rate did not differ from patients undergoing subtotal colectomy [106, 107]. Conversely, patients with pancolitis or severe distal colonic disease have been reported to have longer disease-free intervals [108] and wean from chronic medications more often when treated with subtotal colectomy or proctocolectomy when compared to those undergoing segmental resection. However, these patients also had a higher incidence of permanent diverting ileostomy [109, 110] suggesting that segmental resection for pediatric patients with colonic Crohn disease is preferable when possible. Additionally, temporary fecal diversion with an ileostomy is an option allowing reversal when their disease burden is better controlled. Laparoscopic techniques are possible and show similar advantages to those described in small bowel resection [111].

Perianal Disease

Approximately 10–62% of patients will develop perianal manifestations of Crohn disease [112, 113]. Patients presenting with perianal disease tend to have a more aggressive disease with higher rates of both perianal and intra-abdominal operations [114]. Perianal Crohn disease falls into three distinct categories: (1) tissue destruction (anal fissures, tags, and deep ulcers), (2) fistula and abscesses, or (3) rectal stricture (Fig. 40.6).

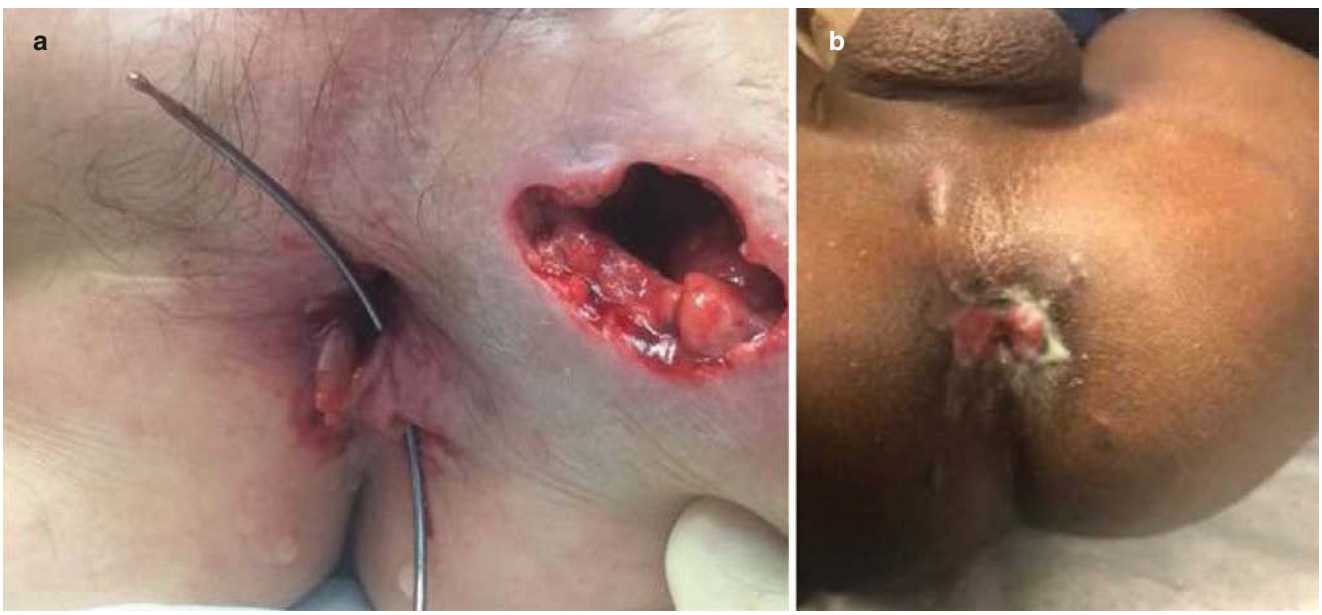

Fig. 40.6 Perianal Crohn Disease: (**a**) Fistula and abscess (**b**) Anal stenosis

Fistulizing perineal disease is an area in which surgical intervention has classically been avoided given the risk of nonhealing wounds and incontinence. However, with newer therapeutics, the goals of treatment have been to completely heal the abscesses and have complete fistula closure. The use of early surgical evaluation has been found to provide important information to help guide the medical management. While fistulotomy and incision and drainage of local abscesses were fraught with long-term complications in the past, the use of new biologic agents such as infliximab has rendered early surgical intervention not only safe but necessary for rapid control of the disease.

Medical therapy for the perineal disease has been greatly improved with the advent of biologic agents yet more than half ultimately require surgical procedures [115]. Two controlled trials support the efficacy of infliximab in achieving closure of perineal fistulas [116], and the combination of infliximab and surgical treatment for the fistulizing perineal disease can result in marked improvement of perineal disease which is superior to infliximab alone [117–119]. Conversely, infliximab treatment does not prevent the need for surgery for fistulizing Crohn disease [120].

Treatment algorithms in pediatric inflammatory bowel disease centers have evolved to include an aggressive surgical approach early. Of children presenting with perianal symptoms, 3% will eventually be diagnosed with Crohn. Those at highest risk are those patients that are males aged 10 years or older who present with a perianal fistula [121]. Additionally, recognizing documented Crohn disease-associated symptoms prior to presentation with perianal symptoms is key to diagnosing these children early.

Examination under anesthesia is particularly useful in the pediatric population. Comprehensive rectal examination is often difficult in the clinic setting for younger patients that are unable to cooperate fully with the exam. General anesthesia in the operating room provides the ideal environment to carefully evaluate the extent of disease with delineation of fistula tracts, abscesses, and rectal strictures. A complete assessment of the extent of the disease is important to help guide medical therapy.

Once the extent of the disease is determined, therapeutic measures can be performed during the same anesthetic. Perianal abscesses should always be evacuated [122]. Most are near the skin and can be drained through a small skin incision. If fistulae-in-ano is present, they can be probed to ascertain the anatomy (Fig. 40.6a). All fistulas are treated with the placement of a non-cutting silastic seton. This allows drainage both internally and externally rather than having an uncontrolled fistula which would be a persistent source of recurring abscesses. Overall setons are well tolerated and can be left in place for long periods of time if there continues to be persistent signs of inflammation or infection. Fistulotomies are discouraged, as muscle division carries a high risk of incontinence and the risk of non-healing perineal wounds [123]. For women with rectovaginal fistulas, any surgical repair should be approached with caution, especially in the presence of active inflammation. Initial surgical treatment may improve the response to subsequent pharmacologic therapy.

With the examination of operative management of perianal Crohn disease, it can usually be divided into simple or complex diseases based on the type of surgical procedure. In a study by Langer et al., the majority of perianal disease was simple (~75%) requiring abscess drainage ± seton insertion while ~25% of pediatric patients had more complex perianal disease requiring loop ileostomy ± more extensive surgery [124]. In those that had a more complex perianal disease, all underwent defunctioning ileostomy and 50% of those patients underwent additional operations including subtotal colectomy, proctocolectomy ± anal sparing, or plastic surgery reconstruction with perineal flap/graft. In this study, ~9% of patients had a such severe perianal disease that they required proctocolectomy compared to adults where severe perianal disease requiring proctocolectomy with permanent ileostomy was seen in as many as 20% of patients [112, 124].

Instillation of fibrin glue into fistula tracts has been attempted following curettage with the thought that fibrinogen and thrombin are able to cause a clot and promote hemostasis and angiogenesis while acting as "scaffolding" for fibroblasts to migrate to and adhere with mechanically sealing of the tract. In a small randomized controlled trial comparing simple or complex fistulas randomly assigned to receive fibrin glue injection or observation alone after seton removal, clinical remission at 8 weeks was significantly better in the fibrin group at 38% compared to observation alone at 16% (OR 3.2, $P = 0.04$) [125]. However, it was also found that fibrin glue may be more effective in those patients with simple fistulas compared to complex fistulas.

Anal fistula plugs have also been attempted. These are usually (a) a cone-shaped device with lyophilized, rolled, porcine small intestinal submucosa or (b) a tubular, multilegged button made from bio-absorbable polymers. Similarly to the fibrin glue, it is used as a matrix in the fistula to allow for the in-growth of collagen and producing fibroblasts. The plug is inserted into the tract with the end of the plug within the anoderm and tapered legs through the tract. In the systematic review, follow-up has been ~3.5–12 months with variable success rates of 29–86% in patients with Crohn disease [126].

The use of autologous adipose tissue-derived stem cells involves curettage of the fistula tract followed by injection of the fistula with stem cells from the patient or a healthy donor. Results from previous studies have reported healing of complex perianal fistulas in 71% of 24 patients that received adipose stem cells mixed in fibrin glue compared to 16% of 25 patients who received fibrin glue alone ($P < 0.001$) [127]. In

patients with transsphincteric fistulas, ligation of the interspincteric fistula tract (LIFT) is a relatively new approach for anal fistula closure that entails creating an intersphincteric incision, isolating and ligating the fistula tract at both the internal and external sphincter, and performing curettage of the external tract with the widening of the external tract at the skin. Results have been promising in patients with a 60% rate of healing at 2 months, and 67% at 12 months with no development of fecal incontinence [128]. Long-term results have demonstrated better healing with laterally located fistulas compared to midline fistulas.

Lastly, an endorectal advancement flap is an attractive and useful option for the closure of a fistula. This procedure is usually performed after the fistula tract has matured through the use of seton drainage. The internal opening is identified within the anus and a "U" or square-shaped incision is made in the mucosa surrounding the fistula with or without muscle fibers of the internal sphincter. This flap of anoderm and submucosa is raised and brought down so that it reached below the muscular internal opening. The internal fistula opening is closed and the new flap is trimmed and sutured close. In systematic review and metanalysis, both the endorectal advancement flap and the LIFT procedure have been excellent options for high perineal fistula disease in Crohn patients. The overall success rate has been 61% (45–76%) with endorectal advancement flap vs. 53% with the LIFT procedure. In comparison, incontinence rates have been significantly higher with the endorectal advancement flap compared to the LIFT procedure (7.8 vs. 1.6% respectively) [129].

Rectal Strictures

Low rectal and anal strictures are usually the result of chronic fibrosis and long-standing inflammation. They generally form extremely slowly which allows patients to accommodate over time to the relative narrowing of the rectum. They can be successfully treated with transanal dilations [116]. Younger pediatric patients may require dilations under anesthesia on a regular basis, while older patients will tolerate dilations in the office or at home. Medical therapies can help to control luminal inflammation, particularly topical therapies. Incontinence can result from over dilation of rectal strictures or operative damage to the muscles during fistulotomy, but it is often difficult to separate the impact of the dilations relative to the underlying disease process. Tight irregular strictures longer than 3–4 cm without a clear lumen are a relative contraindication to dilation because perforation of the rectum is possible, particularly in small pediatric patients (Fig. 40.6b). Initial dilation in the operating room guided by fluoroscopy may reduce the risk of subsequent outpatient dilations. Treatment with dilations may be needed for many months, and ultimately the result is dependent on systemic control of the disease process. Patients with tight, long or refractory strictures may eventually require a diverting colostomy and possible total proctocolectomy. The combination of anal stricture and colonic Crohn disease is a predictor of poor outcomes ultimately leading to fecal diversion in more than 50% of patients [130]. Optimal timing for total proctocolectomy with end ileostomy can be difficult to determine but in patients with worsening anal canal disease and inability to dilate along with significant impairment of bowel function may ultimately require total proctocolectomy with end ilesotomy to improve quality of life [131].

Impact of Medical Therapy

Many of the drugs used to treat Crohn disease have the potential to increase complications following surgical procedures due to their immunosuppressive effects. Steroids significantly impair wound healing, impact growth, and increase infectious complications. Risks of abdominal wound infection, abdominal wound dehiscence, and anastomotic dehiscence are all potentially increased in the presence of steroids. While the risks of operating on Crohn patients being treated concurrently with steroids are likely increased, the data in the literature to support that fear is circumstantial. Studies have demonstrated an apparent increased risk of early complications in patients with ulcerative colitis undergoing definitive surgery while on chronic steroids, while complications were not increased in patients weaned off steroids prior to surgery [132]. Asthma patients treated with steroids during the perioperative period failed to show an increased complication rate over controls [133] suggesting that the impact of steroids on Crohn patients may be cumulative with the other risk factors in these patients. Infliximab therapy does not appear to increase the rate of perioperative complications associated with bowel resections for Crohn disease [64, 134]. With a specific examination of pre-operative infliximab, no significant differences have been found in major complication rate, minor complication rate, reoperation rate or 30-day mortality [135].

Additionally, several studies have demonstrated a reduction in hospitalization and surgery with biologic use. In an observational study, scheduled therapy with infliximab significantly reduced the need for surgery compared to episodic use with the effect more striking in those who achieved mucosal healing [136, 137]. Additionally, anti-TNF therapy has been found to be associated with a significant reduction in the likelihood of surgery (OR 0.26, 95% CI 0.14–0.48) with similar effects for both infliximab and adalimumab with no reduction in likelihood with azathioprine or vedolizumab [138]. One, five and 10-year rates of surgery for Crohn disease patients of 14, 28, and 39% respectively were studied in the 1990s and have not changed during the biological era. Lastly,

the 5 and 10-year re-operative rates are close to 25 and 35% respectively and these have decreased historically from much higher rates but are similar to the pre-biologic era.

Post-operative Recurrence

Early Recurrence Predictors

Recurrence of Crohn disease following surgical resection is common and 30% will develop clinical recurrence during the first year after surgical resection with approximately 80% demonstrating endoscopic recurrence that precedes clinical symptoms [139]. Thus, endoscopic recurrence is the strongest predictor of disease progression [140]. In many cases, medical therapy is discontinued following surgical treatment, but continued therapy with several drugs has been investigated and found to improve disease-free intervals. Establishing the recurrence risk for individual patients and performing endoscopic surveillance is important to help guide therapy [141]. While some studies fail to demonstrate an advantage to prophylactic therapy [142], others have proposed specific algorithms for follow-up and treatment [143, 144].

In an Australian randomized post-operative Crohn endoscopic recurrence trial (POCER), the efficacy of endoscopically tailored treatment was evaluated [145]. There were 174 adult CD patients who all received medical prophylaxis starting immediately after surgery and after randomization (2:1) further step-up in treatment was based on findings at ileocolonoscopy at 6 months (endoscopy group) or clinical symptoms (control group). They found that ileocolonoscopy performed at 18 months following surgery had recurrence of 49% in the endoscopy group vs. 67% in the control clinical group ($p = 0.03$). Thus, ileocolonoscopy continues to be recommended at 6 months following resection to monitor for postoperative endoscopic recurrence [146]. Additionally, there is a poor correlation between post-operative endoscopic recurrence and clinical symptoms, blood inflammatory markers such as CRP and Crohn disease activity index [147, 148].

Lastly in the POCER study, calprotectin was found to be an effective screening tool in patients who require colonoscopy for detecting mucosal recurrence. They found that the level of calprotectin correlated well with endoscopic recurrence but neither CRP nor CDAI. A level of >100 μg/g of calprotectin indicated endoscopic recurrence with a sensitivity of 0.89 and negative predictive value of 0.91, thus colonoscopy could be avoided in 47% of patients using calprotectin as a screening tool. While the POCER study was in adults, a more recent study in pediatric patients found that at fecal calprotectin level >139 μg/g at the time of endoscopy for an increase of 70 μg/g compared to the first post-operative value was also suggestive of endoscopic recurrence while a fecal calprotectin level of >101 μg/g or increase of 21 μg/g indicated histological recurrence [149].

Agents including the 5-aminosalicylate formulations, antibiotics, steroids, and azathioprine have been examined. None of these therapies have convincingly been shown to prevent recurrent lesions [150]. Infliximab has been reported effective in a prospective randomized trial where remission was maintained in 93% of patients in the infliximab group and only 53% of patients in the control group [151]. Importantly, early postoperative treatment with infliximab does not appear to be associated with an increase in adverse events [141]. The use of infliximab to prevent recurrence in children has also been reported [152]. The antibiotics metronidazole and ornidazole have shown efficacy, but cannot be used in the long term because of side effects [153]. 6-Mercaptopurine and azathioprine may be more effective than mesalamine [116, 154, 155].

With examination of biologics at 12 months postoperatively following surgery for Crohn disease, anti-TNF-α therapies have been found to be significantly better than placebo either alone [*P*-score 0.98, RR 0.13; 95% CI 0.04–0.39] or in combination with 5-aminosalicylates [*P*-score 0.81, RR 0.30; 95% CI 0.12–0.75] or 5-nitroimidazoles [*P*-score 0.75, RR 0.40; 95% CI 0.23–0.69] [156]. Similarly, in a meta-analysis of 14 clinic studies examining anti-TNFα agents compared to other conventional therapies, they found that early initiated postoperative anti-TNFα treatment currently is the most effective therapeutic choice in preventing the continuum of histological, endoscopic and clinical postoperative recurrence without increasing the frequency of adverse events [157]. Both infliximab and adalimumab were found to be equivalent in preventing endoscopic postoperative recurrence [157].

Given the risk of recurrent disease, it is important to resect only the grossly involved segment of the intestine at the time of the initial operation. Fortunately, there is some evidence to suggest that the involved segments of the intestine in subsequent operations for ileal disease are shorter than those involved at the initial presentation [158].

Adjuvant Procedures

Finally, there are well-documented complications of growth and development in the pediatric population [159]. Pediatric patients are at particular risk for nutritional complications because of the normal rapid growth and development in children. Malnutrition is highly prevalent in inflammatory bowel disease, especially with active Crohn disease and has the potential to affect the entire gastrointestinal tract. Delayed puberty, short stature, iron deficiency, micronutrient deficiencies and bone demineralization may all be indications for supplemental nutritional support. Malnutrition severity is often influenced by the activity, duration and extent of dis-

ease as well as the magnitude of inflammation which drives catabolism.

Oral nutritional supplements are the first step when improvement in nutrition is indicated in IBD. Sometimes oral intake is not sufficient and enteral feeding with the use of nasogastric tube or surgically placed gastrostomy tube is required. In some cases, exclusive enteral nutrition is effective and is recommended as the first line of treatment to induce remission in children and adolescents with acute active Crohn disease [160]. When enteral nutrition is administered, it should be given via an enteral feeding pump rather than boluses as this has been found to have lower complication rates than bolus delivery.

Total parenteral nutrition is indicated when it is not possible for the child with Crohn disease to receive enteral intake. This may occur if the gastrointestinal tract is dysfunctional if the child has short bowel disease, if there is an obstruction or if there are complications from a previous surgery such as an anastomotic leak or high output intestinal fistula [160]. The parenteral nutrition must fulfil the specific needs of the individual patient.

Surgical adjuncts to care such as gastrostomy tubes and surgically placed central lines for chronic parenteral access may prove to be lifesaving measures for some patients. Compliance with medical regimens in the pediatric population can be challenging, and providing these types of devices early with minimal trauma may help minimize the impact of the disease on these nutritional issues. Low residue diets are frequently used in pediatric patients with progressive stricturing disease in the small bowel. The social impact of an indwelling nasogastric feeding tube may inhibit compliance in the teenage population making these children candidates for percutaneous or laparoscopically placed gastrostomy tubes. The laparoscopic approach allows direct visualization of the stomach to properly site the tube, secure the stomach to the abdominal wall, and place a primary button device without the scarring associated with the open approach.

Patients unable to tolerate adequate enteral feedings are often candidates for supplemental parenteral nutritional support. In these cases, surgically placed central venous access devices may significantly improve the lifestyle by providing stable chronic venous access for infusions and blood sampling. Either cuffed catheters or port devices may be indicated.

Surgical Treatment of Ulcerative Colitis

41

Peter Mattei

The surgical treatment of patients with medically refractory ulcerative colitis (UC) is often accomplished in multiple stages but typically culminates in the complete removal of the colon and rectum (*proctocolectomy*). Although not a cure in the traditional sense, this effectively removes the target organ of the disease and, with the creation of a neorectum, allows the majority of patients to achieve a very high quality of bowel function and normal activities. Proctocolectomy with ileoanal reconstruction has evolved from the earliest operations that included appendicostomy, which allowed colonic irrigation, and simple ileostomy, which diverted the fecal stream. These allowed some patients relief of their symptoms, but the diseased colon remained an ongoing source of morbidity and a significant risk of malignant degeneration, which meant that most patients would eventually be offered proctocolectomy and permanent ileostomy, which for a long time was the standard of care [1]. More recent advances have included the creation of a functional neorectum using the ileum (*pouch*) and minimally invasive techniques that have improved recovery and cosmesis. There is increasing emphasis on achieving normal bowel function, minimizing complications, and improving the overall quality of life [2]. Today, although most patients can expect to undergo a safe operation with a good outcome, a relatively low risk of serious postoperative complications, and overall excellent functional results, [3] the surgical treatment of UC remains less than ideal, principally due to the threat of undiagnosed Crohn disease, inflammation of the pouch (*pouchitis*), and, in few patients, pouch failure necessitating total proctectomy and permanent ileostomy [4].

Indications for Surgical Intervention

The primary treatment of patients with UC remains medical [5]. With modern drug treatments, most patients do well and remain largely free of debilitating symptoms for many years. Ultimately, however, it is estimated that approximately 20–30% of adults and 15–20% of children with UC will ultimately require an operation [6, 7]. Indications for surgical intervention generally fall into one of the three categories (Table 41.1): *emergent* (perforation, toxic megacolon), *urgent* (hemorrhage, sepsis, pain) and *elective* (intractable chronic and debilitating symptoms such as bleeding, pain, diarrhea or malnutrition), or concern about malignant transformation. One of the most common indications for surgical referral in children is the persistence of bleeding, severe diarrhea, or pain despite maximal medical therapy. Some patients present acutely with rapidly progressive symptoms (*acute severe colitis*) and unless they respond to aggressive medical treatment are forced to consider having an operation within a few days or weeks of disease onset [8, 9]. Others have symptoms that steadily worsen, requiring more frequent blood product replacement and repeated hospitalizations until they are no longer responsive to even the most aggressive treat-

Table 41.1 Indications for surgery in patients with ulcerative colitis

Emergent indications
Toxic megacolon
Colonic perforation
Urgent indications
Intractable bleeding
Unrelenting pain
Unremitting sepsis
Elective indications
Refractory to or complications of medical management
Chronic malnutrition
Poor growth
Delayed sexual maturation
Colonic stricture
Corticosteroid dependence
Mucosal dysplasia
Malignant degeneration

ment modalities. Still others, despite otherwise manageable chronic symptoms, will be referred for surgery due to poor growth or delayed sexual maturation due to persistent inflammation and chronic malnutrition. As always, the anticipated benefits and potential risks of an operation need to be weighed carefully against the expected consequences of disease progression.

Indications for urgent laparotomy include perforation, uncontrolled bleeding, or intractable sepsis. In children, a complication of UC or its treatment is an uncommon indication for operative intervention [10]. Colon *perforation*, though rare, is an indication of urgent laparotomy and should be suspected in patients with UC who present with peritonitis or evidence of free intraperitoneal air. The patient with intractable *bleeding* should also be considered a candidate for urgent colectomy. *Toxic megacolon* includes the combination of sepsis and a massively dilated colon (≥6 cm in diameter) [11]. Though often critically ill, these patients can sometimes be successfully treated with fluid resuscitation and broad-spectrum antibiotics [12]. Colonic stricture, debilitating extraintestinal manifestations, and malignancy are complications that result from long-standing disease and are therefore rarely seen before adulthood [13].

Patients are sometimes referred to a surgeon because of complications from medical management or dependence on corticosteroids. Although most of the drugs used in the treatment of UC are well tolerated, and there are few serious complications that would prompt consideration of an operation, long-term high-dose corticosteroid therapy can cause serious sequelae such as diabetes, hypertension, opportunistic infection, or psychiatric complications. They may also develop debilitating somatic changes, acne, obesity, growth failure, and osteopenia. Patients with incapacitating side effects of medication and no effective alternative should be considered for operative intervention.

Although rare in children, mucosal dysplasia identified on colonic biopsy during routine surveillance is an indication of colectomy. Colonoscopic surveillance is recommended for most patients starting 5–8 years after the onset of the disease [14]. As UC is being identified in younger patients, we might reasonably expect to see more adolescents with dysplasia being referred for consideration of early colectomy [15, 16].

The success of currently available medicines has significantly reduced the likelihood that a child with UC will require an emergency operation. One typically begins to consider a surgical option in the patient who is corticosteroid-dependent or whose chronic symptoms are increasingly refractory to medical therapy. As always, the risks of an operation must be considered in the context of the risks of continued nonoperative management. Perhaps more important to consider is the anticipated functional result and lifestyle implications of undergoing proctocolectomy and pelvic reconstructive surgery [17].

Surgical Procedures

Although *proctocolectomy with IPAA* is the definitive operation for patients with medically refractory UC, in current clinical practice it is rarely performed as a single operation (in some centers it is routinely done in a single stage, [18] but in most centers this is reserved for children with familial polyposis who are generally otherwise healthy). Many children with UC who are referred for consideration of surgical intervention tend to be chronically ill with borderline nutrition and some degree of immune compromise due to weeks or months of exposure to biologics and corticosteroids, making them less-than-ideal candidates for a long and difficult operation. In the urgent or acute setting, the first operation considered might be *abdominal* (or "*subtotal*") *colectomy with ileostomy*, in which the surgeon removes the colon, closes the intra-abdominal end of the colon just proximal to the rectum (Hartmann procedure), and creates an ileostomy. The rectum is preserved so that a restorative procedure can be performed electively after the patient has stabilized and can be prepared properly for the more delicate and demanding proctectomy with J-pouch reconstruction [10, 19]. Historically, urgent colectomy was performed through a long midline incision but is now routinely done laparoscopically [20, 21]. The principal risks are surgical site infection and bleeding, but the majority of children do well and recover quickly. The goal of the operation is to remove ~90% of the diseased organ as quickly and as safely as possible and to allow the patient to return to a state of good health until a more definitive restorative operation can be performed. It also provides a surgical specimen that can be examined histologically when the true diagnosis remains uncertain [19, 22].

In some cases, especially in the younger patient whose colitis is of recent onset or unclear etiology—UC vs. Crohn disease—a *diverting ileostomy* alone might be a reasonable consideration [23]. This will sometimes provide an opportunity to conduct a trial of medical therapy and a more detailed diagnostic work-up in a clinically more stable patient. If there is no clinical improvement within a few weeks, abdominal colectomy is usually the next step. Those who improve then require a careful assessment regarding the next steps. A simple reversal of the ileostomy after a period of clinical remission risks a recurrence of symptoms, especially if the true diagnosis remains elusive. In these patients, one should usually consider abdominal colectomy and eventual procto-

colectomy with IPAA. On the other hand, the diagnosis of Crohn disease might be an indication of partial or abdominal colectomy and a restorative operation in which the rectum and/or part of the colon are preserved (*ileocolostomy* or *ileorectostomy*).

After abdominal colectomy, despite the fact that the rectum remains intact, patients usually do quite well. After approximately 6–8 weeks, assuming the patient is doing well and is well-nourished, plans can be made for the completion of proctectomy and construction of an ileal reservoir. In the past, some patients were given the option of *ileorectostomy*, in which the rectum is preserved and anastomosis is created between the ileum and the rectum. This preserves relatively normal rectal sensory and motor function but also retains the rectal mucosa, placing the patient at risk for persistent proctitis and eventual carcinoma. These patients require frequent and meticulous endoscopic surveillance for dysplasia for the rest of their lives. Because of concerns about the risk of cancer and the burden of a lifetime of surveillance, ileorectostomy is generally considered less than ideal for the definitive treatment of UC in children. However, due to a higher risk of infectious complications and fistulizing perianal disease after ileal reconstruction of the rectum, it may reasonably be considered for those with Crohn's or indeterminate colitis [24] (Table 41.2).

Assuming the patient does well after colectomy and the pathology shows no signs of Crohn disease, the second stage of the operation includes removal of the rectum (proctectomy) and a neorectum is created using the ileum: *ileal pouch-anal anastomosis* (IPAA). An anastomosis is created between the ileum and the anal canal. The ileum may be unmodified (*straight pull-through*) or can be fashioned to create a reservoir or *ileal pouch*. The most commonly used pouch configuration is the *J-pouch*, in which the ileum is folded back on itself for a distance of approximately 8–12 cm and the common wall is obliterated using a surgical stapling device (Fig. 41.1). Other options include the *S-pouch*, in which the ileum is folded twice, and the *W-pouch*, in which the ileum is folded yet again, resulting in an even larger reservoir. The type of pouch is determined by surgeon preference and experience. In general, although a larger pouch might allow patients to achieve a pattern of relatively normal bowel habits sooner, it also tends to cause more stasis and bacterial overgrowth, factors that many believe increase the likelihood of pouch inflammation and infection (*pouchitis*). Given its relative ease of construction and proven track record of excellent functional results, most surgeons currently prefer the J-pouch [3].

There are two accepted methods of creating the ileoanal anastomosis, both of which produce excellent results (Fig. 41.2). One involves *mucosal proctectomy* (the outer muscle layers of the rectum are preserved) *with an ileoanal anastomosis*; the other is *total proctectomy with double-stapled anastomosis*, whereby the anastomosis is made between the pouch and the rectum 1–2 cm above the top of the anal canal (Fig. 41.2). Mucosal proctectomy involves dissecting along a submucosal plane and removal of the rectal mucosa all the way down to the anal transition zone, with circumferential preservation of a short portion of the muscular wall of the rectum. This was originally designed as a way to remove the mucosa and submucosa, which is where the inflammation in patients with UC is found while preserving the presumed motor and sensory function of the rectal musculature [25]. The submucosal dissection can be difficult, especially in patients with severe or long-standing rectal inflammation. The ileoanal anastomosis was traditionally created using a hand-sewn technique through the anus, but many surgeons create a circular stapled anastomosis of the

Table 41.2 Surgical options

Operation	Comments
Ileostomy	Occasionally performed as an isolated procedure, especially in very young children
Abdominal colectomy + Hartmann[a] + ileostomy[b]	Usually performed when an operation is needed urgently
Abdominal colectomy + ileorectostomy	Usually performed for indeterminate or Crohn's colitis Requires lifelong surveillance of rectum
Proctocolectomy + end ileostomy	Formerly the standard of care Overall very good results Not popular because ileostomy is permanent
Proctocolectomy + Kock continent ileostomy	Rarely performed except at a few centers with experience Difficult operation with frequent complications
Proctocolectomy + ileal pouch-anal anastomosis	Current standard of care "J-pouch" is most common variation
1. Mucosal proctectomy + hand-sewn IPAA	Good function Leaves no rectal cuff Technically more difficult
2. Proctocolectomy + double-stapled IPAA	Good function Leaves short cuff of rectal mucosa Requires lifelong surveillance of rectal remnant

[a] Hartmann operation: the proximal end of the rectum is sutured or stapled closed; the anus is patent

[b] "Three-stage" approach: (I) Abdominal colectomy/ileostomy, (II) Ileoanal pouch procedure/ileostomy, (III) Ileostomy closure

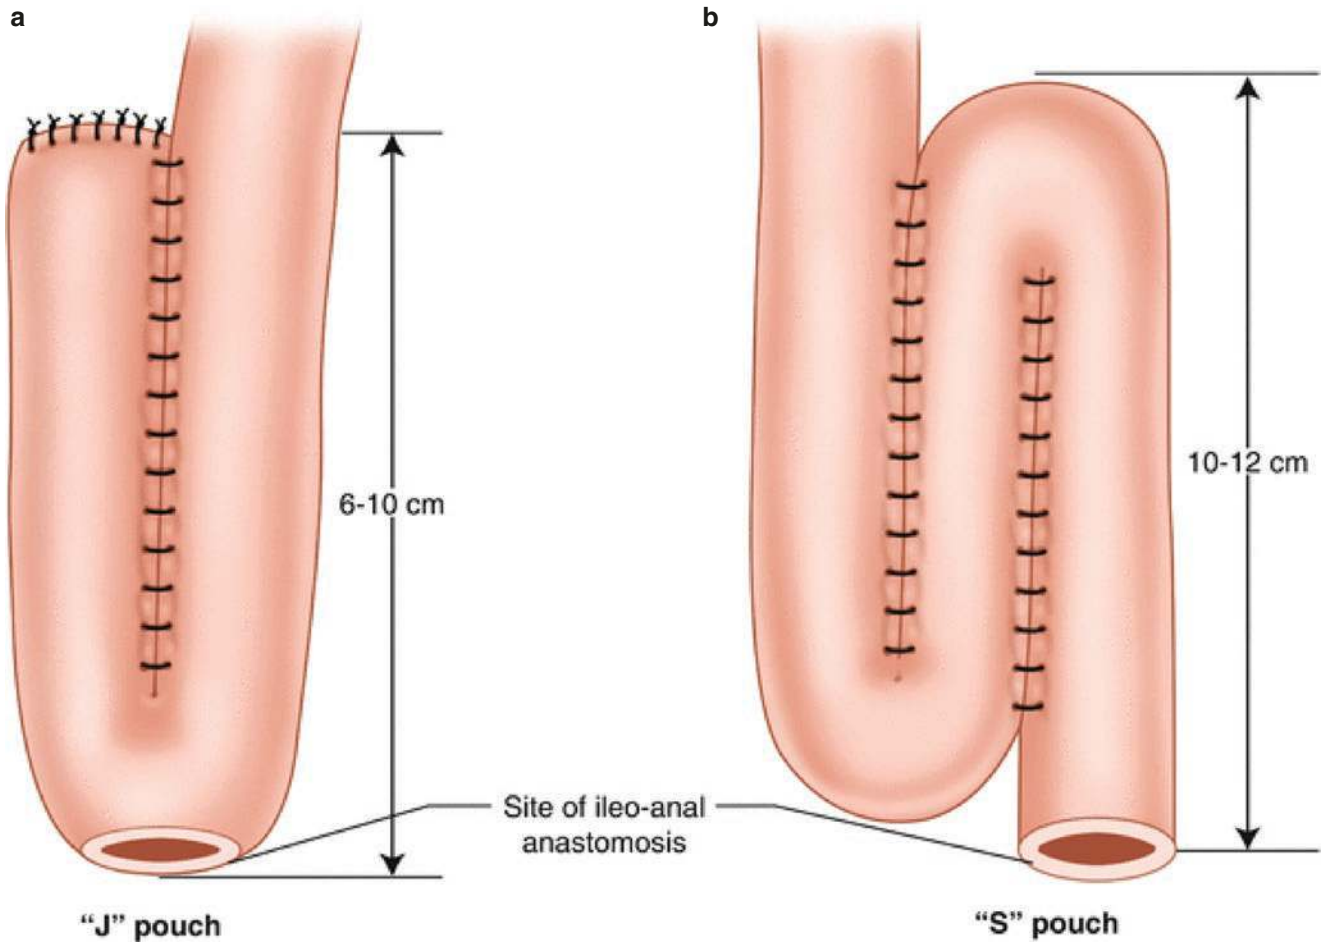

Fig. 41.1 The two most commonly used ileal pouch configurations. (**a**) J-pouch. (**b**) S-pouch. The walls of the jejunal limbs that are brought together are opened using a surgical stapling device so as to create a single lumen that is larger than that of the ileum itself. The ileoanal anastomosis is created by suturing or stapling the lower end of the pouch to the anal canal

pouch to the anal mucosa without having to leave a remnant of the diseased rectum [26].

At the time of ileoanal reconstruction, temporary ileostomy was standard because it was thought to reduce the incidence of anastomotic leak, peritonitis and pelvic sepsis, complications that have been associated with poor pouch function and a significantly diminished long-term quality of life [27, 28]. More recent studies, however, have disproved this idea and many surgeons prefer avoiding diverting ileostomy at the time of the proctectomy and IPAA [29–31]. Ileostomies themselves are also associated with their own morbidity [32]. The ileostomy can usually be reversed after 6–8 weeks, usually after a water-soluble contrast enema confirms good healing, a normal pouch configuration, and good evacuation (Fig. 41.3).

A procedure that is rarely performed anymore but deserves mention is the *Kock pouch* (or *continent ileostomy*) operation [33, 34]. The colon and rectum are completely removed, and the ileum is used to create a reservoir that resides within the abdomen. The end of the ileum is brought out as an ileostomy, but a small intussusception is created just proximal to the outlet, essentially creating a valve that prevents the leakage of stool. The patient does not wear a standard ileostomy appliance and instead uses a plastic tube to evacuate the pouch several times a day. Although the concept is certainly appealing, the functional results of the Kock pouch have been somewhat disappointing and in most centers the complication rate is felt to be unacceptably high [35].

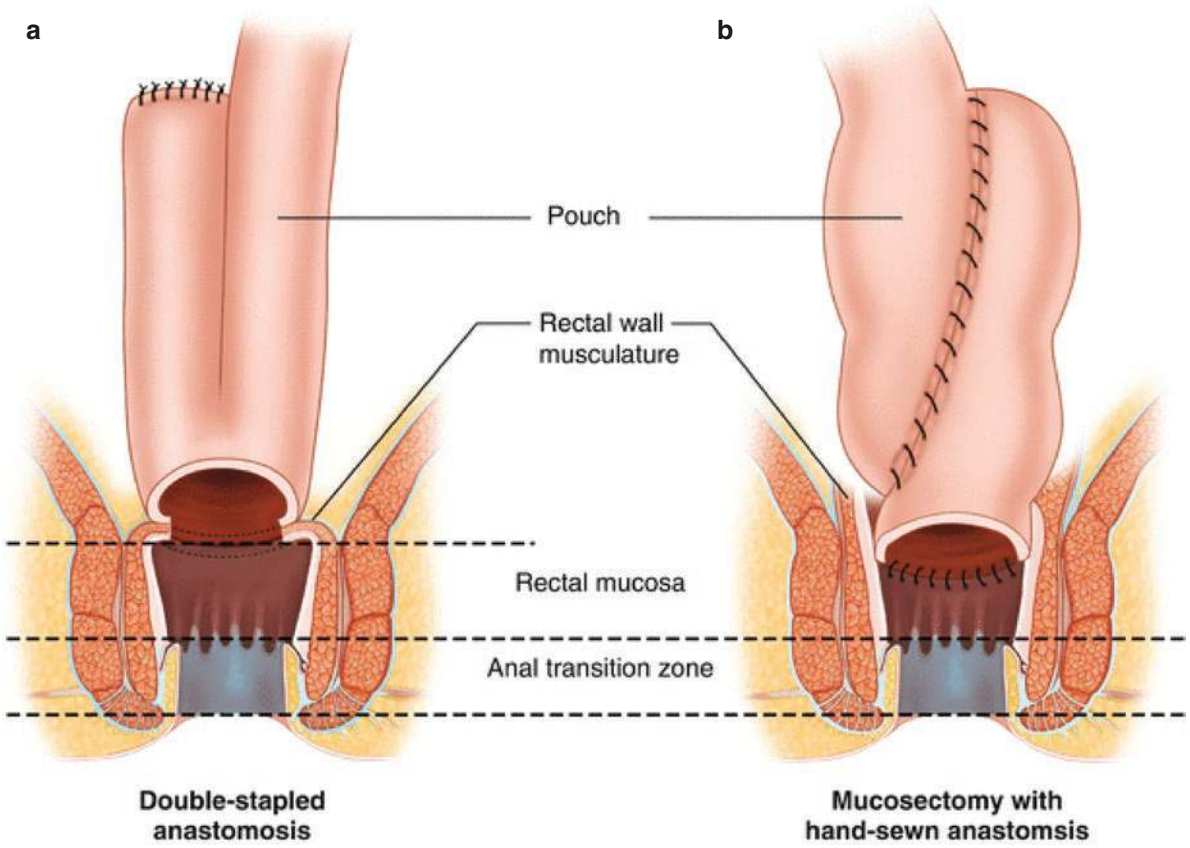

Fig. 41.2 Two commonly used methods for creation of the ileal pouch-anal anastomosis: (**a**) *Double-stapled anastomosis*, so-called because the rectum is first divided and stapled transversely, and then an anastomosis is created between the pouch and the rectum with a specialized stapling device that creates a circular staple line between two hollow viscera (**b**) *Mucosectomy with hand-sewn anastomosis*, in which the mucosa is stripped from the distal rectum, preserving a short segment of rectal musculature, and the anastomosis is performed by hand. Note that with the double-stapled technique, it is unavoidable that a short (1–2 cm) segment of rectal mucosa remains, while after mucosectomy the mucosa is excised all the way down to the anal transition zone. The J-pouch or S-pouch can be used with either method

Fig. 41.3 Contrast study performed through mucous fistula of loop ileostomy. The pouch is situated low in the pelvis, is reasonably capacious without evidence of stricture, and is not twisted or volvulized. Functionally, it is important to note that the patient sensed the presence of contrast, was able to hold it for the duration of the study, and at the conclusion of the study was able to evacuate completely and voluntarily

Surgical Decision Making

Proctocolectomy with J-pouch reconstruction initially was routinely performed as a three-staged operation: (1) abdominal colectomy with ileostomy, (2) proctectomy with J-pouch IPAA and another ileostomy, and (3) ileostomy closure. Each phase was separated by 2–3 months or more. It then became fashionable to do it in two stages ((1) colectomy/proctectomy/J-pouch with ileostomy, (2) ileostomy closure) or even one stage, in which an ileostomy is avoided altogether. The more modern "two-stage" approach is gaining in popularity in both adults and children: (1) laparoscopic abdominal colectomy with ileostomy, (2) proctectomy/J-pouch IPAA/ileostomy closure. Most patients with UC who are considering surgical intervention are chronically, and often acutely, ill: they are anemic, malnourished, and exposed to several immunosuppressive medications including corticosteroids, but they can usually tolerate a colectomy and begin to feel better and improve clinically almost immediately. A few months later, most are asymptomatic and gaining weight off all medication—a much better candidate for proctectomy and J-pouch reconstruction and less likely to require ileostomy diversion [36].

Decisions as to which operation to offer and when are complex and involve consideration of several factors: (1) the overall health of the patient, especially nutrition and corticosteroid dependence; (2) whether the operation is being performed electively or emergently; (3) confidence in the diagnosis (UC or Crohn disease); (4) intraoperative factors such as the length and difficulty of the operation, blood loss, degree of soiling of the pelvis with rectal contents, the blood supply of the ileal pouch, and degree of tension at the anastomosis; and (5) recent administration of biologic agents—some [37, 38] but not all [39–41] studies suggest an increased risk of surgical complications for up to several weeks. Therefore, because most pediatric surgeons would consider long-term functional results more important than the short-term inconvenience of multiple operations or time with an ileostomy, they are more likely to err on the side of caution. Nevertheless, the experienced pediatric surgeon evaluates the published data objectively, considers the individual risk factors and the overall status of the patient on a case-by-case basis, and discusses all options with patients and their families frankly but respectfully.

Preparation for Surgery

Patients who need an urgent or emergent operation are prepared for the surgery with intravenous fluid resuscitation and broad-spectrum prophylactic antibiotics. Patients who are anemic may require a blood transfusion, depending on the surgical and anesthetic standards of the institution. Typically, 1–2 units of packed red blood cells are made available for possible use during or after the operation. For patients receiving corticosteroids, it is still standard practice at some institutions to administer a "stress dose" of corticosteroids.

Patients who are being prepared for an elective procedure should have a formal nutritional assessment. Moderate to severe malnutrition prolongs healing and increases the risk of complications after major surgery. Enteral or parenteral nutritional supplementation is sometimes necessary, even if this means delaying the operation for several weeks. Given that chronic, high-dose corticosteroid therapy can also adversely affect wound healing and increase the risks of an operation, attempts should be made to gradually decrease the dose for patients who are scheduled for surgery, preferably down to the equivalent of 15–20 mg of prednisone daily, but not if this causes the inflammation to become severe. Most children do not require mechanical bowel preparation, as these have been shown to increase the risk of complications unless combined with oral antibiotic bowel preparation [42]. Antibiotics are given intravenously immediately before incision but are either discontinued immediately after wound closure or administered for no more than 24 h postoperatively.

Outcomes of Surgery

The technical results of the operations described for children with UC are generally quite good. Infectious complications and bleeding are uncommon and usually easily managed without sequelae. Even after the most complicated operations, most children recover nicely and are able to tolerate a regular diet within a few days of surgery. The short-term results for patients who undergo a minimally invasive procedure might be slightly better, with the added benefit of improved cosmesis. Regardless of the technique, the overall risk of serious complications or death is very low [43, 44].

Functional Results

The functional results of IPAA are also generally quite good, though there is a great deal of variation between patients and in the same patient over time. The ultimate goal of surgical intervention is for the patient to enjoy a normal lifestyle; however, there are inherent limitations in duplicating normal rectal function with a surgical construct [45]. The ideal functional result of IPAA includes (1) fecal continence especially during the day, (2) four or fewer daily stools, (3) preferably no more than one stool at night, (4) the ability to delay evacuation for at least 30 min, and (5) the ability to distinguish between flatus and stool.

The J-pouch IPAA is the most popular operation for children and adolescents with UC who need surgical interven-

tion, and several large studies have confirmed that the majority of patients have good functional results [20, 46, 47]. In most large series, patients report an average stool frequency of 4–5 per day and once or none at night. Fewer than 5% have soiling or staining, most of which occurs only at night [31]. Approximately 90% of patients can delay defecation for at least 30 min, and most report being able to pass flatus without accidents. Many patients are able to participate in a wide variety of normal activities including athletics. Studies using patient questionnaires document a very good quality of life for the majority of patients after IPAA with 90–95% of patients reported to be satisfied or very satisfied with the results of their operation [48].

When mucosal proctectomy with hand-sewn anastomosis is compared to extra-rectal proctectomy and double-stapled anastomosis, the functional results and quality of life parameters appear to be identical, [49, 50] although the relative simplicity of the double-stapled technique may result in improved results in centers where few such procedures are performed [51]. Patients who require a revision of their pouch also tend to do better than expected, [52, 53] although it is certainly preferable for any complex reconstructive procedure to function well after the first attempt. All in all, careful analysis of the collective experience with the IPAA operation over the past three decades confirms that it is a good operation, with excellent functional results and improved quality of life for the majority of patients with UC who need surgery [54].

Complications

As with any complex reconstructive operation, the complication rate for IPAA is not insignificant, occurring in as many as half of all patients [4, 31]. Complications that occur in the immediate postoperative period—surgical site infection, postoperative ileus, and excessive ileostomy output—are usually easily managed. More serious complications such as small bowel obstruction due to adhesions, parastomal hernia, and pelvic abscess often require operative intervention.

A rare but serious complication of ileal pouch-anal anastomosis is anastomotic leak or disruption. This usually manifests as pelvic sepsis, often with an organizing abscess, or with a clinical picture of a perforated viscus, including peritonitis, shoulder pain, free intraperitoneal air, and occasionally frank sepsis. Partial disruptions typically take the form of a tiny leak and can sometimes be managed conservatively with fluid resuscitation, antibiotics, and percutaneous drainage of the abscess. However, patients who are clinically ill, have frank peritonitis or show signs of more than just a small leak should undergo peritoneal washout and ileostomy diversion. The experienced surgeon will resist the urge to perform a repair, which, under these conditions, is futile and dangerous. Much has been made in the past about the subsequent poor function of the pouch complicated by pelvic sepsis, but many will nevertheless have a good long-term function after successful treatment and ileostomy closure. In patients who are well-nourished and whose pouches are under no tension and have a good blood supply, anastomotic breakdown should be rare and well-tolerated. Routine ileostomy diversion does not prevent all leaks but might make patients with a leak less likely to develop sepsis or need another operation [55].

Long-term complications may interfere with the function of the pouch and may result in less than satisfactory function. A number of patients will develop a *stricture* at the ileoanal anastomosis, which increases the risk of pouch stasis and pouchitis. Symptomatic strictures usually respond to anal dilatation and rarely require surgical revision or ileostomy. When an ileoanal stricture is associated with a *perirectal abscess* or *anal fistula*, the diagnosis of Crohn disease must be considered. Prolapse, stenosis, or retraction of the ileostomy may occur, but because the ileostomy is generally temporary, these complications can often be managed by early closure of the ileostomy.

Pouchitis

Perhaps the most feared potential complication after IPAA is *pouchitis* [56]. The patient with *acute pouchitis* typically presents with increased stool frequency, urgency, or pain and sometimes bloody stools, tenesmus, abdominal distension, or fever. The diagnosis is usually made on clinical grounds, though endoscopic examination of the mucosa may reveal mucosal edema, ulceration, or friable granulation tissue. Biopsies often reveal an acute inflammatory process, with polymorphonuclear leukocyte infiltration, crypt abscesses, or ulceration depending on severity. The true incidence and relative severity of pouchitis have been difficult to evaluate consistently between series, perhaps because of the variable presentation and somewhat subjective manner in which the diagnosis is often made.

Of patients who have had an IPAA for UC, perhaps as many as 40% will have at least one bout of pouchitis. Interestingly, the disease almost never occurs in patients who have undergone proctocolectomy/IPAA for familial adenomatous polyposis. At the opposite extreme, it affects as many as 80% of patients with UC who have primary sclerosing cholangitis [57]. Most patients with acute pouchitis respond promptly to a short course of oral metronidazole and/or ciprofloxacin. Chronic or relapsing acute pouchitis is less common but can be debilitating. Approximately 5–10% of patients eventually require permanent ileostomy or removal of the pouch because of intractable pouchitis [55]. The treatment of severe chronic pouchitis is often similar to that of UC or Crohn disease, including anti-inflammatory enemas,

chronic antibiotic therapy, or treatment with a biologic medication [58].

The cause of pouchitis is unknown, though the fact that it occurs almost exclusively in patients with UC would suggest a specific underlying predisposition. A small but significant percentage of patients with severe pouchitis will eventually be identified as having Crohn disease. Regardless of the etiology, stasis appears to be an important factor that increases the risk of pouchitis. This is supported by the observation that pouchitis is less common after straight ileoanal pull-through [59]. Pouchitis is also more common in the presence of an ileoanal stricture or an excessively dilated pouch. Some patients will respond to serial anal dilatations or daily rectal intubation or saline irrigation; however, surgical revision of the pouch needs to be considered in these situations. Some have found that bulking agents in the form of dietary fiber supplements reduce the incidence of pouchitis, [60] perhaps by promoting more complete evacuation of the pouch. Probiotics may decrease the risk of pouchitis; however, thus far the results of clinical trials have been mixed [61, 62].

As many as 15–20% of children who undergo IPAA will eventually be found to have Crohn disease, developing complications after IPAA including pouchitis, sinus tracts, fistulae, and pelvic abscess [63, 64]. Although some respond well to standard medical therapy, many will eventually require the removal of the pouch and permanent ileostomy. Similarly, many consider indeterminate colitis a contraindication to IPAA, though there are some who advocate the use of pelvic pouch procedures in this subgroup of patients, citing an acceptable complication rate [65]. The presence of terminal ileitis ("backwash" ileitis) at operation does not appear to increase the risk of complications, pouchitis, or pouch failure [63, 66]. Patients who develop severe or recurrent pouchitis, anal fistula, or pelvic sepsis after IPAA should be evaluated for Crohn disease with small intestinal imaging, upper and lower endoscopy with biopsies, and serologic analysis for markers of Crohn disease.

Carcinoma

Long-term complications of UC include colorectal carcinoma. Patients with UC are recommended to have a yearly colonoscopy with frequent biopsies starting several years after the onset of symptoms, and cancer is an indication for colectomy in patients with UC [67]. Patients with high-grade dysplasia are at high risk for carcinoma and are also recommended to undergo colectomy. Those with low-grade dysplasia are observed more closely with colonoscopy every 6 months, though there are proponents of colectomy for these patients as well [68]. Although malignancy is rarely an issue in children, there are several important considerations for the pediatric gastroenterologist. First, as the incidence of UC is increasing [69] and increasingly affecting younger patients, it is more likely that patients will need to begin the surveillance in adolescence. Secondly, patients who undergo IPAA using a double-stapled technique invariably have a 1–2 cm cuff of native rectal mucosa distal to the ileal pouch anastomosis, which necessitates lifelong surveillance because of the risk of dysplasia or cancer within the remnant. Because of the obvious long-term implications, this is an important technical detail that should be passed along to the patient. Lastly, there are occasional reports of cancer developing within the ileal pouch itself or at the ileoanal anastomosis, [70, 71] suggesting that the risk of carcinoma can never be completely eliminated in patients with UC. Patients should therefore undergo periodic endoscopic evaluation of the pouch with biopsies, although the frequency of these assessments has not been standardized [72].

Current Trends and Future Considerations

Patients with UC who have undergone IPAA surgery as children are now able to be evaluated as adults. Several series have reported a significant incidence of infertility in women who have undergone ileoanal pouch procedures, [73–75] with some early series suggesting that the risk is double of what is expected for women matched for age and severity of disease who are treated medically. However, more recent studies suggest the effect is smaller now [76]. The risk of infertility is considerably higher for women with UC who undergo IPAA compared to those with familial polyposis and to those who have had an ileorectostomy. The risk is also significantly higher for those who require an intraoperative blood transfusion. The cause of infertility in these cases is unclear. It is thought that the degree of pelvic surgical dissection might generate adhesions, which are known to have a negative impact on fertility. This has led some groups to adopt empirically the use of enzymatic adhesion barriers during IPAA surgery, although there are no data to support that its use reduces infertility [77, 78]. Nevertheless, it is an issue that should be discussed with any young woman with UC who is considering surgical intervention, as they might reasonably choose to delay the operation until after they have children.

Outcomes research generally supports the view that the functional results are better and the complication rate is lower for complex operations performed at high-volume centers. The IPAA procedure is a technically demanding operation with many pitfalls and potential complications. Although there are no large series in which a direct comparison has been done specifically for IPAA in patients with UC, there appears to be a correlation between the experience of the surgeon and favorable outcomes in a variety of complex colorectal procedures [79, 80]. In addition, several studies

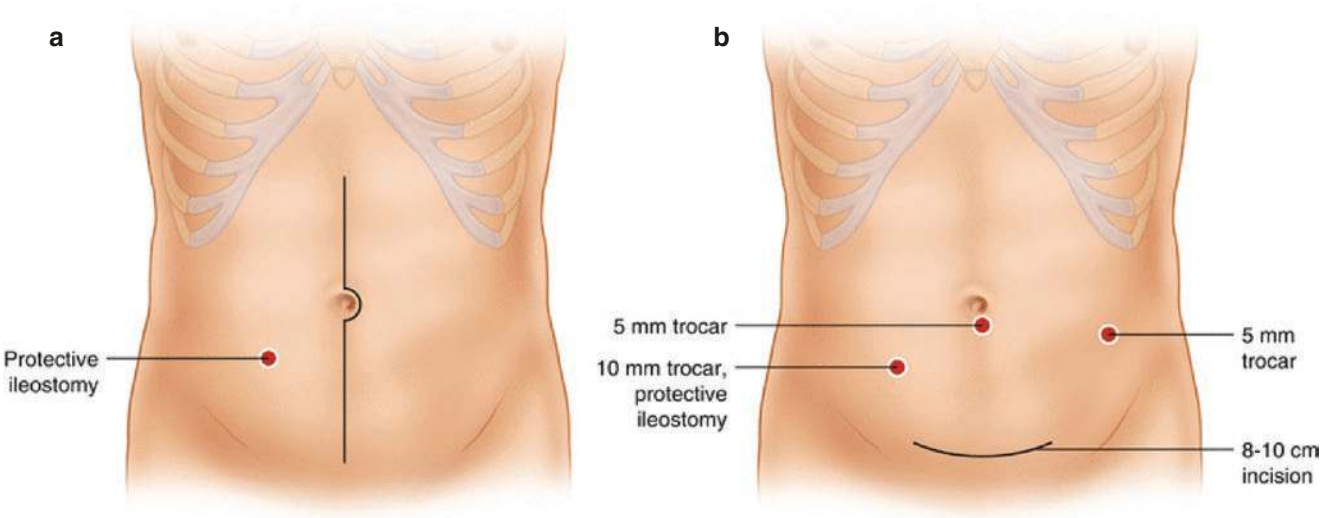

Fig. 41.4 Comparison of (**a**) the long midline incision used for the previously standard approach to open colectomy and ileal pouch-anal anastomosis operation and (**b**) the smaller incisions used during laparoscopic colectomy and ileal pouch-anal anastomosis operation(s). The right lower quadrant laparoscopic incision is used for the creation of an ileostomy. The low transverse incision is a low-transverse (Pfannenstiel) incision used for the creation of the ileoanal pouch after the colon is removed laparoscopically. It can also be used to allow the insertion of the surgeon's hand to facilitate the laparoscopic portion of the operation ("hand-assisted" laparoscopy). The primary advantage of the minimally invasive approach is improved cosmesis; other purported advantages include shorter hospital stay, faster recovery and fewer adhesions

report a significant learning curve for surgeons who perform ileoanal pouch procedures [81]. This suggests that the results of IPAA procedures that are done by experienced surgeons and at high-volume centers are likely to be better overall.

Minimally invasive surgery offers potential advantages such as less scarring, less pain, more rapid postoperative recovery, and improved cosmesis (Fig. 41.4). Many surgeons advocate the use of a laparoscopic-assisted approach, in which the colectomy is performed laparoscopically, while the more delicate pelvic dissection is done through an open incision but one that is much smaller. Although the initial results with this approach have been encouraging, it is too soon to know if the long-term functional results will be the same compared to the more standard open approach. As the technology continues to improve, minimally invasive approaches to complex colorectal surgery in children, including robotic techniques, will eventually become the standard of care for children with UC who need surgery.

Summary

The goals of surgical intervention for UC are to remove the affected organ, restore normal function, and minimize morbidity. The surgical treatment of children and adolescents with UC has improved dramatically over the past 30–40 years, mostly because of technical refinements of the ileal pouch-anal anastomosis procedure. Ileal pouch-anal anastomosis has become the standard of care for patients with UC who require surgical intervention. The majority of patients who undergo IPAA can expect to enjoy an essentially normal lifestyle, although the operation is technically demanding and can be associated with significant morbidity. Surgeons continue to strive to develop restorative operations that more closely duplicate normal anatomy and function with fewer potentially debilitating side effects.

Postoperative Surveillance and Management of Crohn Disease

42

Benjamin Click and Miguel Regueiro

Risk and Diagnosis of Postoperative Crohn Disease

Early and more frequent use of immunomodulators and anti-tumor necrosis factor (TNF) therapies have reduced but not spared Crohn disease (CD) patients the risk of needing an intestinal resection. Recent biologic era population studies have found that the rate or probability of a first major bowel surgery in CD is still 20–30% [1, 2]. Pediatric CD progresses slower to surgery than adult-onset disease, as the reported 5-year cumulative risk for bowel surgery for pediatric CD patients is less than that for adult patients, but still significant at 13.8–47.2% and 28–34.5% at 10 years [3–6]. While the most common indication for surgery in adult CD patients is stricturing or penetrating complications, in pediatrics, inflammatory behavior, medical failure, or poor growth is cited as the most common surgical indication [7–9].

Unfortunately, CD is rarely curable by surgery, and postoperative recurrence (POR) of CD is inevitable for the majority of patients. In the prebiologic era, natural history studies found that 70–90% of CD patients developed endoscopic evidence of POR within 1 year of their surgery and that 30–60% of postoperative Crohn disease (POCD) patients became symptomatic from the recurrent disease within 3–5 years of their surgery [10–12] (Fig. 42.1). Consequently, 50% of POCD patients in the prebiologic era required repeat surgery within 5 years of their first surgery. Clinical recurrence rates for postoperative pediatric CD are equally high and identical to adult rates, reported to be 60–78% at 5 years [13, 14].

Postoperative CD recurrence is often clinically silent. Rutgeerts and colleagues found in their initial seminal study of the natural history of postoperative recurrent CD that 72% of examined patients (21 out of 29) had recurrent endoscopic CD within 1 year of curative resection and that a remarkable number of these patients were asymptomatic [15]. In a subsequent prospective cohort of an 8-year follow-up study of 89 patients after resection, Rutgeerts et al. found that only 20% and 34% of patients were symptomatic 1 and 3 years after surgery, respectively, despite endoscopic disease in 73% and 85% of these patients [11]. More recent data from prospective clinical trials similarly demonstrated the endoscopic and clinical discrepancy, finding a kappa coefficient of agreement between the patients' endoscopic scores and their clinical Crohn Disease Activity Index (CDAI) scores was only 0.12 [16]. Thus, relying on symptoms significantly underestimates mucosal disease activity.

The degree of endoscopic disease activity correlates with progression to symptomatic recurrence. Rutgeerts et al. demonstrated that endoscopic activity at 1 year, as judged by the now classified Rutgeerts score (Table 42.1), directly correlated with the and was the most statistically significant variable in predicting outcome [11]. For example, only 8.6% of patients with no or only mild endoscopic disease at 1 year, as defined by Rutgeerts score i0 or i1, had clinical symptoms at 8 years, while 100% of patients with the severe endoscopic disease, as defined by Rutgeerts score i4, had symptomatic recurrence by 4 years. Although the Rutgeerts score has not been validated as a measure of treatment response, most studies now define endoscopic postoperative remission as i0 or i1, and recurrence as i2, i3, or i4.

These findings have largely been replicated in pediatric cohorts with endoscopic recurrence approximating 50% at 1 year, 77% at 5 years, and 94% at 10 years [9, 13]. Clinical recurrence may be more common in pediatric than adult patients with rates of 55% 1–2 years postoperatively and 50–73% by 5 years [6]. Together, these data suggest that POR follows a similar progressive course in pediatric and adult patients.

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_42

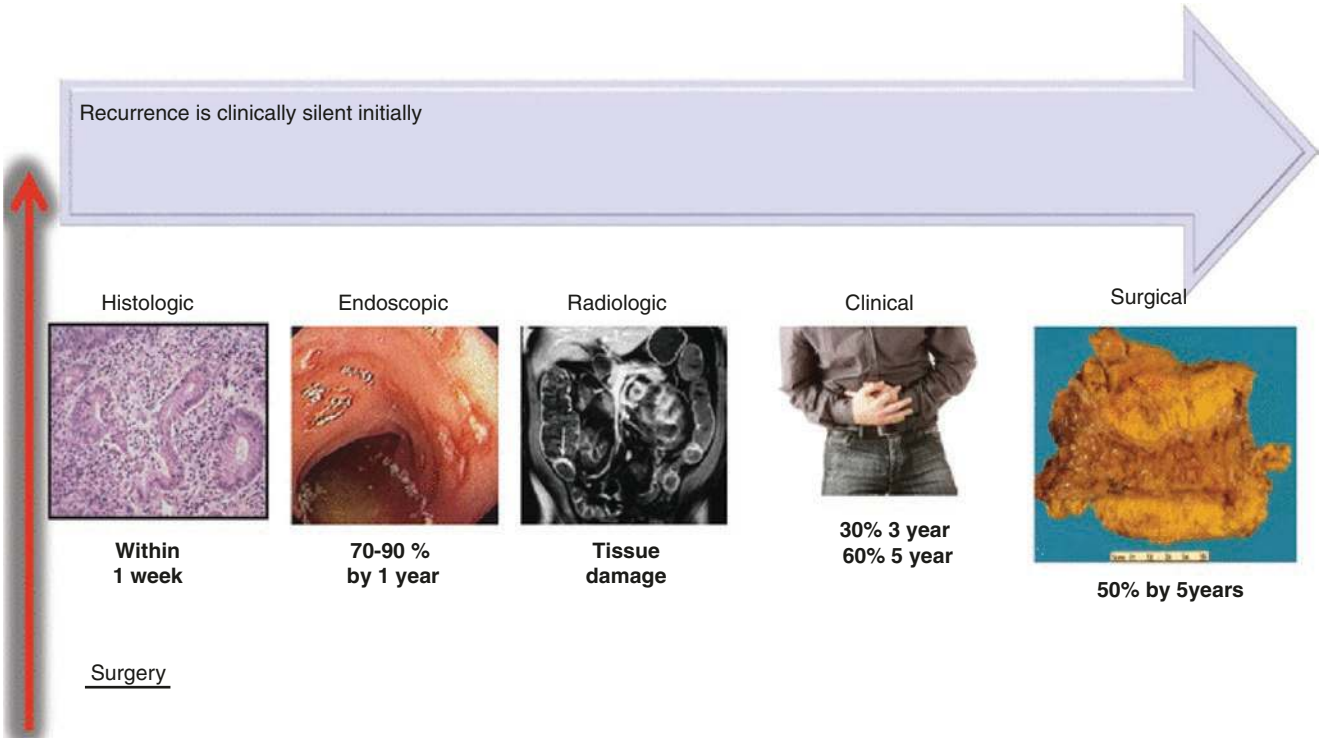

Fig. 42.1 The natural course of postoperative Crohn disease

Table 42.1 Rutgeerts postoperative Crohn disease endoscopic scoring system

Endoscopic score	Endoscopic findings
i0	No lesions
i1	≤5 aphthous lesions
i2	>5 aphthous lesions with normal mucosa between the lesions, or skip areas of larger lesions or lesions confined to the ileocolonic anastomosis (i.e., <1 cm in length)
i3	Diffuse aphthous ileitis with diffusely inflamed mucosa
i4	Diffuse inflammation with already larger ulcers, nodules, and/or narrowing

Since symptom assessment is an unreliable and delayed measure of POR, ileocolonoscopy utilizing the Rutgeerts scoring system is the current gold standard test for POR assessment. The Rutgeerts scoring system defines severity of disease on a 0–4 scale based on the extent of aphthous ulcerations in the neoterminal ileum (Table 42.1) [11]. Complete endoscopic remission with no lesions is classified as i0, while mild disease consisting of five or fewer aphthous ulcers is classified as i1. Moderate disease defined by more than five aphthous lesions with normal mucosa between the lesions, or skip areas of larger lesions or lesions confined to the ileocolonic anastomosis is classified as i2. Diffuse aphthous ileitis with diffusely inflamed mucosa is classified as i3, and the most severe disease characterized by diffuse inflammation with already larger ulcers, nodules, and/or narrowing is classified as i4 disease.

Debate subsequently ensued regarding the heterogeneity of recurrence outcomes in the i2 category. Recent evaluations have suggested a modification of the Rutgeerts score to differentiate between inflammation confined to the anastomosis only, termed i2a, and disease that extends into the neo-terminal ileum, or i2b [17]. The impact of this distinction is still unclear, as some studies have suggested no difference in the risk of subsequent clinical or surgical recurrence between the two categories, while others have suggested increased recurrence risk with i2b compared to more mild disease [18, 19].

Although ileocolonoscopy is sensitive at detecting POR, the invasive nature of the test is associated with patient discomfort, high cost, and procedural risk. Thus, noninvasive assessments are of particular interest. Fecal calprotectin (fCal), produced by gut leukocytes and epithelial cells at sites of mucosal injury including Crohn disease, has been investigated as a potential noninvasive marker of POR. Early reports from small studies suggested that there was no significant difference in fCal levels between CD patients with endoscopic recurrence versus patients in endoscopic remission at 1 year after surgery [20]. In contrast, recent studies have clarified the value of this biomarker. Boschetti and colleagues examined 86 asymptomatic POCD patients within 18 months after surgery and found that patients with endo-

scopic recurrence (i2-4) had significantly higher levels of fecal calprotectin than patients in endoscopic remission (i0-1) (mean ± s.e.m.: 473 ± 78 μg/g vs. 115 ± 18 μg/g; $P < 0.0001$), and that fCal levels correlate with Rutgeerts scores ($r = 0.65$, $P < 0.0001$) [21]. The correlation of fCal and endoscopic activity has been further supported with more recent work including prospective trials and pediatric populations [22–25]. Based on available data, fCal cutoffs between 100 and 150 μg/g have been proposed, identifying endoscopic recurrence with 70–89% sensitivity, 58–69% specificity, and a negative predictive values >90% [26, 27]. Additionally, data suggest that serial fCal levels can predict early endoscopic and clinical recurrence in both pediatric and adults populations, including data as early as 2 weeks postop and demonstrates treatment response [28–31]. Thus, fCal may have a role in perioperative risk stratification, proactive monitoring, and assessing therapeutic response in POCD. Additional cytokine profiles may supplement fecal calprotectin in more accurately monitoring disease activity but these remain investigational at the current time [32].

Investigators have also studied the utility of fecal lactoferrin, a stable product of activated neutrophils, to detect POR with similar correlations to endoscopic activity as fCal, but slightly reduced accuracy [22]. Serum-derived high-sensitivity C-reactive protein has also been evaluated, but with mixed results and reduced accuracy compared to fCal [27].

Serum measurements of protein/lipid oxidation and total antioxidant capacity correlate to postoperative CD recurrence and may be pathogenic as well [33]. Other serum markers of antibacterial antibodies have been shown to be associated with severe postoperative recurrence [34]. While noninvasive biomarkers have been shown to be useful in monitoring of POR and assessing treatment response, at the current time they remain adjunctive to endoscopic monitoring.

Noninvasive radiographic studies such as small intestine contrast ultrasonography (SICUS), computed tomography (CT) or magnetic resonance (MR) enterography, and video capsule endoscopy have also been investigated to evaluate POR. Calabrese et al. reported that SICUS utilizing oral contrast detected POR, defined by increased bowel wall thickness (BWT) ((>3 mm) for at least 4 cm at the perianastomotic area), in 62 out of 67 patients with endoscopic recurrent disease (i1-4) (92.5% sensitivity), and that BWT strongly correlated with the Rutgeerts score ($r = 0.67$, $P < 0.0001$) [35]. Paredes and colleagues had similar findings in their study of contrast-enhanced US utilizing IV contrast in which they found that BWT > 5 mm or contrast enhancement >46% on US had a sensitivity, specificity, and accuracy of 98, 100, and 98.3% for the diagnosis of endoscopic recurrence (i1-4) [36]. Other reports have generated predictive models of future surgical risk based on SICUS characteristics [37]. Despite these positive findings, the use of SICUS in clinical practice in the United States remains somewhat limited due to equipment, training, reimbursement, and body habitus challenges. Both CT and MR enterography have demonstrated utility in detecting recurrent disease activity and correlate well with endoscopic activity with a correlation coefficient of 0.82 in one study [38–41]. Additionally, cross-sectional imaging can identify more proximal disease recurrence not reachable endoscopically as well as transmural and penetrating complications. Capsule endoscopy had a sensitivity of 100% in detecting POR and only had capsule retention in 2.1% of patients [42].

Risk Factors for Postoperative Recurrence

Given the high rates, but variable severity of POR, many studies have sought to elucidate factors associated with or predictive of POR. These include clinical, disease, surgical, histologic, microbiotic, and molecular characteristics.

Patient-level factors that have been suggested as increasing the POR risk include active smoking, gender, race, and family history of IBD [43]. Of these only smoking has demonstrated mostly consistent associations with disease recurrence. In a meta-analysis of nearly 3000 surgical adult CD patients, active smoking was found to nearly double the risk of clinical and surgical recurrence [44]. Endoscopic recurrence data suggest a similar doubling of recurrence rates (70% smokers at year 1 vs 35% nonsmokers) [45]. Furthermore, it is the only modifiable POR risk factor and data suggest that smoking cessation can reduce recurrence rates [45–47].

Certain disease characteristics have demonstrated association with POR. Younger age at disease onset has demonstrated conflicting findings, potentially related to duration of follow-up [3, 4, 43]. Rapid progression from disease onset to surgical indication has been shown in multiple studies to associate with recurrence risk, though varying timeframes have been proposed, with most data suggesting disease duration <10 years as a risk for POR [48, 49]. A history of prior surgical resections for Crohn's has been shown in multiple retrospective and prospective studies to correlate with POR risk and may impart the strongest risk for POR [43, 50]. Both disease location and length of diseased segment prior to surgery have also been evaluated with conflicting results. Some pediatric studies suggest colonic disease as a risk factor, whereas others concluded distal colonic or upper gastrointestinal tract involvement were protective [3, 4]. High clinical disease activity in pediatric populations has similarly described disparate associations with surgical risk [13]. Preoperative medical therapies including corticosteroids or thiopurines have been associated with increased risk, whereas preoperative infliximab and mesalamine were associated with decreased surgical risk [3, 13, 51]. The latter

finding may be related to disease activity control. Complex disease behavior has been consistently associated with increased surgical risk and in meta-analysis, penetrating disease behavior (fistula, abscess) at the time of surgery was associated with increased clinical and surgical recurrence (HR 1.50; 95% CI 1.16–1.93) [52].

Surgery-related factors including surgical approach, radical versus conservative resection margins, perioperative blood transfusions, and postoperative complications have not demonstrated consistent influence on POR. Emerging data evaluating the role of the resective technique and anastomotic configuration have generated provocative results. In a single-retrospective surgical cohort comparing extended mesenteric excision to conventional mesenteric division flush with the mesentery, Coffey and colleagues found significantly lower rates of surgical recurrence with extended mesenteric excision (2.9% vs 40%, $P = 0.003$) [53]. Prospective trials are underway to validate these findings. A recently described novel antimesenteric functional end-to-end anastomosis technique, termed the Kono-S anastomosis, has been associated with significant reduction in endoscopic and surgical recurrence compared to conventional anastomosis [54–56]. In a prospective randomized clinical trial, the Kono-S group had significantly fewer endoscopic recurrence than stapled side-to-side anastomosis (22.2% vs 62.8% at 6 months, respectively) and those recurrences were less often severe (Rutgeerts score $\geq$ i3) (13.8% vs 34.8%, $P = 0.03$), suggesting a potential role for surgical technique selection in CD [57].

Histologic findings including granulomas both in the resected specimen as well and lymph nodes have been associated with modestly higher recurrence rates (OR 1.37; 95% CI 1.02–1.82) [58, 59]. Myenteric and submucosal plexitis have been associated with recurrence in several studies and the plexitis severity may correlate with subsequent endoscopic activity [59–62]. Histologically positive resection margins have been suggested as a risk factor including several recent prospective cohorts [63]. In the prospective REMIND cohort, transmural extent of proximal margin involvement is associated with increased endoscopic recurrence rate [64]. In an analysis of over 500 primary ileocecal resections, microscopic margin positivity was associated with both clinical (HR 2.16; 95% CI 1.14–2.43) and surgical recurrence (HR 2.99; 95% CI 1.36–6.54) [65].

Serologic markers such as anti-Saccharomyces cerevisiae antibodies (ASCA), E. coli (Omp-C), Pseudomonas (I2), flagellin (cBIR), and the anti-glycan antibodies have been explored largely with negative or mixed findings in adult patients [43]. In pediatric populations, the serologic association has been more consistently demonstrated, with risk conveyed potentially related to immune reactivity as measured by serologic markers [66].

Several studies have sought to elucidate the role of IBD genetic risk loci in influencing POR risk. The *NOD2/CARD15* mutations have been associated with higher surgical recurrence rates (OR 3.29; 95% CI 1.13–9.56) and earlier time to repeat surgery in both adult and pediatric cohorts [67–71]. This affect may be further mediated by smoking [72]. Another study suggested *CARD8* homozygosity may also influence POR risk [73].

The role and influence of the microbiome on POR are being actively investigated. Investigators have described recurrence being associated with elevated levels of Proteus, Lachnospiraceae, Fusobacteria, and reduced Faecalibacterium [74–76]. Recently, interest in a novel *Escherichia coli* strain has garnered interest in POCD. Furthermore, the microbial differences may also be influenced by active smoking, suggesting a risk factor interaction. Adherent-invasive *E. coli* (AIEC) has been implicated in CD pathogenesis in both adult and pediatric populations with a prevalence estimated between 36 and 90% individuals when using mucosa-associated and intracellular detection methods [77]. Unique molecular mechanisms allow AIEC to overcolonize intestinal epithelium, form biofilms, invade the lamina propria, and stimulate immune responses [78, 79]. Prospective trials manipulating AIEC to prevent POR are currently underway (NCT03943446).

Similarly, other "-omics" and their relationship to POR are being evaluated including urinary metabolics, ileal tissue and peripheral blood transcriptomics, and others [80–84]. Thus, the future predictive ability will likely improve with incorporation of these various factors that currently remain investigative.

Risk Stratification for Postoperative Recurrence

Given the natural predisposition for POR and associated risk factors, risk stratification has been proposed by many authors and adopted in recent adult gastroenterological societal guidelines [85]. Patients at high risk for recurrence include those who are younger (<30 years), active smoking, two or more prior surgical resections, penetrating disease, with or without perianal disease. Patients deemed low risk include older (>50 years), nonsmokers, first surgery for short segment (<10 to 20 cm) of fibrostenotic disease, and disease duration for greater than 10 years. Inherently, pediatric patients meet age of onset risk criteria and such strata have not been validated in pediatric cohorts. It is the authors' opinion that similar disease phenotypic criteria apply to pediatric patients. Those with multiple prior surgeries, penetrating disease, active smoking, and perianal disease likely represent a higher risk cohort. Genetic influences may confer a stronger risk for POR in pediatric populations. Such risk stratification can help identify patients warranting more aggressive treatment and monitoring after surgery.

Nonbiologic Treatment Options for Preventing Postoperative Crohn Disease

Medical therapies including antibiotics, aminosalicylates, and immunomodulators have been shown to moderately reduce the risk of clinical and endoscopic disease recurrence [86] (Table 42.2). Mesalamine is a safe but with limited efficacy in preventing POR. A Cochrane analysis by Doherty et al. found that mesalamine does reduce clinical recurrence (RR 0.76; 95% CI 0.62–0.94) and severe endoscopic recurrence (RR 0.50; 95% CI 0.29–0.84) compared to placebo, but with a number needed to treat (NNT) of 12 and 8, respectively [87]. A subsequent systemic review and meta-analysis by Ford et al. concluded that mesalamine is of only modest benefit in preventing POR compared to placebo and should only be considered if immunosuppressive therapy is not warranted or is contraindicated [78].

In the aforementioned Cochrane analysis, thiopurine therapy with azathioprine (AZA)/6-mercaptopurine (6-MP) was found to significantly reduce clinical recurrence (RR 0.59; 95% CI 0.38–0.92, NNT = 7) and severe endoscopic recurrence (RR 0.64; 95 CI 0.44–0.92, NNT = 4) compared to placebo and was found to be superior to mesalamine [87]. Similar findings were reported by Peyrin-Biroulet et al. in a concurrent meta-analysis of four controlled trials, in which AZA/6-MP was determined to be more effective than placebo for preventing clinical recurrence at 1 year (mean difference, 95% CI: 8, 1–15%, P = 0.021, NNT = 13) and 2 years (mean difference, 95% CI: 13%, 2–24%, P = 0.018, NNT = 8) after surgery, and endoscopic recurrence (i2-4) (mean difference, 95% CI: 23%, 9–37%, P = 0.0016, NNT = 4) at 1 year after surgery [88].

Metronidazole (20 mg/kg) may significantly reduce the incidence of severe (i3-4) endoscopic recurrent disease compared to placebo-treated patients at 3 months after surgery (3 of 23; 13% vs. 12 of 28; 43%; P = 0.02), and clinical recurrence at 1 year (1 of 23; 4% vs. 7 of 28; 25%; P = 0.044) [89]. Combining metronidazole with AZA may improve outcomes further. POCD patients treated with metronidazole for 3 months and AZA (100–150 mg qd dependent on body mass) for 12 months had significantly less endoscopic recurrent disease (i2-4) at 1 year after surgery than patients treated with metronidazole alone at 1 year after surgery (14 of 32; 43.7% vs. 20 of 29; 69.0%; P = 0.048) [90]. The limitation of metronidazole is that patients often do not tolerate high doses, can develop neuropathies with prolonged exposure, and long-term prevention of recurrence is lost when the antibiotic is stopped. Recent observational data have suggested that lower dose metronidazole (250 mg TID) may confer similar risk reduction compared to placebo, but still associated with an adverse event rate of 22% and discontinuation in 8% [91]. Ornidazole, a nitroimidazole antibiotic with theoretically lower side effects, has been evaluated the prevention of POR. Ornidazole (1 g/day) compared to placebo reduced endoscopic recurrence at 1 year (OR 0.31, 95% CI 0.10–0.94, p = 0.037,) and clinical recurrence at 1 year (OR 0.14, CI 0.037–0.0546, p = 0.005) [92]. However, importantly, a significant portion of patients dropped out of the study due to side effects, primarily neuropathies and dysgeusia.

Probiotics to modulate the microbiome in efforts to prevent POR have largely been unsuccessful. *Lactobacillus johnsonii* LA1 compared to placebo showed similar rates of endoscopic recurrence at 6 months (64% vs 49%, p = 0.15) [93]. Lactobacillus GG had similar null results (60% endoscopic recurrence vs 35.3% on placebo p = 0.297) [94]. Given that single probiotic formulations were ineffective, a probi-

Table 42.2 Risk factors explored for association with postoperative recurrence

otic VSL#3, a formulation of eight different probiotic species, was studied. Endoscopic recurrence was similar in patients treated with VSL#3 for 3 months compared to placebo (9.3% vs 15.7%, $p = 0.19$), despite a reduction in proinflammatory cytokines in the VSL#3 group [95]. Ongoing studies of the characterization and manipulation of the neoterminal ileum and anastomotic microbiome are being conducted.

Other studies have investigated the potential for anti-inflammatory supplements to reduce recurrence rates. Vitamin D deficiency is common in IBD, supplementation is safe, and preclinical studies of high-dose supplementation suggest anti-inflammatory properties. However, Vitamin D at a dose of 25,000 IU weekly failed to demonstrate superiority over placebo to prevent endoscopic (58% vs 66%, $p = 0.37$) or clinical recurrence (18.1% vs 18.6%, $p = 0.91$) at 26 weeks in a prospective randomized trial [96]. Similarly, curcumin, an anti-inflammatory derivative of turmeric with clinical evidence in treating ulcerative colitis, was evaluated in addition to azathioprine to prevent recurrence in a prospective placebo-controlled trial [97, 98]. There was no benefit to curcumin to prevent endoscopic or clinical recurrence and the trial was discontinued early due to futility.

Anti-TNFs for Prevention of Postoperative Crohn Disease

Growing evidence demonstrates that anti-TNF therapy is the most effective treatment to prevent POR and may have the potential to change the natural course of Crohn disease after surgery. Since Sorrentino and colleagues first reported the successful use of prophylactic IFX in a Crohn's colitis patient after a partial colonic resection [99], multiple small randomized and prospective open-label trials have found that IFX and adalimumab (ADA) are superior to placebo, mesalamine, and AZA at preventing POR (Table 42.3) [38, 100–107]. Regueiro and colleagues performed the first randomized placebo-controlled trial examining the ability of IFX (5 mg/kg every 8 weeks) to prevent endoscopic recurrence of Crohn disease at 1 year after ileal resection [103]. In a relatively small study of patients with ileal or ileocolonic disease at moderate to high risk for disease recurrence, the rate of endoscopic recurrence (i2-4) was significantly lower in IFX-treated patients (9.1%, $n = 11$) compared to the placebo group (84.6%, $n = 13$) ($P = 0.0006$). Several other small randomized studies verified that infliximab prevents POR [100, 107]. The protective effects of IFX appear to be a class effect of TNF inhibitors, as ADA has also been found to prevent POR in several small open-label and randomized studies [102, 104, 105]. Overall, anti-TNF therapy is the most effective treatment to prevent POR as verified by recent systematic review and network meta-analysis examining the comparative efficacy of all drugs studied to prevent POR [33] (Table 42.4).

Table 42.3 Summary of nonbiologic postoperative Crohn disease clinical and endoscopic recurrence rates from randomized controlled trials

Intervention	Clinical recurrence (%)	Endoscopic recurrence (%)
Placebo	25–77	53–79
5-ASA	24–58	63–66
Budesonide	19–32	52–57
Nitroimidazole	7–8	52–54
AZA/6-MP	34–50	42–44

The efficacy of prophylactic anti-TNF therapy to prevent endoscopic POR has been supported by the PREVENT study, the largest randomized placebo-controlled POR-preventive treatment trial to date [108]. The PREVENT study was a multicenter trial that enrolled 297 CD patients who had undergone ileocolonic resection and were at increased risk for POR. One hundred forty-seven patients were randomized to receive IFX (5 mg/kg every 8 weeks), and 150 patients were randomized to receive placebo treatment for a 200-week treatment period. The primary endpoint was clinical recurrence prior to or at week 76 defined by Crohn disease activity index (CDAI) score and endoscopic recurrence (i2-4), or the development of a fistula or abscess. The secondary endpoint was endoscopic recurrence alone (i2-4) prior to or at week 76. The study reported that the proportion of subjects with clinical recurrence was numerically lower in the IFX group compared with the placebo group, but the difference was not statistically significant (12.9% vs. 20.4%, $P = 0.097$) (Fig. 42.2). However, IFX treatment significantly reduced endoscopic recurrence compared to placebo treatment (22.4% vs. 51.3%, $P < 0.001$) (Fig. 42.3). Of patients who had a score of i0, there were more receiving IFX than placebo (83.1% vs. 28.4%). Of patients who had

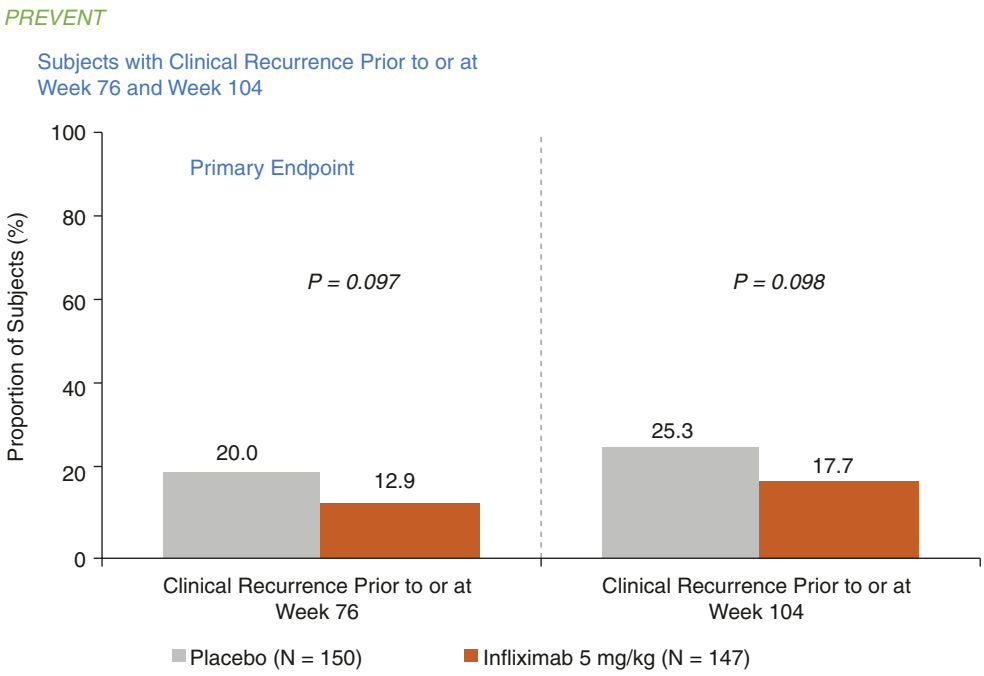

Fig. 42.2 Clinical recurrence was reduced in infliximab-treated patients in the PREVENT study. *P*-values based on the Cochran-Mantel-Haenszel chi-square test stratified by the number of risk factors for recurrence of active CD (1 or >1) and baseline use (yes/no) of an immunosuppressive (i.e., AZA, 6-MP, or MTX)

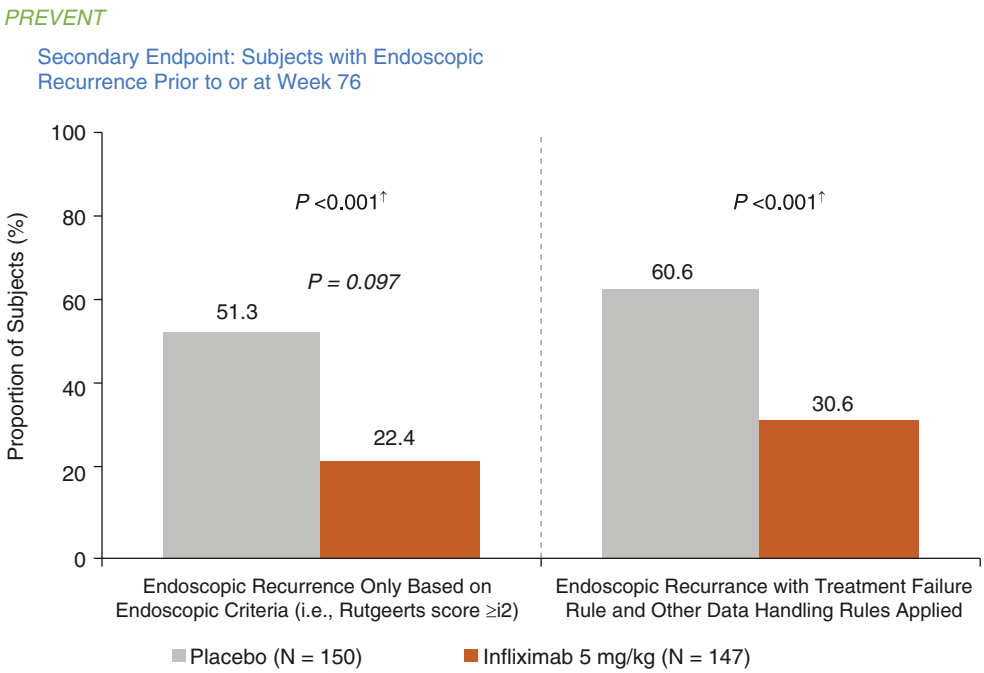

Fig. 42.3 Endoscopic recurrence was significantly reduced in infliximab-treated patients in the PREVENT study. †Nominal *p*-values based on the Cochran-Mantel-Haenszel chi-square test stratified by the number of risk factors for recurrence of active CD (1 or >1) and baseline use (yes/no) of an immunosuppressive (i.e., AZA, 6-MP, or MTX)

more aggressive recurrence, i3 or i4, there were fewer receiving IFX than placebo (16.9% vs. 71.6%). Accordingly, the authors recommend anti-TNF therapy as first-line prophylactic therapy for patients at high risk for POR if no contraindication or documented primary failure previously.

With an increasingly anti-TNF-experienced patient population, there is interest in the efficacy of other monoclonal antibodies to prevent postoperative Crohn disease. In several retrospective studies, postoperative vedolizumab or ustekinumab prophylaxis was associated with higher endoscopic recurrence rates than anti-TNF-treated patients; however, significant retrospective limitations and biases prohibit full interpretation [109, 110]. In a study examining retrospective ustekinumab for POR prophylaxis compared to an azathioprine-treated population as part of a randomized prospective trial, the authors found significantly reduced endoscopic POR at 6 months in ustekinumab compared to azathioprine; however, this risk reduction was not seen for

severe (i3-i4) POR [111]. Prospective studies are underway to better ascertain the role of the alternative mechanisms of action in preventing POR.

Safety of Postoperative Anti-TNFs

The risks versus benefits of continuing prophylactic anti-TNF therapy in patients in long-term remission have also been called into question, considering the cost of treatment and potential for rare, but serious, side effects. Long-term safety data for IFX in the treatment of Crohn disease demonstrate that IFX therapy is associated with a moderate risk for infection, is associated with small increases in the risks of lymphoma and melanoma, but does not increase the risk of mortality [112–115]. Severe Crohn disease and prednisone and narcotic use are associated with a higher risk of infection than IFX therapy, and thus one could argue that the benefits of IFX to prevent severe recurrent disease outweighs the infection risk. In the initial postoperative IFX study, there was no increased risk of adverse events in IFX-treated patients compared to placebo, including postoperative complications up to 1 year after surgery [116, 117]. In the PREVENT trial, rates of adverse events, serious adverse events, infection, and serious infections were similar between infliximab and placebo arms, though more infliximab subjects discontinued therapy due to adverse events [108]. Preventive anti-TNF therapy has been found to be relatively safe in other postoperative studies, including the study of ADA by Savarino and colleagues who reported that ADA-treated patients had fewer adverse events than the azathioprine-treated and mesalamine-treated patients over a 2-year follow-up period [104].

In contrast, the risks of stopping postoperative anti-TNF therapy appear to be higher than continuing treatment, as Regueiro and colleagues found that patients in remission who stop IFX are at high risk for recurrent disease. After completion of the 1-year study, patients were permitted to discontinue (or start) IFX and were then followed for an additional 5 years [117]. Eight of the original 11 IFX-treated patients chose to stop therapy, and all eight developed endoscopic recurrent disease, and five subsequently required repeat surgery. The three other original IFX-treated patients continued their treatment, and none required repeat surgery during the study period. Twelve of the original 13 placebo patients had recurrence and chose to start IFX; seven of these patients achieved endoscopic remission and required no repeat surgery during the study period. Overall, Regueiro et al. found that patients who were treated with IFX for at least 60% of the 5-year study period had a significantly lower risk for repeat surgery, irrespective of their original treatment assignment (20.0% vs. 64.3%, $P = 0.047$). Sorrentino and colleagues found a similar high risk of recurrence, as they reported that 83% of patients ($n = 12$), who were previously in remission for 3 years after surgery on IFX, developed endoscopic recurrent disease 16 weeks after stopping treatment [99].

Enteral Nutrition for Postoperative Crohn Disease

Enteral nutrition in the prevention of CD POR has also been evaluated in several small Japanese studies. One trial of 40 adult patients all receiving mesalamine in the postoperative period, assessed nocturnal self-intubation and infusion of elemental enteral feeding and found that high-volume enteral nutrition (>1200 kcal/day) significantly reduces postoperative endoscopic recurrence compared to low- or no-volume enteral nutrition (<1200 kcal/day) ($p = 0.02$) [118]. A similar non-randomized study of 40 adult Japanese patients found that enteral nutrition significantly reduces endoscopic recurrence at 12 months compared to no therapy (30% vs 70%, $p = 0.027$) [119]. In regards to surgical recurrence, another study found that enteral nutrition compared to placebo reduced recurrence but without statistical significance ($p = 0.08$). The placebo group in this study had a significantly higher cumulative recurrence rate requiring infliximab ($p = 0.03$) suggesting that enteral nutrition may have a role in supplementing or replacing pharmacologic prophylaxis [72, 120]. Limitations to these studies include small and highly motivated adult populations willing to self-intubate nasogastric apparatuses nightly and infuse enteric formulas for indefinite time. It remains to be seen how such findings and management could translate to pediatric or Western cultures. Future large randomized control trials assessing enteral nutrition as a non-pharmacologic therapy are necessary to determine its role in preventing and treating postoperative Crohn disease recurrence (Table 42.5).

Ustekinumab	++?	?

