Ampicillin<sup>1</sup> (2g IV every 4 hours) is the drug of choice in *Listeria monocytogenes* infections. Aminoglycosides are added for synergistic effect. Trimethoprim-sulfamethoxazole (TMP-SMX)<sup>1</sup> (Bactrim, 20mg of trimethoprim/day IV every 6 hours) is an alternative for patients allergic to penicillin. Ampicillin and TMP-SMX may be used in combination. Vancomycin (Vancocin),<sup>1</sup> linezolid (Zyvox),<sup>1</sup> carbapenems, macrolides, and tetracyclines are also effective. Cephalosporins are ineffective in the treatment of listeriosis and should not be used. The duration of therapy is highly variable depending on the clinical situation and is 14 days for bacteremia, 21 days for meningitis, 42 days for endocarditis, and 56 days for neurologic infections. Patients whose disease is promptly diagnosed and treated recover fully, but permanent neurologic sequelae are common in patients with cerebral illnesses. Consuming only pasteurized dairy products and fully cooked meats, meticulously cleaning utensils, and thoroughly washing fresh vegetables before cooking will prevent foodborne listerial infections. Pregnant women and others at risk should avoid soft cheeses and thoroughly reheated ready-to-serve and charcuterie foods.

### Nontyphoidal Salmonellosis

Nontyphoidal salmonellosis consists of several causative organisms classified under the family Enterobacteriaceae; one such organism is *Salmonella enteritidis*. It does not occur normally in humans, but several animals act as reservoirs.

The diarrhea may be watery, with greenish, foul-smelling stools. This may be preceded by headache and chills. Other findings include prostration, muscle weakness, and moderate fever. In August 2020, a multi-state outbreak of *Salmonella enteritidis* was linked to peaches packed or supplied by Prima Wawona packing company. An outbreak of *Salmonella stanley* infection was linked to wood ear mushrooms (dried mushrooms, also called kikuage/dried black fungus) imported to the U.S. Yet another

<sup>1</sup>Not FDA approved for this indication.

non-typhoidal *Salmonella* infection reported in July 2020 was caused by *Salmonella newport*. The likely source was identified as potentially contaminated red onions. A food-borne illness recently reported from Mexico was caused by *Salmonella poona* and linked to consumption of cucumbers. Newly reported include *Salmonella reading* and *Salmonella abony* linked to consumption of alfalfa sprouts.

#### Pathogenesis

The organism penetrates and passes through the epithelial cells lining the terminal ileum. Multiplication of bacteria in lamina propria produces inflammatory mediators, recruits neutrophils, and triggers inflammation. Release of lipopolysaccharides and prostaglandins causes fever and also loss of water and electrolytes into the lumen of the intestine, resulting in diarrhea.

#### Laboratory Diagnosis

Culture in selenite F broth and then subculture on deoxycholate citrate agar isolates the organisms. Plates are incubated at 37°C overnight, and growth is identified by biochemical and slide agglutination tests.

#### Treatment

The antibiotics recommended for gastroenteritis due to nontyphoidal salmonellosis are ciprofloxacin (Cipro)<sup>1</sup> 500 mg PO twice daily, and ceftriaxone (Rocephin) 2 g IV daily, for 3 to 7 days. Amoxicillin (Amoxil)<sup>1</sup> and TMP-SMX<sup>1</sup> are also effective. Therapy is prolonged in bacteremia, endocarditis, or meningitis.

#### Shigella Species

*Shigella* species belong to the family Enterobacteriaceae. Bacillary dysentery is caused by *Shigella flexneri*, *Shigella boydii*, *Shigella dysenteriae*, and *Shigella sonnei*. *S. flexneri* is most common in developing countries where hygiene is poor and clean drinking water is unavailable; *S. sonnei* is most common in developed countries. The watery diarrhea that is present initially becomes bloody after a day or two owing to spread of infection from the ileum to the colon. The illness is caused by exotoxin acting in the small bowel.

Extraintestinal manifestations are recognized, including HUS, Reiter's syndrome, meningitis, Ekiri syndrome (reported in Japanese children and consisting of a triad of encephalopathy due to cerebral edema, bizarre posturing, and fatty degeneration of liver), vaginitis, lung infections, and keratoconjunctivitis. Toxic megacolon, pneumatosis coli, perforation, and rectal prolapse are recognized complications.