[a]Authors opinion. Budesonide may be used for short-term induction therapy, but similar to luminal ileal CD, is not likely effective for long-term therapy

Treating Postoperative Crohn Disease: Waiting for Endoscopic Recurrence

Postoperative natural history studies have taught us that most *but not all* patients will develop recurrent disease. Thus, initiating anti-TNF therapy in all postoperative Crohn disease patients would certainly mean overtreating a subset [121]. Relevant to this concern, it is not known whether prophylactic anti-TNF therapy is more effective than waiting to treat recurrent disease. Yamamoto et al. investigated the impact of IFX therapy on Crohn's patients in clinical remission but who had endoscopic recurrent disease 6 months after ileocolonic resection despite prophylactic mesalamine therapy (3 g/day) [122]. Eight such patients were started on IFX (5 mg/kg every 8 weeks), another eight were started on AZA (50 mg/day), and the remainder was maintained only on mesalamine. They found that infliximab induced complete endoscopic remission in 38%, 6 months after starting treatment, compared to only 13% of AZA-treated patients and 0% of mesalamine-treated patients ($P = 0.10$). Sorrentino and colleagues found similar results when they treated patients with endoscopic disease 6 months after surgery with either IFX (5 mg/kg every 8 weeks) or mesalamine (2.4 g/day) [123]. Fifty-four percent of the infliximab-treated patients ($n = 13$) were in endoscopic remission 1 year after starting treatment compared to 0% of mesalamine-treated patients ($n = 11$) ($P = 0.01$). Adalimumab appears to be equally effective in treating early recurrent disease, as Papamichael et al. showed in their study that ADA promoted endoscopic healing in 60% of treated patients ($n = 15$) who had endoscopic disease 6 months after surgery [102]. Overall, these studies suggest that anti-TNF therapy may be effective at treating early recurrent disease in certain patients, but response is often not complete or universal.

The timing of the first colonoscopy after surgery to detect endoscopic recurrence and prevent progression was assessed in the pivotal POCER study [101]. The primary endpoint was endoscopic recurrence at 18 months. In the trial, 174 postoperative patients were randomly assigned in a 2:1 ratio to either a standard care or active care arm. The active care arm had patients undergo a colonoscopy at 6 months, and if there was active Crohn disease (≥ i2), they had a step up in their therapy, for example, starting AZA/6-MP if previously on no medication or adding ADA to AZA/6-MP. The standard care arm did not undergo a 6-month colonoscopy and only had the 18-month colonoscopy. Both study arms were given metronidazole 400 mg twice a day for 3 months. If patients were intolerant, the dose was reduced to 200 mg twice daily, or was stopped altogether. If they were of high risk (smokers or recurrent surgery or penetrating disease) but medication-naive, patients were given AZA 2 mg/kg or 6-MP 1.5 mg/kg once daily, beginning within 1 month after surgery. Patients intolerant to this regimen were administered ADA 160 mg/80 mg induction followed by 40 mg every other week. Patients without any risk factors for postoperative recurrence, that is, nonsmokers, first surgery, and absence of penetrating disease, received no additional treatment beyond 3 months of metronidazole. The 18-month primary endpoint of endoscopic recurrence was significantly lower in the active care arm compared with the standard care arm (49% vs. 67%, $p = 0.03$). Although not an endpoint of the study, it was interesting that the 6-month postoperative endoscopic recurrence rates for patients receiving AZA/6-MP and ADA were consistent to what has been previously reported (45% vs. 21%). This data suggests that early colonoscopy at 6 months with adjustment in therapy based on findings improves subsequent recurrence rates and may alter the course of postoperative Crohn disease.

Strategies for Postoperative Crohn Disease Management

The questions that remain in the practical management of postoperative Crohn disease are: (1) which patients should receive immediate postoperative therapy, and (2) which patients would it be reasonable to wait to treat endoscopic recurrence? The current prevailing strategy for postoperative Crohn disease management is to stratify postoperative treatment based on risk and treat only those patients at high risk for recurrence with prophylactic medical therapy (Fig. 42.4). Low-risk patients would not initiate medical therapy but undergo early monitoring for POR.

In high risk patients who are receiving preoperative biologic therapy and plan to utilize biologic therapy postoperatively, it is imperative to distinguish therapeutic failure (e.g., active disease progression despite adequate drug exposure) from failure due to preexisting damage (e.g., fibrostenotic stricture) or complication (e.g., penetrating disease). It is the authors opinion that with preexisting stricture or complication, the preoperative biologic exposure does not necessarily represent a failure and the agent or class may be continued postoperatively for prophylaxis, particularly for anti-TNFs (+/− immunomodulator) due to the wealth of evidence for their efficacy in POR. In this situation, the authors also frequently continue the biologic dosing throughout the perioperative period after discussing with the surgical team. Despite historical concerns about risk of perioperative complications with biologics, more recent large prospective studies controlling for confounding factors (e.g., malnutrition, steroids) have not seen such an effect [124]. With verified therapeutic failure, the biologic mechanism of action should be changed postoperatively. If anti-TNFs were used preoperatively, one could consider non-anti-TNF agents despite the relative paucity of postop data for either vedolizumab or ustekinumab.

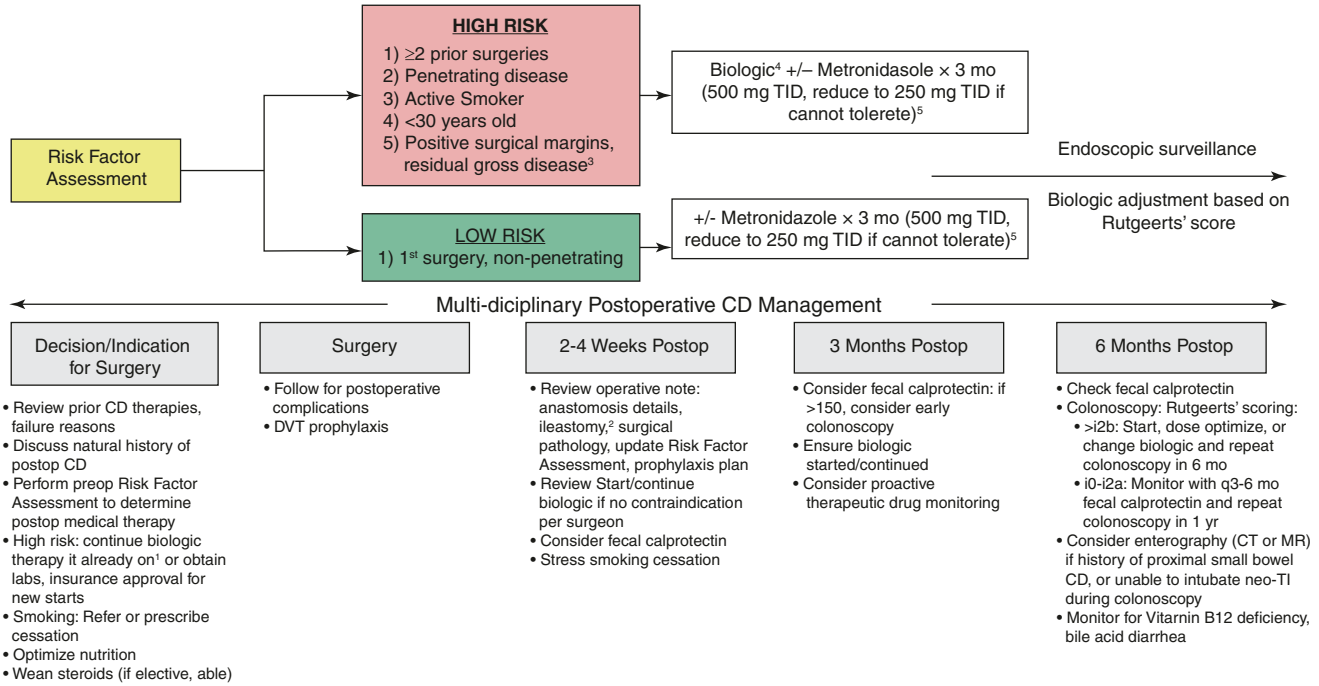

Fig. 42.4 Proposed algorithm for the management of postoperative Crohn disease. Low risk of postop recurrence defined by long-standing Crohn disease, first surgery, and short stricture. High risk defined by multiple prior resections, penetrating disease, active cigarette smoking, young age or with confirmed microscopic or gross disease left in situ. [1]If plan to continue biologic therapy as postop prophylaxis, continue biologic dosing after multidisciplinary discussion with surgeon. If preop biologic deemed failure due to active disease progression while on agent, consider change in biologic class postoperatively. [2]If diverting loop ileostomy present, can delay biologic initiation and postop timeline until ileostomy take down. [3]For other potential risk factors (e.g. myenteric plexitis, transmural involvement), consider early postop monitoring with calprotectin. [4]If no contraindication, prior failure, or other indication, consider anti-tumor necrosis factor therapy ± immunomodulator as first line. Otherwise, consider other biologics despite limited data in postop setting. [5]Authors also consider implementing dietary strategies including Mediterranean diet, Crohn's Elimination Diet, or Specific Carbohydrate Diet based on luminal CD evidence, despite limited data in postop setting

For individuals at high risk, or with surgical or histologic risk factors for recurrence that are awaiting larger validation studies (e.g., myenteric plexitis, transmural lesions, granulomas), one can consider incorporating early biomarker monitoring with fecal calprotectin at 3 months postop. If calprotectin elevated >150 μg/mL, earlier colonoscopy (prior to month 6) to evaluate for recurrence is reasonable though prospective studies have not validated this approach to reduce subsequent recurrence compared to waiting until 6 months.

Individuals identified as low risk for POR would refrain from prophylactic biologic therapy and instead consider metronidazole therapy (20 mg/kg or approximately 500 mg TID) for at least 3 months. If unable to tolerate this dose due to side effects, dosing can be decreased to 250 mg TID. The benefit of postoperative metronidazole appears to be limited to the duration of time the patient is actively taking the medication. As such, POR is likely delayed by postoperative metronidazole rather than prevented. Until the microbiome-altering agent without side effects is identified, and can be sustained long-term, the use of metronidazole beyond 3 months will be limited.

All patients would then undergo a colonoscopy at 6 months from surgery. Concurrent calprotectin measurement is helpful if future biomarker monitoring is desired to align calprotectin levels to endoscopy findings. If the colonoscopy reveals active Crohn disease (≥ i2), untreated patients would be started on biologic therapy, and those receiving prophylactic biologic therapy would undergo therapeutic drug monitoring, dose optimization, or change in biologic agent. Disease activity monitoring with repeat colonoscopy could occur in 6 months to verify mucosal improvement. Those without endoscopic recurrence could be monitored with serial calprotectin every 3–6 months and ongoing colonoscopy surveillance in 1 year with subsequent intervals determined by findings. In individuals with prior proximal CD or incomplete colonoscopies, cross-sectional imaging with enterography (CT or MR) offers a relatively sensitive and accurate detection of POR.

Conclusions

Despite medical and management advances, a significant portion of CD patients require resective surgery. Postoperative recurrence of CD is common, often silent, and requires appropriate therapeutic and monitoring strategies to prevent disease progression. Preoperative risk stratification can help identify patients who may benefit most from prophylactic medical therapy postoperatively. To date, infliximab has been the only biologic prospectively studied for prevention of Crohn disease in high risk patients. Ongoing surveillance with colonoscopy starting at 6 months postoperatively with or without biomarker monitoring allows for early recurrence identification and treatment. There remain many key knowledge gaps in risk factors, biomarkers, and management algorithms for postoperative Crohn disease.

Perioperative Immunosuppression in Inflammatory Bowel Disease

43

Ira L. Leeds, Amy L. Lightner, and Jacob A. Kurowski

Introduction

Inflammatory bowel disease (IBD), a chronic idiopathic disease of the gastrointestinal tract, is characterized by two primary phenotypes—Crohn disease (CD) and ulcerative colitis (UC). Given the pathophysiology of IBD remains largely unknown to date, therapeutics used to treat IBD target a number of different immune-mediated mechanisms. While the immunosuppressive effects of these treatment options are necessary to achieve adequate clinical, endoscopic, and histologic disease response, they also pose risk of opportunistic infection [1–3], have been associated with malignancy [4, 5], and have the potential to increase postoperative morbidity [6].

Postoperative morbidity remains a significant concern for a large number of IBD patients. This is because even with optimal medical therapy, 60–80% of patients diagnosed with CD will require intestinal resection and 20% of patients with UC will ultimately need a colectomy for medically refractory disease [7–9]. Due to the ever-expanding repertoire of monoclonal antibodies and now JAK inhibitors, patients are arriving to the operating room with increasingly advanced disease and overall clinical decompensation after trialing numerous medical therapeutics. Therefore, it is not surprising that infectious complications following major surgery for IBD occur in 20–35% of patients in large, contemporary series [10, 11].

Postoperative infectious complications can lead to long-term sequelae including readmission, reoperation, and even pouch failure in restorative proctectomy patients [12, 13]. Given the potentially devastating consequences of infection following IBD surgery, there is an essential need to understand the optimal management of immunosuppressive agents in the perioperative period. While this has been extensively reported on in the adult literature, there is limited data in pediatric surgical patients. The purpose of this chapter is to describe the known mechanisms of immunosuppression from IBD medical therapy and to assess the risk of initiating, continuing, or restarting medical therapy in the perioperative period.

Effects of Immunosuppression on Operative Outcomes in Pediatric Populations

Different pharmacologic classes suppress the immune system via distinct mechanisms and may then theoretically affect immune-related postoperative outcomes differently. Very little formal evidence exists for the impact of immunosuppression on pediatric surgical outcomes, so we have extrapolated presumed effects in children from the published adult literature when necessary.

Glucocorticoids

Glucocorticoids are a potent immunosuppressive medical therapy for IBD that have historically been the primary therapeutic intervention for acute disease exacerbations. Drugs in this class are highly lipophilic leading to excellent bioavailability and easy access to transcription factors located in cells' nuclei. Glucocorticoids bind to the glucocorticoid receptor to form a complex that then interacts with other biochemical pathways that include: inhibits proinflammatory proteins necessary to activate proinflammatory cytokines such as IL-1 and IL-8; upregulating suppressive cytokines like transforming growth factor-β3 and IL-10; and inhibit proliferation of T-lymphocyte, B-lymphocyte, and macrophages through immune tolerance [14].

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_43

The distributed and wide-ranging effects of glucocorticoids on the immune system may explain why this drug class is also intimately associated with postoperative complications. Subramanian et al. conducted a meta-analysis of seven large observational studies combining 1714 patients that demonstrated a 68% increased likelihood of experiencing an infectious postoperative complication in IBD patients undergoing major abdominal surgery when exposed to chronic corticosteroids preoperatively. The study results also noted a dose-dependent response with those taking over 40 mg of oral prednisone experiencing more than double the risk of an infectious postoperative complication [15]. Thus, a daily dose of 20 mg prednisone has been traditionally recommended as the maximal dose of steroid exposure prior to elective IBD surgery.

Observational studies in pediatric surgical patients have also revealed an association of glucocorticoid exposure and adverse postoperative outcomes. Due to the smaller number of patients included in pediatric studies, the findings of these studies have been limited. Markel et al. identified 51 patients at their institution undergoing first-stage colectomies for UC and found that 43% of patients taking steroids preoperatively had postoperative complications versus only 9% of patients not exposed to steroids [16]. However, due to the small study population size, Markel et al. study was not able to perform multivariable analysis controlling for other variables that might explain this difference. Schaufler et al. similarly studied drug-induced immunosuppression's effect in 51 pediatric patients in their own distinct cohort. Since the vast majority of patients were on steroids, it was not possible to compare the association of steroid exposure on postoperative outcomes [17].

Immunomodulators

Immunomodulators have been a core steroid-sparing agent in IBD medical therapy, along with a preventor of antibody formation to monoclonal antibody therapy that results in a secondary loss of response [18]. The most frequently used drugs in this class include the thiopurine analogues, 6-mercaptopurine and azathioprine, and methotrexate. These drugs are grouped together based on their common pathway that leads to the inhibition of T-lymphocyte proliferation. 6-mercaptopurine and azathioprine are both metabolized to 6-thiosine 5′-monophosphate which is then converted by native lymphocyte metabolic processes into thioguanine nucleotides that disrupt normal DNA replication and synthesis [19, 20]. Similarly, methotrexate disrupts folic acid synthesis thereby impairing DNA replication in T-lymphocytes [21]. While immunomodulators have well described adverse events (e.g., hypersensitivity, T-cell lymphoma), the immunosuppressive risks of these agents are typically described as low relative to glucocorticoids. However, the relatively mild side effects of their use due to focused T-lymphocyte proliferation pathways may also explain why these agents are typically considered less effective treatments of IBD [22].

In contrast to glucocorticoids, immunomodulator use is not associated with worse perioperative outcomes. While no meta-analysis exists, surgical outcome studies that included examined immunomodulator use consistently identify no association between perioperative immunomodulator use and short-term complications [23–26]. Mahadevan et al. report one of the largest series of UC patients undergoing colectomy, and found no association of preoperative exposure to immunomodulators and adverse postoperative outcomes. In fact, patients taking immunomodulators such as azathioprine or 6-mercaptopurine preoperatively ultimately had lower complication rates than those not exposed to immunomodulators (43% versus 49%) [25].

In pediatric populations, the effects of immunomodulator use during surgical therapy for IBD has not been formally studied. However, these medications have historically been well tolerated in children, and we would not expect their immunosuppressive outcomes to vary from those of the adult populations reported above.

Monoclonal Antibodies

Monoclonal antibodies have revolutionized the medical treatment of IBD and have led to a decreased need for surgical management of IBD related to medically refractory disease [27]. However, the introduction of this new pharmacologic class with the Food and Drug Administration's (FDA) approval of infliximab over 20 years ago has led to persistent controversy of their safety in the perioperative period. Some of the controversy has resulted from a number of different targeted pathways including antibodies to tumor necrosis factor-α (TNF-α), α4B7 integrins, interleukin-12 and interleukin-23, which have the potential to result in variable infectious complications.

TNF-α inhibitors Increased production of the cytokine TNF-α results in activation of NF-κB-mediated inflammation implicated in IBD [28–30]. Inhibition of TNF-α through monoclonal antibodies (e.g., infliximab, adalimumab, and certolizumab) has had a profound impact on the outcomes and natural history for both CD and UC.

The effect of TNF-α inhibition on postoperative outcomes has been widely studied, and results have been heterogeneous. Moosvi et al. published a meta-analysis of 41 studies including 20,274 patients reported that patients exposed to anti-TNF-α therapeutics were 13% more likely to develop a postoperative complication, equating to an absolute increase in postoperative complications by 5.5% [31]. An important

caveat to these studies included in this meta-analysis is that controlling for the risk of selection bias (e.g., case severity, serum active drug levels) has been inconsistent and limited; thus, it is unclear whether the association found between anti-TNF-α and perioperative complications is a direct result of these agents or that use of these therapeutics is a surrogate marker of increased disease severity [27, 32]. Given the controversial data, if possible, most surgeons will attempt to time surgery in the middle of a dosing interval of anti-TNF-α therapeutics, maximizing the washout period while preventing antibody formation seen with prolonged discontinuation [33, 34].

These findings are similarly supported in the pediatric literature. Lightner et al. described surgical outcomes in a series of 69 pediatric patients with CD undergoing abdominal operative intervention with or without preoperative exposure to anti-TNF-α therapies within 12 weeks of surgery; the authors found no difference in postoperative infectious complications by anti-TNFα exposure [35]. Similarly, Dotlacil et al. described a Czech pediatric referral center's experience of 41 pediatric patients with CD undergoing surgery, and found no association of anti-TNF-α exposure and adverse 90-day postoperative outcomes [36].

Anti-integrins Vedolizumab, a monoclonal antibody targeting the α4B7 integrin expressed on B- and T-lymphocytes, was introduced with great fanfare because the gut-selective mechanism of action was hypothesized to have reduced systemic immunosuppression compared to any other available therapies to date [37]. However, early reports of vedolizumab's effect on postoperative outcomes were concerning. At Mayo Clinic, 94 patients with both UC and CD treated with vedolizumab within 12 weeks of surgery not only had higher rates of complications than the no biologic therapy control group, but vedolizumab-treated patients also appeared to do worse than those treated with traditional anti-TNFα biologic therapies [38, 39]. As more centers reported their results [40, 41], the findings became similarly ambiguous to the context described above for anti-TNFα biologic agents. On balance, early studies of vedolizumab were likely affected by the same selection bias risks affecting anti-TNFα biologic therapy including the potential for increased disease severity or systemic illness that was unable to be controlled for by statistical analysis. As additional time from vedolizumab's introduction has proceeded, the latest evidence suggests that perioperative risks of vedolizumab may be less than anticipated [42].

Currently, vedolizumab is not FDA approved for use in the pediatric age group but prospective trials are ongoing. Hence, even its use as an IBD medical therapy for children has only limited reporting to date [43]. An important area of future investigation will be whether anti-integrins have functional differences in risk for pediatric populations versus adult populations reported above.

Anti-interleukins Ustekinumab's introduction in 2016 led to a new class of an approved monoclonal antibody, this one targeting interleukin-12 and -23. To date, this class appears similar to both anti-TNFα agents and vedolizumab with regard to adverse postoperative outcomes. Although no pooled analyses are yet published, a multicenter study of 44 CD patients exposed to ustekinumab preoperatively was compared to 169 matched patients on anti-TNFα therapy with no statistical difference observed in the rates of postoperative complications [44]. A large single-center series of 30 CD patients taking ustekinumab were compared to 73 matched patients taking vedolizumab, and no differences were seen in postoperative complications [45].

Similar to vedolizumab, the relatively recent introduction of ustekinumab and anti-integrin IBD therapy limits the literature base for its use in pediatric patients [46]. We anticipate wider reporting of its use, and its effect on postoperative pediatric surgical outcomes, in the future.

Clinical Recommendations

Table 43.1 summarizes the clinically relevant details regarding the immunosuppressive effects of pediatric IBD medical therapy in the perioperative period. The current data in children mirrors that in adults. Glucocorticoids are the most deleterious to postoperative recovery. Monoclonal antibody therapies are unlikely to have a major impact on postoperative complications, and some evidence suggests that they have no effect. Immunomodulators contribute essentially no additional clinically significant immunosuppression to the perioperative period. JAK inhibitors remain unstudied due to their very recent approval.

These summary findings are important because they influence our recommendations for IBD medical therapy in the before and after surgery. The critical goal before surgery is to minimize the glucocorticoid burden. Finally, while studies remain ongoing, the effects of monoclonal antibody exposure on postoperative outcomes remains controversial despite an increasing number of papers on this topic. We typically mitigate any remaining monoclonal antibody risk by planning for surgery at the midpoint of a dosing interval to both minimize the circulating drug levels at time of surgery and immunosuppressive effects. However, surgery is not routinely delayed due to the presence of medical therapy alone.

Table 43.1 Drug class

Drug class	Mechanism of action	Degree of perioperative immunosuppression	Recommendation
Steroids	Intranuclear complex inhibits inflammatory cascade synthesis	+++	Ideally avoid, minimize exposure to ≤20 mg prednisone daily
Immunomodulators	Inhibition of lymphocyte proliferation via DNA replication analogues	+	Can be continued pre- and postoperatively
Biologics	Antigen-specific inflammatory cytokine inhibition	++	Schedule surgery to maximize dose-to-dose nadir during postoperative recovery (i.e., surgery at midpoint of dosing interval)

Conclusion

Optimal management of perioperative immunosuppression may minimize adverse postoperative outcomes. Importantly, decisions about perioperative care benefit from multidisciplinary collaboration pre- and postoperatively to either reduce or cease immunosuppressive regimens.Conflict of InterestDr. Lightner is a consultant for Takeda Pharmaceuticals.

Pouchitis and Pouch-Related Complications

44

Jacob A. Kurowski, Marsha Kay, and Robert Wyllie

Introduction

Total proctocolectomy with Ileal Pouch-Anal Anastomosis (IPAA) has emerged as the surgical procedure of choice for patients diagnosed with ulcerative colitis (UC) and patients with familial adenomatous polyposis syndrome (FAP) with a high burden of rectal polyps since its introduction in 1978 [1]. In pediatric patients diagnosed with ulcerative colitis, specific indications for proctocolectomy include severe disease refractory to medications, toxic megacolon, perforation, and intractable bleeding. In addition, the histopathologic findings of dysplasia or malignancy are strong indications to proceed with IPAA [2]. The latter two entities, however, are rare in pediatric patients. Patients with indeterminate colitis who undergo IPAA have a complication rate similar to that of UC unless the diagnosis of Crohn disease (CD) is ultimately made [3].

Pouch Anatomy

Initially, restorative proctocolectomy was performed using straight Ileoanal anastomosis (IAA) without the construction of a pouch. The results of multiple subsequent studies have shown the superiority of IPAA in comparison to straight ileoanal anastomosis [4, 5]. In the pediatric population, Telander et al. compared 121 children and young adults with either the straight IAA or the J-pouch procedure [4]. They found the J-pouch to be superior in relation to stool frequency and nighttime stool patterns. The IPAA procedure involves total abdominal colectomy with the upper internal anal sphincter and rectal muscular columnar cuff left intact. A pouch reservoir is then created utilizing the ileum and an anastomotic connection is made to the anus. J-type, S-type, and W-type pouch reservoirs have been fashioned, but the most common and successful procedure involves using the J-pouch (Fig. 44.1). Temporary loop ileostomies are performed at the time of pouch creation in either the two-step or three-step IPAA to facilitate healing of the anastomotic connection and are closed at a later date, typically 2–3 months. Contraindications to IPAA include a preoperative diagnosis of pelvic floor dysfunction and decreased anal sphincter muscle tone. CD is a relative but not absolute contraindication and a pouch procedure can be necessary if control of colonic disease is refractory to medical therapy, recognizing the potential long-term complications including pouch failure requiring excision in up to 40% [6, 7].

Pouch Function

Short-term results are excellent with minimal mortality related to the procedure. A majority of patients are satisfied with the long-term outcomes after the IPAA procedure. Maintenance of bowel continence with a satisfactory functional outcome ranks high with these patients. Lightner et al. reported a mean stool frequency of approximately 6 per day and 2 per night along with one-third having occasional or frequent daytime bowel incontinence and two-thirds having occasional or frequent nighttime bowel incontinence in a large, single-center cohort with up to 30 years of follow-up [8]. In addition, quality of life remains relatively high after recovery from IPAA with little difference between UC, CD, or FAP [9]. However, there can be significant morbidity related to IPAA. Long-term complications include pouchitis, pouch dysfunction, issues related to fertility, stenosis, ischemia, and fistulae related to CD.

Pouchitis

Definition and Incidence

Pouchitis is defined as inflammation of the ileal reservoir in patients' status-post proctocolectomy with IPAA. Pouchitis is the most common long-term complication of IPAA and is a significant cause of morbidity related to the procedure. Inflammation in an ileal continence reservoir after proctocolectomy was first described in the literature by Kock et al. in 1977, prior to the first description of the IPAA [10]. This was later coined "pouchitis" when inflammation occurs in the IPAA. Since the initial description, multiple investigators have attempted to characterize pouchitis and delineate the underlying pathophysiology which may be multifactorial. The diagnosis of pouchitis is based on clinical symptoms, endoscopic findings, and histologic findings (Fig. 44.1).

The frequency of pouchitis reported by different groups has varied significantly. However, it is well established that the incidence of pouchitis is higher for patients with ulcerative colitis as compared to patients with FAP. The incidence of reported pouchitis in patients with UC has increased with improvements in medical record data acquisition of both pediatric and adult patients with 10-year rates in both groups in the range of 32–55% and a cumulative incidence at 30 years of 81% [7, 8, 11–15]. In comparison, the incidence

of pouchitis in FAP patients is less than half the UC rate at 22.1% with a median follow-up of 8 years [16].

In pediatric patients, Ozdemir et al. reviewed the outcomes of 433 pediatric patients after IPAA (83.4% with inflammatory bowel disease (IBD), 15.7% with FAP) and found the incidence of pouchitis at 31.9% with a mean follow-up of 9 years [14]. The occurrence of pouchitis was not associated with specific pouch types in this mixed surgical group (J- vs. S-pouch). Shannon et al. reported the incidence of pouchitis incidence at 45% at a mean of 20 years post procedure in pediatric patients along with a change in diagnosis to Crohn disease in 28% [7]. Risk factors for the development of pouchitis in pediatric patients include a high disease activity index at diagnosis of UC, younger age at the time of surgery, and vitamin D deficiency at the time of surgery [11–13].

Etiology and Pathogenesis

Although there has been much interest in defining and classifying pouchitis, the etiology of pouchitis remains unknown. There are a number of proposed factors that may play a role in pathogenesis. It is most likely that the development of pouchitis is multifactorial with several physiological and immunological factors contributing in a susceptible host. The frequency of pouchitis may vary based on the center, surgical experience, and follow-up medical care. Table 44.1 lists the proposed etiological factors that contribute to the development of pouchitis [17].

Fecal Stasis and Dysbiosis

The favorable response of the majority of acute episodes of pouchitis to antibiotic therapy and more recently to the administration of probiotics suggests that bacterial populations are important etiological factors in the development of pouchitis. Pouchitis also rarely occurs until after the takedown of the ileostomy with a resultant resumption of fecal flow to the neo-ileum pouch. However, to date, no single microbial factor has been identified as the causative factor. Fecal stasis in the pouch may also be a contributing factor. A study of rats who received IPAA after colectomy had longer fecal retention and higher rates of inflammation in the pouch compared to rats who underwent straight ileorectal anastomosis [18]. Regarding dysbiosis, 16s ribosomal RNA sequencing has demonstrated altered microbial diversity in patients with pouchitis at multiple taxonomic levels including an increase in the pro-inflammatory Fusobacteria and Enterobacteriaceae species, and a decrease in the anti-inflammatory Bacteroidetes species, similar to that seen in CD [19–21].

Table 44.1 Proposed etiology of pouchitis (Adapted from Macafee et al.) [17]

Immune dysregulation
Dysbiosis
Fecal stasis
Malnutrition
Mucosal ischemia (tension, torsion, or vascular)
Crohn disease, undiagnosed
Colonic metaplasia with associated ulceration
Extraintestinal manifestations of IBD, including primary sclerosing cholangitis
Smoking
pANCA status

Other studies have looked at the role of serological markers, such as antibodies to bacterial and yeast fragments, in the pathogenesis of pouchitis in addition to IBD. Serological markers such as anti-*Saccharomyces cerevisiae* antibodies (ASCA) have been found to be associated with postoperative fistula formation after restorative proctocolectomy [22]. Antibodies to OmpC, an outer membrane porin from *E. Coli,* and I2, an antigen to *Pseudomonas fluorescens*, were found to be predictive of postoperative continuous inflammation of the pouch [23]. In 2001, Fleshner et al. studied the relationship between pouchitis and serum perinuclear antineutrophil cytoplasmic antibody (pANCA), which has cross-reactivity to bacterial antigens including OmpC, in a prospective study [24]. They did not find an overall significant difference in the occurrence of pouchitis in the pANCA-positive versus pANCA-negative groups. They did, however, demonstrate a significant relationship between the development of chronic pouchitis in patients with a high level of pANCA (>100 EU/mL) as compared to patients with a medium level (40–100 EU/mL), low level (<40 EU/mL), or undetectable level of pANCA. Investigating the impact of preoperative pANCA and anti-CBir1 flagellin on the development of pouchitis, a follow-up study by Fleshner et al. showed that patients with a high level of pANCA and positive anti-CBir1 expression have an increased incidence of chronic pouchitis after IPAA [25]. These findings are suggestive of a pathogenic immune response to bacterial antigens.

Infection with *Clostridium difficile* has been increasingly recognized as a problematic cause of diarrhea in IBD patients with both pre- and post-colectomy with IPAA. *C. difficile* as a cause of pathogen-associated pouchitis is diagnosed in up to 10% of adults with an increased risk in patients with recent hospitalization, those receiving antibiotics, and males [26, 27]. When possible, PCR testing for *C. difficile* toxin B is more sensitive than enzyme immunoassay though neither is specific and clinical context needs to be considered for patients who may be colonized with this bacteria [28]. Evaluation with either pouchoscopy or fecal calprotectin levels may help to establish inflammation in the setting of symptoms in patients positive for *C. difficile*. As many of the

patients have already been on metronidazole, vancomycin should be considered first-line treatment. Recurrent or persistent *C. difficile* may also require a fecal microbial transplant to eradicate [29].

Immune Dysregulation

One of the most pursued areas of research is the influence of variations of gene loci on the development of IBD. As cytokines play a major role in the inflammatory pathway that leads to disease manifestations, many studies have focused on the role of cytokines such as Interleukin (IL)-1 alpha, beta, and receptor antagonist (ra) in the etiology of IBD. IL-1 alpha and beta are pro-inflammatory cytokines, whereas IL-1ra is the natural inhibitor of these cytokines. Genetic polymorphisms that lead to a reduction in the ratio of IL-1ra to IL-1 alpha and beta will potentially lead to increased and/or chronic inflammation [30].

It is also possible that an imbalance in the ratio of IL-1 alpha and beta to IL-1ra may influence the initiation of inflammation leading to pouchitis in patients status-post IPAA. In 2001, Carter et al. reported that patients that developed pouchitis had a higher IL-1RN*2 carrier rate as compared with patients that did not have the particular allele, 72% versus 45%, respectively [31]. IL-1RN*2 represents a polymorphism in the IL-1 gene cluster that has been associated with a change in the ratio of IL-1 alpha and beta to IL-1ra and the development of ulcerative colitis. This finding suggests that patients with ulcerative colitis that carry this allele may have an increased tendency of developing pouchitis after IPAA.

More recent studies have identified other genetic polymorphisms and cell-membrane receptors that are associated with pouchitis. The NOD2/CARD15 mutations have been shown to be associated with the development of pouchitis, and in some instances, a more severe manifestation of the primary disease [32–34]. These mutations are also associated with several markers of disease severity in pediatric CD [35]. It is therefore highly probable that these patients may actually have CD involving the pouch.

Intestinal epithelial expression of the innate Toll-like receptors (TLRs) 2, 4, and 5 are activated by bacterial peptidoglycan, lipopolysaccharides, and flagellin and lead to a complex downstream cascade of inflammatory signaling mediated by NFκB. These TLRs have been shown to be upregulated in patients with pouchitis [36]. Lammers et al. showed that patients who possess Toll-like receptor (TLR) 9-1237C and CD14-260T alleles have a higher risk of developing chronic or relapsing pouchitis [37]. Alterations in tight junction claudin-1 and 2 expressions in biopsies of patients with pouchitis also indicate increased barrier dysfunction as a possible cause of the inflammation [38].

A novel concept of immunoglobulin G4 (IgG4) associated pouchitis has been described [39, 40]. Seril et al. demonstrated a high prevalence of IgG4-expressing plasma cells in the pouch of patients with chronic antibiotic-refractory pouchitis (CARP) [41]. Patients with CARP were also more likely to have autoimmune thyroid disease, primary sclerosing cholangitis (PSC), and serum microsomal antibodies suggestive of an autoimmune-mediated pouchitis. Future studies are needed to further investigate the role of IgG4 in the etiology, pathogenesis, and prognosis of patients with pouchitis.

Mucosal Ischemia

During pouchoscopy, if the pattern of inflammation is isolated to a specific limb or wall of the pouch, ischemia should be considered as an etiology of the pouchitis. Ischemia can arise from tension on the pouch when it is pulled into the pelvis during surgery, either from torsion of the pouch when attached to the cuff or by leaving a long cuff resulting in a mobile base for the pouch to rotate on. Ischemia can also occur from decreased tissue perfusion as a vasculitic component of the underlying disease [29]. Ischemic pouchitis can be evaluated under fluoroscopy and by a surgeon for tension-induced ischemia which may require revision. If there is no evidence of tension in the pouch, a more global ischemic process may be the cause. Ischemia has been proposed as a contributing factor in intestinal inflammation after the observation that patients with IBD improved after treatment with hyperbaric oxygen therapy (HBOT). Two studies published in 2020 report the improvement of pouch complications (n = 67) including refractory pouchitis, cuffitis, pouch fistula, pre-pouch ileitis, and ischemic pouchitis in which patients had a significant improvement defined as a decrease in the modified PDAI after a median of 30 treatments with HBOT [42–44]. A 2014 review by Dulai et al. evaluated 17 studies in which HBOT was administered for either UC or CD (including perianal disease) with varying protocols and 86% of patients responded (n = 613, mean 14.6 treatments/patient) [45]. The most common complication from treatment was middle ear barotrauma and tympanic membrane perforation (1.5% of patients, 0.1% of all treatments). More studies including randomized control trials (RCT) should be completed to further evaluate this therapy.

Crohn Disease of the Pouch

Undiagnosed Crohn disease (CD) can present clinically as chronic pouchitis following IPAA. The most common manifestations of CD noted for patients status-post IPAA are fistulizing disease of the pouch, pre-pouch ileitis, and strictures

not related to the anastomosis. In adults, a 2020 single-center study by Kayal et al. reported the development of CD of the pouch in 12% of patients (n = 46/386) at a median time of 2.1 years after completion of IPAA [46]. An additional single-center study by Barnes et al. reported similar results with a 9% cumulative incidence in the development of CD of the pouch in adults (n = 594) [15]. A 2012 study by Coukos et al. also demonstrated the association of ASCA-IgA, ASCA-IgG, and anti-CBir1 flagellin in the development of CD of the pouch or fistula in patients with UC after IPAA [47]. In pediatrics, the rate of CD after IPAA for UC ranges from 5% at 7 years to 28% at 20 years of follow-up [7, 14, 48]. In addition, Shannon et al. reported 28% of pediatric patients with long-term follow-up were ultimately diagnosed as having CD of which 40% required pouch excision [7].

Extraintestinal Manifestations

The presence of extraintestinal manifestations related to inflammatory bowel disease has been studied as possible predictor of the development and severity of pouchitis. One of the first reports in 1990 by Lohmuller et al. looked at extraintestinal manifestations (EIMs) such as erythema nodosum, arthritis, and uveitis to determine a relationship with pouchitis in a retrospective study of 734 patients with IPAA with a mean follow-up of 3.4 years [49]. Their group found that pouchitis occurred in 39% of patients with preoperative EIMs as compared to 26% of UC patients with no preoperative EIMs ($p < 0.001$). They also found an increased risk of pouchitis if postoperative extraintestinal manifestations were later diagnosed. They did not, however, analyze the risk of pouchitis due to individual EIMs.

There are few studies dedicated to analyzing the relationship between primary sclerosing cholangitis (PSC) and the development of pouchitis. In 1996, Penna et al. found that pouchitis occurred in 63% (34/54) of the patients with PSC, while pouchitis only occurred in 32% of the patients without this particular EIM ($p < 0.001$) [50]. This group also reported an increased frequency of chronic pouchitis in patients with PSC versus patients without this disease, 60% and 15%, respectively ($p < 0.001$). In 2010, Wasmuth et al. reported an increase in both acute and chronic pouchitis in those patients with PSC (n = 11), but no increased risk with other EIMs including pyoderma gangrenosum (n = 6) and arthritis (n = 12) [51]. More recently, Barnes et al. reported a 5% incidence of pouchitis in those with PSC compared to 1% without PSC (p = 0.007) and an adjusted odds ratio of 3.94 (95% CI 1.05–14.8) at 2-year follow-up after IPAA; however, this is based on a total of 13/394 patients with PSC in the cohort [15]. Shen et al. also demonstrated that concurrent PSC appears to be associated with a significant pre-pouch ileitis on endoscopy and histology in patients with IPAA [52].

Cuffitis

After IPAA, a region of colonic columnar mucosa remains unless a mucosectomy is performed [53]. It has been shown that patients have markedly better pouch function when mucosectomy is not performed and this is the preferred treatment modality in the absence of dysplasia. As a result, a "cuff" remains above the anal transitional zone (Fig. 44.2). The length of the cuff is dependent on the type of IPAA performed. After a stapled IPAA, the preferred method by adult colorectal surgeons, a region of 1.5–2 cm of diseased mucosa remains. A hand-sewn IPAA has traditionally been performed by pediatric surgeons and leaves a variably smaller cuff region or no cuff when mucosectomy is also performed. Neither method is superior to the other as far as complication rate but the stapled IPAA is typically preferred as it is associated with improved nocturnal continence with higher resting and squeeze pressures of the pouch demonstrated by anorectal manometry [54].

As expected, the remaining diseased columnar mucosa can develop inflammation, a term coined "cuffitis." Patient symptoms include anal pain or discomfort, bleeding, discharge, or diarrhea and endoscopic features typical of colitis in the cuff region (erythema, friability, ulceration). Thompson-Fawcett et al. biopsied the cuff of 113 patients after stapled IPAA and found 13% had evidence of acute inflammation, most of which was mild and 9% were symptomatic [55]. Wu et al. followed 120 patients with cuffitis (12.9%) from their registry of 931 pouch patients over a median of 4 years and found no difference in the demographics, risk factors, extent, or severity of disease compared to controls without cuffitis [56]. Of these patients, 33% responded to topical 5-ASA/steroid therapy, 18% relapsed after initial response to 5-ASA/steroid therapy, and 48% did not respond to topical therapy and required immunotherapy. Sixteen patients (13.3%) with cuffitis ultimately had a failure of the pouch due to CD of the pouch (N = 7; 43.7%), refractory cuffitis (N = 5; 31.3%), or surgical complications (fistula, sinus) requiring diversion or pouch reconstruction (N = 4; 25%) a median of 6 years after IPAA. More recently, Kayal et al. reported the development of cuffitis in 30.1% of patients at a median time of 1 year after IPAA with significant risk factors for cuffitis including a rectal cuff length ≥2 cm and medically refractory disease preoperatively [46]. Cuffitis and greater cuff length were also significant risk factors for pouch failure. As a small segment of colonic mucosa remains in situ, the risk for dysplasia remains equally present in the cuff as in the pouch [57].

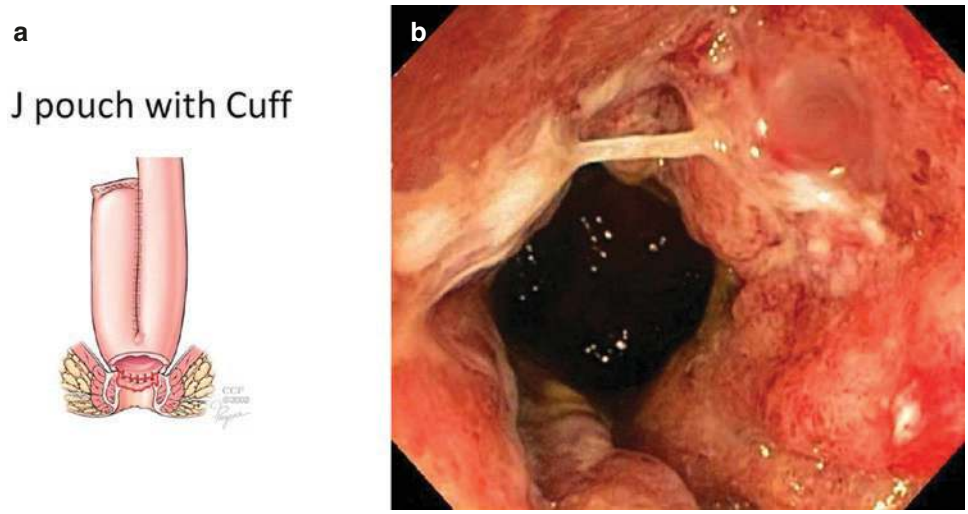

Fig. 44.2 (**a**) Schematic drawing of constructed "J" pouch with cuff outlined in red. (**b**) Inflamed cuff or "cuffitis" at the distal end of J-pouch

Smoking

It has previously been established that cigarette smoking is associated with a reduction in the risk of developing ulcerative colitis. In 1996, Merrett, et al. also described a link between smoking and a reduction in the incidence of pouchitis in patients after IPAA. Their study documented that 18/72 (25%) of nonsmokers were diagnosed with pouchitis, while 1/17 of smokers (5%) were diagnosed with pouchitis. The reason for these findings is unclear, but may be related to the effect of smoking on gut mucosal permeability [58]. Fleshner et al. performed a multivariate analysis of clinical factors associated with pouchitis after IPAA. They showed that smoking and the use of steroids prior to colectomy were associated with acute pouchitis, while smoking in itself appeared to protect against the development of chronic pouchitis [59].

Diagnosis

The first episode of pouchitis occurs most often in the first 6 months after the closure of the loop ileostomy; however, it can occur at any time after IPAA is performed. To accurately make a diagnosis, a combination of clinical symptoms, endoscopic appearance, and histologic findings are typically utilized. The clinical presentation of pouchitis typically includes a combination of increased stool frequency, abdominal cramping, hematochezia, bowel incontinence, and/or low-grade fever. In practice, a presumptive diagnosis of pouchitis is often made based on clinical symptoms alone. However, as in irritable pouch syndrome, the endoscopic and histologic inflammation or lack thereof may not correspond to the degree of symptoms and pouchoscopy is necessary for clinical decision-making. Pouchoscopy still remains the main tool for establishing a diagnosis and also for evaluating other differential diagnoses in suspected cases of pouchitis [60]. Endoscopic findings involve assessing the severity of inflammation of the pouch mucosa. Signs of inflammation include erythema, edema, granularity, mucosal ulceration, and friability. The afferent and efferent limp of the pouch are most often affected and should routinely be biopsied (Fig. 44.1). In addition, if the inflammation of the pre-pouch ileum is visualized, this finding is suggestive of CD, though no standard definition for the extent of inflammation beyond the ileum exists.

Several scales for diagnosing and grading pouchitis have been developed over the last two decades. The PDAI (Table 44.2) is the most commonly used scale encompassing symptoms, endoscopic findings, and histologic grading with a score of ≥7 qualifying as a diagnosis of pouchitis [61]. The modified PDAI was validated to exclude the histologic grading with a score of ≥5 establishing a diagnosis of pouchitis [42].

Histology of the pouch should not classify a diagnosis of pouchitis alone as there is often mild chronic changes including expansion of chronic inflammatory cells, villous atrophy, and crypt hyperplasia even in a normal appearing pouch [62]. These changes are likely the adaptation of the mucosa to its role as a reservoir. Histologic evaluation is invaluable in identifying some of the other secondary causes of pouchitis such as pathogens like cytomegalovirus (CMV) or Candida, ischemia, mucosal prolapse, granulomas, and dysplasia [63].

The histology may be graded on an ABC scale, often used for research purposes. Type A mucosa is described as normal mucosa or mild villous atrophy with no or minimal inflammation. Type B mucosa is described as transient atrophy

with temporary moderate to severe inflammation followed by normalization of the architecture. Type C mucosa is described as persistent atrophy with permanent subtotal or total villous atrophy developing from the early functioning period accompanied by severe pouchitis and thus requires follow-up pouchoscopy to diagnose [64]. Type B and C mucosa are most often found in pouchitis and are discussed as a predictor of outcomes later in this chapter. When a diagnosis of pouchitis is made, evidence of acute and chronic inflammation is typically present on biopsy samples.

Other laboratory tests such as stool studies for *Clostridium difficile* infection may be important, especially in patients with chronic antibiotic refractory pouchitis. Inflammatory markers in the serum may be useful noninvasive adjuncts in the evaluation of patients with suspected pouchitis. Studies evaluating the erythrocyte sedimentation rate (ESR) as a marker of pouchitis have shown that despite its role as a nonspecific marker of inflammation, it does correlate with PDAI and episodes of pouchitis [65, 66]. Elevation of the serum C-reactive protein is a nonspecific marker of inflammation, but this was also found to correlate with the PDAI score and the presence of endoscopic inflammation in the pouch and afferent limb. Fecal inflammatory markers usually are reflective of the presence of intestinal inflammation. Fecal calprotectin and lactoferrin levels have been found to correlate with pouchitis and PDAI scores in a number of studies [67, 68]. These fecal markers could serve as potential adjunctive tests in the initial evaluation of patients with pouchitis but their role in the overall management of these patients still needs to be clearly elucidated.

Table 44.2 Pouchitis disease activity index (PDAI) (Adapted from Sandborn et al.) [61]

Clinical criteria	Score
Stool frequency	
Usual postoperative stool frequency	0
1–2 stools/day > postoperative usual	1
3 or more stools/day > postoperative usual	2
Rectal bleeding	
None or rare	0
Present daily	1
Fecal urgency or abdominal cramping	
None	0
Occasional	1
Usual	2
Fever (>100.5 °F)	
Absent	0
Present	1
Endoscopic criteria	
Edema	1
Granularity	1
Friability	1
Loss of vascular pattern	1
Mucus exudates	1
Ulceration	1
Acute histologic pattern[a]	
Polymorphonuclear infiltration	
Mild	1
Moderate with crypt abscesses	2
Severe with crypt abscesses	3
Ulceration per low-power field (mean)	
<25%	1
25–50%	2
>50%	3

Pouchitis defined as a total PDAI score of 7 or above

[a]Modified PDAI excludes the acute histologic pattern with a score of 5 or above defining pouchitis [42]

Classification

The classification of pouchitis can be made based on several different factors (Table 44.3). Severity varies from remission to severely active. Duration varies from acute (less than 4 weeks) to chronic (more than 4 weeks or more than 3 episodes of pouchitis in a 12-month period). Frequency varies from infrequent to continuous. Chronic pouchitis can also be differentiated by the response to therapy including chronic antibiotic-dependent pouchitis (CADP) and antibiotic-refractory pouchitis (CARP). CADP describes those that continue to respond to antibiotics but are unable to discontinue without relapse, while CARP describes those who do not respond to antibiotics and lack features of CD of the pouch. Response to therapy is described as antibiotic-responsive, antibiotic-dependent, or antibiotic-resistant (refractory) [6, 9]. In addition, it must be considered that not all patients status-post IPAA with symptoms of diarrhea and abdominal pain will truly have idiopathic inflammatory pouchitis. Other disease entities that may result in pouchitis include cuffitis, stenosis of the pouch, CD, and infectious bowel disease (most often secondary to *Clostridium difficile* or Cytomegalovirus). Yet, others will have functional symptoms without inflammation as in the case of irritable pouch syndrome.

Table 44.3 Classification of pouchitis (Adapted from Wu and Shen) [104]

Classification	Description
Severity	Remission
	Mildly active
	Moderately active
	Severely active
Duration	Acute (less than 4 weeks)
	Chronic (more than 4 weeks)
Frequency	Infrequent (1–2 episodes)
	Relapsing (more than 3 episodes)
	Continuous
Response to therapy	Antibiotic-responsive
	Antibiotic-dependent
	Antibiotic-refractory

Treatment

Most of the published literature for the treatment of pouchitis is retrospective with fewer than 20 prospective, RCTs, none of which are in the pediatric age group [69]. Therefore, a majority of treatment regimens for both acute and chronic forms of pouchitis are based on empiric data alone. Treatment approaches include both primary prophylaxis and treatment following the development of symptoms.

Prophylaxis

The use of probiotics is proposed to increase the normal, healthy flora of the colon such that concentrations of unhealthy microflora are reduced and the incidence and severity of pouchitis are decreased. The De Simone Formulation (formerly known as VSL#3) (Visbiome®, ExeGI Pharma, Rockville, MD) contains four strains of *Lactobacillus*, three strains of *Bifidobacterium*, and *Streptococcus thermophilus*. One week after ileostomy closure, an RCT demonstrated 10% (2/20) of patients treated with 1 packet of the De Simone Formulation (900 billion bacteria) developed acute pouchitis within 12 months versus 40% (8/20) of patients who received placebo [70]. In a separate study, the first episode of pouchitis has also shown to be delayed in patients given *Lactobacillus rhamnosus* GG following IPAA; however, probiotics have not been found to be efficacious in the treatment of acute pouchitis [71, 72]. There is an ever-growing number of probiotics now on the market while there is a paucity of RCTs to evaluate primary prophylaxis of pouchitis or if one particular brand of probiotics is more effective than another.

Acute Pouchitis

Acute episodes of pouchitis respond to antibiotic therapy most of the time. The first-line antibiotics of choice for acute pouchitis are a 14-day course of metronidazole (15–20 mg/kg/day divided BID or TID) or ciprofloxacin (20–30 mg/kg/day divided BID). In the past, metronidazole alone was considered to be first-line therapy. The first controlled study with this drug was published by Madden et al. in 1994 [73]. They performed a double-blind, crossover trial comparing metronidazole with placebo in 11 patients with chronic pouchitis and reported that patients treated with metronidazole had a decrease of three bowel movements per day as compared with an increase of one bowel movement per day on placebo ($p < 0.05$). Treatment with metronidazole may be limited due to the adverse events of nausea, metallic taste, and paresthesia. Later studies showed the efficacy of ciprofloxacin. In an unblinded RCT by Shen et al., it was reported that both ciprofloxacin and metronidazole significantly improved PDAI scores [74]. In addition, the ciprofloxacin group experienced significantly larger reductions in PDAI scores and decreased side effects as compared with metronidazole. Fluoroquinolones have been associated with arthropathy and tendon rupture in all ages and this should be considered when prescribed to children. Both metronidazole and ciprofloxacin are now considered first-line therapy for acute pouchitis (Fig. 44.3).

Rifaximin, an inhibitor of bacterial DNA-dependent RNA polymerase, has been used as monotherapy in a pilot study by Isaacs et al. [75]. This study showed clinical remission occurred more frequently in patients on rifaximin (2/8) compared to the placebo (0/9), but the difference was not significant ($p = 0.2$). Patients were treated with rifaximin for 4 weeks and there was no difference in adverse events between treatment and placebo.

Chronic Pouchitis

In pediatric patients, Nyholm et al. reported that 19% developed chronic pouchitis with a median follow-up of 6.4 years, an incidence similar to adults [9, 48]. The medical treatment of chronic pouchitis including CADP and CARP is less studied. Shen et al. conducted an open-label trial using rifaximin as a maintenance agent after initial treatment with a conventional antibiotic, for adult patients with CADP ($n = 53$) [76]. After 96% of patients responded to initial therapy, 65% of these initial responders maintained remission at 3 months on a daily median dose of 200 mg rifaximin. Larger trials with long-term follow-up of patients are needed to fully understand the benefits that may accrue from the use of rifaximin in the treatment of patients with pouchitis. The anecdotal goal for the treatment of CADP is to maintain the lowest dose of antibiotics possible.

Tinidazole, a nitroimidazole derivative, has been used in combination with ciprofloxacin in the treatment of CARP [77]. This combination led to a significant reduction in the PDAI scores and also an improvement in quality of life scores after 4 weeks of therapy. In 2004, a study evaluating the effectiveness of combination therapy of rifaximin and ciprofloxacin was published in patients with CARP [78]. Eight patients with chronic pouchitis refractory to ciprofloxacin alone were treated with rifaximin and ciprofloxacin for 2 weeks. Eighty-eight percent (7/8) of the patients responded to therapy and five went into remission for at least 6 months. Additional medications that have been used in the treatment of CARP include 5-ASA products (i.e., oral mesalamine, rectal mesalamine suppositories, and enemas), topical and oral steroids (i.e., prednisone or budesonide), bismuth-containing products, and anti-TNF therapy. In a prospective, open-label study, Gionchetti et al. reported 15/20 patients treated with oral

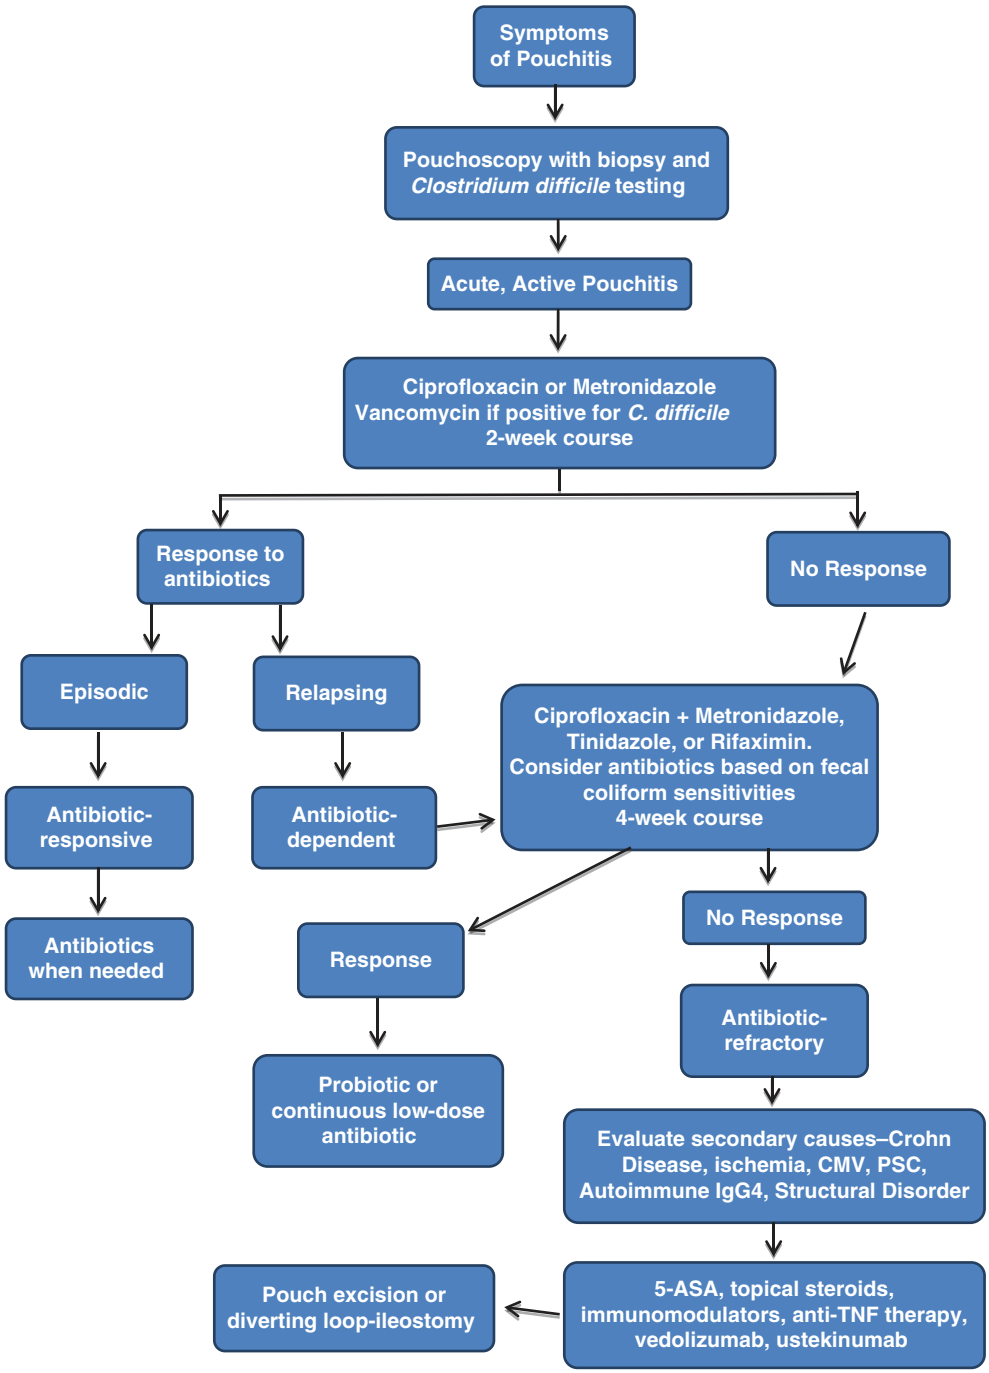

Fig. 44.3 Treatment algorithm for management of pouchitis (Adapted from Shen) [6]

budesonide 9 mg daily achieved clinical remission of CARP at 8 weeks [79]. In a retrospective review, Chopra et al. reported that 8/13 patients had a favorable or moderately favorable response of pouchitis (excluding CD of the pouch) to oral budesonide 9 mg daily at follow-up [80].

In an RCT published in 2000, Gionchetti et al. showed that treatment with the De Simone Formulation for 9 months following antibiotic treatment compared with antibiotic treatment alone was statistically significant in maintaining remission from pouchitis [78]. In 2005, a double-blind placebo-controlled trial examined the expression of pro-inflammatory cytokines in patients diagnosed with pouchitis who were treated with the De Simone Formulation [81]. The results revealed that the expression of mRNA for the pro-inflammatory cytokines IL-1 beta, IL-8, and IFN-gamma in patients treated with the De Simone Formulation was significantly decreased as compared with placebo. The levels of all of these cytokines were decreased at least twofold. A pooled meta-analysis of placebo-controlled RCTs on the use of probiotics showed that probiotics were beneficial in the

management of pouchitis, though each study evaluated patients in different stages of the disease [82].

For patients' status-post IPAA who are subsequently diagnosed with CD of the pouch or CARP, anti-TNF therapy including infliximab is an option that has been utilized as a part of the treatment regimen. In the adult population, a systematic review of papers and abstracts reported a cumulative short-term response of 80% and long-term response of 50% in 140 patients treated with infliximab for chronic pouchitis [83]. There is one case series in the pediatric literature supporting these findings in which 3/4 of patients treated with infliximab for CD of the pouch remained on infliximab therapy at a 2-year follow-up with a significant response [84].

Several reports have been published on the efficacy of vedolizumab for refractory pouchitis [85–88]. The largest study was a multicenter, retrospective cohort by Gregory et al. who reported a 51.8% clinical response, 19.3% remission, and 54% endoscopic response at any point during 12-month follow-up in 83 patients with either CD of the pouch, CADP, or CARP treated with vedolizumab [85].

There have been two reports on the use of ustekinumab for CD of the pouch or chronic pouchitis, one multicenter, the other single-center. Weaver et al. reported a clinical response rate of 83% after 6 months of ustekinumab treatment in 56 patients from four US centers; however, only 11% of patients with CD of the pouch and none with chronic pouchitis were in clinical remission at 6 months [89]. Interestingly, males were significantly less likely than females to respond to ustekinumab (30% vs 83%; $p = 0.014$). There was also no difference in the rate of response in those treated with biologics versus no biologics prior to colectomy. In a single-center retrospective study of CARP only (CD of the pouch excluded) by Ollech et al., 50% of patients had a clinical response on ustekinumab during a median follow-up time of 12.9 months ($n = 24$) [90].

There has been limited evaluation of the use of fecal microbiota transplantation (FMT) in chronic pouchitis. The single RCT of FMT for CADP was halted due to a lack of response. This was followed by a prospective, open-label pilot study in adults who did not find a significant change in the PDAI or endoscopic scores of 19 patients who received a single FMT for chronic pouchitis [91]. At current, there is no evidence of efficacy of FMT for the treatment of acute or chronic pouchitis.

The medical treatment algorithm for acute and chronic pouchitis is shown in Fig. 44.3. The antibiotic treatment of the first, acute episode of pouchitis should be either metronidazole three times per day for 14 days or ciprofloxacin twice per day for 14 days. If a patient is diagnosed with antibiotic-dependent or antibiotic refractory pouchitis, alternative therapies include prolonged antibiotic therapy or a combination of various antibiotic therapies with the option of additional therapy with probiotics such as the De Simone Formulation. Failure of response to these therapeutic options should warrant the consideration of other secondary causes of pouchitis such as *Clostridium difficile* and other pathogens in the stool. The addition of anti-inflammatory or immunosuppressive therapy to the treatment regimen should be considered at this point.

Surgical

Pouch failure is an unfortunate consequence that results from a number of complications with the most common being pouch dysfunction, pouch fistulae, refractory pouchitis, pelvic sepsis, anastomotic leak, pouch prolapse, stricture, and development of Crohn disease. In adults, pouch failure occurs more commonly in Crohn disease than in UC (13.3% vs 5.1%) [9]. In pediatrics, with a mixed series of indications for IPAA over a 27-year period and mean follow-up of 9 years, 9% (39/433) had pouch failure requiring small bowel diversion or excision of the pouch of which 4 were for pouchitis and 3 for Crohn disease [14]. Pouch failure can result in excision of the pouch, diversion with a proximal loop ileostomy, or an inability to reverse a diverting ileostomy from primary colectomy.

Outcome

One of the most concerning potential complications of long-term inflammation of the surgically created pouch is dysplasia and progression to malignancy. Overall, the incidence of dysplasia in the pouch is more common for patients with FAP than for those with ulcerative colitis. For patients with FAP, dysplasia is more often related to the development of adenomas in the pouch. For patients with IBD, the development of dysplasia is related to ongoing chronic inflammation. A 2016 systematic review and meta-analysis analyzing the risk of neoplasia after colectomy for IBD reported a pooled prevalence for dysplasia in the pouch of 0.8% ($n = 7647$) and carcinoma in the pouch of 0.5% ($n = 8403$) [92]. The cumulative incidence of dysplasia in the pouch in that series was 0.6%, 1.5%, and 3.0% at 5, 10, and 20 years post-IPAA, respectively.

No long-term studies have been performed to delineate the overall risk of malignancy in the pediatric patient population. In an early report looking at the incidence of dysplasia after IPAA, Sarigol et al. did not find any evidence of dysplasia in the biopsies obtained during pouchoscopy from 76 children with a mean follow-up of 5 years after IPAA including 5 of which had dysplasia at time of colectomy [93]. Gullberg et al. compared the risk of dysplasia in adult's status-post IPAA with Type A histology of the pouch (normal mucosa or mild villous atrophy) compared with Type C

histology of the pouch (persistent atrophy with severe inflammation). They determined that 5/7 of patients with Type C mucosa developed dysplasia while no patients 0/14 with Type A mucosa developed dysplasia after a median of 9 years with IPAA [94]. These findings are consistent with other research and confirm that patients with Type C mucosa are at a higher risk of dysplasia and possibly malignant lesions in the pouch. There are currently no consensus guidelines for endoscopic surveillance for dysplasia screening for adults or pediatric patients who are status-post IPAA.

Noninflammatory Pouch-Related Complications

Irritable Pouch Syndrome

Irritable Pouch Syndrome (IPS) was initially described by Shen et al. when 42% of adult patients enrolled for endoscopic evaluation of pouchitis symptoms had normal endoscopic and histologic evaluations [95]. The most common symptoms of IPS were increased stool frequency (88.5%) and urgency or abdominal pain (46.1%). In the study by Shen along with a 2007 study by Schmidt et al., IPS could not be differentiated from pouchitis based on clinical symptoms [96]. A follow-up study by Makkar, Shen et al. surveyed those with IPAA and found the quality of life of patients with IPS was similar to those with pouchitis [97]. Patients with IPS were more likely to be taking medication for depression, anxiety, or pain, including narcotics, than those with pouchitis. These findings stress the importance of endoscopy to diagnose pouchitis, as IPS represents a common and significant entity that should be treated as a functional disorder rather than an inflammatory one.

Floppy Pouch Complex

Floppy Pouch Complex (FPC) is a relatively new diagnosis described in 2018 by Khan et al. to characterize a number of mechanical pouch issues related to an elongated and malleable pouch resulting in the folding of the pouch, pouch prolapse, or afferent limb syndrome [98]. FPC typically presents with dyschezia associated with straining and sensation of incomplete evacuation, similar to that of a patient with constipation or proctitis. Pouchoscopy is helpful to evaluate for pouchitis and for signs of FPC, while defecography is often the best test to exhibit abnormal descent, protrusion, or redundancy of the pouch resulting in folding. Pouch prolapse is classified as either full-thickness prolapse, which may be seen on a physical exam with straining, or mucosal prolapse, which requires pouchoscopy and a contrast enema or defecography to visualize. Both types of prolapse may result in ischemia with ulcerations in the region of redundant tissue. Afferent limb syndrome (ALS) occurs when the inlet of the pouch from the small bowel is angulated or twisted without a luminal stricture and results in partial obstruction of the small bowel leading into the pouch. Milder forms of FPC including prolapse are often treated with fiber and biofeedback to avoid straining. Severe and refractory FPC may require pexy of the pouch or pouch reconstruction. It is important to note that none of the treatments for FPC have been validated. Further, recognition of mechanical pouch issues as a significant complication of IPAA is important as these may also have a significant impact on pouch function and quality of life.

Fertility

While fertility has not been shown to be affected in those with UC prior to surgery, issues related to female fertility after surgery are a well-recognized complication. The historical rate of infertility after IPAA has been reported as high as 90%, and a 2019 Cochrane review estimated a fivefold increase in the relative risk of infertility 24 months pre- to post-IPAA [99, 100]. A Danish series examining birth rates over 30 years in women with UC after IPAA reported a 50% decrease in live births (27.6 children/1000 years) compared to those with UC without IPAA (56.8 children/1000 years) [101]. As infertility post-IPAA is often due to the structural impact on fallopian tubes, in theory, a laparoscopic approach to IPAA should offer a decrease in scarring and improvement in potential fecundity. While several studies have been published demonstrating lower rates of infertility with laparoscopic IPAA, the sample sizes have been insufficient to draw any significant conclusions [99].

Assisted reproductive technology (ART) for women after IPAA has a success rate of at least 50%, which is similar to that of the general population [102]. Potter et al. examined rates of pregnancy in women who underwent IPAA before 20 years of age (n = 93) and found that 73% were able to become pregnant of which 21% required ART, and 88% had a successful live birth [103]. While this study included patients with FAP in addition to patients with UC after IPAA, the rates of pregnancy, live birth, and ART were statistically similar in the two groups. Recognizing the potential impact of fertility complications is important when counseling patients, even when the issue may be many years away as in pediatric patients.

Summary

Total proctocolectomy with IPAA is the surgical procedure of choice for pediatric patients with ulcerative colitis. The procedure is generally well tolerated; however, pouchitis is the most frequent cause of morbidity. The majority of patients will experience isolated, acute episodes of pouchitis. Pouchoscopy remains the main tool for establishing the diagnosis of pouchitis, although other emerging noninvasive tests may serve as useful adjuncts in the diagnostic process. Therapeutic guidelines are generally empirically derived. Most patients respond to antibiotic treatment with ciprofloxacin or metronidazole. Others may be treated with a combination of probiotics, antibiotics, anti-inflammatory medications, and/or immunosuppressive medications. Takedown of the pouch is uncommon and is required only in a small minority of patients. There is however an increased incidence in the development of CD in pediatric patients with longer-term follow-up but a change in diagnosis to CD does not inevitably result in pouch failure. Dysplasia and malignancy are concerns for patients with chronic pouchitis and severe inflammatory changes. To date, dysplasia and malignancy of the pouch have not been diagnosed in pediatric-aged patients, although they may be at a higher risk for these complications in their lifetime due to the long duration of disease and other yet undetermined factors. In addition, noninflammatory complications of the pouch including irritable pouch syndrome, floppy pouch complex, and reduced fertility may have a significant impact on quality of life.

Enteral Feeding Devices and Ostomies

45

Judith J. Stellar

Gastrostomy

Children and adolescents with inflammatory bowel disease (IBD) often suffer the consequences of malnutrition and growth failure. Enteral nutrition as a therapy has been discussed prior to this chapter. Enteral access either via nasogastric tube (NGT) feedings or direct enteral access via a gastrostomy tube (G-tube) is an option for children with inflammatory bowel disease. Once it is clear that a patient requires supplemental calories to support growth and development, a trial of feedings via NGT is often done prior to more invasive percutaneous feeding tube placement. The trial of NGT feedings demonstrates tolerance of supplemental enteral formula and allows the patient and family to become familiar with the feeding delivery system, particularly the feeding bag setup and the pump. It is essential that families are educated regarding NGT placement, feeding administration, and maintenance of the tube and equipment.

Younger children may pose difficulty in keeping the NGT in place. There are products such as the AMT Bridle®, which help prevent the patient from pulling out the tube. Older children and adolescents may choose to place the NGT in the evening and remove it in the morning so as not to have to go to school or do other activities with the tube visible. For many patients and families, nasogastric tube feeding is cosmetically unappealing and difficult to maintain on a long-term basis. Eventually, this approach not only becomes burdensome but also causes daily discomfort. In these instances, if the supplemental feedings appear to be needed on a long-term basis, it becomes necessary to consider percutaneous gastrostomy tube (G-tube) placement.

Gastrostomy tube feeding is appealing for a number of reasons, but particularly because the tube does not require daily or frequent insertions and it is not visible to the outside world. The indications for placement are to provide long-term nutrition to patients who cannot orally ingest sufficient calories for appropriate weight gain and growth and for disease treatment. There are a variety of methods for G-tube placement including open surgical, laparoscopic, percutaneous endoscopic gastrostomy (PEG), or percutaneous radiologic gastrostomy (PRG). Several studies have compared surgical versus non-surgical techniques [1–4]. The type of procedure will depend on a number of patient-related factors including comorbidities, congenital anomalies, and the need for concomitant surgical procedures such as fundoplication. Non-surgical placement of a gastrostomy tube was first described 35 years ago [5, 6], and since that time the technique has been refined, including pre-procedural imaging such as an upper gastrointestinal series and/or abdominal ultrasound to delineate the anatomy. In the past, a percutaneously placed tube, either endoscopic or radiologic, was most often a tube that extends off the abdomen and is approximately 25–30 cm long and consists of an internal bumper and an external crossbar or securing disc (Fig. 45.1). More recently, a procedure for initial placement of a low-profile

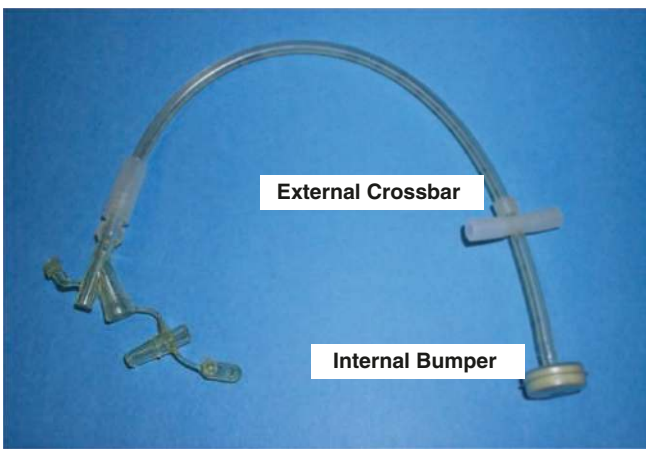

Fig. 45.1 Typical initial PEG/PRG tube with internal "bumper" and external "crossbar"

percutaneous G-tube has become popular and shown to be safe and effective in pediatric patients [7–9]. These types of tubes are available in a mushroom button style as well as a low-profile balloon style and are manufactured by a number of companies including but not limited to the Boston Scientific EndoVive™ One-step Button™, the Applied Medical Technologies AMT® Initial Placement Gastrostomy (MiniOne®), or Avanos Medical Introducer kit for gastrostomy tubes. A similar technique has also been reported for the primary placement of GJ tubes [10]. With the earlier technique of internal bumper and external crossbar, most centers would recommend waiting 12 weeks before changing an initial PEG or PRG tube to a low-profile device in order to maximize healing of the track and decrease the risk of gastric dehiscence. However, the more recent technique using T fasteners Kimberly-Clark, Roswell, GA; Boston Scientific, Natick, MA) or U sutures for securing the stomach wall to the abdominal wall (Fig. 45.2), combined with the initial placement of a low-profile device, avoid the need for a long tube and can be replaced earlier than the 12 weeks, if needed. There have been some experiences with complications of T fasteners resulting in dislodgement [10, 11].

When a G-tube is placed surgically, whether an open technique or laparoscopic, the type of initial tube can vary from a standard mushroom-type tube such as the Malecot or Pezzer, a standard balloon tube with external retention disc, or most often, a low-profile balloon tube, such as AMT MiniOne® or MIC-KEY®. The choice is often based on surgeon's preference while accounting for any clinical benefits of one type of tube or another for a particular patient. An initial surgically placed G-tube could be changed within 4–6 weeks. Regardless of the method of G-tube placement, the timing, method, and personnel involved in initial tube change vary from institution to institution. Commonly an initial PEG- or PRG-placed tube, without T fastener gastropexy, remains in place for 12 weeks then is replaced with a low-profile device or standard replacement tube under fluoroscopic guidance, although some centers do the first change after 6 months of initial tube placement [12]. Thereafter, the tube can be changed by nursing staff or parents who have been thoroughly educated on the G-tube change procedure.

It is essential that families are well educated regarding the care and maintenance of enteral feeding devices and, as mentioned, it is preferable that the success of enteral nutrition via nasogastric tube has been previously documented. Once the decision has been made to pursue gastrostomy tube placement, it is important that the family be familiar with the type of gastrostomy tube being placed, i.e., standard PEG vs. low-profile gastrostomy tube, the length of time that the family can expect the initial tube to be in place and who will perform the first change. All of these vary with institutions and specialties. An example of this is a surgically placed gastrostomy tube that could be a balloon low-profile device, a balloon replacement tube, or a mushroom-type Malecot® tube. Table 45.1 depicts some of the various types of gastrostomy and GJ tubes and securement techniques. The personnel involved in the tube replacement procedure also varies based on who placed the original tube and the direct visualization is now recommended either through radiology or a repeat endoscopic procedure.

Care of the gastrostomy post placement is simple. The skin around the G-tube should be washed daily with mild soap and water. A small amount of serous or mucoid drainage is normal. Use of hydrogen peroxide should be avoided as it causes unnecessary drying and irritation of the skin. It is important for the tube to have a good fit and to be well stabilized. Excessive movement in the tract can cause leakage,

Fig. 45.2 Example of "T fasteners" for initial low-profile G-tube placement

Table 45.1 Examples of types of enteral feeding devices and securement devices

Gastrostomy tubes		**GJ tubes**	
Initial non-surgical G-tube 	Initial PEG/PRG tube with internal bumper and external crossbar 		Initial GJ tube with J limb threaded through G-tube
Low profile 	Low profile balloon tube 		Standard replacement GJ tube
Mushroom tube secured 	Standard mushroom tube (Malecot® or Pezzer®) 		Low profile balloon GJ Tube
	Standard balloon tube Can be initial surgical tube (e.g., Avanos®) 		Low profile balloon trans-gastric jejunal tube
	Low profile mushroom type tube (e.g., Bard®) 		"G-JET" low profile balloon GJ tube (AMT®)

Securement devices and techniques		G, GJ-tube belts	
	Hollister Drain/Tube Attachment Device® Can be used to secure and stabilize both G-tubes and GJ tubes Secure tubes in a vertical fashion thus avoiding lateral traction on the stoma		Benik® enteral tube securement belt used to prevent accidental dislodgement of tube https://www.benik.com/peds/wrap/g-tube
	Other commercially available tube holders such as "Cinch®" and "GripLock®" Use these products with caution due to potential for applying lateral traction on the tube thereby causing erosion or "key-holing"		G-tube Wrap-Gus Gear https://gusgear.net/product/g-tube-wrap/
	Four-way tape method for low-profile device For initial securement while track is healing in a vertical fashion		Tuubezz G-tube belt https://www.tuubezz.com/

erosion of the stoma, and hypergranulation tissue formation. Similarly, excess traction on the tube can cause mucosal prolapse and erosion of the tract. Dressings should be minimized and only added as needed. A small amount of serous or mucoid drainage is normal after initial placement and should resolve over time if the tube has a good fit and is well-stabilized. If the patient has a low-profile tube in place, it is important to remove the feeding extension when not in use. Keeping the feeding extension in place at all times defeats the purpose of a low-profile tube and can cause undue lateral traction on the stoma, thereby causing erosion of the tract, "buried bumper syndrome," leakage, and/or mucosal prolapse.

Complications of Gastrostomy/Gastrojejunostomy Tubes

Commonly encountered complications of enteral devices include infection, leakage, hypergranulation tissue, peristomal skin breakdown, stomal prolapse, stomal erosion, tube migration, tube obstruction, and persistent fistula after removal [12–18]. Although there is a paucity of randomized controlled trials, Townley et al [16] present a rapid scoping review of literature regarding tube-related complications in children and treatment methods utilized. Table 45.2 outlines common complications and treatment strategies based on the author's 30-year experience.

Table 45.2 Management of common complications of percutaneous enteral tubes

Problem	Likely etiology	Prevention	Treatment
Dislodgement	Improper or inadequate securement	Adequate securement; use of products such as Griplock® or Hollister Drain Tube Attachment Device® to secure to abdominal wall; use of protective belts such as Benik Belt®; disconnect extension tubing when not in use to avoid lateral traction on tube	Replacement and securement
Leaking, peristomal irritant dermatitis	Inadequate stabilization, poorly fitting tube, inadequate balloon volume; stomal enlargement/erosion	Adequate fit of tube; securing properly; adequate balloon volume	Consider alternative type of tube; secure well; increase balloon volume to maximum recommended; consider removing tube to allow site to contract; peristomal skin protection with silicone sealant, cyanoacrylate, or moisture barriers
Hypergranulation	Inadequate stabilization, moisture, friction	Adequate stabilization, decrease moisture, avoid moist dressings	Silver impregnated hydrofiber or alginate; topical steroid ointment; chemical or surgical cauterization
Infection	Preoperative/pre-procedure antibiotics; treatment of oral, gut or vaginal fungal colonization; immunosuppression	Treatment of oral, gut or vaginal fungal infection; avoid pressure injury from too tight a tube fit which can lead to cellulitis	Topical antifungal powder, sealed in with silicone liquid sealant; topical antifungal ointment or cream; topical antifungal spray; oral or systemic antibiotics
Obstruction	Inadequate flushing, build-up of residue within tube	Consistent flushing schedule before after all feeds and medications; dilute medications, use liquid solutions whenever possible	Flushing, declogging agents (Clog-zapper®)

Infection

Gastrostomy tube infections are more common in the first several weeks following percutaneous placement. It has been estimated that 25–33% of patients develop a peristomal infection [16, 18–20]. Few studies have addressed the issue of peristomal infections in children. The underlying medical condition of the child may influence their risk for infection and hinder wound healing. Antibiotic prophylaxis with the placement of percutaneous endoscopic gastrostomies is recommended [19, 20].

Infection of the peristomal area can present with a variety of symptoms. Fever, spreading erythema, tenderness, pain, induration, and purulent discharge are typical. However, the yellow-brown crusty discharge that is commonly seen around the gastrostomy site is not a sign of infection, a finding that is confusing to families and caregivers. There can be mild erythema from friction at the site which is also not indicative of infection. In case of infection, treatment with a topical antibiotic may be all that is needed; however, oral antibiotics may be necessary. Most infections respond to a first-generation cephalosporin. Abscess formation adjacent to the stoma is another potential complication. These lesions have a rapid onset of a pustule or a red-purple fluid-filled lesion that is tender to the touch. When it ruptures, a punctuate opening is apparent and may drain for several days. Treatment with warm compresses and antibiotic therapy is recommended. Although there is little prospective comparison data available, a retrospective review of surgical vs PEG/PRG G-tube placement technique revealed surgically placed G-tubes had a lower infection rate than PEG/PRG tubes but PEG/PRG-placed tubes had lower costs and length of stay [17]. Fungal infections can occur, characterized by a shiny erythematous rash with satellite lesions. This should not be confused with irritant dermatitis due to leakage of caustic gastric secretions (Fig. 45.3).

It is important to assess the for the proper fit of the tube as a tight-fitting low-profile device can lead to a pressure injury including deep tissue injury and cellulitis at the site (Fig. 45.4). This is especially concerning in patients who have abdominal distention or changes in abdominal girth due to their underlying illness or disease process. Once the tight-fitting tube is removed, the site can usually heal. The tube may have to temporarily be replaced by a standard (long) tube and the low-profile device can be replaced after the injury is completely resolved.

Feeding tubes may become colonized with microbial organisms, yeast, and fungus. There have been more than 100 different microorganisms isolated from gastrostomy tubes with the most common being *Candida, Pseudomonas*, *Escherichia coli*, *Enterobacter cloacae*, *Streptococci*, *Lactobacillus*, *Staphylococcus aureus*, and *Bacteroides.* The significance of gastrostomy tube colonization is unclear; however, in the face of recurrent infections, culture of the site and treatment with the appropriately sensitive antibiotic is recommended.

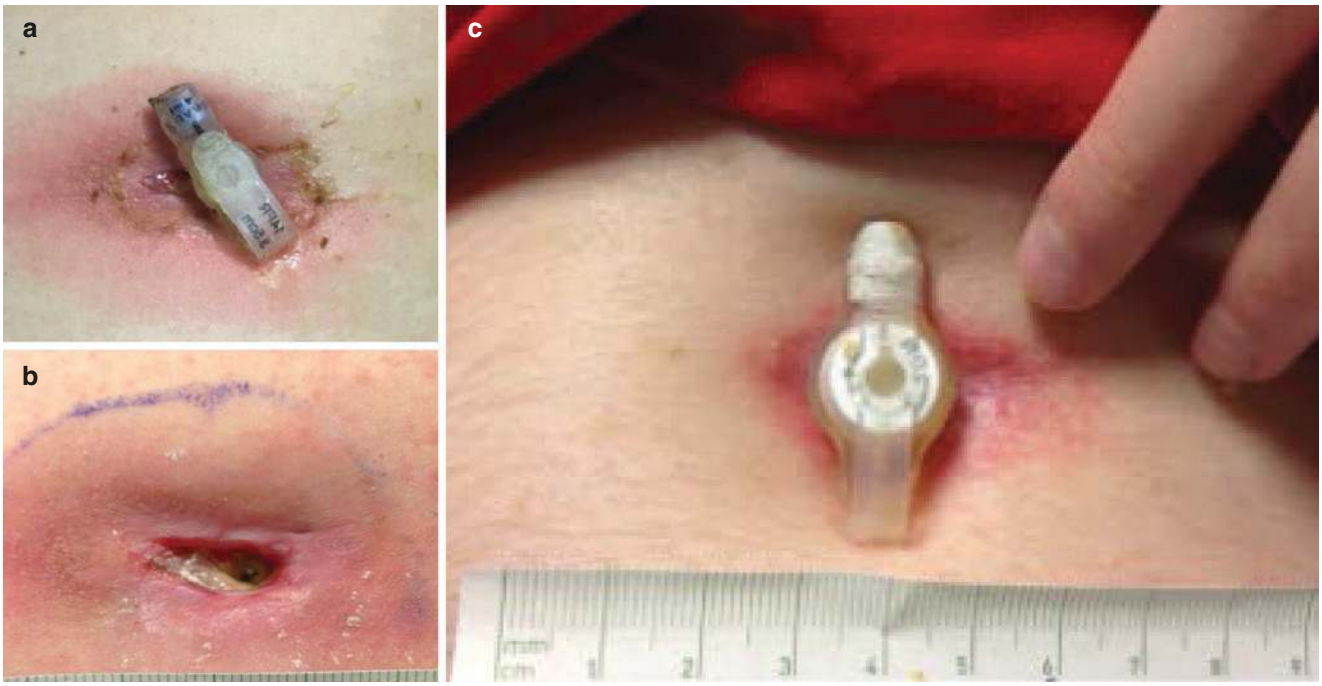

Fig. 45.4 Tight-fitting low-profile tubes. (**a**) Cellulitis, (**b**) Erosion (same patient), (**c**) Tight tube in teen with Crohn disease after gaining weight

Tube Migration and Dislodgement

Migration of the gastrostomy tube is well documented and includes scenarios where the balloon migrates causing gastric outlet obstruction, the jejunal limb of a GJ-tube migrating to the esophagus or retracting into the stomach, and further migration of these tubes into the distal small bowel causing diarrhea with aberrant tract formation has been reported [14]. The buried bumper syndrome (retrograde migration of the gastrostomy tube's internal bumper into the abdominal wall or into the stoma tract) is well described [21–23]. This occurs when there is traction placed on the external portion of the gastrostomy tube that results in excessive tension on the internal bumper at the time of placement. A false tract may develop as a late complication when the shaft length of the low-profile gastrostomy tube is not resized in a growing child [24]. Failure to remeasure the shaft length may result in a too short tube causing the balloon or internal bumper to move up into the tract. Leakage and focal abdominal discomfort may result. Long-term migration of the bal-

loon into the tract may result in the development of a false tract or dilatation of the gastric opening. This allows for drainage of gastric contents onto the skin resulting in peristomal skin excoriation and breakdown. Gastrocolic fistula formation has also been reported due to tube migration [25].

It is important to remeasure the stomal tract correctly and accurately. It is best to measure with the patient in both a supine and sitting position. If the measure significantly differs in either position, the tract length should be the average between the two measurements. It is recommended that tracts be remeasured at least annually. Patients who are gaining or losing weight, however, will need to have the fit remeasured more frequently. Figure 45.4c depicts a teenager with Crohn disease who initially at the time of tube placement was thin and undernourished, then gained weight while undergoing treatment causing a tight-fitting tube.

Tube migration can also occur in children with a GJ tube in place, where the jejunal limb of the tube can migrate proximally or coil backwards. In the latter, instance the child may demonstrate leakage of formula from the gastric limb of the tube or leakage of formula from the stoma. There have even been reports of GJ tube migration into the esophagus. A return trip to the interventional radiology suite is warranted and the tube can then be rewired and repositioned or replaced. If the child exhibits signs of intestinal obstruction, GJ tubes have been identified as a lead point for intussusception and this should be investigated whenever there is a concern for intestinal obstruction [14, 26, 27].

Leakage, Stomal Erosion, and Peristomal Skin Breakdown

Leakage, stomal erosion, and peristomal skin breakdown are all interrelated complications (Fig. 45.5). Chronic leakage is a worrisome complication as it leads to chemical, irritant dermatitis (Fig. 45.3b). Leakage of gastric contents often results in peristomal skin breakdown and pain, and can contribute to potential infection, and proliferation of hypergranulation tissue (Fig. 45.6). The first goal is always to ascertain

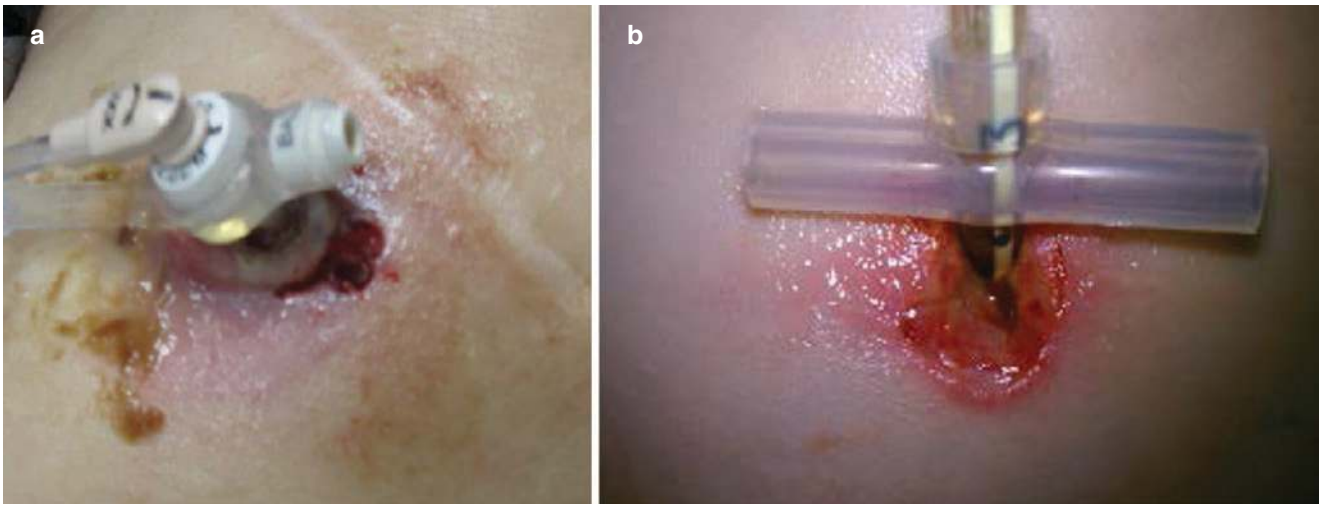

Fig. 45.5 (**a**) Stomal erosion, (**b**) Erosion with "keyholing"

Fig. 45.6 Hypergranulation tissue

the cause of leakage and take steps to stop it. A good fit and proper stabilization are both crucial to preventing leakage. For low-profile balloon tubes, remeasuring the shaft length and ensuring the proper fit of the gastrostomy tube is the first step. Ensuring that there is adequate water in the balloon is important. While most manufacturers recommend that the balloon be inflated with 4–6 mL of water, most can accommodate several additional mLs safely. It is important to be cognizant of the size of the child and their gastric volume, to avoid exceeding gastric capacity. If the leakage is from an enlarged or eroded stoma tract, increasing the diameter of the gastrostomy tube (for example, going from a 14 French to a 16 French) should be avoided. Increasing the lumen size of the tube only further dilates the stoma diameter. Alternatively, removing the gastrostomy tube for a short period allows the stoma to contract. If the gastrostomy is relatively recently placed, often a few hours may be enough time to allow the tract to contract. Longstanding gastrostomies may require removal of the tube overnight or even longer to get the tract to scar down.

For severe leakage and stomal erosion, more aggressive interventions may be warranted. These include temporary removal of the tube and placement of a nasojejunal tube for post-pyloric feedings, while the stoma contracts and the peristomal skin heals. Placement of a smaller caliber balloon tube allows the site to scar down while still utilizing the balloon to stent secretion leakage. The small caliber balloon tube can be secured with manufactured tube stabilizers such as the Hollister Drain-Tube Attachment Device®. This type of device is often used to secure mushroom-type tubes such as Malecot® and Pezzer® tubes. Other strategies for minimizing gastric secretions include placement of an NG sump or placement of an ostomy pouch to help contain secretions while the site contracts. Many patients benefit from changing to a different type of tube if leakage is a chronic issue. If all interventions fail and the site remains enlarged, eroded with profuse leakage, surgical revision may be necessary.

Wound management of the eroded gastrostomy tube site is a challenge. While awaiting improvement in stoma contraction, the peristomal skin must be protected from caustic gastric secretions. The guidance of a wound and ostomy nurse may be necessary. Skin barriers and absorptive dressings are helpful in preventing ongoing damage from gastric secretions. Skin barriers containing zinc oxide and other topical barriers used to treat diaper dermatitis may provide comfort to the patient and protect the skin from further breakdown. Use of silicone skin sealants such as Cavilon No Sting Barrier® (3M), or cyanoacrylate skin sealant such as Marathon® (Medline) can be useful in protecting the skin. There are numerous wound dressings that can support wound healing of the stoma. Absorptive dressings include foams (e.g., Mepilex®), hydrofibers (e.g., Aquacel®), and hydroconductive (e.g., Drawtex®) dressings and have been effective when used around gastrostomy tubes when indicated to address excessive leakage.

Hypergranulation Tissue

Hypergranulation tissue (Fig. 45.6) is a frequent complication of gastrostomy tube [16, 18, 28]. For some patients, it is a minor complication but in others it results in unsightly tissue that is painful and friable where often times there is increased exudate and bleeding. Hypergranulation is a proliferation of capillaries that forms around the external stoma and occasionally within the gastric opening. This excessive, abnormal tissue can also harbor bacterial. Current treatment options are limited. Oftentimes this excessive proliferation of tissue can lead to other issues such as leakage and erosion of the surrounding skin in addition to pain and bleeding. In these more severe cases, it is important to treat the condition. The usual treatment for hypergranulation consists of attempts chemical cauterization with silver nitrate, topical steroid cream, and foams or pectin-based powders. A randomized controlled trial (RCT) comparing hydrogel, saline, and soap and water, with small sample size revealed a hydrogel dressing had best results in deterring hypergranulation tissue [29]. A RCT by Leon et al. [28] investigated the use of a hydrocolloid dressing, with or without silver, and found no difference between standard care, hydrocolloid or silver hydrocolloid. Another option is the topical cream GranuLotion®. Although there are no RCTs investigating this particular treatment, and ineffective results found by the author, there are anecdotal reports from families of a positive response in some cases.