Tossed salads, chicken, and shellfish are the commonly incriminated foods. Person-to-person spread by anal intercourse or oral sex also occurs. Prepared food acts as a vehicle of transmission. Spread of infection is also linked to flies.

Children are at high risk during the weaning period, and increasing age is associated with decreased prevalence and severity. Children in daycare centers, persons in custodial institutions, migrant workers, and travelers to developing countries are also at high risk.

#### Pathogenesis

The virulence factor is a smooth lipopolysaccharide cell wall antigen, which is responsible for the invasive features, and the Shiga toxin, which is both cytotoxic and neurotoxic. Shigellae survive the gastric acidity and invade and multiply within the colonic epithelial cells, causing cell death and mucosal ulcers, and spread laterally to involve adjacent cells but rarely invade the bloodstream.

#### Laboratory Diagnosis

Shigellosis can be correctly diagnosed in most patients on the basis of fresh blood in stool. Neutrophils in fecal smears strongly suggest infection. Any clinical diagnosis should be confirmed by cultivation of the etiologic agent from stools. Cary-Blair medium is the transport medium of choice, and MacConkey agar or deoxycholate citrate agar (DCA) as well as a highly selective medium

such as xylose-lysine deoxycholate (XLD), Hektoen enteric (HE), or *Salmonella-Shigella* (SS) agar are also used.

#### Treatment

Ciprofloxacin (Cipro, 500 mg PO twice daily for 3 days) is the antibiotic of choice for shigellosis. Alternative agents are pivmecillinam (Selexid),<sup>2</sup> ceftriaxone (Rocephin),<sup>1</sup> and azithromycin (Zithromax).<sup>1</sup>

#### Staphylococcus aureus

A notable incident of staphylococcal food poisoning occurred in February 1975 when 196 of 344 passengers and one flight attendant aboard a jet from Tokyo to Copenhagen via Anchorage contacted a gastrointestinal illness characterized by nausea, vomiting, and abdominal cramps. The flight attendant and 142 passengers were hospitalized. Symptoms developed shortly after a ham and omelet breakfast had been served. *S. aureus* was incriminated as the offending agent and ham as the vehicle of the outbreak. The source was traced to a cook with pustules on his fingers.

*S. aureus* is ubiquitous in the environment. Only strains that produce enterotoxin cause food poisoning. Food is usually contaminated by infected food handlers.

#### Pathogenesis

If food is stored for some time at room temperature, the organism can multiply in the food and produce enterotoxin. Most food poisonings are caused by enterotoxin A, and the isolates commonly belong to phage type III. These are heat stable, and ingestion of as little as 23 µg of enterotoxin can induce symptoms. The toxin acts on the receptors in the gut, and sensory stimulus is carried to the vomiting center in the brain by vagus and sympathetic nerves.

Because the ingested food contains preformed toxin, the incubation period is very short. In severe illness, profound hypotension occurs. Death is known to occur at extremes of age and in the malnourished.

#### Laboratory Diagnosis

The presence of a large number of *S. aureus* in food can indicate poor handling or sanitation; however, it is not sufficient evidence to incriminate the food as the cause of food poisoning.

Staphylococcal food poisoning can be diagnosed if staphylococci are isolated in large numbers from the food and their toxins are demonstrated in the food or if the isolated *S. aureus* is shown to produce enterotoxins. Dilutions of food may be plated on Baird-Parker agar or mannitol salt agar. Enterotoxin may be detected and identified by gel diffusion.

#### Treatment

Therapy is mainly supportive. Antibiotics have no role in the treatment because they are not antitoxins. Intravenous fluids and electrolyte replacement are imperative in the severely dehydrated patient.

#### Yersinia Species

The *Yersinia* species that cause food poisoning are commonly *Yersinia enterocolitica* and rarely *Yersinia pseudotuberculosis*. Pigs and other wild or domestic animals are the hosts, and humans are usually infected by the oral route. Serogroups that predominate in human illness are O:3, O:5, O:8, and O:9.

Yersiniosis is common in children and occurs most often in winter. *Y. enterocolitica* is associated with terminal ileitis and *Y. pseudotuberculosis* with mesenteric adenitis, but both organisms can cause mesenteric adenitis and symptoms that cause a clinical picture resembling appendicitis, resulting in surgical removal of a normal appendix. Rarer strains of *Y. enterocolitica* are likely to cause systemic infections, especially in patients with diabetes or in iron overload states. In Japan, a form of vasculitis, called Izumi fever, occurs, and in Russia a scarlet fever–like illness has been reported.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

### Pathogenesis

*Yersinia* organisms can survive and grow during refrigerated storage. Strains that cause human yersiniosis carry a plasmid that is associated with a number of virulence traits. Ingested bacteria adhere and invade M cells or epithelial cells.

### Laboratory Diagnosis

Suspect food is homogenized in phosphate-buffered saline and inoculated into selenite F broth and held at 4°C for 6 weeks. The broth is subcultured at weekly intervals on deoxycholate citrate (DCA) or *Yersinia*-selective agar plates. This is termed *cold-enrichment technique*.

### Treatment

Antibiotics are not recommended for gastroenteritis caused by *Yersinia enterocolitica* and the less-common *Yersinia pseudotuberculosis*, but bacteremia and extraintestinal infections require treatment with ciprofloxacin<sup>1</sup> (500 mg PO or 400 mg IV twice daily for 2 weeks). Third-generation cephalosporins (cefotaxime<sup>1</sup> [Claforan]), amoxicillin<sup>1</sup> (Amoxil), TMP-SMX<sup>1</sup> (Bactrim), amoxicillin-clavulanate<sup>1</sup> (Augmentin), carbapenems, and gentamicin (Garamycin) are also effective agents in therapy.

## Viruses

### Noroviruses

Noroviruses (formerly called Norwalk or Norwalk-like viruses and small round structured viruses [SRSV]) and sapoviruses belong to the family Caliciviridae and are the most common cause of gastroenteritis. They account for about 90% of epidemic non-bacterial outbreaks of gastroenteritis around the world. Norovirus infection often affects people during the winter months and is therefore sometimes called winter vomiting disease; however, people may be affected at any time of the year. After a norovirus infection, immunity lasts only for 14 weeks and is incomplete. Persons with blood group O are more susceptible to infection, whereas those with groups B and AB are partially protected. Norovirus infection outbreaks more commonly occur in closed or semiclosed communities, such as prisons, dormitories, cruise ships, schools, long-term care facilities, and overnight camps—places where infection can spread rapidly from human to human or through tainted food and surfaces. Infection outbreaks can also result from food handled by an infected person.

Outbreaks have often been linked to consumption of cold foods, including salads, sandwiches, and bakery products. Salad dressing, cake icing, and oysters from contaminated waters have also been implicated in gastroenteritis outbreaks. Weight loss, lethargy, low-grade fever, headache, and (rarely) ageusia occur. Vomiting is more likely with infections caused by norovirus than sapovirus.

### Pathogenesis

Norovirus strains that infect humans are found in genogroups I, II, and IV. GII.4 strains are more commonly associated with person-to-person transmission, and GI strains are identified more commonly in shellfish-associated outbreaks.

Noroviruses were shown to differentially bind to histo-blood group antigens, and the binding pattern correlates with susceptibility to infection and illness. A number of enzymes are important in the synthesis of histo-blood group antigens, including fucosyl transferase-2 (FUT-2, secretor enzyme), FUT-3 (Lewis enzyme), and the A and B enzymes. The glycan produced by FUT-2H type 1, serves as a viral receptor for noroviruses.

### Laboratory Diagnosis

The virus can be recovered from the infected person's stool and vomitus during illness for about 2 weeks. Electron microscopy and reverse-transcriptase polymerase chain reaction (RT-PCR) antigen-detection assays are performed on stool samples.

Serologic assays are not available for clinical use. However, infection can be diagnosed by identifying a fourfold or greater increase in antibody titer between acute and convalescent sera using norovirus virus-like particles as antigen.