Cauterization of hypergranulation tissue with silver nitrate has been utilized for years. It can result in significant complications if applied improperly. Burns to the surrounding skin are not uncommon and it is essential to protect the peristomal skin. Cauterization is not ideal—it can be painful and may need to be repeated to eliminate the hypergranulation tissue. In addition, chemical cautery causes trauma and inflammation to the tissue, and thus can further exacerbate proliferation of the abnormal tissue. It is important to protect the healthy peristomal skin with a skin barrier, acrylate skin sealant (Cavilon No Sting Barrier® for example) or surgical lubricating jelly. An alternative to chemical cautery is treatment with absorbent silver-impregnated dressings such as hydrofibers or alginates [30]. The silver serves as an antimicrobial to treat the increased bioburden thought to occur with hypergranulation tissue, while the absorptive qualities of the dressing addresses excess moisture.

Although there is little data to support the use of corticosteroid creams in the treatment of granulation tissue, however, dermatologists have used topical steroids in the treatment of postoperative granulation tissue for several years [31]. It is thought that the topical steroids have an anti-

Fig. 45.7 Stomal prolapse

angiogenic effect on the granulation tissue similar to that of systemic steroids in the treatment of large capillary hemangiomas. Anecdotal reports on the successful use of triamcinolone cream in the treatment of granulation tissue are available [16, 18]. The usual dose is 0.1% triamcinolone cream twice daily for 2 weeks has met with some success and some centers implement a short course (2 weeks) of Triamcinolone 0.5%.

Prolapsed gastric tissue (Fig. 45.7) is often confused with hypergranulation tissue. The tissue with gastric prolapse is a deeper red, shiny, and more granular in appearance. Cautery with silver nitrate has no effect on this tissue, which is typically intermittent. Most important in treatment is proper fit of the tube, adequate securement, and avoidance of multiple layers of dressing or excessive traction on the tube.

Tube Obstruction

Obstructed tubes are an issue primarily with gastrojejunal devices. Migration or dislodgement of these tubes is common in children with gastrointestinal dysmotility. To prevent tube clogging, frequent flushing is recommended, before and after bolus feeding or medication administration and every 2–4 h during continuous feedings. Families should be instructed on how to administer medication and which medications are more likely to cause tube obstruction. Water is recommended with a volume large enough to clear the tube, approximately 10 mL with each flush. Vigorous flushing with small volume syringes and warm water may help generate enough pressure to clear the tube. In addition, use of pancreatic enzyme mixed with sodium bicarbonate might help relieve tube obstruction, although there may be concern for tube degradation with these ingredients. There is a commercially made product—Clog Zapper® (Avanos Medical) which is effective in clearing tube obstructions.

Fistula Formation

A persistent gastrocutaneous fistula is one that does not close spontaneously in 4–6 weeks after the gastrostomy tube has been removed. Approximately 25% of all children who had an endoscopically placed gastrostomy tube will suffer this complication [12, 14, 24, 32]. The longer the gastrostomy tube is in place, the less likely the fistula will heal spontaneously. Oftentimes, the track becomes epithelialized which would prevent closure of the track. A variety of techniques for promoting closure have been reported in the literature but all with limited success. Tract cauterization and use of fibrin glue have been reported in adults [13]. If the track has epithelialized, then surgical coring out of the track to create a fresh wound may be warranted. Surgical consultation and closure is usually recommended if the tract has not closed within 4–6 weeks.

Gastrocolonic fistulas may develop after the placement of a percutaneous gastrostomy due to the technique and lack of direct visualization [12–14, 32]. Fecal drainage from the stoma, foul breath or leakage of formula or medications from the rectum or refractory diarrhea should raise the suspicion of a gastrocolonic fistula [25]. Surgical closure of the fistula with a replacement of the gastrostomy tube is necessary.

Ostomy Education and Management

Children and adolescents with inflammatory bowel disease, as with many chronic illnesses, modify many aspects of their lives to gain control of their disease. Medications, dietary changes or limitations, and surgery all play a role in the management of IBD. Activities may need to be limited, and relationships are affected, all of which impact a patient's lifestyle. Many patients who undergo operative intervention ultimately feel physically better after surgery as they gain control they had previously lost. Despite feeling better after surgical intervention, oftentimes the impact of surgery, and in particular fecal diversion, can affect their body image and self-esteem. Preoperative education should occur whenever possible. For those patients who undergo urgent fecal diversion, where preoperative education is not possible or limited, education and support postoperatively becomes essential in assisting the patient and family to adapt to life with an ostomy.

For the majority of children and adolescents with inflammatory bowel disease, having a surgical intervention that results in

an ostomy is associated with fear. For many patients, surgery is recommended either emergently or urgently due to a complication of the disease. It is important that the patient and family be well prepared. David and colleagues [33] describe a qualitative study on perceptions of ostomy educational needs in patients with IBD and their caretakers and found that preoperative education was lacking. Stressing the positives of surgery is important and education can assist in easing anxiety and fear of the unknown. Many have never heard the words stoma or ostomy and the information they have may be incorrect. It is important that the patient and the family understand that living with an ostomy requires a life-style adjustment, and that new skills will be acquired and mastered.

From a healthcare provider perspective, patient/family education prior to the surgery and preoperative marking of the stoma site are essential. The placement of the stoma is important for successful secure pouching and optimal patient satisfaction and outcomes. Ideally, a certified Wound, Ostomy, Continence Nurse (CWOCN) collaborates with the surgeon to select a site that is ideal in terms of creation of the stoma. A joint position statement between the Wound Ostomy Continence Nurses Society and American Society of Colon and Rectal Surgeons outlines key points and patient characteristic factors in stoma site marking [34]. However, there is a small subset of experienced pediatric surgeons who perform a large volume of ostomy surgeries and are expert at stoma siting. The stoma is ideally placed not only within the rectus muscle but also accommodates the patient's body contour, clothing selections, and avoids creases and skin folds. Successful site marking occurs with the patient awake and interactive. The patient is assessed in lying, sitting, and standing positions with typical clothing in place. In many cases, especially in patients with Crohn disease, ostomy surgery is performed on an urgent basis. In these situations, an experienced pediatric surgeon who cares for a large volume of patients with IBD can properly identify the landmarks for stoma siting.

It is important for the patient, with the help and support of their family, to adapt to having an ostomy. Healthcare providers can help educate the patients and family to alleviate common misconceptions. Education should take place within a developmental framework. In 2011, the Wound, Ostomy Continence Nurses Society published a best practices for pediatric ostomy care which includes educational and behavioral intervention for all age groups [35]. More recently, this same professional society published clinical guidelines for management of the adult patient with an ostomy [36] which can be applied to the over 18 years/young adult population cared for within a pediatric setting. Through education and support, clarification and reassurance can be provided regarding such common misconceptions such as ostomies do not smell, they are not visible under clothing, and that sports participation is possible. Swimming, scuba and sky diving, and even professional football are all possible with an ostomy. There are a variety of "stoma guards" on the market which provide protection during contact sports, examples include but are not limited to Stealth Belt, Stoma Guard. In addition, there are several companies who produce clothing and accessories for ostomates, including pouch covers, swimwear, and intimacy clothing. Adolescents fear intimacy with a stoma. This too needs to be addressed up front. If the healthcare professional is uncomfortable with the topic, then arranging a consultation with another provider or a CWOCN who can address these issues is important prior to surgery when possible, or at least during postoperative education in both the hospital and outpatient settings.

Family education and support is important. The preoperative discussion should include what the stoma will look like, how it functions, how it is managed, what the appliance or pouching system will look like. Have the pouching system available so that the patient and family can visualize how the stoma is fitted and how the pouch is emptied. Encourage the patient to wear a pouch prior to surgery so they are familiar with the sensation of the pouch on their abdomen and to be familiar with what to expect after surgery.

One of the most common problem encountered in ostomy management is leakage from around the pouching system. It is important to be able to maintain the seal on the pouching system for a predictable period of time, for most patients 5–7 days, minimum of 3 days. Leakage results in denuded peristomal skin, and more importantly, loss of confidence and frustration for the patient. It is important for the patient to be able to predict the timing for changing the pouching system, thus allowing them to change it on a scheduled day and avoid the worry that the system will fail in the interval.

Common stomal and peristomal problems include peristomal skin conditions, poor healing, stomal retraction, or prolapse or parastomal hernias [37]. Prevention and early recognition of peristomal complications is key to achieving patient satisfaction and positive adaptation. Table 45.3 outlines common peristomal complications and recommendations for prevention and treatment. Early intervention and treatment can minimize the long-term complications. One of the more common problems encountered is irritant dermatitis. This often occurs with ileostomies from leakage of caustic stool on the skin under the appliance. Prevention and treatment centers around appropriate appliance selection and sizing. Allergic contact dermatitis is treated by removing the offending product and then using a topical anti-inflammatory in a spray form and replacing the product. Poor wound healing contributes to muco-cutaneous separation. The separated area is filled with an absorptive dressing, then covered with a hydrocolloid dressing in an effort to isolate the wound from fecal output. Candidiasis of the peristomal skin area is best treated with a topical antifungal powder that can then be

Table 45.3 Common stoma and peristomal complications: prevention and treatment

Problem	Likely etiology	Prevention	Treatment
Peristomal irritant contact dermatitis 	Leakage of caustic effluent on peristomal skin	Proper fit of appliance and use of barrier seals as caulking to prevent leakage and undermining of wafer barrier	Alter appliance, sealants and barrier rings or caulking as needed; protect skin with silicone or cyanoacrylate sealants
Peristomal allergic contact dermatitis 	Contact/allergic dermatitis related to appliance and accessory products, in this case the tape border of wafer	Use minimal variety of products necessary for good fit and good seal	Patch testing; switching appliance to alternative product; topical treatment with steroid sprays or powders
Peristomal fungal infection 	Colonization of mouth, gut, vagina; immunosuppression	Keep peristomal skin clean and dry; treat existing infection (oral, vaginal)	Use of antifungal powder and "seal in" with liquid sealant; topical antifungal spray; oral or systemic antifungal agent if needed or if severe in compromised patient
Peristomal pyoderma gangrenosum 	Disease process-extraintestinal manifestation of IBD adjacent to stoma, caused by trauma, inflammation, irritation, abrasion, or pressure	Appliance with good fit Avoid pressure, abrasions, and trauma	Topical, intralesional, or systemic steroids; immunologic or biologic agents; topical dressings of silver impregnated hydrofiber, alginate, or other absorptive dressing with antimicrobial
Stoma retraction 	Short length of intestine for stoma creation; stoma within crease; increased weight gain	Adequate length of stoma	Use of convex wafer and belt to assist in improving stoma profile
Stoma prolapse 	Enlarged fascial opening, increased intra-abdominal pressure	Avoid convex wafers and/or belts in immediate post-operative period; avoid increased intra-abdominal pressure	Protect prolapse; can use lubricant inside pouch to prevent rubbing against prolapse; cut radial slits in wafer barrier to allow to accommodate prolapse

(continued)

Table 45.3 (continued)

Problem	Likely etiology	Prevention	Treatment
Mucocutaneous separation 	Poor healing, mechanical	Maximize medical treatment of IBD, maximize nutrition, whenever possible prior to surgical creation of stoma; consider avoidance of convex wafers in immediate post-op period	For area with depth, pack area with gelling hydrofiber, with silver if there is concern for infection, or alginate and cover with thin hydrocolloid; obtain good seal of appliance to prevent stool coming in contact with wound with the goal of isolating the wound from stool intrusion
Peristomal folliculitis 	Irritation and local infection of hair follicles due to mechanical trauma	Careful shaving of peristomal hair if interfering with appliance adherence	Clean peristomal skin with antibacterial soap, rinse and dry well. Can treat with topical antibiotic powder. Consider treatment with systemic antibiotics if severe or not responsive to cleansing regimen. Reduce frequency of shaving
Stomal necrosis above fascia (pink stoma visible) 	Superficial ischemia, sloughing  Same stoma after sloughing of superficial necrotic layer	Proper position and length of stoma construction to avoid vascular compromise	Monitor/observe if superficial necrotic tissue will slough revealing a viable stoma Emergent surgical revision is required if necrosis is below the fascial level
Parastomal hernia 	Not seen very frequently in pediatric. Occur when there is a defect or weakness in the muscle of the abdominal wall	Proper position and construction of the stoma; avoidance of muscle straining in post-op period	Refer to surgeon Consider use of hernia support belt Instruct patient to report symptoms of incarceration (dark stoma, severe pain, no gas or stool output, vomiting)

"sealed in" with a silicone sealant. More uncommon complications include stomal granulomas, suture granulomas, and peristomal abscess. Peristomal abscesses, though rare, should be treated with systemic antibiotics and topically with an absorptive foam product.

Pyoderma gangrenosum (PG) may occur at or near the stoma of patients with IBD, or elsewhere on the skin. Classically, a full thickness, painful ulcer develops in the peristomal area with a halo of purple discoloration (Fig. 45.8). The etiology is thought to be due to pathergy-trauma such as abrasion, scratching, or pressure. The ulcers are extremely painful with significant drainage. If the ulcer is large, it may interfere with the pouch seal resulting in leakage and further skin breakdown. Treatment of peristomal PG can be difficult and varies. Topical, intralesional, and systemic corticosteroids may be necessary and found to effective as well as immunomodulator therapy and biologic agents. Topical tacrolimus ointment or solution, or cyclosporin has also been reported to assist with wound healing [38–41]. Absorptive dressings such as silver-impregnated hydrofiber (for example Aquacel AG) or a calcium alginate will absorb moisture and exudate [36, 37].

Fig. 45.8 Peristomal pyoderma gangrenosum. (**a**) Intralesional steroid injection, (**b**) Absorptive silver-impregnated hydrofiber dressing

When associated with a fecal stoma, there is the additional challenge of managing stool output and preventing stool intrusion into the wound. Once the wound is dressed, this primary dressing is then covered with a transparent thin hydrocolloid or transparent film and the ostomy wafer is then placed over this. It is important that the PG wound be protected from stool soilage for optimal wound healing. Avoidance of peristomal trauma and pressure is key to minimizing risk of PG. This includes the use of convex wafers and ostomy belts. In addition to modifying the appliance as needed and topical dressings, maximizing medical management of disease process is integral to managing peristomal PG.

Preparing a patient and family for living with an ostomy, whether temporary or permanent, is a planned approach. It should provide them with education regarding the stoma, the skills necessary to care for the stoma, and emotional support. Oftentimes, this is required of families while also managing disease flares, treatments, and side effects. Patients with ileostomies must be taught how to monitor for and treat dehydration. In addition to family preparation, the health care team needs to take the developmental level of the patient into consideration. A school-aged child with an ostomy has different needs and concerns than an adolescent. This age group may pose the most challenge regarding acceptance and adaptation [42]. The adolescent is not only is dealing with biologic and sexual maturation, but they are also striving to achieve independence and autonomy within the greater social environment and often mentoring from others who have gone through ostomy surgery can reassure and guide them in the adaptation process [43]. Transitions from hospital to home and school, and return to sports, work and other activities are important landmarks. The patients and families need support and resources to help guide them through these transitions. There is a wide array of resources and accessories available to ostomates and it is important that the patients explore these options. Figure 45.9 depicts examples of ostomy accessories which can help with these transitions. A supportive healthcare team can be crucial for successful adaptation and positive self-image for the patient, and positive adjustment for the entire family.

Clinical Indices for Pediatric Inflammatory Bowel Disease Research

46

Oren Ledder and Dan Turner

Introduction

Clinical research relies on standardized markers which accurately reflect a response to interventions. For both practical and ethical reasons, invasive measures are best avoided when possible and thus clinical indices will always play some role in assessing outcomes, both in practice and in the clinical trial setting. Various indices have been developed for pediatric use due to specific aspects of the disease in that population. While some indices were primarily developed for research purposes, many are also widely used to standardize assessment in clinical practice.

Assessment of Instruments Used in Clinical Research

Disease activity is a concept for which no gold standard exists. Even in ulcerative colitis (UC), where colonoscopic examination is highly important in evaluating disease activity, it still cannot be regarded as a gold standard because the degree of inflammation is subjective, mucosal healing lags after clinical improvement, and perhaps other measures are more important, such as histological remission. Therefore, disease activity is best measured using multi-item indices which often incorporate clinical symptoms, laboratory parameters, and, when feasible, also endoscopic findings.

According to accepted standards of health indices development [1], the introduction of a new measure for use in clinical research should follow a multistep process of item generation, reduction, grading, weighting, and evaluation [2, 3]. A list of all potentially useful items is generated by a panel of experts and then reduced to include only the most relevant items. These items are then evaluated for their ability to explain the desired attribute (e.g., signs and symptoms, disease activity, or quality of life); each item is graded and may be assigned a weight according to its ability to reflect the concept which is targeted. The final measure is then evaluated to define cut-off scores that correspond to clinically important disease states such as remission and mild to severe disease activity. For clinical indices that will be used to determine changes over time (evaluative measures), a definition of "response" (i.e., the minimal important difference) is also required.

Once the instrument has been developed, it must be evaluated for validity, reliability, responsiveness, and feasibility [4–6]. Briefly, ***validity*** is the degree to which the instrument measures the concept that it purports to measure [7]. The ***reliability*** of an instrument relates to its stability on repeated measures both over time and by different raters at one point in time [8]. ***Responsiveness*** refers to the instrument's ability to correctly identify change over time in the concept being measured. It is not merely sensitivity to change but rather the ability of the instrument to detect changed from unchanged patients. A highly responsive index is invaluable in clinical trials, as it allows performing the trial with a smaller sample size [9–12]. Finally, ***feasibility*** encompasses both respondent and administrative burden. An instrument is feasible if the participant and researcher report that the instrument is completed within reasonable limits of participant discomfort and both participant and researcher time constraints.

Outcomes in Pediatric Inflammatory Bowel Disease

Crohn Disease Activity Indices

One of the first Crohn disease (CD) activity indices developed in adults was the Crohn Disease Activity Index (CDAI) published in 1976 by Best and colleagues [13]. This index includes clinical symptoms, IBD-related complications,

physical examination findings, laboratory tests, weight, and use of medications to treat diarrhea. Since its publication, it has been used extensively in most clinical trials in adult Crohn disease, only recently supplanted by patient reported outcomes (PRO) (detailed later in this chapter). The CDAI has been criticized for its complex calculation, potentially poor inter-observer agreement [14, 15] and poor correlation with endoscopic appearance [16, 17] which is becoming an increasingly important outcome. Simpler versions have been developed, the most commonly used being the Harvey–Bradshaw Index (HBI) which incorporates only clinical symptoms and physical exam findings [18]. The respondent burden is significantly lower than the CDAI, with no need for a symptom diary or blood work.

For children, the Pediatric Crohn Disease Activity Index (PCDAI) was developed [19]. This instrument ranges from 0 to 100 points and contains patient symptoms (based on a 7-day recall), physical examination findings, laboratory parameters, and growth measures (Appendix 1.1). Despite its several limitations, the PCDAI performed well in multiple pediatric IBD clinical trials as a measure of disease activity. The weight variable requires a reading at an interval of at least 4 months with weight loss being quantified as a percentage ([current weight—previous weight]/previous weight). The height variable at diagnosis is scored according to the number of channels crossed downward if prior measurement is available and, if not, according to the current centile. The height variable on follow-up visits employs height velocity, measured over a minimum period of 6–12 months [20, 21]:

$$\frac{\text{Height velocity} = 2^{\text{nd}}\,\text{height} - \text{baseline}\left(\text{cm}\right)}{\text{Time}\left(\text{year}\right)}$$

To compare children of different ages and gender, the height velocity is converted to a z-score:

$$\frac{z - \text{score} = \text{Observed height velocity} - \text{Mean height velocity for age and sex}\left(\text{cm / year}\right)}{\text{SD of the mean height velocity}\left(\text{for age and sex}\right)}$$

The z-score corresponds to the standard deviation (SD) of the child's height velocity.

The PCDAI has been evaluated in seven cohorts of children with CD (Table 46.1) [19, 22–24]. In a head-to-head comparison, Otley et al. [22] showed that the PCDAI was highly correlated with physician global assessment ($r = 0.86$), higher than the CDAI ($r = 0.77$), the modified CDAI ($r = 0.76$) and the HBI ($r = 0.72$). In the largest study to date, test–retest reliability on stable patients has been shown to be good [25]. Responsiveness to change was demonstrated and the minimal clinically important change, to define "response," was found to be at least 12.5 points [23], also in the larger study which used several methods to attain this "minimal important difference" corresponding to moderate change [25].

The optimal PCDAI cut-off score that defined remission has been open to some discussion. The initial study found that a PCDAI score of ≤10 points discriminated active from quiescent disease. Other studies found that PCDAI scores of <10 and <15 points were more sensitive and specific, respectively [22, 24]. In a more recent large study of 366 children, the best cut-off values were <10 points or <7.5 without the height item points for remission, 10–27.5 for mild disease, 30–37.5 moderate disease, and 40–100 for severe disease. This yielded the best accuracy (Table 46.1) acknowledging that the growth item is irrelevant in adolescents who passed the growing-tanner stages and that height typically improves several weeks or months after remission has been achieved (i.e., low responsiveness). The PCDAI does not differentiate well between moderate and severe disease activity and the feasibility of the PCDAI is only moderate. In the registry of a pediatric IBD collaborative research group, only 47.6% of the registered visits had a valid PCDAI score, compared to 97.6% with the Pediatric UC Activity Index (PUCAI—see below) [26]. Similarly, data to complete the PCDAI from the ImproveCareNow registry were available in the charts of only 20% of 3643 clinical visits [27]. Besides the low feasibility of the index and the limitations imposed by the growth item, the inclusion of the perianal item is debated as it reflects a different concept than luminal disease activity.

Given these shortcomings of the PCDAI, and since its development was judgmental by a small experts' panel, the PCDAI has been revised by a mathematical weighting on 437 children [28] (Appendix 1.2). This weighted PCDAI, termed wPCDAI, excluded three items shown to be redundant in a multivariable model: height velocity, abdominal examination, and hematocrit, thereby improving its feasibility. The score range of the wPCDAI is 0–125. In the validation cohort, it had higher correlation with physician global assessment (PGA) and ESR than the original PCDAI (0.75 vs 0.67 and 0.58 vs 0.49, respectively). The discriminant validity was better with the wPCDAI: it differentiated those in remission from active disease (area under the ROC curve 0.95), and unlike the original PCDAI, differentiated well between moderate and severe disease (area under the ROC curve 0.87). wPCDAI performed well as a primary outcome measure in recent studies assessing response rates to a sec-

ond biological agent [29] and repeated courses of nutritional therapy in CD [30] in which remission was defined as wPCDAI <12.5 and response as decrease in wPCDAI >17.5.

In addition to the wPCDAI, a number of abbreviated PCDAI instruments have been proposed to increase the feasibility of the PCDAI for use in retrospective chart reviews [31, 32]. The abbreviated PCDAI (abbrPCDAI) retained the three history variables (abdominal pain, general well-being, and stools per day), weight variable, abdominal exam, and perirectal disease. A larger study presented a short version of the PCDAI (shPCDAI), excluding items with a low frequency of completion in a patient registry [27]. The difference between the shPCDAI from the abbrPCDAI is that the extraintestinal manifestation item has replaced the perianal item and new weights have been mathematically assigned to each item, reflecting their relative importance to PGA of disease activity. The exclusion of the lab items in both indices increased their feasibility but at the expense of reduced validity when compared head-to-head with the other PCDAI versions [33]. Nonetheless, these versions may be used in retrospective studies when not all items required for the full index are available. A third abbreviated version, a modified PCDAI (modPCDAI), aims to provide a measure of disease activity in pediatric Crohn disease when only blood tests are available (e.g., in administrative databases) [34].

PCDAI has a poor correlation with endoscopic assessment of mucosal healing both at diagnosis (r = 0.33) and following induction therapy (r = 0.34) and is an inferior

marker than both CRP and fecal calprotectin [35]. Further analysis on two large prospectively collected cohorts (ImageKids and GROWTH studies) showed that all four PCDAI versions (i.e., PCDAI, wPCDAI, abbrPCDAI, and shPCDAI) had at best, fair correlation (r = 0.42–0.45) with mucosal healing [33].

A validated non-invasive marker of subclinical inflammation and mucosal healing is becoming an increasingly critical need given the increasing recognition of progressive intestinal damage even in the absence of clinical disease [36–40]. Nonetheless, repeated endoscopic evaluation is not feasible in children. Significant progress was made to address this gap with the recent development and validation of the Mucosal Inflammation Non-invasive (MINI) Index for pediatric Crohn disease [41] (Appendix 1.3). Utilizing clinical, biochemical, endoscopic, and magnetic resonance enterography data from the large dataset of the prospective ImageKids study, and validated on three independent patient cohorts, an index was developed in a blended mathematical judgmental clinimetric approach to identify children with mucosal healing. The MINI index incorporates stool frequency and character, fecal calprotectin, ESR and CRP in a weighted categorized index. A MINI index score below 8 identified children with mucosal healing with 88% sensitivity and 85% specificity. Among the 12% of children with MINI ≥8 with active mucosal inflammation, 86% of these had merely mild inflammation [41].

Perianal Crohn Disease

In classification of perianal CD, a distinction should be made between the detailed anatomic description of perianal fistulas and an assessment of fistula activity [42]. There are two disease activity measures traditionally used in adult clinical trials to follow perianal CD activity: the Perianal Disease Activity Index (PDAI) and the Fistula Drainage Assessment (Appendix 2.1). The PDAI contains 5 items, each scored 0 to 4, with higher scores representing more severe disease [43]. In the validation cohort, it had moderate correlation with both physician and patient assessment of perianal disease activity (r = 0.72 and 0.66, respectively). In the Fistula Drainage Assessment, [44], a fistula is considered closed when it no longer drained, despite gentle finger compression. A response has been defined in clinical trials as a reduction of 50% or more in the number of draining fistulas, and remission as absence of any draining fistulas on two consecutive visits [45–47]. Its high feasibility is an advantage, but a major limitation of the PDAI is the subjectivity in "gentle finger compression." In addition, the main drawback of both clinical indices is the dependency on external appearance rather than the real status of the fistula. Therefore, MRI-based indices are gradually replacing these legacy scores.

van Assche et al. generated an index, subsequently referred to as the van Assche index, which scores number of fistula tracks, location (extra/intersphincteric, transsphincteric, or supra sphincteric), extension (infralevatronic or supralevatronic), hyperintensity on T2-weighted images, collections, and rectal wall involvement [48, 49]. The MRI-based index is relatively simple to calculate with high interobserver concordance and acceptable responsiveness, yet has only been partially validated [50, 51].

More recently, a newer MRI index for assessing perianal fistulas, termed the magnetic resonance index for fistula imaging in CD (MAGNIFI-CD), was developed and validated utilizing paired baseline and week 24 MRI scans from 160 patients [52]. The index consists of weighted scoring of eight items: number of fistula tracts, hyperintensity of primary tract on T2-weighting, hyperintensity on T1 weighting, dominant feature (fibrous, granulation tissue or fluid/pus), proctitis, fistula length, extension, and presence/features of inflammatory mass. This index has yet to be externally validated.

Of MRI features of perianal disease, recent pediatric data suggest that perianal fistula length assessed by MRI was found to be the best predictor of treatment response [53], yet there lacked a unique perianal disease indices developed or validated in children. Utilizing the ImageKids study dataset, a pediatric-specific MRI index of perianal CD, termed Pediatric MRI-based Perianal Crohn disease index (PEMPAC) (Appendix 2.2), was recently developed and validated [54]. Ninety-five pelvic MRI's on 80 children were centrally read by two readers and scaled for perianal disease severity on a visual analog scale. Radiological items selected by a Delphi group were assessed in different multivariable statistical models whereby fistula number, length and location of the fistulas, hyperintensity on T2-weighted imaging, and collections >3 mm were identified as the items with the greatest correlation to radiological global assessment. The PEMPAC correlates strongly with radiological global assessment and performed comparably with the van Assche index in its ability to differentiate remission from active disease, and demonstrated good responsiveness to change.

Ulcerative Colitis Disease Activity Indices

The earliest classification of UC disease activity was a qualitative scale published by Truelove and Witts in 1955 [55]. Arbitrary quantitative indices have since been introduced, including the Powell-Tuck Index [56], the Mayo Clinic score [57], Rachmilewitz Index [58], and Lichtiger Score [59] with the Mayo score which has been until recently in widespread use [60]. The recent shift away from these indices relates to their more subjective nature, with regulatory bodies requiring more objective indices such as endoscopic scores (as

described below). Additionally, there has been a recent trend, also encouraged by regulatory agencies, to utilize patient reported outcomes instead of, or in addition to physician-derived indices.

The first three scores include an endoscopic evaluation of the rectosigmoid as part of the global assessment. Their validation has been largely a side product of clinical trials in which they have been used and developed. Seo and colleagues developed and evaluated an UC disease activity index [61, 62], weighted against the Truelove and Witts classification but it is hardly used. Walmsley and colleagues developed a Simple Clinical Colitis Activity Index that removed all laboratory parameters [63]. Given its high feasibility, it has gained popularity especially in retrospective research studies. The Endoscopic Clinical Correlation Index (ECCI) was developed prospectively in 137 adults with items chosen based on their ability to predict endoscopic outcome [64]. The ECCI is highly correlated with the endoscopy colitis score ($r = 0.81$), higher than the Seo, Truelove and Witts, Powell-Tuck, and Walmsley's simple colitis index; however, separate validation is not available to assess reliability and responsiveness. In a prospective head-to-head study in adults of all non-invasive UC disease activity indices, the Walmsley index and PUCAI (see below) were best in assessing disease activity when compared to a number of parameters including the Mayo score [65] (Appendix 3.1).

Endoscopic evaluation of the colonic mucosa in UC is invaluable in questionable clinical cases, before major treatment changes and for cancer surveillance, but is not routinely needed to confirm mucosal healing, especially in the presence of low fecal calprotectin [66]. Unlike CD, UC has a more homogenous presentation and thus 80–90% of patients in complete clinical remission will also have mucosal healing or near-mucosal healing [26, 65]. Endoscopic assessment is not without limitations. It is subjective with low inter-observer reliability [67]. Endoscopic appearance lags after clinical improvement, thereby underestimating response to treatment [68]. Furthermore, limited sigmoidoscopy may not reflect the entire disease burden (i.e., the product of severity and extent) especially in children in whom extensive disease is the most common phenotype.

The PUCAI was developed with the aim of reflecting disease activity and mucosal inflammation without invasive measures, hence making it attractive for repeated use (Appendix 3.2) [69]. The feasibility and reliability of the PUCAI were demonstrated on 2503 pediatric UC patients in the ImproveCareNow registry; all items in PUCAI were satisfactorily completed in 96% of visits [70]. PUCAI demonstrated good discrimination between remission, mild and moderate disease, good correlation to PGA ($r = 0.76$) with PUCAI score changes correlating well with PGA score changes over follow-up visits.

The PUCAI is tightly correlated with endoscopic appearance of the colonic mucosa [65, 71] and the correlation with the Mayo score is as high as 0.95 [65, 71, 72]. Predictive validity of the PUCAI is high as per multiple studies. The T72 infliximab trial in children with UC showed that PUCAI-defined remission was not inferior to sigmoidoscopy in predicting 1-year steroid-free sustained remission [72], a finding replicated also in ambulatory UC children [73]. The PUCAI strongly predicted the need for short-term treatment escalation in pediatric UC [26] and the type of surgical intervention, when needed [74]. In two independent cohorts of children requiring admission for intravenous treatment of corticosteroids for UC exacerbations, the PUCAI has shown strong predictive validity of outcomes important to patients, accurately identifying those who will require treatment escalation to second-line medical therapy or colectomy [75, 76]. In this setup, the PUCAI has shown to have superior predictive validity to five fecal biomarkers, including calprotectin [65, 77]. These findings were recently replicated in a large retrospective cohort of adults hospitalized with acute severe colitis, showing superiority of the PUCAI over the legacy adult tools in this setup—the Oxford and the Lindgren criteria [78].

The corresponding PUCAI cut-off scores of remissions (<10 points), mild (10–34 points), moderate (35–64 points) and severe (≥65) disease have been validated in several cohorts and found to have sensitivity, specificity, and area under the ROC curve of >95% [26, 65, 71]. In the regulatory T72 trial evaluating the effectiveness of infliximab in pediatric UC, the PUCAI determined week 8 remission rate was 33%, identical to the rate of complete mucosal healing found by sigmoidoscopy [79]. Similarly, the week 12 remission rate in a clinical trial evaluating Beclomethasone 17,21-dipropionate (BDP) in children with UC, was similar whether determined by sigmoidoscopy or the PUCAI [80], as well as when comparing sigmoidoscopy, ultrasound, and the PUCAI [81].

The PUCAI has also demonstrated predictive abilities regarding surgical management of patients with UC requiring restorative proctocolectomy with ileal pouch-anal anastomosis. A high preoperative PUCAI was significantly predictive of the likelihood of a staged procedure [74]. Beyond its use purely as a marker of disease activity, PUCAI has also been shown to correlate with both children and parents health-related quality of life scores [82].

The recent ESPGHAN-ECCO guidelines on the management of pediatric UC incorporated the PUCAI in evaluating response to treatment, while combining this score with fecal calprotectin results [83]. Specifically, while the goals of treatment in active UC should be clinical remission as defined by PUCAI, since ~20% of these children have endoscopic inflammation, the guidelines recommend fecal calprotectin as a tool to help select those patients requiring endoscopic evaluation.

Patient-Reported Outcomes

Patient-reported outcomes (PRO) involves the report of health status coming directly from the patient without interpretation of the of the patient's response by a clinician or anyone else [84]. There has been developing interest over recent years in PRO as a tool for IBD research, led by the US Food and Drug Administration (FDA). Since PROs capture signs and symptoms of the patients not necessarily related to disease activity and endoscopic appearance, any PRO should be supplemented by an objective measure of inflammation such as fecal calprotectin or endoscopic evaluation. The accuracy of self-reported IBD medical history in comparison to medical records was shown in one study to be fairly good for major factors such as disease type and previous surgical procedures; however, it was poor when more detailed medical information was assessed [85].

An inventory PRO in adults with UC includes stool frequency, bleeding, and general well-being and was shown to correlate well with the Simple Clinical Colitis Activity Index (SCCAI) ($r = 0.71$). However, the patient-generated assessment under-reported active disease in 10% of the study cohort [86].

PRO in the pediatric population presents several unique challenges such as age-related vocabulary, comprehension of health concepts, unclear determination of lower age limit for which responses would be reliable and valid, and the appropriate use of parents or carers to contribute to the reportable outcomes [87]. Recently, a PRO measure of signs and symptoms for pediatric UC, the TUMMY-UC index, has been developed following nearly 150 concept-elicitation and cognitive interviews with children with UC and their caregivers. This work identified good correlation between children and their caregivers regarding the order of importance of various symptoms reflective of perceived disease activity [88]. The TUMMY-UC has a PRO version for adolescents older than 12 years of age and an observer-reported version for younger children who have shown poor understanding of the questions. Each version is composed of eight items which were graded as most important by children and caregivers, including abdominal pain, stool frequency, stool consistency, nocturnal stooling, amount of blood, frequency of bleeding, fatigue, and urgency [89]. The TUMMY-UC has shown high correlation with global assessment of children, caregivers, and physicians, as well as will the PUCAI. In pediatric CD, the development of a corresponding PRO, the TUMMY-CD, is also underway.

Gastrointestinal Endoscopy Indices

Crohn Disease

Mucosal healing in CD has been associated with better long-term outcomes [90]. Indeed, the recent ECCO/ESPGHAN position paper recommends mucosal healing, as a desired treatment target [91]. Two groups have developed standardized approaches to endoscopy findings in CD. The first designed the Crohn Disease Endoscopic Index of Severity (CDEIS) by incorporating endoscopic findings, previously shown to have high inter-rater reliability [92], into a regression model using the physician global assessment of endoscopy severity as the dependent variable [93] (Appendix 4.1). The index was found to have high inter-rater reliability ($r = 0.96$), and was highly correlated with the physician endoscopy assessment in an independent cohort ($r = 0.81$). It has subsequently been used in multiple clinical trials evaluating endoscopic endpoints [94–96]. However, due to its complexity, Daperno and colleagues developed the Simplified Endoscopic Activity Score for Crohn disease (Appendix 4.2) [97]. The SES-CD had high inter-rater reliability (ICC = 0.98) and was highly correlated with the CDEIS ($r = 0.92$). Lower correlations were found between both the SES-CD and CDEIS and other parameters of disease activity including the CDAI (0.39 and 0.36 respectively) and C-reactive protein ($r = 0.47$ and 0.45 respectively) confirming that in CD, mucosal findings do not necessarily reflect the patient's clinical status.

There is no unique endoscopic instrument for pediatric CD but there is no evidence that endoscopic characteristics differ in children. The SES-CD seems to be a valid alternative to its more complicated counterpart also in children.

There is a lack of a universally accepted definition of endoscopic healing (EH) and endoscopic response (ER). Based on a systematic review, a recent Delphi group consensus of the IOIBD defined ER as a 50% decrease in the SES-CD or CDEIS, and EH as SES-CD ≤ 2 or CDEIS < 3 and a lack of any ulcerations including aphthous ulcers [98].

Upper gastrointestinal (UGI) CD is associated with earlier onset and more severe disease [99] and its identification may assist in predicting disease course and directing appropriate therapy. Recently, an UGI SES-CD score was developed, by applying the SES-CD to the UGI tract, specifically scoring the esophagus, stomach body, antrum, and duodenum [100]. The score was assessed on the ImageKids dataset of 202 children among whom 81 were followed for 18 months. Identification of UGI CD involvement by the UGI SES-CD index was associated with higher wPCDAI, PGA of inflammation, ileocolonoscopic SES-CD, fecal calprotectin, and radiological global assessment of damage on MRE. There was, however, no association between initial UGI SES-CD and disease course over follow-up [100].

In recent years, data are accumulating on the value of histologic healing over endoscopic remission, with the assumption that deeper healing improves outcomes. Histological healing in CD, as opposed to in UC as described later, is complicated by a lack of a well-validated index and insufficient data justifying the added benefit of treatment escalation to obtain this endpoint. This was formalized by the recent STRIDE-II guidelines which did not adopt histologic remission as a formal treatment target [98].

Endoscopy is an important outcome in assessing postoperative interventions in CD [101]. Rutgeerts and colleagues [101] proposed a scoring system for recurrent endoscopic disease at the surgical anastomosis (Appendix 4.3). Although quite subjective, higher Rutgeerts scores consistently predicted a more severe clinical course [101]. Patients with no or mild endoscopic lesions (termed i0 and i1, respectively) at 1-year postoperative endoscopy had good long-term outcomes, as opposed to those with clearly progressive disease (i3 or i4) who developed early clinical recurrence and were more prone to a complicated disease outcome in subsequent years. Rutgeerts score i2 is a heterogenous group defined as moderate lesions in the terminal ileum (i2a) or lesions confined to the ileocolonic anastomosis (i2b); however, recent data demonstrate equivalent rate of postoperative occurrence in both subgroups, hence calling into question the benefit of subdividing i2 [102].

Standard endoscopic indices are limited to assessment of the colon, terminal ileum, and developing indices of the upper GIT. Full small bowel assessment was made possible by the introduction of the wireless capsule endoscopy. The Lewis score was developed as a measure of mucosal inflammatory activity based on villous edema, ulcers, and stenosis [103]. (see Appendix 4.5) The Lewis score was validated for the evaluation of small bowel CD, demonstrating strong inter-observer agreement [104]. The Lewis score has been shown to correlate with fecal calprotectin and CRP, [105] serve as a useful clinical tool for patients with suspected CD, [106] and to assess the true inflammatory burden and extent of mucosal healing in patients with clinically quiescent disease [107]. A Lewis score of 135 is designated normal or clinically insignificant, a score between 135 and 790 defined as mild inflammation, and ≥790 is moderate or severe [103]. The Lewis score has also been shown to be the sole predictor of both short-term and long-term (out to 2 years) disease exacerbation in patients with quiescent CD [108]. A Lewis score ≥350 predicted subsequent flare with greater accuracy than fecal calprotectin and MRE, while an increase in Lewis score of ≥383 on follow-up capsule studies predicted imminent disease exacerbation within 6 months.

A second capsule index in use is the Capsule Endoscopy Crohn Disease Activity Index (CECDAI) was developed [109] and validated [110] yet the correlation with fecal calprotectin was found to be stronger in the Lewis score than the CECDAI [111]. While both of these scores incorporate similar parameters, the Lewis score is derived from the most severely involved of the three tertiles, whereas the CECDAI is a cumulative score that represents the summation of segmental scores for proximal and distal small bowel.

More recently, a new pan-enteric video capsule was developed to assess the entire bowel in Crohn disease [112]. The software for this system incorporates a novel quantification system for both small bowel and colonic inflammation assessing "most severe lesion," "most common lesion," and "extent of involvement." This intuitive index has yet to be assessed for validity against clinical, biochemical, or radiological indices. In the interim, it is reasonable to quantify the small bowel using the traditional Lewis score and the colon—by lack of ulceration, as described above.

Ulcerative Colitis Endoscopic Assessment

No endoscopic index in UC has been developed in children but yet again, there is no reason to believe that adults are different than children in assessing the bowel mucosa. Two endoscopic indices used in clinical trials are the Ulcerative Colitis Endoscopic Index of Severity (UCEIS) [67] (see Appendix 4.4) and the Mayo endoscopic subscore (MES) [113]. The MES is a four-point scoring system in which patients with normal/inactive, mild, moderate, or severe disease are given scores 0–3. The UCEIS was only recently validated and demonstrated high intra-investigator and inter-investigator reliability (0.96 and 0.88, respectively) [114]. Subsequently, a Modified Mayo endoscopic subscore (MMES) was developed which factored both severity and distribution of mucosal inflammation [115]. While the UCEIS and the MES have been extensively evaluated, they have only recently been validated for disease responsiveness with the MES performing poorly compared to the UCEIS [116–118].

Despite the lack of consensus, most commonly defined endpoints for these indices are Mayo endoscopy subscore ≥1-point decrease or UCEIS ≥2-point decrease to define endoscopic response. Recent consensus recommends Mayo endoscopic subscore of 0 points and UCEIS of ≤1 point to define endoscopic healing [98, 119]. Some endoscopic assessments have shown to have low reliability [120, 121].

The benefit of histological remission over macroscopic endoscopic healing has been demonstrated in UC both for predicting long-term remission [122, 123] and in cancer prevention [124]. While numerous histologic indices have been developed, the Nancy index [125] and the Robarts histopathology index (RHI) [126] have been most extensively validated. The RHI is significantly more complex and time consuming than the Nancy index yet both have been recommended for clinical trials, whereas the Nancy index may be more suitable for observational studies an potentially in clinical practice [127]. What remains to be determined is the number needed to treat to achieve clinically meaningful outcomes over endoscopic healing alone and hence the utility of these indices in clinical practice remains uncertain [98, 127].

Quality of Life, Disability, and Other Related Instruments

Both adults and children diagnosed with IBD are at increased risk of emotional distress, disability, depression, fatigue, and

decreased social functioning [128, 129]. Thus, quality of life (QOL)-related assessment has been increasingly recognized as an important and independent clinical outcome in IBD research and can be scored by both generic- and disease-specific instruments. A thorough discussion of QOL instruments available for pediatric IBD research is found in Chap. 51. In brief, health-related QOL (HRQOL) is impacted by actual and perceived disability, fatigue, work/school absence, and other factors relating to the physical, psychological, familial, and social sequelae of the disease. Several indices have been developed and validated in adults, including the IBD Disability Index (IBD-DI), a survey relating to 19 items scaled for severity from 1 to 5 [130]. The IBD-DI has been validated and found to have high intra- and inter-rater reliability, strong construct validity, and excellent responsiveness [131]. More recently, the IBD Disk was developed as a shortened, patient-administered survey, adapted from the IBD-DI [132]. Ten items are scored based on level of agreement with the overall score illustrated on a multicolored disk with the area outlined by "joining the dots" reflecting the extent and aspects of QOL-related burden. Pediatric-specific QOL studies have been less well developed, with most data utilizing generic, rather than disease-specific QOL measures [133].

Radiographic Indices

Brief mention should be made about currently available radiographic modalities which are now part of the mainstay of measuring disease in IBD, more so in CD. These modalities were described in greater detail in an earlier section of this book. As outcomes shift from clinical response and remission to mucosal healing, subtle findings of inflammation and intestinal damage may only be detected by use of various imaging techniques. Transmural healing has not yet been included as a formal treatment target but nonetheless, it is well recognized as a vital adjunct measure in CD, both in clinical practice and in the research setting [98]. Moreover, the assessment of bowel damage as an important disease endpoint is increasingly incorporated using validated multi-items tool. The advent of bedside abdominal ultrasound (US) assessment has increased the feasibility of measuring this concept repeatedly. It is non-invasive, lacks radiation, and relatively cheap, but it is operator-dependent [134]. In a large prospective trial comparing small bowel US to MRE, while MRE outperformed US in sensitivity and specificity, both were found to have high sensitivity for detecting small bowel lesions and could be considered valid first-line investigations [135]. Recently a Simple Sonographic Score was developed and validated, derived from the two US findings of greatest correlation with disease activity: bowel wall thickness and color Doppler signal, and found to accurately reflect CD activity [136].

For MRE in adults, the MaRIA and Lémann scores have been developed to assess inflammatory activity and damage, respectively [137–139]. More recently, a simplified MaRIA score (sMaRIA), which lacks the need for gadolinium injection has been developed [140] for quantifying treatment response in luminal CD [141]. Most recently, a pediatric MRE-based disease activity index has been developed: the Pediatric Inflammatory Crohn's MRE Index (PICMI) [142, 143]. The PICMI was developed and validated as part of the ImageKids study, a multicenter international study which recruited 240 children (5–18 years) diagnosed with CD, undergoing MRE, ileocolonoscopy, and upper tract endoscopy within 14 days. PICMI was developed specifically for pediatric CD and includes the entire small and large bowel and does not require colon preparation or enema. The weighted items retained following multivariable regression modeling are wall thickening, DWI, ulceration, edema, and comb sign: 3 × Wall thickness (>3 mm) + 9 × DWI (0/1) + 6 × Ulcers (0/1) + 6 × Edema (0/1) + 9 × Comb sign. The PICMI was highly correlated with the MaRIA and the sMaRIA (0.79 and 0.77, respectively, unpublished). The PICMI does not require the use of the T1 sequences pre- and post-enhancement, and thus can be calculated without the use of Gadolinium.

Summary of Clinical Outcome Measures

Various instruments are available to measure clinical outcomes in pediatric IBD (Table 46.2). Valid pediatric clinical indices and quality of life-related measures exist for both UC and CD as well as recently developed PRO's and MRE-related indices. The evaluation of health-related indices is

Table 46.2 Clinical indices for research in pediatric inflammatory bowel disease

Clinical trial outcome	Instrument	
	Crohn disease	Ulcerative colitis
Disease activity index	Physician global assessment PCDAI/wPCDAI TUMMY-CD (future) MINI index	Physician global assessment PUCAI TUMMY-UC
Perianal disease activity index	Fistula Drainage Assessment PEMPAC	N/A
Endoscopic scores	CDEIS (assessed only in adults) SES-CD (assessed only in adults) UGI-SES-CD Lack of ulcerations Lewis score (adults)	UCEIS (adults) Mayo endoscopic subscore (adults)
Quality of life instruments Generic Disease-specific	Multiple (e.g., PedsQL, Child QOL questionnaire) IMPACT-III	Multiple (e.g., PedsQL, Child QOL questionnaire) IMPACT-III

an ongoing process and therefore, the development of new indices and the re-evaluation of the performance of existing indices will continue to be explored in different clinical and research settings. Furthermore, each index should not be seen in isolation—combining different indices can often provide a more complete assessment of the patient. For example, combination of wPCDAI or TUMMY-CD (as a PRO measure) with the MINI index or fecal calprotectin would provide a more complete picture of the patient, relating not only to clinical sequelae of the disease but also reflecting attainment of mucosal healing. Additionally, HR-QOL indices helps formulate a more holistic assessment of the patient to better implement multiple aspects of the management plan.

Appendix 1

Appendix 1.1: Pediatric Crohn Disease Activity Index [19] History (Recall, 1 week)

Abdominal pain						**Score**
0 = None	**5** = Mild: Brief, does not interfere with activities			**10** = Moderate/Severe: Daily, longer lasting, affects activities, nocturnal		_____
Patient functioning, general well-being						**Score**
0 = No limitation of activities, well	**5** = Occasional difficulty in maintaining age appropriate activities, below par			**10** = Frequent limitation of activity, very poor		_____
Stools (per day)						**Score**
0 = 0–1 liquid stools, no blood	**5** = Up to 2 semi-formed with small blood, or 2–5 liquid			**10** = Gross bleeding, or ≥6 liquid, or nocturnal diarrhea		_____
Laboratory						
Hematocrit (HCT)						**Score**
<10 years:			11–14 years (Male):			
0 = ≥33%	**2.5** = 28–32%	**5** = <28%	**0** = ≥35%	**2.5** = 30–34%	**5** = <30%	
11–19 years (Female):			15–19 years (Male):			
0 = ≥34%	**2.5** = 29–33%	**5** = <29%	**0** = ≥37%	**2.5** = 32–36%	**5** = <32	_____
Erythrocyte sedimentation rate (ESR)						**Score**
0 = <20 mm/h	**2.5** = 20–50 mm/h	**5** = >50 mm/h				_____
Albumin						**Score**
0 = ≥35 g/L	**5** = 31–34 g/L	**10** = ≤30 g/L				_____
Examination						
Weight						**Score**
0 = Weight gain or voluntary weight stable/ loss	**5** = Involuntary weight stable, weight loss 1–9%			**10** = Weight loss ≥10%		_____
Height at diagnosis						**Score**
0 = <1 channel decrease	**5** = ≥1 to <2 channel decrease			**10** = >2 channel decrease		_____
Height at follow-up						**Score**
0 = Height velocity ≥ −1SD	**5** = Height velocity < −1SD, > −2SD			**10** = Height velocity ≤ −2SD		_____
Abdomen						**Score**
0 = No tenderness, no mass	**5** = Tenderness, or mass without tenderness			**10** = Tenderness, involuntary guarding, definite mass		_____
Perirectal disease						**Score**
0 = None, asymptomatic tags	**5** = 1–2 indolent fistula, scant drainage, no tenderness			**10** = Active fistula, drainage, tenderness, or abscess		_____
Extraintestinal manifestations						**Score**
(Fever ≥ 38.5 °C for 3 days over past week, definite arthritis, uveitis, E. nodosum, P. gangrenosum)						
0 = None	**5** = One			**10** = ≥Two		_____
Total Score:						

Appendix 1.2: Weighted Pediatric Crohn Disease Activity Index (wPCDAI) [68] History (Recall, 1 week)

Abdominal pain			**Score**
0 = None	**10** = Mild: Brief, does not interfere with activities	**20** = Moderate/Severe: Daily, longer lasting, affects activities, nocturnal	_____
Patient functioning, general well-being			**Score**
0 = No limitation of activities, well	**10** = Occasional difficulty in maintaining age appropriate activities, below par	**20** = Frequent limitation of activity, very poor	_____
Stools (per day)			**Score**
0 = 0-1 liquid stools, no blood	**7.5** = Up to 2 semi-formed with small blood, or 2–5 liquid	**15** = Gross bleeding, or ≥ 6 liquid, or nocturnal diarrhea	_____

Total Score (0–125):			

Appendix 1.3: The MINI Index

Item	Points
1. Stool	
0–1 Normal or liquid stools, no blood	0
≤2 Semiformed with small blood, or 2–5 liquid	4
Gross bleeding, or ≥6 liquid, or nocturnal diarrhea	8
2. Fecal calprotectin	
<50 µg/g	−3
50–99.9 µg/g	0
100–299.9 µg/g	5
300–599.9 µg/g	7
600–899.9 µg/g	9
≥900 µg/g	12
3. ESR and CRP	
ESR < 10 mm/h and CRP <5 mg/L	0
30 > ESR ≥ 10 mm/h or 10 > CRP ≥ 5mg/L	1
50 > ESR ≥ 30 mm/h or 30 > CRP ≥ 10mg/L	2
ESR ≥ 50 mm/h or CRP ≥ 30 mg/L	5
Sum of MINI	−3 to 25

User guide:

1. While it is possible to score the MINI index with either CRP or ESR, both are preferred
2. Score the highest of CRP or ESR
3. The stool item: The intent is to score the stool pattern during the preceding week. First categorize the subject as having blood in the stool or not

If there is no blood in the stool, score as follows:

- Formed stools or up to 1 loose stool daily = 0
- 2–5 liquid or very loose stools on 1 or more days = 4
- 6 or more liquid or very loose stools on 1 or more days or any nocturnal diarrhea = 8

If blood is present in the stool, score as follows:

- Small amounts of blood (on toilet paper or small spots in stool) = 4
- Any gross bleeding (large amounts on stool or colors the water in the toilet) = 8

CRP C-reactive protein, *ESR* erythrocyte sedimentation rate, *MINI* Mucosal-Inflammation Non-invasive

Appendix 2

Appendix 2.1: Perianal Crohn Disease Activity Index [43]

Discharge	
0	No discharge
1	Minimal mucous discharge
2	Moderate mucous or purulent discharge
3	Substantial discharge
4	Gross fecal soiling
Pain/restriction of activities	
0	No activity restriction
1	Mild discomfort, no restriction
2	Moderate discomfort, some limitation activities
3	Marked discomfort, marked limitation
4	Severe pain, severe limitation

Restriction of sexual activity	
0	No restriction sexual activity
1	Slight restriction sexual activity
2	Moderate limitation sexual activity
3	Marked limitation sexual activity
4	Unable to engage in sexual activity
Type of perianal disease	
0	No perianal disease/skin tags
1	Anal fissure or mucosal tear
2	<3 perianal fistulae
3	≥3 perianal fistulae
4	Anal sphincter ulceration or fistulae with significant undermining of skin
Degree of induration	
0	No induration
1	Minimal induration
2	Moderate induration
3	Substantial induration
4	Gross fluctuance/abscess
Total score = sum of total score per category	

Appendix 2.2: Fistula Drainage Assessment [44]

	Definition
Remission	Fistula closure or absence of any draining fistulas for at least 4 weeks
Response	≥50% decrease in draining fistulas for at least 4 weeks

Appendix 2.3

Parameter	Score
Maximal hyperintensity on T2-weighted imaging	
None	0
Mild	2
Pronounced	4
Total length of fistulas	
None	0
Short (1–25 mm)	2
Medium (26–50 mm)	4
Long (>51 mm)	6
Number of fistulas	
None	0
Single	4
Multiple	8
Collections (>3 mm)	
Absent	0
Present	11
Location	
None	0
Inter-sphincteric	3
Trans-sphincteric	6
Extra-sphincteric	9
Trans-sphincteric and inter-sphincteric	12
SUM OF PEMPAC (0–41)	

- **Cut-off values**: PEMPAC<10 (*Remission*), PEMPAC 10–15 (*Mild disease*), PEMPAC 16–29 (*Moderate disease*), PEMPAC ≥30 (*Severe disease*)
- A change of at least 4 points denotes the minimally important difference
- In case of more than one fistula, the location should be scored according to the highest scored fistula

Appendix 4

Appendix 4.1: Crohn Disease Endoscopic Index of Severity [93]

	Rectum	Sigmoid and left colon	Transverse colon	Right colon	Ileum	Total
Deep ulceration (12 present, 0 absent)						1
Superficial ulceration (6 present, 0 absent)						2
Surface involved by the disease (/10 cm)[a]						3
Ulcerated surface (/10 cm)[a]						4

$$\frac{\text{Total A} = \text{Total}1 + \text{Total}2 + \text{Total}3 + \text{Total}4}{\text{No.of segments explored}(1-5)}$$

CDEIS = Total A + 3 (ulcerated stenosis present) + 3(non-ulcerated stenosis present)

Adapted from Daperno and colleagues [97]

[a]Analog scales converted to numeric values

Appendix 4.2: Simple Endoscopic Score for Crohn Disease [97]

	Score per segment			
Variable	0	1	2	3
Size of ulcers	None	Aphthous ulcers (0.1–0.5 cm[a])	Large ulcers (0.5–2 cm[a])	Very large ulcers (>2 cm[a])
Ulcerated surface	None	<10%	10–30%	>30%
Affected surface	Unaffected segment	<50%	50–75%	>75%
Presence of narrowing	None	Single, can be passed	Multiple, can be passed	Cannot be passed

SES-CD = Total score from each segment (rectum, sigmoid and left colon, transverse colon, right colon, ileum)
Final score = Total SES-CD score − 1.4 (number of affected segments)
[a]Diameter

Appendix 4.3: Rutgeerts Score for Postoperative Endoscopic Disease Recurrence [101]

Grade	Endoscopic finding
0	No lesions in the distal ileum
1	≤5 aphthous lesions
2	>5 aphthous lesions with normal mucosa between the lesions or skip areas of larger lesions or lesions confined to the ileocolonic anastomosis
3	Diffuse aphthous ileitis with diffusely inflamed mucosa
4	Diffuse inflammation with already larger ulcers, nodules, and/or narrowing

Appendix 4.4: Ulcerative Colitis Endoscopic Index of Severity (UCEIS) [65]

Descriptor (score most severe lesions)	Likert scale anchor points	Definition
Vascular pattern	Normal (1)	Normal vascular pattern with arborization of capillaries clearly defined
	Patchy loss (3)	Patchy loss or blurring of vascular pattern
	Obliterated (5)	Complete loss of vascular pattern
Mucosal erythema	None (1)	The color of the mucosa is normal
	Light red (3)	Some increase in color of the mucosa that is probably abnormal, but would be best compared side by side with a normal examination
	Dark red (5)	Red or crimson color of the mucosa that is similar to blood—that is, clearly abnormal even if not compared with a normal examination (does not include intramucosal hemorrhage)
Mucosal surface (Granularity)	Normal (1)	Smooth mucosa with a sharp light reflex, similar to a polished surface
	Granular (3)	Mucosal surface diffuses reflected light causing minor variation in the surface
	Nodular (5)	Evident nodular variation in mucosal surface
Mucosal edema	None (1)	Normal appearance: no white or yellow substance visible
	Probable (3)	Slight swelling and thickening of mucosa
	Definite (5)	Marked thickening and edema of the mucosa with blunting of the mucosal folds
Mucopus	None (1)	Normal appearance: no white or yellow substance visible
	Some (3)	White or yellow deposits on the mucosa unrelated to any bowel preparation
	Lots (5)	Mucopus substantially covering the mucosal surface unrelated to any bowel preparation
Bleeding	None (1)	No visible blood
	Mucosal (2)	Some spots or streaks of coagulated blood on the surface of the mucosa ahead of the scope, which can be washed away
	Luminal mild (3)	Some free liquid blood in the lumen
	Luminal moderate (4)	Frank blood in lumen ahead of endoscope or visible oozing from mucosa after washing intraluminal blood
	Luminal severe (5)	Frank blood in the same lumen with visible oozing from a hemorrhagic mucosa
Incidental friability	None (1)	No bleeding or intramucosal hemorrhage before or after passage of the endoscope
	Mild (2)	No bleeding at the site of assessment before, but minor bleeding or intramucosal hemorrhage after, passage of the endoscope
	Moderate (3)	Intramucosal hemorrhage without overt bleeding before passage of the endoscope
	Severe (4)	Overt bleeding after passage of the endoscope
	Very severe (5)	Overt bleeding from the mucosa

Descriptor (score most severe lesions)	Likert scale anchor points	Definition
Contact friability	None (1)	No bleeding from the mucosa after light touch with closed biopsy forceps
	Probable (3)	Intramucosal hemorrhage or minor bleeding after light touch with closed biopsy forceps
	Definite (5)	Overt bleeding mucosa after light touch (within 10 s) with closed biopsy forceps
Erosions and ulcers	None (1)	Normal mucosa, no visible erosions or ulcers
	Erosions (2)	Tiny (≤5 mm) defects in the mucosa, of a white or yellow color with a flat edge
	Superficial ulcer (3)	Larger (>5 mm) defects in the mucosa, which are discrete fibrin-covered ulcers in comparison with erosions, but remain superficial
	Deep ulcer (4)	Deeper excavated defects in the mucosa, with a slightly raised edge
Extent of erosions or ulcers	None (1)	None seen during endoscopy
	Limited (2)	<10% of the affected mucosa
	Substantial (3)	10–30% of the affected mucosa
	Extensive (4)	>30% of the affected mucosa

Appendix 4.5: Lewis Score [103]

Parameters	Number	Longitudinal extent[a]	Descriptors
Villous appearance (worst-affected tertile)	Normal—0	Short segment—8	Single—1
	Edematous—1	Long segment—12	Patchy—14
		Whole tertile—20	Diffuse—17
Ulcer (worst-affected tertile)	None—0[b]	Short segment—5	<1/4—9[c]
	Single—3[b]	Long segment—10	1/4—1/2—12[c]
	Few—5[b]	Whole tertile—15	>1/2—18[c]
	Multiple—10[b]		
Stenosis (whole study)	None—0	Ulcerated—24	Traversed—7
	Single—14	Nonulcerated—2	Not traversed—10
	Multiple—20		

Lewis score: Score of the worst-affected tertile [(villous parameter × extent × descriptor) + (ulcer number × extent × size)] + stenosis score (number × ulcerated × traversed)

[a] Longitudinal extent: short segment:<10% of the tertile; long segment: 11%–50% of the tertile; whole tertile:>50% of the tertile

[b] Ulcer number: single: 1; few: 2–7; multiple:≥8

[c] Ulcer descriptor (size): proportion of the capsule picture filled by the largest ulcer

Clinical Trials (Clinical Perspective)

47

Marina Aloi and Salvatore Cucchiara

Introduction

Several epidemiologic studies report that up to 30% of new inflammatory bowel disease (IBD) cases are diagnosed in childhood [1]. Pediatric IBD (PIBD) seems to be more extensive and severe than the adult-onset forms, with a frequent need for second-line therapies, including immunomodulators and biologics, and a more complicated disease course [2, 3]. However, excluding most patients with very early-onset IBD (VEOIBD) receiving the diagnosis when younger than 6 years, particularly those with the infantile-onset IBD (patients younger than 2 years), pediatric and adult-onset disease seem to share mechanisms, diagnostic work-up, endoscopic, and histopathological features [4]; moreover, not uncommonly, therapeutic pediatric strategies are simply "extrapolated" from adult trials in "off-label" use. Indeed, randomized clinical trials (RCTs) in children could be more difficult for several reasons: first of all ethical concerns, due to the natural vulnerability of this population, and for the relative paucity of eligible patients, because of the lower number of incidents and prevalent cases compared with adults. Moreover, parents, worried about possible therapy adverse events and/or additional invasive tests and visits, are more hesitant to have their children recruited in interventional trials than adult patients. Similarly, physicians hesitate to enroll young patients in interventional studies involving invasive procedures.

The other side of the coin is that children with IBD represent a unique cohort of patients to be explored, as far as aspects such as the initial host immune response, the need for early treatment, genotype-to-phenotype relationship, and the natural disease course, are concerned. Above all, because of the higher impact of environmental factors that may influence adult-onset disease (e.g., comorbidities, disease duration, drugs, smoking), the knowledge of the pathogenetic pathways of pediatric IBD can provide insights into the initial mechanisms underlying the disease [5].

A crucial factor when evaluating the efficacy of different treatments in children with IBD is the ability to compare new drugs to known therapies in a meaningful way. Randomized clinical trials lead to gold-standard evidence on the efficacy of pharmacologic and nonpharmacologic treatment of IBD. An ideal clinical trial should answer to well-defined primary research endpoints in specific study populations and should provide significant results both statistically and clinically. Steps that describe RCTs are: clear definition of the primary (and secondary) outcomes; definition of the eligible population; randomized assignment to the treatment regimen; and standardized and well-defined interventions. Moreover, a well-defined study population, based on explicit outlined inclusion and exclusion criteria, is mandatory when designing an RCT. The trial design should be sufficiently linear to fulfill the trial's questions; on the other hand, it must not be so weighty that patients and physicians cannot complete the study. Furthermore, clinical trials conducted in children must balance quality with feasibility while considering unique age-specific ethical considerations. Enrolling children in clinical trials of drugs that are already widely used in adults is, therefore, particularly challenging, and a placebo-controlled design in this circumstance is most often untenable for many investigators and parents. Very recently, several PIBD experts published a comprehensive review to highlight the pediatric challenges in regulatory trial design [6]. The authors underlined the importance of avoiding unnecessary and irrealistic endpoints in designing pediatric trials (i.e., too many invasive procedures, unrealistic sample power, etc.), and tried to identify easily attainable outcomes combining objective disease measures as well as patient clinical symptoms. At the same time, pharmacokinetic/pharmacodynamic (PK/PD) pediatric data, along with specific dosing and safety, should be always evaluated in pediatric-conceived drug trials. Furthermore, the authors claimed that no placebo studies should be performed in children if the

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_47

study drug was previously shown to be superior to placebo in children and/or in adults. Indeed, one of the main barriers to perform a pediatric RCT is the potential need for a placebo arm. Although a randomized, double-blind, parallel-group trial is regarded as the ideal study design for assessing the efficacy of a new drug, this can prompt ethical and feasibility problems for pediatric studies [7]. Placebo-controlled trials are indeed hardly suitable for clinical trials for the vulnerable population of children with IBD. According to an evidence-based, expert-driven practical statement paper of the pediatric ECCO committee on the outcome measures for clinical trials in pediatric IBD [8], a placebo may only be considered for pediatric trials when evaluating additional treatments, provided that both study groups (treatment and control) receive effective therapy. In line with this position, a recent joint position paper from ESPGHAN, ECCO, the global PIBDnet, and the Canadian Pediatric IBD network, further states that placebo should only be accepted in children with IBD when true equipoise exists against the active therapy. In contrast, it should not be used when previous adult trials have already shown the efficacy of the active treatment, supported by clinical experience in children [9].

Identifying the correct endpoints when designing pediatric clinical trials is also crucial to achieve significant results. The ECCO experts identified several important outcomes for RCTs in pediatric IBD, the first being the recommendation to define steroid-free mucosal healing (MH) as assessed by endoscopy as the primary end-point for all preauthorization trials for a new drug authorization. Mucosal healing has emerged as a specific treatment endpoint in adult IBD, both in clinical trials and in clinical practice, as it is associated with a reduced risk of disease exacerbations in the long-term, treatment escalations, hospitalization rate, and colectomy [10, 11]. Prospective studies in children have rarely been performed using MH as a primary outcome so far [12]. In the case of therapies already demonstrated to induce MH in adult trials, ECCO experts recommend using objective measures of disease activity [weighted Pediatric Crohn Disease Activity Index (wPCDAI) or Pediatric Ulcerative Colitis Activity Index (PUCAI)] as primary endpoints. However, very recently, adulthood and pediatric gastroenterologists, on behalf of the International Organization for the Study of IBD (IOIBD), have recommended that even in children the long-term therapeutic goal is deep remission (which includes endoscopic healing of the mucosa, normalization of biohumoral, and fecal markers of inflammation in addition to the disappearance of symptoms), while the goal of a deeper remission (including transmural and histological healing) requires further research, mainly to define whether these targets justify more aggressive and expensive methods, with associated additional risks [13].

Recently, the Food and Drug Administration (FDA) has declared that pediatric studies are not necessarily required for all new treatments. However, "extrapolation" from adult trials should always take into account drug pharmacokinetics, pharmacodynamics, and evaluation of potential and real side effects/toxicities. It is still emphasized that the pharmaceutical industry should focus on pediatric pharmacokinetic studies for those medications with a strong potential impact on children. On the other hand, specific pediatric outcomes, including the effect on growth and bone-related variables, cannot be evaluated based on adult studies. Therefore, an accurate balance between the concerns of conducting a pediatric trial and the advantages of having well-defined data should be always be sought for any proposed trial.

Summary

Up to now, only few RCTs in children with IBD have been performed. Although pediatric and adult IBD probably share their pathogenetic mechanisms, histopathological damage, and response to therapies, an accurate balance between the usefulness of the data from adult studies and those required for the optimal knowledge of efficacy and safety of new drugs for pediatric IBD must always be considered. Partial extrapolation of adult data is reasonable and tolerable, if including data on drug pharmacokinetics, pharmacodynamics, and safety. A placebo should not be used in pediatric clinical trials when the superior efficacy of a new drug has already been documented in adults. However, pediatric RCTs are needed to identify specificities of treatment strategies in children, as well as to understand the long-term impact of new treatment strategies on specific outcomes (growth and bone-related issues), thus ensuring that children with IBD can access new treatments in a reasonable time frame.

Global Regulatory Industry Perspective of Clinical Trials

48

Timothy Cripps and Andrew E. Mulberg

Key Stakeholders in Drug Development Process

Pediatric drug development presents novel challenges and opportunities. The following chapter will review relevant laws guiding drug development in the USA and EU, provide an overview of the drug development process in general, and highlight some of the specific challenges for pediatric patients in clinical trials, utilizing inflammatory bowel disease as an example.

The drug development process in the USA and EU is guided by regulations. With particular respect to children, the goal of these regulations is to improve the health of children aged 0–17 years by promoting the study of therapeutic agents in pediatrics, while establishing protections for this vulnerable population. Drug development involves a collaborative effort among regulators, industry sponsors, academic researchers, and individual investigators.

Regulatory Agencies

In the USA, each step in the drug development process is regulated by the Food and Drug Administration (FDA). The agency regulates a wide variety of products, including food products, drugs for human and animal use, cosmetics, biologic agents, medical devices, radiation-emitting products, and animal feed. The agency's actions, under current US laws, regulate all phases of the drug development process.

In the EU, the regulatory network of Member States' national regulatory agencies, the EMA, and the EC regulates all phases of drug development and post-authorization lifecycle management. National regulatory agencies and the EMA cooperate and share expertise in the assessment of new medicines and of new safety information. They also rely on each other for the exchange of information in the regulation of medicine. This is underpinned by EU legislation which requires that each Member State operates to the same rules and requirements regarding the authorization and monitoring of medicines.

Efforts to standardize the drug development process across countries and promote international cooperation have been increasing, augmented through the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH). The mandate of ICH is to bring together regulatory authorities and the pharmaceutical industry to discuss scientific and technical aspects of pharmaceuticals and develop ICH guidelines. Since its inception in 1990, ICH has gradually evolved, to respond to increasingly global developments in the pharmaceutical sector and these ICH guidelines are applied by a growing number of regulatory authorities. Given the difficulty in enrolling sufficient numbers of pediatric patients into trials in general, this is of particular relevance for pediatric drug development as outlined in the ICH E11(R1) guideline on clinical investigation of medicinal products in the pediatric population.

Industry Sponsors

Industry sponsors conduct research to identify potential therapeutic targets and seek biological or chemical agents that will affect a target to treat disease. Once a suitable target is identified, the sponsor will begin a rigorous process of preclinical, followed by clinical development, with the goal of ultimately identifying a product that can be brought to market. Close collaboration between industry sponsors and global regulatory health authorities is vital to expeditious development of new drugs and biologic molecules. Some sponsors will choose to utilize a contract research organization (CRO) to handle the planning and implementation of some or all of a clinical trial. This is particularly helpful for

smaller companies that may not have the required experience, infrastructure, or resources to successfully run a large clinical trial.

Academic Researchers

Apart from private firms, scientists and physicians at academic institutions also participate in various steps in the drug development process. Both university-based and government-funded research laboratories conduct vital basic science investigations to identify molecular mechanisms of disease, which may ultimately result in new drug target identification. Physician-scientists often participate in this work and provide clinical context which allows for a more direct translation of basic science concepts to clinical care. Additionally, social science research into optimal methods to measure the clinical outcomes of importance to patients (development of patient-reported outcome tools or PROs) may also be conducted by academic staff and have direct implications on clinical trials.

Investigators

Once a proposed product has been rigorously tested in nonclinical studies and models, it must then be tested in patients. Clinical trial investigators are typically physicians treating patients with the condition of interest. They may be located in an academic or private practice setting. In collaboration with industry sponsors, individual investigators will share the responsibility for enrolling suitable patients into drug trials, monitoring the safety of those patients, and generating data that will ultimately be used to make a final determination of the safety and efficacy of a given new drug product.

Regulations Guiding Pediatric Drug Development

This section will briefly review some of the major legislative changes in the US and EU which guide the pediatric drug development process today.

In the early 1900s, global regulations pertaining to the manufacturing, marketing, and distribution of drug products were minimally restrictive. The existing US regulations at that time, under the Food and Drug Act of 1906, did not prohibit false therapeutic claims, nor did they provide FDA significant power to enforce the regulations that did exist [1]. Thus, the US market was filled with products that lacked adequate safety or efficacy testing.

Sulfanilamide Tragedy 1937 and the Food, Drug, and Cosmetic Act of 1938

"Elixir of Sulfanilamide" was a liquid preparation of a commonly used antibiotic, manufactured and distributed widely without adequate safety testing. After the deaths of more than 100 people in 1937, many of them children, it was ultimately discovered that the manufacturer had utilized ethylene glycol, a poisonous substance, as a solvent [2]. It was in part this tragedy that spurred Congress to pass new legislation imposing stricter regulations on the industry and providing FDA with increased authority to regulate the pharmaceutical industry. This came in the form of the **Food, Drug, and Cosmetic Act (FDCA) of 1938**, which President Roosevelt signed into law.

One of the critical provisions in the law mandated premarket approval of all new drugs. This meant that a drug manufacturer was required to prove to the FDA that its product was safe for use prior to marketing. The new law also contained provisions that extended FDA control to cosmetics and devices; provided safe tolerances be set for unavoidable poisons; authorized standards of identity, quality, and fill of container for foods; authorized factory inspections; and added penalties for those who violated these laws [1]. The passage of FDCA was an important step in improving the safety of the drugs available in the marketplace, as previously there had been no standard requiring demonstration of the safety of pharmaceutical products. The FDCA was subsequently updated with the **Durham–Humphrey Amendment of 1951**, which established the need for medical supervision in the use of certain drug products and defined for the first time which drugs would be available by prescription only.

Thalidomide Tragedy 1957–1961, the Kefauver–Harris Amendments of 1962, and the European Directive 65/65/EEC

Thalidomide was launched in Europe in 1957 and proclaimed a "wonder drug" for insomnia, morning sickness, coughs, colds, and headaches, by the manufacturer. At this time, drugs were not thoroughly tested for potential harm to the fetus and use during pregnancy was not strictly controlled. While initially considered safe, it was ultimately concluded that thalidomide was responsible for teratogenic deformities in children born after their mothers used it during pregnancy, prior to the third trimester, resulting in the drug being withdrawn from all markets in 1961. By this time, *thalidomide had been introduced into 46 different countries worldwide resulting in the estimated* deaths of

approximately 2000 children and serious birth defects in more than 10,000 children [3].

The Thalidomide tragedy has arguably had the most profound effect in shaping medicines regulation in the modern era. Although thalidomide was never approved for marketing in the USA, it spurred a major change in the history of US drug regulation with the passage of the **Kefauver–Harris Amendments (KHA) of 1962** to the FDCA [4]. The KHA first introduced into law the requirement that a drug product be proven efficacious. They led to the requirement of two adequate and well-controlled trials for demonstrating efficacy of a new drug product. Additionally, these amendments provided a number of other safeguards, including formal rules guiding good manufacturing process, provision of a 180-day period for FDA to review a new drug application, requirement of an affirmative decision by the agency to approve a drug before marketing, and requirements of drug manufacturers to report adverse events associated with drug use to FDA [5].

In Europe, **Directive 65/65/EEC** on the approximation of provisions laid down by law, regulation, and administrative action relating to medicinal products was established as a direct result of the thalidomide disaster to further develop harmonization in the Community. In 1975, two further Directives were introduced, the first on approximation of the laws of Member States relating to analytical, pharmacotoxicological, and clinical standards and protocols in respect of the testing of proprietary medicinal products (**Directive 75/318/EEC**), and the second on the approximation of provisions laid down by law, regulation, and administrative action relating to medicinal products (**Directive 75/319/EEC**). The introduction of these directives represents a milestone for initiating EU harmonization with the final long-standing aim of creating a "common market" for medicines. The ensuing Council Regulation EEC/2309/93 established the European Medicines Agency (formerly known as the European Medicines Evaluation Agency) in 1993 and its Committee for Human Medicinal Products (formerly known as the Committee for Proprietary Medicinal Products) which formulates the opinion of the Agency on questions relating to the submission of applications and granting marketing authorizations in accordance with the centralized procedure.

Orphan Drug Regulations

Orphan Drug Regulations are particularly relevant to the pediatric population, as many orphan diseases are conditions that affect children disproportionately, including certain cancers, cystic fibrosis, sickle cell disease, and inflammatory bowel disease. In the US, the **Orphan Drug Act of 1983** was established, whereas in Europe, the **Orphan Regulation (EC) No 141/2000** was adopted in 1999. The regulations have introduced incentives for companies to develop drugs for rare diseases such as fee reductions on regulatory submissions, access to accelerated/fast track regulatory pathways and the EU centralized procedure, rare pediatric disease priority review vouchers in the US, research grants in the EU, and grants for the costs of clinical testing expenses in the US. By providing significant incentives, the regulations have resulted in an increased interest in conditions previously overlooked by many pharmaceutical companies, due to perceived lack of financial benefit [6].

Pediatric Drug Regulations (US)

Legislation guiding pediatric drug development in the US was first established with the **Pediatric Labeling Rule of 1994** issued by FDA, to further promote access to drugs for children. The rule introduced the concept of pediatric extrapolation—allowing the agency to label drugs for pediatric use in some limited circumstances based on less than the standard of two adequate, well-controlled clinical trials.

The **Food and Drug Modernization Act (FDAMA)** reauthorized the FDCA and focused on reforming and modernizing many facets of the regulation of food, drugs, and cosmetics and represented the next major development in pediatric legislation in the US. One important facet was a financial incentive offered to companies for pediatric drug development. The law allowed FDA to grant 6 months marketing exclusivity to drugs which were studied appropriately in a pediatric population. However, despite companies starting to take advantage of marketing exclusivity, there remained a major deficiency in the availability of strong clinical evidence to support the safe and effective use in children of many prescription drug products [7].

Despite additional benefits for companies developing drugs for orphan indications and FDAMA incentives, the gap between high-quality evidence informing the use of many drugs for children, compared with adults, remains wide. Even when pediatric studies are conducted, there is often a lag of many years between the approval of a new drug for adults and the availability of adequate data to support labeling in children. To further bolster pediatric research, the **Best Pharmaceuticals for Children Act (BPCA) of 2002** was enacted. In addition to extending the financial incentive of 6 months of market exclusivity from FDAMA, BPCA established a program to promote pediatric drug development, through the National Institutes of Health (NIH). The act was reauthorized in 2007 and later permanently reauthorized in 2012 and provided additional measures including a process through which FDA can issue a request to a manufacturer to conduct specific trials in children, if deemed necessary by the NIH. If the manufacturer chooses not to conduct those trials, the NIH may do so [8].

More recently, the **Pediatric Research Equity Act (PREA) of 2003** was passed. The most comprehensive piece of legislation regulating pediatric drug development to date, PREA provides authority to the FDA to require sponsors to conduct studies in pediatric patients when a marketing application is first submitted to FDA for a new active ingredient, new indication, new dosage form, new dosing regimen, or new route of administration. However, under certain circumstances (e.g., if the disease for which the drug is used does not occur in children), FDA may grant a waiver for studies under PREA [9]. PREA was reauthorized in 2007 and expanded as part of the **Food and Drug Administration Safety and Innovation Act (FDASIA) of 2012**.

Pediatric Drug Regulations (EU)

Pediatric development is governed in Europe by the EU Pediatric Regulation (EC 1901/2006). All applications for a Marketing Authorization for a new medicinal product must include the results of studies as described in an agreed upon Pediatric Investigation Plan (PIP), unless the pediatric development is exempt because of a deferral or waiver. This requirement also applies when a Marketing Authorization holder pursues a new indication, pharmaceutical form, or route of administration for a drug that is already authorized and covered by intellectual property rights.

Pediatric Drug Regulations (Rest of World)

Beyond the requirements outlined for the US and EU, pediatric development is also mandated in Switzerland to support adult development and is a prerequisite for the submission of adult Marketing Authorization Applications, although exemptions do exist. Special regulations for obligatory pediatric development do not exist for any other region/country, although rewards and incentives may be available.

Overview of Clinical Trials

Once a pharmaceutical company has identified a compound of interest, non-clinical studies will be conducted. This typically includes animal pharmacology and toxicology studies, to assess the potential therapeutic benefit of the drug in a disease model and to permit an assessment of whether it is reasonably safe for initial testing in human subjects. Depending on the targeting of an individual new molecular entity to the pediatric population, juvenile animal toxicity studies may also be required to asses for potential effects on growth and development and assessment of effects on specific developmental systems and are especially important in the development programs for drugs that will ultimately be used in children.

Clinical trials are typically divided into four phases.

Phase I Clinical Trials

Phase I clinical trials typically involve the first exposure of humans to the new drug. Typically, these studies are conducted in healthy adult volunteers and may enroll very small numbers of patients (often less than 50 patients). For ethical reasons, pediatric subjects are typically excluded from phase I clinical development programs, until the risk–benefit profile in human subjects is more clearly understood.

Phase I trials often involve the administration of a small, single dose to a small number of subjects in order to understand various aspects of its pharmacokinetics in the human body. Particular interest is paid to collecting multiple blood samples over time, in order to assess the pharmacokinetic (PK) profile of the drug. These data will be compared with PK data collected in animal models, to help direct the testing of further doses and to determine safe starting doses for use in the clinical trials. These studies may provide additional insight into the metabolism, clearance, elimination half-life, etc. of the drug in humans. Specific attention is paid to any safety concerns, including changes in vital signs, laboratory parameters, and subject symptoms [10]. Further investigation may include dose escalation strategies to test larger doses, once initial safety is confirmed. A major goal of a phase I study is to obtain sufficient understanding of pharmacokinetics to inform the design of a phase II trial which will allow safe initial evaluation of efficacy in patients.

Phase II Clinical Trials

A phase II clinical trial utilizes the background information obtained from the phase I trial to adapt the development program toward the patient population of interest. Goals of phase II studies include demonstrating proof of concept in a specific disease population, determining the optimal drug dosing regimen for a given disease, and exploring the exposure–response relationship [11].

Phase II trials are designed to be relatively short in duration and small in size and may use an early clinical response or biomarker as the endpoint of interest. They often enroll 100–200 patients, or sometimes less. The ultimate goal is to confirm that the drug will likely be successful in further development, before undertaking a large, long-term phase III program, and to obtain the needed supportive information to inform the design of those pivotal trials.

Phase III Clinical Trials

Phase III trials are designed to utilize the previously determined effective dose to demonstrate efficacy in a specific patient population. Phase III trials are typically large (may include hundreds to thousands of patients), aim to enroll a diverse patient population, and will be statistically powered to demonstrate efficacy of the study drug in the given population. Various trial designs can be employed, including comparing the new drug to a previously approved alternative (to demonstrate non-inferiority or superiority) or to a placebo (to demonstrate initial efficacy). Apart from efficacy, safety measures are assessed carefully to determine if infrequent but serious adverse events may occur [12].

Phase IV Clinical Trials

In the USA, phase IV trials are those conducted after initial approval of a new drug. This may include studies mandated by the regulatory agency for a variety of reasons. FDA routinely issues post-marketing requirements (PMRs) for studies to obtain additional safety and efficacy data after the initial approval. This may include further studies to better assess the safety and effectiveness of the drug in various subpopulations, such as specific age groups or ethnicities that were not well represented in the original trials that supported approval. Deferred pediatric studies required by PREA are also included. Other phase IV studies may be conducted to understand the long-term safety and/or efficacy of a product (which can be done via a long-term observational study or registry protocol). They may assist in the detection of very rare but serious adverse events. Due to the low incidence of these types of events, it may take thousands of patients and follow-up over many years to obtain the required data to fully understand the risks [13].

Key Concepts in Clinical Trial Conduct

Good clinical practice (GCP) refers to a collection of rules, regulations, and standardized procedures which are designed to protect participants in clinical trials. These standards are designed to ensure that the trial is conducted such that the credibility and accuracy of the data generated are maintained. Required components of GCP include an institutional review board (IRB), specific requirements for informed consent documents, a standardized approach to evaluation and reporting of adverse events which may occur during clinical trials, and use of a data monitoring committee. This section will describe each of these components in more detail.

Institutional Review Board (IRB)

The statutes governing the regulation of an Investigational New Drug (IND) in the USA specify that clinical investigations must be approved by an IRB. An IRB is a group of individuals designated to carry the responsibility of reviewing a proposed clinical study to ensure that it will be conducted in accordance with standard ethical principles. An IRB may be specific to one hospital or healthcare institution, or, more commonly in large multicenter trials, a centralized IRB may be utilized to oversee the study at multiple cooperating sites.

Informed Consent

A key component of good clinical practice is obtaining the research subject's informed consent to participate. As specified in the Code of Federal Regulations (21 CFR 50.2), "no investigator may involve a human being as a subject in research covered by these regulations unless the investigator has obtained the legally effective informed consent of the subject or the subject's legally authorized representative. An investigator shall seek such consent only under circumstances that provide the prospective subject or the representative sufficient opportunity to consider whether or not to participate and that minimize the possibility of coercion or undue influence. The information that is given to the subject or the representative shall be in language understandable to the subject or the representative. No informed consent, whether oral or written, may include any exculpatory language through which the subject or the representative is made to waive or appear to waive any of the subject's rights, or releases or appears to release the investigator, the sponsor, the institution, or its agents from liability for negligence."

The informed consent document (ICF) is a written form prepared by the investigator or sponsor which details the risks, benefits, and responsibilities of the research participant and the sponsor of the clinical trial. The form serves to document the discussion that the consenting investigator must have with the participant, allowing him/her the opportunity to ask questions and ensure that the subject understands what is involved in participating in the trial.

Required components of the informed consent document include (1) a statement that the study involves research, explanation of the research, and a description of the procedures involved in the study and expresses explanation of what is considered "experimental," (2) a description of known or anticipated possible risks or discomfort that a subject may experience, (3) a description of any benefit that the study may provide to the subject or to other patients in the future, (4) an explanation of other reasonable treatment options/alternatives that are available to the patient, (5) an

explanation of confidentiality of the study records, and (6) an explanation of any compensation and, if more than minimal risk is involved, what remedies or treatments are available in the event of illness or injury and who to contact/how to report any injury or illness that might result from participation. The ICF should specifically detail if required care would be billed to the patient's insurance, covered directly by the sponsor, and what would occur if study participation was terminated due to an adverse event [13].

Pediatric Considerations

For pediatric patients, both parental permission and patient assent are required in most cases. The risks and benefits of proposed pediatric participation in a research study should be discussed in detail with the parent or legal guardian of the pediatric subject. The parent or guardian must provide their permission on an informed consent document, to permit their child to participate in research. Assent refers to the willingness of the child to participate. The IRB, when considering procedures for enrollment in a given study, will determine the age at which pediatric subjects' assent will be required. Typically, some degree of assent should be solicited once the child possesses the intellectual and emotional ability to comprehend the concepts involved. The age at which this occurs varies based on the clinical situation and research in question. However, the guiding principle is that when a child is capable of understanding the nature of participation, assent must be sought. Waiving the requirement for assent should only be considered in well-defined circumstances, such as if the child's capacity for understanding is so limited that they cannot be consulted, if the intervention holds the prospect of direct benefit or well-being to the child and is only available in the context of the research, or if the research meets other conditions for waiver of informed consent for adults, as specified in the regulations [14].

Adverse Event Reporting

The clinical trial protocol should provide specific guidelines for the collection and reporting of adverse events that may occur during the trial. Adverse events will generally be reported by the investigator to the IRB, and a subset of such events must be reported promptly to the FDA. Reportable events include serious adverse events (SAEs), defined in the Code of Federal Regulations, including death, life-threatening illness, hospitalization, disability or permanent damage, congenital anomaly or birth defect, or other serious events such as those where intervention was required to prevent permanent impairment [15]. In general, events must be reported to the IRB if they are unanticipated and serious and may have implications for the continuing trial. For clinical trials conducted under an IND application, a sponsor is also required to notify the FDA in a written safety report of "any adverse experience associated with the use of the drug that is both serious and unexpected [16]."

Data Monitoring Committee

An independent data monitoring committee (DMC) may be formed to assist in the conduct and analysis of data in a clinical trial. A DMC may be appropriate for trials of long duration (when interim analysis would be appropriate and important), for trials with endpoints that include survival/mortality (where a finding of futility may require early termination of a study), in trials that involve vulnerable populations (such as elderly patients, children, or patients with disabilities), in trials involving treatment that is high risk to subjects, and in large multicenter trials. The goal of a DMC is to evaluate incoming/cumulative data on an ongoing basis and provide feedback to the sponsor regarding the continuing safety of the trial participants, as well as the ongoing validity and benefit of continuing the trial [17].

Highlights of the Regulatory Review Process

In the USA, the first regulatory step in drug development is the submission of an Investigational New Drug (IND) application to the FDA. They are categorized as commercial (utilized for a drug that will ultimately seek marketing approval) and noncommercial research.

Current Federal law prohibits transportation or distribution of unapproved drugs across states lines. The IND provides an exemption from that legal requirement for investigational drugs. Further, the IND provides the FDA with the necessary data to ensure the potential safety of investigational products. Once an IND application is submitted, current regulations require that the applicant not commence clinical trials until 30 days of elapse; during that time, the FDA makes a determination regarding the safety of the planned clinical trials. IND applications must provide animal pharmacology and toxicology data, manufacturing information, clinical protocols, and investigator information.

For the purposes of developing a new drug that will ultimately seek marketing approval, a commercial investigator IND is submitted. This type of application seeks permission to begin the first human trials of an investigational drug in the USA.

Non-commercial INDs are used to gain access to an investigational drug for research or limited treatment purposes. This may occur under a non-commercial investigator, emergency use, or treatment IND.

An investigator IND is submitted by the person who actually conducts the investigation and under whose immediate

direction the investigational drug is administered or dispensed. This type of application may be utilized when an academic researcher wishes to study the effects of an investigational drug in a particular patient population, though he/she is not necessarily connected to the pharmaceutical company that is developing the drug.

An emergency use IND allows the FDA to authorize limited use of an experimental drug in an emergency clinical situation that does not allow time for submission of an IND. This situation may occur when there is no acceptable approved medical treatment for a given condition, and a prescribing physician wishes to seek permission to treat a patient or limited number of patients with an unapproved agent.

A treatment IND is submitted for experimental drugs showing promise in clinical testing for serious or immediately life-threatening conditions, while the final clinical work is conducted and the FDA review takes place. A treatment IND may be utilized to allow patients who are completing a phase III trial access to continue the drug, until final approval is obtained [18].

Once a sponsor has completed all investigations, the next step in the regulatory process is the submission of a new drug application (NDA). Utilizing the information submitted as part of the NDA, the FDA reviewer must reach the following conclusions:

- *Whether the drug is safe and effective in its proposed use(s) and whether the benefits of the drug outweigh the risks*
- *Whether the drug's proposed labeling (package insert) is truthful and not misleading and what it should contain*
- *Whether the methods used in manufacturing the drug and the controls used to maintain the drug's quality are adequate to preserve the drug's identity, strength, quality, and purity* [18]

Similar to the NDA, used for approval of drugs, a biologics license application (BLA) is a request for permission to "introduce, or deliver for introduction, a biologic product into interstate commerce [19]." The BLA should contain enough information for an FDA reviewer to reach the same conclusions (listed above) for drugs.

Regulatory Safeguards for Pediatric Patients Involved in Clinical Trials

Pediatric patients are considered a vulnerable population, and their participation in clinical trials requires specific safeguards that are detailed in regulation. For any clinical research involving pediatric patients, the Code of Federal Regulations provides specific criteria that an institutional review board (IRB) must rely upon to make decisions regarding the approval, monitoring, and review of biomedical and behavioral research. These criteria are listed below.

Criteria for IRB Approval of Pediatric Research

1. Research not involving greater than minimal risk to the children [20].
2. Research involving greater than minimal risk but presenting the prospect of direct benefit to the individual child subjects involved in the research [21].
3. Research involving greater than minimal risk and no prospect of direct benefit to the individual child subjects involved in the research, but likely to yield generalizable knowledge about the subject's disorder or condition. This type of trial must only represent a minor increase over minimal risk [22].
4. Research that the IRB believes does not meet the other conditions but finds that the research presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health or welfare of children (this trial requires a special level of governmental review beyond that provided by the IRB) [23].

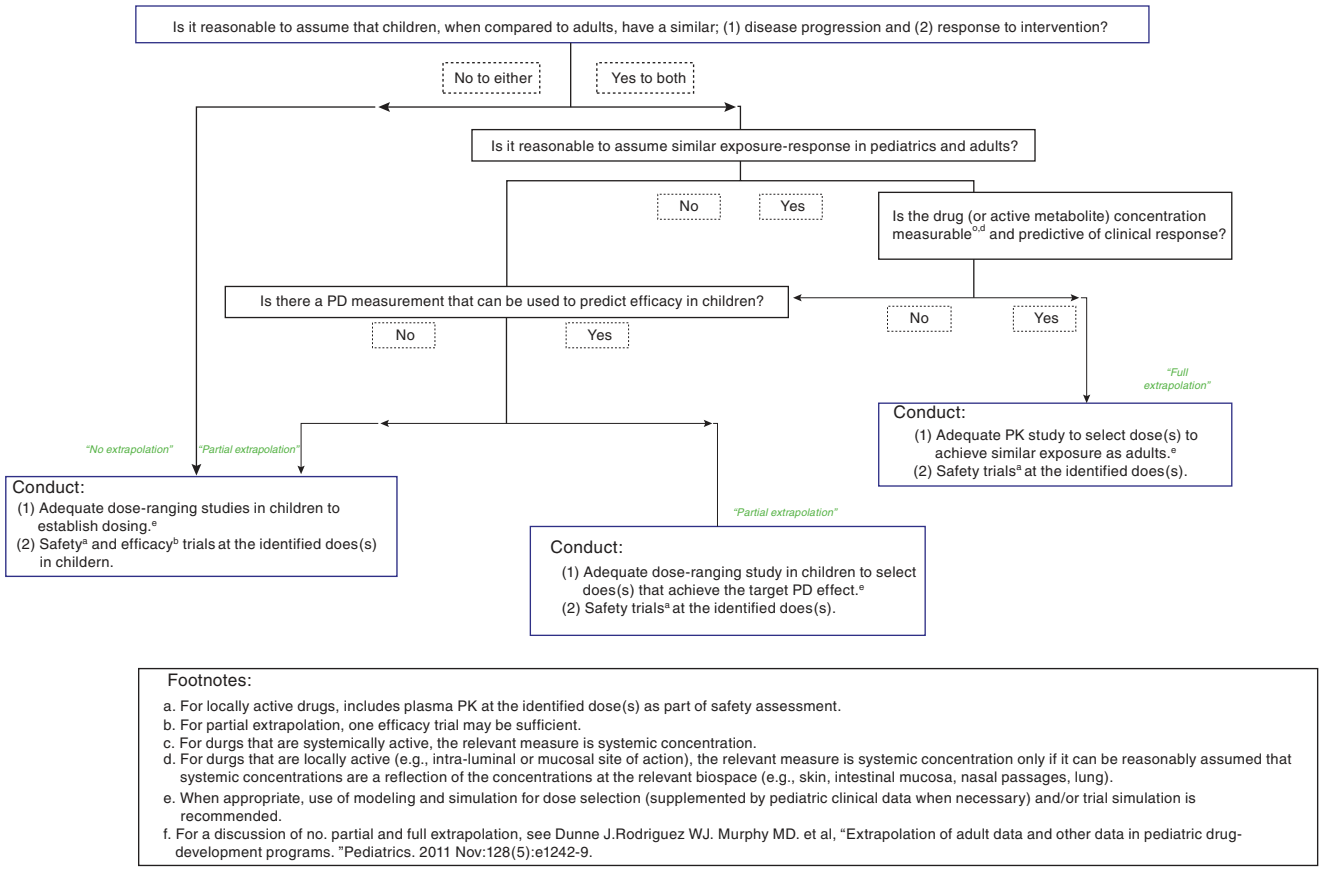
As a general rule, children should not be enrolled in a clinical investigation unless their enrollment is necessary to achieve important scientific and/or public health objective(s) directly benefiting children.

Pediatric Extrapolation

Given the unique challenges of conducting pediatric clinical trials, including the vulnerabilities of the pediatric population, ethical limitations on participation, and logistical challenges of studying children, the concept of pediatric extrapolation was developed. The goal of extrapolation is to leverage the available data from adult trials and to minimize the size and scope of the trials needed in pediatric patients, while still maintaining a standard of evidence to support safe use of drugs in pediatric patients.

The Pediatric Research Equity Act of 2007 states that "if the course of the disease and the effects of the drug are sufficiently similar in adults and pediatric patients, the Secretary may conclude that pediatric effectiveness can be extrapolated from adequate and well-controlled studies in adults, usually supplemented with other information obtained in pediatric patients, such as pharmacokinetic studies." It should be noted that only effectiveness (not safety) can be extrapolated.

The following algorithm illustrates the pathway used to determine if and when extrapolation may be appropriate [24].



From FDA's Draft Guidance for Industry: General Clinical Pharmacology Considerations for Pediatric Studies for Drugs and Biological Products, Dec 2014.

For conditions where the disease progression and response to intervention are expected to be similar between pediatric patients and adults, extrapolation may be appropriate. In this setting, depending on the degree of similarity and availability of exposure-response data in children and adults, a determination will be made as to how much additional safety and efficacy data are needed to support use of the drug in pediatric patients. Applying the extrapolation approach may reduce the burden on pediatric patients, by requiring fewer efficacy studies or smaller studies, and/or pharmacokinetic and safety studies only, depending on the disease process in question.

Pediatric-Specific Issues in IBD Trials

Using the general pediatric drug development principles described above, the development of drugs for the treatment of IBD in pediatric patients continues to evolve. In the USA, approvals for IBD products in adults continue to outnumber pediatric approvals. Pediatric approvals lag behind those for adults by a number of years, effectively restricting access to the newest advances in therapies for pediatric patients. Important pediatric IBD drug development program considerations include, but are not limited to, use of extrapolation, adequate dose selection, use of placebo arm, the burden of repeat endoscopies, and measuring outcomes that matter to patients.

A claim of efficacy requires a product demonstrate a meaningful change in a prespecified measurable endpoint. In inflammatory bowel disease, there have been a variety of different indices utilized to measure clinical response to therapy in drug trials. For example, a published review of pediatric trial data submitted to the FDA from 1950 to 2008 of products used to treat patients with ulcerative colitis (UC) identified three disease activity indices utilized as endpoint measures for the three pediatric UC products approved during that time (Colazal, Remicade, and Azulfidine). The Modified Sutherland UC Activity Index (MUCAI) was used for the Colazal pediatric trial (2006) [25]. The Mayo score and the Pediatric UC Activity Index (PUCAI) were used for the Remicade pediatric trial (2011) [26]. It should be noted that Azulfidine was initially approved for UC in 1950 and granted pediatric approval in 2009 based on full extrapolation of efficacy from adult trials; therefore, no pediatric trial was conducted. The results of this review suggest that there exists a lack of consensus on the most appropriate primary endpoint for pediatric UC trials, and the same problem exists

in the study of Crohn disease [27]. Considerable debate continues in the field as to the definition of clinical response and/or remission and how best to measure it. Historically, endoscopic appearance of the mucosa was considered the gold standard for evaluating response to therapy in an IBD trial. Others have suggested that mucosal healing, as described on histology specimens (and so requiring biopsy), is the preferred endpoint of interest. Particularly in pediatric patients, where it is necessary to limit the number of endoscopies during a trial, less invasive measures of disease activity are becoming increasingly important. However, from a regulatory standpoint, the use of a non-invasive endpoint, or biomarker, introduces additional complexity. A biomarker must first be clearly demonstrated to correlate well with the outcome of interest, before it can be qualified for use in a trial that will support product labeling [27].

To quantify meaningful changes in signs and symptoms, patient-reported outcome (PRO) and observer-reported outcome (ObsRO) instruments can be used. Changes in symptoms are subjective, however, so standardization of the definitions of the symptoms of interest and carefully designed tools for their measurement are crucial. FDA has recently published guidance for industry on their development and use ("Guidance for Industry: Patient-Reported Outcome Measures: Use in Medical Product Development to Support Labeling Claims") [28].

The gold standard of evidence to support a claim of efficacy involves a double-blind, placebo-controlled clinical trial. However, inclusion of a placebo arm in a pediatric trial, particularly for patients who have a serious chronic medical condition such as inflammatory bowel disease, is controversial. Trial design is evolving over time to minimize exposure to placebo and risk from lack of treatment for patients. This may include use of an open-label induction period, followed by randomized withdrawal phase, use of an active comparator instead of placebo, or the use of randomization rates of more than 1:1 to minimize the number of subjects receiving placebo.

Given the lack of consensus across countries and regulatory agencies, international consensus regarding pediatric IBD trial outcome measures would facilitate drug development. In an attempt to develop a consensus statement regarding pediatric UC trial outcome measures, the *i*-IBD Working Group was convened in 2012 by scientists from the US Food and Drug Administration, European Medicines Agency, Health Canada, and the Pharmaceuticals and Medical Devices Agency of Japan. The *i*-IBD Working Group "concluded that outcome measurements in pediatric UC trials must account for both endoscopic disease activity of UC and improvement of signs and symptoms." The group also recommended that assessment of signs and symptoms be used as a co-primary endpoint in pediatric UC trials in conjunction with endoscopic parameters of mucosal appearance to assess disease severity [29]. A similar approach should be taken for Crohn disease.

Studying drugs to treat IBD in children presents a number of challenges, though they are not unique to this disease process. Careful assessment of study design, judicious use of placebo arm, limiting invasive procedures during the trial, consideration of patients' reported symptoms, and increasing collaboration internationally and across various regulatory agencies are all measures that will contribute toward advancing drug development in the field.

Part VII

Special Considerations

Infectious Complications of Pediatric Inflammatory Bowel Disease

49

Monica I. Ardura and Sandra C. Kim

Introduction

The role of infections in the pathogenesis of inflammatory bowel diseases (IBDs) remains incompletely understood. Current hypotheses suggest that pathogenic or commensal gut flora act as potential cross-reactive antigens leading to a dysregulated immune response that may trigger both primary disease and relapses in IBD [1]. Animal models have demonstrated that bacterial colonization is a prerequisite for the development of intestinal inflammation in susceptible hosts, but proof of causation in humans is lacking [2, 3]. Although the exact role of microbes in causing IBD remains to be clarified, infections do play an important role in the clinical course and management of patients with IBD. Infections may be a presenting manifestation of IBD and may exacerbate disease activity. Herein, we will focus on the infections that may occur as complications of the primary inflammatory disease or secondary to therapeutic modalities, including surgery and pharmacologic therapies that modulate immune system activity.

Much of the data regarding infections in patients with IBD are extrapolated from reports of clinical trials and population-based observational studies in adults; the pediatric data are limited to reported adverse events in pharmacoepidemiological and registry studies, as well as case series that are specific for a pathogen or immunomodulatory therapy [4–6]. The lack of large, population-based cohort studies in the pediatric IBD population makes it difficult to reliably calculate and compare rates of infections. Factors predisposing patients with IBD to infectious complications include severity of underlying IBD, medical co-morbidities, malnutrition, abdominal surgery, and immunosuppressive medications. When compared with adults with IBD, children with IBD have more extensive luminal disease, are more likely to require systemic steroids, and typically have a more severe disease course [7, 8]. These differences, coupled with a higher likelihood of acquiring primary infections during childhood and increasing use of combination immunomodulator and biologic therapies, may place pediatric patients with IBD at risk for infectious complications.

Antibiotic Use for Treatment of IBD

Based on the rationale that antibiotics could potentially medically modulate and suppress the host inflammatory response to commensal or pathogenic gut flora [9], their clinical use has preceded evidence-based data. Antibiotics have been utilized broadly for the treatment of IBD luminal and fistulizing disease, maintenance of disease remission, treatment of abscesses, and as prophylactic therapy to prevent postoperative recurrences. Much of the data are derived from patients with Crohn disease (CD); the presence of transmural inflammation in CD is an inherent risk factor for formation of fistulae and possible perianal disease. Indeed, the incidence of perianal CD in children is estimated to be 10–62%, but the exact role of putative bacteria and data for therapeutic benefit of antibiotics for non-suppurative perianal disease are unclear. Perianal fistula and abscesses may represent sterile inflammation or be infectious; small studies describing the microbiology of perianal fistulas have differing results with important antibiotic implications [10–12].

In US tertiary pediatric centers, there is a wide practice variation of antibiotic prescribing for children hospitalized with IBD exacerbations, ranging from 27 to 71% [13]. This heterogeneity in antimicrobial use is likely a reflection of lack of robust efficacy data in the published literature. Systematic reviews of the available small, randomized trials in adults evaluating the efficacy of antibiotic therapy in

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_49

helping to induce remission or prevent relapse in IBD have variable results given distinct methodologies, early and differing endpoints, case definitions and disease severities, and utilization of different antibiotics (single or dual), sometimes in combination with other therapies [14–16]. When evaluating pooled antibiotic use, patients who received antibiotics, compared with placebo, were more likely to have induction of remission of active UC and CD, and fewer relapses in patients with colonic but not isolated small bowel CD [16]. However, the varied antibiotics used in these trials (predominantly metronidazole and ciprofloxacin) preclude firm conclusions. A recent Cochrane review evaluating the efficacy of antibiotics (analyzed individually or pooled by antibiotic class) for both the induction and maintenance of remission in CD among published randomized trials failed to confirm robust evidence of clinically meaningful efficacy [17].

In three randomized controlled trials (RCTs) evaluating antibiotics to treat perianal fistulas, the use of metronidazole or ciprofloxacin demonstrated a trend towards reducing fistula drainage in patients with CD (RR 0.8, 95% CI 0.66–0.98, not statistically significant) [14]. Despite lack of controlled studies and conclusive efficacy data in children, pediatric treatment algorithms also recommend antibiotics for perianal fistulizing disease [18, 19]. The role of antibiotics to prevent post-operative recurrence of ileal or ileocolonic CD is unclear, though there is a trend of reduced risk for clinical and endoscopic recurrence in patients who received metronidazole over those who received placebo [20]. The optimal approach to prevention of post-operative recurrence is unknown, and no clear prophylactic strategy is preferred. There is evidence to suggest that initiation of immunomodulatory therapies for patients in higher-risk disease categories may decrease post-operative CD recurrence [21, 22].

There are less data regarding efficacy of antibiotics for UC than CD. In clinical trials of adults who presented with severe UC, there were no differences in outcomes when intravenous empirical antibiotics were used as adjuncts to steroid therapy [23]. Recently, the PRASCO study showed that hospitalized children with acute severe colitis (ASC) who received a quadruple antibiotic cocktail (amoxicillin, vancomycin, metronidazole, and doxycycline/ciprofloxacin) along with intravenous corticosteroids (versus IV corticosteroids alone) had significant improvement clinically by day 5. While overall clinical response since this initial study has been reported to be 20–50%, those who do respond do so fairly rapidly. These findings suggest a potential unrecognized infectious trigger leading to the clinical response [24]. There have been limited studies in adult patients with UC which suggest a limited role of a multi-antibiotic regimen in patients with UC. Given these results, antibiotics should not be routinely used in patients with UC unless an infection, such as *Clostridium difficile,* is suspected, pending diagnostic testing results, or in the presence of toxic megacolon.

Clinical benefit of antibiotics (ciprofloxacin alone or in combination with metronidazole or rifaximin) has been observed in some trials for pouchitis, the most common complication after ileal pouch–anal anastomosis in patients with UC [25]. In addition, there is evidence to suggest that VSL#3, a probiotic preparation, decreases pouchitis in patients with UC post-colectomy [26].

To further illustrate the complex interplay and immunopathogenesis of antibiotics, the microbiome, mucosal immunity, and IBD, a genome-wide association study demonstrated that in a small subset of children with newly diagnosed CD, short-term (<3 months) antibiotic use prior to IBD diagnosis amplified the microbial dysbiosis associated with CD by decreasing presumed protective bacterial species [27]. The complexity of the potential gut microbiome–host association has been corroborated by other population-based studies noting that higher cumulative exposure to systemic antibiotics, particularly broad-spectrum antibiotics, may associate with the development of new-onset IBD [28–31]. These studies provide some circumstantial evidence of an association between antibiotic use and later IBD diagnosis, that requires additional study and consideration of judicious antibiotic use in young children.

While there are insufficient data to recommend universal use of antibiotics for inducing or maintaining remission in active IBD, there may be some benefit as adjunct therapies as outlined above; antibiotics may provide potential benefit because of their immunomodulatory properties, including suppressing tumor necrosis factor (TNF)-alpha synthesis, and not by direct antimicrobial effects on the microbiome [32]. Altering the gut microbiome with the use of antimicrobials may indeed have a role in modulating primary IBD activity, but requires further rigorous prospective, controlled studies in larger populations of patients with IBD.

Infections Associated with Underlying IBD

Antimicrobials have an established role in the management of patients with IBD for microbiologically proven infectious complications of underlying disease, including intra-abdominal abscesses. Evidence-based guidelines for empirical antimicrobial therapy of intra-abdominal abscesses have been put forth by multiple professional societies [33, 34]. In high-risk patients with complicated intra-abdominal infections, including those who are considered immunocompromised, empiric therapy with cefepime and metronidazole or piperacillin–tazobactam monotherapy are appropriate; a carbapenem (e.g., meropenem) is preferred in patients with a prior history of infection with extended-spectrum beta-lactamase (ESBL)-producing *Enterobacteriaceae*. Targeted

antimicrobial therapy should be further guided by microbiologic culture data, local epidemiology, and patient's history of bacterial colonization and resistance patterns. Visceral abscesses, frequently in the liver, have been described, particularly in patients with CD; these may occur alone and unrelated to hepatobiliary disease or as a complication of an intra-abdominal infection or cholangitis [35]. Results of aerobic and anaerobic bacterial cultures obtained from drainable abscesses help guide antimicrobial therapy. Duration of antimicrobial treatment will ultimately depend on ability to achieve source control, and a composite of clinical improvement, normalization of laboratory values, and resolution on follow-up imaging studies.

Patients with IBD may also be at higher risk for urinary stone formation leading to urinary tract infections and have a higher disease severity than patients with urinary stones who do not have underlying IBD [36]. In addition, some infections may mimic IBD lesions or occur concurrently in patients with underlying IBD. In particular, sexually transmitted infections, like syphilis and lymphogranuloma venereum, can cause proctocolitis and lead to rectal lesions resembling CD [37]. Thus, a high index of suspicion and appropriate diagnostic testing should be performed in sexually active adolescents with IBD who are not responding to standard therapies.

Patients with IBD may be more prone to infections of the gastrointestinal (GI) tract due to microbial dysbiosis or impaired epithelial barrier function [38]. Enteric infections may mimic, be a presenting symptom of, or lead to exacerbation of IBD; most cases of infectious colitis are caused by bacterial enteropathogens. For example, *Yersinia* spp. can classically cause an acute ileitis indistinguishable clinically from acute Crohn ileitis. As such, it is recommended that patients with a clinical presentation concerning for IBD or with previously diagnosed IBD presenting with diarrhea, especially if bloody, should have diagnostic testing performed for bacterial pathogens, including *Clostridium difficile (C. difficile),* and receive appropriate antimicrobial therapy [19, 24].

Rates of infection in children with IBD are difficult to discern given diverse testing modalities of varied sensitivities, overall prevalence of disease, and clinical indications for testing (screening or worsening colitis symptoms). Further, there is a wide variation in diagnostic practices among gastroenterologists caring for children with IBD. A survey of pediatric gastroenterologists confirmed that 29% of children undergoing an initial evaluation for colitis symptoms and possible CD did not have stool testing performed [39]. In a large study of US children presenting with newly diagnosed UC, the diagnostic yield of routine enteropathogenic stool testing was retrospectively evaluated; testing included bacterial stool culture, including *Yersinia*, ova and parasite examination, Giardia and *Cryptosporidium* antigen, *C. difficile* toxin A/B by PCR, and viral testing (by culture, rotavirus EIA, quantitative adenovirus PCR, viral culture for adenovirus, cytomegalovirus (CMV), and enterovirus) and electron microscopic examination [40].

Clostridium difficile

In the same study 863 test samples from 152 pediatric patients with UC, *C. difficile* was the most commonly detected organism in 13.6% of samples, followed by adenovirus (1/13, 7.7%), non-typhoidal *Salmonella* species (4/220, 1.8%), and parasites (2/151, 1.3%). In retrospective cohort studies from the US and Europe, children with IBD and diarrheal relapse in whom stool was evaluated by a combination of microscopy, bacterial culture, and/or detection of *C. difficile* toxin, 10–20% of relapses were associated with infections, most commonly *C. difficile* and *Campylobacter* spp. [41, 42]. When evaluating for parasitic infections in 149 children presenting with IBD flares, systematic testing detected *Cryptosporidium* by enzyme immunoassay in 4.6% of patients (7/149) [43]. More unusual enteric infections with mycobacteria, including *Mycobacterium tuberculosis,* which has a proclivity for the terminal ileum and cecum and nontubercular mycobacteria, or fungi, such as histoplasmosis, require additional diagnostic testing (culture, staining, and PCR evaluation) to distinguish the granulomatous inflammation of infection from underlying IBD. Although the diagnostic yield of testing for enteric pathogens seems to be low, a high index of suspicion and eliciting epidemiological risk factors are important so targeted antimicrobials can be prescribed when needed.

Lack of judicious antibiotic use may also promote proliferation of resistant bacterial strains or increase the risk of other infections. *C. difficile* is an important cause of antibiotic-associated diarrhea and a frequent cause of healthcare-associated infection in the United States, with a rising incidence in pediatrics [44–46]. Patients with IBD have been found to be at increased risk of *C. difficile* infection (CDI) [47]. Risk factors for CDI in adults and children with IBD include hospitalization, previous antibiotic therapy, immunomodulatory medications, use of proton pump inhibitors, and presence of severe colonic disease. Patients with IBD receiving immunomodulators and corticosteroids may be at higher risk of CDI (corticosteroid use RR 3.4, 95% CI 1.9–6.1); TNF antagonists do not seem to increase this risk [48]. However, some patients with IBD develop CDI without any identifiable risk factors.

In children with IBD, CDI is prevalent, as documented by the disproportionate increase in *C. difficile*-associated hospitalizations. Additionally, risk factors in this pediatric subpopulation may differ [49, 50]. In addition to increased *C. difficile* detection, pediatric patients with IBD who are diag-

nosed with CDI were also found to have active colonic disease and a more severe disease course [51]. Currently, it is recommended that all patients with IBD who require hospitalization for disease flare undergo testing for *C. difficile* and, if severe colitis is present, empirically start on antimicrobial therapy; further, escalation of immunosuppression should be avoided in the setting of symptomatic and untreated CDI, if clinically possible [52, 53].

Although the increasing incidence and severity of CDI has been related in part to the emergence of the North American pulsed-field type 1 (NAP1) strain that produces more toxin, some of the increase in CDI incidence may be related to changing diagnostic modalities from cell culture cytotoxicity neutralization assays to enzyme immunoassays (specific, but lacking sensitivity), and most recently to highly sensitive molecular assays. Clinicians should be aware of the method and details of *C. difficile* testing performed at their institutions to improve the clinical interpretation of results in pediatric patients [54].

The detection of *C. difficile* by PCR methodology, although sensitive for infection, may not be specific for disease [55]. The majority of molecular tests detect *C. difficile* toxin genes (A, B, or both) that are present, but do not detect actual toxin production which is required for CDI disease pathogenesis. Thus, in children *C. difficile* toxin gene detection by PCR does not reliably distinguish between *C. difficile* colonization (detection of *C. difficile* in an asymptomatic patient) and *C. difficile* disease (detection of *C. difficile* in a patient with symptoms consistent with CDI, varying from mild diarrhea to fulminant colitis). In a non-controlled trial, application of the recommended two-step testing in children, including a subpopulation with IBD, was inadequate to differentiate colonization from disease [56]. Indeed, interpretation of *C. difficile* PCR testing is even more challenging in children with IBD, in whom worsening colitis may be from underlying disease, CDI, or both. *C. difficile* colonization in the US healthy adult population has been estimated to be 3–7%, with rates of 4–20% for individuals that require hospitalization [57]. High *C. difficile* colonization rates are known to occur in infants <1 year of age and young children; thus, testing for CDI is discouraged. Colonization rates in children older than 3 years of age have been estimated to be <5% [58]. However, in asymptomatic patients with IBD, *C. difficile* carriage has been detected in 8% of adults and 17% of children and may be higher in patients with UC versus CD [59–61]. The possibility of over-diagnosing patients with CDI through the use of molecular testing has been corroborated in a large, prospective observational study of hospitalized adults, in whom *C. difficile* detection by molecular PCR results but a negative toxin immunoassay had outcomes similar to patients with negative *C. difficile* testing by either method [62]. This represents a clinical conundrum to clinicians faced with a child with IBD, worsening colitis symptoms, and detection of *C. difficile*, where distinguishing colonization from disease in a time-sensitive fashion may not be possible. Evolving data applying multiomics suggest potential biomarkers that may help distinguish disease processes [63]. Additional prospective studies are required in pediatric IBD patients to reliably and accurately understand colonization from disease and diagnose CDI. The optimal treatment of CDI in patients with underlying IBD is another area of ongoing study, including the use of fecal microbiota transplantation for recurrent CDI [53, 64].

Cytomegalovirus

The exact role of CMV infection in patients with IBD remains poorly defined, and CMV infection (detection of CMV) must be distinguished from disease (detection of CMV in the presence of clinical signs, symptoms, and end-organ involvement). Several studies have established an association between severe IBD (in particular steroid-refractory UC) and CMV-induced disease with reported prevalence rates of 21–36% [65, 66]. The diagnosis of active CMV colitis in patients with IBD is challenging and requires additional testing. Histopathology continues to be the gold standard for diagnosis, but this may not always reveal the enlarged viral inclusion cells that are classic of CMV infection. To improve diagnostic sensitivity, immunohistochemical staining for CMV should also be performed on tissue specimens. In patients with steroid-refractory UC with unremitting symptoms who undergo lower endoscopy with biopsy, specimens should be sent for histopathology and immunohistochemical staining for CMV [24]. Similarly, detection by nucleic acid amplification testing (NAAT) alone is insufficient to confirm CMV disease. Prospective studies are required to better define disease, establish prevalence, and to determine which patients may benefit from antiviral treatment.

Coronavirus 2019 (COVID-19)

Since the initial case patient with coronavirus disease 2019 (COVID-19) in the United States reported GI symptoms, including pain, nausea, vomiting, and diarrhea, GI manifestations have been increasingly described and SARS-CoV-2 has been detected in stool and GI tract tissue specimens [67–71]. Early observations from the COVID-19 pandemic reported that symptoms, including diarrhea and enteritis, were more frequent in children compared with adults, both during acute COVID-19. In addition, GI manifestations have been associated with Multisystem Inflammatory Syndrome in Children (MIS-C), also referred to as Paediatric Multisystem Inflammatory Syndrome temporally associated

with SARS-CoV-2 (PIMS-TS) [72–75]. Given these implications, there has been an urgent need to understand the role of SARS-CoV-2 in the pathogenesis of infections in children with underlying IBD and receiving immunosuppressive therapies. Mechanistically, SARS-CoV-2 has been found to enter host cells via ACE2 receptors, with reports of a 100-fold higher ACE2 expression in the GI than respiratory tract [71, 76, 77].

Emerging data demonstrate that children of any age can be infected with SARS-CoV-2 and that they generally have less severe disease than adults. Currently, preliminary data in patients with underlying IBD suggest that having a diagnosis of IBD alone is not a risk factor for neither acquiring SARS-CoV-2 infection nor worsening disease severity [78–82]. Initial pediatric data from case reports and voluntary reporting to registries are also reassuring. As of early May 2021, there are a total of 672 patients ≤19 years of age with underlying IBD reported to have COVID-19 in the SECURE-IBD registry, comprising 11.3% of the total 5959 reported COVID-19 cases in patients with IBD [83]. In addition, reported outcomes in patients ≤19 years of age have been reassuring; the majority have been managed as outpatients (94.6%), 29 (4.3%) required hospitalization, 6 (<1%) required admission to the intensive care unit, and 3 (0.4%) required mechanical ventilation. Importantly, there are no reported deaths in children and young adults ≤19 years of age to date, compared with the overall mortality of 2% in adult patients with IBD and COVID-19. Among those adult patients with IBD who have worse outcomes, rates of hospitalization were highest in older age groups (starts increasing to 22% in individuals 50–59 years, with increases to 44% by 70–79 years of age), in those with ≥2 co-morbidities (41%) and with moderately to severely active IBD disease (24%) [83, 84]. Despite concerns for the impact of immunosuppressive therapies on underling COVID-19 infection in patients with IBD, patients on TNF antagonist monotherapy did not have increased risk for adverse outcomes with COVID-19 infection. However, receiving systemic corticosteroids for underlying IBD at the time of COVID-19 diagnosis has been associated with worse SARS-CoV-2 disease and outcomes [aOR 6.9 (95% CI, 2.3–20.5)] along with immunomodulators (methotrexate) and 5-aminosalicylates/sulfasalazine [84]. The optimal therapy and management of underlying IBD in patients with COVID-19 remains unknown, but an individual approach that takes into consideration underlying host factors and co-morbidities, severity of infection, and net state of immunosuppression seems prudent to consider and weighed against the risk of IBD disease exacerbation [82, 85, 86].

There are still many questions regarding the relationship between infection and disease activity in patients with IBD. Further research that help delineate host and microbiome immune profiles may allow for improved diagnostic and management strategies, including prognosis and therapies [87, 88]. Recent genome-wide association studies link IBD to host–microbe pathways central to sensing/signaling and mucosal-initiated effector responses [89].

Increased Risk of Infections Secondary to Therapies

The benefits of immunosuppressive treatment for IBD should be weighed against the potential risks, including infectious complications, in each individual patient before starting immunosuppressive therapies. This may be particularly important for patients with a history of chronic, recurrent, or opportunistic infection, for those with identifiable risk factors for infection, and for patients with other co-morbid medical conditions that may predispose them to infections.

Infections have been associated with all immunosuppressive therapies for IBD, most frequently with systemic corticosteroid therapies but also with anti-metabolites, purine analogues, alkylating agents, and more recently given an increase in their use, with TNF antagonists [90, 91]. Serious infections are defined as infections requiring hospitalization or parenteral antimicrobial therapy and any opportunistic infections. Risk factors for severe infections in patients with IBD include young age, severity of underlying disease, and time-dependent exposure to immunosuppressive therapies, including immunomodulators and TNF antagonists. In patients with IBD, monotherapy with corticosteroids (odds ratio, OR 3.4, 95% confidence CI 1.8–6.2), azathioprine or 6-mercaptopurine (OR 3.1, 95% CI 1.7–5.5), and infliximab (OR 4.4, 95% CI 1.2–17.1) were associated with increased risk for opportunistic infections in univariate analysis [92]. Multivariate analyses confirmed this finding and importantly noted that the risk for infection was further increased 14-fold in patients receiving two or more of these immunosuppressive medications concomitantly (OR 14.5, 95% CI 4.9–43). An increase in adverse infectious events, including opportunistic infections in patients receiving combination immunosuppressive therapies has been confirmed in other IBD studies [93, 94]. Pediatric patients are considered to be severely immunocompromised if they have a known primary immunodeficiency disorder that affects phagocytic, cellular, or humoral immunity or have a secondary immunodeficiency from receipt of immunosuppressive therapies, including high-dose systemic corticosteroids (defined as ≥2 mg/kg/day of body weight or ≥20 mg/day of prednisone for ≥14 days), methotrexate >0.4 mg/kg/week, azathioprine >3 mg/kg/day, 6-mercaptopurine >1.5 mg/kg/day, and biologic agents (e.g., TNF antagonists, anti-CD20), or are receiving combination immunosuppressive medications [95, 96].

Purine Analogues

Mercaptopurine and azathioprine are used for maintenance of remission in IBD. Purine analogues can directly alter cell-mediated immunity, resulting in viral and fungal infections. The incidence of infections in case series of patients receiving these therapies ranges from 0.3 to 7.4%, most frequently with viral infections, particularly herpes viruses, like varicella zoster virus (VZV), herpes simplex virus (HSV), Epstein-Barr virus (EBV), and cytomegalovirus (CMV) [92, 97–99]. These agents may also cause myelosuppression; the presence of leukopenia itself, even without thiopurine use, is associated with an increased risk of infection and sepsis. The duration and severity of neutropenia can also predispose to infections with bacteria (e.g., *Pseudomonas* spp.) and fungi (*Candida* and *Aspergillus* spp.), while severe lymphopenia (<600/μL) can lead to severe primary viral infections or viral reactivations [100–102]. The highest rates of infection, and most serious infections, were reported when thiopurines were used in combination with other immunosuppressive therapies.

Corticosteroids

Corticosteroids have a broad range of anti-inflammatory activities and have historically been a mainstay in IBD treatment. However, corticosteroids have been shown to be a major independent risk factor for the development of infections and infection-related mortality (OR 2.1, 95% CI 1.15–3.83) [103]. In one study, the relative risk of infection in IBD patients receiving corticosteroids was 1.4 (95% CI 1.1–1.9), with increasing risk at higher corticosteroid doses (>10 mg/day of prednisone) and duration of therapy beyond 14 days [104]. Not surprisingly, infections with multiple pathogens have been reported in association with corticosteroid use. In IBD patients, the use of systemic corticosteroid therapy has also been associated with increased rates of intra-abdominal abscesses in patients with both perforating (OR 9.03, 95% CI 2.4–33.8) and non-penetrating disease (OR 9.31, 95% CI 1.03–83.91); this effect seemed to be dose dependent, with increasing abscess rates in patients receiving >20 mg of prednisone/day [105, 106]. Similarly, post-operative complications were increased in patients receiving corticosteroids (pooled analysis OR 1.68, 95% CI 1.24–2.28) and are up to twofold higher in patients receiving greater than 40 mg of oral corticosteroids prior to surgery [107].

Worsening severity of primary viral infections or reactivations are well-described complications of systemic corticosteroid use. In IBD patients, both primary varicella and zoster infections have been reported most frequently. In pediatric IBD patients, the use of corticosteroids as monotherapy (prednisone >10 mg/day) or in combination with other immunosuppressant medications (TNF antagonists or thiopurines) was associated with an increased risk of VZV infection, including severe infection, with a case fatality rate of 25% [108]. Ideally, patients with IBD who have not received varicella vaccine or are known to be seronegative (VZV IgG negative) should receive the two doses of vaccine (with appropriate intervals) at least 4 weeks before any immunosuppressive regimen is initiated [95]. Due to the prolonged interval recommended between the first and second dose, necessary vaccinations should ideally be provided at the time of IBD diagnosis to allow sufficient time to both mount a serologic response and not interfere with timing of immunosuppressive therapies. Infection prevention by optimizing vaccine-preventable infections is discussed further in Chap. 55.

Tumor Necrosis Factor Antagonists

TNF antagonists is crucial to intracellular pathogen defense and ensuring a robust cell-mediated immune response. The majority of data regarding infections in patients receiving TNF antagonists have been extrapolated from adults with IBD and other autoinflammatory diseases [109, 110]. TNF antagonists have a differential infection risk that depends on the agent and other host or environmental factors [111, 112]. It is not surprising that granulomatous infections secondary to *Mycobacteria* spp. and fungi (e.g., endemic species; *Candida; Aspergillus* and other molds; *Pneumocystis jirovecii*) and infections with intracellular bacteria (e.g., *Bartonella; Brucella; Listeria; Salmonella; Legionella; Nocardia*) have been reported in patients receiving TNF-α inhibitors [113, 114]. The majority of these infections occurred in the first 6 months of starting infliximab, and in the case of mycobacterial infections, likely reflected reactivation of latent infection. Infections or reactivations with viruses, including Hepatitis B, Hepatitis C, and herpesviruses have also been described [108, 115–118].

The TNF antagonists most commonly used for the treatment of IBD in children in which there are sufficient published data related to infection are infliximab and adalimumab. When compared with adults with IBD receiving TNF antagonists, the overall incidence of reported serious infections in children with IBD receiving TNF antagonists was significantly lower [90]. A recent systematic literature review of infections in children with IBD receiving TNF antagonists reported a predominance of mild and mostly viral infections, with incidences of 3–77% of cases; severe infections occurred less frequently, but were varied, with incidences of 0–10% [118].

An increased risk of mycobacterial and fungal infections has been associated with TNF-α inhibitor therapy. *Mycobacterium tuberculosis* is the most frequent granulo-

matous infection reported in patients treated with infliximab and the risk is further increased when the TNF antagonist is combined with other immunomodulators [119–121]. Infections with *M. tuberculosis* are more common than non-tubercular mycobacterial infections. However, it is unknown to what extent TNF antagonist therapy increases the risk of *M. tuberculosis* disease in children. Two cases of *M. tuberculosis* presenting with disseminated disease have been reported in children with IBD during infliximab therapy despite baseline non-reactive tuberculin skin testing [122, 123]. Current guidelines recommend screening for tuberculosis prior to initiating therapy with TNF antagonists though the optimal testing strategy is unknown [19, 24, 96, 124]. Immunodiagnostic screening with both a tuberculin skin test (TST) and an Interferon-Gamma Release Assay (IGRA) at the time of IBD diagnosis and before initiation of any immunomodulatory therapies, particularly steroids and TNF antagonists, will increase diagnostic sensitivity and allow for more optimal patient management [114].

Histoplasmosis is the most common endemic mycosis in the US, prevalent in the Ohio and Mississippi River valleys, and is the most common fungal infection associated with TNF-α therapy in adults and children, either as a newly acquired infection or by reactivation or reinfection [110, 125]. Histoplasmosis has been described in pediatric patients with IBD receiving TNF antagonists [126–128]. Importantly, IBD patients with histoplasmosis (and similarly with other endemic fungi) most frequently presented with non-specific symptoms indistinguishable from IBD (fever, malaise, weight loss, abdominal pain) or had a pulmonary clinical manifestation similar to community-associated pneumonia, not responding to conventional antimicrobial therapy; thus, a high index of suspicion is warranted in patients receiving TNF antagonists [128]. Diagnostic testing should involve multiple testing modalities if possible, including histopathology, fungal tissue cultures, serologic testing, and antigen detection (in both blood and urine). The sensitivity and specificity of the different tests will depend on the clinical presentation (e.g., pulmonary vs. disseminated), infection severity, and timing of infection. In a patient with compatible signs and symptoms, a high diagnostic sensitivity may be achieved when both urine and serum antigen testing are performed concomitantly, as well as serology (by immunodiffusion and complement fixation) [129]. Other fungal infections in patients with IBD receiving TNF-α inhibitor therapies have also been reported [113, 130, 131].

Pneumocystis jirovecii pneumonia (PCP) has been described in patients with IBD, most commonly CD, who receive high-dose steroids (even during the tapering phase), calcineurin inhibitors, and TNF antagonists [132]. The crude incidence of PCP in IBD patients was estimated to be 10.6/100,000 in a health claims database; although PCP cases have been reported in children with IBD, the overall pediatric incidence is unknown [133]. However, given the higher mortality from PCP in the non-HIV population, PCP prophylaxis should be considered in high-risk children with IBD, including those receiving multiple immunosuppressive agents (TNF antagonists plus a calcineurin inhibitor, TNF antagonists as part of a triple immunosuppression regimen, or combination therapies that include high-dose corticosteroids), malnourished children on combination immunosuppression therapies, and in young children <6 years of age with severe IBD in whom an underlying immunodeficiency disorder is possible [96, 134, 135].

TNF-α inhibition may facilitate the risk of primary viral infection and reactivation [136]. Reactivation of hepatitis B, hepatitis C, or progression of viral liver disease have been described in patients receiving TNF antagonists. Therefore, it is recommended that all patients with IBD be screened for hepatitis B prior to receipt of any TNF antagonist; patients with risk factors or evidence of elevated transaminases should also be screened for hepatitis C [96, 117, 124, 137, 138]. In particular, reactivation of HBV after initiation of immunosuppressive therapy has been associated with significant morbidity and mortality. High- and moderate-risk patients who require therapy with TNF antagonists and are Hepatitis B surface antigen positive (or Hepatitis B surface antigen negative but Hepatitis B core antigen positive) and do not have liver injury may be candidates for antiviral prophylaxis and viral monitoring during biologic therapy [139]. In addition, VZV infections with rates of 11.3/1000 patient years have been reported in patients with IBD receiving TNF antagonists [140]. Primary varicella seems to occur more frequently in susceptible patients with CD than those with UC, and risk of disseminated disease is increased in patients receiving highly immunosuppressive therapies, with case fatality rates of up to 25% [108]. Similar varicella screening recommendations are recommended before starting TNF antagonist therapy as described under the corticosteroid section (see above).

Conclusion

The use of biological agents and immunomodulatory therapy has improved IBD management. Infections, including serious infections, albeit rare, are increasingly being described in patients with IBD receiving immunosuppressive therapies. A heightened index of suspicion, timely diagnostics, and targeted therapies are needed for optimal patient management. Given the limited pediatric data, there are ample opportunities for robust pediatric studies to improve our understanding of infectious burden in this population, optimize preventative strategies, and improve patient outcomes.

Psychological Aspects of Inflammatory Bowel Disease in Children and Adolescents

50

Jill M. Plevinsky and Kevin A. Hommel

Introduction

Youth with pediatric inflammatory bowel disease (IBD) are at greater risk for psychosocial challenges, including deficits in health-related quality of life, symptoms of anxiety and depression, poor social, academic, and family functioning, and suboptimal adherence and self-management. Many of these psychosocial issues are related to the unpredictable relapsing and remitting disease course as well as the embarrassing nature of the symptoms. Treatments can also cause side effects and it may take time for newly diagnosed children to find the treatments that work best for them, which can be frustrating for children and their families. Frequent medical appointments and procedures may also interrupt day-to-day life. As a result, youth with IBD may withdraw from peers, limit their activities, and miss school, all of which are critical, developmentally normative activities that promote psychosocial adjustment during childhood and adolescence. Concerns with appearance (e.g., short stature, changes in weight), pressure to engage in risk behaviors, and the perceived stigma of having a chronic gastrointestinal illness also impact psychosocial functioning. In response to these concerns, pediatric IBD care has emphasized a multidisciplinary approach involving psychologists and social workers as core members of the care team. The following chapter will provide an update on the psychosocial literature in pediatric IBD from the previous chapter on the topic written in 2017 by Drs. Bonney Reed-Knight, Laura Mackner, and Wallace Crandall [1]. Several psychological aspects of IBD will be reviewed, including health-related quality of life, pain and symptom management, emotional functioning, social functioning, academic functioning, body image, family functioning, adherence and self-management, and health behaviors (e.g., physical activity, sleep, and substance use). Evidence-based efforts to address psychosocial aspects of IBD will also be reviewed, and recommendations for future research and intervention will be provided.

Health-Related Quality of Life

Health-related quality of life is a critical aspect of psychosocial functioning in pediatric IBD and is also the most well examined due to the rigorous development of both general and disease-specific measures (e.g., PedsQL, IMPACT-III [2]) and robust evidence of associations with demographic characteristics and disease activity in addition to anxiety, depressive symptoms [3], social functioning, school functioning, family conflict, poor self-image, and suboptimal medication adherence [4, 5]. Emerging research continues to confirm that increased psychosocial difficulties (e.g., distress and pain catastrophizing [6], illness perceptions, anxiety, and depressive symptoms [7]), gastrointestinal symptoms [8], and disease severity are associated with poorer health-related quality of life [9–11].

Findings from a recent study suggest that disease activity may be the main correlate of quality of life in youth with IBD, with extra-intestinal manifestations (e.g., musculoskeletal pain, liver disease) associated with even more impaired quality of life [12]. However, this study was cross-sectional and longitudinal research examining health-related quality of life in pediatric IBD is limited. One study confirmed that this association may hold over time and found that health-related quality of life at baseline, disease activity at baseline, and changes in disease activity predicted changes in health-related quality of life over time [13]. An additional longitudi-

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_50

nal study found that changes in disease activity and health-related quality of life may be also assessed via change in other patient-reported outcomes, including the PROMIS pediatric measures of anxiety, depressive symptoms, pain interference, fatigue, and peer relationships [14].

Pain and Symptom Management

Abdominal pain is a primary, prevalent symptom of pediatric IBD, yet literature examining the psychosocial correlates of this construct is relatively limited. Pain is most often associated with active disease, but it can also be present during periods of clinical remission. A recent systematic review concluded that several psychosocial factors are associated with pain in pediatric IBD [15]. Given that pain can also be heavily associated with functional disability and reduced health-related quality of life across youth with chronic medical conditions, it is critical that pain be considered as a component of psychosocial functioning in pediatric IBD. Most adolescents report abdominal pain regardless of disease activity, females reported abdominal pain more often than males, and abdominal pain is significantly associated with poorer health-related quality of life and increased activity limitations [15, 16]. Although pain may significantly decrease during the first year after diagnosis, it is important for providers to recognize risk factors for increased pain and the impact of pain on the child or adolescent's overall well-being [17].

Pain catastrophizing, or the tendency to magnify or exaggerate the threat or seriousness of pain, has also been shown to predict increased functional disability in youth with IBD [18]. Additionally, coping abilities, anxiety, depression, and beliefs about what symptoms might mean (e.g., "My stomachaches mean I'm really sick") were strongly associated with increased symptom reporting and not related to disease severity [19]. The unpredictable nature of the disease course and the experience of pain and IBD symptoms can bring about psychological distress in children and adolescents in the form of anxiety and depression, which in turn can lead to increased reporting of IBD symptoms and related functional disability [5]. Given that treatment decisions are often in part based on symptom reporting, it is also important to consider the impact of psychosocial functioning when assessing pain and symptoms in pediatric IBD.

Social Functioning and Peer Relationships

A diagnosis of IBD during childhood or adolescence can significantly affect social functioning, including spending time with friends and maintaining friendships. Friendships are critical for normative adolescent development and may be challenging to develop and maintain for youth with IBD due to discomfort around disclosing their diagnosis and symptoms [20, 21], missing out on activities due to dietary restrictions or fatigue and worrying that their friends just "feel sorry for them" [22]. A study examining belongingness found that youth with IBD who perceive that others are stigmatizing their illness report less social belongingness, which may have implications for increased depressive symptoms [23]. However, positive social support may ameliorate the effects of peer victimization in this population [24]. Therefore, youth with IBD may benefit from cognitive behavioral treatments that address perceived stigma and belongingness and promote peer relationships to support social functioning.

Youth with IBD often seek peer support from other youth with IBD. Online support groups are increasingly popular with adolescents and young adults seeking this type of peer support [25]. A recent study examined how young people with IBD utilize online support groups (e.g., sharing personal experiences, sharing information about IBD [26]); however, data do not yet exist on how participation in these groups may affect psychosocial outcomes.

Camps for youth with IBD are available across the country and can be another way for youth with IBD to meet one another and access social support. Research suggests the benefits of camp include improvements in health-related quality of life, social functioning [27], and overall psychosocial adjustment [28]. Focus groups suggest that peer mentoring may also be another way by which youth with IBD can access social support from other patients. Findings from these groups suggest that youth with IBD are seeking support, role models, and information/education from their peers [29].

Academic Functioning

School functioning includes academic performance, school attendance, educational attainment, and psychosocial functioning in the school setting, and children and adolescents with IBD are at risk for poor school functioning [30, 31]. Several studies suggest that school functioning is more consistently predicted by demographic and psychosocial factors. Specifically, older age, socioeconomic status, parent marital status, and mental health diagnoses have all been associated with poorer aspects of school functioning [32–35].

The majority of studies in this area have focused on school attendance, with most suggesting that youth with IBD have significantly more absences from school compared to healthy peers [30, 32, 36, 37]. Increased school absences have been associated with internalizing problems (e.g., anxiety, depression) [32], as well as concerns with not feeling well at school, not having access to bathrooms, not being able to keep up with assignments, and their teachers' understanding of IBD

[35]. Despite increased absences, there appear to be no differences in educational attainment [34], academic performance [33], or other aspects of school functioning [32] when compared to healthy peers. This discrepancy may be due to increased rates of special education supports, including Individualized Education Plans or 504 plans. These supports offer accommodations for youth with chronic medical conditions, including additional time to complete assignments. Common accommodations for youth with IBD may include "any time" bathroom passes, a place to rest during the day if needed, access to medication, and access to snacks or water throughout the day, among others [38]. Children with IBD and their families often require support from the medical team in establishing these plans with their school systems. Accommodations provided may promote academic success both in elementary and high school and may also promote success in higher education as well [39].

The transition to and experience in college is also challenging for adolescents and young adults with IBD, especially since this transition may often involve moving away from home or transitioning to another medical team. Several elements of the college experience pose unique challenges to those with IBD (e.g., bathroom access, dining options, medication storage) [40]. College students with IBD reported greater difficulty adjusting to college compared to healthy peers. College adjustment, which consists of academic functioning, social adjustment, emotional adjustment, and school attachment, is not only linked with success during college (e.g., retention) but also graduation rates and even future economic success. Poorer college adjustment in young adults with IBD has been associated with poorer health-related quality of life [41, 42]. Class attendance is lower for older college students with more severe disease as well [42]. Although most college students with IBD report average college adjustment, one study indicated that nearly half of students reported social-emotional adjustment to college within the very low to low range, and reported that having IBD impacted their choice of college [39]. College-bound youth with IBD may benefit from support from their medical team, school counselors, disability support services, and other psychosocial support during the college application process to avoid inappropriately perceiving their IBD as a limiting factor [39]. Providers can also be helpful with putting plans in place to support adjustment to college and providing resources for how to navigate the college experience while still best managing their IBD [40, 43].

Body Image

Body image is a significant concern for children and adolescents with IBD, especially with respect to growth, development, and changes in weight due to disease processes or treatment (e.g., steroids). Since the previous version of this chapter, two studies have examined body image dissatisfaction: one utilized an item from the IMPACT-III (e.g., "I look awful", "I look bad") and another administered the Adapted Satisfaction with Appearance questionnaire. Across both studies, patients with body dissatisfaction were older, reported more active disease, and reported greater depressive symptoms [44, 45]. Body image has been examined in adults with IBD as well as with a recent systematic review suggesting female gender, older age, fatigue, disease activity, and steroid use were most commonly associated with body image dissatisfaction [45]. Given that body image is so closely related to overall health-related quality of life, interventions designed to improve health-related quality of life should include aspects related to improving body image.

Emotional Functioning

Adjustment to and coping with a diagnosis of pediatric IBD can be difficult for both youth and their parents. A recent qualitative study with patients and their parents identified several challenges related to their IBD diagnosis, including the unpredictable nature of the disease, a disrupted sense of normalcy, and increased difficulties with treatment decisions, managing relationships, and life transitions [46]. They reported coping through social support, maintaining a positive attitude, behavioral strategies for managing emotions (e.g., deep breathing), and maintaining confidence in their medical team [46]. Emerging research has also examined specific aspects of adjustment in youth with IBD and their parents, specifically illness uncertainty and illness intrusiveness which have both been associated with youth and parent overall psychological adjustment [47].

Youth with IBD exhibit higher rates of anxiety and depressive disorders compared to both healthy youth and youth with other chronic medical conditions [4, 48]. Recent prevalence rates drawn from a systematic review suggest 16.4% of youth with IBD report anxiety symptoms and 4.2% report anxiety disorders. 15% of youth with IBD report depressive symptoms and 3.4% report depressive disorders [49]. Findings have been mixed regarding factors influencing elevated anxiety and depressive symptoms: one study indicated that perceived functional disability was the primary influence [50], while others cite demographic factors such as disease severity, lower socioeconomic status, corticosteroid treatment, parent stress, and older age at diagnosis [51]. Since emotional functioning can impact pain, sleep, substance use, adherence, and negative illness perceptions [51], both anxiety and depression have been studied extensively in pediatric IBD.

Anxiety symptoms reported by youth with IBD frequently are around school anxiety, separation anxiety, and general anxiety [52]. Emerging research in anxiety in pediatric IBD has incorporated the IBD-Specific Anxiety Scale [53] which measures how often respondents worry about using the bathroom, experiencing pain, medication taking, medical procedures, and IBD symptoms. Notably, IBD-specific anxiety is associated with overall poorer psychosocial functioning and increased healthcare utilization [54, 55], yet patient health communication may explain the link between anxiety and symptoms in this population [56]. Therefore, improved patient–provider communication about aspects of IBD-specific anxiety (e.g., symptoms) may alleviate some anxiety symptoms and interventions to manage anxiety in this population may require tailoring to include aspects of both IBD-specific anxiety and generalized anxiety depending on the patient's needs [57].

Depressive symptoms are very commonly reported by youth with IBD; however, most youth with IBD do not experience clinical levels of depressive symptoms [58]. One of the largest studies of youth with IBD and depression found evidence for three subtypes of depressive symptomology: 75% fell within a mild subtype characterized by low depressive symptoms and highest quality of life; 19% fell within a somatic subtype characterized by fatigue, changes in appetite, loss of interest in activities, and depressed mood with highest disease activity; and 6% fell within a cognitive subtype characterized by the highest depressive symptoms, anxiety, and functional IBD symptoms [59]. Youth with IBD may be more at risk for experiencing depressive symptoms due to a combination of neurobiological (e.g., inflammation, pain, sleep disturbances) and psychosocial factors (e.g., illness perception, illness-related stressors) [60]. Increased depressive symptoms have been associated with disease severity [61], symptoms and functional disability [19], how family stress contributes to pain-related distress [62], nonadherence and risk of relapse [63], increased length of inpatient hospital stays [64], and overall health-related quality of life [7, 65]. However, many symptoms of depression are confounded with common symptoms of IBD, including changes in appetite, changes in sleep, and low energy which may make it difficult for providers to determine whether symptoms can be addressed via psychosocial intervention, medical intervention, or a combination of both. Multi-disciplinary teams, including behavioral health providers, are equipped to assess for comorbid depressive symptoms and support adaptive coping with both IBD and depressive symptoms [66]. As such, guidelines have recently been developed around screening all children and adolescents with IBD for depression starting at age 12 [67].

Family Functioning

Family functioning, or the dynamics within the family environment, have been related to both parent and child health and psychosocial outcomes in pediatric IBD [68]. Suboptimal family functioning may be characterized by difficulties with family communication, family problem-solving, delineating roles and responsibilities within the family, and family conflict, all of which have been reported by families of youth with IBD [69, 70]. These difficulties may arise throughout the disease course and the child's development. For example, a flare-up or introduction of a new treatment regimen may disrupt existing routines within the family, which may lead to family dysfunction. Additionally, as a child develops into an adolescent and subsequently into a young adult, their desire for independence may increase and they may want to take more ownership over their IBD treatment, which may be difficult for families to navigate [71]. Broadly, family functioning has been found to be an important predictor of both parent and child health-related quality of life [3]. Family functioning can also be affected by the child's behavioral difficulties [70], emotional symptoms [72], and pain [73], or fatigue.

Parent functioning is a critical component of family functioning and is often found to be driven by their child's disease course [74]. Parenting stress has been most commonly examined with the Pediatric Inventory for Parents, which assesses both the frequency and intensity of a variety of stressors that come up when caring for a child with chronic medical condition [75]. It is critical to assess parenting stress in caregivers of youth with IBD since it has the potential to negatively affect disease management, which can result in poorer health outcomes [75] as well as child depressive symptoms [72, 76] and poorer child health-related quality of life [74]. Greater parenting stress has also been associated with increased disease severity; however, most studies examining this are cross-sectional, suggesting that this relationship may be bidirectional [72, 74].

Adherence and Self-Management

Medication nonadherence rates vary widely, ranging from 2 to 93% in pediatric IBD [77] with poorer adherence associated with negative health outcomes (e.g., treatment escalation [78]) and increased healthcare costs [79]. Many studies have documented the association between poorer psychosocial functioning and poorer medication adherence in pediatric IBD [63, 80, 81]. Managing pediatric IBD is complex and may include any combination of daily oral medications, weekly or bimonthly subcutaneous injections, or periodic

infusions in addition to surgical procedures and various healthcare maintenance tasks (e.g., routine lab work, immunizations, bone density scans) [63]. This complexity can put a strain on various aspects of psychosocial and behavioral functioning [82], including health-related quality of life [83], emotional functioning (e.g., anxiety, depression) [81], social functioning (e.g., missed activities), academic functioning (e.g., missed school days), and family functioning (e.g., family conflict) [84]. Given that adherence can also be influenced by psychosocial functioning, interventions to improve aspects of psychosocial functioning closely linked to adherence, such as motivational interviewing, problem-solving skills training, and family-based interventions are likely to also improve adherence [85].

Clinical practice around adherence monitoring varies widely; 25% of responding pediatric GI providers reported using a screening tool, approximately half cited using objective measures (e.g., lab values), and most reported using patient and caregiver reports [86]. The most commonly identified barriers to adherence include forgetting, interference with activities, and being away from home [77, 87], and both cross-sectional and longitudinal research suggest that barriers to adherence impact medication adherence [88, 89]. Therefore, adherence promotion interventions in pediatric IBD have primarily utilized a problem-solving approach that helps patients and their families first identify barriers to adherence and work to test various solutions to those barriers [90], while others have taken a multicomponent approach by also incorporating education, behavior modification, and family functioning [91].

Self-Efficacy and Disease Knowledge

Self-efficacy and disease knowledge are important skills for the long-term management of IBD. Self-efficacy refers to one's belief in their capacity to perform behaviors that are needed to meet a goal, which is why this concept has been examined with respect to disease management in pediatric IBD. The IBD Self-Efficacy Scale for Adolescents and Young Adults (IBDSES-A) is a validated, disease-specific measure that assesses disease management self-efficacy [92], and several measures have been used to assess disease knowledge with the most recently validated being the Inflammatory Bowel Disease Knowledge Inventory Device 2 (IBD-KID2) [93]. Notably, both self-efficacy and disease knowledge are suboptimal in adolescents with IBD [94, 95]. Specific areas of knowledge deficits include medications (e.g., dose, side effects, refill frequency), appointment management (e.g., frequency, how to schedule), and the effects of substance use (e.g., smoking, drugs, and alcohol) [94, 95]. These constructs are related with greater self-efficacy being linked to greater disease knowledge [95]; therefore, as adolescents with IBD become more responsible for their care and prepare to transition to adult care, they may require interventions to promote self-efficacy and disease knowledge, such as problem-solving skills training and increased involvement in their clinic visits and treatment decisions [95].

Health Behaviors

In addition to medication taking, there are several other health behaviors that are impacted by psychosocial functioning in youth with IBD. The three that have garnered the most attention in recent years have been sleep, physical activity, and substance use. Broadly, sleep is critical for both physical and psychosocial health for all children and adolescents; however, youth with IBD often report sleep difficulties and fatigue. Those who report difficulty sleeping also report increased anxiety, depression, somatic complaints, and aggressive behavior [96]. Impaired sleep has also been associated with active disease in multiple studies, suggesting an association between sleep disturbances and inflammatory pathways [97, 98]. Adolescents endorse that symptoms interfere with their sleep (e.g., waking to use the bathroom, abdominal pain), resulting in fatigue [99] which is a common symptom reported by youth with IBD. Yet, improved health-related quality of life is associated with better sleep [100]. Therefore, sleep ought to be routinely assessed and considered in the context of disease activity. Whether sleep is affected by symptoms or psychosocial functioning, youth with IBD may benefit from behavioral sleep intervention to increase overall sleep quality.

Physical activity is another health behavior that may impact health outcomes in pediatric IBD and has been linked with psychosocial functioning. Although one study suggests that most patients continued to exercise and participate in sports after their IBD diagnosis [101], several studies report that most children and adolescents report that their IBD has interfered with their participation in sports [102, 103] and physical activity [104, 105]. This can result in poorer exercise capacity [106], which may impede future physical activity endeavors. Decreased physical activity may not only be a result of pain or fatigue [105] but may also be associated with disease symptoms [104] and body image concerns [103]. Addressing these barriers to sports participation and physical activity in general may help promote this health behavior in youth with IBD.

Substance use, including alcohol use, tobacco use, and marijuana use, is a developmentally normative adolescent behavior, yet has been understudied in adolescents with IBD. Given the rise in the use or cannabis to manage IBD, medical providers are encouraged to recognize the perceived

benefits (e.g., symptom reduction) and understand the potential detrimental effects and risks of its use [107–109]. Prevalence of marijuana use appears to be particularly high in young adults with IBD with most not disclosing their use to their medical team and approximately half without knowledge of adverse effects [110]. Broadly, adolescents and young adults with chronic illnesses use substances at similar or greater rates than their healthy peers [111, 112], and may experience more adverse health outcomes as a result. In addition to marijuana use, alcohol use is also common in adolescents with chronic medical conditions and was found to be associated with poorer medication adherence in a study that included youth with IBD [113]. Adolescents and young adults with IBD endorsing multi-substance use in the last 30 days were older, more likely to be male, more likely to have active disease, and more likely to have been hospitalized in the past year compared to those who abstained [114]. Additionally, they reported greater barriers to adherence, lower disease management self-efficacy, and poorer health-related quality of life [114]. Although this group likely represents a small percentage of adolescents and young adults with IBD, it is notable that substance use can be associated with health and psychosocial outcomes.

Psychotherapy and Other Resources

Increased recognition of the psychosocial impact of pediatric IBD has led to increased resources in pediatric IBD centers to provide multi-disciplinary care to children and their families [115]. These efforts have included additional personnel (e.g., psychologists, social workers) and most recently, implementation of mental health screenings as a standard of care [116]. One recently published approach describes this integrated model as well as data collected from newly diagnosed patients with IBD. Recommendations include routine surveillance via developmentally appropriate psychosocial data collection to inform referrals and close ongoing collaboration between psychosocial providers and the medical team to address the biological, psychological, and social needs that may impact treatment [117, 118]. Screening efforts examining health-related quality of life have shown associations with healthcare utilization such that those reporting poorer health-related quality of life had more IBD-related hospitalizations, clinic visits, emergency room visits, telephone contacts, and psychosocial referrals [119]. Annual depression screening is recommended for all adolescents 12 and older as well [67].

Cognitive behavioral interventions continue to be effective for addressing anxiety and depression. Pilot data suggest that youth with comorbid IBD and anxiety benefited from a 13-session cognitive behavioral treatment program compared to those receiving standard care with significant and sustained reductions in IBD-specific anxiety [120]. Cognitive behavioral therapy has also been examined in adolescents with IBD and comorbid subclinical anxiety and depressive symptoms; however, disease-specific cognitive behavioral therapy did not appear to perform better than standard medical care in reducing these symptoms [121, 122] or improving medical outcomes (e.g., relapse) [123]. Therefore, cognitive behavioral interventions are likely most appropriate for youth with IBD who meet full diagnostic criteria for anxiety or depression and other, less intensive interventions may be more appropriate for those reporting subclinical psychological symptoms.

Mind–body interventions have also emerged as a potentially effective adjunct to the standard medical treatment for IBD. These interventions include not only psychotherapy as described above but also relaxation, mindfulness, biofeedback, yoga, and hypnosis. These therapies may be especially helpful for those in IBD who experience associated symptoms consistent with irritable bowel syndrome (IBS) (e.g., when a patient in clinical remission is reporting significant symptoms) due to the bidirectional brain-gut connection [124]. Preliminary evidence suggests that relaxation and mindfulness techniques are feasible [125, 126] and can improve psychological functioning in adults with IBD, and that heart rate variability biofeedback and yoga may help with pain management and improve anxiety [127]. Many adolescents report using mind–body techniques (e.g., relaxation, guided imagery, meditation) to manage their symptoms, and those with more severe disease and poorer health-related quality of life were more willing to consider using relaxation or meditation in the future [128].

As digital health and mHealth tools are becoming more widely used by adolescents and young adults with chronic illnesses, several mobile apps have been developed to assist with adherence and self-management as well as other psychosocial aspects of pediatric IBD (e.g., pain and symptom tracking, coping, tracking health behaviors). One existing review of mobile apps for IBD self-management assessed 26 apps; however, the majority do not have professional medical involvement and therefore do not include evidence-based guidelines [129]. It is important that future development of these tools include medical professionals, psychosocial professionals, and patients in the design and development process.

Summary

Overall, children and adolescents with IBD experience psychological difficulties across a variety of domains with research suggesting significant risk for impairments in health-related quality of life, increased anxiety and depressive symptoms, school absenteeism, parenting stress, and

suboptimal adherence and self-management. Despite this association between psychological issues and IBD, research examining psychotherapy and the use of psychopharmacologic treatment is limited in pediatrics [130]. This may in part be due to a disruption in psychosocial development; a recent study suggested that youth with IBD achieved fewer social and psychosexual developmental milestones compared to healthy peers [131]. This can have important implications for adult functioning, especially related to work-related productivity and disability status [132, 133].

Given the prevalence of psychosocial challenges in this population, providers are increasingly recognizing the value of routine psychosocial assessment and the inclusion of behavioral health providers (e.g., psychologists, social workers) in routine clinical care [115]. Yet, a recent survey suggests there are still significant gaps in the psychosocial care of youth with IBD. Specifically, 30–40% of youth surveyed indicated family/peer relationships, school/extracurricular activities, and mood were not addressed by their healthcare team. Many also reported that substance use, sexual health, and body image were also not discussed [134]. A multidisciplinary approach to treating pediatric IBD will allow for these psychosocial issues to be addressed, which will have a positive impact on health outcomes broadly.

Measurement of Quality of Life in Pediatric Inflammatory Bowel Disease

51

Amy Grant and Anthony Otley

Introduction

The burden of disease imposed on children and youth by Crohn disease (CD) and ulcerative colitis (UC) may be considerable, as manifested by clinical parameters, such as symptoms, number of hospitalizations, growth retardation, and frequent need for surgery [1–5]. However, increasingly the psychosocial burden of inflammatory bowel disease (IBD) on young patients is being considered alongside these important clinical parameters [6–8]. One means of assessing the psychosocial burden is through evaluation of health-related quality of life (HRQOL). The purpose of this chapter is to provide the reader with an understanding of the concept of HRQOL, the approaches to its measurement in children, more specifically in pediatric patients with IBD. Finally the gaps in knowledge of HRQOL in pediatric IBD and the future directions for research in this area will be discussed.

Quality of Life: Concepts/Definitions

In 1948 the World Health Organization defined health as being not only the absence of disease and infirmity but also the presence of physical, mental, and social well-being [9]. Since that time quality-of-life issues have been increasingly recognized as important parameters in determining health status. A single definition of quality of life is difficult to find [10, 11]. Without a clear definition, multiple interpretations of what quality of life "is" have evolved. This has led to the development of a number of different measures which assess varying aspects of quality of life. This failure to achieve a unifying definition has hampered the ability to make comparisons between quality-of-life outcomes. Most current definitions include the concept of the multidimensional nature of quality of life and incorporate domains of social, physical, and emotional functioning of the individual [12]. With HRQOL one is attempting to ascertain the impact of the disease, concentrating on the health-related aspects of quality of life. Quality-of-life outcomes have been conceptualized by viewing the domains in two dimensions: objective assessments of functioning or health status (the *y* axis in Fig. 51.1) and more subjective perceptions of health (the *x* axis) [13]. While the objective assessment is integral for describing an individual's degree of health, the individual's subjective perceptions and expectations modify the objective assessment into the real quality of life experienced (or Q, as expressed in Fig. 51.1 by the intersection of the *x* and *y* coordinates). Because perceptions and expectations may vary from individual to individual, two people with the same health status may have very different qualities of life [13].

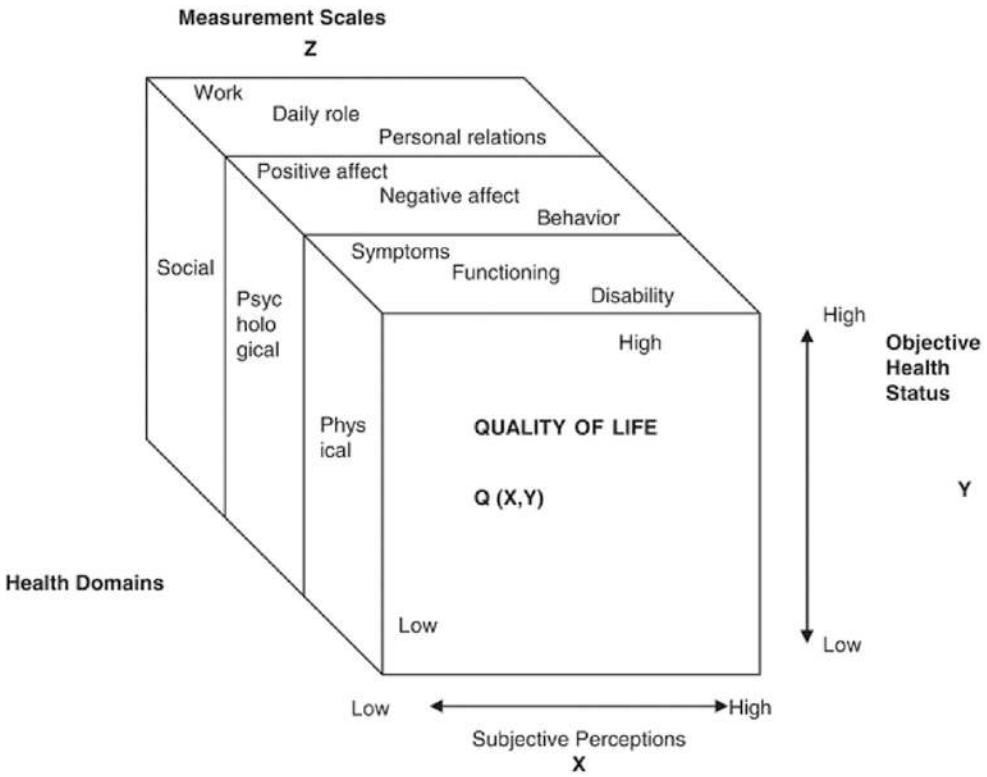

Fig. 51.1 Conceptual scheme of the domains and variables involved in a quality-of-life assessment. The *x* axis represents subjective perceptions of health, the *y* axis represents objective health status, the coordinates Q(*X, Y*) represent the actual quality of life, and *Z* represents the measurement of the actual quality of life associated with a specific component (i.e., positive affect) or domain (i.e., the psychological domain) (Adapted from Testa and Simonson [13])

Why Measure Health-Related Quality of Life?

Over the past several decades, a dramatic increase in the employment of quality-of-life outcome measures has been evident in the adult and pediatric clinical trials' literature. In part, this is a result of the trend to expand the traditionally selected, "objective" outcome measures of morbidity (i.e., days hospitalized, number of infections) and/or mortality to include assessment of the emotional and functional status of participants. The single-minded focus on mortality and morbidity as outcomes in health is being steadily superseded by broader considerations of quality of life. This broader consideration is currently being espoused by the Food and Drug Administration (FDA) which is now mandating inclusion of patient-reported outcomes (PROs) alongside more objective measures (i.e., endoscopic evaluation) in the design of clinical trials to evaluate new drug therapies in IBD [14–16].

One of the first stages in evaluating a new measure is to determine the "phenomenon of interest," to define the conceptual framework underlying the measure [17]. In IBD the primary outcome measure traditionally selected for use in clinical trials has been a multi-item disease activity index [18], such as the pediatric Crohn disease activity index (PCDAI) [19, 20]. However, measures, such as the PCDAI, have concerns around feasibility (i.e., difficulty collecting all required laboratory data) [21], short-term responsiveness to change in clinical status based on the inclusion of questions that do not show short-term change (i.e., height velocity) [22], and construct validity given the low correlation with objective markers of inflammation or fecal calprotectin levels [23, 24]. For disease activity measures, the concept is to use the degree of intestinal inflammatory activity as a surrogate measure of the patient's health status. This framework is based heavily on physician perceptions, with little input about the patient's perception of the disease on their health status [18]. There is now consensus around a desire to move away from sole reliance on objective measures of disease and to develop co-primary endpoints using concurrent endoscopic or less-invasive objective measures (e.g., MR enterography, fecal calprotectin) and quality of life assessment [15]. Use of quality of life addresses this deficiency of focusing only on physician perceptions. Because existing measures of disease activity are not sensitive enough to assess the full impact of the disorder, HRQOL measures have been developed to do this [25].

Approaches to Health-Related Quality-of-Life Measurement

The ideal assessment of HRQOL would involve lengthy, detailed interviews between the patient and an independent interviewer, an impractical procedure in day-to-day clinical care or a clinical trial. A self-administered questionnaire that is easy to understand, complete, and covers all the important aspects of the patient's HRQOL is a more attractive means of

assessing HRQOL. The questionnaire should include all relevant elements or "domains," of HRQOL. These domains may cover physical, functional, emotional, and cognitive well-being and, in case of disease, disease-related aspects. Each domain consists of a number of "dimensions" or questions. A balance needs to be struck between including a sufficient number of dimensions so that a complete assessment of HRQOL can be made, while being careful not to create a questionnaire so lengthy that it becomes burdensome for the respondent to complete. The advantage of combining questions into domains is that interventions can be directed at these domains, attempting to ameliorate that aspect of HRQOL.

There are two basic types of HRQOL measures: generic and disease specific. A generic measure is designed to measure all aspects of health and related quality of life and can include items and domains that are broadly applicable to various diseases and populations. Although disease-specific questionnaires include some of these same issues, they also address issues specific to the particular disease. Disease-specific questionnaires are more sensitive to disease-related changes in patients' health status than generic questionnaires.

Generic measures can take several forms, from instruments with global assessments using single indicators (e.g., "What is the quality of your life on a scale of 1–10?"), utilities (e.g., standard gamble, time trade-off, Child Health Utility 9D CHU) [26], or multi-item measures which give a health profile, such as the Pediatric Quality of Life Inventory (PedsQL) [27–29]. One of the advantages of a generic measure is its generalizability. Generic measures permit comparisons between "healthy populations" and different disease groups, interventions, and demographic and cultural groups [30, 31]. Generic questionnaires, such as the Medical Outcomes Study Short Form (SF-36) for adults [31, 32] or the Child Health Questionnaire for children [33], have been applied to groups with no defined illness, allowing normative values to be generated for these healthy populations. When such normative data are available, it offers the potential to make comparisons as to burden of illness between populations affected with and without chronic illness [34]. The chief disadvantage to generic measures is their insensitivity to important clinical change. This stems from their inherent lack of specificity, a result of the inclusion of many items which may not be relevant to the individual patient with an isolated disease. This can be addressed by the use of a disease-specific measure that focuses on concerns relevant to a particular patient group. "Specificity" is achieved by the inclusion of dimensions and domains which are targeted to the disease in question. For example, in the Pediatric Asthma Quality of Life Questionnaire, a measure developed by Juniper et al. [35], the symptom domain includes questions, such as "How much did tightness in your chest bother you during the past week?" and "How often did your asthma wake you up during the night in the past week?" This specificity makes the questionnaire more sensitive to important clinical change in asthma, which is an important criterion when choosing an outcome measure in a clinical trial. In the adult literature, disease-specific questionnaires have been developed for a number of diseases, including IBD [36], rheumatoid arthritis [37], breast cancer [38, 39], and asthma [40, 41]. Increasingly disease-specific questionnaires have been developed for use in the pediatric population as well [40, 42–48].

Any measurement tool should be tested prior to use to ensure it fulfills the fundamental psychometric characteristics of a good measure. A HRQOL questionnaire would be one example of a measurement tool. The psychometric characteristics to be assessed include sensibility, reliability, validity, and responsiveness to change (Table 51.1).

Table 51.1 Four fundamental measurement characteristics to be assessed of any measure

Measurement characteristic	Definition	Examples of what to look for
Sensibility	Do the components of the instrument make sense and is it feasible to administer and complete?	• Readability statistics • Number of questions left blank • Inappropriate inclusions or important omissions of items
Reliability	Are similar scores obtained on subsequent assessments if no change in disease status has occurred?	• Test–retest reliability most commonly reported (either as intraclass correlation coefficient or Kappa value) • Instruments with good reliability require smaller sample sizes
Validity	Is the instrument measuring what it was intended to measure?	• Criterion validity testing when a gold standard exists to compare to • Construct validity testing when no gold standard exists, and hypotheses are generated and tested on how the instrument would be expected to function
Responsiveness	Does the instrument score change with a change in disease status?	• No one accepted way to evaluate • Want to know over what time period an instrument is responsive (i.e., short term, 4 weeks, or longer term, 6 months)
Minimal Importance Difference	What is the smallest difference in score that is perceived as important, that could lead to a change in patient management or outcomes?	• Can be evaluated using multiple approaches (anchor based or distribution based) • Anchor-based methods may be more conservative • Distribution-based methods do not take into account patient perspectives

Sensibility is a measurement characteristic with many aspects and for a questionnaire should include assessment of feasibility for both the person administering and completing the questionnaire (i.e., time to complete and mark, readability), as well as a critical review of the appropriateness of items included or omitted. *Reliability* looks at whether a measure has reproducibility, (i.e., if the same result is obtained when the same (unchanged) entity is measured again) [30]. For example, assuming that HRQOL is influenced by disease activity or medication use, one would expect a reliable HRQOL questionnaire to show very similar scores when given to a patient at time one and again at time two if no interval change in disease activity or medication has occurred. *Validity* is concerned with whether a questionnaire actually measures what it is intended to measure. Ideally one would like to measure the validity of an HRQOL measure comparing it with a gold standard. Unfortunately, HRQOL is a concept for which no gold standard exists. Thus, a process of construct validity testing must be carried out. This involves generating hypotheses, called constructs, and studying whether the measure acts as one would expect. The final characteristic, *responsiveness* to change, relates to the ability of the questionnaire to detect change over time, characteristics important for use in clinical settings. A very responsive HRQOL questionnaire should be able to detect even a small change in disease status. Last but not least is the importance of measuring not only the statistical difference in scores when there is a change in disease status as per responsiveness but also understanding the clinical significance of the change in HRQOL scores. This clinical or meaningful difference is represented methodologically by the "Minimal Important Difference," which measures the degree of change corresponding to a clinical change as perceived by a patient, physician or caregiver [49]. Both responsiveness and the related minimal importance difference characteristics are especially important in determining the sample size for studies in which HRQOL is a main outcome, as the expected amount of change determines how many participants are needed to show a statistically and/or clinically significant change.

Health-Related Quality-of-Life Assessment in Pediatrics

Making quality-of-life assessments in a pediatric population requires the awareness of several key methodological issues: whether to ask children directly [50, 51] and how to allow for varying developmental level and age [10, 52]. It is not always possible to obtain the child's assessment of their quality of life, whether due to age and/or developmental or disability limits to comprehension. In these instances a proxy is sought. The proxy reporter of the child's quality of life is most often their parent/caregiver but in some cases may be another individual, such as a teacher or physician [51]. The wide developmental spectrum seen across the pediatric age group can affect both children's perception of their own quality of life and the relationship between a child and proxy score. The quality of a child's self-report is highly dependent on their expressive and receptive language abilities [10]. As well, differences in time perception and memory related to their developmental stage will affect a child's ability to respond to questions based upon experiences during a specific time period [51]. Within a given culture, developmental tasks can vary by age such that some quality-of-life items may be appropriate for a specific age range but not for another. For example, perceptions on relationships with the opposite sex will vary with age. Other issues likely related to developmental age include position bias, the tendency to choose the first answer; acquiescence response bias, the tendency to agree with the interviewer; and limited understanding of negatively worded items [53].

When both a child and parent are able to complete an assessment of HRQOL, research has generally shown that proxies tend to have a low-to-moderate agreement [54] between child and parent HRQOL reports, while others have found moderate to high agreement. Despite differences in the degree of concordance across studies, most find greater concordance on more observable measures (e.g., physical well-being [54]) and lower concordance on more subjective measures (e.g., emotional well-being). Pantell et al. showed that parents and teachers agreed fairly well in reporting on child functioning but markedly less well for recent functional status, certain types of subjective feelings in regard to illness, information needs, emotional states [55], and family functioning [56]. Agreement among raters may differ as a result of factors, such as child sex, age, condition [57], as well as both child psychosocial [58, 59], and parent psychosocial comorbidities [60], such as anxiety, depression, and post-traumatic stress related to a child's condition.

Realizing that the degree to which there is agreement for proxy ratings in some areas of response varies, it is unclear to what extent differences in response pattern are due to limitations in abstract reasoning, differential influences from demographic or psychosocial influences, or true differences in perspective or opinion. Further research should seek to disentangle these effects in order to appropriately identify young patients who may benefit from interventions to improve HRQOL.

Health-Related Quality-of-Life Assessment in Inflammatory Bowel Disease: Adult IBD Perspective

Measurement of HRQOL in IBD has received a lot of attention over the several decades, with the result that there are now validated outcome measures that have been used in clinical trials or cross-sectional studies (Table 51.2). Early attempts at assessing HRQOL in IBD, however, were hampered by a number of methodological issues: healthy or medical comparison groups were not used, studies were done by retrospective analyses [61, 62], non-standardized instruments [62–65] and unskilled interviewers were used to obtain the data, and insensitive outcome factors (i.e., ability to work) [61, 65, 66] were used as measures of HRQOL.

The main disease-specific HRQOL instrument currently used is the Inflammatory Bowel Disease Questionnaire (IBDQ) which was developed for IBD patients and to be used in clinical trials [36, 67, 68]. It is a 32-item questionnaire, consisting of 30 items chosen most frequently and rated most important by adult IBD patients and two items added based on feedback obtained by clinicians who had practices heavily weighted with IBD patients. The four domains covered in IBDQ include bowel symptoms (10 items), systemic symptoms (5 items), emotional function (12 items), and social function (5 items). Responses are based on a seven-point Likert scale in which 1 represents the worst function and 7 represents the best function. Thus, the higher the score, the better the quality of life. The questionnaire can be self-administered [69, 70] and takes approximately 15 min to complete. The IBDQ has undergone extensive testing of its measurement characteristics, including several randomized controlled trials [67, 71, 72] and cross-sectional studies [73]. From a large multicentered Canadian trial of maintenance therapy, an intraclass correlation coefficient of 0.70 was calculated for test–retest reliability in 280 patients with stable disease over an 8-week period [67]. Responsiveness testing using a modified responsiveness index developed by Guyatt et al. indicated that all IBDQ indices reflected deterioration for those patients whose condition worsened during the study [74]. Construct validity testing in the original publication of the measure, and with subsequent use of the IBDQ in trials, has shown it to be a valid measure of HRQOL in adult patients with IBD. This

Table 51.2 Disease-specific IBD health-related quality of life measures (adult and pediatric)

Name	Format	Scales	Comments
Adult Inflammatory Bowel Disease Questionnaire (IBDQ)	32-item Likert scale Interview format	Bowel symptoms, systemic symptoms, social function, emotional function	Well standardized; designed for clinical trials; developed on "sick" patients—GI referrals and inpatients
Modified IBDQ	36-item Likert scale Self-administered	Bowel symptoms, systemic symptoms, social function, emotional function, functional impairment	Derived from IBDQ; developed on "well" patients—local chapter of NFIC
Cleveland Clinic Questionnaire	47-item Likert scale Interview format	Functional/economic, social/recreational, affect/life in general, medical/symptoms	Correlates with SIP; developed on UC/CD surgical/non-surgical groups; quality-of-life index distinguishes groups
Rating Form of IBD Patient Concerns (RFPIC)	25-item visual analog scale Self-administered	Impact of disease, sexual intimacy, complications, body stigma	Correlates with SIP and SCL-90; developed on "well" patients—CCFA national sample
UC/CD Health Status Scales	9- or 10-item Likert scale Physician/patient scoring	Ulcerative colitis, Crohn disease	Standardized to healthcare use, function, psychological distress in CCFA national sample
Pediatric Computer-based animated questionnaire	35-item visual scale Children ages 5–11 years	30 generic questions, five disease specific (more detail not specified)	Only 16-patient pilot study reported to date Child does not have to read
PEDIBDQ	45-item Likert scale Children ages 8–18 years	Physical, emotional, and social	Reported in abstract form, with validation and reliability data
IMPACT	35-item Likert scale Self-administered Children ages 10–17 years	Bowel, emotional, functional, tests/treatments, systemic, body image (IMPACT-I, II); Well-being, emotional, social, body image (IMPACT III new domains)	Three versions (IMPACT-I, II, and III). Developed using several pediatric IBD cohorts; in use in clinical trials

Abbreviations used: *CCFA* Crohn and Colitis Foundation of America, *CD* Crohn disease, *CDAI* Crohn disease activity index, *GI* gastrointestinal, *NFIC* National Foundation for Ileitis and Colitis, *SCL-90* Symptom Checklist-90, *SIP* Sickness Impact Profile, *UC* ulcerative colitis

measure has been shown to have strong correlation with patient, relative, and physician global ratings of HRQOL and discriminate between the groups of patients who did or did not require surgery [67]. Some researchers have expressed concern about the use of a single measure to describe the HRQOL for IBD, because of the frequently disparate nature of its component diseases, CD and UC [75]. For example, because CD can affect variable locations in the bowel, the range of symptoms can also vary greatly, with differences exacerbated by relapsing and remitting disease activity. This is compared with UC in which the bowel disease is limited to the colon. Given these differences, some researchers have suggested that a different or separate approach to HRQOL evaluation for these two diseases may be required. This issue was apparently not addressed in the development of the IBDQ [36, 67]. Given the increasing number of many available cross-culturally adapted versions of the IBDQ [76–83] and the development [84] and subsequent validation [85, 86] of the ten-item Short Inflammatory Bowel Disease Questionnaire (SIBDQ), it seems unlikely that other HRQOL measures for adult IBD patients will be developed, unless it is to target specific subgroups missed in the IBDQ item generation, such as patients with ileostomy.

Health-Related Quality-of-Life Assessment in Pediatric Inflammatory Bowel Disease

As is the case with pediatric quality-of-life assessment in general, consideration of quality-of-life issues in pediatric IBD has lagged behind that of the adult IBD cohort. The earliest semblances of quality-of-life inquiry were from a number of centers which reported the results of long-term follow-up or cross-sectional assessments of their pediatric IBD populations [2, 3, 87–93]. In many instances, rather than actually describing the quality of life, they were describing the functional status of the patients [87–89, 92, 93].

Goel et al. [87] and Lindquist et al. [89] did not use a formal measure to describe quality of life but rather, in their description of the current status [87] or clinical course [89] of the patients, included limitations on social activities, school attendance, or occupation as descriptors. Farmer and Michener [90, 91] developed a simple measure which provided three categories of quality of life: "Good—meaning ability to function in a nearly normal manner with minimal interference from the illness and its sequelae; Poor—indicated severe effect on life style, requiring medication and often frequent hospitalization; Fair—suboptimal but adequate functioning, i.e., chronic illness and partial disability." Patients were categorized based on interviews by trained personnel. The researchers acknowledged that their view of quality of life was a composite of several elements of the patient's life and that patients might experience varying degrees of quality of life over a long period of time. Patients were asked to consider the cumulative effect of the illness and treatment and to describe their current state of health. Farmer and Michener's long-term follow-up study of 522 patients (followed from 1955 to 1974) with onset of CD under age 21 found that approximately two-thirds of patients considered their functioning to be in the fair level, with only 6% rating their functioning as poor [90, 91]. Given the marked changes in management over the past five decades, it is unclear what relevance quality-of-life outcomes in such a cohort would have compared to a similar present-day cohort. More recently researchers have sought to assess quality of life in pediatric IBD using measures with domains which encompass a broader concept of quality of life [94–97]. MacPhee et al. [97] completed an assessment of 30 pediatric IBD patients using a number of generic psychological and quality-of-life questionnaires. Their study emphasized social supports and coping strategies. They used the Quality of Life for Adolescents and Parents questionnaire [98], a generic measure which gives a total satisfaction score with health status and similar scores for subscales.

Thomas et al. [94, 95] describe the early stages of development of a disease-specific quality-of-life questionnaire which they used to assess quality of life in their pediatric CD cohort. Focus group meetings were held with pediatric patients of ages from 8 to 17 years (two groups, 8–12 years and 12–17 years of age) to learn how their disease and its treatment affected their lives at school, at home, and with friends. An 88-item questionnaire was constructed based on the areas identified in the focus groups. The questionnaire contained six domains of HRQOL, including symptoms and treatment, social life, emotional state, family life, education, and future aspects. No data on validity, reliability, or sensibility were provided for this questionnaire [94, 95]. The questionnaire was used in one pilot study involving 16 children from one academic IBD program in England. Acknowledging the limitations of a small sample size, they found that CD appeared to most adversely affect the HRQOL of children as manifested through school absenteeism, fatigue limiting sports activities, and difficulties in taking holidays.

Moody et al. [96] studied quality of life in pediatric CD using a questionnaire they developed in conjunction with a British national lay committee of Crohn in Childhood Research Association (CICRA) members. Limited information is provided on the questionnaire's development, and its length and exact format are unclear from the published report [96]. Results from 64 valid questionnaires were received in a pilot study. The mean age of the children in this study was 14.1 ± 2.8 years (range 6–17 years). In this cohort 60% of the children reported prolonged absences from school, with a mean 3 ± 2.8 months' absence in the previous 12 months. Eighty percent of those who had taken examinations felt that their marks had suffered due to ill

health. Seventy percent of patients with CD were unable to participate in sports on a regular basis, 60% did not feel comfortable leaving their homes, and 50% did not feel they could play outside with their friends because of the illness. Forty percent of children also reported concerns about taking holidays and being able to have sleepovers at friends' homes. This study would suggest that CD has a major impact on the quality of life of pediatric patients. However, caution should be exercised in making these conclusions as there are several limitations of the published study. It is not clear if the questionnaire underwent any validity testing to ensure it was measuring what it intended to measure. Given the study design, in which a general mailing was sent to members of a society, there may be a strong response bias in favor of those whose quality of life is poor. As well, the authors do not tell us the number of questionnaires distributed, nor do they clarify the response rate.

Preliminary development of the Pediatric Inflammatory Bowel Disease Questionnaire (PEDIBDQ) for children and teens [99, 100] and a computer-based animated program to assess HRQOL for young children 5–11 years of age [101] have been reported in abstract or manuscript form. Further work has not been reported using these questionnaires, however. In the mid-1990s, researchers at the Hospital for Sick Children in Toronto, Canada, began work on a disease-specific measure, the IMPACT questionnaire [102], which today is the most commonly employed disease-specific measure for assessing HRQOL in the pediatric IBD population.

Ryan et al. [103] reported on the incorporation of HRQOL screening into clinical practice and its clinical utility in predicting disease outcome and healthcare utilization. One hundred twelve IBD youth ages 7–18 years completed the Pediatric Quality of Life Inventory, Version 4.0 (PedsQL 4.0), with retrospective chart reviews conducted to examine disease outcomes and healthcare utilization for 12 months after baseline quality of life assessment. They demonstrated that youth who reported lower HRQOL at baseline, on average, had increased healthcare utilization as measured by IBD-related hospital admissions, emergency department visits, use of psychological services, telephone calls to clinicians, GI clinic visits, and referral to pain management.

IMPACT

The Development of the Impact Questionnaire

There are three English iterations of the IMPACT questionnaire at present, and work is actively underway on translation of IMPACT-III into other languages. Work on IMPACT began in the mid-1990s because at that time there was no published disease-specific HRQOL instrument available for pediatric patients with IBD. Generic pediatric HRQOL questionnaires, such as the Child Health Questionnaire [33, 104], were felt to be insensitive to the disease-specific issues of IBD. Concerns about wording issues, including inappropriate omissions and inclusions for a pediatric target audience, led researchers at the Hospital for Sick Children in Toronto to seek a pediatric-derived instrument over the adult-derived IBDQ [48]. For example, one question in the IBDQ [67] pertains to limitation of sexual activity by IBD, an issue which was felt to be of limited relevance in a pediatric cohort, except perhaps for the older adolescent. Issues not covered by the IBDQ which were felt to be of likely relevance to a pediatric cohort included growth concerns and limitations on school and extracurricular activities.

Defining how a new HRQOL tool will be used is important in guiding the development process, as this helps ensure that the end product is addressing the underlying need. The IMPACT developers sought to create a questionnaire which would serve both as a descriptive and evaluative tool. As a descriptive tool, the measure would facilitate recognition in individual patients of disparity between apparent IBD activity and severity, organic disease-related phenomena, which the physician is accustomed to assessing, and emotional or functional disability. As an evaluative tool, it was to be incorporated as an outcome measure in clinical trials to assess change in HRQOL over time.

In the development of IMPACT, there was a focus on children aged 10–17 years. Younger patients were excluded because of concern that systematic exploration of quality of life among very young children would require significantly modified methods. Items to be included in the final questionnaire were generated chiefly from interviews of pediatric patients with IBD. Items universally of greatest importance for all IBD patients were included, as well as some items rated as very important by one subgroup of patients (CD or UC), even if not by others [102].

The original IMPACT [48], or IMPACT-I as it is currently known, consisted of 33 questions, and responses were given using a visual analog scale. Each question was scored out of seven, so that the final total score would be similar to what was seen with the adult IBDQ. Thus, the range of scores possible for IMPACT-I was 0–231. During the cross-cultural adaptation and translation process of IMPACT-I into the Dutch language, a modified version was developed [105]. This version, IMPACT-II, eliminated or modified four questions and added a new question, resulting in a 35-item questionnaire with simplified wording of the response options for the visual analog scale. IMPACT-II was available in both English [106] and Dutch [107] language versions. Some researchers preferred a Likert response scale, and IMPACT-III [108] was created, which is identical to IMPACT-II save for the five-point Likert response scales and anchors (Fig. 51.2). IMPACT-III is available in over 65 languages (as well as culturally adapted versions in English, French, and Spanish) (see Table 51.3). IMPACT-III is the questionnaire used for ongoing cross-cultural adaptation.

Fig. 51.2 Sample IMPACT-III question. As opposed to IMPACT versions I and II which used visual analog response scales, IMPACT-III uses a five-point Likert response scale

[a]As of March 2021

Through cohort studies, and more recently in randomized controlled trials [108–110], IMPACT has demonstrated itself to be a valid measure of disease-specific HRQOL in pediatric IBD patients 10 years of age and over. From this work, while disease activity and disease severity are two factors which have been identified as strongly correlated with HRQOL, regression modeling clearly shows that they can only explain a small part of the HRQOL "puzzle" [48, 106]. As well work to date has not shown any influence of disease type (CD or UC) in influencing the performance of IMPACT. With age there remains less clarity. The original validation did not show any significant differences in perceived HRQOL across the age group studied.

Research has shown that the perceived HRQOL as assessed by IMPACT is most influenced by the current health status rather than that suffered over the previous 12 months [48]. That the IMPACT questionnaire is greatly influenced by the patient's current health status is an important feature for its use in clinical trials. If IMPACT scores continued to be influenced more by the patient's health status over the preceding year than by their current disease status, short-term responsiveness to change in clinical status would be compromised.

To date the IMPACT questionnaire has been used to evaluate HRQOL in pediatric IBD patients in a number of research studies, involving a variety of study designs [106, 111–114]. These studies provide a preliminary picture of what the HRQOL is in this population, and increasingly the data obtained from such studies will allow clinicians and researchers to develop an improved understanding of the factors which both positively and negatively influence HRQOL in older children and teenagers with IBD.

Description of the Instrument (IMPACT-III)

The IMPACT-III questionnaire takes about 10–15 min to complete and contains 35 questions. Each question is scored on a five-point scale (Fig. 51.2). Individual questions within IMPACT are equally weighted. The scores are standardized to a 0–100 scale, with higher scores representing better quality of life.

The 35 questions originally encompassed six domains: bowel (7 concerns), body image (3 concerns), functional/social impairment (12 concerns), emotional impairment (7 concerns), tests/treatments (3 concerns), and systemic impairment (3 concerns) (Table 51.4). Perrin and colleagues relooked at the domain structure for IMPACT and through exploratory factor analysis proposed four factors with good to excellent reliability for IBD responses: general well-being and symptoms, emotional functioning,

Table 51.4 IMPACT-III: 35 questions sorted by four domains

Domain	Question
Well-being	Stomachaches
	Not being able to eat what you want because of disease
	Worried about having a flare-up How much energy Having to miss out on hobbies Diarrhea
	Having fun Being sick How did you feel How tired did you feel Able to play sports as much as you would like Able to go to school
Social functioning	Worries about health in future Being ashamed Is it harder to make friends Worried about blood with bowel movement Worries not to be able to go out on dates Teased or bullied because of the disease or treatment Worries about ever having an operation Afraid about not making to the bathroom in time Try and keep your disease a secret Difficulties to travel or go on holiday Able to talk to anyone about worries
Emotional functioning	How do you feel about taking medicines Worried about having a chronic condition
	The influence of the disease upon the family
	Thinking it is unfair to have this disease
	Being angry to have this disease
	Having rules imposed because of the disease
	How do you feel about investigations
Body image	How do you feel about height
	How do you feel about weight
	How do you feel about the way you look
	Being happy
*Not in a domain	Having to pass gas

social interactions, and body image (two questions were dropped which did not fit well with any domain, "feel about tests/treatments" and "how condition affects family") [115]. Similarly, as part of the cross-cultural adaptation and translation of the Croatian version of IMPACT-III, Abdovic et al. used factor analysis of their cohort data to propose a five-domain structure (dropping two items) [116]. However, a major limitation of these two studies is the lack of robust representation across the spectrum of disease activity among participants, such that a vast majority had inactive or mild disease. In response to these proposed domain structures, the IMPACT-III questions were reexamined with a large and robust sample consisting of data from two pediatric clinical trials (involving patients with CD and UC) as well as a cohort of children from the Crohn's & Colitis Foundation IBD Partners Kids & Teens study [117]. This combined cohort consisted of patients across the developmental age spectrum, and was balanced across gender, disease type, and disease activity. A new psychometrically validated four domain structure was created, of which many questions overlap with former domains. The new domains consist of the following: Well-being (12 concerns), Social (11 concerns), Emotional (7 concerns), and Body image (4 concerns). One question was not included in the domain structure as it did not fit well onto any domain, but given that it did not detract from overall questionnaire reliability this question remains as part of the IMPACT-III total score. This domain structure is now recommended for scoring the IMPACT-III questionnaire.