### Treatment

There is no specific treatment for norovirus infection. Hydration is generally adequate for most patients. In developing countries, oral rehydration therapy is the treatment of choice. Effective hand washing, careful food processing, and education of food handlers along with chlorination of water are important preventive measures. A vaccine for norovirus is in clinical trials.

### Rotavirus

Among the seven rotavirus species (A to G), rotavirus A, B, and C can cause disease in humans. Rotavirus A is the most common and is the major cause of waterborne outbreaks in humans. Infections are referred to as infantile diarrhea, winter diarrhea, or acute viral gastroenteritis. Children 6 months to 2 years of age, premature infants, the elderly, and the immunocompromised are particularly prone to more-severe symptoms caused by infection with group A rotavirus. Rotavirus can survive in water for days to weeks, depending on water quality and temperature. Waterborne outbreaks are most common, followed by spread by fomites. Rotaviruses infect intestinal enterocytes; diarrhea may be caused by malabsorption secondary to the destruction of enterocytes, villus ischemia and activation of the enteric nervous system, and intestinal secretion stimulated by the action of rotavirus nonstructural protein 4 (NSP4), a novel enterotoxin and secretory agonist with pleiotropic properties.

Outbreaks caused by group B rotavirus, also called adult diarrhea rotavirus, have also been reported in the elderly and adults. Such infections are rare and usually subclinical. Group C rotavirus has been associated with rare and sporadic cases of diarrhea in children in many countries. Subclinical infection to severe gastroenteritis leading to life-threatening dehydration can occur. The illness has an abrupt onset, with vomiting often preceding the onset of diarrhea. Up to one third of patients have fever of about 39°C. The stools are characteristically watery and only occasionally contain red or white cells. Symptoms generally resolve in a week.

Respiratory and neurologic features in children have been reported. Rotavirus infection has been associated with other clinical conditions including sudden infant death syndrome (SIDS), necrotizing enterocolitis, Kawasaki's disease, and type 1 diabetes.

### Laboratory Diagnosis

Electron microscopy, direct antigen detection assays (ELISA, immunochromatography, latex agglutination), and nucleic acid detection (e.g., RT-PCR, polyacrylamide gel electrophoresis [PAGE]), are used mainly in epidemiologic studies during outbreaks.

### Treatment

Dehydration due to group A rotavirus infection is treated with early institution of oral and intravenous fluids. The role of probiotics,<sup>7</sup> bismuth subsalicylate (Pepto Bismol),<sup>1</sup> inhibitors of enkephalinase, and nitazoxanide (Alinia)<sup>1</sup> are not clearly defined. Antimicrobials and antimotility agents should be avoided. A marked fall in deaths from childhood diarrhea following introduction of rotavirus vaccines (Rotarix, RotaTeq) has been reported from various parts of the world, and surveillance information has not revealed an association of any serious adverse reactions with the vaccine.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

## Other Pathogens

### *Cryptosporidium*

Transmission of *Cryptosporidium* is usually by the fecal-oral route, often through food and water contaminated by livestock mammal feces. Persons most likely to be infected by *Cryptosporidium parvum* are infants and young children in daycare centers; those whose drinking water is unfiltered and untreated; those involved in farming practices such as lambing, calving, and muck-spreading; people engaging in anal sexual practices; patients in a hospital setting (from other infected patients or health care workers); veterinarians; and travelers.

### Pathogenesis

*Cryptosporidium* spp. are believed to be noninvasive. Malabsorption resulting from the intestinal damage caused by prolonged protozoal infection can be fatal. Although host cells are damaged in cryptosporidiosis, the means by which the organism causes damage is not known. Mechanical destruction and the effects of toxins, enzymes, or immune-mediated mechanisms, working alone or together, may be instrumental. In the immunocompromised, the illness is much more debilitating, with cholera-like diarrhea.

### Laboratory Diagnosis

Traditionally, cryptosporidiosis is diagnosed by microscopic observation of developmental stages of the organism in an intestinal biopsy specimen. Oocysts can be recovered from stool samples by formalin-concentration techniques, staining with a modified Ziehl-Neelsen acid-fast stain. Serologic tests (ELISA, immunofluorescence antibody, PCR) are of added value.