Readability statistics for the IMPACT-III are excellent with a Flesch–Kincaid Grade level of 4.8, a Flesch Reading ease of 74.3, and 1% passive sentences. This suggests a very appropriate level of wording given the target population of ages 10 and above.

Practical Issues for Use of IMPACT

Administration and Instructions to Respondents

The person administering IMPACT-III should verbally review the written instructions provided on the initial page of the questionnaire with the child completing the questionnaire. It is important that the responses are the child's, and parents should be specifically asked not to help their child with the answers. It is, therefore, helpful to have an assistant nearby to answer questions that the respondent might have, so that the parent(s) will not have to aid them. It should be made clear that if the child feels that the issue raised by a particular question is not a problem for them (i.e., questions mention blood in stool, but they have never had blood in stool), then the child should mark it as "best quality of life" response. This will help decrease the number of questions left blank.

Scoring

By convention, the higher the score, the better the quality of life. For IMPACT-III the "good" quality of life anchors are always presented on the left, with the "poor" quality of life anchors on the right. There are five Likert response options per question. For scoring purposes, from left to right, they can be numbered 100 through 0, decreasing in increments of 25. This scoring system was developed in order to normalize the total and domain scores out of a 0–100 range. This facilitates easier interpretation of scores across domains, groups of participants, and across studies using other HRQOL tools using the same standardized scoring system. To obtain a total

score, responses from all questions completed are summed and divided by the number of questions completed to compute a standardized score ranging from 0 to 100. Domain scores can be obtained by summing the responses for each question within a domain and similarly dividing by the number of questions completed within each domain (Table 51.4). Additional criteria and guidance are available around calculating scores when there are a high number of missed questions.

Interpretation of HRQOL scores is another important area to consider. In IBD, the HRQOL outcomes from either IBDQ or IMPACT have usually been reported as the mean total score for study participants at various study time points. Other ways of reporting HRQOL outcomes would be to focus on the mean scores of a domain (i.e., the well-being domain) for study participants at various study time points. The latter may be optimal when a specific intervention would be expected to have a predominant influence on a specific domain.

Deficiencies in Current Knowledge and Areas for Future Research

There is still much we have to learn and understand about HRQOL in pediatric IBD. Although we have a tool with which to assess disease-specific HRQOL in this population, a number of unanswered questions remain.

Identifying the Factors which Influence HRQOL

Disease type on its own, that is having UC or CD, does not appear to affect HRQOL [118, 119] differently. While some factors, such as disease activity and severity, are known to negatively influence HRQOL for both UC and CD [120–122], further research is needed to understand how this relationship may change as disease activity changes, or based on how disease activity is measured as some discrepancies have been reported. When disease activity is reduced or patients are in remission, disease state is less closely related to HRQOL outcomes [123]. Even for patients in remission, demographic, psychosocial, and other gastrointestinal symptoms can influence HRQOL. For patients with CD, experiencing residual pain despite having more controlled symptoms is related to lower HRQOL [124]. Varni et al. also found that stomach pain and constipation predicted HRQOL after controlling for other factors known to influence quality of life including age, sex, and ethnicity [125]. Thus, pain when discordant from disease state appears to play an important role in understanding patients emotional functioning, disability, and quality of life.

Furthermore, additional research is needed to elaborate on other key factors which may influence HRQOL. Many studies have found certain demographic factors to influence HRQOL. Having female gender [119, 121] and being older [119] consistently predict lower HRQOL across several studies. In terms of psychosocial influences, both patient depression and anxiety have been found to be related to HRQOL, while the influence of each may differ across disease type.

Hommel and colleagues have begun to explore non-disease-specific factors, such as behavioral dysfunction, which may influence HRQOL [126]. They describe two main types of behavioral dysfunction: internalizing symptoms (such as anxiety and depression) and externalizing symptoms (such as aggression and disruptive behavior). In their study they demonstrated that greater disease severity, externalizing symptoms, and internalizing symptoms were all independently associated with a lower HRQOL as assessed by the IMPACT questionnaire. As well, their findings suggested that internalizing symptoms had a mediating effect on the relationship between disease activity and HRQOL.

Engelmann and colleagues [127] conducted a cross-sectional study of 47 German adolescent IBD patients where they assessed disease activity, HRQOL (using IMPACT-III), and quality of life (using EQ5D, a measure of generic quality of life) and whether psychopathology was present using the Clinical Assessment Scale for Child and Adolescent Psychopathology (CASCAP). The CASCAP is a tool to assess psychopathology using data derived from patient and parent interviews. Fifty-five percent of patients fulfilled DSM-IV criteria for one or more psychiatric disorders, including adjustment disorders (25.6%), major depressive disorder (17.0%), anxiety disorder (6.4%), learning/developmental disorders (4.2%), and attention deficit/hyperactivity disorder (2.1%). Not surprisingly, patients with psychiatric comorbidity had significantly lower total IMPACT scores compared to those without this comorbidity. However, the effects of psychiatric comorbidity differed across categories of disease activity, where psychiatric comorbidity affected the HRQOL and quality of life scores only for patients with mild disease activity. A limitation of this study was the amalgamation of a range of psychiatric diagnoses together as one factor, where it may be that certain diagnoses have a greater or lesser influence on HRQOL/quality of life.

Capturing HRQOL assessments through one moment in time, as has been done in the majority of cross-sectional studies to date, is a significant limitation. Because HRQOL is likely influenced by multiple factors, both disease-specific and non-disease-specific, ensuring a sufficient sample size and following the study population over time will be important features of future study designs to address some of these limitations. Overcoming these limitations will be important in helping us to better understand the factors which influence HRQOL. By gaining an improved understanding of factors

which influence HRQOL, we can then work on developing specific interventions to target these factors, with the goal to improve HRQOL in these patients [128, 129].

Comparisons of HRQOL Between Patients with IBD, Patients with Other Chronic Pediatric Illnesses, and Healthy Peers

As IMPACT is increasingly used in clinical and research settings, an improved understanding of HRQOL in patients with pediatric IBD should result. Also important, however, is understanding how these patients fare when compared to children with other chronic illnesses as well as to healthy peers. To make these comparisons, generic HRQOL tools will need to be employed. Preliminary work looking at quality of life issues between patients with IBD and those with other chronic illnesses was carried out by Ingerski and colleagues [130]. They compared HRQOL across eight pediatric chronic conditions: obesity, eosinophilic gastrointestinal disorders, IBD, epilepsy, type 1 diabetes, sickle cell disease, post-renal transplantation, and cystic fibrosis [130]. Using the PedsQL generic HRQOL tool, these authors showed that it was youth with obesity and eosinophilic gastrointestinal disorders who had lower HRQOL than youth with other chronic illnesses. However, limitations of this work were the small number of patients in some of the chronic illness groups (e.g., 34 of 589 patients had IBD), and considerable variation was present across disease groups in terms of demographic and disease-specific sample characteristics [130]. Thus, further work needs to be done in this area but with a priori matching of participants across important demographic and disease-specific factors. Additionally, early work has also been done comparing HRQOL of pediatric IBD with healthy peers [131]. Not surprisingly they demonstrated in 55 children, ages 7–19 years, that older children with IBD had significantly lower HRQOL scores compared with age-standardized peers. Kunz and colleagues have carried out the largest study to date comparing HRQOL assessments of youth with IBD to published group data of chronically ill, acutely ill, and healthy comparison groups [120]. The 136 youth with IBD studied reported lower psychosocial functioning than the healthy comparison group, higher physical and social functioning than the chronically ill group, and lower school functioning than all published comparison groups. More work needs to be done to better characterize the degree and nature of any differences in HRQOL between pediatric IBD patients and those with other chronic illnesses and healthy peers. If consistent differences are noted, and in particular if impairments in HRQOL are demonstrated, then healthcare providers will have evidence to better advocate for research to identify interventions which will target these HRQOL impairments.

Assessing Disease-Specific HRQOL in Pediatric IBD Patients Not Captured by IMPACT Questionnaire

IMPACT is a tool to evaluate HRQOL in pediatric patients aged 10–17 years inclusive. The researchers who developed the questionnaire were concerned that issues of importance to younger patients with IBD may be different than the older cohort which was involved in the development of IMPACT. Also a self-administered questionnaire for these patients less than 10 years of age would be problematic given the developmental and comprehension concerns in the younger age range [11]. It is most likely that younger patients would require assistance in completing the questionnaire and/or a different method of delivery [11], such as computer-based questionnaire with video and/or audio components [101]. This is an area which requires further consideration, but it will be necessary to determine whether the relatively small population of patients with IBD who are less than 10 years of age can justify the development of a tool specifically for this age group.

During the development of IMPACT, patients with ostomies or those with disease limited to the rectum were not included. Therefore, the applicability of IMPACT to this cohort of patients has not been established. There may be HRQOL issues unique to this population not addressed by IMPACT. As well, IMPACT development involved participants who had been diagnosed with IBD for at least 6 months. The researchers wished to have a body of "lived experiences and concerns," and it is not clear whether the perception of issues influencing HRQOL is the same when the diagnosis is more recent. Despite this, many studies have included participants from the time of their diagnosis, not waiting for the 6 month time point from diagnosis to carry out the first HRQOL evaluation.

The Impact of Family on the Assessment of HRQOL in Pediatric IBD Patients

The role that family, both parents and siblings, plays in the HRQOL of pediatric IBD is just starting to be explored. There are multiple areas to be addressed. First is the whole issue of self-report and proxy-reported assessments of HRQOL. As discussed previously, in pediatrics there can be the added challenge of age or developmental status which may limit the ability to secure a self-report of HRQOL. The argument can be made regardless of whether a pediatric patient can self-report that having a parent's perspective on their child's HRQOL can add important information which impacts management decisions. A more comprehensive picture of youth HRQOL can be obtained through inclusion of the complementary perspectives of both child and parent-proxy reports

of HRQOL [120]. It is not yet clear, based on some of the disparate findings of the few studies which have looked at concordance between youth with IBD and parent-proxy HRQOL reports, exactly how strong the agreement is across domains. An initial study by Loonen et al. found that parent-proxy reports of social functioning were significantly lower than youth reports, but differences were not noted across other domains [105]. Ingerski et al. reported lower parent-proxy HRQOL scores across all domains of the PedsQL compared with youth self-report [130], except for the school functioning domain, where youth self-reported HRQOL was significantly lower than parent-proxy reported HRQOL. Using the KIDSCREEN-GROUP 2004, a self-report questionnaire consisting of five domains of general quality of life (physical activity, children's mood, family life, friends, and school performance), Mueller et al. compared scoring between 110 Swiss children with IBD and their parents [132]. In this study parents scored overall quality of life, as well as mood, family, and friends domains, lower than the children themselves, with better concordance noted for school performance and physical activity domains.

Gallo and colleagues from Argentina concurrently assessed HRQOL using IMPACT-III in 27 patients and one of their parents (82% mothers) [133]. As a specific parent-proxy report version of IMPACT-III has not been developed, the authors used a non-validated approach, asking the parents to interpret the questions from their child's perspective. With this method they showed moderate-to-high agreement between parent-proxy and patient ratings on most IMPACT-III domains, except for the emotional functioning domain where parents underreported (compared to the child's report) their child's HRQOL. Another consideration in the interpretation of parent-proxy ratings of their child's HRQOL is the quality of life of the parents themselves. Sattoe et al. suggest that assessing parents' quality of life may be more useful than asking parents for a parent-proxy report [134]. Researchers have shown that parent's own quality of life was significantly related to ratings of their child's quality of life [135–137]. More work needs to be done to understand these differences in proxy vs. self-reported HRQOL as well as factors that influence parents' perceptions of youth's HRQOL [130]. Regardless of differences noted, the inclusion of both patients' and parents' measures of quality of life can provide complementary perspectives, each of which should be respected [132].

A second area to be explored is the role that families play on an individual's perceived HRQOL. When family life is dysfunctional, there can be decreased emotional and behavioral functioning [138], while adaptive family relationships have been associated with positive psychological functioning [139]. Building on data among youth with end-stage renal disease and diabetes showing that there is a significant relationship between family functioning and HRQOL, researchers explored these issues in a cohort of adolescents with IBD, seeking to identify which domains of family functioning may be particularly problematic [140]. After statistically controlling for known impacts of disease severity and diagnosis, their data showed that teens from families with clinically elevated difficulties in problem solving, communication, and general family functioning reported lower HRQOL. This area needs to be studied further to ascertain whether a causal link exists between family functioning and HRQOL and, additionally, in the context of a prospective study, how this may vary over time.

Research has also highlighted the importance of examining maternal and paternal functioning separately, as there can be a differential impact on HRQOL outcomes [141]. As well, careful consideration of the potential interplay between the child and parent psychological status and the child's HRQOL has also been shown to be important [142]. Hommel and colleagues studied these issues, and their data suggested that adolescent depressive symptoms may serve as a mechanism by which parent distress is linked to poorer HRQOL in adolescents with IBD [142]. In a study of 99 adolescents with CD and their parents, Gray and colleagues further explored family level predictors of HRQOL by studying parenting stress as a potential mechanism through which disease activity affects HRQOL [143]. HRQOL was assessed using patient-completed IMPACT-III, while parents were given a measure of medically related parenting stress, the Pediatric Inventory for Parents. Disease activity was assessed from chart reviews. In this cohort drawn from three study sites, they demonstrated that parenting stress because of the occurrence of medical stressors partially mediated the disease severity–HRQOL relation. This study would indicate that as disease severity increases, parenting stress also increases, and patient HRQOL decreases. Additionally, several researchers have found that parental psychological distress [144, 145] and depressive symptoms [146] are also related to poorer HRQOL, which appears to be true even if patients are in remission. This demonstrates the importance of both patient and parent well-being in improving patient HRQOL. Discordance between parent-proxy and child scores, where parents estimate lower HRQOL than their child, may also result in increased likelihood for psychology referral in youth with IBD [147]. Better understanding of the relationship between family functioning and HRQOL may allow practitioners to better identify adolescents who are at higher risk for impaired HRQOL and to focus on families in need of support services or psychological intervention [140].

Cross-Cultural Comparisons of HRQOL in Pediatric IBD

A further gap in assessment of HRQOL in pediatric IBD is the lack of comparisons across different cultures and/or

languages. Other IBD outcome measures, such as the commonly employed disease activity measures, can be utilized irrespective of culture or language. They collect fundamental information which are not limited by ethnicity or language. This is not true for quality-of-life assessments. While we now have the generic and disease-specific tools to evaluate HRQOL across cultures and languages, there remains no reported comparison of HRQOL across cultures or languages. There have been an increasing number of published HRQOL reports from individual countries using cross-culturally adapted versions of IMPACT-III [116, 132], but none have specifically contrasted HRQOL across cohorts of pediatric IBD patients from different countries. Cultural differences with respect to disease perception and illness experience are becoming more apparent with the increasing immigrant population residing in Western countries [148]. The exclusion from a study of a group or population, based on culture or language, could lead to a systematic bias in studies of healthcare utilization or quality of life [149].

Irritable Bowel Syndrome and Functional GI Disorders in Inflammatory Bowel Disease

52

Khalil I. El-Chammas and Manu R. Sood

Irritable bowel syndrome (IBS) is a disorder characterized by altered bowel habits and abdominal pain in the absence of a detectable structural abnormality. There are no clear diagnostic markers for this illness and all definitions are based on clinical symptoms. Getting an accurate history from a child can sometimes be difficult and until recently IBS was not a common diagnosis made in children. Some pediatricians still view IBS as nothing more than a somatic manifestation of psychological stress [1]. Availability of better techniques to study bowel motility and sensory function along with advancements in functional brain imaging has improved our understanding of the pathophysiology of IBS. It is now thought that IBS symptoms result from the convergence of multiple factors, including a genetic predisposition, an infectious or inflammatory injury to the gastrointestinal (GI) tract leading to altered sensory perception by the brain, and an underlying bowel dysmotility. Functional abdominal pain and visceral hypersensitivity can coexist in patients with inflammatory bowel disease (IBD). Emerging data suggest that there may be an overlap in the symptoms and etiopathogenesis of IBS and IBD. In this chapter we will discuss how to make a symptom-based diagnosis of IBS and review the pathophysiology and management of IBS. We will also discuss the sensory perception and enteric nervous system changes in patients with IBD and how these can predispose to the development of functional GI symptoms.

Epidemiology

A large proportion of children with IBS are still categorized under a broad umbrella of functional abdominal pain disorders, and the prevalence of IBS in children is underrecognized. Subcategorizing children presenting with chronic abdominal pain into IBS, dyspepsia, and functional abdominal pain is important because it helps narrow down the differential diagnosis, reduces the number of unnecessary investigations, and helps better target the therapy. In a study of 478 children referred to a large gastroenterology clinic with functional abdominal pain, 26% of the subjects had symptoms of diarrhea-predominant IBS [2]. Another pediatric study of 171 subjects with chronic abdominal pain reported that 68% of subjects fulfilled the clinical criteria for the diagnosis of IBS [3]. Community-based studies from North America and China suggest that 8–17% of school children have IBS-like symptoms [4, 5].

Clinical Features

In a majority of patients, a good clinical history is sufficient to diagnose IBS and differentiate it from organic diseases that can mimic IBS symptoms (Table 52.1). To standardize the diagnosis of IBS, symptom-based criteria have been developed and amended by the Pediatric Rome Committee (Table 52.2) [6]. Specific alarm symptoms, which alert the clinicians to the increased likelihood of an underlying organic disease, can help in the management and planning of investigative workup. In a large study of 606 children, the following alarm symptoms were more likely in children with Crohn disease compared to those with pain-associated functional gastrointestinal disorders (FGIDs), including IBS, hematochezia, weight loss, and difficulty in gaining weight. Nocturnal abdominal pain and sleep disruption were not helpful in differentiating children with IBS from those with Crohn disease [7].

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_52

Table 52.1 Diseases that can mimic IBS symptoms

Diarrhea-predominant IBS
GI infections
Inflammatory bowel disease
Celiac disease
Carbohydrate malabsorption (lactose, sucrose, fructose, sorbitol)
Lymphocytic and collagenous colitis
Food intolerance
Constipation-predominant IBS
Celiac disease
Hypothyroidism
Anal sphincter/pelvic floor abnormality
Tethered spinal cord
Colon motility disorder
Neoplastic disorders (rare in children)

Table 52.2 Rome IV criteria for the diagnoses of irritable bowel syndrome [6]

Must include all of the following:
1. Abdominal at least 4 days per month associated with one or more of the following:
(a) Related to defecation
(b) Change in frequency of stool
(c) Change in form (appearance) of the stool
2. In children with constipation, the pain does not resolve with resolution of the constipation (children in whom the pain resolves have functional constipation, not irritable bowel syndrome)
3. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition

The criteria should be fulfilled for at least 2 months before diagnosis

Abdominal pain is a prerequisite for the diagnosis of IBS. The pain can vary in intensity and location but is usually restricted to the lower abdomen; it can be episodic or superimposed on a background of constant ache. It is usually relieved by the passage of stool or flatus and exacerbated by meals. Almost 50% of adults with IBS also have symptoms of dyspepsia, and overlap between other pain-associated FGIDs and IBS has been reported [8]. Urinary bladder irritability and pelvic pain have also been associated with IBS-like symptoms.

Most patients with diarrhea-predominant IBS pass liquid or semiformed stool at frequent intervals. It can be accompanied with the passage of mucus, but passage of blood is rare. A majority of patients will report difficulty falling asleep, rather than sleep disruption. In patients with constipation-predominant IBS, the constipation initially can be episodic but usually becomes continuous. With time symptoms become refractory to treatment with laxatives. Stool consistency can be hard and the stool may be narrow in caliber. It can be associated with the feeling of incomplete evacuation; the child can spend a long time sitting on the toilet straining unsuccessfully to have a bowel movement. This can lead to rectal mucosal prolapse and development of solitary rectal ulcer syndrome, associated with passage of blood in the stool and tenesmus [9]. Adults with dyssynergia, a disorder where the subject is unable to coordinate bearing down with pelvic floor relaxation during defecation, can have symptoms that mimic IBS [10]. Constipation associated with dyssynergia can improve with biofeedback training, and this should be considered in the differential diagnosis in adolescents with constipation and lower abdominal pain. Some patients have periods of constipation alternating with diarrhea. Abdominal bloating, belching, and flatulence are also common symptoms.

Pathophysiology

The pathophysiology of IBS is likely to be multifactorial, and alterations in GI sensory perception, central neuronal dysfunction, abnormal motility, stress, psychological abnormalities, and luminal factors have all been implicated. The submucosal nerve plexuses receive sensory input from the bowel lumen through the sensory receptors. The enteric nervous system communicates with the brain through neural pathways as well as by immune and endocrine systems. The pain signals are transmitted from the primary sensory afferent neurons with cell bodies in the dorsal root ganglia to the dorsal horn of the spinal cord. Spinal pathways run to the thalamus and relay messages to the limbic system and the sensory cortex. The combined functioning of the GI motor, sensory, and central nervous system activity is termed the brain–gut axis. Abnormalities along the brain–gut axis, such as altered peripheral sensory perception, hypersensitivity of sensory neurons in the dorsal horn, and increased activation of brain regions associated with visceral pain sensation, have been reported in IBS [11].

Visceral hyperalgesia (an exaggerated pain response to a sensory stimulus) has been reported in children with IBS [12, 13]. Visceral hyperalgesia could result from sensitization of primary sensory afferent fibers innervating the gut or the neurons receiving input from visceral afferents along the brain–gut axis (Fig. 52.1) [11]. Peripheral sensitization of nerves within the GI tract can result from noxious injury and the release of inflammatory mediators and nerve growth factor by the fibroblasts and mast cells in the bowel wall. The resulting increase in transcription of the neuropeptides, substance P, and calcitonin gene-related peptide initiates nerve activation and the release of yet more substance P and recruitment of previously silent nociceptors [11].

Recent advances in functional brain imaging have provided a novel insight into the pathophysiology of chronic pain states and how supraspinal mechanisms of brain reorga-

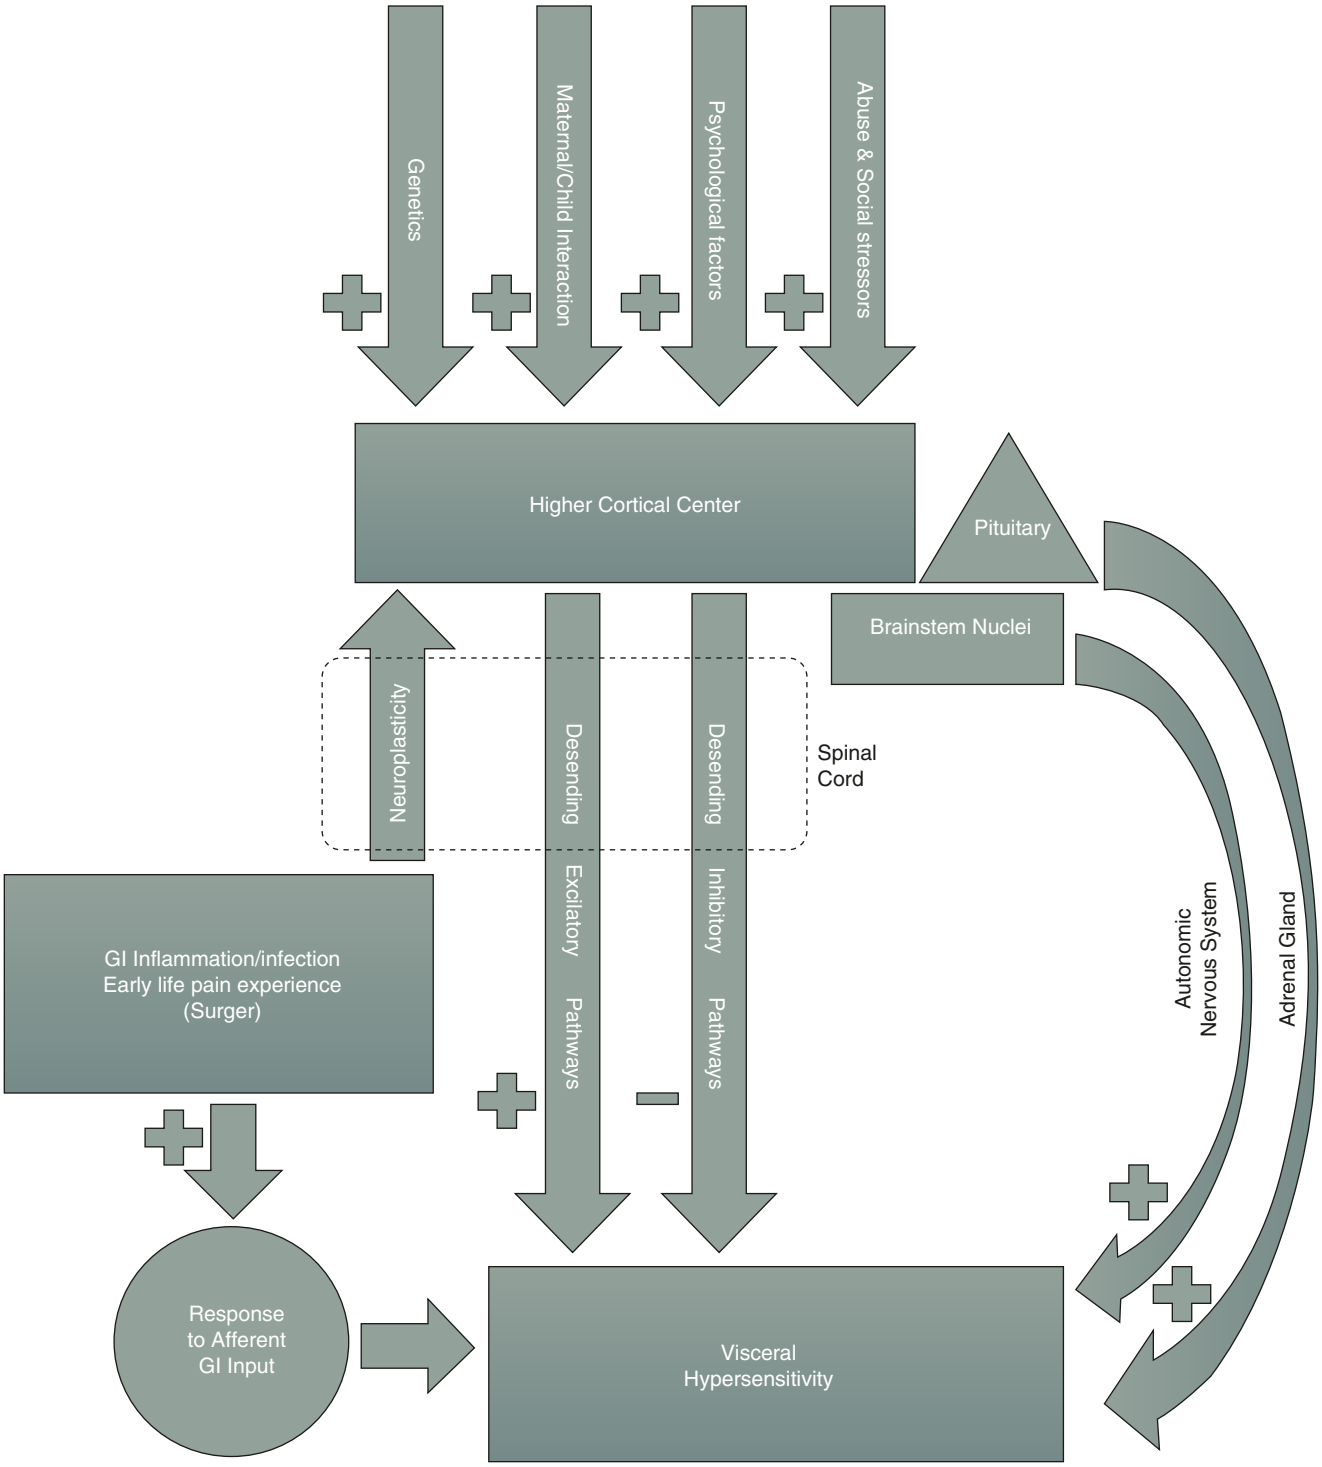

Fig. 52.1 Flowchart showing interaction between the sensory neuronal pathways and stress-related activation of the hypothalamus–pituitary adrenal axis. Stress-related activation of cortical and subcortical brain regions induces the release of increased quantities of corticotropin-releasing hormone (CRH) and adrenocorticotropin (ACTH) from the anterior pituitary. This in turn stimulates the release of glucocorticoids from the adrenal glands. In response to ANS activation, cells of the adrenal medulla produce catecholamines, such as adrenaline and noradrenaline. These have potential to modulate activity of the sensory neuronal pathways and cause visceral hypersensitivity. The cortical and subcortical brain centers can facilitate or inhibit the activation of second-order spinal neurons in response to visceral afferent stimulus

nization facilitate pain learning behavior and long-term maintenance of central sensitization. Tillisch and coworkers conducted a meta-analysis of 18 adult studies in which functional MRI or PET scans of the brain had been performed together with balloon distension of the rectum in patients with IBS and healthy controls [14]. Patients with IBS demonstrated a greater spatial extent of brain activity than controls, specifically in regions associated with pain modulation and emotional arousal. The authors concluded that published data support a role for central nervous system dysregulation in the pathogenesis of IBS [14]. A novel functional connectivity analysis approach to functional brain imaging studies allows one to measure temporal correlation of neurophysiological events and estimate how spatially distinct brain regions coactivate or work together in a specific brain states, therefore offering a practical tool for evaluating cortical modulatory effects on brain functioning during rectal distension stimulation in health and IBS. The human brain, intrinsically, is organized into distinct functional networks supporting various sensory, motor, emotional, and cognitive functions. Of particular relevance to the understanding of visceral hypersensitivity and altered brain–gut interaction in IBS is an intrinsic brain network, the salience network [15]. The salience network plays an important role in disparate attentional, cognitive, affective, and regulatory functions. In a recent study of adolescent patients with IBS, rectal balloon distension showed greater activation of neural structures associated with homeostatic afferent and emotional networks, especially the anterior cingulate and insular cortices. Compared to healthy controls, IBS subjects also showed excessive coupling of the salience network with the default mode network and executive control network [16]. Adult IBS patients show greater engagement of cognitive and emotional brain networks, including the salience network during contextual threat, suggesting that they may overestimate the likelihood and severity of future abdominal pain [17].

Low-Grade Inflammation

Following gastroenteritis 7–31% of adults develop persistent low-grade inflammation and IBS-like symptoms [18–21]. A study of a large outbreak of waterborne infection with *Campylobacter jejuni* and *E. coli* O157 in Walkerton, Ontario, yielded 228 cases of postinfectious IBS and 581 controls who had fully recovered. This study found a number of single nucleotide polymorphisms that distinguished postinfectious IBS patients from infected controls who had fully recovered [22]. The relevant genes were CDH1 coding for E-cadherin, a tight junction protein controlling gut permeability, Toll-like receptor (TLR) that mediates the cellular response to bacterial DNA, and IL-6 [22]. TLRs are normally downregulated to avoid inappropriate activation of the immune system by gut commensals [23]. Recently, increased expression of TLR-4 has been reported in females with IBS, predominately of mixed or diarrhea-predominant IBS [24]. Increased intraepithelial and lamina propria lymphocytic infiltration, together with an increase in enteroendocrine cells, has also been reported in bowel biopsies obtained from postinfectious IBS patients [21]. These changes can persist for up to 12 months and are associated with increased mucosal permeability [18, 21]. In children with IBS, immune cells' presence in the rectal mucosa was associated with a higher availability of 5-HT with higher 5-HT content and lower SERT mRNA compared to control subjects suggesting that mucosal inflammation may induce peripheral sensitization [25]. Bacterial gastroenteritis and Henoch-Schönlein purpura during early childhood can lead to development of IBS-like symptoms in later life [26, 27]. Bowel inflammation and pain in early childhood may lead to alteration in afferent signal processing due to neuroplasticity which can manifest in later life with functional pain during psychosocial stress.

Gut Microbiota

Studies using fluorescent in situ hybridization to detect bacterial 16s RNA suggest that there is an increase in bacteria within the mucus layer in patients with IBS [28]. Recently, great advances have been made in understanding the microbiota through the development of culture-independent technologies and, in particular, metagenomics. There are great diversity and interpersonal variation in the bacterial species and strains present in the gut microbiota. Although studies of fecal microbiota in IBS are limited, a recent pediatric study reported a significantly greater percentage of the class γ-proteobacteria especially *Haemophilus parainfluenzae* in patients with IBS. A *Ruminococcus*-like microbe was also more common in IBS subjects compared to controls in this study [29]. Several adult studies have reported reduced biodiversity of gut microbiota in patients with IBS [30]. Fermentable oligosaccharides, disaccharides, monosaccharide, and polyol (FODMAP) diet which lowers the intake of several fermentable carbohydrates has been shown to decrease GI symptoms in adults and children. In one pediatric study, the baseline gut microbiome composition and microbial metabolic capacity were associated with efficacy of FODMAP diet, suggesting that evaluation of gut microbiome may be helpful in predicating response to dietary intervention [31, 32].

Altered Motility

Abnormal rectal, colon, and small bowel motility has been implicated in IBS pathophysiology. Interpretation of colon motility studies in adults with IBS is hampered by a relatively primitive understanding of normal colon motility and its intrinsic variability. Abnormalities in colon motility and abnormalities in response to food and stress have been reported in patients with IBS [33] Abnormalities in small bowel motility, such as repetitive bursts of contractions or clusters, prominent high-amplitude waves in the terminal ileum, and an exaggerated jejunal motor response to a meal, have also been reported in adults with IBS [33, 34].

There is also a suggestion that patients with IBS handle small bowel gas differently, and there is slow transit of gas directly infused into the small bowel in adults with IBS [33]. Abdominal bloating and flatulence can also result from higher colonic fermentation in IBS [33, 35, 36]. Some patients without evidence of small bowel bacterial overgrowth can benefit from treatment with unabsorbable antibiotics [37], which raises the question of a qualitative change in bowel bacterial flora in IBS.

Biochemical Changes

Serotonin (5-hydroxytryptamine: 5-HT) is secreted in copious amounts by the gut enteroendocrine cells and serves as a critical messenger for GI fluid secretion and motility. It activates at least five different receptor types, and the 5-HT_3 and 5-HT_4 receptors are the most extensively studied in IBS [38]. The transporter of 5-HT (SERT) mediates the reuptake of 5-HT by the neurons and crypt epithelial cells and terminates its action.

Plasma 5-HT concentration is elevated in IBS patients [39], and the proportion of 5-HT secreting enteroendocrine cells is elevated in the GI tract in postinfectious patients with IBS [18]. Increased rectal mucosal 5-HT concentration has also been reported in children with IBS. The presence of low-grade inflammation was associated with higher 5-HT concentration in rectal mucosa in this study [25]. Symptom relief by serotonergic agents including 5-HT_3 antagonists and 5-HT_4 agonists provides additional support for a possible role of 5-HT in IBS pathophysiology [40].

Genetics

Familial aggregation and twin studies suggest that there may be a genetic predisposition to developing IBS [41, 42]. Twin studies have shown that the concordance rate for IBS is higher in monozygotic compared to dizygotic twins [43]. However, the presence of IBS in the respondent's parents made a much larger contribution to the risk of having IBS than did the presence of IBS in one's twin, suggesting social learning may be more important than the environmental factors in determining illness behavior [43]. Family members of patients with IBS are more likely to have the condition, compared to their spouse controls. To date, nearly 60 genes involved in different pathways, including serotonin, adrenergic, inflammation, and intestinal barrier function, have been studied to determine whether specific genetic variants may be associated with IBS [44]. Interleukin-10 is an anti-inflammatory cytokine, and fewer patients with IBS have the high IL-10 producing (G/G) genotype compared to healthy controls [41]. Four different studies have explored the association of SERT gene polymorphism in IBS [41]. SERT is important for terminating the GI activity of 5-HT. The wild-type l/l polymorphism results in normal function, whereas the presence of the short allele (s/l or s/s) results in impaired SERT function. As a group, SERT polymorphism was similar in healthy subjects and IBS patients, but some differences were observed in subgroups of IBS patients, and these differences could be population specific.

Psychological Factors

Community-based studies in adults have shown that IBS patients are indistinguishable from the rest of the population in terms of psychological comorbidities [45]. Higher psychological comorbidities have been reported in a subset of IBS patients who seek medical help [45]. Patients with psychosomatic disorders, such as depression have activation of the immune system and elevated CRP [46]. Adults who develop postinfectious IBS are more likely to develop depression [47], and depressive symptoms have also been linked to relapses of colitis [48] and disease activity [49] in patients with IBD. It is not clear if the depression is the result of chronic ill health or leads to the development of IBS. In children social learning of illness behavior can also contribute to the development of IBS; children of mothers with IBS are more likely to seek medical help for functional GI symptoms [50]. Children with IBS who have significant psychological comorbidities run a more protracted illness course and are less likely to respond to treatment [51].

Visceral Hypersensitivity and IBD

Bowel injury and inflammation can induce functional and structural changes in the enteric neurons and muscles. Increased numbers of ganglion cells, axonal degeneration, and a reduced number of interstitial cells of Cajal have been reported in IBD [21]. In Crohn disease there is increase in substance P and its receptors in the GI tract [21]. The bowel

innervation shifts from a predominantly cholinergic to a substance P predominant innervation in ulcerative colitis (UC) [21]. Increased expression of nerve fibers expressing transient receptor potential vanilloid type 1 (TRPV1) receptor in IBD and IBS has been reported [52] as well as in quiescent IBD patients with IBS-like symptoms [53]. The expression of TRPV1 is a feature of afferent pain fiber and upregulated by inflammation [53]. These changes can cause alteration in bowel sensory perception. Patients with active UC show a decreased threshold for painful and non-painful rectal distension stimulus [54]. The hypersensitivity can be widespread, and a lower pain threshold to esophageal distension has been reported in adults with UC [55]. In contrast, patients with isolated ileal Crohn disease have an increased pain threshold following rectal distension [56]. It appears that the development of visceral hypersensitivity in IBD may depend on the disease activity, type of inflammation, and region of the GI tract involved.

There is a considerable overlap between IBS and IBD symptoms. Adults who develop IBD may have a prodrome of IBS-like symptoms that can be as long as 7 years [57]. Some of these patients could have a delayed diagnosis of IBD, but some may have GI inflammation not severe enough to make a diagnosis of IBD but sufficient to cause IBS-like symptoms. Up to 57% of adults with Crohn disease and 33% with UC have symptoms, like pain and bloating, when in clinical, laboratory, and endoscopic disease remission [58]. Since a few inflammatory cells located strategically near the enteric nerves or myenteric ganglion cells can alter bowel function in IBS, similar changes could be responsible for the functional symptoms in patients with Crohn disease, which cause transmural inflammation [59–61].

Evaluation of placebo response in Crohn disease provides indirect evidence to the existence of functional GI disorders in these patients. Placebo therapy can alter the natural course of Crohn disease. In a meta-analysis of 23 adult studies using Crohn Disease Activity Index (CDAI) to measure Crohn disease activity, the pooled median remission rate with placebo was 19% (range 0–50%) [62]. Significant predictors of a placebo response were duration of participation in the study and number of clinic visits. The placebo effect increased with the increasing study duration (Fig. 52.2), suggesting that frequent contact with medical professionals relieved symptoms in some patients. A high CDAI and CRP at recruitment showed a negative correlation with the placebo response, suggesting that patients with a low or normal CRP and a comparatively mild clinical disease activity were more likely to respond to a placebo. Therefore, the obvious question is whether some of these patients with Crohn disease had functional GI symptoms to begin with and were therefore more likely to respond to a placebo.

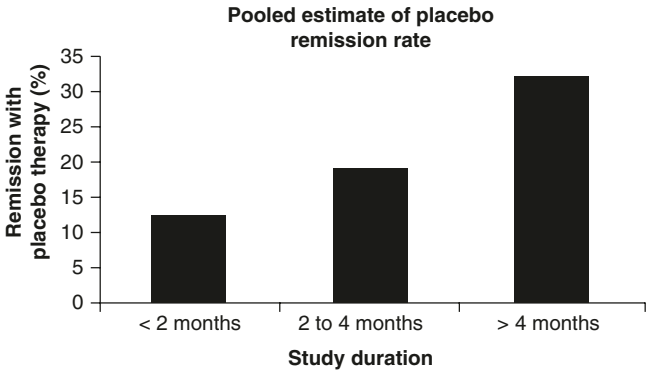

Fig. 52.2 Data from meta-analysis of 23 studies that used CDAI to measure disease activity in Crohn disease. The pooled estimate of remission with placebo therapy increased with study duration

Diagnosis

The diagnosis of IBS is based on clinical symptoms and signs (Fig. 52.3), and investigative workup, including endoscopic evaluation, may be necessary in a small percentage of children especially in the presence of alarm features. Abdominal pain is a common symptom in children with celiac disease but the prevalence of IBS is unknown. Adult studies suggest that 5–17% of celiac disease patients have IBS-like symptoms, and in one study of 1032 adults with celiac disease, 37% were diagnosed with IBS prior to the diagnosis of celiac disease [63]. More than 90% of these adults have improvement in IBS-like symptoms after starting gluten-free diet. Lactose intolerance has been reported in 15–25% of adults with IBS. However, it is yet to be determined if lactose exclusion results in resolution of IBS symptoms. In one large pediatric study, anemia, hematochezia, and weight loss were most predictive of Crohn disease in children presenting with chronic abdominal pain, with a cumulative sensitivity of 94% and specificity of 62% [7]. When evaluating children with lower abdominal pain and altered bowel symptoms one needs to consider the risk of harm associated with invasive test, such as colonoscopy, and this must be balanced against the risk of a missed diagnosis. Fecal calprotectin has a high negative predictive value (100%) in populations with low prevalence for organic disease, i.e., primary care screening of patients for IBD. One has to remember that the low positive predictive value of the test necessitates need for further investigations in patients with elevated fecal calprotectin levels. A meta-analysis has shown the clinical utility of fecal calprotectin to distinguish organic GI diseases, such as IBD from functional GI diseases, leading to less patients who have a functional GI disorder undergoing unnecessary endoscopy [64].

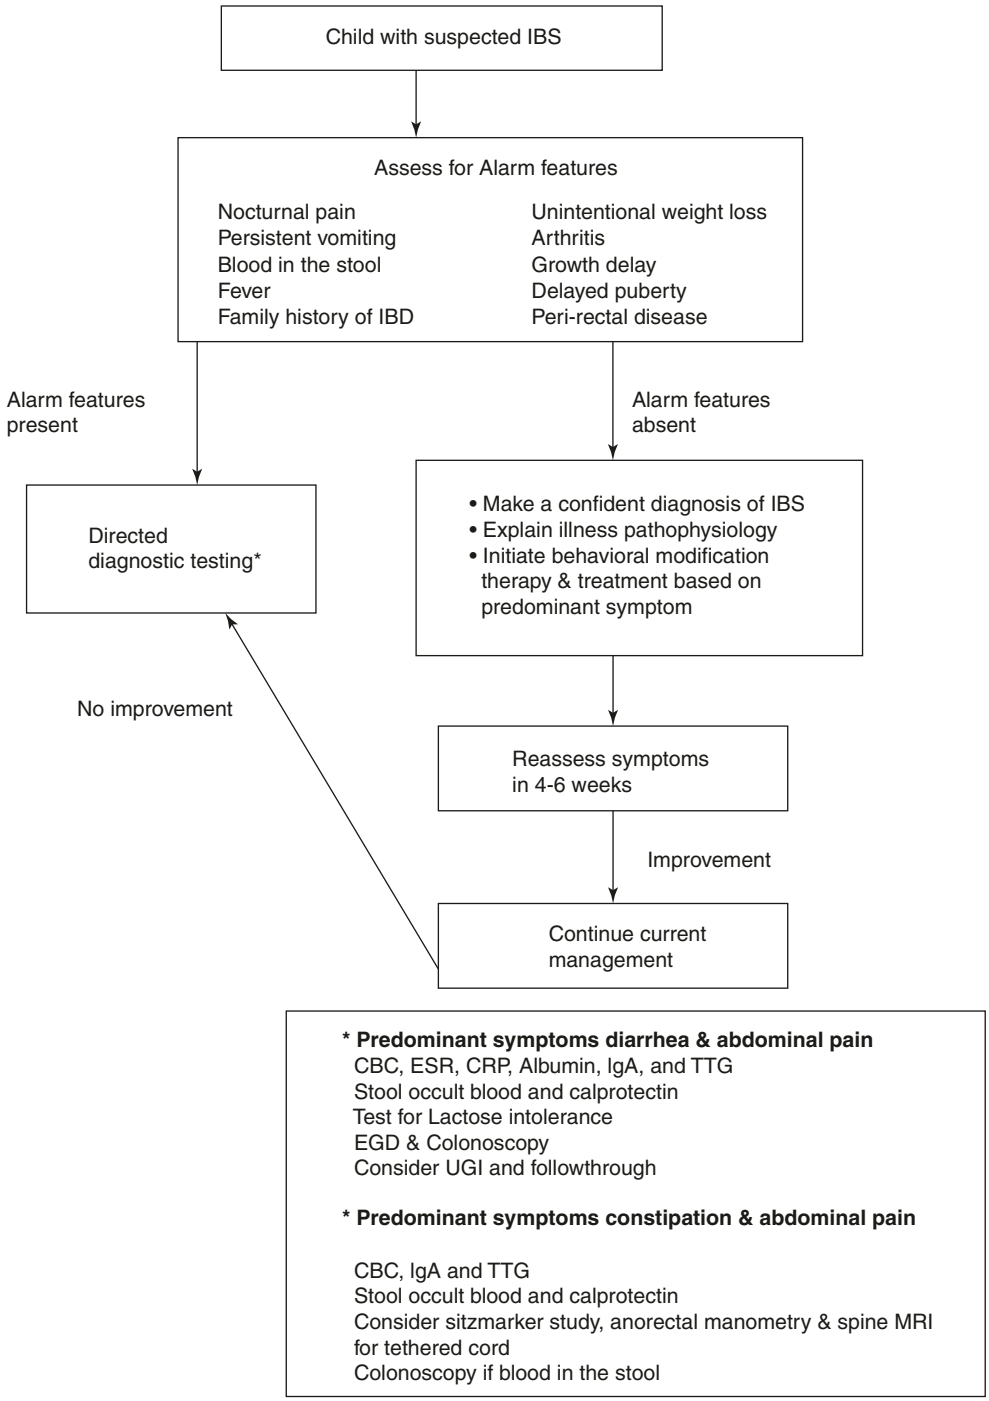

Fig. 52.3 Algorithm for management of children presenting with symptoms consistent with the diagnosis of IBS

Treatment

When evaluating children with IBS, it is important to allocate sufficient time for the consult to allow the child and family to share their concerns. One must acknowledge the presence of pain, adopt an empathic and non-judgmental point of view, and educate and reassure the child and the parents by explaining the source of symptoms in the absence of an identifiable cause [65]. It should also be made clear that the improvement will be slow, and the focus should be on normalization of psychosocial functioning, rather than trying to identify the cause for the symptoms.

Cognitive behavioral therapy (CBT), family intervention, and guided imagery, a form of relaxed and focused concentration, have been successfully used to treat functional abdominal pain in children and are also effective in IBS [64].

Adult studies have shown that attention management techniques, such as hypnosis and mindfulness meditation, are useful to treat IBS symptoms. Patients with prolonged illness and complex psychological comorbidities, which interfere with participation in a treatment plan, may require early referral to a multidisciplinary team, which includes a pain psychologist and a gastroenterologist [51]. CBT is based on the belief that our thoughts, behaviors, and feelings interact, and CBT aims to reduce or eliminate physical symptoms through cognitive and behavioral changes. It guides the patient to modify or change cognitive distortions and negative thinking and enables the patient to substitute these with more realistic thoughts, such as that the pain is likely to subside and does not represent a terminal illness. Several randomized controlled trials to test the effectiveness of pain interventions in children with functional abdominal pain using a self-management approach that includes component of CBT have yielded encouraging results. However, methodological difficulties and different criteria used to classify patients can make interpretation difficult. Cognitive behavioral and relaxation therapy are emerging as the first-line treatment for children with functional abdominal pain and are also useful to treat children with IBS.

Dietary triggers, such as caffeine, fatty meals, and carbonated soft drinks, should be eliminated. A lactose-free diet can help patients with IBS symptoms associated with lactose intolerance. Increasing dietary intake of fiber can help patients with constipation-predominant IBS, but metabolism of the bulking agents by gut bacteria can produce gas, which can worsen symptoms of bloating and flatulence. A meta-analysis in adults with IBS suggested that soluble fiber sources, such as psyllium, ispaghula, and calcium polycarbophil, may be more effective in improving global IBS symptoms compared to insoluble fiber [66, 67]. An innovative approach for treatment of IBS in adults comprises a reduction in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs) in the diet [68, 69]. These short-chain carbohydrates have common functional properties in that they are poorly absorbed, osmotically active, and rapidly fermented by bacteria. A recent multicenter randomized controlled study in adults reported that FODMAP diet was not superior to traditional IBS dietary advice in adult patients [70]. In a small randomized placebo-controlled trial in children with IBS, a quarter of the study cohort reported improvement in abdominal pain and frequency of bowel movements only with FODMAP diet and another third reported improvement with FODMAP and typical American childhood diet. However, the symptom response was evaluated over a relatively short period of 2 days [31]. Dietary advice is an important component of symptom management in patients with IBS; however, FODMAP diet and traditional dietary advice may have similar beneficial effect on symptoms, and some experts have raised concerns about safety of FODMAP diet used over prolonged period of time.

Polyethylene glycol 3350 and milk of magnesia can be used as a stool softener in patients with constipation. Lubiprostone, a type 2 chloride channel agonist, is effective in treating constipation and constipation-predominant IBS in adults [71]. Pediatric trials documenting efficacy in pediatric age group are lacking. Menthol, the active ingredient in peppermint, inhibits smooth muscle contractions by blocking calcium channels. Enteric-coated peppermint oil capsules can help relieve abdominal pain [72]. Peppermint oil can, however, cause rectal burning, esophageal pain, and allergic reactions [72]. There are no controlled studies in children showing the efficacy of anticholinergics in IBS and adult trials have also produced conflicting results. In general, the anticholinergic effect in adults with IBS is comparable to a placebo [72]. The authors do not prescribe antispasmodics, but if a patient is already using them and finds them useful, then the authors do not discontinue the medication. Loperamide can be useful to reduce the stool frequency in diarrhea-predominant IBS patients.

Tricyclic antidepressants (TCAs) are useful in treating IBS symptoms in adults [72]. TCAs act primarily through noradrenergic and serotonergic pathways and have antimuscarinic and antihistaminic properties as well. TCAs facilitate descending inhibitory pain pathways and alter GI physiology to improve IBS symptoms. Amitriptyline has sedative properties that can be used to improve sleep quality when given at bedtime. The usual dose of amitriptyline is 0.2 mg/kg once at bedtime, but higher dose can be tried if there is no improvement in 2–3 weeks. A randomized controlled trial in 83 children with pain-associated FGIDs, including IBS, reported no significant difference between placebo and amitriptyline group after 4 weeks of amitriptyline therapy [73]. The amitriptyline dose in this trial was fixed, and the treatment duration was relatively short and may have affected the outcome. TCAs can cause cardiac dysrhythmia in patients with prolonged QT syndrome; therefore, an electrocardiogram prior to starting the therapy is advisable.

In recent years several organisms, such as *Lactobacillus* GG, *L. plantarum*, *L. acidophilus*, *L. casei*, the probiotic cocktail VSL#3, and *Bifidobacterium animalis*, have been used to treat IBS symptoms, such as bloating, flatulence, and constipation. However, only a few products have been shown to be effective in relieving pain and global symptoms in IBS [74–78]. One organism *B. infantis* was reported to be superior to both a *Lactobacillus* and placebo in relieving abdominal pain, bloating, and difficult defecation and also improved composite score in IBS patients [78, 79]. A meta-analysis concluded that *Lactobacillus rhamnosus* GG moderately increases treatment success in children with abdominal pain-

related FGIDs, particularly children with IBS [80]. The probiotic cocktail VSL#3 was reported to be superior to placebo in relieving abdominal pain and bloating and improve global symptom score in children with IBS [81]. The emerging data seem to suggest that probiotics may have a role in the treatment arsenal of pediatric IBS.

Neuromodulation has recently been shown to be an effective treatment modality for IBS. Dysregulated brain–gut axis signaling, which leads to visceral hyperalgesia, is part of the complex pathogenesis of IBS [82]. Central nervous system pathways play a vital role in the increased sensation of pain in response to physiologic stimuli, with numerous brain imaging studies documenting the structural and functional connectivity abnormalities in both adult and pediatric patients with IBS [82–84]. Functional MRI performed during rectal distension on adolescents with IBS and adolescent controls showed that greater activation in neural structures of the homeostatic afferent and emotional arousal networks in the IBS patients, supporting the role of altered salience network functioning as a neuropathological mechanism of IBS symptoms [16]. While deep brain and spinal cord stimulation, which have been shown to improve abdominal pain and altered bowel habits in adult IBS patients [85] are invasive, peripheral neurostimulation is a non-invasive approach to deliver modulation of the central pain pathways via stimulation of peripheral cranial neurovascular bundles in the external ear. The safety and efficacy of peripheral neuromodulation with an auricular device delivering percutaneous electrical nerve field stimulation, which is thought to stimulate branches of several cranial nerves (V, VII, IX, X) that project to the brainstem, compared to a sham device, have been demonstrated, namely, with significantly reduced worst abdominal pain and composite pain scores both short and long term, while improving global well-being and functioning [86].

"Irritable" Pouch Syndrome

Total proctocolectomy with ileal pouch–anal anastomosis is performed in patients with fulminant colitis or ulcerative colitis refractory to medical management. The most common long-term complication of ileal pouch–anal anastomosis is pouchitis [87] and presents with increased stool frequency, urgency, abdominal cramping, and bleeding (see Chap. 44) [87]. Patients with ileal pouch–anal anastomosis who have symptoms but no identifiable structural abnormalities are thought to have irritable pouch syndrome. It resembles other pain-associated FGIDs characterized by visceral hypersensitivity in the presence of normal rectal biomechanics. In one adult study of 61 symptomatic patients with ileal pouch–anal anastomosis, 42% had no macroscopic or microscopic inflammation of the pouch [87]. Almost half of the patients with symptoms but no pouch disease responded to treatment with antidiarrheal, anticholinergic, and antidepressants, similar to what has been used in treating patients with IBS [88].

Summary

The onset of IBS symptoms most likely represents the convergence of genetic and psychosocial factors, perhaps triggered by some external stimulus, such as a dramatic life event or an enteric infection or inflammatory condition. Dysmotility, hypersensitivity, and disturbed brain perception may be the consequence of these events rather than the primary abnormality. Persistent low-grade bowel inflammation may be responsible for IBS symptoms following a bacterial GI infection.

In some patients IBS symptoms may predate the development of IBD, and a subset of IBD patients can have "functional" GI symptoms. Altered bowel sensory and motor function due to inflammation-induced changes in the bowel neuromuscular apparatus may be responsible for "functional" GI symptoms in IBD. In due course we may realize that immune dysregulation plays a central role in the pathogenesis of both IBS and IBD and they are the two ends of a spectrum of GI inflammatory disorders.

Most patients with IBS have mild disease and require education, reassurance, and lifestyle changes. A smaller proportion with moderate to severe symptoms can benefit from CBT and treatment with pharmacological agents.

Inflammatory Bowel Disease in Pregnancy

53

Abigail J. Meyers and Sunanda Kane

Introduction

While the incidence of ulcerative colitis has remained stable, the incidence of Crohn disease (CD) has increased over the past few decades [1]. It is not clear whether this is due to improved diagnostic techniques, environmental or genetic influences, or other factors not yet identified. However, the consequence of this trend is a growing population of patients in their formative and childbearing years.

Having intercourse, age of sexual debut, and pregnancy rates do not differ among adolescents with and without disability based on a study by Suris et al. [2]. Disability, defined "as a long-term reduction in ability to conduct social role activities, such as school or play, because of a chronic physical or mental condition," [3] does not interfere with sexuality of an adolescent [4]. Thus, adolescent patients with inflammatory bowel disease (IBD) may be sexually active and are at risk for pregnancy. This chapter will review how pregnancy affects the adolescent with IBD both in terms of disease and management options and how IBD and its therapies may affect a pregnancy.

Contraception

The management of contraception in those female patients with IBD who do not wish to become pregnant differs from that in normal female patients. A recent study by Gawron et al. found that a quarter of women with IBD were not using any form of birth control even though they were at risk for an unintended pregnancy [5]. The most important goal still remains the selection of the most reliable method of birth control. Literature continues to have limitation in the effects of birth control on IBD symptoms.

Barrier methods of contraception are acceptable but are not as effective as alternatives. The use of intrauterine devices (IUDS) is considered a Category 1, or without restriction for use in IBD. However, it is not usually recommended, as any complaint of abdominal/pelvic pain could potentially delay the correct diagnosis of active IBD versus pelvic inflammatory disease [6]. There is additional risk of sexually transmitted illnesses in the younger population due to sexual behaviors, such as increased numbers of partners. There is a single case report of a patient who experienced an exacerbation of Crohn disease after insertion of a levonorgestrel intrauterine system [7]. However, no strict contraindication exists to preclude their use in the appropriate patient.

The data regarding the safety of oral contraceptives (OCs) in IBD are conflicting suggesting that the benefit overall outweighs risk but needs to take into consideration disease status, postoperative anatomy and smoking status [8]. Early studies suggested an increased risk (odds ratios ranging from 1.2 to 6) for the development of Crohn disease and ulcerative colitis with OC use. Several of these studies did not, however, account for tobacco use. Reports from Europe, where contraceptives contain a higher estrogen content, continue to show modest increases in risk for the development of Crohn disease after adjusting for cigarette use (odds ratios 1.2–2.0) [9]. A meta-analysis by Cornish et al. suggests that the overall OR is significantly higher for the incidence of Crohn disease with an odds ratio of 1.46 (1.26–1.70) [10].

Additional data suggest that OC use may exacerbate disease activity. Two small prospective studies have found an increased risk of disease recurrence after induction of remission in Crohn disease with OC use [9, 11]. Timmer found a hazard ratio of 3 (1.5–5.9) for increased disease activity following medical induction of remission. Alternatively, Gawron et al. have demonstrated that OCP use can help with cyclical symptoms of IBD and only a small proportion of women report symptomatic worsening [12].

Other considerations for OC use include increased risk of venous thromboembolism (VTE) and impaired absorption. Women with IBD are at a threefold higher risk for VTE than

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_53

the general population [13]. It may be prudent to consider delaying OC use until disease has achieved more optimal control. Women with significant bowel resection do not have absorption concerns with OCs [14].

At this time, no standard guidelines exist for OC use, as there are many preparations available. The variable amounts of progesterone and estrogen are the factors that determine the side effect profile. The choice of which OC preparation to use has to be individualized, taking into consideration other factors, including patient history, parity, and personal preferences. It does appear prudent to try a formulation that contains the lowest amount of estrogen possible or the progesterone only formulations, given the additional risk factors of smoking and predilection toward thromboembolic events in patients with IBD. Hormonal contraception in the transdermal formulation may be considered because it avoids the addition of another oral pill for the adolescent patient as well as its delivery despite possible decrease in absorption during active flares in a patient with IBD.

Fertility

Adolescents with chronic conditions are just as likely to have sexual intercourse as their peers [3]. Even though adolescents may not be trying to get pregnant, the rising age of marriage and decreasing age of first intercourse combined with the inconsistent use of contraception has led to the continued trends of teenage motherhood [15].

Overall, the fertility rates for female patients with ulcerative colitis are essentially the same as those of the normal population [16]. Active Crohn disease, however, can reduce fertility in several ways, depending upon the location of inflammation [17]. Active inflammation in the colon and terminal ileal disease have been shown to decrease fertility. Active ileal inflammation can cause inflammation or scarring of the fallopian tubes and ovaries because of their proximity to the terminal ileum in the lower abdomen. Female patients with perianal disease may have secondary dyspareunia and decreased libido, contributing to lower fertility rates. The systemic effects of Crohn disease, including fever, pain, diarrhea, and suboptimal malnutrition, have also been implicated in decreased fertility. Female patients who have had any surgical resection are at risk for adhesions, which can also impair tubal function. Newer data have suggested that despite a decreased fertility rate, surgery does not affect success of in vitro fertilization in women with IBD compared to the general infertility population [18].

None of the medications used to treat IBD has an adverse effect on female fertility, but it is important to remember that sulfasalazine therapy reduces sperm motility and count in males [19]. These effects are not dose related and do not respond to supplemental folic acid. A sperm analysis study has failed to show significant differences on count or morphology in men with exposure to 6-mercaptopurine (6-MP) compared to established WHO criteria [20]. In addition, further epidemiologic work has failed to demonstrate an effect on birth outcomes in children born to fathers on 6-MP, despite an early study that suggested this association [21, 22].

Effect of IBD on Pregnancy

If a woman is doing well and in remission, there is no evidence to suggest that her risk of a flare is greater than that of a non-pregnant patient. While there is no minimum required time period for a patient to be in remission prior to a planned conception, at least 3 months is recommended. If active disease is present, it is likely to continue through pregnancy and will place the pregnancy at greater risk for a complication [23].

Female patients with inactive IBD at the time of conception appear no more likely to experience spontaneous abortion, stillbirth, or children born with a congenital abnormality [24]. Most studies suggest that babies born to female patients with IBD, regardless of disease activity, are of smaller birth weight [25] and more likely to be born preterm and small for gestational age [26].

The presence of IBD does not appear to have an impact on maternal complications related to pregnancy, including hypertension or proteinuria [27]. Broms et al. demonstrated that women with IBD were more likely to experience venous thrombosis and hemorrhage in the setting of active disease [28].

Effect of Pregnancy on IBD

The activity of IBD at conception remains the primary predictor of the course of pregnancy. For female patients with quiescent UC at the time of conception, the rate of relapse is approximately the same in pregnant versus non-pregnant patients [29]. This is in contrast to the presence of active disease at the time of conception, which is associated with continued or worsening disease activity in approximately 70% of female patients. Comparable observations are seen in CD [23]. The older literature suggested a trend for disease to flare in the first trimester, but this was documented prior to the accepted practice of maintenance therapy, continued even during pregnancy. Some patients will have symptomatic disease only when pregnant, with quiescence between pregnancies and exacerbations during subsequent pregnancies. The clinical course or outcome of previous pregnancies cannot predict either the clinical course of IBD or the outcome of pregnancy.

There are data suggesting that a history of childbearing changes the natural history of Crohn disease [30]. Female patients having been pregnant had fewer resections or longer intervals between resections as compared to female patients who had not had children but otherwise similar disease. One theory proposed is the inhibition of macrophage function by relaxin. Relaxin is a hormone produced exclusively during pregnancy which may result in less fibrosis and stricture formation by this inhibition of macrophages. In addition, a more recent population-based study of pregnancies in Copenhagen has suggested that pregnancy can change the natural history of IBD; women were less likely to experience a flare of their disease following pregnancy compared with those women who had not experienced a pregnancy [31].

Management of IBD During Pregnancy

Clinical Assessment

The main priority is to establish and maintain remission before the patient conceives. One of the problems in CD is the accurate definition of disease activity. In CD, a patient may feel fine even though she has an elevated C-reactive protein or an abnormal colonoscopy and/or X-ray. Many pregnant patients will have intermittent abdominal discomfort related to changes in bowel habits or gastroesophageal reflux that commonly occurs during pregnancy. In addition, abdominal pain in the pregnant IBD patient could be related to cholelithiasis, pancreatitis, toxemia, or a problem with the pregnancy itself. Clinically, these processes can be distinguished from a flare of IBD by a careful history, examination, and laboratory evaluation.

It is important to remember that during pregnancy, hemoglobin and albumin levels decrease by 1 g/dL, sedimentation rate increases two- to threefold, and there is a 1.5-fold rise in serum alkaline phosphatase. It is also important to keep in mind that a growing uterus changes normal anatomy, with the terminal ileum and appendix higher in the right upper quadrant.

In terms of radiographic testing, ultrasound exams are safe, as is magnetic resonance imaging [32] without gadolinium. Clearly, it is best to avoid exposure of the fetus to radiation from abdominal X-rays, especially early in the pregnancy. However, the absolute risk to the fetus of abdominal radiography is minimal, and clinical necessity should guide the decision making [33, 34].

There is no evidence that, if indicated, a sigmoidoscopy or colonoscopy will induce premature labor [35]. Most patients with IBD can be evaluated with sigmoidoscopy without full colonoscopy. However, if full colonoscopy is necessary to establish diagnosis or severity of disease, sedation with propofol with close fetal monitoring is suggested [35, 36].

Medical Therapies

The key principle to management is to remember that the greatest risk to pregnancy is more likely active disease than active therapy. Since there are limited definitive data available on the safety of IBD medications in pregnancy, the focus therefore should be on establishing remission before conception and maintaining remission during pregnancy. The two fundamental issues considering medical therapy in the pregnant IBD patient are regarding the outcome of the pregnancy: whether the mother is taking medications for her IBD compared to those who are not and whether the medications used to treat the pregnant patient are safe and effective.

Most investigators have shown that medical therapy, when analyzed as an independent variable, has no effect on pregnancy outcome [3, 16]. Those patients who have been reported to have adverse birth outcomes tend to occur more often in the setting of active disease. Table 53.1 outlines the relative safety profiles of those medications used in IBD.

Antidiarrheals

Loperamide use has not been associated with an increased rate of first trimester fetal malformations, spontaneous abortion, low birth weight, or premature delivery [37] and is considered low risk. One has to keep in mind, however, that increased stool frequency may be a sign of increased activity and loperamide use should be monitored. Diphenoxylate with atropine is teratogenic in animals, and fetal malformations have been observed in infants exposed during the first trimester [38]. Antispasmodics and anticholinergics have been associated with non-life-threatening fetal malformations and are best avoided during pregnancy [39].

Aminosalicylates

Sulfasalazine has been used for over 50 years in the treatment of ulcerative colitis. Sulfasalazine crosses the placenta with fetal serum levels equivalent to maternal levels [40]. Multiple studies have shown that despite this phenomenon,

Table 53.1 Safety of IBD medications during pregnancy

Low risk when indicated	Contraindicated
Oral, topical mesalamine	Methotrexate
Sulfasalazine	Thalidomide
Corticosteroids	Diphenoxylate
Total parenteral nutrition	
Loperamide	
Azathioprine/6-MP	
Biologics	
Tofacitinib[a]	
Metronidazole	
Ciprofloxacin[b]	

[a] Conflicting and limited data
[b] Not safe in third trimester

there appears to be no increased incidence of abnormal birth outcomes [41]. Sulfasalazine has been shown to inhibit folate acid metabolism, which can cause neural tube defects in the fetus [42]. While the risk of fetal abnormalities has not been shown to increase with sulfasalazine and its derivatives, pregnant female patients taking sulfasalazine should still supplement their diet with 2 mg of folate daily.

5-Aminosalicylic acid (5-ASA) and its metabolite acetyl-5-aminosalicyclic acid are found in both maternal and fetal plasma in female patients taking mesalamine; however, a meta-analysis of published studies has demonstrated its lack of effect on the incidence of adverse birth outcomes [43]. The use of topical 5-ASA agents during pregnancy has not been associated with any increase in adverse birth outcomes related to its use during pregnancy.

Antibiotics

The most frequently used antibiotics in IBD include predominantly metronidazole and ciprofloxacin. Animal studies have not shown any evidence of teratogenicity or increased fetal loss with metronidazole. Short courses of metronidazole during the first trimester of pregnancy for *Trichomonas vaginalis* have been shown to be well tolerated and low risk [44, 45]. In a study of 228 female patients exposed to metronidazole during pregnancy followed prospectively through their pregnancy, 86% of female patients were exposed during the first trimester [44]. The malformation rate was 1.6% in the treatment group and 1.4% in the control group. Female patients with IBD require the use of metronidazole for longer periods of time, and there are limited data regarding prolonged use of this medication.

In animal studies, no teratogenicity has been seen with ciprofloxacin, although musculoskeletal abnormalities have been identified in immature animals [46]. Moskovitz et al. found that in 27 patients who were receiving 1 g/day, even in the first trimester, its use appeared to be safe (18 patients) [47]. Another study investigated the effects of fluoroquinolones in the first trimester and did not show an increased risk of congenital malformations, prematurity, or low birth weight [48].

While these data are comforting, this information applies to the non-IBD population, where antibiotics are used short term. These agents are more commonly used for longer durations in IBD, and the use of these two antibiotics during pregnancy should currently be restricted to short-term courses.

Corticosteroids

As shown in studies for rheumatological conditions as well as for IBD, corticosteroids during pregnancy have largely been regarded as low risk [49]. Corticosteroids cross the placental barrier, but the fetal–maternal serum concentration of the steroids varies between different corticosteroid preparations. Prednisolone and prednisone are more efficiently metabolized by the placenta than dexamethasone or betamethasone, and fetal levels of this steroid are approximately eight- to tenfold lower than that of the maternal circulation [50]. Since corticosteroids are conjugated more rapidly to biologically less active sulfates in the fetus than the adult, a suppressive fetal blood concentration is not often reached with therapeutic doses used during pregnancy.

Among female patients with IBD, corticosteroids have not been found to be harmful to the fetus [22]. Mogadam et al. studied the effects of steroid use in 185 out of 531 pregnancies in female patients with IBD and did not find a statistically significant increased incidence of prematurity, spontaneous abortions, stillbirth, or development defects in the ulcerative colitis subgroup (4.6% in the treated group vs. 2.2% in the untreated group; $P > 0.10$) [49]. In the Crohn disease subgroup, patients did significantly worse in the treated group compared to the untreated group (13.5 vs. 1.9%, $P < 0.1$). Patients with CD may have more severe disease and require more medical intervention to control the activity of the disease, and it is possible that the severity of the illness in CD itself may have caused these patients to not fare as well as the ulcerative colitis patients.

Budesonide is a modified corticosteroid with about 10% systemic absorption and can be used for the induction of remission for IBD [51–53]. Beaulieu et al. looked at 539 female Crohns patients with 60 pregnancies in 41 women and 8 of these women received budesonide during pregnancy. Seven women carried to full term and 1 woman delivered at 35 weeks. They had no congenital abnormalities, spontaneous abortions, or other fetal or maternal adverse effects and no increased incidence of gestational diabetes or preeclampsia [54].

Immunosuppressants

As more patients with IBD are treated with immunosuppressants, there is a growing need for information on their effects on the pregnant patient and growing fetus.

Immunomodulators

There is a large body of literature on the use of immunomodulators among pregnant transplant recipients and those patients with autoimmune diseases [54, 55]. It is generally believed by the most experienced IBD clinicians that immunomodulators, such as 6-MP, azathioprine, and even cyclosporine, can be used safely during pregnancy if the mother's health mandates therapy, based on the evidence from these other conditions.

Thiopurines are used for steroid-sparing and steroid-dependent IBD. Azathioprine (AZA) is a prodrug of 6-MP and does cross the placental barrier, but the immunomodulatory effects of azathioprine do not affect the fetus due to the lack of inosinate pyrophosphorylase in the fetus, an enzyme

which converts azathioprine into the active metabolites of 6-MP and *S*-methyl-4-nitro-5-thioimidazole [56]. Several human studies have suggested that AZA and 6-MP are low risk during pregnancy when used for IBD [57].

An older study with a small number of pregnancies suggested its safety [58]. Francella et al., in a retrospective cohort study, investigated the possible toxicity of 6-MP from a review of records of 485 patients who had received the drug [57]. Of the 462 female patients who were contacted, 155 had conceived at least one pregnancy after developing IBD. Pregnancies were analyzed based on whether the patients had taken 6-MP before or at the time of conception compared with those IBD patients who had their pregnancies before taking 6-MP. There was no statistically significant increase in spontaneous abortion rates or major congenital malformations among patients taking 6-MP compared to control subjects [RR 0.85 (95% CI, 0.47–1.55), $P = 0.59$]. The authors concluded that the use of 6-MP or AZA and its beneficial effect on maternal health outweighed any risk to the fetus and that it was not unreasonable to continue its use throughout pregnancy. Recently, results regarding pregnancy in a prospective French cohort of Crohn patients have become available. There were no observed differences in the outcome of pregnancy for patients treated with thiopurines compared to women with CD who used no medications during pregnancy [59, 60].

In IBD, methotrexate is used in the management of steroid-dependent or steroid-resistant Crohn disease as an alternative to azathioprine and 6-MP. Methotrexate is a known abortifacient, showing increased risk of spontaneous abortions in various studies, currently used therapeutically at high doses in tubal pregnancies [61]. Therefore, methotrexate is a category X medication. Patients who are started on methotrexate should be strongly advised to use reliable contraception. If termination of a pregnancy is not possible, high doses of folic acid therapy are recommended to prevent CNS abnormalities, including anencephaly, meningomyelocele, and hydrocephaly. The optimum management includes careful counseling and effective contraception prior to any initiation with methotrexate therapy [62].

Biologic Agents

As biologic agents become increasingly prevalent for the treatment of IBD, more data are emerging in the pregnant population marking the overall safety of continuing certain biologic therapies throughout the duration of pregnancy to keep disease well controlled. A recent meta-analysis included 48 studies comprising 6963 patients and biologic therapy in IBD pregnancies was associated with comparable rates of early pregnancy loss, preterm birth, still birth, low birth weight, and congenital malformations as the general population and meta-regression did not reveal an association of disease activity on adverse outcomes [63]. Special consideration to vaccines for the infant when born includes delaying live virus vaccinations by 6 months with in utero biologic exposure [64]. MMR and varicella are live vaccines but given at 1 year and are appropriate for the infant exposed to biologic therapy in utero.

Anti-tumor Necrosis Factors (TNFs)

The early safety literature with infliximab includes one study by Katz et al. suggesting that infliximab exposure for CD or rheumatoid arthritis (RA) during pregnancy does not lead to a statistically significant increase in adverse outcomes compared to that of the general population, using the National Center for Health Statistics database between 1976 and 1996 for comparison [65]. Of 96 female patients who were studied, live births (67, 95% CI: 56.3–76.0 vs. 67%), miscarriages (17, 95% CI: 8.2–23.2 vs. 15%), and therapeutic terminations (16, 95% CI: 11.5–28.0 vs. 19%) were not statistically different from that of the general population. In this review, 8 of 14 miscarriages in female patients who were exposed to infliximab occurred at or before 10 weeks. It is thought that these miscarriages early in pregnancy were related more to disease activity than infliximab use. Maternal IgG is transported across the placenta as early as the late first trimester [66], but efficiency of transport is poor, so total fetal IgG levels are low until the late second or early third trimester, suggesting that it is not the infliximab exposure that would be contributing to this early miscarriage rate observation. A case–control study from France of pregnant women treated with infliximab versus those not failed to show any increased risk in pregnancy or neonatal outcomes [67]. A recent study from France of 1457 IBD pregnancies exposed to anti-TNF demonstrated no increased risk after 24 weeks gestation for complication in pregnancy; however, there was an increased risk for flare [68].

Because adalimumab is also a full antibody, it too crosses the placenta after week 20 of pregnancy. Drug can be detected in cord blood of the newborn up to 6 months following in utero exposure [69].

Certolizumab pegol does not cross the placenta as it is a pegylated Fab fragment [70]. However, at this time there is no recommendation to switch a patient from one agent to another if she is in remission solely because of these properties [71].

The European Crohn's and Colitis Organisation performed a meta-analysis in 2016 concluding that anti-TNF therapy does not increase adverse pregnancy outcomes when compared to the general population [72]. Similarly, the Rotterdam experience demonstrated safety of stopping anti-TNF therapy in the second trimester for those patients in remission, but those who demonstrate active disease to continue their anti-TNF therapy given that uncontrolled IBD is associated with poor pregnancy outcomes [73, 74]. Children born to mothers using anti-TNF therapy have been studied

up to 1 year of life without concerns of increased risks [68, 72]. It is recommended to continue anti-TNF therapy throughout pregnancy to decrease risk of IBD flare. If in remission, anti-TNF could be discontinued during the second trimester, especially with infliximab.

Anti-integrins

Vedolizumab crosses the placenta but data suggest that it is low risk during pregnancy and carries a B safety rating [75, 76]. A retrospective review was done of 46 pregnancies reported from six vedolizumab clinical trials; 24 female participants received vedolizumab with 11 of these women having live births with 9 at full term. Four of the women had spontaneous abortions but half of these women had moderate to severe disease activity demonstrating again that disease status plays a larger role in outcomes [77]. A recent systematic review of four studies looking at pregnancy outcomes in female patients with IBD on vedolizumab demonstrated an increased incidence of preterm births (OR 1.97, 95% CI, 1.10–3.54) but no difference in number of live births or congenital malformations [78]. This was demonstrated in a subgroup analysis of a Nielsen's large meta-analysis that preterm birth was higher in women with vedolizumab use than anti-TNF users [63].

Interleukins 12 and 23

Pregnancy safety data with use of ustekinumab is limited in the IBD literature. Recently, Volger et al. demonstrated data from spontaneous reporting, clinical studies and registries of 478 pregnancies with exposure to ustekinumab during pregnancy or within 3 months prior to conception. About 72% of these pregnancies resulted in live births with a rate of congenital anomalies being 3.9%. The rate of spontaneous abortion was 18.4%. Given these outcomes were consistent with the general population, ustekinumab exposure during pregnancy appears safe [79]. Recommendation is to continue medication through pregnancy to maintain remission and plan last dose 6–10 weeks before delivery and continuing therapy postpartum [80–82].

Small Molecules (Janus Kinase Inhibitor)

Tofacitinib data are limited but given that it is a small molecule, it may cross the placental barrier. Previously preconception contraception counseling was recommended given the limited safety data. Reviewing the safety databases retrospectively for UC, RA, psoriatic arthritis, and psoriasis demonstrated 158 pregnancies reported with maternal and paternal exposure of 74 and 84, respectively, without any reports of fetal death [79]. There were 19 reported spontaneous abortions and 93 healthy newborns. However, contraception was required for enrollment in the clinical trials so there is further limitation in follow-up and under reporting as women were discontinued in the trial upon becoming pregnant. Recent updates to the OCTAVE trials reported 34 pregnancies with exposure to tofacitinib and 15 maternal first trimester exposures demonstrated 60% healthy newborns, 13.3% medical terminations, 13.3% spontaneous abortions, and 13.3% lost to follow-up [80]. Due to the limited data, contraception is recommended and further monitoring will be performed in clinical studies.

Breastfeeding

The advantages of breastfeeding are well known, but the effects of IBD medications on breastfeeding still remain unclear. The breastfeeding initiation rates among adolescent mothers are approximately 35–40% [83] and are significantly less than the national rate, which is 60%. In a study by Kane et al., only 44% (54/122) of female patients with IBD had breastfed their infants, the majority of whom had UC [84]. A more recent study done in Canada showed the opposite; women with IBD nursed more frequently than the background population [85]. In neither study was there an increased risk for disease activity associated with the act of nursing itself; disease activity was related to cessation of therapies to treat disease.

Table 53.2 summarizes the safety data regarding medications and their use during breastfeeding.

Sulfasalazine and other forms of 5-ASA are excreted into the breast milk with milk concentrations that are about 40–50% of the maternal serum levels with outcomes suggesting its safety during breastfeeding [86]. There is one case report of diarrhea in a nursing infant of a mother who used mesalamine suppositories 6 weeks after childbirth with four additional challenges of breastfeeding following suppository administration leading to similar results [87].

In the case of immunomodulators, a small retrospective study from Austria looked at long-term safety outcomes of children breastfed with mothers taking thiopurine comparing to mothers without thiopurine use and all children had appropriate mental and physical development without increased hospitalizations or infections [88]. A prospective study done by Christensen [89] demonstrated milk concentrations were highest within the first 4 h of maternal ingestion and only equated to 0.0075 mg/kg bodyweight. Thus, it seems reason-

Table 53.2 Safety of IBD medications during breastfeeding

Safe to use when indicated	Contraindicated
Oral mesalamine	Methotrexate
Topical mesalamine	Ciprofloxacin
Sulfasalazine	Metronidazole
Corticosteroids	Loperamide
Azathioprine/6MP	
Biologics	

able to suggest that drug exposure is minimal and to minimize it further that a mother could nurse right before taking her dose.

Approximately 5–25% of the maternal serum concentration of corticosteroids reaches breast milk, and the amount received by the infant is considered minimal [50]. The commonly used corticosteroids, prednisone and prednisolone, result in low breast milk concentrations with doses of <20 mg of corticosteroids deemed to be safe to use during nursing [90]. Some suggest that breastfeeding is safer if delayed for 4 h after ingestion of steroids [91].

It is not mandated that women using biologic agents need to stop nursing. A prospective study was performed investigating detectability of biologics in breast milk and if breastfeeding during treatment was associated with increased infections or functional delays in the infant [92]. Infliximab, adalimumab, certolizumab, and ustekinumab were detected in breast milk. Infection and development were not different between infants from mothers receiving biologic, immunomodulatory, or combination therapy than those infants from unexposed mothers.

Other medications, such as metronidazole, ciprofloxacin, and methotrexate, should be discontinued in nursing mothers given their high concentrations in breast milk.

Mode of Delivery

The mode of delivery should most often be an obstetrical decision and not solely based on the presence of IBD. Adolescents have lower Cesarean section rates than adult women [93]. The indications for Cesarean section for obstetrical reasons are not different in female patients with IBD. The presence of UC does not have a significant impact on the method of delivery, nor it is an indication for a section per se. However, active perianal disease in Crohn disease may worsen after a vaginal delivery. One retrospective study of female patients with CD found that 18% of those without previous perianal disease developed such disease after delivery, usually involving an extensive episiotomy [94]. A retrospective chart review from 2014 found that there was no difference in risk of symptomatic flares of perianal disease with a vaginal delivery versus a C-section [95]. In addition, a recent study failed to demonstrate any influence the mode of delivery on the natural history of disease [96]. General guidelines include a planned C-section for any woman with known perianal or rectal CD or if the birth appears to be more complicated than initially presumed.

There has been debate whether female patients who have had ileal pouch–anal anastomosis (IPAA) should deliver vaginally or whether Cesarean section should be planned. In one study of 43 pregnancies in female patients' status post-IPAA, pregnancy was well tolerated, with a complication rate lower than in female patients who had an ileostomy [97]. Although more Cesarean sections were performed in female patients with IPAA, the explanation was likely due to the uncertainty about the pouch function. An extended follow-up of female patients with an IPAA who delivered vaginally showed no adverse long-term effects on pouch function. The type of delivery in patients with an IPAA should be dictated by obstetrical considerations. Other surgeons feel that the risk to permanent pouch failure is higher with a vaginal delivery and recommend any patient with surgery for UC undergo Cesarean section.

Surgery and Pregnancy

In the pregnant IBD patient, elective surgical procedures are uncommon, but those that are performed in the second trimester do not appear to carry a significant increase in perinatal morality in female patients without IBD [98].

The indications for surgery during pregnancy are identical to that of non-pregnant patients. These include obstruction, perforation, abscess, and hemorrhage. The approach of continuing medical therapy may only further increase the risk to both mother and fetus. In the ill pregnant IBD patient, the greater risk to the child is continued maternal illness rather than surgical intervention [99]. In general, doing what is best for the mother results in what is ultimately best for the fetus.

In patients with Crohn disease, Hill and colleagues described three pregnant patients with intraperitoneal sepsis, requiring surgery [100]. All three female patients recovered and delivered healthy infants. Most reports suggest proceeding to surgery when indicated. A variety of procedures have been performed, including proctocolectomy, subtotal colectomy with ileostomy, hemicolectomy, or segmental resection, and combined subtotal colectomy and Cesarean section. Two general points should be made: (1) primary anastomosis carries a greater risk of postoperative complication rate, and thus a temporary ileostomy is generally preferred, and (2) if the fetus is significantly mature, then Cesarean section along with bowel resection is indicated.

In female patients who have a total proctocolectomy with IPAA prior to pregnancy, there is controversy regarding postoperative fertility and sexual function. An early study suggests that these are maintained [101], but most recent studies [102, 103] suggest a significant decrease in fertility following this type of surgery. The good news, however, is that there are new data to suggest that in vitro fertilization in these patients is successful [104]. During actual pregnancy, however, female patients with IPAA did note an increase in stool frequency, incontinence, and pad usage, with symptoms resolving after delivery.

Pregnancy has not been shown to complicate stoma function. Female patients may experience some prolapse due to abdominal pressure, but no increased risk to the pregnancy is encountered.

Transition of Care

The time to transition of care from a pediatric gastroenterologist to an adult gastroenterologist should be an individualized decision. Factors, such as autonomy level, activity of disease, and transitioning in other phases of life, all should be taken into account. When the adolescent patient becomes pregnant, there may be consideration of transitioning care to the adult provider, depending on the pediatric and adult gastroenterologist's experience and comfort level in dealing with pregnancy [105].

Summary Points

- Adolescents with IBD are at risk of pregnancy.
- Fertility is affected in postsurgical UC and in active CD.
- There is no increase in adverse outcomes with quiescent IBD.
- Active disease at conception increases the risk for adverse outcomes.
- The majority of medications for IBD are safe in pregnancy and breastfeeding—active disease is more deleterious than active therapy.

Pediatric Inflammatory Bowel Disease Care in Low- and Middle-Income Countries

54

Almuthe Christine Hauer

Introduction

The inflammatory bowel diseases (IBDs) have been regarded traditionally as diseases of westernized nations. However, the epidemiology of IBD is changing worldwide, as was shown in the largest systematic review to date including 147 population-based studies. Herein, Ng et al. revealed a worldwide increase in IBD incidence since 1990, including newly industrialized countries in Africa, Asia, and South America, with annual increases of up to 17.8% for Crohn disease (CD) and 14.9% for ulcerative colitis [1]. A similar trend was shown for pediatric-onset (<19 years at diagnosis) IBD when analyzing 144 population-based studies from 38 countries. Annual incidences were as high as 11.4/100,000 person-years in Asia, the Middle East, and Oceania compared to 15.2/100,000 in North America, and in time-trend analyses, almost 70% of CD studies reported an increasing incidence [2]. These data indicate that pediatric IBD (PIBD), too, has become a global disease, thus highlighting the need not only for research into its prevention but also for innovations in healthcare to manage this complex and costly disease.

Even in high-income countries (HICs), the quality of PIBD management may differ with significant diagnostic delays in remote German regions due to a lack of referral centers [3] or widespread variation in treatment and disease monitoring in North America [4]. Still, these observations contrast sharply with many low- and middle-income countries (LMICs) where, in addition to a general lack of resources, structured health insurance systems, and well-equipped centers, there are neither formally trained pediatric gastroenterologists nor training programs available [5]. Therefore, almost invariably general practitioners or pediatricians without special training will care for children with IBD who enter a healthcare system where diagnostic facilities are limited, as are the treatment options. Importantly, current guidelines usually target an audience with a subspecialist level of training, often assisted by cutting-edge diagnostic and treatment facilities.

In this chapter, recent guidelines on PIBD diagnostics and treatment published by ECCO (European Crohn's and Colitis Organization) and ESPGHAN (European Society for Paediatric Gastroenterology, Hepatology, and Nutrition) are analyzed for their potential to be adjusted to everyday practicalities and real-life scenarios focusing on the so-called middle-income countries (MICs) with limited resources, but a somewhat structured healthcare system and documented increase in PIBD. Such MICs or "countries in transition" are defined on the basis of an "inequality-adjusted human development index" (IHDI) of <0.75 (the highest IHDI worldwide 0.889, Norway), which also takes into account the distribution of average achievements in health among the countries' populations, thus capturing losses in human development due to inequality. In 2020, an IDHI of <0.75 was applicable for countries such as Armenia, Bulgaria, Colombia, Indonesia, and Jordan [6].

Diagnostic Evaluation

Accurate diagnosis of PIBD should be based on a combination of history, physical examination, laboratory examination including basic and more specific serological and intestinal markers, as well as invasive examinations including esophagogastroduodenoscopy (EGD) and ileocolonoscopy (IC) with histopathology (Table 54.1). Importantly, children with chronic diarrheal symptoms should have an infection that could mimic PIBD ruled out [9]. In many LMICs, there is a high prevalence of intestinal infections and the absence of a sole diagnostic gold standard could lead to delays in diagnosis and accurate assessment of the disease [10, 11].

Table 54.1 Diagnostics: examples of modifications

Published recommendations (ECCO/ESPGHAN guidelines, position papers)	LMIC-specific modifications, alternatives, and considerations
Clinical evaluation and laboratory tests	
Clinical evaluation (including growth monitoring and PIBD activity indices)	• Translation of Disease Activity Indices into patients' languages • Creation of mobile applications
Complete blood cell count including red blood count and platelet indices	• Further evaluation (iron, vitamin B12, folate) according to anemia subtype
CRP, ESR, albumin	• CRP and correlation with (transmural) inflammation in Crohn disease (CD) • Combining CRP, ESR and fecal markers to improve specificity, if not too costly
Testing of TPMT activity recommended prior to therapy with 6-Thioguanine	• Testing of TPMT activity phenotypically more cost-effective than genetically • Close monitoring of WBC and liver enzymes (early at onset of 6-TG therapy)
Testing for latent tuberculosis (TB) infection/intestinal TB by • Mantoux Tuberculin Skin Test (TST) or • Interferon-Gamma Releasing Assay	• Anti-TB therapy to be considered prior to (CD) treatment (endemic areas)
Exclusion of enteric infections (including *Clostridium difficile*)	• Stool microscopy for *Entamoeba histolytica* • Check for unusual infective agents and parasites (endemic areas) • Anti-amoeba therapy prior to IBD treatment in endemic areas
Fecal Calprotectin as surrogate markers of mucosal healing or inflammation (also in post-operative setting)	• Consecutively elevated FCal levels to select patients for endoscopy
Imaging	
Magnetic resonance enterography (MRE) imaging as modality of choice in pediatric CD (for small bowel evaluation), at diagnosis and for follow-up	• Intestinal ultrasound (IUS) most valuable alternative for small bowel evaluation (CT enterography similarly accurate, but radiation a disadvantage)
Endoscopy	
Esophagogastroduodenoscopy (EGD) and ileocolonoscopy (IC), performed: • By a pediatric gastroenterologist • After age-appropriate bowel preparation • Under general anesthesia/deep sedation • In a setting suited for children • With personnel trained in PIBD	EGD and IC performed: • By an adult gastroenterologist • In collaboration with a pediatrician • Recording of endoscopy in video format for further analysis (smartphones) Selection criteria for sedation according to ASA classification system • If no anesthesiologist is available, moderate and deep sedation considered to be performed by endoscopist (if trained in advanced pediatric life support)
Pediatric + adult gastro- and colonoscopes	• Use of adult gastroscopes for EGD and IC in children with BW > 10 kg
Histopathology	
Standardized histologic examination of endoscopic biopsies essential to initial PIBD work-up and follow-up	• Histologic examination recommended: Reduction of histopathologists' workload mandatory • Treatment of biopsies (immediate fixation by immersion in buffered formalin or equivalent prior to transport; [7])
Worldwide definition of PIBD phenotypes according to "Paris Classification" of endoscopic and histopathological findings	• Focus on histopathologic differentiation of IBD, in particular CD and ITB
Routine sampling of a minimum of 7–8 biopsies from upper gastrointestinal tract at initial evaluation (with two or more biopsies from each site)	• Routine sampling of 2–3 biopsies in total (1 duodenal, 1–2 gastric, unless there are macroscopic changes in the esophagus)
Routine sampling of a minimum of two biopsies from the terminal ileum, cecum, transverse colon, sigmoid colon, and rectum	• Routine sampling of 4 biopsies in total (1 terminal ileum, 1 ascending and descending colon, 1 from rectum)
Implementation of digital whole-slide imaging for visualization of the entire tissue on one slide with many digital products already available [8]	• With digitization of pathology laboratories still lacking: • Specific training of histopathologists regarding IBD diagnosis • Promotion of direct cooperation between LMIC and HIC institutions with exchange programs

Clinical Evaluation and PIBD Activity Indices

Systematic evaluation is not only mandatory in the initial PIBD diagnostic work-up but also essential for adequate disease monitoring. With the high growth failure prevalence, adequate growth assessment must therefore be performed at each visit, with a review of patients' growth charts [3, 12, 13]. Because locally developed growth charts are not always easily obtained, WHO (World Health Organization) growth charts and references could be used instead. For monitoring of disease activity, PIBD disease activity indices are of further interest. As stated elsewhere, the Pediatric Ulcerative

Colitis Activity Index (PUCAI) allows a symptom-based assessment that helps predicting clinical remission and correlates well with colonoscopic scores [14–16]. For pediatric CD, several indices are available. For example, the weighted Pediatric CD Activity Index (wPCDAI) combines symptoms, findings on physical examination, and basic laboratory test results, which are widely available. Translating these disease activity indices to LMICs' languages could expand their use as monitoring tools.

Serological Tests

Widely available, easy-to-use, and non-invasive objective markers are not only needed to monitor IBD activity but can also prevent unnecessary repeated endoscopic evaluations [17]. The heterogeneity of LMICs, both ethnically and economically, the test availability, and their costs represent major challenges in generalizing recommendations.

A complete blood cell count is a widely available tool, and while leukocytosis might be present in acute inflammation, leukopenia could be a side effect of immunosuppressants. In PIBD, both hemoglobin level and platelet counts were shown to add a diagnostic value in symptomatic children, with pooled AUC (area under the curve) of 76% and 79%, respectively [17]. Because IBD can be accompanied by thrombocytosis, the platelet count may help differentiate between IBD and infectious processes, as thrombocytosis is a relatively uncommon finding in infectious diarrhea [18]. Mean platelet volume (MPV), a readily available test may be another useful marker because it is influenced by the degree and type of mucosal inflammation, and when compared with white blood cell count, ESR (erythrocyte sedimentation rate), or CRP (C-reactive protein), it has a similar accuracy regarding IBD activity with lower levels in patients with active ulcerative colitis [19]. Additionally, the neutrophil–platelet ratio was found promising for assessing disease activity in ulcerative colitis [20], while in patients with CD, better evidence was found for the neutrophil–lymphocyte ratio [21].