### Treatment

Nitazoxanide (Alinia, 500 mg PO twice daily for 3 days) is recommended with antiretrovirals for HIV-positive patients. Fluid replacement and antidiarrheal agents are also given.

### Trichinosis

Trichinosis is due to *Trichinella spiralis* infection, commonly as a result of consuming improperly cooked pork. Recent outbreaks

in North America have been attributed to consumption of bear meat rather than pork. The parasite lodges in the extraocular muscles, deltoid, biceps, intercostals, diaphragm, tongue, or masseter and produces severe weakness with pain, fever, and cough along with splinter hemorrhages and eosinophilia.

Moderate *T. spiralis* infection is treated with mebendazole (Vermox 200–400 mg PO three times daily for 3 days) or albendazole<sup>1</sup> (Albenza 400 mg PO twice daily for 7–14 days). For severe infections, prednisone is added in a dose of 1 mg/kg/day for 5 days.

### Neurocysticercosis

Neurocysticercosis is caused by *Taenia saginata* infection, commonly as a result of consuming improperly cooked pork or contaminated raw vegetables and water. The parasite lodges in the central nervous system and skeletal muscle and presents as intracranial calcifications and ring-enhancing lesions on radioimaging studies. Other than leukocytosis, eosinophilia, and raised erythrocyte sedimentation rate, antibodies to species-specific antigens of *T. solium* can be detected by immunosorbent assay and complement fixation-tests. Treatment is aimed at controlling seizures and relief of hydrocephalus. Albendazole (15 mg/kg/day for 8–28 days) or praziquantel (50–100 mg/kg/day in three divided doses for a month) are given for parenchymal cysticerci with glucocorticoids to suppress the inflammatory response around the dying parasites. Surgery may be required to reduce intracranial pressure.

### Dinoflagellate toxins

Dinoflagellates, a very large and diverse group of eukaryotic algae in the marine ecosystem, are the major group producing toxins that impact humans. Dinoflagellate toxins are structurally and functionally diverse, and many present unique biological activities. Five major seafood poisoning syndromes caused by toxins have been identified from the dinoflagellates (Table 4): paralytic shellfish poisoning (PSP), neurotoxic shellfish poisoning (NSP), amnesic shellfish poisoning (ASP), diarrhetic shellfish poisoning (DSP) and ciguatera fish poisoning (CFP). Symptoms include allergic manifestations, neurologic including paresthesia of the extremities, headache, ataxia, vertigo, cranial nerve palsies, and paralysis of

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** Seafood Poisoning Caused by Neurotoxins Identified from Marine Dinoflagellate Species

TYPE OF POISONING	TOXINS	SOURCES OF TOXINS	PRIMARY VECTOR	ACTION TARGET
PSP	Saxitoxins and gonyautoxins	<i>Alexandrium</i> spp., <i>Gymnodinium</i> spp., <i>Pyrodinium</i> spp.	Shellfish	Voltage-gated sodium channel 1
NSP	Brevetoxins	<i>Kerenia brevis</i> , <i>Chatonella marina</i> , <i>C. antiqua</i> , <i>Fibrocapsa japonica</i> , <i>Heterosigma akashiwo</i>	Shellfish	Voltage-gated sodium channel 5
	Yessotoxins	<i>Protoceratium reticulatum</i> , <i>Lingulodinium polyedrum</i> <i>Gonyaulax spinifera</i>	Shellfish	Voltage-gated calcium/sodium channel?
CFP	Ciguatoxins	<i>Gambierdiscus toxicus</i>	Coral reef fish	Voltage-gated sodium channel 5
CFP	Maitotoxins	<i>Gambierdiscus toxicus</i>	Coral reef fish	Voltage-gated calcium channel
AZP	Azaspiracids	<i>Protopteridinium crassipes</i>	Shellfish	Voltage-gated calcium channel
Palytoxin poisoning	Palytoxins	<i>Ostrepsis siamensis</i>	Shellfish	Na <sub>v</sub> K <sub>v</sub> ATPase

respiratory muscles as well as gastrointestinal. Symptomatic treatment and antihistamines are the mainstay of treatment.