CRP, when available at a reasonable cost is one of the most widely used inflammatory markers in IBD. An increase in CRP level correlates with acute inflammation, both intestinal and extraintestinal. In a study of 91 children with chronic gastrointestinal symptoms, CRP was elevated in 60% of patients with ulcerative colitis (UC) and in 100% of patients with CD [22]. CRP has a relatively short half-life, returning to baseline values quite rapidly once the inflammatory stimulus has resolved. It may therefore be a better measure of remission and response to therapy than other inflammatory markers in patients with IBD [23]. Furthermore, an elevated CRP in an asymptomatic CD patient may suggest transmural damage in a silent Crohn disease [24].

ESR serves as another surrogate measure of inflammation since acute inflammation is associated with increased levels of plasma proteins and higher plasma viscosity resulting in ESR prolongation. ESR can therefore be used as a non-specific inflammatory marker [25] and it is readily available at a reasonable cost. Alper et al. reported that almost two-thirds of children with IBD had an elevated ESR at diagnosis, which was even higher in patients with CD compared with UC (72% and 23%, respectively). They also showed that ESR correlated well both with endoscopic and histologic activities in pediatric Crohn disease colitis [26].

Albumin, a negative acute phase reactant is downregulated during acute inflammation. Its level at diagnosis has been shown to serve as a prognostic factor in patients with UC [27]. In contrast, in CD, a serum albumin level >3.8 g/dL was associated with better control of the disease [28].

Testing of thiopurine methyltransferase (TPMT) activity (genotype or phenotype) may help identify patients at risk of profound myelosuppression and is recommended prior to treatment with 6-thioguanine, when available. However, cytopenia can still occur despite normal TPMT activity. In addition to availability and cost-effectiveness in LMIC, it was shown that ethnicity may determine the rates of TPMT deficiency and new genes are being recognized which affect the drug response and metabolism. This test might therefore be individualized according to the specific population, as is testing for new mutations. For example, NUDT15 gene mutation leads to reduced tolerance of 6-MP in patients of South Asian descent [29–33].

Microbiological Investigations

In LMICs, tuberculosis (TB) is often endemic with a much higher frequency than IBD and routine BCG (Bacillus Calmette Guerin), vaccination is practiced. Also, the risk of latent TB or TB reactivation is present, and therefore, intestinal TB that mimics CD must be excluded. This should be based on a combination of history taking, physical examination, review of immunization and nutritional status, chest X-ray, Mantoux tuberculin skin test, and/or an Interferon-gamma releasing assay, according to the local prevalence and national recommendations [34–36]. For LMICs, World Gastroenterology Organization Global Guidelines consider a trial of anti-TB therapy for 2–3 months in CD management to determine the response in endemic areas [37]. Finally, TB testing prior to any anti-TNF therapy is mandatory.

Because immunosuppression can have harmful effects on patients with acquired immunodeficiency syndrome (AIDS), HIV testing must also be part of the initial diagnostic workup. It is however noteworthy that concomitant use of highly active antiretroviral therapy (HAART) and biologics now allows the control of viral replication and induces and

maintains remission in HIV-positive patients with IBD [38, 39]. Because a low CD4+ count might exert protection in patients with IBD and concomitant HIV infection, as a low CD4+ cell count was shown to be associated with a stable disease course and fewer relapses [40], it might be worthwhile to perform this test in the specific scenario just mentioned.

Prior to endoscopy, several other infections must be excluded, according to test availability and local practice [41]. In endemic areas, stool testing for *Entamoeba histolytica* and more extensive investigations for unusual infective agents and parasites should be performed [9]. In the diagnosis of amoebiasis easily performed stool microscopy cannot be replaced even by PCR and it remains the only way to prove hematophagous trophozoites thus indicating whether the disease-causing stage has been reached [42]. While the Centers for Disease Control recommend a minimum of 3 stool samples collected over a period of 10 days to improve the diagnostic sensitivity to 85–95%, World Gastroenterology Organization Global Guidelines consider a course of anti-amoeba therapy to be administered in UC and CD management in endemic areas and when there is limited access to diagnosis [42, 43].

Screening for *Clostridium difficile* infection is not only recommended at initial diagnostic workup for PIBD but also recommended in all patients with a suspected new exacerbation of IBD and before treatment modification according to test availability and local practice [9, 34, 41].

Fecal Calprotectin

Fecal calprotectin (Fcal) is a non-invasive diagnostic tool to detect mucosal inflammation, although not specific for IBD [9, 41]. However, its high sensitivity has proven to be cost-effective in distinguishing IBD from non-IBD in children, although in healthy infants, higher concentrations are found than in older children [44]. According to World Gastroenterology Organization Global Guidelines, Fcal could be helpful in the selection of further investigation, including endoscopy in developing countries with medium resources available, but it is not mentioned for LMICs [37]. While there is no ideal cut-off value to reflect mucosal inflammation and predict disease outcome, a Fcal value <100 mg/g usually reflects remission [41, 45]. Fcal is therefore a useful surrogate marker of mucosal healing, and its monitoring together with PUCAI allows an adequate assessment of disease activity in pediatric UC, without the need for endoscopy [46]. Repeated Fcal measurements may be used to longitudinally track changes in a patient's condition. In patients with UC, an endoscopic evaluation should be considered when Fcal is high, due to its good correlation with clinical disease activity, and endoscopic and histological indices [45]. Despite its broad use in many countries worldwide, the cost of Fcal is still relatively high, and in many LMICs not fully covered by national insurance programs. Research is still needed on cut-off values in the pediatric population and more importantly in developing countries, because of the varying range of normal values in healthy children by age.

Imaging

Objective evaluation of IBD extent and activity usually includes imaging; however, some techniques are not always available in LMICs. For example, to correctly differentiate CD and UC at diagnosis, small bowel evaluation should be always performed [9]. Indeed, several atypical phenotypes of UC, CD, and IBDU have been reported in children, and the involvement of the small bowel is useful to correctly define CD, evaluate the degree and the extent of the inflammation, and define the presence of disease-related complications [47, 48]. Moreover, in those patients whose ileum could not be intubated, imaging may help to reach a correct diagnosis and monitor disease [9]. The choice of which test to perform depends on local availability and expertise, and includes preferably magnetic resonance enterography (MRE), intestinal ultrasound (IUS), or capsule endoscopy, but when unavailable possibly computed tomography enterography (CTE) and small bowel follow-through (SBFT).

MRE is the preferred imaging modality at diagnosis and during follow-up as it allows to evaluate both the changes of the bowel wall and thus the degree of transmural inflammation, as well as perianal CD and extraintestinal complications (fistulae, abscesses) with no radiation exposure. In many LMICs, MR scanners are currently not widely accessible, especially in the smaller and more peripheral centers [49]. Moreover, the radiologist's expertise is another limitation of this technique, as no simple score systems for use in routine clinical practice have been developed so far. While SBFT is an alternative method to evaluate small bowel disease activity and extent, it is limited by the high-radiation exposure and the lack of assessment of peri-intestinal abnormalities [41]. Therefore, IUS which allows a dynamic real-time bowel assessment is a valuable alternative to MRE [50], even if its performance is strictly related to the operator's extensive training and experience. Published data report good performance of IUS for the diagnosis of CD (79.7% sensitivity, 96.7% specificity) and for the evaluation of already known disease (89% sensitivity, 94.3% specificity; [51]). Bowel wall thickness (≥3 mm) is the best IUS parameter for defining an active bowel disease with the highest sensitivity for ileal, right, and left colon lesions. Increased bowel wall vascularity or mesenteric hypertrophy are further signs of bowel inflammation that may be detected by IUS, as

are fistulae, abscesses, and stricture [51]. Based on those data, considering the wide availability, the low costs, and non-invasiveness for patients, IUS is the primary imaging modality in case of suspicion of PIBD or for disease monitoring. With regard to monitoring CD, cross-sectional imaging by IUS can be used [41], along with laboratory markers (CRP) and clinical evaluation. If available, small intestinal contrast ultrasonography (SICUS) is also an alternative to MRE, due to its good cost-efficacy and because it is also well-tolerated by patients [52]. Since capsule endoscopy, MRE and IUS were shown to be comparable in CD [53], monitoring can be performed by any of these as well as SBFT and CTE, based upon local availability and expertise. However, due to high-radiation exposure, SBFT and CTE should not be repeated routinely for patient monitoring.

Endoscopic Evaluation

Esophagogastroduodenoscopy (EGD) and ileocolonoscopy (IC) are costly and time-consuming but mandatory for the diagnosis of IBD and essential for disease monitoring. In PIBD, endoscopic evaluation is recommended to be performed by a pediatric gastroenterologist after an age-appropriate bowel preparation, under general anesthesia (GA) or deep sedation in a setting suited for children [9]. According to World Gastroenterology Organization, Global Guidelines even in LMICs adults with suspected IBD should have a flexible full-length colonoscopy including ileoscopy accompanied by biopsies, if available [37]. However, when it comes to PIBD, there is a striking difference between LMICs and HICs in the number of formally trained pediatric gastroenterologists [5]. While in some developed world regions there will be one pediatric endoscopist for every 100,000–200,000 inhabitants, in Bangladesh there are only 2 or 3 pediatric endoscopists for a population of around 150 million [54, 55]. In LMICs, late diagnosis, avoidable complications, and even death may occur in complex gastrointestinal cases because of limited health staff and specialists in pediatric gastroenterology [5]. As an alternative, pediatric endoscopy services might be performed by adult gastroenterologists in collaboration with pediatricians, which was reported by some LMICs to be proven safe and effective [56–58].

According to the NASPGHAN (North American Society for Pediatric Gastroenterology, Hepatology and Nutrition) guidelines for training in pediatric gastroenterology choosing the right type of anesthesia is a competency requirement [59]. Standardized pre-sedation risk assessment using the ASA-Physical Status Classification System should be performed in order to determine the appropriate level of sedation for EGD [60]. However, the choice of anesthesia not only depends on patient and procedure-related factors but also the limited availability of anesthesiologists. Anesthesiologist-administered sedation is preferred in children with ASA class III–V, while children in ASA class I and II can be examined safely by non-anesthesiologists [61]. All endoscopists performing pediatric procedures should be certified for pediatric advanced life support and familiar with resuscitation protocols including airway management [62].

ESGE (European Society for Gastrointestinal Endoscopy) and ESPGHAN guidelines suggest that the choice of the type of instrument should depend on the child's weight and age [63]. However, a standard adult gastroscope can be used for EGD in children with a body weight ≥10 kg and a standard adult gastroscope for colonoscopy, if a pediatric colonoscope is not available. For children 2.5–10 kg, a pediatric or adult gastroscope can be used for colonoscopy, and for infants <2.5 kg, a pediatric gastroscope should be used.

Endoscopic evaluation is recommended before major treatment changes, to diagnose complications (stenosis, dysplasia), and to exclude other diagnoses (ischemia or CMV infection). The standard CD endoscopic index of severity (CDEIS) and/or the simplified index, Simple Endoscopic Score for CD (SES-CD), which are validated endoscopic indices for the assessment of CD activity in children, are recommended [64, 65]. Complete mucosal healing (MH) is defined as an SES-CD or CDEIS of 0, while endoscopic remission is defined as SES-CD or CDEIS ≤2. For assessment of UC activity in children two easy-to-use scoring systems, the Mayo endoscopic score and UC Endoscopic Index of Severity (UCEIS) are recommended [64, 66]. ESPGHAN Porto IBD Group stated that a complete MH is defined as a Mayo or UCEIS of 0, while endoscopic remission is defined as Mayo or UCEIS ≤1.

According to the ECCO-ESGAR (European Society of Gastrointestinal and Abdominal Radiology) guideline for diagnostic assessment in IBD, small bowel involvement should be evaluated in all newly diagnosed patients with CD, with a small bowel capsule endoscopy (SBCE) as an option and/or small bowel endoscopy by means of capsule endoscopy (CE) or enteroscopy [41]. Capsule endoscopy has the advantage of detecting even residual inflammation despite normal serum and stool inflammatory markers, as well as MH, and has therefore rapidly expanded worldwide. However, it is expensive and is not yet available in most developing countries [67, 68], which is also the case for enteroscopy.

The cancer surveillance program recommended in pediatric UC after 10 years from disease onset should best be performed in remission in order to discriminate between dysplasia and inflammation and carried out by an experienced pediatric or adult gastrointestinal endoscopist [64, 66]. An independent gastrointestinal specialist pathologist is needed to confirm the presence of low-grade or high-grade dysplasia [41, 64] and surveillance intervals should be individualized according to a risk stratification (e.g., family history of colorectal cancer).

Histopathology

Standardized histologic examination of endoscopic biopsies is an essential component of initial diagnostic workup for IBD and follow-up. In children, further "PIBD-Classes" have been developed that standardize the differentiation into five categories [69, 70]. Also, the dynamic features of PIBD phenotype with changes in disease location and behavior over time should be captured adequately in order to ensure the therapeutic goal of "mucosal healing." To define such phenotypes in a standardized manner, the evidence-based "Paris Classification" of endoscopic and histopathological findings should be used worldwide, since this also offers long-term predictive properties (ileal location at CD diagnosis indicating a long-term worse outcome; [71]). However, recent surveys from LMICs have shown significant shortages of pathology services, which are both of insufficient scope, with a disproportionately low ratio of pathologists per patient population enumerating 1,555,000 patients per pathologist in Sub-Saharan Africa, as well as inadequate quality as compared with HICs [72]: Global Guidelines include therefore a "cascade for IBD diagnosis" depending on available resources. However, flexible full-length endoscopies with biopsies and histological interpretation are now generally recommended even in LMICs [37] with pathologists' workload and costs of material to be kept down as much as possible including standardized reduction in number obtained biopsies (Table 54.1).

Since Crohn disease-associated granulomas were found in a significant proportion of children only in the upper GI tract biopsies, EGD should be performed in all children at the initial evaluation with two or more biopsies obtained from each site, irrespective of the upper GI tract manifestations and endoscopic appearance [15].

For reliable diagnosis of UC and CD, ileocolonoscopy with a minimum of two biopsies from the inflamed regions should be obtained [41]. The revised Porto Group criteria recommend obtaining biopsies from the terminal ileum, cecum, transverse colon, sigmoid colon, and rectum [9]. Identifying histologic changes in areas that appear normal on endoscopy in order to stage the extent of disease is particularly important with regard to CD diagnosis, as is the assessment for non-caseating granulomas.

Differentiating CD from intestinal tuberculosis (ITB) is mandatory in the developing world, where TB may be endemic and where the IBD incidence is on the rise. In these regions, large or confluent/caseating granulomas would be indicative for ITB and caseating necrosis on biopsy is even regarded as the exclusive feature further emphasizing the importance of histology in LMICs [8]. Histopathologic findings such as crypt architecture distortion are features of chronic colitis and would be atypical in acute infectious colitis [37].

Digitizing slides, even up to 40,000–200,000 slides per month is feasible, albeit only in HICs. While this system is not yet widely used in clinical setting, digitization with digital whole-slide imaging (WSI) makes a specimen more reproducible thus allowing capture and visualization of the entire tissue on a slide [73]. WSI solutions allow for potential migration of the entire workflow from the manual to the digital and could eventually reduce barriers between hospitals, regions, and countries, thus facilitating pathology consultations and referrals. However, costs of adequate scanning systems are still much higher than of microscopes. While providing virtual pathology services at remote sites might eventually facilitate international consultations, it is important for now to focus on training histopathologists in LMICs, particularly regarding IBD diagnosis, and to enforce direct cooperation between LMIC and HIC institutions.

Pharmacological Therapy

Inflammatory bowel disease treatment is individualized with a broad variety of medical and surgical options, as well as nutritional therapy, particularly in PIBD (Table 54.2). In LMICs many of the recommended non-biologic IBD medications like corticosteroids, mesalamine, methotrexate, and 6-thioguanine are available and international guidelines as to their indications and use can be adhered to. However, several medications like budesonide, 6-mercaptopurine, and tacrolimus, and preparations as enemas are not. In addition, neither genetic testing for drug tolerability (TPMT genetics) nor therapeutic drug monitoring (TDM) can be performed. When initiating thiopurines weekly monitoring of blood counts in the first month of treatment, and from then on at regular intervals is therefore necessary to identify patients at risk of profound myelosuppression. Similarly, liver and pancreatic enzymes need to be obtained. To guide therapy in patients with a suboptimal response, potentially interesting is the use of applications that are predictive for a low 6-TG level or patients' non-adherence [74].

PIBD treatment with biologics is still a challenge in the vast majority of LMICs. Vedolizumab and ustekinumab are largely unavailable and although adalimumab (ADA) is more often available than infliximab (IFX), both medications are too expensive for health systems to bear their costs. Negotiations between treating physicians and health authorities remain largely ineffective leaving patients and families alone in their search for funding by private means through charities or pharmaceutical companies. The introduction of effective biosimilars with a potential to substantially reduce costs [75] is necessary on a large scale. A comparison of the cost-effectiveness of IFX and ADA is similarly important in this context and was one of the topics addressed in a systematic analysis of 11 randomized clinical trials in adult patients

Table 54.2 Pharmacological, nutritional, and surgical therapy: examples of modifications

Published recommendations (ECCO/ESPGHAN guidelines, position papers)	LMIC-specific modifications, alternatives, and considerations
Measuring thiopurine metabolites in patients with incomplete response on stable thiopurine dosage	• Check patients' adherence with therapy
Change in treatment in patients with active disease despite adequate 6-TG level after at least 12 weeks of thiopurine treatment	
Anti-TNF: Top-down strategy	• Implementation of equally effective biosimilars with substantial cost reduction
	• Research of cost-effectiveness SC vs. IV biologics in PIBD
Therapeutic drug monitoring for anti-TNF treated patients at end of induction and during loss of response	• Empiric anti-TNF dose increase/interval decrease, add immunomodulator
Options following anti-TNF failure: ileocecal resection for limited Crohn disease (CD) Colectomy in Ulcerative Colitis (UC)	Ileocecal resection for patients with limited CD (laparoscopic approach preferred, if available)
	• Cyclosporine IV in refractory CD and UC
Exclusive Enteral Nutrition (EEN) as first-line therapy in active luminal CD	Unavailability of EEN: (a) Other effective induction therapies: corticosteroids, combinations of antibiotics, CD exclusion diet, combined with Partial Enteral Nutrition (PEN) (b) Negotiations with official scientific bodies (National Societies for PGHN, supported by ESPGHAN/sister societies) with governmental bodies/ insurances • Search for other financial means (grants, foundations, supply by industry)
PEN for maintenance of remission in CD	• Immunomodulators
Nutritional assessment at follow-up food fortification and/ or supplemental formula in selected cases	• Specifically trained physicians or nurses to replace dieticians/NTs • Continuous training in PIBD nutritional aspects of nurses by physicians
In Acute Severe Colitis (ASC), daily monitoring of body weight, caloric intake, hydration status including review by dietician/nutritional therapist (NT)	
Monitoring of micronutrients, e.g., vitamins D, B12, folate	• Micronutrient supplementation on clinical grounds, if no laboratory tests • Vitamin D supplementation as a routine
Surgery	
Ulcerative colitis	
• Elective surgery: Restorative proctocolectomy (+ IPAA + covering loop-ileostomy), performed by experienced surgeon (at least 10 pouches/year) • ASC: Three-stage procedure (subtotal colectomy with ileostomy first) • Minimally invasive laparoscopic approach	• Travel of experienced surgeon from another center (national/HIC) needed
• Suspicion of pouchitis: pouchoscopy with mucosal biopsies at first suspected episode of pouchitis	• If colonoscope unavailable, use of gastroscope possible instead • If endoscopy unavailable: (a) Digital examination (b) Exclusion of intestinal infections (c) Repeated measurements of FCal
First-line therapy for pouchitis: 14-day course of ciprofloxacin and/or metronidazole Persistent cases: Combined metronidazole + ciprofloxacin or oral/topical budesonide Cuffitis: Topical mesalamine	
Crohn disease	
Prevention of postoperative recurrence: anti-TNF significantly better compared to conventional therapies, even in unselected patients with CD Infliximab and adalimumab equally effective in preventing endoscopic postoperative recurrence	If anti-TNF therapy unavailable, in children with limited (≤0 cm) non-stricturing ileocecal CD with failure of conventional therapy or with growth delay, resection should be considered a reasonable alternative

with CD [76]. While a comparable efficacy of both drugs was shown, it is understandable that a drug administered subcutaneously is less expensive since less personnel and infrastructure support is needed. In addition, traveling to appointments is less often required potentially adding to patients' adherence. However, the extent to which treatment costs are offset by improved outcomes and fewer hospitalizations and surgeries, needs further systematic evaluation. So far, studies comparing IBD biologics including their cost-effectiveness, have been solely in adults [77].

When anti-TNF-agents are used, TDM is recommended [78], but this is unavailable in LMICs. Therefore, in case of a lack of initial response or loss of response (LOR), an empiric dose increase/interval decrease is recommended, with the addition of an immunomodulator, if not already used as combination therapy. Dose-escalation, interval shortening, or both were shown to improve treatment efficacy [79]. In fact, two randomized controlled trials did not show that empirical escalation of infliximab is inferior to TDM-based escalation in patients with CD [80, 81]. The addition of an immunomodulator in patients who have lost response due to development of anti-drug-antibodies is an established strategy for regaining response while salvaging the anti-TNF therapy [82]. However, when a patient is not responding or losing response to one anti-TNF agent after treatment optimization, a switch within class (infliximab to adalimumab or vice versa) is recommended [78], because it has been shown that patients who are intolerant or experience immunogenic failure have a high rate of response when switching "in class" [83, 84]. In the absence of other biologic classes, there are a few options following anti-TNF failure, which might be considered in LMICs. Enteral therapy may be effective in some cases, while for more severe cases, ileo-cecal resection for limited CD can offer excellent short-term and long-term results. This may be true even in the treatment of naïve patients [85] as shown in a pediatric study with clinical remission rates of 79% at 1 year and 56% at 2.5 years post resection, along with a significant effect on linear growth [86]. Regarding the efficacy of cyclosporine for induction of remission in CD one study demonstrated benefit in terms of colectomy-free survival in patients with refractory Crohn disease colitis [87]. In patients with UC and in the absence of biologics, colectomy should be considered, or alternatively a trial of remission induction with cyclosporine as a bridge to maintenance thiopurine therapy. Cyclosporine and infliximab demonstrated similar short-term efficacy for corticosteroid-refractory and acute severe UC in four randomized controlled trials [88, 89].

In patients with acute severe ulcerative colitis (ASC), if available up-front intensified induction with infliximab should be considered (10 mg/kg at weeks 0, 1, 4 and every 4 weeks thereafter) until complete response is achieved. Once achieved, a cautious de-escalation to standard dosing can be considered under close monitoring [90].

Nutritional Therapy

ESPGHAN guidelines cover a wide variety of nutritional topics related to PIBD [45, 66, 78]. Apart from the recommendation of exclusive enteral nutrition (EEN) and special diets for a variety of indications, other aspects including clinical assessment of the nutritional status, treatment of selective mineral and vitamin deficiencies, or use of partial enteral nutrition (PEN) to support the nutritional status of children with IBD deserve attention. In fact, although many specific formulas and diets are not available in LMICs, adjustments of many recommendations related to nutrition in PIBD seem feasible.

Although EEN is the recommended first-line therapy in active luminal CD [78], in LMICs EEN may not be accessible to all patients or covered by health insurance. In such cases, other effective induction therapies may be used, such as corticosteroids (CS), combination of antibiotics, or a CD exclusion diet (CDED) in combination with PEN. Based on meta-analyses, CS are equally effective as EEN [91, 92] but aside from their well-known side effects, they have lower rates of mucosal healing [93, 94]. There are data showing effects of azithromycin plus metronidazole [95], as well as good tolerability and efficacy of CDED in induction of remission of mild-to-moderate luminal CD in children [96]. In both cases, replication studies are needed before stronger recommendations can be made.

If PEN is unavailable for nutritional support in PIBD, nutritional modifications and fortification of food under the supervision of trained dieticians are an alternative and PEN can even be omitted as a maintenance therapy if adequate medication like immunomodulator is available instead. If CDED plus PEN is used, the specific protocol should be followed as published [96] and strict supervision by trained personnel is necessary to prevent deviations from the diet. At the same time, comprehensive efforts are necessary to make EEN and PEN available for all pediatric patients with CD and covered by health insurance companies. This should be achieved by negotiations between official scientific and clinical bodies (National Societies for PGHN) with governmental bodies and insurers. In the meantime, other financial resources like grants, foundations, or industry should be utilized, ideally on the initiative of local PIBD experts and in PIBD centers.

According to the ESPGHAN position paper on Nutrition in PIBD, a regular nutritional assessment should also be an integral part of follow-up and food fortification and/or supplemental formula are recommended in select cases [97]. In ASC, body weight, caloric intake, and hydration status should be monitored daily, including review by a dietician as needed [45]. However, in LMICs, there are often neither dieticians nor nutritional therapists (NT) available. Although a specifically trained physician or nurse can partly fulfill this role, dedicated dieticians or NTs are indispensable to any PIBD center. At the same time, PIBD specialists should regularly train dieticians/NTs and IBD nurses regarding all aspects of EEN/PEN.

Monitoring of micronutrients like vitamin D, folic acid, and B12 status is recommended at least in selected PIBD patients [97], as is DXA in high-risk patients with prolonged

malnutrition, delayed puberty, and/or steroid dependency [66]. However, in some LMICs, less common laboratory tests to measure vitamin or trace element levels, or DXA imaging may be lacking and/or are not covered by health insurance. Again, negotiations with responsible authorities are needed to achieve implementation and financial coverage of these important laboratory and imaging methods, which cannot be replaced by other less costly investigations.

Surgery

Despite recent significant advances in medical management, surgery continues to play a major role in the management of PIBD. As previously stated, in many LMICs, experience with PIBD is limited due to a lack of resources and infrastructure, and the absence of trained specialists in pediatric gastroenterology, as well as pediatric surgery.

A surgeon in LMICs is most likely to encounter PIBD during the course of an exploratory laparotomy for suspected appendicitis. Owing to an often observed background of malnutrition in many instances, primary anastomosis and strictureplasty are associated with significant risks. Parenteral nutrition is often unavailable and post-operative management of complex surgical interventions is therefore extremely challenging. Because of religious requirements, there is often a strong resistance to a stoma in Muslim cultures, although a religious ruling to accommodate such conditions exist [98]. The stigma of a stoma might compromise marriage and reduce the chances of starting a family. Surgeons often find themselves in a difficult position when it comes to surgical options and outcomes are difficult to quantify when compromises have to be made. In addition, continuity of medical care often falls to the individual surgeon and patients are dependent on the enthusiasm and expertise of an individual practitioner [99].

In UC, total colectomy is curative and restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA) and a covering loop-ileostomy is the recommended elective surgery [45]. Three-stage procedure (subtotal colectomy with ileostomy first) is recommended for patients with complicated disease like acute severe colitis or severe malnutrition. However, the final choice of the surgical approach should be individualized. In a multicenter retrospective ESPGHAN study, surgeon's experience of <10 pouch surgeries/year (regardless of whether pediatric or adult surgeon) was the only factor associated with increased rate of (chronic) pouchitis [100]. However, in a survey of UK pediatric surgical centers, the median experience with IPAA was 0.9 cases/year of consultant practice and the majority had arrangements for joint operating with adult surgeons [101]. In LMICs, children with UC who require this type of surgery or a three-stage procedure should be operated in a pediatric care environment and in all instances collaboration of pediatric and adult surgeons is imperative. Creation of a national network and at least one IBD Referral Center/country, or in the closest country nearby, as well as visiting programs could be beneficial. Experienced surgeons from HICs could assist and advise surgeons from LMICs during surgeries (live video communication, "Tele-Porto," see ESPGHAN homepage), thus building twinned centers (exchange programs between LMIC and HIC centers). Given the risk of postoperative complications, especially with limited experience plans should be in place for follow-up consultation and alternative management in case of subsequent complication.

The ECCO-ESPGHAN guidelines recommend pouchoscopy at the first suspected episode of pouchitis [45]. If there is no available colonoscope to perform pouchoscopy with biopsies, according to recent adult guidelines, a gastroscope might be used and valuable information could be added by a digital examination [102]. There is consistent evidence that FCal is also a useful surrogate marker in the postoperative setting, as it shows a good correlation with the presence of pouchitis, confirmed by endoscopy. Serial measurements of FCal in asymptomatic patients can predict the short-term development of pouchitis, thus leading to early medical intervention [103]. In refractory pouchitis, not responding to the recommended antibiotic therapy (ciprofloxacin and/or metronidazole) and if no anti-TNF agents are available, thiopurines could be used. Topical mesalamine is recommended only for treating cuffitis.

Surgery for CD is not curative and limited resection is the key principle thus preserving bowel length. Surgical resection in children with CD is usually reserved for those who are refractory to anti-TNF therapy, have stricturing [B2] disease with prestenotic dilatation, or penetrating [B3] disease [104]. In the recent LIR!C trial which compared laparoscopic ileocecal resection and infliximab treatment in non-complicated patients with CD, the long-term outcome of patients in the surgical arm was excellent, with only 26% of 69 patients requiring anti-TNF therapy and none requiring a second resection [105]. Laparoscopic ileocecal resection was a cost-effective treatment and provided quality-of-life outcomes similar to treatment with IFX [106]. Another adult study compared early surgery in this category of patients with biologic treatment. Costs were significantly lower for early surgery vs. biologic treatment. Also, the quality-adjusted life years value was significantly better for early surgery vs. biologics (6.24 ± 0.01 and 5.81 ± 0.01, respectively). All these data support the strategy of early surgery (higher efficacy and less cost) compared with biologic therapy [107]. Hence, laparoscopic resection of both stricturing and actively diseased terminal ileum [<40 cm] can be offered as a sound therapeutic option in an interdisciplinary context, with a benefit and risk profile comparable to medical therapy [108]. Pediatric data are scarce and no RCTs are available,

but favorable clinical remission rates after resection have been shown, as mentioned previously [85]. Since for most patients surgery is not curative and postoperative recurrence (POR) is common, postoperative endoscopic evaluation at 6–9 months after bowel resection is recommended [64] to guide treatment adaptation. However, in LMICs, colonoscopy may be not easily available and Fcal and IUS can be considered as non-invasive alternatives to detect postoperative recurrence, especially after small bowel resection [41]. In patients who underwent surgical resection, and if anti-TNF-agents are not available, shortly after surgery thiopurine over 5-ASA maintenance is recommended to reduce postoperative recurrence risk. Metronidazole and enteral nutrition can be considered as alternatives, and 5-ASA may be considered for colonic disease. However, in patients with high risk of recurrence, any effort to provide anti-TNF agents should be made as strong evidence in adults with ileocolonic resections and primary anastomoses shows that they are the most effective strategy for the prevention of endoscopic recurrence [78]. A meta-analysis of studies including the comparison of anti-TNF (IFX, ADA) to non-biological comparators (azathioprine, mesalamine, and placebo) showed that anti-TNF-agents were significantly better in preventing clinical, endoscopic, and severe endoscopic and histological POR compared with conventional therapies, even in unselected CD patients. IFX and ADA proved to be equally effective in preventing endoscopic POR [109]. Even if the evidence is weak in support of the use of 5-ASA/sulfasalazine and antibiotics, they could represent an option in LMICs. Use of metronidazole is supported by a recent study, in which a metronidazole course over 3 months was associated with significantly lower endoscopic recurrence versus the control group [110]. Most pediatric CD patients in real-world settings will receive maintenance therapy administered within 4 weeks from surgery [78]. Anti-TNF naïve patients may use a thiopurine. However, endoscopic recurrence on thiopurine monotherapy should trigger a step-up to anti-TNF therapy, and IFX and ADA are probably equally effective in reducing POR [78]. However, since in many LMICs, no anti-TNF biosimilars are available, the options are limited. Relapse prevention with methotrexate might be an option, but there are no specific data available in this regard.

Conclusion

Pediatric IBD has become a global disease but its adequate management in LMICs remains a substantial challenge probably for years to come. Enhancing possibilities of formal training in pediatric gastroenterology including endoscopy, histopathology, and surgery is crucial, as is the continuous search for optimizing low-cost diagnostics and therapies. ESPGHAN has therefore initiated PIBD Masterclasses to be held regularly in LMICs and at a low cost. Voluntary peer-to-peer remote consultations for difficult PIBD cases by experts of the ESPGHAN "Porto Group" were also implemented, and are meant as a "physician-to-physician telemedicine service." Finally, an ESPGHAN Position paper on PIBD care in limited resource countries is underway and will address in detail the topics outlined in this chapter.

Immunizations in the Child with Inflammatory Bowel Disease

55

Athos Bousvaros and Ying Lu

Introduction

The vast majority of children and young adults with inflammatory bowel disease (IBD) will undergo treatment with immunosuppressive medications at some point during their lives. Such treatment may be short lived (e.g., a brief course of corticosteroids during a colitis flare) or prolonged (e.g., combination therapy with immunomodulators and infliximab for moderate to severe Crohn disease) [1]. Treatment with immunomodulators or biologics increases the risk of opportunistic infections, such as herpes zoster [2, 3], Epstein-Barr virus [4], or cytomegalovirus [5]. Some of these illnesses (especially influenza, pneumonia, and varicella) are potentially preventable by the judicious use of vaccines. While the ideal time to immunize patients with IBD is prior to the onset of any immunosuppression, for many patients delaying treatment to "catch up on immunizations" is not possible. Papers in both adults and children have emphasized the safety of inactivated vaccines in immunocompromised IBD patients [6–8]. Most such papers also suggest withholding live vaccines in this population, despite a paucity of data on this topic [7]. The Infectious Diseases Society of America has also prepared a guideline on vaccination of the immunocompromised host which provides in-depth recommendations, as well as areas highly in need of future research [9].

Underimmunization

The immunization rate for routine primary vaccines varies greatly among children with IBD around the world, ranging from 24% in France [10] to 90% in Canada [11] and Australia [12]. However, vaccination rates tend to be especially low for varicella (18–39%) [13, 14], pneumococcus (4–32%) [10, 12, 13, 15], meningococcus (24%) [13], human papillomavirus (HPV) (6–42%) [13, 14], and influenza (8–30%) [10, 12, 13, 16]. Factors contributing to low influenza vaccination rate include concerns that the vaccine will be ineffective, fear that patients will experience an adverse effect of the vaccine, concerns that the vaccine may cause a flare of their disease, and that the vaccine was not offered to patient [10, 16, 17].

In a survey of 178 pediatric gastroenterologists, only 28% believed that primary care providers (PCPs) were solely responsible for immunizations. The vast majority (94%) of pediatric gastroenterologists routinely assessed immunization status. Specifically, 63.5% assess at time of diagnosis, 30% at "well" visits, and 44% before starting immunosuppressive therapy. Vaccines most commonly assessed were influenza, hepatitis B, and varicella. Physicians were more likely to review immunizations if they implemented a reminder mechanism. The most common barriers to vaccination included inability to offer vaccinations in the immediate area, lack of coordination of care with PCP, and poor access to immunization records [18]. In a survey of adult patients with IBD, 50% acknowledged that preventing infectious diseases was important for patients, but this did not result in getting immunized. Main reasons for not getting vaccinated included lack of information from physician (47.5%), lack of awareness (35%), perceived lack of benefit (33%), and concerns about adverse events (26%). Patients thought the most reliable source of information about vaccinations was their gastroenterologist (58%) compared to general practitioner (35%) [19]. These concerns have been addressed by several pediatric studies that demonstrate inactivated vaccines are generally safe and effective in children with IBD [8, 19–23]. Therefore, methods to increase vaccination rates include

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_55

educating patients, providing the vaccine in the gastroenterology clinic [24], coordinating care among the gastroenterologist, PCP and patient, utilizing a reminder system (by having a checklist or inclusion in electronic record template) [18], utilizing nurses, and prescribing vaccines to be administered at a local pharmacy if vaccines cannot be administered at the medical office [25]. If patients are not seen regularly, an automatic reminder can be sent through the patient portal to get vaccinated [26].

The authors of this chapter recommend that the pediatric subspecialists share responsibility with the PCP in making sure their immune compromised patients are protected against vaccine-preventable diseases, such as influenza. Children with IBD often have more frequent visits to their specialist than general pediatrician and look to the specialist to assess benefits and risks of various interventions (including immunization). The GI specialist therefore has an important role in educating patients about vaccines and in making sure that the appropriate vaccines are administered (either by the pediatrician or specialist) at the appropriate times.

Who and When to Immunize?

The Centers for Disease Control and Prevention published an updated immunization schedule, summarized in Table 55.1. It is generally recommended by experts in the field that inactivated vaccines be given as per the recommended schedule to patients with IBD [27]. There is a theoretical risk of viral dissemination with live vaccines in patients who are receiving "significant immunosuppression." Fortunately, IBD is uncommon in the child under 5 years, so the majority of live vaccines [including Measles/Mumps/Rubella (MMR), varicella] will be completed before the onset of the disease and before the onset of immunosuppressive therapy.

Patients receiving aminosalicylates as monotherapy are not considered immunosuppressed. These patients may receive all immunizations as recommended in Table 55.1. Patients considered "significantly immunosuppressed" include those who are severely malnourished or receiving high-dose steroids (≥20 mg/day or ≥2 mg/kg/day for at least

Table 55.1 Summary of immunization recommendations from Centers for Disease Control and Prevention [60]

Immunization	Type	Route of administration	Patient age at time of recommended administration
Hepatitis B	Inactivated	Parenteral	0–18 months (three doses)
Diphtheria and tetanus toxoids and acellular pertussis	Inactivated	Parenteral	2–6 months (three doses) 15–18 months (one dose) 4–6 years (one dose)
Tetanus and diphtheria toxoids and acellular pertussis	Inactivated	Parenteral	11–12 years (one dose)
Haemophilus influenza type b	Inactivated	Parenteral	2–6 months (three doses) 12–15 months (one dose)
Pneumococcal	Inactivated	Parenteral	2–6 months (PCV13 vaccine, three doses) 12–15 months (PCV13 vaccine, one dose) 2–18 years (in immunocompromised patients, PCV13 and/or PPSV23 depending on prior pneumococcal vaccinations, revaccinate with one dose of PPSV23 5 years after first dose of PPSV23)
Inactivated poliovirus	Inactivated	Parenteral	2–18 months (three doses) 4–6 years (one dose)
Hepatitis A	Inactivated	Parenteral	1–2 years (two doses)
Human papillomavirus	Inactivated	Parenteral	11–12 years (two doses if initial dose given at 9–14 years old; three doses if initial dose given at 15 years or older)
Meningococcal	Inactivated	Parenteral	11–12 years (one dose) 16 years (one dose)
Influenza injection	Inactivated	Parenteral	6 months, then annually Younger than 9 years, two doses if not previously received two doses of tri- or quadrivalent influenza vaccine
Influenza intranasal	Live attenuated	Intranasal	2 years, then annually
Rotavirus	Live attenuated	Oral	2–6 months (two or three doses depending on brand)
Measles Mumps Rubella	Live attenuated	Parenteral	12–15 months (one dose) 4–6 years (one dose)
Varicella	Live attenuated	Parenteral	12–15 months (one dose) 4–6 years (one dose)

14 days), thiopurines, methotrexate, cyclosporine, tacrolimus, anti-tumor necrosis factor therapy, ustekinumab, tofacitinib, vedolizumab, and natalizumab. For this group of patients, live vaccines are generally not recommended [6, 7, 27]. Therefore, it is ideal to immunize prior to starting immunosuppressive therapy, especially with live vaccines. If the patient is clinically stable enough to start immunosuppressive therapy at a later time, then it is ideal to wait at least 4 weeks after varicella vaccination, and at least 6 weeks after MMR vaccination, to initiate therapy. If the patient will be taken off immunomodulators or biologics, it is recommended to wait at least 3 months prior to administering live vaccines, and for corticosteroids, at least 1 month [6, 7].

Inactivated Vaccines in Children with IBD

In general, a useful rule is that inactivated vaccines can be administered safely to IBD patients, irrespective of the degree of immunosuppression. In a recent meta-analysis, 39–100% of children with IBD demonstrated adequate immunogenicity post-vaccination in general. Immune response to vaccines was not significantly decreased in pediatric IBD patients receiving immunosuppressive therapy compared to those on non-immunosuppressive therapy or healthy controls [23]. The majority of patients in general achieved post-vaccination seroprotective levels. However, among all vaccines, influenza B induced the weakest immunogenicity. Patients did not experience vaccine-associated serious adverse side effects or IBD flares [23, 27].

The trivalent influenza vaccine is both safe and immunogenic in children and young adults. This vaccine is usually administered in the fall and protects against three strains of influenza. The trivalent influenza vaccine has generated protection against two strains of influenza A and one strain of influenza B. (In recent years, the quadrivalent influenza vaccine was developed which included a second strain of influenza B.) Three prospective studies have demonstrated that the trivalent influenza vaccine is usually well tolerated in children with IBD, including those receiving immunosuppressive therapy. However, immunogenicity may be reduced, especially in patients receiving biologic therapy. Mamula et al. performed a prospective study using the 2002–2004 vaccine, in which 51 children with IBD and 29 healthy children were immunized. Compared to the healthy controls, children with IBD receiving combination therapy (with immunomodulators and biologics) were less likely to respond to two of the three strains in the influenza vaccine [28]. In contrast, Lu et al. demonstrated a good response to the 2007–2008 influenza vaccine, and a high prevalence of seroprotection to both influenza A strains in the vaccine. The less immunogenic influenza B strain, however, resulted in a decreased rate of seroprotection in patients receiving anti-TNF therapy [29]. DeBruyn and colleagues again demonstrated excellent safety and immunogenicity to the two A strains in the vaccine but decreased immune response to the B strain [30]. It should be noted that strain B is also less immunogenic even in healthy children [31]. A subsequent study by deBruyn of 137 children with IBD receiving maintenance infliximab therapy demonstrated that timing of vaccination relative to infliximab infusion (immunization at time of infliximab versus midway between infusions) did not impact serological protection [32]. None of these studies demonstrated any increase in adverse events or increase in IBD flares. In summary, data from influenza vaccine studies in pediatric IBD support the recommendation that children with IBD receive annual influenza immunizations. Even patients on immunosuppressive therapies respond well to the two A strains in the vaccine, though antibody titers to the B strain may be reduced.

Hepatitis B vaccination has also been assessed in children with IBD. Patients with latent hepatitis B who are treated with anti-tumor necrosis factor inhibitors are at risk for viral reactivation leading to severe viral hepatitis or even liver failure [33, 34]. In studies where pediatric IBD patients were tested for immunity against hepatitis B, 49–63% were found to have the antibodies [35, 36]. Urganci et al. administered the hepatitis B vaccine series to children with IBD who were not previously vaccinated. Seroconversion was achieved in 70% of IBD patients compared to 90% of healthy controls ($p = 0.02$). Of children who did not achieve seroconversion, a subsequent booster dose resulted in an adequate response in 50% (7/14) of IBD patients and 60% (3/5, p = NS) of controls. There were no vaccine-associated adverse events [20]. Moses and colleagues conducted a prospective study of hepatitis B status in their pediatric IBD population on infliximab therapy and documented that 13% had never been immunized against hepatitis B, and that approximately half of patients who were previously immunized did not have protective levels of anti-HBs. The investigators then administered a booster vaccine to 34 of these patients without protective titers and noted a 76% response rate. Children and young adults receiving infliximab more frequently (approximately every 5.9 weeks) were less likely to respond to the booster dose of hepatitis B [35]. In the adult IBD scientific literature, Gisbert and colleagues found that therapy with anti-TNF was associated with a suboptimal vaccine response, but not with immunomodulators [36]. In another study, Gisbert et al. demonstrated that the rate of seroconversion for patients who received the vaccine series on an accelerated double-dose schedule (months 0, 1, 2) was higher than the single dose at the standard schedule (months 0, 1, 6) (75% vs. 41%, $p < 0.001$) [37].

Of children with IBD tested for hepatitis A antibody testing, 21–51% were found to have immunity [14, 20]. Studies evaluating the immunogenicity of hepatitis A vaccine sug-

gest that both children and adult patients with IBD mount an excellent response (97–100%) after receiving two doses [20, 21, 38]. However, the rate of seroconversion was lower in adult patients on anti-TNF therapy compared to those who were not on anti-TNF therapy (92.4% vs. 99.1%, $p = 0.001$), and in patients treated with ≥2 immunosuppressants compared to those on <2 immunosuppressants (92.6% vs. 98.4%, $p = 0.03$). There was no difference in rate of seroconversion between patients on TNF inhibitor monotherapy and those on TNF inhibitor combined with another immunosuppressant [38]. The vaccine was safe and did not exacerbate IBD [20, 21].

The theme of suboptimal immunogenicity associated with TNF inhibitor therapy extends to pneumococcal vaccine as well. One pediatric study of patients with IBD aged 5–18 years with no history of pneumococcal immunization were administered one dose of pneumococcal conjugate vaccine (PCV13). Immunogenicity was similar between patients with IBD and healthy controls (90.4% vs. 96.5%, p = NS). However, the geometric mean titer was higher in patients who were not on immunosuppressive therapy compared to those who were treated with TNF inhibitors or immunomodulators [39]. These findings are similar to a recent adult IBD study by Pittet and colleagues, where the seroprotection rate of PCV13 vaccine increased from 43.9% at baseline to 90.4% post-vaccination ($p < 0.001$). However, patients treated with TNF inhibitor therapy attained slightly lower seroprotection rates than counterparts on other types of immunosuppressive therapy (thiopurine, methotrexate, oral corticosteroids) or non-immunosuppressive therapy. The vaccine was safe for all treatment groups [40]. Several studies within the adult IBD literature agree that the immune response to 23-valent pneumococcal polysaccharide vaccine (PPSV23) is decreased in patients receiving TNF inhibitor therapy (either as monotherapy or in combination with immunomodulators, 45–63%) compared to patients not receiving immunosuppressive therapy (78–89%) and to healthy controls (85%). Immunomodulator monotherapy was not associated with a hindered immune response (79%) [41–43]. The vaccine was well-tolerated without serious adverse events [39, 42, 43].

In contrast, the immunogenicity of HPV vaccine does not appear to be diminished by immunosuppressive therapy. Jacobson and colleagues administered three doses of Gardasil to girls and young women age 9–26 years while being treated with immunomodulator or TNF inhibitor therapy for IBD. All patients developed an excellent immune response with 96–100% seropositivity to HPV types 6, 11, 16, and 18. The geometric mean titers for each serotype were similar to those of healthy historical female controls from Merck. The IBD patients did not have experience serious adverse events or worsened disease activity related to the vaccine [22]. Similarly, immunosuppressive therapy does not hinder the immune response to *Haemophilus influenza* type b vaccine. A small study by Dotan and colleagues concluded that thiopurine monotherapy generally does not impair the cellular or humoral response to the vaccine in adults with IBD [44].

This theme of adequate immunogenicity is again reflected in two prospective studies that administered the diphtheria [23] and pertussis [45] booster vaccine in adolescents with IBD who had no history of booster immunization after age 6 years or a history of infection. Subjects achieved a similar seroprotection rate for diphtheria irrespective of whether they were treated with or without immunosuppressive therapy (93.8% vs. 92.9%, p = NS). Similarly, there was no difference in response rates for pertussis booster among patients with IBD receiving no immunosuppressive therapy, those on thiopurine monotherapy, those on combination thiopurine and TNF inhibitor therapy, and healthy controls [45]. There were no vaccine-associated serious adverse events for either booster [23, 45].

Immunizing the Child with IBD: Practical Aspects

When a child is newly diagnosed with IBD, the ideal time to immunize is before the start of any immunosuppressive therapy. However, as many children with IBD are acutely ill, treatment can often not be withheld. Thus, the clinician is often caught between "a rock and a hard place": should the patient be immunized and treatment postponed, or should therapy be instituted with plans to vaccinate at a later time? Making these decisions involves a careful assessment of the risk/benefit ratio and an informed discussion with the parents. If possible, one can consider using exclusive enteral nutrition to induce remission and buy time to catch up on immunizations before starting immunosuppressive therapy.

For patients with mild to moderate ulcerative colitis who are undergoing corticosteroid induction, but in whom maintenance therapy with aminosalicylates is planned, immunizations can usually be postponed until after an initial course of corticosteroids. Once corticosteroids are weaned, and aminosalicylate therapy is started, both inactivated and live vaccines can be given. There is no consensus on how long corticosteroids need to be stopped before immunizations are given, but expert opinion suggests that 4 weeks after discontinuation of steroids is probably safe [6, 9].

More problematic is the child with moderate to severe Crohn disease or ulcerative colitis who may require corticosteroid treatment and subsequent immunosuppression with thiopurines, antibody to tumor necrosis factor, or calcineurin inhibitor. In these children, obtaining immunization records from the primary care pediatrician and assessing whether the recommended immunization series have been administered is important. If children received their recommended MMR

and varicella immunizations in childhood, they are probably at low risk of contracting these illnesses. Pediatric patients with IBD who had titers drawn were found to have immunity to 66% to measles, 61% to mumps, and 79% to rubella [14]. Obtaining individual serum titers to measles and varicella virus may also be helpful in documenting immunity. A positive antibody to measles virus is relatively good evidence of ongoing seroprotection, but the antibody to varicella vaccine is less reliable.

One area of ongoing controversy is whether varicella vaccine can be safely administered to some children on immunomodulators. The American Committee on Immunization Practices does allow for the administration of zoster vaccine (which is more potent than varicella vaccine) to adults on low-dose 6-MP (≤1.5 mg/kg/day), azathioprine (≤3 mg/kg/day), or methotrexate (≤0.4 mg/kg/week) [46]. Of children diagnosed with IBD, the percentage who have immunity to varicella varies widely, from 9% in the UK to 71% in Canada, with older age being associated with seroprotection [14, 47]. Moreover, Harris and colleagues in the UK retrospectively collected data over a decade (2009–2018) and found that pediatric patients with IBD who were immunized with varicella needed less post-exposure prophylaxis (0% vs. 28%, $p = 0.0006$) and had fewer varicella-related hospital admissions (4% vs. 22%, $p = 0.01$) compared to those who were not immunized [47]. Our group published a case series of six children with IBD on 6-MP or infliximab therapy who had received varicella vaccine (either inadvertently by their primary care physician, or deliberately after discussion of risks and benefits), and all experienced no adverse effects. Five of the six children developed an immune response [48]. Ansari et al. vaccinated ten pediatric patients with IBD with a negative or unknown varicella titer prior to starting immunosuppressive therapy. Post-vaccination antibody levels were obtained in eight of these ten patients, and all eight responded [49]. Thus, in the rare situation where there is a high prevalence of wild-type varicella, the benefits of protection against the wild-type virus might outweigh the risk of the immunization. Clearly, more data are needed in this very understudied area.

Another question that frequently comes up in these patients is whether family members can receive routine live vaccines. Once again, there is a paucity of data. Expert opinion suggests that family members can receive live vaccines (including measles, varicella, or zoster vaccine) except the oral polio and intranasal influenza vaccine, even if there is an immunosuppressed patient with IBD in the house. However, if a vaccine-associated rash develops in the affected family member, they should avoid close contact with the patient until lesions clear [9, 50]. Unfortunately, a study by Waszczuk and colleagues on this "cocoon immunization strategy" to protect immunocompromised patients by vaccinating close contacts found that only 40% of children of adult patients with IBD were immunized with at least one recommended vaccine. The most common reasons parents gave for not vaccinating their children were belief that immunizations were unnecessary (52%) and concern about side effects (25%) [51].

Women with IBD of childbearing age are often receiving immunomodulators and biologics to keep their disease in remission throughout pregnancy. Infliximab, if given in the third trimester, can pass transplacentally and enter the fetus's bloodstream. Therefore, there is potential for infants born to women with IBD to have a reduced response to inactivated vaccines, and to be at risk for complications of live vaccines. However, in a small study, immunoglobulin levels (IgG, IgM, and IgA) and antibodies to tetanus toxoid and *Haemophilus influenza* type b (Hib) were drawn in infants at least 6 months old of age and born to mothers who received at least one dose of infliximab or adalimumab during the third trimester. The study found that all infants had adequate immunoglobulin levels except half had a low IgM level. The vast majority (92%) mounted an adequate response to both tetanus and Hib vaccines [52]. A study by Beaulieu and colleagues demonstrated similar findings. Infants of mothers with IBD treated or not treated with biologic therapy during pregnancy had similar seroprotection rates between the two exposure groups for Hib (71% vs. 50%, $p = 0.41$) and tetanus toxoid (80% vs. 75%, $p = 0.66$). The median infliximab level in cord blood was similar between infants who did or did not mount seroprotective levels to Hib ($p = 0.3$) or tetanus toxoid ($p = 0.93$) [53].

For patients in whom influenza or varicella infection is suspected or confirmed, immunosuppressive therapy should be held until the patient is clinically improving or the infection resolves. Patients with IBD, regardless of their medication status, should be treated with antiviral medications (including oseltamivir) when clinically indicated. If patients being treated with immunosuppressive therapy lack immunity against varicella and experience a significant exposure to varicella, then VariZIG or acyclovir should be given. VariZIG should be administered as soon as possible and within 96 h of exposure. If >96 h have elapsed since exposure, or VariZIG is unavailable, then some experts suggest giving acyclovir within 7–10 days of the initial exposure. If immunocompromised patients acquire varicella infection, then intravenous acyclovir is recommended [54].

COVID-19 Infection and Vaccine Development: Relevance to Inflammatory Bowel Disease

At the time this chapter is being written, we are in the midst of a pandemic with a coronavirus variant called COVID-19 (COrona VIrus Disease-2019). As of January 2021, approx-

imately 85 million cases of COVID-19 have been reported worldwide, with 1.8 million deaths. The United States is the epicenter of the pandemic, with approximately 20 million cases reported, and over 345,000 deaths [55]. COVID-19 is a positive-sense single-stranded RNA virus, transmitted primarily through droplets. The most important protein in the COVID-19 virus is called the spike (S) protein, which is divided into two main subunits. The S1 subunit regulates receptor binding to cells through angiotensin-converting enzyme 2, and the S2 subunit promotes membrane fusion [56]. Common clinical symptoms of COVID-19 infection include cough, fever, myalgia, shortness of breath, and loss of taste or smell. The COVID-19 virus is highly contagious, and in a subset of individuals can result in severe pneumonia or death. Individuals thought to be at high risk include the elderly, obese patients, individuals with diabetes, and patients on high levels of immune suppression. Studies thus far of the IBD population suggest that corticosteroid therapy may increase the risk of severe COVID-19 infection, while patients on anti-TNF agents do not appear to be at increased risk for severe disease [57]. Fortunately, pediatric patients seem to have a lower risk of disease than older adults.

The pandemic has resulted in an unprecedented and highly ambitious scientific program to develop vaccines, so the pandemic may be curtailed. As of January 2021, a number of vaccines have already been developed, and been tested in phase 3 trials. At this point in time, two vaccines have been given emergency use authorization (EUA) by the Food and Drug Administration to be administered in the United States: one developed by Moderna and the National Institute of Allergy and Infectious Disease, and the other developed by BioNTech and Pfizer. Both these vaccines target the RNA region that generates the spike protein. At the current time, these vaccines are only being administered to healthcare professionals and very high-risk individuals, but we anticipate that this will change significantly by the time this chapter is published. For both of these vaccines, two immunizations are necessary. The BioNTech-Pfizer vaccine is administered as a two-dose series, 3 weeks apart, and according to the EUA, can be administered to individuals over 16 years of age. In contrast, the Moderna vaccine is administered as two doses 1 month apart, and under the EUA can be given to individuals over 18 years of age. Based on phase 3 trials, the vaccines have over 90% efficacy in the general population, though the efficacy in the elderly may be slightly decreased (around 85%). Adverse effects include injection site pain, fatigue, headaches, muscle aches, chills, and fever [58, 59]. Given that these vaccines are inactivated, we anticipate that they will be administered to patients who are receiving immune suppressive therapy in the future. However, at the time this chapter is being written the authors do not have any data on the safety or efficacy in patients with IBD. The recommendation at the current time is to follow current CDC guidelines for prevention of COVID-19 infection, including appropriate social distancing, good hand hygiene, and mask wearing; see www.cdc.gov for additional information on COVID-19.

Summary

Immunizations that can be given safely and should be given to children with IBD as part of the recommended immunization schedule include diphtheria and tetanus boosters, influenza, pneumococcal, meningococcal, human papillomavirus, hepatitis A, and hepatitis B. In general, the less immunosuppression a patient is receiving, the more likely they are to mount an effective immune response. Live vaccines, including measles virus and intranasal influenza vaccine, should not be given to IBD patients being treated with immunosuppressive therapy. Varicella live attenuated vaccine has been given without complication to some patients on mild immunosuppression but is generally not recommended. Therefore, providers should ideally inquire about immunization status at time of diagnosis and vaccinate if necessary prior to starting immunosuppressive therapy, especially in the case of live vaccines. Both primary care physicians and patients need additional education on the safety and efficacy of inactivated vaccines.

Colitis-Associated Cancers

56

David Faleck and David Kelsen

Clinical Presentation of Colitis-Associated Cancers

The signs and symptoms of a primary colitis-associated cancer frequently overlap with those of active inflammatory bowel disease. For patients with ulcerative colitis and Crohn disease who have ongoing symptoms of IBD, change in bowel function is a frequent occurrence. Diarrhea and rectal bleeding may be attributed to active IBD, and abdominal pain and bowel obstruction may be interpreted as sequelae of IBD. More ominous signs such as anorexia and weight loss may also be ascribed to active IBD. Patients with Crohn disease involving the small bowel may undergo surgery for stricturing disease, and it may not be recognized until during the operation, or even until pathology is reviewed that there was malignant transformation of the bowel. For patients with less active IBD, which may have been quiescent for years, new symptoms may also be ascribed initially to a flare and managed medically. Thus, a delay in diagnosis appears to compound a more aggressive biology (see Systemic Therapy for Advanced Colitis-Associated Cancer, below), which results in a large percentage of CAC being diagnosed at more advanced stages [1]. The overlap in signs and symptoms of the underlying inflammatory bowel disease with those of developing cancer in an IBD patient leads to an emphasis on prevention and early detection.

Pathogenesis and Genomic Alterations in Colitis-Associated Bowel Cancers

Currently, colitis-associated cancers are felt to be due to direct or indirect effects of chronic inflammation. As opposed to CAC, the key genomic-driving factors in the development of the much more common sporadic colorectal cancers (CRC) have been known since the late 1990s [2, 3]. Rather than arising from dysplasia in a chronically inflamed IBD gut mucosa, mutations in the Wnt or Mismatch Repair pathways lead to the development of adenomatous polyps. The pathways of sporadic CRC and its precursor adenomatous polyp mirror those occurring in familial cancer syndromes (Familial Adenomatous Polyposis (FAP) and Lynch Syndrome, responsible for ~3–5% of CRCs), which are the result of an inherited (or for ~30% of FAP patients, spontaneously acquired) germ-line cancer susceptibility gene.

Eighty to eighty-five percent of sporadic colorectal cancer develops in the setting of abnormalities in the Wnt pathway. In this process, loss of *APC* (a tumor suppressor gene) function due to point mutation occurs as an initiating or "gatekeeper" event for subsequent molecular alterations that culminate in the development of an adenoma. This is the key genetic abnormality in FAP, which leads to widespread development of innumerable adenomas. Loss of TP53 (also a tumor suppressor gene) function occurs later in the sequence, typically at the transition of an adenoma to carcinoma. Activating Kras mutations (an oncogene) are a frequent subsequent event. In sporadic CRC, the incidence of Kras and other mutations differs between right sided vs. left side colorectal cancers.

The remaining 15% of sporadic CRCs arise through a mutator pathway that involves loss of function of DNA base mismatch repair (MMR) genes, e.g., *hMLH1* and *hMSH2* (germ-line mutations of mismatch repair genes are responsible for Lynch Syndrome which is identified in ~3% of CRC). In this pathway, loss of MMR gene function results in a phenotype termed *microsatellite instability* (*MSI*). Sporadic CRCs that demonstrate MSI are often diploid (as opposed to the aneuploid state of chromosomal instability Wnt pathway-related tumors), tend to occur in the proximal colon, and frequently display histological features such as a medullary or solid growth pattern, a signet-ring cell histology, a plethora of tumor-infiltrating lymphocytes, and an adjacent inflammatory reaction often referred to as a "Crohn-like reaction." Another distinguishing feature of MSI-positive sporadic

CRCs is the better survival of patients with those tumors compared to those without MSI. The hyper-mutated state of dMMRP/MSI high cancers also has therapeutic implications: these cancers are responsive to immune modulation therapy using agents targeting PD1 or CTLA4 [4] (Fig. 56.1).

While colitis-associated cancers share several features in common with sporadic CRC, there are also important differences. Similarities include that both arise from a precursor dysplastic lesion. However, in the case of sporadic CRC, the dysplastic precursor is a discrete, polypoid growth called an

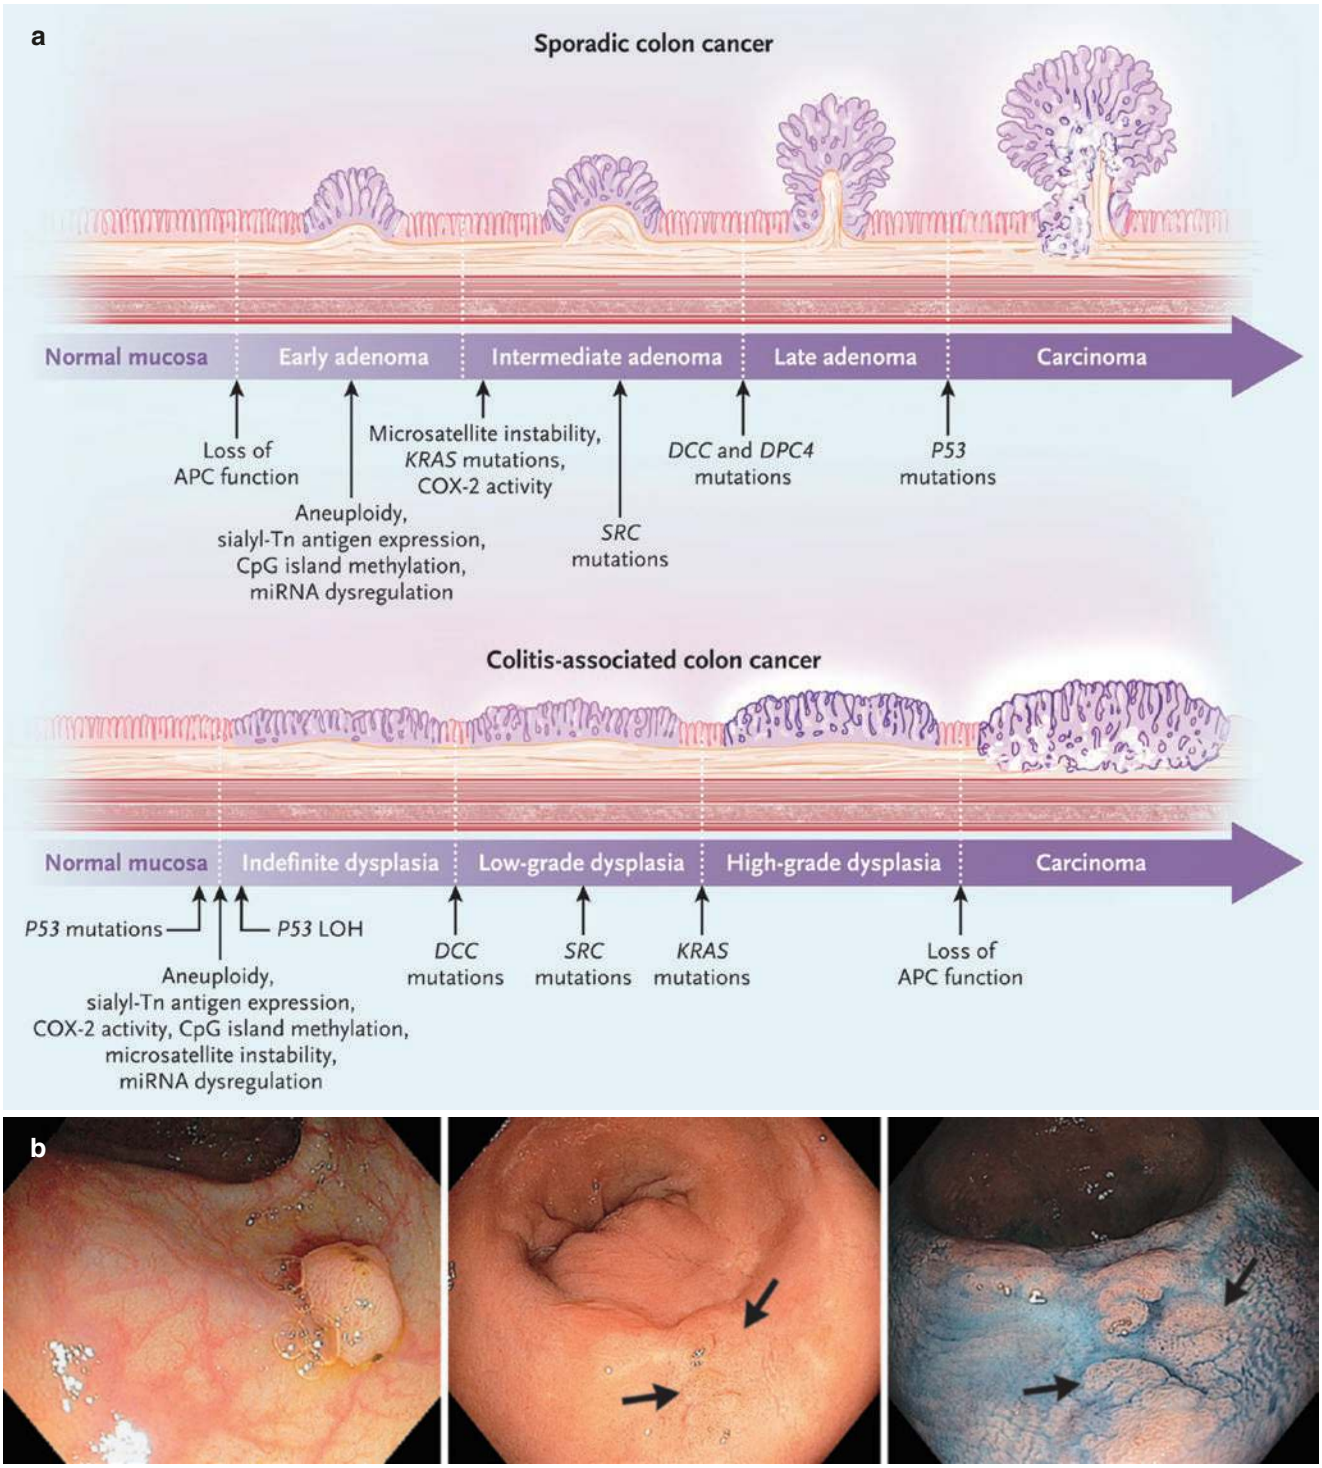

Fig. 56.1 Genomic alterations in the initiation and progression to cancer in sporadic colon cancer compared to colitis-associated colon cancer. (**a**) is a schema comaring the genomic steps in the development of "sporadic (not CAC, not inherited germline) colon cancer; (**b**) shows a polypoid lesion (From Beaugerie L, Itzkowitz SH. Cancers complicating inflammatory bowel disease. N Engl J Med. 2015 [5])

adenoma, which typically progresses through greater degrees of dysplasia and increasing villous histology and eventually leads to cancer. In IBD, while dysplastic areas may appear polypoid, they are frequently flat or only slightly raised. The substantial differences in the overall spectrum of genomic alterations between CAC and Sporadic CRC are described below [6, 7].

Clinical differences between sporadic CRC and CAC include a younger median age at the time of diagnosis for CAC patients than sporadic CRC patients. Dysplasia and occasionally even CAC may be multifocal, suggesting a precancerous "field change" of the colonic mucosa compared to the colons of patients with sporadic (non-familial syndromes) adenomas and colon cancer, where synchronous cancers are rare [8]. The risk for both synchronous and metachronous neoplasia leads to different surgical approaches: colitis-associated neoplasms are often treated with more extensive resections, including subtotal colectomy or total proctocolectomy, particularly for patients with ulcerative colitis, whereas sporadic cancers are treated with more limited resections for cancer. Finally, recent data suggest worse outcomes for patients with later-stage CAC, with shorter survival for advanced-stage CAC patients when compared to same stage CRC patients [1].

Spectrum of Genomic Alterations in Colitis-Associated Cancer

Although sporadic CRC and CAC share several types of molecular changes, the frequency of these molecular alterations differs (Fig. 56.2) [6, 7]. As shown, *APC* mutations are more common in sporadic colon cancer; this molecular alteration is much less frequent in CAC and as shown above, they occur later in the progression to cancer. There is also a difference in frequency of APC mutations between UC and Crohn Disease-associated cancers: recent data from next-generation sequencing analysis of colitis-associated cancers suggest that *APC* mutations may be more common in Crohn-associated cancers than in cases associated with UC (Fig. 56.3) [6].

TP53 alterations are nearly universal in colitis-associated cancers, and may be the initiating event. The majority of these *TP53* alterations are missense mutations occurring in the DNA-binding domain of p53. Many of these missense mutations may also possess gain-of-function capacities, including enhancement of invasive properties, attenuation of apoptosis, and increased genomic instability [9, 10]. The early presence of mutant p53 in the inflamed colon of IBD patients may be a driver of the subsequent progression to

Gene	CAC (n = 47)	TCGA-CRC (n = 212)	FM-CRC (n = 3117)	CAC *v* TCGA-CRC	CAC *v* FM-CRC
	Percent altered			*P*-value	
TP53	89%	52%	75%	**<.001**	**.02**

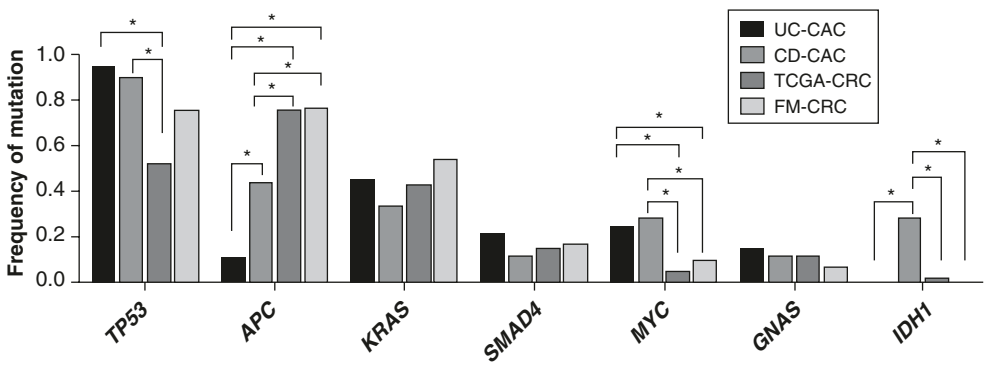

Fig. 56.2 Comparative analysis of the frequency of alterations in recurrently altered genes in CAC and in sporadic CRC. Top: Table showing the frequency of alterations in the indicated genes in the CAC cases overall (UC associated plus CD associated) vs. the frequency of alterations in the same genes as found in TCGA-CRC and in the FM-CRC, and associated *p* values based on Fisher's exact test. Bottom: Bar graph showing the relative frequency of GAs in the indicated genes in CAC associated with UC (UC-CAC), CAC associated with CD (CD-CAC), TCGA-CRC, and FM-CRC. Differences in the frequency of alterations that were statistically significant, based on Fisher's exact test, are indicated with a star. (From Yaeger et al. Gastroenterology 2016)

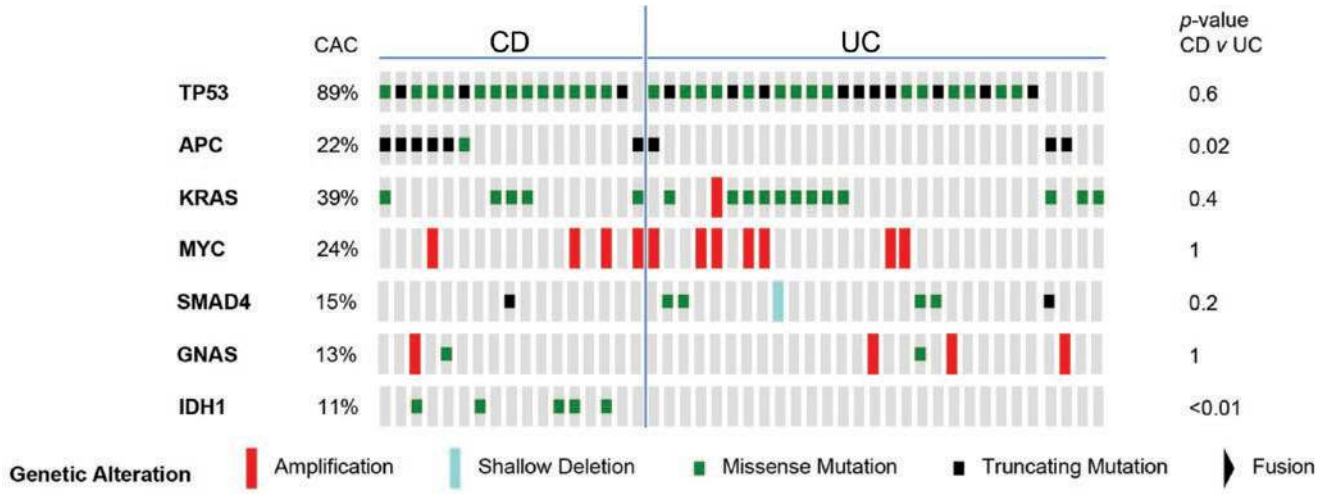

Fig. 56.3 Spectrum of Selected Genomic Alterations (analyzed by Next Generation Sequencing) of Colitis-Associated Cancers comparing underlying IBD by Crohn Disease and Ulcerative Colitis. Note that APC mutations, while less frequent than in sporadic Colorectal cancer, are found at a higher rate in Crohn Disease CAC. IDH1 mutations are also seen more commonly in Crohn Disease CAC

carcinoma by invigorating inflammation in the immediate microenvironment of the cells with mutant p53 [10]. Using a murine model, where exposure to dextran sodium sulfate (DSS) induces an acute colitis, Cooks et al. studied the role of mutant *TP53* versus loss of *TP53* on the development of adenomas and progression to carcinoma [10]. The mice with mutant *TP53* developed more frequent inflammation-associated colon cancer and developed carcinoma much earlier than mice with knockout of one *TP53* allele, suggesting that mutant p53 may not only make the mice more susceptible to chronic inflammation but also accelerate the development of carcinoma on an inflammatory background. *TP53* mutations can be detected in mucosa that is histologically non-dysplastic or indefinite for dysplasia [11].

Besides the incidence of APC and TP53 mutations, there are other substantial differences in the spectrum of genomic alterations between CAC and sporadic CRC. *IDH1* mutations at the R132 hotspot occur in about 10–15% of colitis-associated CRC, particularly in cases associated with CD [6, 12]. IDH1 R132 mutations are exceedingly rare in sporadic colorectal cancer and occur in no more than 1% of cases [13]. The R132 mutation in *IDH1* results in a mutant isocitrate dehydrogenase enzyme that cannot participate in the oxidative carboxylation of isocitrate, leading to dysregulated cellular metabolism, interfering with the generation of the key-reducing agent (NADPH), and producing the oncometabolite 2-hydroxygluatarate, which is associated with an altered epigenetic state with the CpG island methylator phenotype (CIMP) [14]. Other recurrent genetic alterations identified in CAC include *MYC* amplification, which occurs in both sporadic CRC and CAC but is significantly more common in CAC, and alterations in fibroblast-growth factor signaling, including FGFR1/FGFR1 amplification and translocations and ligand amplifications [6]. A recent report has found a difference in extracellular matrix remodeling in peritumoral stroma comparing CAC with CRC, both in a preclinical model and in human CAC [15]. The role of the bowel microbiome and altered bile acid composition as factors inducing the genomic changes associated with colitis-associated cancers are areas of active investigation.

Epidemiology and Incidence

Crohn and Rosenberg first described rectal cancer as a complication of UC more than 80 years ago [16]. It quickly became apparent that IBD, both ulcerative colitis and Crohn disease, are associated with an increased risk of bowel cancers; colorectal cancer in both UC and Crohn disease, and small-bowel cancers in Crohn disease. The magnitude of the risk has been the subject of study over the last several decades. While clearly elevated compared to the general population, the incidence of bowel cancer in patients with IBD is probably lower than previously thought. Nonetheless, it should be recognized that CACs are among the most serious complications of IBD and pose an important cause of morbidity and mortality in these patients [17].

Early estimates of the incidence of CAC were based largely on series developed from individual institutions, usually large referral centers, and likely overestimated the lifetime risk of CAC. In a meta-analysis of the risk of CRC in ulcerative colitis reported in 2001, in which 116 studies were included, Eaden and colleagues found the overall prevalence of CRC to be 3.7% and an overall incidence rate of 3 cases per 1000 person years duration [18]. The risk increased with each decade of active disease and corresponded to a cumula-

tive incidence of CRC of 2% at 10 years, 8% at 20 years, and 18% at 30 years disease duration. Based on this meta-analysis and earlier studies, typical estimates of CRC incidence ranged between 0.5% and 1% per year after 10 years of colitis.

More recent studies raise the possibility that prior reports overestimated the incidence and risk of CAC [19]. Data from France [20], Denmark and Sweden [21], Canada [22], and Olmsted County, Minnesota [23] have suggested a CAC incidence (mostly in UC patients) of between 1 in 500 and one in 600 per year, far lower than the 1 in 300 rate calculated in Eaden's meta-analysis. These have corresponded to relative risk calculations ranging from 1.1 to 2.7 times the general population. Meta-analyses based on these and other more recent population-based cohorts found cumulative incidence of CAC in ulcerative colitis of 1% at 10 years, 2% at 20 years, and 5% at >20 years disease duration [24]. The risks appear higher for patients with long durations of IBD, especially IBD beginning in pediatric patients [25], and those with more extensive colitis.

The risk of CAC in Crohn disease involving the colon appears similar, with a meta-analysis of Crohn colitis finding a risk of 2.9% at 10 years, 5.6% at 20 years, and 8.3% at 30 years of disease [26]. Patients with Crohn disease that is isolated to the small bowel do not appear to be at increased risk of colorectal cancer [27]. Lightner et al. recently reported a comparison of endoscopically assessed rate of progression from dysplasia to adenocarcinoma, in Crohn Disease vs. Ulcerative Colitis. They found that although dysplastic events were more common in UC, the rate of progression to adenocarcinoma was not significantly different [28]. These data support current surveillance guidelines which do not distinguish between UC and Crohn colitis regarding when to start surveillance nor interval of endoscopic surveillance.

While variation in study populations may account for some of the observed decline in CAC rates over time, improvement in endoscopic surveillance techniques (see below), and better control of inflammation with new anti-inflammatory agents as well as possibly a modest benefit from chemoprevention (see below) may play a role as well. Although the risk is lower than thought in the 1990s and early 2000s, the overall data support an increased risk for CAC in both ulcerative colitis and Crohn disease, supporting the use of surveillance and early detection programs.

Conditions Increasing the Risk of Colitis-Associated Cancers

As noted above, several clinical variables have been suggested to affect the risk of developing CAC. These variables include age at IBD diagnosis, duration of active IBD, anatomic extent of bowel inflammation, degree of inflammatory activity on endoscopy and histology, concomitant primary-sclerosing cholangitis (PSC), and a family history of colorectal cancer. Table 56.1 classifies these different risk modifiers.

Table 56.1 Risk modifiers of colorectal cancer in ulcerative colitis

Accepted risk modifiers	
Duration of colitis	*Long duration of colitis increases risk*
Age of onset	*Early age of onset increases risk, possibly independent of duration*
Extent of disease within the bowel	*Greater extent increases risk*
Degree of Inflammation	*Increased cumulative inflammation increases risk*
PSC	*Presence of PSC increases risk*
Family history of carcinoma	*Family history of CRC increases risk*
Possible risk modifiers	
Sulfasalazine/5-ASA	*Use may reduce risk*
Biologics/Small Molecules	*Control of inflammation may reduce risk*
Folic acid	*Supplementation may reduce risk*
Ursodeoxycholic acid	*Use may reduce risk in UC patients with PSC*
Unlikely risk modifier	
Glucocorticoid use	
6-MP/AZA use	

PSC primary-sclerosing cholangitis, *CRC* colorectal cancer, *UC* ulcerative colitis, *AZA* azathioprine

Duration of Colitis

As noted above, the total duration of colitis is associated with an increased risk of colorectal cancer in both ulcerative colitis and Crohn disease [26]. Surveillance guidelines, thus, recommend initiation of surveillance in patients with active colitis for 8 years [29–31]. However, up to 20% of patients will develop CRC sooner than 8 years after diagnosis [32], though whether this is due to diagnostic delays, long-standing subclinical disease, or accelerated carcinogenesis is not well understood. As such, the development of effective non-invasive biomarker assays for early detection of CAC is a high priority to enable more efficacious screening from the time of diagnosis of IBD.

Age of Onset of Inflammatory Bowel Disease

Important to pediatricians, age of colitis onset, perhaps as a variable independent of disease duration, has been implicated to modify the risk of CAC [33]. An early report found that at 35 years of follow-up, 43% of subjects with documented UC prior to age 15 had developed CRC [34]. Several more recent studies have confirmed elevated rates, if not the

magnitude, of this early study. In a Swedish national cohort study [35], patients with pediatric-onset (<18 years) IBD had a HR of 19.5 for long-term increased risk of CAC compared to matched non-IBD patients, though the risk of cancer before age 18 remained exceedingly low. Similarly, in a population-based study from Denmark and Finland, patients with pediatric-onset IBD were found to have elevated incidence of colorectal cancer relative to non-IBD controls (SIR 15.3) [36]. Although the precise magnitude of lifetime CAC risk for younger patients who develop UC or CD is still not fully determined, CAC itself is very rarely diagnosed in patients in their late adolescence but has been identified in patients in their 20s or 30s. Importantly for pediatricians, early control of inflammation may serve to lessen the cumulative inflammatory burden (see below), which offers the opportunity for long-term risk reduction in the development of CAC for individuals with pediatric-onset IBD.

Anatomic Extent of Colitis

The length of involved colon also correlates with cancer risk: the greater the surface area of colitis, the greater the cancer risk. A risk gradient by colitis extent has been observed in several studies, with isolated proctitis conferring minimally increased risk, and extensive colitis conferring a risk up to 4.5 times control, with left-sided colitis conferring a moderately increased risk [19, 21]. As histologic inflammation appears to be a key driver of neoplasia (see next section), the microscopic extent of disease should be used to define areas at risk [37].

Histologic Inflammation

Several studies have demonstrated that degree and cumulative burden of histologic inflammation are important predictors of CRC risk. Data from the St Mark's surveillance program in the UK first demonstrated that histologic severity of inflammation correlated with colorectal neoplasia or cancer risk [38], and these data have been since replicated in other cohorts [39]. More recently, the concept of cumulative inflammatory burden has been described by the St Mark's group [40] and validated externally [41], which quantitates the actuarial degree of histologic inflammation over time per individual across surveillance colonoscopies. Cumulative inflammatory burden was found to be an important, independent predictor of CRC risk and supports a theoretical role of inflammatory control as chemoprevention.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease in which there is progressive inflammatory fibrosis of the biliary tree. It is an infrequent complication of IBD, affecting 2–8% of patients with ulcerative colitis. Conversely, among patients with PSC, 62–72% have underlying IBD [42], prompting the recommendation to screen for IBD at the time of PSC diagnosis [43]. Patients with PSC have been observed to have a markedly increased risk of CRC [21, 42] and CRC-related death (e.g., HR 8.3 in a recent population-based study [21]) and so are recommended for annual colonoscopies. Recent data support an increased incidence of CAC in children with concomitant IBD and PSC as well [25]. The explanation for this marked increased risk appears to be multi-factorial. Colitis activity in PSC is often mild or even subclinical, and so patients with PSC may have a longer duration of inflammation than suspected clinically, raising their risk for CRC. Additionally, accelerated carcinogenesis has been proposed due to altered bile acid metabolism, gut dysbiosis, and distinct genotypes [44].

Family History of Colorectal Cancer

Family history of CRC has long been recognized as a risk factor for the development of sporadic colorectal cancer. In patients with IBD, a family history of colorectal cancer may add to the personal risk of development of CRC as well. Nuako and colleagues at the Mayo Clinic were the first to clearly demonstrate this increased risk, calculating an odds ratio of 2.3 (95% CI 1.1–5.1) in their case–control study [45]. In a population-based study from Scandinavia, Askling and colleagues found a similar elevated risk of 2.5 (95% CI 1.4–4.4) [46]. It is suspected that patients with a positive family history for colorectal cancer may have two independent driving factors increasing their personal risk of colorectal cancer: inflammation from IBD and an inherited cancer susceptibility gene. The genomic alterations associated with CAC are different than those associated with germ-line (inherited or spontaneous) mutations; future analysis of germ-line and somatic tumor specimens will allow a more precise estimate of each factor's contribution of in the development of colorectal cancer in patients with IBD. Recent genomic alterations analysis regarding the spectrum of genomic alterations in colitis-associated cancer versus sporadic colorectal cancer, discussed above, excluded from the analysis patients with a known germ-line cancer susceptibility gene mutation.

Prevention of Colitis-Associated Cancers

Pharmacotherapy and Chemoprevention

As with sporadic and familial colorectal cancer, investigators are actively seeking medications that might decrease the risk of developing CRC in IBD. The introduction of more effective drug therapy for moderate and severe IBD, by decreasing chronic inflammation, may in itself decrease the risk of dysplasia and cancer but conclusive proof for this remains elusive. A variety of preventative agents have been studied in IBD, primarily in retrospective studies, with mixed results.

Sulfasalazine/5-Aminosalicylates

Sulfasalazine and their derivative 5-aminosalicylic acid (5-ASA) products are the most commonly used medications for management of IBD and have been investigated for their chemopreventive effects. Studies assessing their role in reducing CAC have been limited to case control and cohort analyses given the logistical challenges in conducting a randomized, blinded clinical trial, and have yielded conflicting results [47–49]. Several systematic reviews and meta-analyses pooling these heterogenous data have demonstrated significant chemopreventive benefit with approximately 50% reduction in CAC incidence, in spite of not dysplasia, which raises questions about the biologic plausibility [50, 51]. Nonetheless, as a generally well-tolerated agent with favorable safety profile, the use of these agents should be encouraged in all patients with mild-moderate UC who achieve remission with these agents.

Thiopurines

Before the more recent widespread use of biologics for IBD, the purine analogs azathioprine and mercaptopurine were commonly used maintenance therapies in IBD and still are an important component of the IBD armamentarium. While these agents have been linked to an increased risk of certain malignancies, including lymphoma and non-melanoma skin cancer [52, 53], their relationship with CRC is less clear. Several studies and meta-analyses have assessed their impact on development of dysplasia and CAC and have failed to demonstrate a consistent benefit [54–56], and given their risk profiles, these agents are not recommended for the purposes of chemoprevention alone.

Biologics/Small Molecule Agents

Biologic agents including anti-TNF therapy (e.g., infliximab, adalimumab, certolizumab, golimumab), anti-integrins (e.g., vedolizumab), and newer anti-interleukin agents (e.g., ustekinumab), as well as the small-molecule JAK inhibitors (e.g., tofacitinib) have changed the landscape of IBD therapy and have driven the goals of therapy to increasingly rigorous endpoints including endoscopic and histologic healing [56, 57]. However, while control of inflammation may account for some of the apparent decreasing incidence of CAC discussed above [21], the impact of these agents, both individually and collectively, on the risk for CAC has not been well studied. Despite more than 20 years of anti-TNF use, scarce data have assessed the relationship with CAC [55]. Some evidence of a protective effect emerged from a recent database-based study that found significantly lower rates of CRC in both UC (OR 0.78) and CD (OR 0.69) for patients treated with anti-TNF agents [58]. At present, the use of these agents should be guided by therapeutic targets in IBD, which includes achieving mucosal healing, but there are insufficient data to recommend one class of agents over another for prevention of dysplasia or cancer.

Folic Acid

Folic acid has been studied for chemoprevention in sporadic colorectal cancer with mixed results [59, 60], and several non-controlled studies have assessed its role in prevention of CAC. Two studies by Lashner [61, 62] specifically looking at this outcome, were statistically negative but had favorable point estimates, and a meta-analysis of these along with eight other studies that assess folic acid chemoprevention as a secondary outcome found an overall significant benefit in chemoprevention of CRC with a pooled HR of 0.58 [63]. While more robust data are needed to support this intervention, given the low cost and the low risk of adverse events with folic acid supplementation, this can be considered for at risk patients.

Ursodeoxycholic Acid

Ursodeoxycholic acid, an exogenous bile acid used in the treatment of PSC, has also been studied. In UC-PSC patients, an impressive chemopreventive effect has been demonstrated, with a 40% difference in neoplasia noted between the ursodeoxycholic acid-treated group (32%) and the

untreated group (72%) [64]. This was additionally demonstrated in a randomized clinical trial of ursodeoxycholic acid in which a 74% reduction in dysplasia or CRC was noted [65]. Newer data, however, from the same group that studied it in the earlier trial, demonstrated that high-dose ursodeoxycholic acid at 28–30 mg/kg per day actually gave rise to *more* colorectal neoplasia [66]. As the benefits of ursodeoxycholic acid on PSC are questionable at best, it is uncertain whether low-dose administration should be given as a chemopreventive agent in patients with concomitant IBD and PSC.

Screening, Surveillance, and Risk-Reducing Surgery

Screening and Surveillance

For screening and surveillance to be effective, they should reduce CRC mortality in IBD patients. Pending the development of effective chemoprevention regimens and/or effective early detection biomarkers to identify patients in whom dysplasia or very early CAC is developing, endoscopic screening and surveillance are the primary modalities used for prevention of CAC. Endoscopic modalities may be effective either through the prevention of CRC by the removal of precursor lesions, or through early detection of CRC at a more curable stage. No prospective, randomized trials have been performed to unequivocally demonstrate a mortality benefit to surveillance colonoscopy, but multiple non-randomized studies support this contention. A recent Cochrane review evaluated multiple cohort studies and found a significantly lower rate CAC-associated death in the surveillance group (8.5%) compared to the non-surveillance group (22.3%) (OR 0.36 (95% CI: 0.19–0.69), $p = 0.002$) [67]. Additionally, this review found a significantly higher rate of early-stage CAC detection in the surveillance group (15.5%) compared to the non-surveillance group (7.7%) (OR 5.40 (95% CI: 1.51–19.30), $p = 0.009$).

Screening for dysplasia in IBD is generally recommended after 8 years of colitis that extends proximal to the rectum in UC [29] and involves more than one third of the colon in CD [30]. Surveillance for dysplasia is continued every 1–3 years according to current US guidelines [29, 30, 68] (though can be extended up to 5 years in low-risk patients per current European guidelines [31]), adjusted according to patient risk factors and results of prior colonoscopies. For patients with concomitant PSC, screening is recommended from the time of diagnosis, and surveillance is performed annually.

In the past, the finding of dysplasia on an endoscopic biopsy led to consideration of total proctocolectomy [69, 70].Older studies suggested that the presence of LGD or especially HGD was a high-risk marker that should prompt consideration of colectomy [71]. (Figure 56.4 shows the histology of low-grade dysplasia, high-grade dysplasia, and colitis-associated adenocarcinoma). These series suggested a high rate of progression (>50%) from even LGD to advanced neoplasia [72], and a substantial rate of finding an undiagnosed synchronous cancer (e.g., ~20% [73–75]) for colectomies done for a pre-operative diagnosis of LGD. However, with advances in endoscopic technology for dysplasia detection and endoscopic techniques for dysplasia resection, there has been a paradigm shift in the management of IBD-associated dysplasia over the last two decades. This shift was best captured in the SCENIC (Surveillance for Colorectal Endoscopic Neoplasia Detection and Management in Inflammatory Bowel Disease Patient) guidelines published in 2015 that elevated the role of endoscopy to the forefront in detection and management of IBD-associated dysplasia [68].

Endoscopic Detection

Most dysplasia was previously believed to be flat or invisible [76], thus, necessitating total colectomy when an area of dysplasia was detected [71]. To enhance detection of dysplasia in the era of fiberoptic colonoscopy, random surveillance biopsies were introduced in the early 1990s based on a modeling study suggesting that 33 non-targeted biopsies could enhance detection of colonic dysplasia [77]. Thereafter, performance of four quadrant random biopsies every 10 cm (or in each of 8 colonic segments) was adopted for IBD surveillance exams and recommended in numerous guidelines [78–80]. However, with the advent of improved imaging techniques including high-definition white light endoscopy, dye-based chromoendoscopy, and virtual chromoendoscopy, more recent studies have found that the vast majority of dysplasia is, in fact, visible [81–83]. This recognition has called the utility of random biopsies into question [78, 84], with data compiled by the SCENIC guidelines finding that only 1/1000 random biopsies reveal dysplasia and that only 1–1.5% of patients undergoing surveillance would not have dysplasia detected in the absence of random biopsies [68]. More recent guidelines reflect the diminishing value placed on random biopsies and suggest that these can be omitted in the setting of chromoendoscopy [31] or possibly even with high-definition white light [29]. Nonetheless, some recent data do suggest a role for random biopsies in the highest risk patients, such as those with concomitant PSC, a history of dysplasia, or active inflammation [85, 86], and so these continue to be performed at the discretion of the endoscopist.

High-definition white light has been found to be superior to standard white light in the detection of neoplasia in the setting of IBD [87] and is now widely recommended wherever available [68]. Two imaging enhancement techniques, dye-based chromoendoscopy and virtual chromoendoscopy, have also shown promise in enhancing detection of dysplasia and are incorporated into many surveillance recommendations. Dye-based chromoendoscopy, the application of methylene blue or indigo carmine dye spray to provide a contrast between dysplastic and non-dysplastic colonic tissue, has been shown to enhance detection relative to standard-definition white light [68]. Its additive benefit above high-definition white light, however, remains a matter of debate; several recent randomized trials showed enhanced detection with chromoendoscopy [88], while others showed no benefit [89] and a recent meta-analysis found no benefits in pooled randomized trials [90]. This persistent uncertainty, as well as the added cost and procedure time with its use, have limited the uptake of dye-based chromoendoscopy in the general gastroenterology community. Nonetheless, chromoendoscopy is performed by many IBD specialists, can be readily learned by practicing gastroenterologists [91], and is recommended in the highest risk patients and in particular scenarios, e.g., evaluation of the so-called "invisible" dysplasia (dysplasia detected on random biopsies).

Virtual chromoendoscopy employs light-filtering technology such as narrow-band imaging (NBI) built into modern colonoscopes and has been proposed as a more efficient and less costly alternative to dye-based chromoendoscopy for enhanced detection of dysplasia. Early studies of this technology found that it was no better than standard-definition or high-definition colonoscopy and so the SCENIC guidelines recommended against its use [92, 93]. However, more recent studies of NBI in IBD have shown, which may be equivalent to dye-based chromoendoscopy in detection of dysplasia and is quicker and cheaper to perform [94, 95], leading to recent guidelines suggesting that it can be used as an alternative to dye-based chromoendoscopy for IBD surveillance [29]. Especially with incremental improvements with new, second-generation NBI which uses brighter image enhancement and has been found to increase adenoma detection in the general screening population [96], virtual chromoendoscopy can serve as an important adjunct to routine surveillance colonoscopies and may offer benefits of ease of use, lower cost, and increased familiarity over dye-based chromoendoscopy.

Endoscopic Resection

A second-key factor in the paradigm shift in the management of IBD-associated dysplasia was the pivot from using dysplasia as a *marker* for future colon cancer and, thus, a signal for colectomy, to recognizing dysplasia as a *precursor* lesion that could be effectively resected, thereby preventing the development of colon cancer. In 1999, two groups reported that after polypectomy for polypoid LGD in the setting of IBD, there were no subsequent colorectal cancers observed over a follow-up period of 3–4 years [97, 98]. Multiple subsequent studies confirmed a low rate of progression to CAC after complete endoscopic resection of polypoid lesions, with a meta-analysis finding a pooled annual CAC incidence of 0.5% after resection of polypoid dysplasia [99]. This heralded the shift towards endoscopic resection of dysplasia in IBD, which was augmented by enhanced ability to detect dysplasia (as discussed above), improved universal nomenclature for describing dysplastic lesions [68, 100] (e.g., Paris Classification), and the evolution of enhanced resection techniques such as endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) [101]. This shift was highlighted in the SCENIC guidelines, in which endoscopic surveillance, rather than colectomy, was recommended as the preferred approach after complete endoscopic resection of polypoid dysplasia [68].

In contrast to the clear recommendations after removal of polypoid dysplasia, the natural history and ability to com-

pletely resect non-polypoid dysplasia remained a matter of some debate, with SCENIC providing a more qualified "suggestion" for endoscopic surveillance after resection, rather than "recommendation." Nonetheless, there is an effort to move away from even this classification of polypoid dysplasia versus non-polypoid dysplasia in favor of a distinction between endoscopically resectable and non-endoscopically resectable dysplasia [102]. New techniques such as ESD, an advanced resection technique pioneered in Japan and now entering into more common practice in the US [103], continue to push the envelope of "endoscopic resectability." Several studies have examined the short-term success of advanced endoscopic techniques such as ESD for removal of flat dysplasia and found that despite the added challenges of fibrotic tissue, ESD is technically feasible with good immediate success in expert hands, with en bloc lesion resection rates of 80–100% and clear pathologic margins (R0) resection of 76–80%, comparable to that in the non-IBD population [104–109]. However, the long-term efficacy in preventing CAC and the rates of metachronous neoplasia after resection of these high-risk lesions are less clear but appear to be high and require very close surveillance if an endoscopic approach is selected [110].

In sum, endoscopic techniques for detection and resection of IBD-associated neoplasia have made tremendous advances over the last several decades and have prompted a paradigm shift from primary surgical to primary endoscopic management of dysplasia in the setting of IBD (Fig. 56.5). Importantly, this should be coupled with effective pharmacotherapy to maximize healing of underlying colitis in order to facilitate effective detection and mitigate against the risk of further dysplasia. Nonetheless, there are still numerous indi-

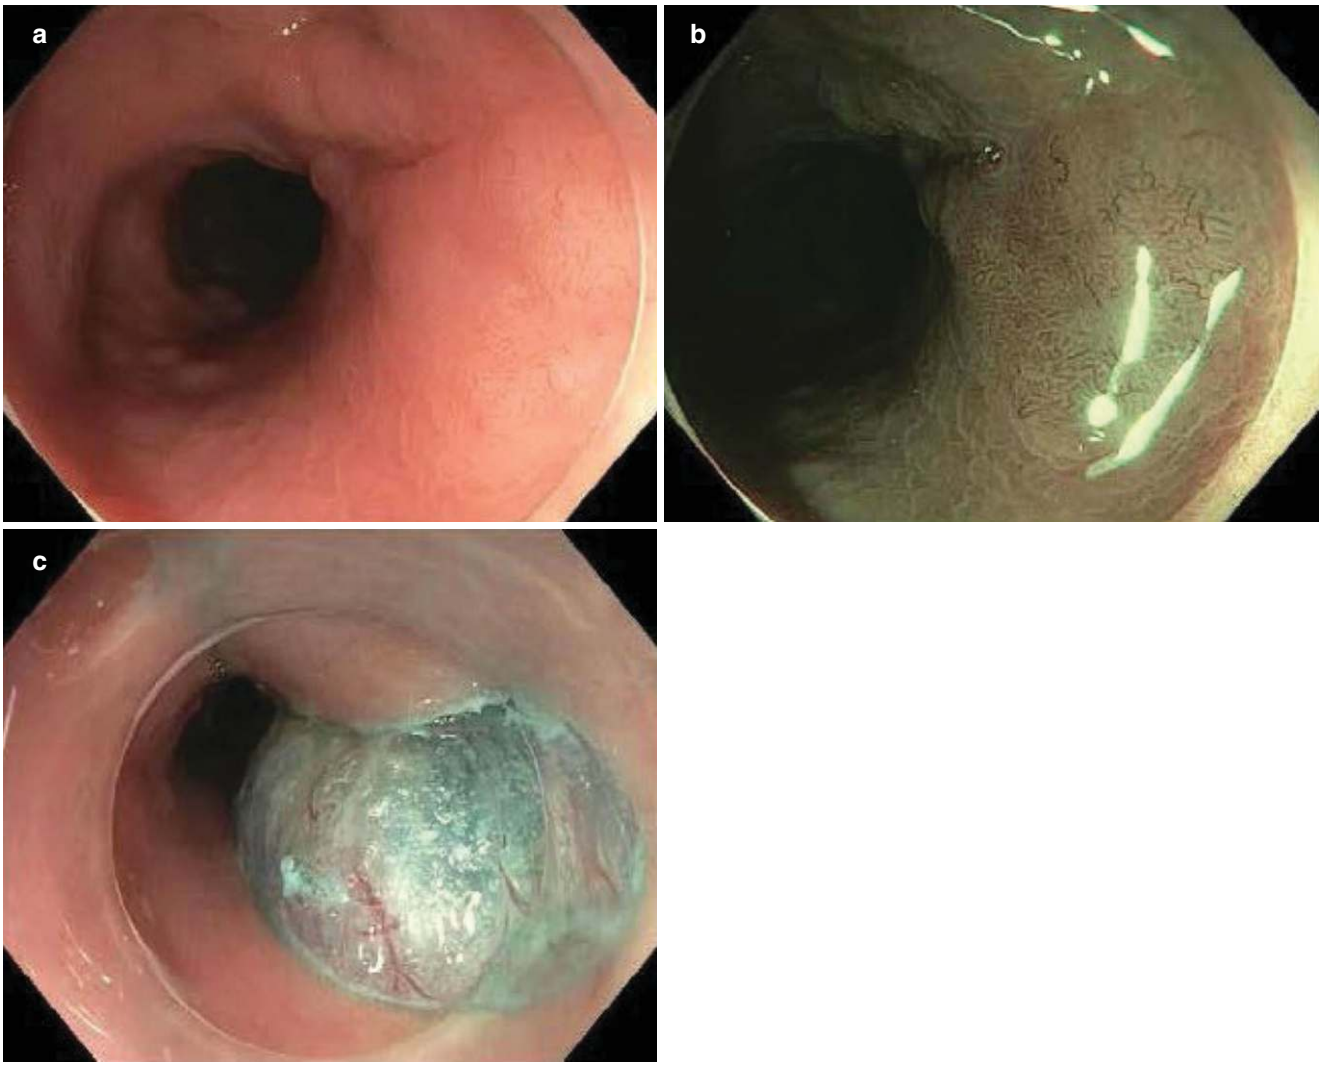

Fig. 56.5 Flat dysplasia in IBD seen with (**a**) high-definition white light endoscopy and (**b**) narrow-band imaging. (**c**) Flat lesion after endoscopic submucosal dissection. Pathology revealed low and focal high-grade dysplasia with clear margins. (Courtesy of Dr. Makoto Nishimura, MD, Memorial Sloan Kettering Cancer Center)

cations for surgical management in the modern era. The detection of invasive adenocarcinoma of the colon in the setting of IBD is a clear indication for surgical management, generally with total proctocolectomy. In other high-risk individuals, such as patients with endoscopically unresectable dysplasia, persistent invisible dysplasia, or multifocal flat or high-grade dysplasia, risk-reducing surgery may be recommended to decrease the risk of CAC [111].

Risk-Reducing Surgery

Prophylactic resection of the organ at increased risk for the development of cancer in high-risk populations is an accepted approach for several malignancies. For women who have been identified as carriers of germ-line mutations in cancer susceptibility genes such as BRCA 1 or 2, with a high lifetime risk for breast or ovarian cancer, prophylactic bilateral mastectomy and bilateral salpingo-oophorectomy have been demonstrated to decrease the risk of development of breast and ovarian cancer [112]. Patients with inherited or spontaneous germ-line mutations of the APC gene are at high risk for colorectal cancer; prophylactic proctocolectomy with the option for ileoanal anastomosis decreases the risk for colorectal cancer [113]. A similar approach has been used for IBD patients felt to be at high risk for the development of CAC, i.e., those with endoscopically unresectable dysplasia, or those with high-risk dysplasia, and these patients are generally recommended for definitive surgical management. Nonetheless, the spectrum of patients with multifocal or advanced neoplasia that are managed endoscopically versus surgically continues to evolve as discussed above and remains a priority area for further investigation.

Biomarkers

Identifying biomarkers, including genomic changes associated with dysplasia and early-stage CAC, which can be found in, e.g., blood or stool, are a high priority. The objective is to develop a robust bioassay which will identify dysplasia or CAC in asymptomatic (for cancer) patients with either Crohn disease or ulcerative colitis. Among potential biomarkers currently being studied, there are blood-based (plasma) assays for circulating tumor DNA and exosome protein cargo, and stool biomarkers. If a sensitive and specific assay was available, patients with a positive biomarker would then undergo endoscopic evaluation to localize the site of dysplasia or carcinoma. Several methodologies, including those mentioned above, are under study, but none has yet been proven to be adequately sensitive and specific to non-invasively identify dysplasia and carcinoma.

Systemic Therapy for Advanced Colitis-Associated Cancers

Currently, although the emerging genomic data outlined above have demonstrated a difference in the spectrum of genomic alterations between CAC and sporadic colorectal cancer, as well as differences between CAC comparing ulcerative colitis versus Crohn disease, cancers arising in inflammatory bowel disease are staged using the same systems as for sporadic colorectal cancer. In the United States, the AJCC Cancer Staging Manual, eighth edition presents the staging system for colorectal cancer [114]. This and other data clearly show that the earlier the stage of a colon or rectal cancer, the better the outcome if the disease is resectable with curative intent.

While it was previously felt that stage-for-stage there was no difference in outcome for patients with CAC developing in the setting of Crohn disease or ulcerative colitis, this may not be true for more advanced cancers. Cure rates after resection of early-stage CAC (stage I and II) are similar to those of cure rates after resection of early-stage CRC. Recent data, however, suggest that for patients with Stage IV (metastatic disease) cancers, outcomes using the same systemic therapies are worse for CAC patients compared to CRC patients.

Because CAC is uncommon, currently the same systemic therapy regimens used to treat sporadic CRC are employed in patients with CAC (cytotoxic chemotherapy with or without VEGF or EGFR targeted antibodies). It should be noted that studies comparing outcomes for advanced CAC versus CRC patients receiving systemic therapy are retrospective, involve small numbers of patients and frequently from a single institution. With this in mind, and for example, investigators from Memorial Sloan Kettering Cancer Center recently reported the results of a retrospective, matched control cohort analysis comparing outcome, measured as objective tumor response, and progression-free and overall survival, in a group of 18 CAC patients and 18 CRC patients. Genomic alterations analysis was performed in all patients [1]. Standard-of-care chemotherapy regimens were used and were balanced between the two groups. While the response rates were similar (CAC 35.7% vs. CRC 57.1%, $p = 0.45$), the median duration of response for CAC was significantly shorter (1.4 months vs. CRC 11.8 months, $p = 0.006$). There was no difference in dose density of first-line therapy between cohorts, suggesting that shorter response duration for CAC was due to more rapid development of chemotherapy resistance. Median overall survival was significantly shorter for CAC patients (13 vs. 27.6 months), $p = 0.034$. The median duration of survival of 27.6 months for CRC patients is quite consistent with what is currently expected for patients with stage IV sporadic CRC. As expected, there was a difference in the spectrum of genomic alterations

between CAC and CRC cohorts. However, alterations associated with a poor prognosis (e.g., B-Raf) were no more frequent in the CAC cohort. Similar results have been reported in two other series. These data suggest that while currently the same chemotherapy regimens are used for both CAC and CRC, better understanding of the possible rapid development of resistance in CAC and the development of regimens targeting the genomic alteration seen more commonly in CAC are important in developing better therapies for advanced-stage CAC patients.

Small-Bowel Adenocarcinoma in Crohn Disease Patients

Small-bowel adenocarcinomas are much less common than colorectal cancer in both the general population as well as in patients with IBD. In 2020, ~5300 new cases are anticipated in the USA; only a small percentage is associated with IBD [115]. While the duodenum is overall the most common portion of the small bowel for adenocarcinoma (approximately 50%), in Crohn-associated small-bowel cancers, the distal ileum is a more common primary site, followed by the jejunum. Patients with Crohn disease are at significantly increased risk of small-bowel adenocarcinoma and small-bowel adenocarcinoma-related death, with increased incidence estimates of ninefold compared to the general population in a recent population-based cohort from Scandinavia [116], to over 60-fold in prior studies [117]. Small-bowel adenocarcinoma has its own staging classification in the AJCC eighth edition.

While an asymptomatic small-bowel primary adenocarcinoma might be found during surveillance imaging, symptoms such as obstruction or bleeding more commonly precede the diagnosis. However, frequently these symptoms are attributed to underlying Crohn disease, and adenocarcinoma is rarely suspected. Therefore, an abrupt change in symptoms or in imaging appearance in previously stable Crohn disease patient should prompt suspicion of the development of a small-bowel cancer. Differentiating a benign stricture from the rare development of small-bowel adenocarcinoma may not be possible prior to an operation.

For patients in whom pre-operative testing has confirmed small-bowel adenocarcinoma arising in IBD, staging procedures include those routinely performed for other bowel cancers. These include CT scans of the chest, abdomen, and pelvis. FDG-PET CT scan may be used to evaluate for metastatic disease; however, increased FDG avidity within the small bowel may be due to inflammation. The extent of both adenocarcinoma and underlying Crohn disease determines the extent of surgical resection for operable cancers. Additionally, in a patient in whom adenocarcinoma of the small intestine is diagnosed, especially distal ileal cancer, underlying inflammatory bowel disease should be considered.

Other Malignancies

While the increased risk of colorectal and small-bowel adenocarcinoma in the setting of long-standing IBD are well known, several other types of malignancy appear to be increased in patients with IBD. These can be generally categorized into disease-related malignancies and immunosuppressive medication-related malignancies, though there is frequent overlap between the two. Disease-related malignancies include not only intestinal adenocarcinomas, as discussed above, but also anal carcinoma, cholangiocarcinoma, intestinal lymphomas, and possibly prostate cancer. Anal carcinoma occurs at higher rates and at younger ages in patients with IBD [118] and can be related to chronic perianal fistulae, often adenocarcinomas [119], or HPV-related squamous cell cancers, which may occur more readily in the setting of chronic immunosuppression [118]. The diagnosis of anal cancer can be challenging due to concomitant perianal disease that presents with overlapping symptoms, and the disease is often diagnosed late and carries a poor prognosis [120]. Cholangiocarcinoma risk is markedly elevated in the setting of concomitant PSC [121] and significantly increases all-cause mortality [122], especially in young patients (<40 years) with PSC-IBD [123]. Intestinal lymphomas appear to occur at increased frequency in patients with IBD and may be a sequela of both chronic intestinal inflammation as well as chronic immunosuppression, though the absolute risk of intestinal lymphoma remains low [124, 125]. Several recent studies also note an increased risk of prostate cancer in men with IBD, though whether this is due to disease-related factors (e.g., chronic pelvic inflammation or systemic immunosuppression) versus an ascertainment bias (e.g., due to more frequent health contact or rectal examinations) is not yet clear [126, 127].

Immunosuppression-related malignancies that occur in patients with IBD include extra-intestinal lymphomas, skin cancers, cervical cancer, and urinary tract cancers. Anti-TNF therapies and thiopurines have both been implicated in an increased risk for lymphoma [52, 128] including the rare but highly fatal hepatosplenic T-cell lymphoma that has been observed in young men often on combination therapy with both of these agents [129]. Skin cancers can occur as a result of immunosuppressive therapy, with thiopurines conferring an increased risk of non-melanoma skin cancer [53, 130] and anti-TNF therapy possibly increasing the risk of melanoma [131, 132]. Cervical cancer rates are increased in women with IBD, possibly related to the impact of immunosuppres-

sive medications on HPV activation and activity [133, 134]. Finally, urinary tract cancers are more common in the IBD population, in particular in older men who smoke or who have a history of thiopurine exposure [135, 136].

Summary

While the incidence of colitis-associated cancers is lower than reported in previous decades, CAC remains an important risk for patients with ulcerative colitis and Crohn disease. CAC in pediatric patients is fortunately very rare, but individuals with childhood onset IBD remain at substantial lifetime risk for CAC. Currently, identifying patients at elevated risk, aggressive control of modifiable risk factors such as chronic inflammation, and endoscopic surveillance for detection and resection of dysplasia and early detection of colitis-associated cancers remains the standard of care. Small intestinal cancer occurs at an increased rate in patients with Crohn enteritis, but the absolute risk remains small. The genomic events leading to dysplasia and cancer are better understood, but key driver events need to be more clearly identified. Eventually, targeting these driver events may lead to more effective prevention strategies. Finally, the development of highly specific and adequately sensitive blood or stool-based biomarkers to detect dysplasia and CAC at its earliest stage in patients with IBD remains an unmet medical need.

Quality Improvement in Inflammatory Bowel Disease

57

Jennifer L. Dotson, Shehzad A. Saeed, Jeremy Adler, and Richard B. Colletti

Introduction

In recent decades, research has generated an enormous growth of medical science, technology, and therapeutics. Knowledge from basic research, translational research, randomized clinical trials, and outcomes research has enabled experts in many fields to develop and disseminate evidence-based clinical practice guidelines with recommendations for medical practitioners. Yet health services research suggests that health care could perform a great deal better than it does today. For example, an audit of medical records of 4000 adults in 12 cities in the USA showed that only 55% of recommended preventive, acute, and chronic care was being received [1]. Similar deficits have been observed in ambulatory pediatrics [2]. A study of 3000 hospitals found that only five of ten recommended care measures were provided to a large majority of patients [3]. A report of the Institute of Medicine, Crossing the Quality Chasm, calls for improvements in six dimensions of healthcare performance: Safety, Timeliness, Efficiency, Effectiveness, Equity, and Patient centeredness (STEEEP) [4]. The National Scorecard on U.S. Health System Performance, an assessment of healthcare outcomes, quality, access, equity, and efficiency, found that the U.S. achieves an average score of only 66%. If the U.S. improved performance in key areas, it could save an estimated 100,000–150,000 lives and 50–100 billion dollars annually [5].

Improving the care of patients requires more knowledge; achievement of improvements requires the application of the principles of continuous quality improvement [6, 7]. Quality improvement in health care is the application of knowledge to make changes that result in better care and outcomes.

One of the barriers to quality improvement is unnecessary variation in care. Unnecessary variation, which erodes quality and reliability and adds to costs, is derived in part from habitual differences in practice style that are not grounded in knowledge or reason [8]. Variation makes it impossible to determine if a change in practice results in change in care because small improvements are frequently obscured by the background noise of variation. Quality improvement efforts

can reduce unnecessary variation; reducing variation is a necessary prerequisite to improve quality. To attain continuous quality improvement in health care, it is necessary to repeatedly measure the processes and outcomes of care and design, implement interventions to improve the processes of care, and re-measure to determine the effect of the interventions [9]. In this chapter, we present an introduction to quality improvement and how it has been applied to pediatric inflammatory bowel disease, with brief discussions of variation in care, the Chronic Illness Care Model, the need for quality improvement, the Improvement Model, the improvement collaborative, the ImproveCareNow Network, next steps/future directions, maintaining improvement, and administrative and funding considerations.

Variation in Care

Inflammatory bowel disease (IBD) is the most common serious chronic gastrointestinal disease afflicting children and adolescents in North America, yet there is currently considerable variation in the way gastroenterologists diagnose and treat IBD [10, 11]. Variation in care can be due to underuse, overuse, or misuse of diagnostic and therapeutic interventions. An example of underuse is failure to obtain small bowel imaging or neglecting to identify and treat growth failure; an example of overuse is unnecessary prolonged prednisone treatment [12]; and an example of misuse is prescribing infliximab to a patient with tuberculosis [13]. While some variations are due to patient needs or preferences, many variations are due to a lack of adherence by practitioners to best practices. Other variations are due to lack of data to guide practice leading to different practice strategies based on anecdotal experience or other non-evidence-based reasons [10]. Standardization of care occurs when physicians agree to provide care in a uniform manner of care appropriate for each patient. This can be evidence based, or in the absence of evidence, can be based on expert opinion or consensus. Standardization of care reduces unnecessary variation and, when combined with systematic studies of planned variations (including randomized studies), can lead to increased knowledge and improved outcomes.

Figure 57.1a is a theoretical example of a wide variation in the number of diagnostic tests performed prior to initiating treatment (labeled Before). When a larger number of tests than average are performed, it could indicate overuse of some tests, while a smaller number than average could indicate underuse. In this example, after a successful quality improvement project leading to less unnecessary variation in care, there is less overuse and less underuse than before,

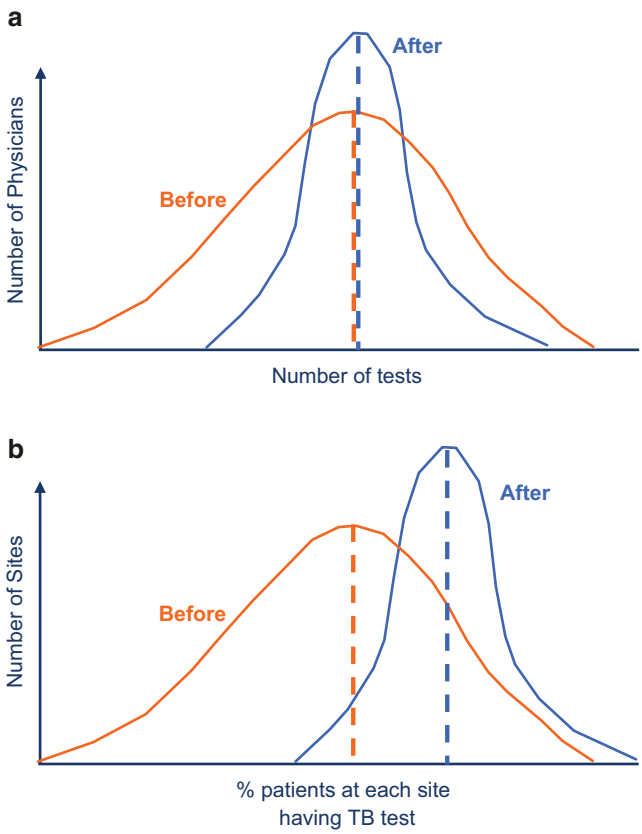

Fig. 57.1 Variation in care. (**a**) Improving quality by decreasing variation. (**b**) Improving quality by shifting distribution

although the average number of tests is the same. Figure 57.1b is a theoretical example of a wide variation and a low percentage of patients at most sites having a skin test for tuberculosis before initiating infliximab therapy (labeled Before). After a successful improvement project, there is less variation and a higher rate of skin testing.

Variation in care has been demonstrated in pediatric IBD [10, 11, 14]. In one study, pediatric gastroenterologists enrolled patients with Crohn disease who were starting treatment with a thiopurine (6-mercaptopurine or azathioprine) or infliximab [11]. Data from 250 patients at 80 sites were examined for variation in diagnostic and therapeutic interventions. Diagnostic studies in which care was uniform-included complete blood count, performed in 100% of patients, erythrocyte sedimentation rate and colonoscopy in 96%, and upper endoscopy in 89%. However, imaging of the small bowel had not been performed in 19%, and a stool test for pathogens had not been performed in 29%. Thiopurine methyltransferase (TPMT) had been measured in 61% of patients before treatment with a thiopurine; in 85%, TPMT was normal. Nonetheless, even when TPMT was normal,

40% of patients received an initial dose of thiopurine that was lower than recommended. Testing for tuberculosis before initiating treatment with infliximab was not documented in 30%. In addition, 36% of severely underweight patients were not receiving a multivitamin supplement, supplemental formula, or tube feeding [14]. The same study also demonstrated widespread inter-center variation in the treatment of newly diagnosed children with Crohn disease, even after adjusting for possible differences in case mix between institutions [14]. Variation in the use of immunomodulators and infliximab in patients with Crohn disease has also been reported [10, 15]. This considerable variation in diagnostic and therapeutic care in pediatric IBD, reflects the presence of underuse, overuse and potentially misuse of interventions that may lead to unintended differences in healthcare costs and outcomes.

Documentation of variation in care has been important in efforts to standardize and improve care in other fields of medicine [3]. For example, the Epidemiologic Study of Cystic Fibrosis demonstrated large variations in practice patterns regarding the prescription of various therapies as well as the fact that a significant proportion of CF patients are not monitored as recommended by the Cystic Fibrosis Foundation (CFF) [16, 17]. In this study, only 58% of patients had quarterly visits to their CF Care Center, 76% had biannual spirometry, 79% had annual airway cultures and 68% had annual chest radiographs [18]. CF Registry reports are now presented in such a way as to reveal practice variation among practice sites, partly in order to motivate an evaluation of this variation and to promote standardization where indicated.

The Chronic Illness Care Model

The Chronic Illness Care Model provides a useful framework for developing changes to the system of IBD care [19–21]. Wagner and colleagues conducted an exhaustive literature review and program assessment to identify the key components of systems of healthcare delivery that result in improved outcomes for patients with chronic illness. Wagner's model includes the following components: family and patient self-management support; decision support; delivery system design; clinical information systems; community resources; and the healthcare organization (Fig. 57.2). Family and patient self-management support includes the methods used by the clinic to increase families' participation in care. Decision support includes the use of care protocols that are integrated into practice systems. The delivery system design component includes the use of planned encounters,

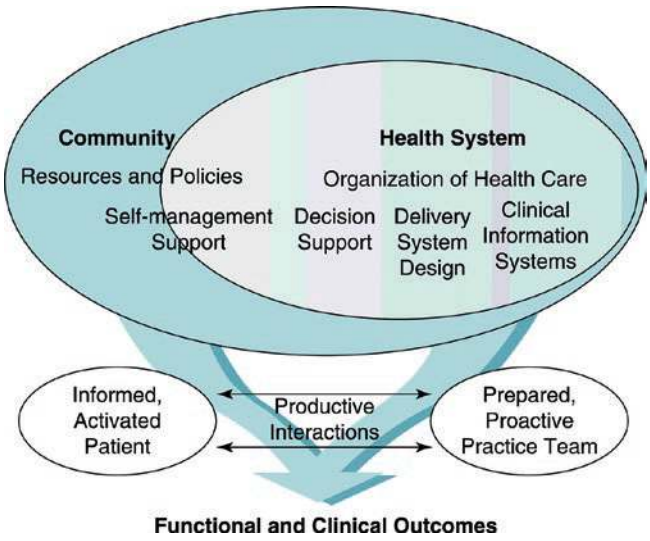

Fig. 57.2 The Chronic Illness Care Model. (Adapted from EH Wagner, *Joint Commission Journal on Quality Improvement* 2001;27:65, by permission)

clarity in the roles and responsibilities of team members with appropriate training, and the use of regular meetings of the care team to review performance. The clinical information system refers to the ability of caregivers to access data and use registries for care and to provide regular feedback to the team, and also information technology to facilitate scheduling and patient tracking. A prepared proactive practice team interacts with an informed activated patient to improve functional and clinical outcomes.

Improvement science is broadly defined as the science of implementing and testing change. There are many different ways in which improvement science is applied in practice. Each involves the common theme of methodically implementing and testing small changes, and then adopting or rejecting the changes based on the findings of testing [22]. Improvement interventions can range from prospective randomized controlled trials to observational studies [23]. The application of improvement science has led to major advances in quality in the automobile, microchip, and other industries [24–26] which raises the question whether it works in health care or not. Quality improvement interventions utilizing the Chronic Care Illness Model in asthma, congestive heart failure, depression, and diabetes have improved clinical outcomes, processes of care, and quality of life [27]. Studies of controlled trials of interventions that contain at least one element of the Chronic Care Model have demonstrated significant improvements in care [28]. In a cohort study to determine the effect of a specialist nurse on the outcome of 340 patients with IBD, intervention resulted in a 38% reduction in hospital

visits, a 19% reduction in hospital length of stay, a 10% increase in patients in remission, and improvement in patient satisfaction [29]. A multi-center randomized controlled trial of a quality improvement project in IBD showed similar results [30]. In the United Kingdom, development of a pediatric IBD service has improved provision of services and access to care for patients [31]. In Australia, the implementation of a dedicated IBD service was associated with a reduction in the use of steroids and opiates as well as a reduction in hospitalizations for IBD [32].

The Need for Quality Improvement in IBD

Have Crohn disease outcomes improved during the last four decades? In a report published in 2004, a structured systematic literature review was performed to evaluate measurable outcomes in Crohn disease. Evaluation of mortality, cancer, disease recurrence, extra-intestinal manifestations, and medication use failed to show consistent evidence for improvement in inflammatory bowel disease outcome during the previous four decades [33]. However; more recent studies have shown decreased mortality in IBD [34], decreased colectomy rate in ulcerative colitis [35], and decreased surgical rates in pediatric Crohn disease within 3 years of diagnosis [36]. Despite advances in research and therapy, the application of knowledge to the improvement of health outcomes and quality of life has lagged. Hospitalization rates for IBD, particularly Crohn disease, increased from 1988 to 2011, contributing to a substantial rise in inflation-adjusted economic burden [37, 38]. Further, even in the era of biologics, the proportion of patients with inflammatory bowel disease not entering remission remains high [39]. Are we optimizing biologic therapies? Are patients with IBD receiving optimal care? A study found that adults with IBD referred for a second opinion often were not receiving optimal medical therapy [40]. There was prolonged use of corticosteroids, failure to use steroid-sparing agents, suboptimal dosing of mesalamine and immunomodulatory medications, inadequate measures to prevent metabolic bone disease, and inadequate screening for colorectal cancer.

A study of the pediatric patients' diagnostic evaluation diagnosed with IBD also identified substantial gaps in small bowel imaging, though this was found to improve over the 5-year course of study [41]. Other evidence indicates a shift toward magnetic resonance imaging and away from ionizing radiation in pediatric IBD [42]. Many pediatric patients diagnosed with Crohn disease had not been tested for intestinal pathogens, had not had imaging of the small intestine, were not receiving a multivitamin supplement, had not been tested for TPMT prior to treatment with a thiopurine, had not been tested for tuberculosis prior to treatment with infliximab, and were receiving suboptimal dosage of medications [11].

Another important aspect of pediatric IBD care needing a quality improvement focus is transition to adult GI care, with the goal of proving comprehensive and uninterrupted care for the adolescent and young adult. The term "transition" refers to the longitudinal process of obtaining the knowledge and skills necessary to care for oneself and one's chronic disease in an adult setting, whereas "transfer" refers to the eventual physical move from pediatric to adult care. Across multiple chronic diseases, it has been demonstrated that poorly managed transitions can result in inappropriate utilization of healthcare resources and adverse health outcomes [43, 44]. The variable (and often complete lack of) transition care processes as well as inconsistent measures of transition readiness in many institutions across the United States continue to put young adults at risk for adverse health outcomes at transition [45–47].

Quality improvement in adult gastroenterology has previously focused on endoscopic procedures [48–56]. More recently, there has been an emphasis on reducing venous thromboembolic events in hospitalized IBD patients [57, 58]. However, the American Gastroenterological Association (AGA) Task Force on Quality in Practice issued a report recommending the formation of an AGA Quality Center to assure uniform documentable excellence in quality of clinical care and GI practice, to support the aims for quality health care set forth by the Institute of Medicine, to identify key quality of care indicators in the treatment of digestive diseases and how they will be measured, to develop programs and tools to assist in implementing evidence-based guidelines and measuring and reporting adherence to quality indicators, and to develop patient education materials to ensure that patients have appropriate expectations regarding high-quality, patient-centered, evidence-based care [59]. In 2011, the AGA developed a set of IBD process measures, approved by the American Medical Association's Physician Consortium for Performance Improvement that focus on transitioning patients to corticosteroid-sparing therapy and preventive care. The AGA subsequently developed a series of quality improvement measures called the Physician Quality Reporting System (PQRS) [60]. The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) has also developed a set of process measures. In conjunction with measure development, the AGA has also developed the Digestive Health Outcome Registry (DHOR) to help practices develop benchmarking, outcomes measurement, and population management capabilities for patients with IBD [61].

The Improvement Model

The Improvement Model is the foundation of a system for innovation and a framework for developing, testing, and implementing incremental change [62]. The model is based on three questions (Fig. 57.3): What are we trying to accomplish? How will we know that a change is an improvement? What change can we make that will result in improvement? Any approach to improvement must be based on building and applying knowledge. Within the overall framework, the Plan-Do-Study-Act (PDSA) Cycle is a structured application of the scientific method that provides a means to learn rapidly in complex organizational settings. The Plan phase consists of stating the objective of the test, making predictions, and developing a plan to carry out the test. The Do phase consists of carrying out the test, documenting problems and unexpected observations, and beginning an analysis of the data. The Study phase consists of completing the analysis of the data, comparing the test data to predictions, and summarizing what was learned. The Act phase consists of deciding upon and carrying out the changes to be made, and considering what will be the objective of the next cycle. The Improvement Model means applying the principles of using data; developing, testing, and implementing changes; and working collaboratively to bring about improvement in the outcomes of health care (Fig. 57.4). The improvement model can be applied to any aspect of health care.

Improvement Collaborative

An improvement collaborative is a sequential process in which a group of multidisciplinary teams from different practice sites work intensively together using the principals of improvement science to improve the delivery of care and the quality of life of patients [63, 64]. Improvements consist of redesigning delivery systems to ensure that patients receive recommended care and are not subject to underuse, overuse, or misuse. An improvement collaborative includes three main phases: (1) a design and development phase, in which the aim and measures for the project are developed (see Table 57.1), and changes to be tested are identified and summarized using formal methods for the design of new processes and systems; (2) an implementation phase in which practice sites work together to test and adapt changes in care delivery; and (3) a dissemination phase, where, as changes in the processes of care delivery are tested and reliably achieve desired goals, they are disseminated to other and eventually all pediatric gastroenterology practice sites. Participating sites collect data about their patients' care, share data about the outcomes of care with all of the other sites, identify sites that are performing better, examine reasons for the better performance, set benchmarks for outcomes, and share ideas to enable the other sites to improve their outcomes. Participating sites gather together for conferences to share data and ideas, and then return to their sites to perform PDSA improvement projects there, gathering and sharing new data in an incremental process (Fig. 57.5).

Table 57.1 Measurable outcomes of treatment of pediatric IBD

Disease activity
Remission rate
Interval between relapses
Complication rates (e.g., fistula)
Nutritional status
Growth, final adult height
Days missed from school
Emergency department visits
Hospitalization rate
Hospital length of stay
Surgery
Patient and family satisfaction
Patient quality of life
Adverse drug events (e.g., infusion reactions)
Therapeutic drug monitoring
Surgical complication rate
Objective biomarkers of disease activity: calprotectin, lactoferrin, hemoglobin, erythrocyte sedimentation rate, c-reactive protein, albumin
Procedural assessments: endoscopy, imaging

An IBD improvement collaborative is intended to encourage practices to adopt a more organized approach to IBD care. It is based on models of behavior change and diffusion of innovations in medical practice including involvement of opinion leaders in the medical community, recognition of a performance gap, involving physicians and staff in developing a strategy to make changes to close the gap, compatibility of the intervention with current practice, and reinforcement of positive change [65]. It is designed to identify and address barriers in the way care is delivered in IBD clinics.

This type of systems' intervention is especially important in pediatric IBD clinics because many pediatric IBD practice sites operate within large tertiary medical centers with relatively rigid infrastructures requiring significant and determined effort to change; IBD care is characterized by a complex mixture of preventive and chronic therapeutic interventions; distance and other factors make frequent return visits difficult for many patients, so accidental omission of services and other missed opportunities for care are difficult to recognize and are harder to correct; and the responsibility

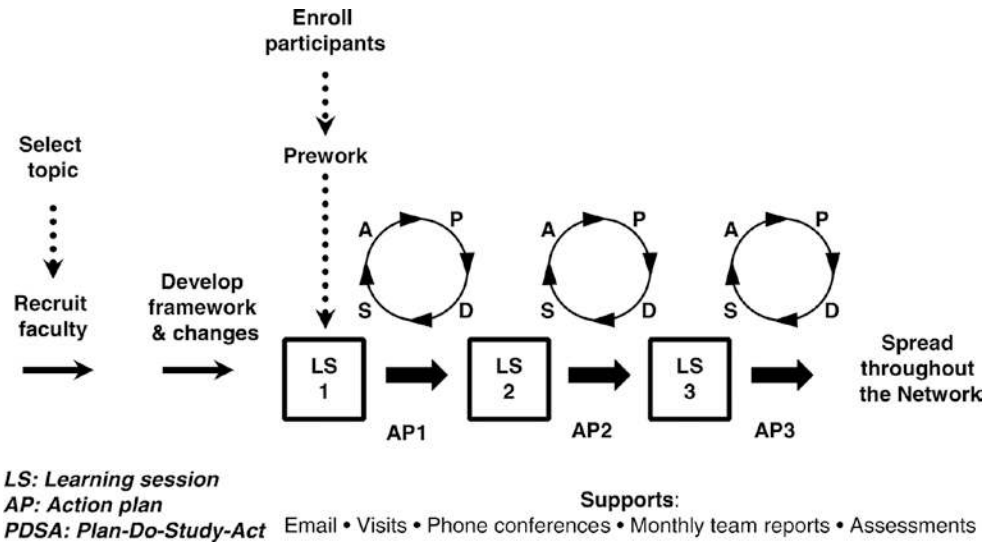

Fig. 57.5 A schematic drawing of the sequence of events in an Improvement Collaborative. (Adapted from a presentation of the Institute for Healthcare Improvement)

for care is shared by multidisciplinary teams and multiple physicians with diverse responsibilities who may overestimate the consistency with which they deliver specific services [66].

The ImproveCareNow Network

The first improvement collaborative in IBD, called ImproveCareNow, was established in early 2007; its global aim is to build a sustainable network of all pediatric gastroenterologists in the US to improve the care and outcomes of children with Crohn disease and ulcerative colitis [67]. In its first 5 years, it grew from 8 to 34 centers, with approximately 300 pediatric gastroenterologists and 10,000 pediatric IBD patients. By 2020, the ImproveCareNow Network grew to 110 centers across 38 states in the US and internationally, including England, Belgium, and Qatar, which include approximately 970 pediatric gastroenterologists and 35,000 patients (www.improvecarenow.org). The six primary drivers of the ImproveCareNow Network are (1) a prepared proactive practice team; (2) accurate diagnosis and disease classification; (3) appropriate drug selection and dosage; (4) adequate nutritional intake; (5) adequate growth monitoring; and (6) informed, activated, and engaged patients and families.

ImproveCareNow developed and implemented five major interventions: (1) enrollment and data quality; (2) consistent reliable care; (3) population management; (4) pre-visit planning; and (5) self-management support. The centers aimed to identify and enroll all of their IBD patient population, collect data from all visits using a standardized template for data elements, and provide complete and accurate data in a timely fashion. ImproveCareNow developed a Model IBD Care Guideline for Consistent Reliable Care, based on an integration of evidence and consensus, and key clinical measures, and process and outcome measures, to monitor the performance at each center and the collaborative as a whole [68]. In addition, algorithms for nutrition and growth were developed.

A population management tool was developed and used to ensure that patients were being seen regularly, and to identify patients who were not receiving model IBD care and who could benefit from for a proactive change in their management. A pre-visit planning checklist was developed and implemented at centers to review important clinical data, to identify and highlight variables that fall outside of protocol guidelines (e.g., drug dosages and results of previous laboratory tests), identify and arrange for needed resources at the time of visit (e.g., pre-ordering laboratory tests; scheduling a dietician), and assist the clinician in preparing an agenda of important issues requiring attention at the visit. In 2011, a systematic program was undertaken to develop tools for patient and family self-management support, including providing patient education, eliciting patient and family priorities for visits, confirming patient understanding of new information, setting and monitoring patient goals collaboratively, and improving adherence.

One of the primary strengths of the ImproveCareNow network is a focus on learning from data. Each participating center receives monthly reports with tables and longitudinal graphs of their performance on the key clinical and data quality measures, and a twice-monthly population management reports. These electronic reports provide both aggregate and individual patient- and visit-level data that can be used to monitor populations of patients and identify subgroups of patients in need of attention or intervention. The reports are used to identify sub-populations of patients with medical issues in need of attention, for example, patients who are on systemic steroids or patients with suboptimal nutritional status. They also are used to identify patients who have outgrown the doses of their medications. The reports can also facilitate failure mode and affect analyses to study problems and gain insights to inform improvement efforts. The reports also include run charts and control charts to help identify special-cause variation when a significant change from baseline has occurred. Centers also have the ability to compare their performance to that of other centers and of the entire network [69].

The data that inform these reports are collected from each patient at each outpatient visit. ImproveCareNow has developed processes by which automated data transfer can be done from electronic medical record systems to populate the data registry. This has reduced the burden of data collection and errors associated with duplicate data entry for many of the participating network sites. For sites without the capability of electronic data transfer, manual data entry is performed. There are numerous quality checks to minimize errors in manual data entry. Data collection includes all the data necessary for calculating the short pediatric Crohn disease activity index (sPCDAI) and the pediatric ulcerative colitis activity index (PUCAI) [70–72].

The ImproveCareNow Network has implemented a process for generating automated pre-visit planning forms that can be automatically generated on demand for each patient (Fig. 57.6). These forms are one-page summary sheets that are pre-populated with patient-specific historical data pulled from the registry. These forms served to streamline the pre-visit planning process for each practice. The automation was part of a larger emphasis on improving the digital architecture of the ImproveCareNow network registry [69].

Fig. 57.6 Automated pre-visit planning form for one patient pre-populated with data drawn from the ImproveCareNow registry specific to the individual patient. The form includes summary information about the patient's disease phenotype as well as longitudinal data from the last several visits including weight, height, and laboratory information

The first ImproveCareNow report of outcomes was based on a 3-year follow-up of 6 of the initial centers with 1188 patients [73]. Changes in care delivery were associated with an increase in the proportion of visits with complete disease classification, measurement of thiopurine methyltransferase (TPMT) prior to initiation of thiopurines, and patients receiving an initial thiopurine dose appropriate to their TPMT status. There were significant increases in the proportion of Crohn disease (55–68%) and ulcerative colitis (61–72%) patients with quiescent disease (between 2007 and 2015). There was also a significant increase in the proportion of Crohn disease patients not taking prednisone (86–90%). These findings suggest that improvements in the outcomes of patients with Crohn disease and ulcerative colitis were associated with improvements in the process of chronic illness care. Variation in

the success of implementing changes suggests the importance of overcoming organizational factors related to quality improvement success. As ImproveCareNow grew and sustained its improvements, the Network was recognized as an exemplar of pediatric collaborative improvement networks [74]. After 7 years, the ImproveCareNow Network outcomes had improved further and the clinical remission rate for children with IBD increased to 77% [75, 76], and by 2020, it was 82% (www.improvecarenow.org, Fig. 57.7a, sustained remission noted in Fig. 57.7b). To further improve outcomes, ImproveCareNow is creating a learning health network in which patients and parents play an integral role in participation and governance of the network and work together with network clinicians and researchers [63].

The adult IBD community has also developed a quality improvement collaborative through the Crohn's and Colitis Foundation, IBD Qorus™, which includes over 50 sites. In 2020, they embarked on a new initiative called Treat to Target to encourage more frequent monitoring to ensure treatment strategies that align a remission-based therapeutic goal with the patient's personal goals regarding quality of life. Thus far, two care pathways have been developed to aid in the recognition and treatment of anemia and nutrition.

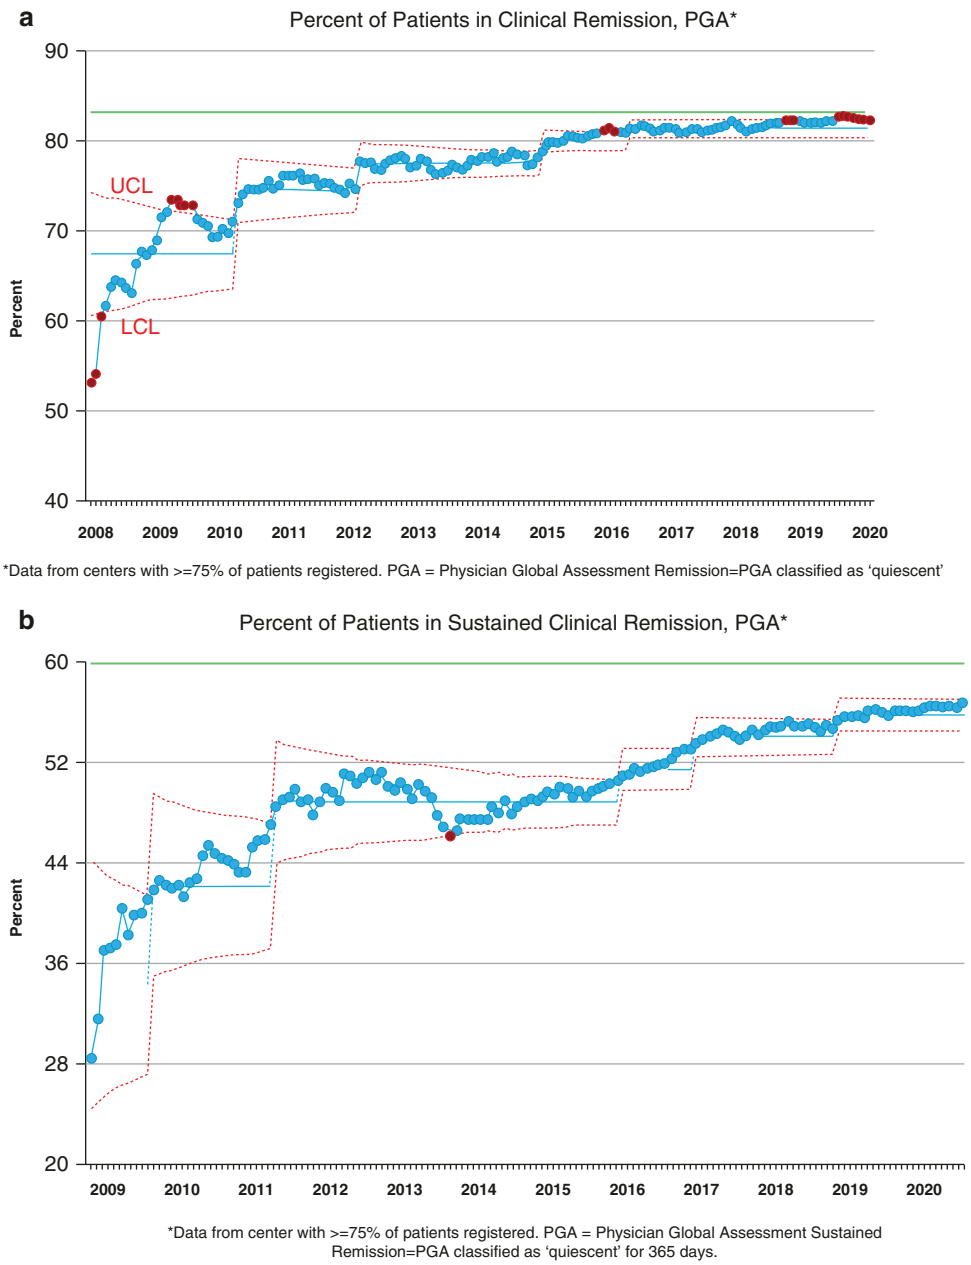

Fig. 57.7 (**a**) Improvement in remission rate, based on Physician Global Assessment, of a cohort of patients with Crohn disease in the ImproveCareNow Network from 2008 to 2020. Monthly results for all centers combined are presented as a control chart (Shewhart chart). The center line represents the mean proportion; the dashed upper and lower control limits (UCL and LCL, respectively) reflect the inherent variation in the data and were calculated as ±3 standard deviations of the centerline proportion. The shift in center line indicates a special-cause variation in remission rate. (**b**) Improvement in sustained remission rate from 2009 to 2020

Learning Health Network

A Learning Health Network, as originally conceived by the Institute of Medicine (now the National Academy of Sciences) is a community of clinicians, researchers, other professionals, and patients and families; working together with a focus on improving outcomes; using safe, effective evidence-based care; and providing better care at lower cost [77]. In a Learning Health Network, research is a natural outgrowth of clinical care; new knowledge is generated easier, faster, better, and cheaper. Innovative technology may also be employed so data are available in real time and can be used for clinical, research, and improvement purposes. The key drivers of a successful learning health network—an enhanced registry, improvement science, a robust research infrastructure, and a community of engaged stakeholders—are exemplified by the ImproveCareNow Network [74]. Data obtained at the time of a clinical encounter are analyzed by the enhanced registry and presented for clinical use as previsit planning and population management reports [69]. An enhanced registry can also generate a quality performance report that identifies gaps in care, enabling the center improvement teams to identify and focus on specific aspects of its care delivery system applying improvement science methods to improve processes and outcomes. Education and training of each center's improvement team in improvement science are essential to achieve improved care and outcomes. The repository of data is also a gold mine for research enabling retrospective and prospective observational cohort studies of natural history, real-world evidence of clinical care and outcomes, and pragmatic clinical trials. A Learning Health Network can also facilitate the development of new drugs by studies of real-world and long-term effectiveness of drugs; optimizing medication use by clinicians and patients; engaging clinicians and patients to prioritize and design studies; data queries to identify potentially eligible research subjects to facilitate study design and recruitment; conducting prospective drug efficacy studies; and conducting postmarket surveillance to monitor for serious adverse events. A registry that is 21 Code of Federal Regulations (CFR) Part 11 compliant and produces Study Data Tabulation Model (SDTM) and Analysis Data Model (AdAM) reports can further contribute to drug development by meeting standards of regulatory agencies. The National Academy of Sciences suggests extensive participation of patients and families in leadership, governance, education, communication, and other operations, which is necessary to optimize the success of a learning health network [78]. A Learning Health Network also provides opportunities for academic and professional advancement, leadership, and career development by enabling research, networking, building collaborations, and providing opportunities for committee involvement and leadership.

Leveraging the power of learning health systems and networks provides opportunities for higher level and more complex interventions to be tested and implemented. For example, the ImproveCareNow Network has developed a series of Learning Labs (i.e., a group of sites focusing on a specific topic or goal such as population management, previsit planning, clinical standardization/personalized care, COVID-19 response, and transition to adult care). The movement of clinical practice toward a treat-to-target approach has prompted a Learning Lab (consisting of over 25 centers) to address therapeutic drug monitoring via a care pathway. As part of the design process, a workgroup of clinicians, researchers, patients, and parents reviewed published literature and performed an environmental scan of current practice. This information was then used to develop and implement interventions and measures to address the clinical standardization of therapeutic drug monitoring for anti-TNF alpha therapies, a project still in process.

Maintaining Improvement

In any quality improvement effort, once an improvement is achieved, it must be maintained. Different challenges exist for sustaining an improvement. These range from challenges maintaining consistent error-free data collection, and reminding clinicians to continue reviewing data regularly to updating treatment protocols to remain consistent with the evolving literature. New clinicians require onboarding, and as patients transition from pediatric to adult care, new patient representatives need to be recruited.

Ongoing data monitoring enables centers to detect deterioration in processes or detrimental changes in outcomes. Such data can then allow data analyses to facilitate identifying areas or processes in need of modification in order to return to the prior level of improvement. An example of maintaining improvement includes ensuring that once a center's remission rate improves, they are able to maintain that high level of remission. Some challenges to maintaining a high remission rate include staffing changes; changes in treatment paradigms; availability of new medications; insurance or policy restrictions on access to medications; and the occurrence of pandemics or natural disasters.

Maintaining an updated registry with ongoing monitoring can allow a center to become aware if there is a change in either process measures such as timely data entry, or outcomes such as hospitalization rates or remission rates. Regular population management meetings with review of center-level registry data help the clinicians and staff to detect changes in data. If a particular measurement, such as proportion of patients with adequate nutrition status, has a stable pattern over time, called *common-cause variation*, then if there is a deviation from that rate, it is identified as

special-cause variation. Detecting special-cause variation provides an opportunity for the team to investigate the circumstances and identify potential reasons for the change.

In order to maintain improvement efforts in clinical practice, such monitoring of data must become an integral part of clinical care. Embedding processes of monitoring data into routine care enables clinicians to keep track of their population of patients and proactively address issues in care as they arise.

Improvement Science in the Business of Health Care

Improvement science and methods can play an important role in the leadership, business, and finances of healthcare systems. QI skills are in effect a problem-solving mindset. Health system leaders value system thinkers who are in a continuous improvement mode to facilitate efficiencies across the system. This mindset allows segmentation of complex clinical and operational issues into aims that can be achieved by application of the model for improvement. The approach of system leaders who use improvement science as a business strategy includes (a) purpose driving the mission and vision of organizations; (b) viewing the organization as a system; (c) a process or system of obtaining information to improve; (d) planning based on the data obtained and integrated with business strategy; (e) managing individual and team improvement activities by carrying out PDSA cycles to implement improvement; and (f) incorporating the perspectives of key stakeholders, such as customers and employees, as well as managers of operational and business units [62].

Improvement science and methods can be leveraged across the health system in both clinical and non-clinical domains. In addition to the clinically focused activities described above, examples in the non-clinical setting include the patient experience, business operations, and system-wide dashboards of key measures of system success.

The Triple Aim of Health Care was conceptualized in 2008 by the Institute for Healthcare Improvement as the simultaneous pursuit of three aims: improving the experience of care, improving the health of populations, and reducing per capita costs of health care [79]. Value in healthcare is quality per unit of cost; higher quality (better outcomes and patient experiences) and lower cost mean higher value. Improvement science methods can be applied to both improving outcomes and reducing unnecessary resource utilization in system and microsystem operations and workflow, as well as in management of population health strategies and complex diseases. Current fee-for-service and volume-based reimbursement models for clinical care delivery lead to excess cost from services that are not necessary. The emerging models of value-based care focus on disease prevention, care coordination, and case management as well as paying providers for improved outcomes and patient experiences within a defined population. The concept of an IBD Medical Home, as championed by Regueiro et al., has shown significant reduction in Emergency Department utilization, as well as increased adherence and improved quality of care [80–83].

Conclusion

While the fundamental purpose of research is to gain knowledge, the goal of quality improvement is to improve care and outcomes. Ultimately knowledge gained through research can be applied to clinical care, and quality improvement can advance care through complementary methods, so both research and quality improvement are necessary to improve outcomes [84, 85]. The road map of translational research begins with basic biomedical science and advances to clinical efficacy knowledge, to clinical effectiveness knowledge and finally to improved healthcare quality and value [86]. Measurement and accountability of healthcare quality and cost, implementation of interventions and healthcare system redesign, and scaling and spread of effective interventions are necessary to transform the healthcare system.

There has been a growing interest in quality of care, particularly in the era of health care reform and its emphasis on performance, accountability, and value in health care [87]. Multiple stakeholders have emerged with strong interests in defining what quality is, how it should be measured, and how the results should be used. These include patients and patient advocacy groups; providers and their professional societies; Medicare, Medicaid, and commercial payers; foundations; certifying boards and credentialing bodies; not-for-profit organizations, notably the National Quality Forum, as well as the National Committee for Quality Assurance; and business consortia such as The Leapfrog Group, an organization which fosters public reporting of healthcare quality and outcomes (hospital quality ratings). The Patient Protection and Affordable Care Act emphasizes quality measurement and requires Medicare to develop mechanisms for Accountable Care Organizations, a delivery model that rewards groups of providers with payments if they can contain costs, improve quality, and assume financial risk for their outcomes. In summary, issues related to quality of care have permeated all areas of healthcare delivery, including training, credentialing, clinical care, access to care, outcomes, documentation, cost, and reimbursement [88]. As the quality landscape continues to change, so too will its impact on the practicing clinician [89].

Fostering Self-Management and Patient Activation

58

David Alain Wohl and Justin Vandergrift

Introduction

As chronic medical conditions, such as inflammatory bowel disease (IBD), predominate as a reason for seeking medical care, both patients and their healthcare providers have increasingly recognized the importance of their forging a long-term partnership in which both take actions to achieve clinical goals. In this model, the provider provides guidance, advice and feedback, while the patient engages in behaviors aimed at achieving and maintaining health, and there is a degree of shared responsibility for outcomes. The patient side of this bargain is often described as *self-management*.

Below, we outline what self-management is, highlight evidence that self-management can improve clinical outcomes, and provide guidance on how healthcare providers can cultivate strong self-management of children living with IBD—all from the perspective of parents of young patients with Crohn disease.

Defining Self-Management

Although often equated with adherence to medication and clinic visits, self-management entails a number of complex, evolving, and life-long activities, of which adherence is but one part. Therefore, successful self-management of chronic disease is not pegged to any one action but is characterized by the cultivation of a number of behaviors and strategies that lead to a better quality of life and increased likelihood for improved disease-related outcomes.

Fig. 58.1 Tasks (outer circle) and skills (inner circle) that support disease self-management [1, 2]

A concise and useful conceptualization of self-management includes *tasks* that need to be undertaken and the set of *skills* that are required to help achieve them (Fig. 58.1) [1]. Clinicians can help patients identify unfulfilled tasks and work to help develop the skills that may be lacking.

Self-Management Tasks

The model calls for three major tasks: *medical management, role management, and emotional management*. *Medical management* addresses some of the most obvious elements of taking care of one's self including adhering to medication or a specific diet or nutritional intervention. *Role management* involves the patient making minor or

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_58

major lifestyle and activity adjustments in response to disease, for example, having specific accommodations at school or avoiding certain sports for those with colostomies. In *emotional management*, the many fears, anxieties, and frustrations that accompany a chronic illness are acknowledged and addressed as part of handling life with the disease.

For each task there are obvious leverage points that clinicians can use to make the patient aware of the problem and work together to arrive at a solution. Importantly, though, efforts to successfully develop these self-management tasks will require cognizance of a patient's perceptions and priorities. For example, in the case of a child living with IBD for whom avoiding abdominal cramps is a primary focus, the medical, role, and emotional management has to be conducted largely within the stated context of reducing pain and discomfort—even if the clinician's priority is to ensure control of inflammation and promote proper growth. Therefore, clinician recommendations regarding the need to take daily oral medication (medical), eliminating trigger foods (role), and referral to a clinical psychologist (emotional) are, in the case above, all couched as being part of the plan to keep the pain away.

Self-Management Skills

These key tasks can be achieved through developing a set of six skills that *Loring and Holman* recently added and which provide a greater sense of the work involved in self-management [2]. These skills include *problem solving, decision-making, resource utilization, patient–provider partnership, action-planning*, and *self-tailoring*. As described below, each skill can call on innate resources of the patient and family and/or be fostered and supported through intervention.

Problem-Solving is a core self-management skill. Obstacles to well-being and quality of life are inevitable, and being able to tackle them is critical to manage chronic illness. To do this, patients need to be capable of defining the problem, developing potential solutions, implementing these solutions, and evaluating the results. Advice and support from family, providers, and community may be necessary. For example, an 11-year old with indeterminate colitis dreads going to the clinic to get his anti-TNF infusion. He finds it boring, and "not fun," and he hates feeling sedated by the pre-medication. His parents discuss the problem with the physician and she considers infusion without pre-medication. His parents suggest that they download favorite TV shows for him to watch during the infusion and then go out to his favorite pizza shop afterward.

Decision-Making can follow problem-solving and is enhanced by education and training. When a 15-year old with Crohn disease receiving weekly methotrexate injections developed a fever of 101 °F on the day of his shot, based on instructions they had received at the clinic, he and his parents decide to hold the injection and contact the on-call clinician the next day.

Resource Utilization is becoming an increasingly important element of disease management. Paradoxically, as more information becomes available and accessible to patients regarding their condition, particularly online, there is less clarity as to which sources provide the most relevant and valuable advice. In pediatric IBD, the Crohn's & Colitis Foundation website (www.crohnscolitisfoundation.org) is a trove of reliable information in written and video format. ImproveCareNow (ICN), a large network of pediatric IBD programs dedicated to quality improvement, supports blogs and patient/parent discussion forums (www.improvecarenow.org). The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) also has a site for families to learn more about digestive diseases including IBD (www.gikids.org). Teaching patients and families to access these and other reliable resources has become integral to successful self-management.

Patient–Provider Partnering can be considered the keystone skill for managing a chronic disease—one on which all other self-management skills rely—but is also the most complex. The doctor–patient relationship model has traditionally been 'vertical,' with the healthcare provider issuing orders that the patient was expected to dutifully follow. While this model may be more applicable to the management of acute medical problems (e.g., appendicitis), it is ill-suited for longer term care. In recent years, patients have advocated for a more 'horizontal' or level relationship with their healthcare providers—clinics and hospitals, vying for healthcare dollars, have obliged. Strong partnerships between children with IBD, their families, and the clinician lead to greater trust, adherence, and engagement.

Action-Planning can be thought of as a next step to problem-solving and decision-making and entails skills for making a behavior change and sticking to it. A college freshman at an out-of-state school has been using nightly tube feeds to help keep her Crohn disease in remission since she was 12 years old. Now living in a single room dorm, she often feels like not 'dropping the tube,' especially on weekends, and is missing feeds. During her clinic visit, she is able to discuss the problem with the clinician and nutritionist and together they develop an action plan to take weekends off from the tube and use oral supplements these days instead. The patient feels she can do this, and implements the plan.

Self-Tailoring calls for a practical approach to use the self-management skills. Not every self-management skill is needed at all times and there must be some adaptation of response to fit the current demand. However, this tailoring is conducted by the patient/family. Therefore, the high school

senior learning how to re-order his own medications from a specialty pharmacy calls on problem-solving and action-planning skills to keep his refills from running out.

Self-Management for Kids

Together, these skills and the core tasks are intended to provide a path toward minimizing the deleterious effects of a chronic illness, while maximizing opportunities to maintain well-being and quality of life. It should be recognized that this self-management framework was developed following work with adult patients. For children, particularly those who are younger, much of the self-management heavy lifting is done by parents. The 'self' in self-management, therefore, is not 'myself' but is 'my child living with IBD,' and perhaps 'my other family members affected by my child's illness.' This is an important distinction and the literature speaks even less to this self-management by proxy model than it does to traditional self-management.

That said, the principles of self-management can be applied to and adopted by the parent of a child living with IBD. Naturally, over time, there is a shift from parent management to self-management by the patient. This transition process can be smooth, or not, as discussed in Chap. 61 and below.

For the healthcare provider, supporting and motivating health promoting behaviors for a parent or caregiver is going to look different than it will for a child.

Does Self-Management Really Matter?

Intuitively, good self-management could be expected to produce better health outcomes. While this is a reasonable assumption, medicine is replete with examples where good sense did not translate into good results. An evidence-based approach to the incorporation of self-management into medical care in general has been challenged by its complexity and a lack of uniformity in its definition. Most of the work in this area has focused on medication adherence, which via self-report, pill count, and pharmacy refill can be more readily estimated and quantified.

For children living with IBD, risks for suboptimal medication adherence that have been identified include predictable treatment-specific factors such as patient perceptions regarding the side effects and the complexity of the regimen [3, 4], as well as pill size and taste [4, 5]. Among the patient-level factors linked to suboptimal IBD medication adherence, it will come as no surprise to the parent of a teenager that none are as potent as adolescence [5, 6]. During this period of childhood development, there is a desire for autonomy, a strong interest in peer relationships, and more challenging school and social demands—all developmentally appropriate but potential barriers to adherence for all but those with the most well-developed self-management skills. Additionally, perceptions that the IBD medication is not necessary or not working can lead to missed doses [3, 6]. Family-level barriers to adherence include conflict and dysfunction, while high parent involvement in IBD care facilitates adherence and models self-management skills [5, 7–9]. Lastly, provider-level factors also can influence medication adherence in children. Satisfaction with the provider, provider trust, continuity of care with same provider, and verbal support by the provider are each associated with higher adherence in children across different disease states [10].

Overall, these studies describe a spectrum of a behavior (adherence) influenced by multiple factors across different levels. These associations are instructive insomuch as they can guide interventions, most of which have had modest effects on medication-taking.

Even less is known about what works best to foster strong true self-management behaviors more broadly. A recent meta-analysis looked at published randomized controlled trials of self-management interventions for IBD in adults [11]. Only six studies met the researchers' criteria for inclusion. The studies had disparate populations, sample sizes, primary outcomes, and interventions. One, a psychologist-delivered intervention, had all of the self-management skills proposed by Lorig and Holman, while most included two skills (*decision-making* and *patient–provider partnering*). Overall, there was an emphasis of the interventions on disease management with less attention paid to dealing with symptoms, education, and lifestyle accommodations. There was a generally favorable effect on disease activity in four of the six studies, and positive quality of life impact in three. This analysis provides a signal for the benefits of self-management in IBD, while making plain the severe limitations of the research that has been conducted thus far. Again, much less is understood about this approach in children with chronic diseases such as IBD.

How to Cultivate Self-Management

Given the potential benefits of self-management in pediatric IBD, the question that arises is how to foster these skills. As mentioned above, for some, self-management comes naturally. These patients and families are engaged in the care being provided, are proactive, adherent, and work closely with the medical team. For others, self-management skills have to be cultivated. Unfortunately, most clinics are not well-equipped to evaluate and support self-management

among their patients. Training and education takes time which is generally not reimbursed.

However, there are opportunities to promote self-management that are low-intensity and inexpensive. Foremost is development of a trusting patient–provider relationship, or ideally a trusting patient–*clinic* relationship. As mentioned above, a lack of connection between child (or parent) and provider can have consequences including poor adherence to medication and care. Additionally, electronic record systems (EMRs) are providing patients more direct access to their records and to their providers. Many support electronic communication portals for reporting of issues between visits—a boon to those, like us, who 'lean in' hard to self-management for our children. Increasingly, there are technological innovations that facilitate self-management including applications that send reminders to take medication or track stool frequency, and devices that measure physical activity.

Lastly, an aspect of self-management that has not been explicitly mentioned by those who have conceptualized it is community connectivity. Like *resource-utilization*, community connectivity involves tapping into a source of information and support, but here the resource is obtained on a human-to-human level and is reciprocal. In the existing model of self-management described above, skills are present or, ideally, developed by patients and professionals. Increasingly, patients are learning from other patients how to best manage their disease. This can occur face-to-face during support groups or educational forums, or virtually on the internet.

In pediatric IBD, ImproveCareNow has created a network of clinics with the mission of raising the quality of medical care and services. An intentional byproduct has been the creation of a community of parents of children with IBD. These 'parent-leaders' work with their clinics to achieve better self-management and ultimately better outcomes for families at their centers by rapidly sharing and distributing advances and knowledge to other families. The connectivity of patients, families, and providers through technology adds an entirely new and novel tool to bolster self-management awareness and skills.

Parent and Patient Activation

Through interactions with patients and their families, clinicians can find those who are willing to go the extra step to learn, educate, and participate. Often these 'activated' patients and families are eager to help the clinic to understand what life with IBD is really like between the clinic visits and these insights can create solutions for self-management issues which can be shared and applied to other patients.

The core of this activation is the understanding that patients and families are experts in the care of IBD. Their experiences are tangible, personal, and value-rich because their child's disease is forefront to daily activities. Often a family will develop a simple solution at home that solves common problems faced by many patients. These 'silent solutions' can dramatically change outcomes for hundreds of families but will remain silent if the clinic does not engage the patient and their family.

Clinicians can discover such pearls where they may least expect it. A simple question asking the patient *if* they are taking their medication often gets a simple answer. Probes for *how* and *when* they take medication, what they do to not forget a dose, or how they overcome side effects, delivers richer information and will encourage greater interaction between the family and provider.

Clinic parent-leaders are parents of children with IBD who are willing to work with families at the clinic to distribute advances and knowledge. The parent-leader might organize events with other parents to share ideas about treatment or answer questions from newly diagnosed parents. Other examples include quarterly newsletters prepared by the parent-leader and distributed to other clinic IBD families; at some centers mentoring programs have been established where newly diagnosed families or those facing invasive interventions such as initiation of nasogastric tube feeds, or major events such as surgery, speak with a 'veteran' family that has been through the experience.

Co-production

Following patient activation is co-production. Co-production is best summed as an environment where clinicians and patients share decision-making and work in harmony to create a better healthcare experience. At its core, co-production requires trust between patients (parents) and providers. The benefit of co-production is a better system of treatment for all patients.

According to Ruth Dineen, Founder and Co-Director of Co-Production Wales, "*co-production is an approach to public services which enables citizens and professionals to share power and work together in equal partnership, creating opportunities for people to access support when they need it and to contribute to social change*" [12]. She outlines four key features of co-production:

- Values all participants as equals and assets
- Develops and supports peer networks
- Reciprocity so that benefits accrue to all involved
- Outcomes focus such that the outcome of interest is that which matters most to the individuals, rather than process

Co-production only occurs when clinicians value parents and patients as partners and experts in their disease. This trust is essential in developing a bi-directional communication where clinicians provide advice to patients and patients provide feedback to clinicians. Co-production will bloom where communication flow is open, honest and non-judgmental.

Below are four examples of co-production from IBD clinics that work with a parent leader. Each problem and solution was created through a foundation of open communication, valuing of opinions, and with the goal of producing better outcomes for other families at the clinic.

Pill Cases

During a routine call with a parent-leader, a nurse practitioner described the difficulties another family was having while their child was tapering off prednisone. Careful not to share identifying details, the nurse practitioner related how the child's family incorrectly followed the taper sequence three times and was putting him at risk for complications.

The parent-leader came up with a simple solution to solve the issue. If the taper sequence was pre-loaded into pill cases, then patients would have less difficulty in following the schedule. The parent-leader raised funds and bought pill cases for the entire clinic. This clinic has an on-site pharmacy. Now when a prednisone taper is prescribed, the medication is pre-loaded into pill cases before the family leaves the clinic. This simple solution costs less than $2 per patient, is easy to implement, and can change the outcomes for countless patients.

This solution presented itself because of trust between the clinic and their parent-leader. No confidential information was shared, just a simple exchange of ideas and solutions.

Shot Anxiety

A parent-leader in another clinic identified a simple solution to help children who receive injections at home. This parent saw that 'shot time' was often met with anxiety and was creating a difficult family life for many patients. Through research, this parent identified a device which uses sensory confusion to make shot administration easier. She purchased the device (less than $25) and used it at home with great success. Adherence improved, anxiety was lessened, and both the child and her family were less tensed around injection time.

During a clinic visit the parent-leader mentioned their success with the device to the physician. Later, she helped the clinic obtain grant funding to purchase additional devices so that all patients at the clinic who received injections at home could benefit.

Spanish Language Educational Videos

One parent-leader met a Spanish speaking family sitting in the IBD waiting room, while waiting for their own appointment and noticed that the hospital provided an interpreter for them during the visit. However, at the end of the visit, the after visit summary and disease information given to them was in English, not Spanish. The parent-leader saw the family throw all printed materials into the trash can as they left the clinic.

In response, this parent proposed that the clinic shows short educational videos in English and Spanish. These videos featured children asking providers common questions about IBD, covering treatment and how will it interfere with their daily life. In one version, a Spanish-speaking physician answered the young patient's questions. During the filming, the parent-leader noticed the interest of the patient's father peaked. After filming the child, the father and mother asked if they would participate in the video. The result is a rich video where the parents asked questions at the forefront of their child's care (https://youtu.be/fton8Vx95K4?t=6m31s). The questions asked were perfect and familiar to many IBD families. This example, in particular, demonstrates that most people will help and educate others if provided the opportunity to do so.

The Need for Reliable Education

As described above in the description of the *resource utilization* skill, parents and patients need quality information to better manage IBD. This need for reliable data and guidance is at its peak during three phases of treatment: diagnosis, before procedures and surgery, and during medication changes. Although the internet can be a useful tool for finding information, it is recommended that clinicians steer patients towards sites which contain unbiased and useful information as early in the relationship as possible.

The Crohn's & Colitis Foundation, ImproveCareNow, and NASPGHAN (http://www.naspghan.org/ and www.gikids.org) all have websites that are content-rich and unbiased. Information is presented in written and video formats.

Self-education can be supplemented with interactive events. Several major IBD clinics, including the Center for Pediatric IBD at Children's Hospital of Philadelphia, hold annual education sessions for patients and their families https://www.chop.edu/health-resources/ibd-education-day-2022-videos. Educational events can even be facilitated by a

parent-leader. Parents have also established resource libraries for patients, quarterly newsletters, and monthly educational seminars or 'Q&A' nights. Each of these is designed with the aim of steepening the learning curve for patients and families so that with knowledge they will be more confident in their treatment decisions and self-management.

Conclusions

Self-management of a chronic illness like IBD can seem as easy as following medical advice and taking medication as directed. However, the successful navigation of a life-long condition that can be quiescent and then flare is anything but simple. Each child living with IBD, and each of their families, need to develop strategies that will optimize well-being and minimize the risk of adverse outcomes.

These strategies allow the patient to take on tasks that encompass therapeutics, lifestyle adjustment, and coping while leveraging a set of necessary skills. Clinicians can facilitate such self-management by becoming familiar with their patients and understanding where they are on the spectrum of self-management. Opportunities for intervention must be identified and then acted on.

Patient/parent activation can be a powerful self-management tool that enhances empowerment and engagement in care, while also providing lessons that can be shared and applied to help others. Considering parents and patients as partners, who can co-produce solutions, will allow clinicians to better care for their patients, and address commonly encountered problems.

Advocacy for Pediatric Patients with IBD

59

Joseph A. Picoraro, Angela Sandell, Courtney Kren, and Ross M. Maltz

Introduction

Advocacy encompasses individual, community, and state and federal efforts to speak up for positive change. Pediatricians perform advocacy at the individual and community level every day for their patients. The physician–patient partnership is well equipped to optimize patient outcomes, not only by ordering tests and prescribing treatment, but by learning about the needs of the patient and family and supporting those needs. In some offices, a team of people including physicians, social workers, psychologists, nurses, dietitians, and administrative staff work together to address patient needs while in others, the physician takes on many of these roles. In this chapter, we will address ways in which the physician and medical team can support patients living with inflammatory bowel diseases (IBD) and their families in navigating barriers to their best outcomes. Chapter sections will cover advocating in school, obtaining health insurance, navigating insurance company denials, acquiring social security disability, and attaining leave for family and caretakers.

Advocacy Directed at Schools

Children with IBD often experience challenges in school functioning, including attendance, academic progress, and participation in school and extracurricular activities. Children with chronic illness miss school more often than their healthy peers. Students with IBD miss school due to medical appointments, hospitalizations, scheduled infusions for biologic medication administration, or for simply feeling unwell. Patients also experience symptoms in school that can interfere with their ability to learn. As a result, school performance may suffer [1, 2].

The conditions and environment of school may also present challenges to children with IBD. In one qualitative and explorative analysis, approximately 15% of parents reported that schooling was substantially compromised by their child having IBD [3]. Families also reported dissatisfaction with school facilities (i.e., bathrooms) to accommodate needs of their children [3]. Patients were frustrated by a lack of understanding of their disease by their teachers [3]. Additionally, grade point average suffered in a separate adjusted analysis [4]. To mitigate the challenges faced by pediatric patients with IBD, pediatric gastroenterologists can help facilitate school accommodations.

Legislation exists to provide a framework and legal construct for physicians to advocate for their patients in school. Enacted to promote the inclusion and integration of people with disabilities into the mainstream, Section 504 of the Rehabilitation Act of 1973 bans disability discrimination [5]. The main definition for one with a disability who is protected under Section 504 is a "person who has a physical or mental impairment that substantially limits one or more major life activities." IBD is considered a physical disability because it interferes with life activities, namely, bowel, digestive, and immune functioning. Under Section 504, students with disabilities have the right to reasonable accommodations.

Section 504 covers students in kindergarten through post-secondary education. All schools that accept federal funding are required to adhere to Section 504 and provide reasonable

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_59

accommodations to those with disabilities. Despite not a financing statute, Section 504 does provide for enforcement of the mandate; a school that is found by the Office of Civil Rights to be out of compliance with Section 504 may lose its federal funding. A 504 plan is used in schools to help students with chronic illness and other disabilities to obtain individualized accommodations so that their academic success is not impacted by their health. A 504 plan helps teachers to know what the needs of the student are and how they can best address them. Under this statute, the student with IBD, their parent or guardian, and the school administration formulate a plan to accommodate the student's additional needs due to their underlying condition.

A 504 plan can be initiated by the parent or school and is a modifiable document that is required to be reviewed annually. For patients with IBD, 504 plan accommodations may include but are not limited to: unlimited restroom privileges, stop-the-clock testing, excused school absences for medical reasons, home tutoring during times of need, and allowance of snacks and water in the classroom. Parents and providers can work with the school to advocate for what the child specifically needs. A 504 plan is not only for those with active disease; it is also meant to be in place for patients with inactive disease. Planning for active disease preemptively makes that time easier to navigate than if the plan was not already in place. Pediatric gastroenterologists are poised to know the needs of the student and should be an integral part of the plan's development. The Crohn's and Colitis Foundation outlines key components to consider when devising a 504 plan for the student. They also provide a template to guide plan development, which can then be tailored to the individual student [6].

Students with IBD may also be supported through the Individual with Disabilities Education Act (IDEA) [7]. This federal legislation states that all are entitled to free and appropriate public education. Individuals in kindergarten through twelfth grade who live with a disability that affects their full participation in school (without assistance) are covered by the IDEA act. Schools are required to identify these students and develop an individualized education plan (IEP) to outline support for the student. A committee is convened to design each student's plan, and schools are financially reimbursed by the federal government for services provided in the IEP. Examples of impairments that affect school participation and are covered by the IDEA are autism, traumatic brain injury, and/or visual or learning impairments. While the act does not cover physical disabilities like IBD, for students with both IBD and neurological or developmental disabilities, their IBD accommodations would be covered in their IEP and they would not require a separate 504 plan. The IEP should include all accommodations the child may need in school because of their IBD and should outline plans for when the child has active disease, regardless of their disease status at the time of plan formulation.

Patients with IBD benefit when their pediatric gastroenterologist participates in school advocacy. Families may not be aware that their child can receive services in school which ensure that their academic success is not impacted by their health. We can serve our patients best when we partner with them to optimize their education. Resources are available to encourage families to be their best advocates. With the support of their pediatric gastroenterologists, students with IBD can look forward to their best performance and participation in school.

Advocacy Directed at Insurance Companies

Obtaining Health Insurance and the Options Your Patients Have

Treating IBD can be costly [8]. One study estimated on an annual basis, IBD patients incurred a threefold higher cost of care and double out-of-pocket costs than non-IBD patients [8]. Over nearly a 20-year period, the annual health care expenditures nearly doubled for IBD patients, with pharmacy expenses being the largest cost driver [9]. It is essential for patients to have some form of health insurance in order to cover the expenses of care and treatments.

The majority of Americans receive their health insurance via their employer. It can be the least expensive option for families since employers pay for part of their insurance. Some employers will offer health coverage on the first day of work, while others require a period worked before the employee is eligible for benefits. In 2010, the passage of the Affordable Care Act expanded coverage for young adults to stay on their parents' insurance until the age of 26.

If your patient does not have health insurance because their family is unemployed, between jobs, or let their previous insurance lapse, what are their options? What assistance and advice can your office help provide them? Outside of employee-sponsored health insurance plans, patients may be eligible to obtain health insurance via multiple options such as Medicaid, Children's Health Insurance Program (CHIP), Children with Special Health Care Needs (CSHCN) funding, Health Insurance Marketplace, or financial assistance through the individual hospital (see Table 59.1). Patients may also receive financial assistance for medications through pharmaceutical companies. For more information on various health coverage options, please refer to www.usa.gov/finding-health-insurance.

Although the federal government contributes funding, Medicaid is administered and operated by states. Patients are eligible for Medicaid if they are a United States citizen, have

Table 59.1 Health insurance and pharmaceutical assistance options

Options to obtaining health insurance
• Medicaid
• Children's Health Insurance Program (CHIP)
• Children with Special Health Care Needs (CSHCN)
• Health Insurance Marketplace
• Financial assistance through the individual hospital
Financial assistance for medications
• Pharmaceutical Co-pay assistance programs
• Pharmaceutical assistance programs cover medication costs

a social security number, are a resident in the state they are applying for coverage, and meet individual state financial requirements. If your patient's family makes too much money to qualify for Medicaid, they may be eligible for low-cost or free health insurance via CHIP. Patients can determine if they are eligible for Medicaid or CHIP by visiting their state Medicaid website or by answering a few questions at https://www.healthcare.gov/lower-costs/. Patients can apply for Medicaid and CHIP via their state Medicaid agency. Applications are typically done online, in-person, or over the phone.

The Health Insurance Marketplace was created by the Affordable Care Act, which allows people to purchase health insurance that best meets their needs. Applicants must apply during the limited enrollment period that takes place every year from November 1st through December 15th. There is a special enrollment period if a family has experienced a new life event. Qualifying new life events include changes in household (got married, had a baby, adopted a child, got divorced and lost health insurance, or loss of insurance because a family member passed away), change in residence (moving to a new home in a new zip code or county), or sudden loss of health insurance. To determine if your patient is eligible go to https://www.healthcare.gov/coverage-outside-open-enrollment/special-enrollment-period/.

Depending on the state your patient lives in, they may be eligible for coverage of their health care through Children with Special Health Care Needs (CSHCN). Authorized by Title V of the Social Security Act, CSHCN receives funding via the federal Maternal and Child Health Services Block Grant. Through CSHCN, services for diagnosis and treatment may be covered for children and youth with medically eligible conditions. However, with the broad and flexible scope of Title V legislation, each state may implement their CSHCN services differently. Additionally, medical eligibility for CSHCN coverage may vary between states. In Ohio, for example, CSHCN funds are administered through a state program called Children with Medical Handicaps (CMH). IBD is an eligible diagnosis under CMH, and as long as the patient is under the age of 21 and meets financial guidelines, this program will cover the costs of office visits, imaging, lab work, procedures/anesthesia, hospitalizations, and even treatment/medications. To determine if your patient is eligible for CSHCN coverage, contact your state's health department. You can also find your state's Toll-free Maternal and Child Health Information Line by visiting https://mchb.hrsa.gov/maternal-child-health-topics/children-and-youth-special-health-needs.

If your patient does not qualify for any of the programs listed above, or if they have private health insurance and are struggling to pay medical bills, another option would be to seek financial assistance through the individual hospital. Most hospitals have patient account representatives that can screen patients and help them apply for financial assistance through their institution. Financial assistance offered can vary between each hospital but may help cover a portion of your patient's owed medical expenses.

Medication costs continue to increase [9] with high out-of-pocket costs for families [8]. Co-pay assistance programs by pharmaceutical companies can cover a significant amount of out-of-pocket costs per year for patients with private insurance. Each pharmaceutical company offers their unique plan and some limit copays to $5 per treatment. While co-pay assistance programs will cover the cost of the medication, it will not cover the cost of the facility fees to infuse the medication. Patients can sign up for some co-pay assistance programs online, but some will require both the provider and patient signature.

If your patient does not have insurance, an additional option to cover medication costs are through patient assistance programs offered by individual pharmaceutical companies. Patient assistance programs can provide patients with the medication for free, but similar to co-pay assistance programs, it does not cover the cost of the facility fees to infuse the medication. Most patient assistance programs also require a paper application with both the patient and provider signature. Additionally, patient assistance programs have financial guidelines to determine eligibility. Patients will then need to provide a proof of income, which usually requires their most recent federal tax return. Most patient assistance programs need to have the patient's financial information renewed annually in order to maintain coverage.

Navigating Insurance Company Denials and Prior Authorizations

Navigating prior authorizations and denials are exceedingly common and time consuming for medical offices. If an insurance company denies coverage for a medication, patients usually have no idea how to appeal the decision and do not have the proper medical documentation and medical litera-

ture justification to appeal the decision. It becomes the responsibility of the provider's office to file the appeal. Nationally, approximately 39–59% of health insurance appeals are reversed [10]. Thus, appealing a denial is not a waste of time or resources, and it is beneficial to the patient. It can also be challenging for a patient to appeal a denial without the physician advocating for them.

Increasingly, health insurance companies are requiring that physician offices obtain prior authorization before they will grant coverage of the medication. Prior authorizations are in place to help keep healthcare costs down. Insurance companies want to verify that it is medically necessary, the use of the medication follows up-to-date recommendations, and the drug is the most economical option to treat that condition. While prior authorizations are supposed to create checks on the system and make sure that it is cost effective, they also lead to treatment delays and place additional administrative burden on providers and their offices. Many states have passed laws that regulate the prior authorization process by limiting the length of time insurers have to complete the prior authorization review. This whole process does interrupt the shared decision-making process between a patient and their provider. During the office visit, different medications are discussed to treat their condition, along with risks and benefits, and a decision is made between the patient and the provider. Ultimately, insurance approval is required and made without the input of the patient or the provider.

Prior authorizations may be denied if proper documentation was not submitted to the insurance company. If that is the case, the prior authorization is resubmitted with all of the proper medical information such as diagnosis, medication, dose, TB status, and other therapies tried and failed. The Affordable Care Act established common-sense consumer protections, and this requires insurance companies to inform the patient why a claim was denied and how to appeal the decision. It also guarantees the right to an internal appeal. Prior authorizations are usually denied because of three reasons: (1) the insurance company requires a patient to try an insurance preferred medication prior, (2) the insurance company deems the therapy experimental, or (3) administrative denial.

Appealing a denial on behalf of your patient to the insurance company can be confusing, though it is important that you update the patient on the process and the status of the appeal. The provider's office should submit the necessary documentation that pertains to the relevant exception that you are seeking (see Fig. 59.1). Depending on the patients insurance, it may require a peer to peer or a letter of medical

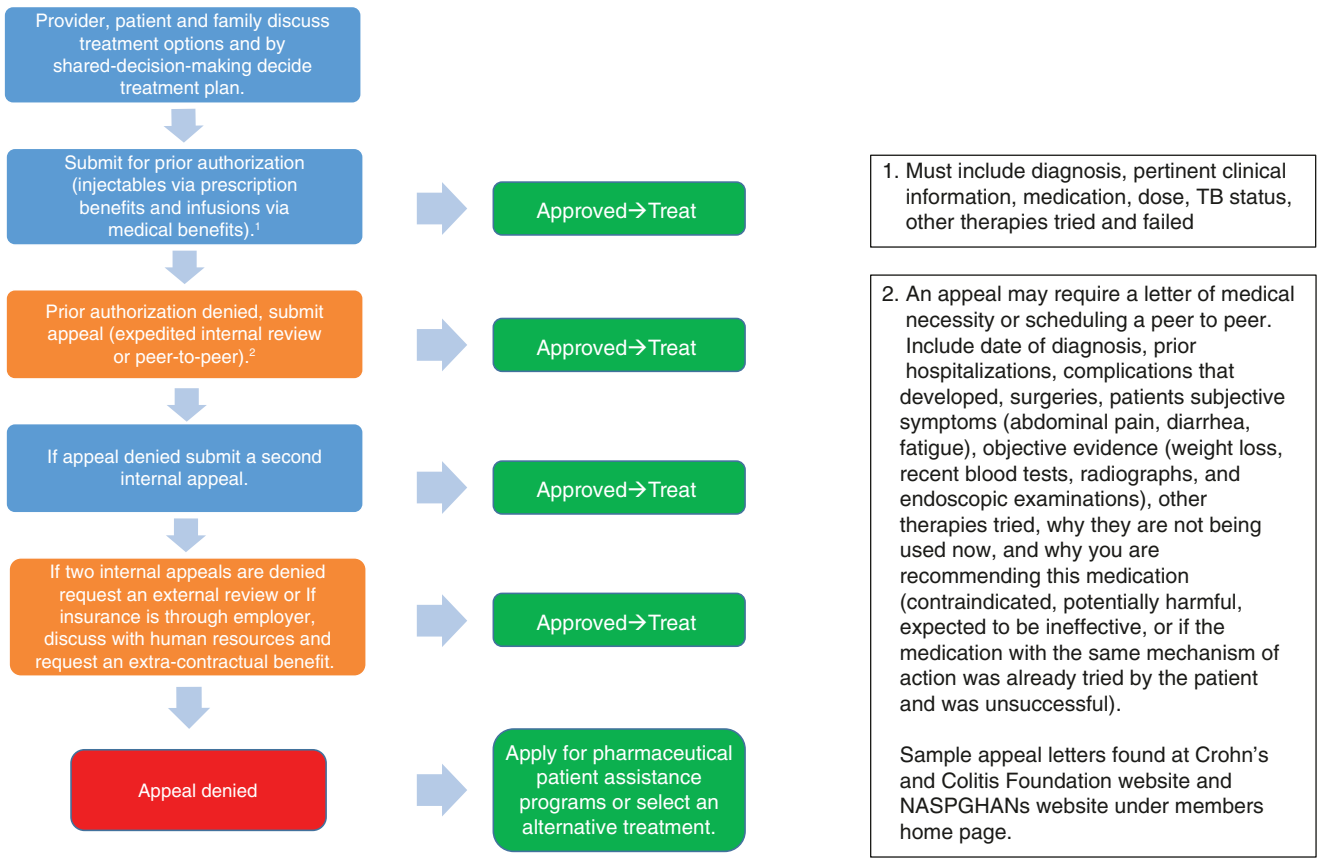

Fig. 59.1 Prior authorization and appeal process algorithm

necessity that includes the patient's illness in detail. The history should include the approximate date of diagnosis and the effects on the patient's life (including a history of prior hospitalizations, complications that developed, and surgeries). The patient's subjective symptoms (e.g., abdominal pain, diarrhea, fatigue) are important, but objective medical evidence is vital (i.e., weight loss, recent blood tests, radiographs, and endoscopic examinations) demonstrating ongoing intestinal inflammation. They include which conventional medications have been utilized and why they are not being used now (e.g., lack of efficacy, adverse effects) and highlight why a given condition requires a specific medication and explain why the insurance company recommended medications are contraindicated, potentially harmful, expected to be ineffective, or if the medication with the same mechanism of action was already tried by the patient and was unsuccessful. General appeal letters for medications, dose adjustments, and tests/procedures can be found on the Crohn's and Colitis Foundation website and NASPGHANs website under the member's home page and clinical practice. http://www.crohnscolitisfoundation.org/science-and-professionals/programs-materials/appeal-letters/ and https://naspghan.org/.

Experimental/investigational appeals can be challenging because these therapies are usually newer, more expensive, and off-label because it is only approved for adults and not yet approved for pediatrics. It is important to highlight the patients' medical course and medications that have failed them in order to highlight the patient's specific need for the novel therapy requested. It is recommended that the physician attaches published, peer-reviewed literature and supportive information that reassures the novel treatments' safety and efficacy to the appeal. Insurers tend to appreciate randomized longitudinal trials in which patients are followed for a significant period and involve placebos or a control group.

When writing a letter of appeal to an insurance company, it is very important to not let the insurer equate "off label use" with "investigational" use. When the FDA approves a medication for use, they typically approve it for one very narrow indication. An "indication" implies a specific disease, condition, or age group. For example, the FDA may approve a medication for patients with ulcerative colitis over 18 years of age. However, that does not mean that the medication should be restricted to that population. According to the American Academy of Pediatrics, "the term off label does not imply an improper, illegal, contraindicated or investigational use. Therapeutic decision-making must always rely on the best available evidence and the importance of the benefit for the individual patient" [11].

A third type of denial by insurers is an administrative denial. This type of denial occurs when there is a coverage request for a treatment that is expressly excluded from coverage. In an administrative denial, a coverage request will be denied without regard for medical necessity. However, it is possible to force an insurer to conduct a medical necessity review.

If the initial internal appeal is denied, a second appeal will need to be submit. If two internal appeals are denied, the Affordable Care Act established the right to take your appeal to an external review, which consists of an independent third party that reviews the insurer's decision. In addition, under the Affordable Care Act, every state has a Consumer Assistance Program (CAP) to help consumers with insurance appeals. The CAP in your state may be in your state's Insurance Department, or it may be a separate entity. The CAP is funded largely by federal grant funds.

At last, if your patient obtains its medical insurance through their employer, you may recommend that the patient discusses the issue with their human resource department. Employees can ask their employer to grant an extra-contractual benefit, which provides coverage for something that otherwise would not be covered.

Unfortunately, if all internal and external appeals are denied, then patients can apply for patient assistance programs through the individual pharmaceutical company or select an alternative treatment covered by their insurance company.

In summary, navigating health coverage options and working with insurance companies can be extremely frustrating and time consuming for you, as well as your office staff. It is important that you become a strong advocate for your patient because ultimately it is in the best interest for your patient and their health. It is also crucial that you keep the patient and their family up to date throughout the process, especially if coverage is denied. Laws over the years have been created to protect patient rights and improve the appeals process. It is important that as physicians, we advocate for our patients in the office setting and in state and federal government.

Social Security Disability Benefits

Many people do not realize that children may be eligible for Supplemental Security Income (SSI), one of two forms of Social Security disability benefits. There is often confusion about SSI and Social Security Disability (SSDI) because you apply for both programs with the Social Security Administration (SSA). While both SSDI and SSI provide financial assistance to individuals living with disabilities, SSDI benefits are determined based on both the individual's disability and personal/family work history. When determining eligibility for SSDI benefits, the individual/family needs

to have worked long enough to be insured under the social security system. SSI does not require a work history and gives money to individuals, including infants and children, who have medical impairments and meet both citizenship and financial guidelines. Typically, the financial guidelines are for those with low income and few resources. For more information about eligibility guidelines for SSI and SSDI, please refer to ssa.gov/benefits/.