### Tetrodotoxin poisoning

It is a neurotoxin concentrated in the skin and viscera of puffer fish, and other fishes of the order Tetraodontiformes and in some amphibian, octopus, and shellfish species. Human poisonings occur when the flesh or organs of the fish are improperly prepared and eaten. Tetrodotoxin acts by blocking the conduction of nerve impulses along nerve fibers and axons and interferes with the transmission of signals from nerves to muscles. Onset of symptoms usually is 30–40 minutes but may be as short as 10 minutes; it includes lethargy, paraesthesia, emesis, ataxia, weakness, and dysphagia; ascending paralysis occurs in severe cases with high mortality (1–2 mg is lethal). Management is symptomatic.

### Group B Streptococcus (GBS)

GBS bacteria is found in 15%–30% of adult human intestines and urinary tract. Rarely implicated in infections of skin, joints, heart and brain, a recent outbreak of food-borne illness caused by the Type III GBS ST283 strain was reported in Singapore during the period of January–July 2015. It is the largest of its kind and first association to food-borne transmission of GBS to people via consumption of “yusheng-style” raw fresh water fish. The primary case presented with giddiness and suffered bouts of vomiting and diarrhea. Further studies are ongoing to establish the link between increase in cases of Group B streptococcus (GBS) infection to consumption of raw fish. Treatment is symptomatic.

### Newer Trends in Foodborne Illness

New or unusual pathogens and food hazards are identified in course of investigating outbreaks. In 2011, a novel outbreak of sprout-associated illness caused by a strain of *Escherichia coli* O104:H4 was reported from Germany and France. This enteroaggregative and Shiga toxin-producing strain caused severe illness leading to HUS and death. In 2008, an outbreak following consumption of chicken caused by *Arcobacter butzleri* (found in poultry) was reported from Wisconsin. The calcivirus Sapovirus is emerging as the likely cause of oyster-associated foodborne outbreaks in Japan. New and unsuspected food vehicles are also being identified that had not been previously recognized as problematic (Box 1).

#### BOX 1 New Food Vehicles Identified in Outbreaks

- Bagged spinach
- Carrot juice
- Peanut butter
- Broccoli powder on a snack food
- Dry dog food
- Frozen potpies
- Canned chilli sauce
- Hot peppers
- White and black pepper
- Raw cookie dough (likely the flour)
- Hazelnuts
- Fenugreek sprouts
- Papayas
- Pine nuts
- Raw scrapped tuna
- Clover sprouts
- Herbs
- Avocado, guacamole

Reprinted from Braden C, Tauxe R: Emerging trends in foodborne diseases, *Inf Dis Clin-ics N Am* 27:517–533, 2013.

#### BOX 2 Miscellaneous Organisms Implicated in Foodborne and Waterborne Illnesses

- Adenovirus 40, 41
- Bacillus anthracis*
- Bacillus mycoides*
- Burkholderia cepacia*
- Burkholderia pseudomallei*
- Clostridium bifermentans*
- Corynebacterium diphtheriae*
- Coxiella burnetii*
- Dientamoeba fragilis*
- Enterococcus faecalis*, *E. faecium*
- Erysipelothrix rhusiopathiae*
- Francisella tularensis*
- Henipa virus
- Klebsiella* spp.
- Leptospira* spp.
- Mycobacterium bovis*
- Parvovirus B
- Pediococcus*
- Pestivirus
- Picobirnavirus
- Proteus* spp.
- Pseudomonas aeruginosa*
- Pseudomonas cocovenanans*
- Reovirus
- Streptobacillus moniliformis*
- Taenia solium*, *T. saginata*
- Torovirus
- Toxoplasma gondii*

Changing patterns of disease presentation have seen important foodborne challenges emerging. Chagas disease is emerging as a foodborne infection linked to fresh, unpasteurized acai and guava juice. Infected triatomid insects present in fruits are implicated. Outbreaks of Nipah virus encephalitis in Bangladesh and India have been linked to drinking of palm sap, toddy, and well water contaminated with urine of feeding giant fruit bats, the vector of Nipah virus.

More syndromes and other systemic disease presentations are being linked to foodborne infection. The feco-oral transmission of pathogens leading to other systemic manifestation include *Campylobacter* sp. (Guillain-Barre syndrome, irritable bowel syndrome), *Toxoplasma gondii* (behavior changes and neuropsychiatric manifestations) and *Salmonella choleraesuis* (aortitis). Foodborne outbreak of Group G streptococci (GGS) pharyngitis in a school dormitory in Japan (2016) presented with sore throat and fever in a majority; implicated food was a broccoli salad.

### Miscellaneous

Many other organisms are implicated in foodborne and waterborne illnesses (Box 2). Some are discussed elsewhere in this book. Amebiasis, brucellosis, cholera, hepatitis A and E, giardiasis, typhoid fever, and other foodborne intestinal nematodes and cestodes are covered in the infectious diseases section of this text and are not covered in this section.

## CURRENT THERAPY

- The treatment of choice is metronidazole (Flagyl)<sup>1</sup> or tinidazole (Tindamax); tinidazole can be given as a single dose.
- Albendazole (Albenza)<sup>1</sup> and nitazoxanide (Alinia) are alternative agents.
- Paromomycin (Humatin),<sup>1</sup> a poorly absorbed aminoglycoside, is commonly recommended during early pregnancy when other agents are avoided.
- True drug resistance has not been documented, but refractory or recurrent cases can be treated by two drugs: a nitroimidazole combined with quinacrine (Atabrine)<sup>2</sup> or albendazole.<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

*Giardia lamblia* is the most common parasitic cause of diarrhea. It is found globally with manifestations that range from asymptomatic to chronic diarrhea with weight loss and malnutrition. Infection occurs when cysts are ingested, most commonly from contaminated water or more direct fecal oral transmission. Less commonly, infections are acquired from food or from zoonotic sources. The cysts excyst in the small intestine and replicate as trophozoites, which cause the disease associated with the organism. The diagnosis is made by the microscopic detection of cysts or trophozoites from fecal samples or by immunoassays of fecal samples. The treatment of choice for symptomatic patients is tinidazole (Tindamax) or metronidazole (Flagyl),<sup>1</sup> while treatment of asymptomatic people depends on the circumstances. Irritable bowel syndrome is common after symptomatic infection, so patients with persistent symptoms should only be treated when persistent infection is documented.

## Background

*Giardia lamblia* (syn. *Giardia intestinalis*, *Giardia duodenalis*) was initially described by Leeuwenhoek in the 17th century while doing a microscopic examination of his own diarrheal feces. However, *G. lamblia* was not widely accepted as a human pathogen until the 1960s, when a number of outbreaks were reported in travelers to endemic areas. The presumed source of infection in these cases was contaminated drinking water. Subsequently, *Giardia* has become the most commonly identified parasitic cause of diarrhea, and, along with *Cryptosporidium* species, is among the most commonly identified parasitic causes of water-borne diarrheal disease.

## Organism

*Giardia* species are members of the diplomonad (two bodies) group of flagellated protozoans. The life cycle consists of the environmentally resistant cyst, which infects its host on ingestion. It is oval in shape, is about 8 μm × 12 μm in size and contains four nuclei. It excysts into pear-shaped trophozoites in the proximal small intestine that are about 10 to 12 μm by 5 × 7 μm in size. Two symmetrically placed nuclei are in the body of the trophozoites and four pairs of flagella aid with motility. A ventral concave disk uses primarily mechanical means to attach to the intestinal wall of the host. While still in the small intestine, some of the trophozoites then encyst into the cyst form, which is passed in the feces to continue the cycle of infection. The *Giardia* species are all parasitic and were initially assigned to species on the basis of host of origin. However, in 1952, they were divided into three species (*Giardia agilis*,

<sup>1</sup>Not FDA approved for this indication.