For a child to be eligible for disability benefits, they must have a medically proven physical or mental condition(s) that causes severe functional limitations and must have lasted, or is expected to last, at least 12 months. IBD is a condition listed in the SSA's impairment listing manual. However, there are specific diagnostic criteria that must be met in order for a patient to qualify for disability benefits. If a patient does not meet the diagnostic criteria, they may still qualify if they can show that their condition makes it impossible to work, attend school, or engage in basic activities of daily living. Additionally, multiple impairments that by themselves do not qualify may satisfy the condition of marked, severe limitation when combined. If your IBD patient has another condition(s) also causing impairment on their life, there is a higher chance that they may qualify for disability benefits due to having multiple limitations.

Patients can apply for disability benefits online, over the phone, or by contacting their local Social Security office. While patients will need to request official medical records to submit to the SSA, you can assist your patients in this process by writing a letter of support. This letter should explain the child's condition, brief overview of medical history, current physical or mental limitations, and instructions on how the SSA can request the child's medical records at your institution. It is helpful to inform your patients that once their application is submitted, it can take between 90 and 120 days before they will be notified of a decision. It is also important to let your patients know to be prepared to appeal an initial determination. A majority of individuals who apply for disability benefits are denied after their initial attempt. Appeals can be successful when the application is reconsidered. Helping your patients understands the application and appeal process can make the process of applying for benefits clearer and less stressful.

In addition, an integral part of living with any chronic illness is helping maintain self-identity and promoting patient empowerment. Health care providers must foster an environment that avoids an internalized notion of a "disabled" self-concept. The burden and process of securing entitlements that require the proof of "disability" may be counterproductive to the message we strive to convey—that the child is a whole person, who is more than the disease. Health care providers, who can facilitate the SSI application in an efficient and seamless manner, will help preserve this message.

Family and Medical Leave for Caregivers

Caregivers of children with IBD often risk losing their jobs when they take time-off to care for their children. Providers may be able to spare them this crisis by helping them to maintain employment security under the Family and Medical Leave Act (FMLA). FMLA is a federal law that requires covered employers to provide an eligible employee up to a total of 12 workweeks of unpaid leave during a 12-month period for a serious health condition, or to care for a family member (spouse, child, or parent) with a serious health condition. FMLA is enforced by the U.S. Department of Labor Employment Standards Administration, Wage and Hour Division. While FMLA is a federal protection, some states have their own laws covering employee sick leave. However, in states with family and medical leave laws, employers must adhere to the family and medical leave statutes that provide the most protections to workers. In states without family and medical leave laws, FMLA guidelines must be followed by default.

Employers that are required to follow FMLA guidelines are those in local, state, or federal government agencies, those in public or private elementary or secondary schools, and those in the private sector with 50 or more employees in 20 or more workweeks in the current or preceding calendar year. Employees that are eligible for FMLA must have worked for the same employer at least 12 months, for at least 1250 h during the previous 12 months, and be employed at a location where at least 50 individuals are employed by the employer within a 75-mile area. It is important to note that FMLA does not require paid leave and an employer may permit an employee to use all available vacation, sick, or paid time-off time during such leave. Additionally, the 12 weeks of leave need not be consecutive. For example, a parent of a child who is on infliximab treatments can take a day of leave every few weeks to get the infusions and their job will be protected under FMLA. Employers must post a notice to their employees explaining the rights and responsibilities under FMLA, or they may be fined.

A child has a "serious health condition" under FMLA if he or she is incapable of self-care due to a mental or physical disability that limits one or more of the "major life activities." Just as is the case under the Americans with Disabilities Act, "major bodily functions," including digestive function, are included within "major life activities," so this would apply to children with active IBD. A "serious health condition" is also defined as a condition that continues over an extended period of time, requires repeated visits to a health care provider, and may involve occasional episodes of incapacity. Even if symptoms are inactive, children with IBD have the potential to require this care due to the cyclical nature of this chronic disease. Primary caregivers of children

with IBD should ask for FMLA leave at the beginning of every year, whether or not they use it, so that they are protected if the child's disease becomes active or they need to take off work to care for their child on an intermittent basis.

Caregivers of children with IBD may apply for continuous and/or intermittent leave under FMLA. Continuous leave is typically requested if the child is hospitalized for a long period of time or needs to undergo a surgical procedure. In this case, the caregiver is asking for a consecutive period of time-off so that they can provide care for their child in the hospital or at home until the child recovers. Intermittent leave is typically requested for the child's required routine follow-up, which includes office visits, trips to get labs done, and/or appointments for infusions. Intermittent leave is also beneficial to have for unexpected time-off, such as times when the caregiver may need to take off work to care for their child's episodic flare-up or take their child to the emergency department or urgent care.

When requesting FMLA leaves, the employee must request it in writing with their employer at least 30 days in advance if the need for leave is foreseeable. If the need for leave is unforeseeable, employee requests must be made as soon as possible and must comply with an agency's normal call-in procedures. If a physician anticipates a child who will require increased parental care because of the worsening of the disease, this should be discussed with the family so that the caregivers may request FMLA leave before the crisis occurs. While FMLA does not require the use of any specific form or format, the US Department of Labor offers certification forms that make it easier for employers to understand the reason the employee is seeking leave. For caregivers of patients with IBD, this form is titled "Certification of Health Care Provider for Family's Member's Serious Health Condition." Appendix 1 includes an example of this form filled out for a patient diagnosed with IBD. However, employers may use their own FMLA forms as long as they provide the same basic notice information and require only the same basic certification information.

When filling out FMLA for a family, it is important to demonstrate the need for FMLA leave. You will first want to include a general description about IBD and the patient's date of diagnosis and recent or upcoming office visits and hospitalizations. It is important to make clear that IBD is a lifelong, chronic condition that will require routine care and medical supervision with a gastroenterologist. You will also want to add an estimated frequency that the caregiver may need to take off work to bring their child to follow-up treatments or appointments. Additionally, it is beneficial to note the unpredictable nature of IBD and explain how the caregiver may need to call off work in short notice for potential hospitalizations, episodic flare-ups, procedures, or to seek immediate medical attention. In doing so, it is helpful to emphasize the importance of the caregiver being present so that they can provide their child with psychological support, transportation, and assistance with basic activities of daily living. See Appendix 1 for an example of a filled out FMLA form for an IBD patient. Protecting job security can ensure financial stability and enable parents to focus on their child's acute needs and the impact on the family.

Summary

Children and families living with IBD inherently face many challenges. Awareness, support, and proactive intervention can garner crucial resources to thrive in school, financially, and as a family. Healthcare providers serve in the fundamental position of generating awareness and providing access to these resources. While some care centers will have multidisciplinary support, every clinician should incorporate an approach to address barriers for children with IBD. With attention to policies on 504 plans and IEPs, children can realize their full potential in school. With diligent navigation of health insurance options and patient assistance programs, the cost of care can be more affordable. With dedication and persistence, critical therapies can be accessed. With awareness and execution, caregivers can ensure intact employment and supplemental income. The provider who is an effective advocate will attend to the financial, educational, and social implications of IBD, and ensure a better quality of life for the child and their family.

Acknowledgments We would like to acknowledge the contributions of Jennifer Jaff and Suzanne Rosenthal who wrote the first two published versions of this chapter and Janis Arnold and Athos Bousvaros who wrote the third published version of this chapter.

Appendix 1

Certification of Health Care Provider for Family Member's Serious Health Condition (Family and Medical Leave Act)

U.S. Department of Labor
Wage and Hour Division

DO NOT SEND COMPLETED FORM TO THE DEPARTMENT OF LABOR; RETURN TO THE PATIENT.

OMB Control Number: 1235-0003
Expires: 8/31/2021

SECTION I: For Completion by the EMPLOYER

INSTRUCTIONS to the EMPLOYER: The Family and Medical Leave Act (FMLA) provides that an employer may require an employee seeking FMLA protections because of a need for leave to care for a covered family member with a serious health condition to submit a medical certification issued by the health care provider of the covered family member. Please complete Section I before giving this form to your employee. Your response is voluntary. While you are not required to use this form, you may not ask the employee to provide more information than allowed under the FMLA regulations, 29 C.F.R. §§ 825.306-825.308. Employers must generally maintain records and documents relating to medical certifications, recertifications, or medical histories of employees' family members, created for FMLA purposes as confidential medical records in separate files/records from the usual personnel files and in accordance with 29 C.F.R. § 1630.14(c)(1), if the Americans with Disabilities Act applies, and in accordance with 29 C.F.R. § 1635.9, if the Genetic Information Nondiscrimination Act applies.

Employer name and contact: _____

SECTION II: For Completion by the EMPLOYEE

INSTRUCTIONS to the EMPLOYEE: Please complete Section II before giving this form to your family member or his/her medical provider. The FMLA permits an employer to require that you submit a timely, complete, and sufficient medical certification to support a request for FMLA leave to care for a covered family member with a serious health condition. If requested by your employer, your response is required to obtain or retain the benefit of FMLA protections. 29 U.S.C. §§ 2613, 2614(c)(3). Failure to provide a complete and sufficient medical certification may result in a denial of your FMLA request. 29 C.F.R. § 825.313. Your employer must give you at least 15 calendar days to return this form to your employer. 29 C.F.R. § 825.305.

Your name: _____
First Middle Last

Name of family member for whom you will provide care: _____
First Middle Last

Relationship of family member to you: _____

If family member is your son or daughter, date of birth: _____

Describe care you will provide to your family member and estimate leave needed to provide care:

_____

_____

_____

_____ _____ _____
Employee Signature Date

SECTION III: For Completion by the HEALTH CARE PROVIDER

INSTRUCTIONS to the HEALTH CARE PROVIDER: The employee listed above has requested leave under the FMLA to care for your patient. Answer, fully and completely, all applicable parts below. Several questions seek a response as to the frequency or duration of a condition, treatment, etc. Your answer should be your best estimate based upon your medical knowledge, experience, and examination of the patient. Be as specific as you can; terms such as "lifetime," "unknown," or "indeterminate" may not be sufficient to determine FMLA coverage. Limit your responses to the condition for which the patient needs leave. Do not provide information about genetic tests, as defined in 29 C.F.R. § 1635.3(f), or genetic services, as defined in 29 C.F.R. § 1635.3(e). Page 3 provides space for additional information, should you need it. Please be sure to sign the form on the last page.

Provider's name and business address: _____

Type of practice / Medical specialty: _____

Telephone: (_____) _____ Fax:(_____) _____

PART A: MEDICAL FACTS

1. Approximate date condition commenced: _____

Probable duration of condition: Lifelong chronic duration

Was the patient admitted for an overnight stay in a hospital, hospice, or residential medical care facility?
___No ___Yes. If so, dates of admission: _____

Date(s) you treated the patient for condition: _____

Was medication, other than over-the-counter medication, prescribed? ___No ✓ Yes.

Will the patient need to have treatment visits at least twice per year due to the condition? ___No ✓ Yes

Was the patient referred to other health care provider(s) for evaluation or treatment (e.g., physical therapist)?
____ No ____Yes. If so, state the nature of such treatments and expected duration of treatment:

2. Is the medical condition pregnancy? ✓ No ___Yes. If so, expected delivery date: _____

3. Describe other relevant medical facts, if any, related to the condition for which the patient needs care (such medical facts may include symptoms, diagnosis, or any regimen of continuing treatment such as the use of specialized equipment):

Patient is diagnosed with a condition called Inflammatory Bowel Disease (IBD), which involves chronic inflammation of the digestive tract. IBD is lifelong and requires routine care medical supervision with a Gastroenterologist. IBD if often characterized by recurrent flares of symptoms, which can include severe abdominal pain, bloody diarrhea, fevers, and other medical complications if not monitored closely.

PART B: AMOUNT OF CARE NEEDED: When answering these questions, keep in mind that your patient's need for care by the employee seeking leave may include assistance with basic medical, hygienic, nutritional, safety or transportation needs, or the provision of physical or psychological care:

4. Will the patient be incapacitated for a single continuous period of time, including any time for treatment and recovery? ___No ___Yes.

   Estimate the beginning and ending dates for the period of incapacity: _____

   During this time, will the patient need care? __ No __ Yes.

   Explain the care needed by the patient and why such care is medically necessary:

5. Will the patient require follow-up treatments, including any time for recovery? ___No ✓ Yes.

   Estimate treatment schedule, if any, including the dates of any scheduled appointments and the time required for each appointment, including any recovery period:

   Patient will have infusions/routine clinic visits approximately once every (***) weeks, lasting for (***) hours in duration.

   Explain the care needed by the patient, and why such care is medically necessary: Infusions are needed to induce/maintain remission. Routine clinic visits are needed to monitor labs and prevent any future flares/complications.

6. Will the patient require care on an intermittent or reduced schedule basis, including any time for recovery? __ No ✓ Yes.

   Estimate the hours the patient needs care on an intermittent basis, if any:

   8 hour(s) per day; 1-2 days per week from _____ through _____

   Explain the care needed by the patient, and why such care is medically necessary: In addition to infusions and routine clinic visits, episodic flares, hospitalizations, urgent care/emergency department visits, and even procedures may be required for patients with IBD. If hospitalized, admissions can last anywhere from 3 days to 3 weeks.

7. Will the condition cause episodic flare-ups periodically preventing the patient from participating in normal daily activities? ____No ✓ Yes.

Based upon the patient's medical history and your knowledge of the medical condition, estimate the frequency of flare-ups and the duration of related incapacity that the patient may have over the next 6 months (e.g., 1 episode every 3 months lasting 1-2 days):

Frequency: 1-2 times per _____ week(s) 1 month(s)

Duration: _____ hours or 2-3 day(s) per episode

Does the patient need care during these flare-ups? ____ No ✓ Yes.

Explain the care needed by the patient, and why such care is medically necessary: Flares that occur with IBD can vary depending on their symptoms, duration, and frequency. Flares can often be managed at home with parent supervision, though there are times when a flare may require medical follow-up and/or immediate medical attention. Hospitalizations/ emergent procedures may even be needed if the flare is significant. In these instances, parent care is highly needed.

ADDITIONAL INFORMATION: IDENTIFY QUESTION NUMBER WITH YOUR ADDITIONAL ANSWER.

3, 5, 6, & 7) - Parent care, psychological support, transportation, and supervision is needed for ALL routine follow-up, medical evaluations/treatment, potential hospitalizations/procedures, and episodic flares. Parent care includes assistance with basic activities of daily living, such as helping with hygiene needs, mobility, eating/dietary monitoring, and maintaining continence.

Signature of Health Care Provider **Date**

PAPERWORK REDUCTION ACT NOTICE AND PUBLIC BURDEN STATEMENT

If submitted, it is mandatory for employers to retain a copy of this disclosure in their records for three years. 29 U.S.C. § 2616; 29 C.F.R. § 825.500. Persons are not required to respond to this collection of information unless it displays a currently valid OMB control number. The Department of Labor estimates that it will take an average of 20 minutes for respondents to complete this collection of information, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. If you have any comments regarding this burden estimate or any other aspect of this collection information, including suggestions for reducing this burden, send them to the Administrator, Wage and Hour Division, U.S. Department of Labor, Room S-3502, 200 Constitution Ave., NW, Washington, DC 20210.
DO NOT SEND COMPLETED FORM TO THE DEPARTMENT OF LABOR; RETURN TO THE PATIENT.

Advocacy for Pediatric Patients with Inflammatory Bowel Disease

60

Janis Arnold and Athos Bousvaros

Introduction

Physicians who treat patients with chronic illnesses know that the practice of medicine has come to involve the practice of patient advocacy. Whether it be justifying a prescription for a non-formulary medication or trying to help a child obtain necessary accommodations from a school, physicians who treat children with IBD have to learn to be advocates. Although this is not something we are taught in medical school, it has become an integral facet of practicing collaborative medicine in the United States in the twenty-first century. Use of a medical team approach is most important to meet the advocacy needs of patients. The medical team may involve the physician, nurses, social workers, nutritionists, psychologists, and administrative staff.

In smaller centers, providers may find themselves taking on multiple roles. We will discuss the following five substantive areas in which advocacy for patients is necessary:

1. Navigating school administrative requirements to enable optimal academic plans for ill children with IBD to attend school.
2. Insurance company denials of a needed therapy, including mental health services.
3. Social Security disability assistance for children and adolescents.
4. Family and medical leave for caretakers of children with IBD.
5. Restroom Access Act.

We would like to dedicate this chapter to our former collaborator and close friend, Jennifer Jaff.

Advocacy Directed at Schools

Children with IBD are often embarrassed to attend school because of their digestive symptoms. We once cared for a child who had not been in school for a year and one-half because his parents did not understand that they could request accommodations for him that would have allowed him to stay in school. They essentially hoped his symptoms would resolve, or that he would learn to adjust on his own. The family was unaware of where to go for help, or what legal recourse they had. When the school district sent them forms to fill out to begin the process of evaluating the child for accommodations, the family did not understand what purpose of the forms or the evaluation were, so the child stayed disengaged from school for nearly 18 months. Ultimately, intervention by an attorney with expertise in school advocacy resulted in resolution of the problem and the return of the child to school.

There are two related statutes that provide protection for students with IBD: the Individuals with Disabilities Education Act ("IDEA"), [1] and Section 504 of the Rehabilitation Act of 1973 ("Section 504"). [2] The IDEA applies to state and local education agencies, whereas Section 504 applies to educational institutions that are recipients of federal funds. The two statutes are related, but they are not identical.

Whereas the IDEA applies only to grade and secondary schools, Section 504 pertains to all levels of education—grade school to college to graduate schools that accept federal funding. The IDEA is geared toward students who need special education services related to a learning disability as opposed to students with a physical condition like IBD, whereas Section 504 is broader, and includes physical disabilities as well as learning disabilities (although special education services are available only under the IDEA). Patients with IBD usually do not have a lifelong learning dis-

P. Mamula et al. (eds.), *Pediatric Inflammatory Bowel Disease*, https://doi.org/10.1007/978-3-031-14744-9_60

ability that requires placement in special education classes. However, they may require some accommodations due to school absence during periods of illness, or because their illness sometimes limits their participation. Thus, patients with IBD are more likely to be eligible for accommodations under section 504 than they are for accommodations under IDEA.

The IDEA provides that a child with a disability who needs special education is entitled to a free appropriate public education. The IDEA defines a child with a disability to include children with a number of specific types of disabilities, including visual and hearing impairments, speech and language impairments, autism, traumatic brain injury, and emotional disturbances. While inflammatory bowel disease is not explicitly stated in the IDEA, the law does include a proviso providing assistance to children with "other health impairments." However, children who qualify for assistance under IDEA must have a physical or mental disability that affects their ability to fully participate in school without some form of assistance, whereas children who qualify for accommodations under Section 504 need only to show that they have a medical condition that substantially impairs one or more major life activities, regardless of how they perform in school.

Under the IDEA, the first requirement imposed on the states is to "identify, locate and evaluate" children in need of special education services (called "child find"). Once children are located, the IDEA requires states to meet the needs of those children. The core of the IDEA is the "individualized education program" or "IEP." Under the IDEA, states are required to conduct an evaluation before special education benefits are granted. The evaluation determines whether the child is, in fact, a "child with a disability" and has special educational needs. The process should be initiated by the school, which should provide notice of the evaluation to the parents. The child may be tested and evaluated using a variety of tools; after this evaluation is completed, the actual IEP is formulated.

The IEP should be a separate written statement for each qualifying student that includes a statement of the child's level of educational performance; a statement of goals; a statement of the special education and related services to be provided; an explanation of the extent, if any, of the child's participation in mainstream programs; a statement of any individual modifications; the projected date for commencement of these services; and the duration of the services. In fashioning the IEP, the strengths of the child, the parents' concerns, and the results of the most recent evaluation of the child must be considered.

The IEP "team" includes the parents, at least one non-special education teacher, at least one special education teacher, a representative of the local agency who is qualified to assist in formulating IEPs, other experts brought in at the request of the parents or the State, and, if appropriate, the child. The IDEA provides safeguards to ensure parental involvement at all stages of the child's education, and parents may challenge any aspect of an IEP by requesting a hearing, and if they remain dissatisfied, they may file suit in federal court. Schools that provide services under the IDEA are also eligible for financial support through the state and federal government.

In contrast, Section 504 of the Rehabilitation Act was enacted to promote the inclusion and integration of people with disabilities into the mainstream. Section 504 provides that disabled children cannot be denied the benefits of any program that receives federal financial assistance, including public education. In general, a child is disabled if he or she has a "physical or mental impairment" that "substantially limits" one or more "major life activities" as those terms are used in the Americans with Disabilities Act. [3] Major life activities include bodily functions, such as the bowel, digestion, and immune functions.

Once the student's medical disability is established, the next step is to determine what accommodations (under Section 504) or special services (under the IDEA) must be provided. While section 504 is a more inclusive statute than IDEA, school districts providing services under 504 plans are not reimbursed for their expenses by the federal government. Because Section 504's definition of disability is broader than the IDEA's, many IBD patients will qualify under Section 504 but not under the IDEA. These are called "504-only students." For some patients, accommodations are minimal (e.g., providing medication during school hours, or being excused from physical education class), whereas for other students, accommodations are more extensive (including limiting home work loads and home tutoring). Under the IDEA, a child may be eligible for speech therapy, special education services, and even nursing care. Any assistance a student receives from a school must be provided for free.

Any child who needs accommodation under IDEA or section 504 must be the subject of an evaluation *before* taking any action with respect to placement. Once testing is concluded, schools use the results, as well as teacher recommendations, physical condition, social or cultural background, and adaptive behavior in designing the plan for the student. Parents must have notice and opportunity to examine the evaluation records, there must be a hearing at which the parents and/or other guardian can appear, and there must be a procedure for review of the decision.

There are at least two issues that face IBD patients that are not well addressed by the law. First, children who do well in school are presumed not to need help. The IDEA defines "child with a disability" to mean a child with health problems "who, by reason thereof, needs special education and related services." A student who does not need special educa-

[3] 42 U.S.C. § 12101, *et seq.*

tion because she is performing well academically is not a "child with a disability" under the IDEA. Therefore, only children with IBD who have neurologic or developmental conditions that impair learning are covered under the IDEA. However, this is not the case under Section 504, which provides reasonable accommodations to any student who is substantially impaired by a major life activity, regardless of the effect—or lack thereof—on the ability to learn.

Second, the IDEA does not provide explicit guidance for children with a chronic disease that remits and relapses. However, as of January 2009, Section 504 provides that an episodic illness that is disabling when active also is considered to be disabling when in remission. This presents a challenge for both the parents and the school, because even though Section 504 now recognizes chronic illness, it is difficult to write an IEP or Section 504 plan that is not intended to apply only intermittently. Because chronic illness is cyclical in nature, there will be times when a student needs home schooling or temporary access to typed handouts, and other times when the student has no need for help. The waxing and waning course of IBD and the unpredictability of the illness necessitate that the 504 plan for an IBD patient be flexible and change depending on whether the patient is ill or in remission.

Generally, it is the child's parents in conjunction with the members of the health care team that realize that educational accommodations may be needed for their chronically ill child. In patients with IBD, this need is often recognized during a period of prolonged illness (such as in a hospitalization for intravenous medication or surgery). At this point, parents and members of the health care team should list the child's needs in writing, and discuss with school officials to develop a written plan. A plan under either the IDEA or Section 504 may include accommodations such as seating chart placement, extended time for testing, adjustment of class schedules, use of aids such as tape recorders, permission to photocopy a classmate's handwritten notes, class and/or homework assistance, administration of medication, behavioral support, initiation of tutoring prior to the standard 14 consecutive days of absence, access to bathroom without the required hall passes, permission to have a water bottle in class, or multiple sets of textbooks. For chronically ill patients with IBD, parents and school officials should have this integrated academic plan for IBD students in place.[4]

The IBD Center at Boston's Children's Hospital had the opportunity to work with a high school student who experienced her first severe flare-up of her ulcerative colitis, which had been well controlled for many years. Her symptoms were initially unresponsive to various medications. She ultimately was placed on tacrolimus, which lead her to develop the side effects of hand tingling, joint pain, and hand tremors. Though her medication regimen decreased her GI symptoms enough to allow school re-entry, the side effects from the necessary medication left her unable to fully participate in the classroom requirements, including note taking. Consequently, this interfered with her ability to have the adequate review materials to study for tests. We collaborated with the patient's mother and the school to develop a 504 plan for the patient. Among other plan provisions, relevant accommodations included allowing her to identify a classmate in each course whose notes she had permission to photocopy. It also was detailed that the teacher would, when appropriate, provide the student with typed copies of the class notes and outlines. An additional item was written into her 504 plan which stated that, if she had to be absent unpredictably, the plan coordinator would be responsible for getting the student a copy of the classmates' notes and teacher outlines within 48 h of the missed school days. This protected the student's academic performance and reduced the anticipatory anxiety regarding not being able to keep up with the class notes—anxiety that could lead to exacerbation and prolonging of her disease's symptoms.

Although a Section 504 plan can be implemented during periods of illness, many families and patients find it helpful to coordinate and delineate these educational adaptations prior to what may be experienced as a medical crisis or complications, given our awareness that these disease processes are unpredictable and can change quickly. It is often difficult and burdensome to try to arrange these meetings and plan at times when families are simultaneously focusing on acute medical demands and the family reorganization that must accommodate them. Nonetheless, it is critical that normal school attendance, curriculum participation, and activity should be encouraged during the periods of remission (see Appendix 1).

While written advocacy through letters supporting a 504 plan is helpful, sometimes a direct phone call from the physician or team member to the principal or vice principal is even more effective. For example, we had a patient who could not complete tests in a timely manner because the stress of the test would cause her intestinal symptoms to flare. While written documentation was sent, and most teachers responded adequately to the written documentation, one teacher remained resistant to implementing "stop the clock testing." A call from the patient's physician to the school administration resulted in a more detailed discussion between the principal and the teacher, which enabled the student to receive appropriate accommodations.

COVID-19 Considerations

The unprecedented COVID pandemic has changed the delivery of health care and the navigation of social settings as we know them everywhere. Among the immeasurable implications, the pandemic has also led to necessary restrictions in school settings to mitigate the risk of transmission of this virus. As a result, many of these restrictions have unintentionally, but immovably created barriers and limitations that would otherwise have been able to support students with IBD. For example, many schools have created one-way hallways to reduce traffic and increase physical distance; many of the students with IBD experiencing stool urgency have to walk much farther to get a restroom that may otherwise be very proximal to their location. Additionally, many communal school bathrooms must reduce capacity by taking altering stalls out of use, thereby reducing overall access. These measures to increase safety around COVID are the ones that have had less success of overriding on behalf of the demands associated with IBD. This requires individualized discussions with schools regarding infrastructure limits and student needs, to determine "reasonable" accommodations under the law, in the climate of COVID-19. Remote learning was also commonplace during the COVID-19 pandemic, but almost all school systems now have returned to in person learning. While many IBD patients are receiving immune suppressive therapy, the vast majority of patients are able to attend in person school.

Advocacy Directed at Insurance Companies

Inflammatory bowel disease is a costly illness; one 1992 study estimated the per capita annual costs of Crohn disease ("CD") to be approximately $6500 dollars, though a small number of patients account for the bulk of that cost. [5] Charges for a hospitalization may approach $30,000, especially when that hospitalization involves surgery.[6] In addition, the increasing utilization of highly expensive biologic therapies (including infliximab, adalimumab, and vedolizumab) means that annual costs of medications may be tens of thousands of dollars. For these reasons, coverage by third-party payors is essential for most patients.

Insurance company denials of prescribed therapies are exceedingly common. Often, pediatric prescriptions are automatically denied simply because the patient is under age 18, and the drug has been approved by the FDA for individuals over 18 years. When coverage for a therapy is denied by an insurance company, the patient in all likelihood will not be able to pay for it him or herself. Thus, appealing the decision may be necessary. Nationally, approximately 70% of health insurance appeals are granted. [7] That means, in most cases, appealing is not a waste of the patient's time. However, without the physician's help and advocacy, appeals are difficult, if not impossible.

Yet, not all physicians know what to say to an insurance company. For example, when one physician was sent a denial of coverage for a 30-day supply of ondansetron (Zofran), and the patient asked her to call her insurance company and appeal the denial, the physician's response was "what do you want me to say?" In this case, the patient was also a patient advocate, and could coach her doctor through the appeal by telling her to explain that everything else had been tried and failed, and that intractable nausea required this medication. But what happens to a patient whose physician does not know how to be an advocate?

There are at least two main categories of appeals: ***medical necessity appeals*** and ***experimental/investigational appeals*** due to the nature of the medicine, device, or other treatments. For medical necessity appeals, the physician and patient must highlight the particulars of the patient's medical condition, and why a given condition requires a specific medication. As an example of a ***medical necessity appeal***, a patient who develops nausea from generic sulfasalazine but tolerates enteric-coated brand name sulfasalazine may initially have the brand name drug denied. However, a brief letter from the physician describing the precise adverse event to the generic medication, and the need for the brand name drug will usually result in approval by the insurance company. Here, both forms of the medication have similar proven efficacy, but one form is medically necessary because it is better tolerated by the patient.

The second category, ***experimental/investigational appeals***,[8] typically occurs with a newer, more expensive therapy that is beginning to enter the armamentarium of accepted treatments, or perhaps a medication that is being used off-label, including medications that are approved for adults but not yet for the pediatric population. Typically, in this circumstance, the physician has access to published literature that supports a claim that a given medication or treatment will help their patient. However, the insurance company or other payor either is unaware of the published literature or does not feel the evidence in support of this new treatment is sufficient to provide reimbursement. For this reason, the

[8] Some insurers characterize these as medical necessity appeals. However, regardless of the label the insurer places on the denial, when an insurer denies coverage on the ground that a service has not been studied adequately, our advice regarding the content of the appeal is the same.

payor denies coverage and refuses to reimburse for therapy. This type of appeal (appeal of coverage denial) is the more difficult. The physician and patient must demonstrate that the patient has failed other conventional treatments, highlight the patient's specific need for the novel therapy requested, and provide published, peer-reviewed literature and supportive information that support the novel treatment's safety and efficacy.

When writing a letter of appeal to an insurance company, it is very important to not let the insurer equate "off-label use" with "investigational" use. When the FDA approves a medication for use, they typically approve it for one very narrow indication. An "indication" implies a specific disease, condition, or age group. For example, The FDA may approve a medication for patients with ulcerative colitis over 18 years of age. However, that does not mean the medication should be restricted to that population. According to the American Academy of Pediatrics, "the term off label does not imply an improper, illegal, contraindicated or investigational use. Therapeutic decision making must always rely on the best available evidence and the importance of the benefit for the individual patient" (AAP committee on Drugs, Off Label use of drugs in Children. Pediatrics 2014; 133:563–7).

When appealing the denial of coverage of a treatment that the insurer states is off-label, experimental or investigational, the essential tool for obtaining approval is the appeal letter/letter of medical necessity. In summary, the physician should first describe the patient's illness in detail. The history should include the approximate date of diagnosis, and the effects on the patient's life (including a history of prior hospitalizations and surgeries). Other more conventional medications that have been utilized should be described, and why are not being used now (e.g., lack of efficacy, adverse effects). Peer-reviewed literature supporting the medication the patient now needs should be attached to the appeal. Insurers tend to appreciate longitudinal trials in which patients are followed for a significant period of time, and which involve placebos. This may well be impossible in all cases; for example, if a patient or physician is seeking coverage for a medical device, there may not be a functional equivalent of a placebo that ethically could be used. However, the best literature will be peer-reviewed articles published in medical journals documenting randomized trials in which the treatment is compared to a control group of some kind. Other evidence, including open-label trial data or recent proceedings from medical meetings may also be useful, but will not carry the same weight.

According to one publication, the range of off-label medication use in pediatrics can range from 10% to as high as 80% (Gore et al., Curr Clin Pharmacol. 2017;12:18–25). Because testing medications through clinical trials in pediatrics can be challenging, there is often a lag time of several years between the approval of an effective medication in adults, and the subsequent pediatric approval. Therefore, when one faced with a sick patient and a limited number of options, off-label use is often a medical necessity. In addition to the documentation of the medical necessity of off-label use, given the lack of FDA-approved medications for inflammatory bowel disease, society position statements will also help bolster the case for off-label use to payers. According to the 2014 American Academy of Pediatrics statement on off-label medication use, "the term "off-label" does not imply an improper, illegal, contraindicated, or investigational use. Therapeutic decision-making must always rely on the best available evidence and the importance of the benefit for the individual patient."

If feasible, the physician also should obtain a letter of support from experts in the field stating that the proposed treatment plan is appropriate. In one instance, a physician prescribed adalimumab for ulcerative colitis, and coverage initially was denied as "experimental, investigational or unproven." In this case, once the payor was provided with sufficient information regarding the patient's ulcerative colitis, the failure of other treatments, and the medical literature supporting the efficacy of adalimumab for this condition, they agreed to reimburse for the necessary treatment.

A third type of denial by insurers is an **administrative denial**. Administrative denials do not involve a medical necessity determination. This type of denial occurs when there is a coverage request for a treatment that is expressly excluded from coverage. For example, if an insurance policy expressly excludes abdominoplasty as a cosmetic surgery, a coverage request for abdominoplasty will be denied without regard for medical necessity. Even in this type of case, though, it is possible to force an insurer to conduct a medical necessity review, for example, if a patient requires a medically necessary stoma revision and hernia repair that cannot be performed without the abdominoplasty, the physician may be able to convince the insurance company to consider the medical necessity of the abdominoplasty as long as the insurer agrees that the stoma revision and hernia repair are medically necessary.

Regardless of the type of appeal, there are some general considerations. Insurers will not grant benefits solely based on a patient's subjective report of symptoms. The physician and patient in describing the indication for the appeal must provide "objective medical evidence" (i.e., evidence that can be measured scientifically). In addition to describing the patient's current symptoms (i.e., abdominal pain, diarrhea, fatigue), the physician should provide results of recent blood tests, radiographs, and endoscopic examinations that demonstrate ongoing intestinal inflammation. In addition, if a patient develops an adverse event (AE) to a conventional therapy, the AE should be described in detail (e.g., not simply "infusion reaction to infliximab" but "chest pain and hives with infliximab, which recurred on rechallenge"). While the provider should not ignore the patient's subjective

reports of symptoms, subjective evidence of ongoing disease activity may not be sufficient to prove medical necessity. A physician who writes a letter of medical necessity according to the above guidelines (summarized in Appendix 2) stands a good chance of getting the needed treatment covered. Appendix 3 includes a recent letter from our program requesting a peer-to-peer review on a child who repeatedly had ustekinumab (Stelara) denied by insurance, despite multiple phone calls from the office to the company and specialty pharmacy. This letter resulted in a successful appeal and provision of the medication.

Increasingly, insurance companies and payers are proposing that infusions of biologics be moved to inside the patient's home, rather than an infusion center. This is a smaller cost for insurance companies, but carries significant yet unquantifiable risk for the patients. Many parents may not understand risks and benefits, and we as providers may not know who precisely is administering the infusions. There are regulatory licensing issues that cannot be verified the In-Home Service Agency (IHSA), especially in regard to being licensed to provide this service to children. The IHSA staff would need to know how to get in touch with the on-call providers at a patient's provider office, and there can be significant documentation and thus continuity of communication disruption do after an infusion. It is not always clear if needed labs be drawn, which is important to consolidate into the infusion for patients with needle phobia, and if so, how the results are reported. It is difficult to know how about adverse events are shared with relevant teammembers, and what mechanisms are in place to determine if the patients feel safe and satisfied with the care/infusions that they are receiving. Pragmatic considerations include patient safety, pediatric-trained nurse availability, care coordination, patient-centeredness, shared liability, administrative support, clinical governance, and costs of care.

In pediatrics, documentation has been successful in illuminating these concerns and the implication to children. While clinical guidelines have been established by North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition[9] for assuring safe protocols and pathways for home infusions, significant advocacy can help maintain the administration of these in certified and qualified infusion centers affiliated with the provider, and staffed by trained infusion nurse and nurse practitioners (see Appendix 4).

Nutritional approaches for IBD have included total parenteral nutrition, specific dietary exclusions, partial enteral nutrition (EN), and avoidance of all dietary intake using Exclusive Enteral Nutrition (EEN). Avoidance of all dietary intakes using EEN has been shown to be superior to partial EN when the additional oral dietary intake is not controlled.[11] In small controlled studies, EEN has been shown to be superior to steroids in achieving mucosal healing, while being notably free from important adverse events. For providers and caregivers alike, there may be preference to avoid steroids, especially in children with already delayed pubertal growth or preexisting comorbid psychiatric disorders. However, the cost of EN and EEN can be costly, making it hard for families to afford.

Advocacy documentation that clearly outlines the substance and nutritional rehabilitation and growth parameters are helpful to obtain insurance coverage. When EEN is able to be justified as the primary source of all nutritional intakes, there is a great chance of coverage. Data from studies that show mucosal healing are important in these advocacy letters of medical necessity.

Another area in which letters of medical necessity may be necessary is in obtaining mental health referrals for patients with IBD. Given the stress of IBD and the social stigma associated with its symptoms (rectal bleeding and diarrhea), the risk for exacerbations of IBD during periods of stress, and the mood-altering effects of medications, patients with CD and ulcerative colitis ("UC") often derive significant benefit from psychological support. We are aware [9] the there are often significant associated psychological and social effects resulting from both short-term and long-term steroid use, including mood lability, mania, anxiety, and symptoms mirroring those of depression. Many children with IBD not only have to cope with the unpredictable impact of these emotional ramifications, but also the body image issues that are often secondary to side effects of the unavoidable and recurrent steroid administration necessary to keep the disease process controlled. Studies have demonstrated that a significant proportion of adolescents and young adults with IBD have symptoms of depression, which in turn contribute to decreased quality of life.[5,6,10] Most payors are receptive to the concept that treatment of a chronic illness in childhood requires psychological as well as medical support. On occasion, however, payors will deny mental health services on the grounds that coping with IBD does not warrant formal treatment by a psychologist or psychiatrist. Health care providers caring for children with IBD are acutely aware that anxiety and depression may impact both disease activity and compliance with the medical regimen. Thus, properly timed psy-

Mental health and psychological functioning in children and adolescents with inflammatory bowel disease: a comparison with children having other chronic illnesses and with health children. Journal of Child Psychology and Psychiatry and Allied Disciplines 1992; 33:563–82.

chological or psychosocial intervention often is a crucial factor in overall the treatment success and likelihood of a prolonged remission.

Appealing a denial of psychological support is similar to appealing a denial of any other medically necessary therapy. A letter from the medical team should summarize relevant literature that describes the psychological needs in patients with IBD. The letter also can emphasize the complex relationship between a patient's GI condition, mental health, compliance, and quality of life. It should be emphasized that a patient who is psychologically sound is less likely to undergo recurrent testing and hospitalization for a symptom related to stress and anxiety, all of which [11] would be more costly for the insurance company. This usually is a sufficient reason for insurers to grant limited benefits. While a limited series of sessions is not ideal, these sessions at least allow the patient to gain entrance into the mental health system. At that point, a mental health provider can then determine further indications for ongoing treatment (see Appendix 5).

In one instance, a 14-year-old patient with Crohn Disease had a complicated course of her illness, having been hospitalized twice for unpredictable flares of her disease and a blood clot in the venous portion of her brain, both times leading to lengthy admissions followed by intensive outpatient follow-up. Her illness' sporadic and inconsistent response to her treatment plan led to periods of intense stress and pressure, thereby exacerbating symptoms of her disease. The family lived in a small town in a different state from the one in which her gastroenterologist practices, and the only local mental health providers available practiced from a more psychotherapeutic framework. Her insurance company would not cover services at the urban hospital's specialized medical coping clinic, which was out-of-network for mental health services, yet which provided the specific cognitive behavioral approach that the medical team and family felt would be the best fit for her targeted goals of learning relaxation strategies and coping with the present medical demands. The social worker and physician composed a letter to the insurance company outlining the patient's specific circumstances, the physical and psychological complications, and the importance of the patient obtaining mental health services that were based on a framework specific to her needs at that time. The letter detailed that the clinic specialized in treating children and teenagers with treatment specifically geared toward helping management of comorbid medical and emotional issues related to IBD. The appeal highlighted that the patient's access to particular cognitive-behavioral strategies could reduce the risk factors for a necessary and more costly medical or psychological hospitalization, and the unavailability of access these services through local providers covered under the plan. Her insurance company ultimately authorized coverage for ten treatment sessions, allowing her to learn biofeedback and other concrete mechanisms to help her best cope with the concurrent medical challenges, and provide a forum for ongoing formal assessment and treatment of depression or an anxiety disorder related to the disease process.

Although a good result was achieved in this case, what happens if denials continue to occur? At this point, it may be appropriate to have your patient enlist the assistance of an individual with expertise in conducting health insurance appeals, such as a patient advocate or an attorney. Under the Patient Protection and Affordable Care Act (ACA), all insurance plans must now offer what is called an external appeal. External appeals involve an independent review of the noncoverage decision. All decisions involving the exercise of medical judgment—and in some states, even administrative denials—are subject to external appeal. The independent reviewer, who will be a medical professional with the relevant expertise, has the authority to overturn the insurer's denial of coverage. Thus, do not give up if your first level appeal is denied. Many of the more complex cases—especially those deemed experimental/investigational by the insurer—will be won at the external appeal stage.

Also under the ACA, every state has a Consumer Assistance Program (CAP) to help consumers with insurance appeals. The CAP in your state may be in your state's Insurance Department, or it may be a separate entity. These CAPS are funded largely by federal grant funds.

Finally, under the ACA, as well as under pre-existing law, the insurer must offer to provide a free copy of the materials upon which they relied in denying coverage. In addition, upon request, they have to provide diagnosis and procedure codes so that you can ensure that the denial is not due to a billing error. If you have any question about the reason for the denial of coverage, you or your patient should request a copy of the insurer's file.

Many insurers maintain their clinical policy bulletins on the "provider" section of their website; if not, you are entitled to a copy by mail. If you have a denial based on the fact that the insurer does not believe the treatment you have prescribed is medically necessary or experimental/investigational, you should search the insurer's website for the clinical policy bulletin on point, which will explain exactly when the insurer believes the treatment is or is not medically necessary or experimental/investigational. Note the date on which the clinical policy bulletin was reviewed last, as well as the medical literature on which the insurer relied in formulating its coverage policy. This will suggest the points that you will need to address in your appeal.

[11] Van Limbergen, J et al. Toward enteral nutrition in the treatment of pediatric Crohn disease in Canada: A workshop to identify barriers and enablers. Can J Gastroenterol Hepatol. 2015 Oct; 29(7): 351–56.

If a physician and patient are both frustrated by repeated denials of a treatment thought to be medically necessary, consider three steps:

1. Have your patient discuss the difficulty with the human resources department at their employer, especially if they work for a large employer that self-insures. The employee can ask the employer to grant what is called an "extra-contractual benefit," providing coverage for something that otherwise would not be covered.
2. Request a copy of the insurance company's file, which is guaranteed by law. This information may be valuable in the future.
3. Consider referral to an attorney or patient advocate.

Health insurance appeals can be labor intensive. In addition to the patient's physician, a team of professionals (including nurses, social workers, therapists, and attorneys) may need to assist in preparing the appeal. However, in the United States in 2011, effective advocacy to explain medical needs to third-party payors has become an essential element of care of complex patients.

Of note, insurance appeals and letters indicating medical necessity are getting more complicated, seemingly obstructive and nuanced than ever. There are additional roadblocks that necessitate uninterrupted, coordinated clinician advocacy and data of what is at often avoidable medical stake for patients with risk and impact to safe wellbeing. The impact on physician and provider time is tremendous; pre-prepared data from multiple providers in a practice, outlining the safety implications to children may improve response from payers and insurance companies. Amplifying this to local legislators and state representatives may be indicated.

Social Security Disability

Many people do not realize that children may be eligible for Supplemental Security Income ("SSI"), one of two forms of Social Security disability benefits. [12] However, medically impaired children up to the age of 18 may receive benefits if the income and resources of the parents and child are within allowed limits, as long as the parent worked long enough to be insured under the Social Security system (typically, 40 quarters, or a total of 10 years, with 20 of those quarters occurring in the last 10 years). The child must not be doing any substantial work, and must have a medical condition that has lasted or is expected to last for at least 12 months. A child eligible for SSI will qualify for Medicaid.

Whether a child is considered disabled depends on whether he or she has a physical or mental condition that can be medically proven and which results in marked and severe functional limitations that last or are expected to last at least 12 months. A physical or mental condition that results in marked and severe functional limitations might be one that meets the applicable listing of impairments (see Appendix 6), or it might involve a combination of impairments (for example, Inflammatory Bowel Disease and Attention-Deficit Hyperactivity Disorder, or IBD and depression).

Although both the income and the benefit levels for SSI are low, the value of Medicaid is great for children with IBD. While some physicians do not accept Medicaid assignments, Medicaid coverage for children under the Early and Periodic Screening, Diagnostic and Treatment services ("EPSDT") is extraordinarily broad—broader than most commercial insurance, especially for children with mental health and even dental needs.

In order to assist a family to apply for SSI, the health care provider should consult the listings of impairments set forth in Appendix 6 and write a letter that addresses each element of the listing. The listing itself tells you what sorts of evidence the Social Security Administration ("SSA") will need. For all intents and purposes, this is the same as the "objective evidence" needed in commercial insurance appeals, the listings may require specific testing. For example, the listing for malnutrition associated with a gastrointestinal problem requires a measure of stool fat excretion, even though the current medical standard may be other diagnostics, such as blood tests. Therefore, while the physician is can include any diagnostic testing relevant to the patient's case, he/she should expressly include the diagnostic testing required by the SSA.

Although the SSA will ask you for your medical records, a letter of support that culls the records and explains the child's condition in the terms set forth in the listings of impairments may well be the key to obtaining these benefits. A physician who is asked to write a letter in support of an application for SSI should track the listings of impairments as closely as possible and attach the evidence that the listings mention. The physician or provider who facilitates this process, and who helps successfully obtains SSI benefits for a patient who needs such assistance, is playing a critical role in improving the likelihood of the success of the prescribed treatment plan.

In addition, an integral part of living with any chronic illness is to help in maintaining self-identity, so that self-esteem and feeling victimized by the disease demands does not disempower the patient. As health care providers, we want to attempt to help the patient preserve that sense of control and self-esteem, and thus avoid an internalized notion of a "disabled" self-concept. This is another reason to help make the

[12] The other form of Social Security disability is called Social Security Disability Income, or SSDI. This benefit is available only to patients who have worked and paid into the Social Security system for 40 credits, or 40 quarters (10 years). As such, this benefit is available only to adults.

process of securing entitlement from these state programs as efficient and seamless as possible. The burden of having to go to such lengths to prove disability can often take on a life of its own in the pursuit, and this would be counterproductive to the message we reinforce—the child as a whole person, who is more than the disease. Health care providers, who can facilitate the SSI application to prevent a lengthy proof process, can be doing their part to help preserve this message.

Family and Medical Leave for Caregivers

Caregivers of children with IBD risk losing their jobs when they take time off to care for their children. Providers may be able to spare them this crisis by educating them on the availability of, and helping them to obtain leave and maintain employment security under, the Family and Medical Leave Act ("FMLA"). [13] Covered employers must grant an eligible employee up to a total of 12 work weeks of unpaid leave during a 12-month period to care for an immediate family member (spouse, child, or parent) with a serious health condition. The FMLA applies only to an employee who has been working for the same employer for at least 12 months, for at least 1250 h during the previous 12 months, and at a location where at least 50 individuals are employed by the employer within a 75-mile area.

A child has a "serious health condition" if he or she is "incapable of self-care" due to a mental or physical disability that limits one or more of the "major life activities." Just as is the case under the Americans with Disabilities Act, processing of bodily waste is a "major life activity," so children with active IBD have a "serious health condition" under the FMLA.[9] Even if symptoms are inactive, children with an IBD diagnosis have the potential to require this care, due to the cyclical nature of chronic illness. The FMLA does not provide for paid leave. In addition, an employer may permit an employee to use all available accrued but unused vacation, sick, or PTO time during such leave. The use of other such leave does not extend the time off beyond 12 weeks.

One of the lesser-known aspects of the FMLA is that the 12 weeks of leave need not be consecutive. For example, a parent of a child who is in infliximab treatment can take a day or 2 of leave every few weeks under FMLA.

Primary caregivers of children with IBD should ask for FMLA leave at the beginning of every year, whether or not they use it, so that they are protected if the child's disease becomes active. In order to obtain FMLA leave, the employee must request it in writing, and the physician often must complete paperwork that employers give the employee and provide a medical certification establishing the need or potential need for FMLA leave. An FMLA medical certification can describe IBD as a serious health condition falling into various descriptive categories. Depending on the symptom severity, demonstrating need for FMLA leave may best be accomplished by the physician. The medical certification supporting the need for FMLA leave is in some ways similar to a letter of medical necessity one prepares for a health insurance appeal (see Appendix 7).

If a physician anticipates, a child will require increased parental care because of the worsening of illness, this should be discussed with the family. Parents who may need to take time off from work should request FMLA leave before the crisis occurs. Parents who do so will protect their jobs as long as they do not take more than the maximum twelve weeks of leave during the year. This job security can go far in helping ease caregiver's anxiety, allowing them to better focus on coping with the child's acute needs and the impact on the family.

Restroom Access Act

Patients with IBD may have a debilitating need to use the restroom urgently, while out in public places. This can be difficult, as not all establishments and business have restrooms designated for public use. In response, the advocacy needs around these unpredictable circumstances, many states have now passed Ally's Law, also known as the Restroom Access Act, to support this medical need.

Ally's Law requires that retail businesses with toilet facilities for employees allow customers with certain medical conditions to access these. The bill was named after a teenager in Illinois with Crohn Disease, who was denied access to a store restroom, and suffered embarrassing consequences. This bill first became law in Illinois in 2005. Ally's Law falls under the Americans with Disabilities Act of 1990.

It typically applies when (1) the retail establishment has two or more employees currently working and (2) the employee-only restroom is in a location that is both safe to the patient and not a security risk to the retail establishment. Some businesses may be exempt from the Restroom Access Act. Those with fewer than three employees, for example, are not obliged to let a customer use an employee toilet as it may leave the store open to damage or theft. The law does not require retail stores to alter their facilities for people with eligible conditions and establishments are also not easily liable if a customer sustains an injury, while using an employee restroom.

A store may require the patient to present a document signed by a medical professional attesting to their IBD. The Crohn's and Colitis Foundation has "I Can't Wait" wallet

[13] 29 U.S.C. § 2601, *et seq.* Many states have their own, more liberal version of family and medical leave. You should consult your State's Department of Labor for more information.

cards that can be provided to patients to carry in their personal belongings and show a store employee.

There has been exciting expansion of this Act. While there are visions of a federal act, currently the following states have passed a version of this: Colorado, Connecticut, Delaware, Illinois, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, Ohio, Oregon, Tennessee, Texas, Washington, and Wisconsin.

In many cases, these states have passed the Act as a result of grassroots efforts by those with IBD and their supporters. If there is a state that has not passed this Law, anyone can be a champion for this legislation. The Crohn's and Colitis Foundation has a template model of legislation that can be downloaded and submitted to local lawmakers.[14]

Summary

Inflammatory bowel disease affects more than a patient's intestinal tract; it affects their quality of life, including otherwise routine functions of school and work. In addition, IBD affects families, not just individual patients. Therefore, physicians should become familiar with the ways they can help patients and their families overcome the varied hurdles facing children with IBD. In particular, providers should train themselves, or be trained, in how to appeal insurance company denials, assist in the development of a plan of accommodation for a school-aged child, support an application for Social Security benefits, and point out the availability of Family and Medical Leave to caregiver parents. Collaboration with other members of the medical team such as nurses and social workers to address these issues is essential, as is the ability to identify advocacy resources in the community, which may not be specific to IBD. By providing such services, the physician may alleviate some of the financial, educational, and social complications that can turn a flare of IBD into a more serious destabilizing family crisis. The provider who is an effective advocate will derive gratification from the knowledge that they have helped their patient have a better health-related quality of life. Advocacy has and can continue to change the landscape for the health care profession, research science, and patient resources related to IBD. Provider advocacy and public awareness have a reciprocal impact to create real progress and momentum.

Acknowledgement We would like to acknowledge the contributions of two individuals who are no longer with us, and their collaboration in this work. Jennifer Jaff, Esq (deceased), was the principal author of the first three editions of this chapter. She founded and ran Advocacy for Patients with Chronic Illness, Inc., a legal advocacy group that fought vigorously against insurance company denials, and obtained chronically ill patients access to needed therapies. Suzanne Rosenthal was a cornerstone of the legislative advocacy that appeared in prior editions, and informed our own work and commentary. She was one of the original founder of the Crohn's and Colitis Foundation (formerly of America), and a strong force on Capitol Hill to raise awareness of these diseases among legislators and the lay public.

Appendix 1: Sample Letter for Patient's Student File Regarding Educational Accommodations Needed for an IBD Diagnosis

To Whom It May Concern:

This letter is being written on behalf of our patient, **XXXXX (DOB: XX/XX/XX)**, who recently was diagnosed with Crohn Disease, a chronic inflammatory bowel disease of the intestines. As chronic illness is cyclical in nature, XXX can face gastrointestinal symptoms in a recurrent pattern, with periods of symptom inactivity in between active flare-ups and complications. Cramps may be severe and may be worse when there is a need to use the toilet; symptoms may worsen in an unpredictable manner and conversely, may go into remission for varying lengths of time. During a flare-up, this illness will substantially impair the major life activities of bowel and digestive functions. The medical team is currently working to coordinate the long-term treatment plan as the team explores the impact of these symptoms on her body and her body's response to the medication regimen.

Even if a patient no longer requires an inpatient hospitalization, we could expect the patient still to experience ongoing symptoms until the medical team is able to arrange her maintenance treatment regimen. XXX has been seen for her first outpatient follow-up appointment since diagnosis, and the medical team continues to monitor her symptoms, which continue to intermittently interfere with her ability to attend school for a full day.

In the long term, however, with the understanding and support of her teachers and other school personnel, we expect XXX to participate in school activities. When the medical team better determines the best course of maintenance treatment for her, we have no reason to expect that it should routinely interfere with her academic plan or performance. In addition, XXX may be tardy or absent from school from time to time if her condition is flaring. The disease process can affect many aspects of a person's life; depending on the current symptoms, patients can find it difficult to cope as there is an interference with their physical and social functioning.

We feel it would be helpful for XXX's school re-entry to begin in a partial day format, as her body continues to adjust. In the immediate, short term, we believe it is in XXX's best interest that she be eligible for home tutorial services so that her academic studies are not compromised by this acute period of her condition. These services would also be recom-

mended to have in place, should flare-ups occur in the future, causing her to intermittently and unpredictably miss schoolwork.

We know that the emotional and physical pieces are interrelated in complex ways, and patients can experience flare-ups during times of emotional tensions and stress. This can relate to changes in the physiologic functioning of the gastrointestinal tract. While periods of intense stress and pressure can exacerbate symptoms, it is important to note that they do not cause the disease and are not responsible for the development of the illness.

Please understand the extenuating circumstances facing XXX, should the physical or emotional adjustment to the demands of her chronic illness intermittently impact her ability to carry out her academic responsibilities. Please contact XXX with further questions. Thank you for your time and understanding. We look forward to being able to collaborate with the school in any manner that will optimize her future academic and medical plans.

Appendix 2: Preparing an Effective Insurance Company Letter of Medical Necessity

- Patient's Name (and name of insured if not the patient).
- Patient's Insurance ID number, Social Security number, and date of birth.
- The treatment requested and denied.
- Your specialty and years of experience.
- Your experience with the particular device, medication, or treatment.
- The patient's diagnosis including both subjective and objective support for the diagnosis (patient's subjective complaints **plus** weight loss, recent barium study, endoscopy reports with pathology, etc.).
- What treatments have been tried over what period of time (go back to the date of diagnosis and describe all that has been tried and failed, explain the reason for the failure, i.e., failure to control disease, allergic reaction, adverse event such as pancreatitis).
- If device, medication, or other treatment is considered by the insurance company to be experimental, investigational, or unproven, summary of the medical literature, preferably including copies of the literature (both summary and copies of literature are enclosed).
- Why you believe this therapy or service is clinically indicated for this patient at this time.
- Describe your plan to assess treatment efficacy (whether your therapy will help this patient). For example, in a patient with CD involving the ascending colon, state you will follow the patient monthly, and monitor exam, hematocrit, C-reactive protein, and perform a colonoscopy after 6 months to assess mucosal healing.
- Summarize your medically necessary request again, and offer to talk to any health care professional from the insurance company if additional information is needed.

Appendix 3: Letter of Medical Necessity for Ustekinumab

Dear sirs:

I am writing this letter to request a formal outside peer-to-peer review from a pediatric gastroenterologist for the approval of ustekinumab for my patient _____ Using this medication is medically essential in order to treat her severe, refractory Crohn disease, which remains active despite multiple medications and two surgeries, the most recent being a diverting ileostomy.

To summarize her course, _____ developed her Crohn disease at the age of 9. Her disease involves her ileum, colon, and perianal region. She has been treated with mercaptopurine (disease remained active), infliximab (did well initially but developed antibodies in 2010), adalimumab (no response), certolizumab (no response), thalidomide (partial control of her disease but triggered ovarian failure), methotrexate (disease flared), and vedolizumab (no response). She underwent an ileal resection in 2009, and because of her refractory disease underwent a diverting ileostomy in March 2015.

Unfortunately, the patient's disease has recurred, both at her ileostomy and in her perianal region. We admitted her for intravenous corticosteroids, and administered ustekinumab, a monoclonal antibody that has proven efficacy in Crohn disease, based on randomized phase 2 and 3 clinical trials (papers attached). For some reason, while the initial doses of this medication were approved, we subsequently had a denial by a physician reviewer who has no expertise in pediatric gastroenterology.

_____'s insurance has been very supportive in the past, and understands of the severity of this child's illness and the need for treatment. Our medical options are limited, and a panel of experts in this division supports the use of ustekinumab. The patient has also received an outside second opinion by Dr. _____ (another Crohn expert in the region) who supports this approach. If _____ is not treated, her Crohn disease will progress, resulting in additional hospitalizations and surgeries.

I am a pediatric gastroenterologist who is considered a national authority in the treatment of pediatric Crohn disease (see attached CV). I would be happy to speak with anyone from the insurance or any physician reviewer to describe _____'s clinical situation.

Sincerely,

Athos Bousvaros MD, MPH

Appendix 4: Sample Letter to Support Maintenance of Infusion at Infusion Center

To Whom it May concern:

This letter is being written on behalf of XXX (DOB____) for whom a transition to in home infusions has been proposed to initiate a "non-medical switch" from an infusion center that specializes in the care of pediatric and young adult IBD to another provider. This is being done purely for cost saving purposes to benefit the third-party payor. While such moves may save costs in the short term, we strongly oppose the move for quality and safety reasons. We list the reasons below.

1. Our infusion centers have administered over 10,000 infusions to patients over the last decade, and our incidence of infusion reactions is much lower than that reported in the literature. This is due to careful attention to the infusion, patient and physician education, and among the lowest in the country.
2. When infusion reactions do occur, they can sometimes be life threatening. Some of our patients have developed severe reactions requiring epinephrine, saline boluses, intravenous steroids, and emergent assessment by trained physicians. If these types of reactions occur outside of an infusion center prepared to handle them, we are concerned they could result in severe adverse outcomes.
3. The infusion provider requested has not demonstrated they have expertise in the management of inflammatory bowel disease patients, or children with IBD. Such patients often have symptoms of either active IBD or possible infection when they present for their infusions. If the patient has such an issue, our trained infusion nurses and nurse practitioners are capable of providing thorough assessments, having in on call or house physicians provide consultation. In contrast, the home infusion company or provider that lacks experience will cancel the infusion, and/or refer the patient to the emergency department.
4. The situation above may result in interruption of care, with reduction of the frequency of infusions. Such interruption of care is known to be detrimental to patients, and associated with the development of antibodies to infliximab, loss of response to the therapy, and flares of Crohn's or colitis. This may in turn result in a preventable hospitalization or a change to another medications product that may be less effective or more expensive.
5. We have no oversight or input in the quality control of home care companies. We do not know whether the personnel are certified in adult life support, pediatric life support, or management of inflammatory bowel disease. We do not know how the medication is mixed or administered. There is limited collaboration or interaction with these companies. Based on the experience with parenteral nutrition, we do know that these companies often are prone to medical errors, administer incorrect doses of therapies, and that such interventions are associated with adverse patient outcomes.
6. In addition, it has also been documented that "non-medical switching" by insurance companies is associated with adverse patient outcomes in IBD.

Therefore, we strongly oppose the request for XXX on patient safety and quality grounds. If we are approached by a physician that works for the insurance company that makes such a request, we will take the following actions:

1. We will request of the insurance company physician making the request their name, company they work for, subspecialty (adult or pediatric), whether or not they are board certified in adult or pediatric gastroenterology.
2. We will send a copy of this letter to the patient's insurance company and to the insurance company physician.
3. We will inform the patient that the insurance company has requested a "non-medical switch," and that we oppose such a switch, because we have concerns about patient safety implications. We will notify the patient of the specific physician, and the company requesting the switch.
4. We will ask the patient and/or parent to go to the human resources department of the company they work for, and inform them that the insurance company is requesting a "non-medical switch" that is opposed by the patient's subspecialty physician.
5. We will make it clear that any adverse outcomes that result from this switch should be reported to us, to the insurance company, and to the Massachusetts Commission on insurance.
6. We will carefully track such "non-medical switches," and inform patients and the public about adverse events that occur because of these actions.

I am very willing to meet with medical directors of third-party payors to review our data and present our concerns in more detail. Thank you for your consideration.

Sincerely,

_____, MD

Appendix 5: Sample Letter for Appeal of Denial of Mental Health Benefits

To Whom It May Concern:

This letter is being written on behalf of our patient, **XXX (DOB:)**, whom we follow for her diagnosis of Crohn

Disease, a chronic inflammatory bowel disease of the colon and small intestine. We submit this letter in support of her being permitted to receive out-of-network mental health benefits at/through (agency name/private provider) as a clinical case exception. XXX has had a complicated course of her illness, having been hospitalized several times for unpredictable flares of her disease, both times leading to lengthy admissions followed by intensive outpatient follow-up. Her illness' response to our treatment plan has been sporadic and inconsistent, causing great stress on both her mind and body. We know that the emotional and physical pieces are interrelated in complex ways, and patients can experience flare-ups during times of emotional tensions and stress. This can relate to changes in the physiologic functioning of the gastrointestinal tract; we have seen this occur with XXX. Her medical complications have led to periods of intense stress and pressure, thereby exacerbating symptoms. XXX's specific circumstances are physically and psychologically complicated, and it is crucial to be able to integrate the medical and psychiatric services; this will be critical to providing the most comprehensive and cost-effective care.

(Agency name/private provider) specializes in diagnosing and treating children and teenagers with comorbid physical and psychiatric/psychological issues. (Agency) provides and coordinates integrated plans of treatment, including psychopharmacology, cognitive behavioral therapies, and family work specifically geared toward helping in managing these comorbid populations. Studies have shown that this type of integration of medical and psychiatric services can decrease both medical and psychiatric morbidity, and thus medical costs.

XXX's ability to access these services could be essential in reducing the risk factors for a necessary medical or psychological hospitalization. A hospitalization would be much more costly, both financially and in terms of the missed developmental learning opportunities in the social and academic realms.

It is in XXX's best interest to receive ongoing psychological care in a formal clinical model. However, we would request authorization for at least a two-session evaluation so that the formulation and treatment recommendations can be passed on to community psychiatric providers in their network. We feel strongly that the optimal coordinated care plan would include your insurance plan's willingness to authorize 12–14 treatment sessions so that XXX and her family can have access to the specialized skills of (agency/provider), thereby reducing the chances of an emergent, and perhaps more costly, hospitalization.

Please understand the extenuating circumstances impacting XXX. Thank you very much for your time and consideration in this urgent matter. Feel free to contact XXX with further questions. We look forward to hearing your response.

Appendix 6: Social Security Listing of Impairments for Children with IBD

Section 105.00, Digestive Impairments in Children

A. *Disorders of the digestive system* which result in disability usually do so because of interference with nutrition and growth, multiple recurrent inflammatory lesions, or other complications of the disease. Such lesions or complications usually respond to treatment. To constitute a listed impairment, these must be shown to have persisted or be expected to persist despite prescribed therapy for a continuous period of at least 12 months.
B. *Documentation of gastrointestinal impairments* should include pertinent operative findings, appropriate medically acceptable imaging studies, endoscopy, and biopsy reports. Where a liver biopsy has been performed in chronic liver disease, documentation should include the report of the biopsy. Medically acceptable imaging includes, but is not limited to, X-ray imaging, computerized axial tomography (CAT scan) or magnetic resonance imaging (MRI), with or without contrast material, myelography, and radionuclear bone scans. "Appropriate" means that the technique used is the proper one to support the evaluation and diagnosis of the impairment.
C. *Growth retardation and malnutrition*. When the primary disorder of the digestive tract has been documented, evaluate resultant malnutrition under the criteria described in 105.08. Evaluate resultant growth impairment under the criteria described in 100.03. Intestinal disorders, including surgical diversions and potentially correctable congenital lesions, do not represent a severe impairment if the individual is able to maintain adequate nutrition, growth, and development.
D. *Multiple congenital anomalies*. See related criteria, and consider as a combination of impairments.

105.07 ***Chronic inflammatory bowel disease (such as ulcerative colitis, regional enteritis), as documented in 105.00***. With one of the following:

A. Intestinal manifestations or complications, such as obstruction, abscess, or fistula formation, which has lasted or is expected to last 12 months; or
B. Malnutrition as described under the criteria in 105.08; or
C. Growth impairment as described under the criteria in 100.03.

105.08 ***Malnutrition, due to demonstrable gastrointestinal disease causing either a fall of 15 percentiles of weight which persists or the persistence of weight which is less than the third percentile (on standard growth charts)***. And one of the following:

A. Stool fat excretion per 24 hours:
   1. More than 15 percent in infants less than 6 months.
   2. More than 10 percent in infants 6–18 months.
   3. More than 6 percent in children more than 18 months; or
B. Persistent hematocrit of 30% or less despite prescribed therapy; or
C. Serum carotene of 40 mcg./100 ml. or less; or
D. Serum albumin of 3.0 g./100 ml. or less.

Appendix 7: Preparing an Effective Letter for Family Medical Leave Act provisions

- Caregiver/parent's name (employee).
- Patient's name.
- Patient's diagnosis, date of diagnosis, length of treatment—chronic illness requires lifelong medical attention of some level.
- If relevant, recent or upcoming overnight stay in a hospital including estimation of incapacity after discharge home.
- Explain incapacitation as inability to attend school or perform other regular daily activities during the times of hospitalization, recovery, or scheduled outpatient medical procedures.
- All occasions and specifics of ongoing and continued treatment by a health care provider as an outpatient, specifically outlining caregiver's responsibility for medication administration, monitoring and reporting of bowel habits at home, coordination with other sub-specialty providers, as applicable.
- Phrases indicating episodic, intermittent, unpredictable, cyclical nature of the IBD disease process, with the need for ongoing, periodic outpatient visits.
- Emphasis of importance of the caregiver being present at these visits for active and ongoing discussion with the medical team to be able to participate in progressive treatment plan decisions that impact the child.
- Explanation that child's intermittent incapacity may cause the caregiver to work intermittently or on less than a full schedule.
- Identification of any potential future treatment or collateral providers in the child's care, including medication infusion at a day hospital center, routine exploratory procedures, imaging studies.
- Anticipate the potential involvement of radiologists, laboratory technicians, infusion center staff, physical therapists, dieticians, mental health professionals, so that if a caregiver has to accompany a child to an appointment with one of these providers, without your presence, it can still be validated by the employer as qualifying for FMLA hours.
- Specification that child requires basic medical assistance for medical decision making, transportation to appointments, and psychological comfort to assist in the management of the impact of the treatment regimen, given the interruption to daily functioning, and the invasive nature of portions of the treatment plan.

Transition from Pediatric to Adult Care

61

Jonathan Moses and Sandra C. Kim

Introduction

Transition of care is emerging as an increasingly important area of care in patients with chronic conditions including inflammatory bowel diseases (IBD). Transition from pediatric to adult care is not simply a transfer of patient care from one provider to another. It is a dynamic process defined as the purposeful planned movement of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-oriented health-care systems [1]. Education, communication, and preparation promote self-management skills, confidence, and independence, which help ensure a successful transition. Effective transition requires a multidisciplinary and coordinated approach to ensure successful "graduation" which is marked by independence, effective self-management, and establishment of care with an adult gastroenterologist and adult medical care team. Several medical societies and groups have issued consensus statements regarding the need for coordinated and well-planned transition for adolescents and young adults with chronic medical conditions [2–5]. According to the American Academy of Pediatrics (AAP), the transition should address the following: (1) Ensure that all young people with special health-care needs have an identified health-care professional who attends to the unique challenges of transition and assumes responsibility for current health care, care coordination, and future health-care planning; (2) Identify the core knowledge and skills required to provide developmentally appropriate health-care transition services to young people with special health-care needs and make them part of training and certification requirements for primary care residents and physicians in practice; (3) Prepare and maintain an up-to-date medical summary that is portable and accessible; (4) Create a written health-care transition plan by age 14 together with the young adult and family. At a minimum, this plan should include what services need to be provided, who will provide them, and how they will be financed. This plan should be reviewed and updated annually and whenever there is a transfer of care; (5) Apply the same guidelines for primary and preventive care for all adolescents and young adults, including those with special health-care needs, recognizing that young people with special health-care needs may require more resources and services than other young people to optimize their health; (6) Ensure affordable, continuous health insurance coverage for all young people with special health-care needs throughout adolescence and adulthood [3]. A recent 2018 update to these guidelines from the AAP introduced the "Six Core Elements of Health Care Transition" to serve as a template for individual institutions in the transition of pediatric patients to adult care [6] In addition, the clinical report discusses further integration of the transition process into the health-care system by using quality improvement tools, along with the development of unique billing codes to allow for fair compensation of these services and effective tracking of transition-related interventions.

Similarly, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN), the European Crohn's and Colitis Organisation (ECCO), and the Crohn's and Colitis Foundation have issued specific statements regarding the transition of care for adolescents with IBD [7–9]. NASPGHAN recommendations for the practitioner suggest the following: (1) The pediatric gastroenterologist should begin seeing adolescent IBD patients without their parents to build a relationship promoting independence; (2) Introduce the patient and family to the concept and benefits of transition; (3) Identify a skilled gastroenterologist who cares for young adults and recognizes the different set of expectations that young adults with childhood-onset IBD have versus those recently diagnosed

with IBD; (4) Prepare a detailed medical letter and brief medical summary for the new adult gastroenterologist; (5) Recognition that the timing of transition requires flexibility due to individual special circumstances. These guidelines address a number of issues adolescents with IBD encounter, including the process of moving from parental oversight to independence and self-reliance and transferring care from the nurturing medical care approach commonly seen in pediatric care practices. Other factors that should be incorporated into the transition process include the need for both parents/guardians and pediatric health-care providers (including physicians, nurses, and many other health-care providers) to relinquish caregiver roles of young adults living with a chronic illness and to facilitate successful transfer of care to an adult subspecialist.

Despite these useful guidelines, there is still no "gold standard" or defined best practices for transition of care in IBD, highlighting the need for more research on this vulnerable population [10]. In this chapter, we will outline the recommendations for transition of care in IBD, unique features of the adolescent IBD population, barriers to transition of care, and approaches, skills, and tools that can facilitate a successful transition to adult IBD care.

Background

Although there is growing emphasis on the transition of care for adolescents with chronic medical conditions, there is a relative lack of data about which approaches and models work best in adolescents and young adults (AYA) with IBD [11] although there has been increasing interest in this area. Despite variability in processes between institutions, transition of care for young adults with IBD is important for several reasons. First, up to one-third of parents and one-fourth of teens are apprehensive about transition to an adult provider [12]. Second, youth with IBD have diminished health-related quality of life (HRQOL) [13] that can dramatically increase during adolescence when they are especially vulnerable to psychological stress [14]. HRQOL is a vital aspect of patient care, patient–physician communication, and shared decision-making, with data suggesting worse HRQOL correlates with more negative feelings by AYA with IBD toward the transition process [15]. Finally, a well-planned and coordinated transition to adult care has been shown to improve outcomes in patients with other chronic diseases, with newer data accumulating over the last several years specifically for patients with IBD [10, 14, 16–18]. Factors associated with successful health-care transition include starting the process early, having family members and health-care providers foster personal and medical independence, and confirming that the young adult verbalizes the desire to function in the adult medical world [19]. Recent data using self-determination theory demonstrated factors such as competence (feeling effective) and provider relatedness (support for autonomy from others) can predict transition readiness [20].

The ultimate goal is a prepared, proactive healthcare team and an informed, active patient—a concept particularly applicable to patients with IBD. Evidence supports the idea that pediatric and adult-oriented medical practices represent two different medical subcultures. If young adults and family members are not well prepared for participation in the adult health-care system, they will have trouble with this transition and may not receive the care they need [19]. There is recognition of a "vulnerable" period after transfer of care, and prior to establishing with an adult provider, which can result in poor outcomes for AYA patients, including transfer failure rate of up to 12%, higher utilization of the emergency department for medical care, and increased rate of hospital readmissions [21, 22].

Challenges and Barriers to Transition for Adolescent IBD Patients

Researchers have begun to identify specific barriers to transition in teens and young adults with IBD. These barriers include differences in pediatric-onset versus adult-onset IBD, differences between pediatric and adult care, psychosocial factors, treatment adherence and poorly developed self-management skills, attachment to pediatric providers, individual maturity, and readiness for transition. Recently, two different groups found that patient and parent/guardian attachment to pediatric providers was among the most significant barriers to transition [23, 24]. Not surprisingly, multiple studies have also found that patients with emotional and cognitive delay faced additional challenges in the transition process [23, 25].

Differences between pediatric- or adolescent-onset IBD and adult IBD can also have a significant impact on the transition process. Although pediatric- and adolescent-onset IBD is common, occurring in roughly 20–30% of all cases [26, 27], there are significant differences in pediatric and adolescent disease presentation and severity; most notably, pediatric/adolescent IBD is more aggressive and extensive [28–30]. Van Limbergen and colleagues found patients with pediatric-onset disease were almost twice as likely to have extensive ulcerative colitis (UC) compared to those with adult-onset disease. Similarly, among those children with Crohn disease, 40% had extensive disease compared to 3% of their adult counterparts. Surgery within 10 years of diagnosis was twice as common in pediatric-onset UC. Although there was less surgery in pediatric-onset CD, more than one-third required surgical intervention within 10 years of diagnosis [30].

Goodhand et al. demonstrated that compared to adults, teens have more severe disease. Adolescents were more likely to be on azathioprine (46% vs. 17%, $P < 0.0001$) or infliximab (20% vs. 8%, $P < 0.05$). Furthermore, teens were more likely to require hospitalization (46% vs. 14%, $P < 0.0001$). This is further complicated by the fact that teens were significantly more likely to miss medical appointments than adults (median appointments missed: adolescents 20% vs. adults 0%; $P < 0.0001$). The authors concluded that earlier-onset IBD is more complex, and, therefore, specific adolescent transitioning clinics should be established [28]. This highlights the need for additional research to better understand outcomes and the natural history of IBD in this unique group that spans both the pediatric and adult populations.

Treatment adherence and self-management are key skills that teens must master during the transition process but are often difficult for AYA [31–33]. Several studies have identified barriers to adherence in adolescents that include the following: forgetting to take medications [34], lack of time, feeling well, medication side effects [35], and therapeutic regimen complexity [36]. These barriers can be further exacerbated by the patients' underlying anxiety and depression [34]. In addition to adherence, teens must develop a wide range of self-management skills often lacking in teens with IBD prior to "graduation" from their pediatric provider. Fishman et al. surveyed teenagers aged 16–18 years and found that only 43% confidently knew their medication name and dose and even fewer knew about important side effects. In addition, AYA relied heavily on parents to schedule appointments (85%), request refills (75%), and contact providers between visits (74%) [31]. In a follow-up study, Fishman and colleagues surveyed 294 youth (10 years and older) and found that although 95% could name their medication, just over half knew the correct dose and less than one-third could report a single major side effect [37]. Although self-management skills and independence have been shown to increase with age, they do not necessarily correlate with disease duration, reinforcing the complex nature of teaching skills to teens with IBD [33, 38]. Newer tools measuring self-efficacy and resilience are being studied in an effort to identify assessment tools independent of the patient's chronological age that could potentially be more reliable in predicting successful transition to an adult provider [39].

Differences in approaches to pediatric and adult medical care can have a profound impact on the transition process as well. Hait and colleagues point out pediatric care tends to be multidisciplinary and family focused requiring parental direction and consent. On the other hand, a single physician often provides care in adult medicine; the relationship involves shared decision-making exclusively between the patient and provider rather than the entire family. The adult health-care clinic visit is patient focused, and the provider expects the patient to be autonomous and independent [40].

A survey of adult gastroenterologists in 2009 reported that 51% had received an inadequate medical history from pediatric providers, 55% of young adults with IBD demonstrated deficits in knowledge of their medical history, and 69% did not know their medication regimens [40]. The authors suggested educating the young adult IBD patient is essential but not a substitute for delivering an accurate medical history to the adult provider. In contrast to this survey of adult gastroenterologists, a French survey of 48 young patients with IBD (and their parents) who had transitioned from pediatric to adult care revealed that the majority (85% of patients and 74% of parents) felt they were ready for transition to adult care [12]. Only 22% of patients and 32% of parents were apprehensive of the process. Of the 57% who attended a joint medical visit with the pediatric and adult providers, all considered it beneficial for transmitting records and most (93% of patients and 100% of parents) considered it beneficial for building confidence in the new gastroenterologist, highlighting the benefit and need for more transition clinics. Priorities for a successful transition can also vary greatly between stakeholders, with discordance being demonstrated between patients, caregivers, and physicians, further complicating the process [41, 42].

Transition Steps

The appropriate age to begin teaching these skill sets will vary with each patient's level of maturity and interest. A recent survey of patients and caregivers by Maddux and colleagues reported the majority of respondents chose 16–17 years of ages as the best time to initiate the discussion on transition [42]. However, most societal recommendations endorse starting by age 12–14 years to give the patient and family adequate time for the process and allows each patient the opportunity to gradually assume more responsibility for taking care of their own unique problems. The skill sets involve accruing knowledge (education), developing self-management skills based on that knowledge (focus on independence), and understanding the mutual impact of inflammatory bowel disease and lifestyle decisions on future health and well-being. This process should be tailored to the individual patient based on their needs.

NASPGHAN, the National Alliance to Advance Adolescent Health, and others have made useful planning and readiness checklists to help facilitate the successful transition to adult care (GotTransition.org [43, 44]; NASPGHAN [45]).

Overview of the Transition Process

A number of tools, checklists, and planners to facilitate the transition process and transfer of care are described in Table 61.1. It is important to remember that the process should be tailored to the individual patient and family and may need to be adapted according to factors such as insurance, location, and post-high school plans.

Patients (Age 12–14)

At this age, the patients should be introduced and educated on the idea of transition and begin steps to prepare themselves toward this goal. There are two skill sets that should be attained for this age group.

Skill Set 1

Knowledge related to their illness: This first step is designed to help patients learn about their specific disease, either Crohn disease, UC, or IBD-unclassified (IBD-U). The patient should be able to articulate they have IBD, including both gastrointestinal and extraintestinal symptoms, and recognize when they are having a flare and what might be precipitating the flare (diet, stress, other medications, etc.) and when they should visit their physician. The child should be able to express the impact of his/her disease on daily functioning at school, socially, and at home. Providing handouts with these key points and specific age-appropriate websites can help patients develop resources for ongoing education and new information (e.g., https://www.crohnscolitisfoundation.org/justlikeme).

Skill Set 2

Knowledge related to medications: This step includes information about specific medications they are taking (name, dose, why they are taking the medication, timing of each dose, possible side effects) and establishing a plan to take medications on their own without being reminded. This step is also crucial as a first step in preventing the lapses in adherence to medication, which occurs quite frequently at this age and throughout adolescence [32]. Bell has also noted that adolescent risk taking, magical thinking, and denial can all contribute to poor treatment adherence [49]. Patient education and problem-solving skills training are key approaches to overcome these issues, as is having a positive relationship with health-care providers and family members [50, 51]. Because increased authority from parents and professionals, overprotection, and sick role in teens with chronic disease may lead to learned dependency [49], this is a good time to begin to promote independence by setting a date when the

patient will visit with their provider alone, starting by performing the physical exam without the parents/guardians in the room.

Parents/Family (Age 12–14)

Reiss and colleagues have found that parents often feel excluded when their child transitions to an adult provider, especially after they have dedicated many years of supporting and being involved in their children's health care [19]. Parents may also have concerns about "letting go," and family resistance can be a major barrier to successful transition. In order to prevent these negative feelings, parents should also be informed and educated regarding the eventual need for transition—the process of "letting go," so that their child can function independently as they leave home for work or college. The main role of the family at this time is to support the child through the disease symptoms and exacerbations and to provide a comfortable and protective atmosphere for this transitioning period. Since parents are actively involved in the daily care of their young adult children, they are the key personnel to reinforce the list of items needed at each visit for a successful transition. They should be notified that future clinic visits might include an established period of time for the young adult patient to meet with the health-care provider on their own. As part of the process, the parents can be provided the opportunity and a primary role in making their child independent through each step. They can proactively educate their son/daughter on crucial topic areas including insurance coverage, refilling medications, and scheduling appointments independently. Another important role for parents is to observe and confirm to the pediatric GI team that their child is making progress mastering the skills required for independence prior to the transfer of their care to adult providers.

Pediatric Team (Age 12–14)

The pediatric team often includes the pediatric gastroenterologist, nurse, psychologist, dietitian, and other pediatric subspecialists involved in managing the patient's care. The pediatric gastroenterologist, who is typically the primary provider, will establish the parameters for the support staff in promoting this transition period. Teaching of transition skills (those chosen as most important by each practice or institution) may be directed by a nurse, nurse practitioner, or the gastroenterologist, depending on staffing and availability. It is critically important for the physician to convey the importance of the process to the patient and family so that they understand, recognize, and accept the benefits of increasing the patient's self-management of their disease.

The pediatric gastroenterologist should address the concept of independent clinic visits for the patient with the family. This should start by including the parents for the initial portion of the visit, followed by the gastroenterologist performing the physical exam without parents/guardians in the examination room. Topics the pediatric gastroenterologist should consider addressing include information and guidance regarding drugs, alcohol, dating/sexuality, and health maintenance issues (i.e., diet, exercise). It is also important to address medication adherence, which can impact future health and can be a significant issue in young adults with IBD [52]. Furthermore, potential psychological issues should be screened and identified so that referrals can be placed with mental health professionals. This helps address anxiety disorder/depression which, when left untreated, can hinder the transition process and successful attainment of the necessary self-management skills [34].

Focus on Independence

Patients (Age 14–17)

Patients in this age group should acquire the following two major skill sets that focus on increasing their independence:

Skill Set 3

Knowledge related to procedures and tests: This would include laboratory tests, diagnostic imaging, and endoscopic procedures used in managing the patient with IBD. The goal is for patients to not only be comfortable with the different tests and procedures but also to recognize their importance and purpose in managing their disease long term.

Skill Set 4

Basic medical knowledge: This step emphasizes basic medical knowledge all patients should know, regardless of the presence or absence of a chronic illness. This includes knowing how to measure their weight, take their temperature, and read a thermometer. It also includes learning or knowing where to find telephone numbers and locations for their health-care provider, their clinic, and the hospital. They should be able to articulate their medical history and to identify names of community-based social support groups and organizations (e.g., Crohn's and Colitis Foundation) if they are available in their region. Patients should be able to articulate the medical risk of nonadherence, and they should understand the impact of illicit drugs and alcohol on their illness as well as the interactions with their ongoing medications. This may take a little time in the office demonstrating some of these skills, and it will require some work from the family to help set up their own system for reinforcing this

information. In addition, patients might be asked to prepare questions ahead of time for the doctor and nurse or dietician.

The patients should begin filling their own prescriptions, scheduling their own appointments, and keeping medical information and insurance information. The patient should also develop a method of tracking symptoms and issues related to their IBD. This makes their clinic visit with their physician effective and centered on the patient while helping the patient to demonstrate the ability to be more independent with their health care. During the visit, the patient can privately address questions they have regarding adolescent issues and discuss future plans upon the completion of high school. Patients should be educated, however, that the parent or guardian must legally be informed about the overall condition and high-risk behaviors more common in teens and young adults that could seriously affect their disease.

Parents (Age 14–17)

Since the main focus at this age is to promote independence, the family/parents/guardians should teach their child the intricacies of medical care as if they were out on their own. Examples include the following: maintaining a current medication list, filling and refilling prescriptions, and scheduling clinic appointments. They can provide guidance on organizing medical information in a dynamic fashion, which is crucial. Parents should also provide all information regarding insurance (insurance card, relevant contact numbers). Most importantly, the parents should continue to reinforce the skill sets that the patients need at this developmental stage outside routine clinic visits and to update the pediatric health-care team on their child's progress during the transitioning process.

Pediatric Team (Age 14–17)

The pediatric gastroenterologist as well as the pediatric health-care team should start and continue to focus on the patient instead of the parents or guardians when providing explanations and when obtaining the history. This includes making sure part of the visit occurs without parents in the room and allowing the patient to decide on the appropriate timing. This allows the physician to directly interact with the patient and is essential in the progression toward independence the young adult needs prior to transfer of care. The physician should explain to the patient what the parent or guardian must legally be informed about regarding their condition. During this process, the physician and patient should develop goals and timelines for specific skills required during the transitioning process (i.e., filling prescriptions and scheduling appointments). These visits should also include the opportunity to address sensitive topics including drug and alcohol usage, as well as the impact of disease and on sexuality and fertility. Future work and school timelines need to be considered during this transitioning process to optimize effective timing for the transfer of care as well as identifying future adult providers. Psychosocial monitoring including screens for anxiety, depression, and quality of life as well as transition readiness is recommended given the impact of ongoing psychosocial comorbidities on medication adherence and effective transfer of care.

Self-Management: Health and Lifestyles

Patients (Age 17–18)

This is the crucial period before the actual transfer of care to an adult provider. The two skill sets they need at this stage include the following:

Skill Set 5

General self-management skills: Skills attained in this set put the knowledge acquired in the other skill sets to practical use and help patients move toward independence. The patient should receive an outline or plan for managing their disease, especially as they may leave home for work or school. They should be familiar with their medications and their medical history, learn to call in their own prescriptions, make their own clinic appointments, begin to collect copies of their health records/medical summary for work/school, and learn about adult providers, based on the location of where they will be in the near future (adult gastroenterologists near their new home/school/work). They should carry a copy of their insurance card, either as physical hard copy or as a saved photo on their smartphone, and understand the concept of medical insurance as well as more specific details including eligibility requirements, co-pays, and other potential resources for coverage such as Social Security Disability Insurance (SSDI).

Skill Set 6

Health and lifestyle decisions: The acquisition of skills from this skill set includes the patient gaining a general understanding of the importance of health maintenance and the potential interplay of their disease and lifestyle decisions. General knowledge includes the beneficial effects of exercise and an appropriate diet as well as the adverse effects of drugs, alcohol, and smoking. They should know the specific impact of disease activity on fertility and sexuality and the consequences of nonadherence. Patients should understand that at age 18, they are considered autonomous adults in terms of their health care; they have the right to make their

own health choices, and their health information cannot be shared with others including parents or guardians without permission.

Parents (Age 17–18)

Several studies in other chronic diseases have shown that parents may feel relegated to the sidelines as their children transfer to adult care. If the transition process has been implemented from an earlier age, and the parents have been educated, this should not occur. Parents can have concerns about their sons' or daughters' limitations in self-advocacy or cognitive function, and thus, can be justifiably worried about their ability to cope. These issues should be addressed at this visit, so everyone involved (the parents, the pediatric team, and the patient) can find a solution to overcome any obstacles. Ultimately, at this age, the parents should show less and less responsibility for the patient's care as the patient assumes more responsibility. This is the time where the parents need to officially practice letting go. They should encourage their child to go to their follow-up visit alone or at least allow them to visit with the doctor alone for most of their visit. To address concerns most parents have of missing critical information as they relinquish responsibility to the young adult, it is helpful to have a list of questions for the young adult patient ask at the visit (or let the parents ask separately after the visit but generally with the patient present). They should also understand that once their child turns 18, Health Insurance Portability and Accountability Act (HIPAA) regulations come into play, and the parent cannot obtain medical information unless the patient provides approval. This becomes an issue as parents often call the adult clinic asking for results and medication refills, appointments, and management decisions/plans.

Pediatric Team (Age 17–18)

At this stage, the pediatric team should prepare for the final clinic visits prior to transfer of care. The pediatric healthcare team should remind the patient and the parents that at age 18, patients have the right to make their own decisions. The pediatric team should help identify potential adult IBD providers and encourage and facilitate an initial visit. Ideally, a transition clinic setup is optimal; however, few clinical centers/hospitals have one. A return visit after they have seen the adult provider may be helpful to discuss their experience and troubleshoot any remaining concerns. Plans for insurance coverage should be discussed with the patient and parents. Identifying any insurance coverage is important as this may impact who they may be able to see as they transition. A social worker, if available, should be consulted to further review and educate the young adult patient about medical insurance coverage. Understanding how to navigate the health-care system from a financial perspective is necessary, given the need to have ongoing coverage of medical care. The patient should be provided a summary of their medical history for school or work and obtain any consent for health information in order to provide to the new adult gastroenterologist. In addition, the team should complete a medical summary of the patient to provide to the adult provider. Hait and colleagues have suggested the following to be included in this letter (Table 61.2).

Table 61.2 Medical summary letter

Medical summary letter for transitioning IBD patients
Disease information: date of diagnosis, location, severity
Findings: labs, endoscopy, histology, radiology results, and dates
Medical therapies: dose, duration, adverse reactions, reasons for discontinuation
Surgical history
Psychosocial, developmental, and educational issues

Adapted from Hait et al. [44]

Before the last visit, the provider should ideally confirm that psychosocial needs are addressed to ease the transitioning process as well as any other potential barriers to transfer of care, including financial issues, attitudes, access, and family resistance. These needs can be met through the use of a multidisciplinary approach, involving a dietitian, social worker, and psychologist, when available. The medical team should discuss differences in the cultures of pediatric and adult medicine. It is important whenever possible to refer the patient in times of disease quiescence and social stability when the transition is most likely to be successful. This may occur at different ages for various patients. For those who attend college, the transfer may be after graduation and after a job is secured or graduate education has begun. For those who choose not to attend college, the transfer of care should occur when housing and employment arrangements are stabilized.

Adult Team (Age 18+)

The adult gastroenterologist's role in the early transition process is minimal as the patient only arrives to them at the end of this process around the age of 18; however, his/her role in accepting and facilitating transfer of care is a key. In general, the adult gastroenterologist should only accept the transfer after he or she has been given an adequate medical history of this patient from the pediatric provider. This will help provide the most optimal care as medications, and prior medical and surgical history will be important in ongoing medical care. Since the adult gastroenterologist can potentially have an even longer role in the patient's chronic care, the transi-

tion is crucial in establishing a physician–patient relationship that fosters independence as well as confidence, trust, and communication in both parties.

The adult gastroenterologist's role is to continue to foster this independence with the patient. The patient should continue to be the main focus and should be seen independently from the parents, especially if over-concerned parents tend to drive the visit interactions. At this time, legal implications of health care can also play a role. The patient is solely responsible for their medical information. It will be up to him or her to decide if, and to what extent, the parents should be involved. HIPAA regulations will come into play as parents, once used to obtaining and providing information, now legally do not have a role without the patient's consent. The adult gastroenterologist and the adult care team (nurses, medical assistants) should be aware of this when parents of transitioned patients call for information. However, if the transition process is successful, the patients will contact the office themselves for medical information.

The adult gastroenterologist should acknowledge the parents and work jointly to continue to allow for the patient to remain independent and communicate any issues they have at the first visit. There should be mutual understanding of everyone's role. Since the parents have been a key player in their child's chronic illness, it is understandable the parents will have concerns and questions, as well as some resistance toward the transition. However, with the understanding and acknowledgement that the adult gastroenterologist's goal is to provide optimal care for the patient, then the family, patient, and physician can work together toward this shared goal.

The adult gastroenterologist should confirm the patient has established a relationship with an adult primary care physician, especially if the patient has been seeing a pediatrician for their general health care. Specialists often take on the role of "generalist" due to their frequent interaction related to IBD visits. However, obtaining a primary care provider (PCP) is important to provide optimal care regarding other illnesses such as general health care, immunizations, and screening for other diseases such as breast and prostate cancer and for preventive care for other diseases such as hyperlipidemia, diabetes, and hypertension.

The adult team should confirm that all relevant medical records are obtained, including any outstanding information that may still be needed. This may warrant a phone conversation with the pediatric health-care providers to include specific social history, developmental issues, and family dynamics that may not have been fully explained in the records. The importance of adherence to therapy should continue to be addressed at this time as well as any parental concerns. The adult provider should anticipate and answer any questions about smoking, alcohol, substance abuse, and sexuality as well as the psychosocial impacts their disease may have. They should also educate the patient regarding the adult chronic care model.

Monitoring the Process

Some system should be established to monitor both the teaching of the above skills and what has been learned and retained. Although there is no single validated transition readiness tool for use in pediatric IBD, prior publicans have utilized such transition tools as the Transition Readiness Assessment Questionnaire (TRAQ) and the Smooth Transition to Adulthood with Treatment (STARx) transition readiness questionnaire for this purpose [53, 54]. This can also be accomplished through pop-up messages on an electronic medical record, where objectives and follow-up learning must be recorded by date, or a special form could be kept in the patient's chart to check off each set once taught and then mastered. The patient could also be given a copy of this checklist so they know what the entire skill set contains. A member of the health-care team should be dedicated to documenting this process to ensure patients are making progress in becoming independent. Having set questions at follow-up visits to document what has been learned is also important. Typical questions that patients might be expected to answer at a follow-up visit are as follows: (1) Can you describe your disease? (2) What are your symptoms of IBD? (3) What situations should you avoid? (4) When should you call or see the doctor? (5) What is your doctor's or nurse's phone number? (6) Did you make this appointment? (7) Have you called in one of your prescriptions for refill? (8) What health records have you collected (i.e., endoscopy reports; laboratory test results)? (9) Who is your insurance carrier? Before final transition, time should be set up to do a final review of their competence in all areas, and then when the patient is ready, preparations can be made to transition care to an adult provider. At this point, the patient should already be taking care of his or her health issues, and a successful outcome for transition is likely.

Conclusion

The transition process can be a challenging time period for adolescents living with IBD as they move toward adulthood. However, a successful transition can be implemented if steps are taken early in the process with the combined effort from the patient, the parents/guardians, and the pediatric gastroenterology team. The key is to provide sufficient and early training around the process so that the young adult patient, their family, and their providers can progress through the

process together ensuring adequate time to adapt and prepare for a successful transition and graduation to adult gastroenterology care. A dynamic and supportive process will help young adult IBD patients effectively self-manage their health-care needs and become independent young adults who can manage their own complex medical needs.