## GIARDIASIS

Method of

Rodney D. Adam, MD

## CURRENT DIAGNOSIS

- Giardiasis is the most common intestinal protozoan infection worldwide.
- Most cases result from exposure to contaminated drinking or recreational water.
- The clinical manifestations range from asymptomatic to chronic diarrhea with malabsorption and weight loss.
- The diagnosis can be established by stool microscopy or by immunoassays of fecal specimens.
- Occasionally, the trophozoites can be found in duodenal specimens when fecal assays are negative.
- Serologic testing plays no role in the diagnosis.
- Irritable bowel symptoms are very common after successful treatment of giardiasis.

amphibians; *Giardia muris*, rodents; *G. duodenalis* [*G. lamblia*], mammals and birds) that could easily be distinguished on the basis of morphologic appearance of the trophozoites. Subsequently, the *G. lamblia* morphologic group has been divided into additional species based on differences that can be seen at the ultrastructural or molecular level. Of the organisms that remain assigned to *G. lamblia*, all are found in mammals but are divided into eight genotypes or assemblages (A through H) on the basis of molecular differences with varying host specificities. Only genotypes A and B have been found in humans. It is likely that at least some of these eight genotypes will eventually be assigned to separate species.

### Epidemiology

Giardiasis is the most commonly diagnosed human protozoan infection and is one of the most commonly identified forms of gastroenteritis. Most cases occur from ingestion of contaminated water or by human-to-human transmission through the fecal-oral route. Thus the epidemiology of human infections can be understood by examining these mechanisms of transmission. In the United States most cases are sporadic and occur more often in the summer, probably reflecting infection from recreational water exposure. Infections were more commonly reported in children from ages 1 to 9 years, especially those younger than 4 years of age. In general, the incidence is higher in the northern states, perhaps because cysts survive longer in cool, moist environments.

Direct human-to-human transmission by the fecal oral route also occurs, leading to the higher prevalence found in children in daycare centers. The occasional reports of food-borne transmission most likely occurred because of food being contaminated by infected food handlers.

The greater incidence in children could reflect an increased use of recreational water facilities, daycare exposure, or increased susceptibility to symptomatic disease. The epidemiology of giardiasis in the United States is similar to that found in other developed countries located in temperate regions. However, in developing regions with inadequate availability of purified water, the epidemiology is very different. For example, in a shantytown near Lima, Peru, children were almost universally infected by the age of 2 years, and when treated, they were rapidly reinfected, but there were no symptoms that could clearly be correlated with their infections. Perhaps an outbreak at a ski resort town in the United States can explain these different epidemiologic patterns. In this water-borne outbreak, tourists were disproportionately affected despite drinking from the same water source as the local residents. The conclusion was that the local residents had repeatedly been exposed to water contaminated by *Giardia* cysts and were less susceptible to symptomatic disease.

The degree of zoonotic transmission of giardiasis remains controversial. Human acquisition of infection from dogs or cats has not been well documented, and usually the *Giardia* genotypes found in cats or dogs are distinct from those found in humans (A and B), even in regions where both are endemic. However, genotypes A and B have sometimes been identified in dogs or other animals, so the question is not totally resolved. On the other hand, beavers have been implicated as a source of contaminated water leading to human infections.

### Risk Factors

People with hypogammaglobulinemia, and possibly those with IgA deficiency, are at increased risk for prolonged giardiasis. In animal models, deficiency in cell-mediated immunity (CMI) has been associated with increased risk, but in humans the increased risk has not been associated with defects in CMI.

### Pathogenesis

Infection is initiated by the ingestion of as few as 10 cysts. After passage through the acidic environment of the stomach,

each cyst excysts into two trophozoites in the proximal small intestine. However, gastric acidity is not required, and people with achlorhydria or who are treated with suppressors of gastric acid remain vulnerable to giardiasis. The trophozoites replicate in the proximal small intestine, where they attach to the intestinal mucosa by their ventral disks. The attachment appears to occur by mechanical means facilitated by the suction generated by the ventral disk and the four pairs of flagella as they provide motility. Although the trophozoites attach to the intestinal wall and leave imprints after separating from the wall, there is no well-documented evidence of invasion, either of the intestinal wall or at extraintestinal sites. Toxins have not been identified as causes of diarrhea. However, cysteine proteases, which are also involved in encystation, may be important contributors to the symptoms. The host parasite interaction leads to enterocyte apoptosis and epithelial barrier disruption. The host immune response is mediated through a TH17 response that includes IgA production. An inadequate immune response results in persistence of organisms and an excessive response may be responsible for the prolonged diarrhea and malabsorption that is commonly found in symptomatic people. Irritable bowel syndrome as well as chronic fatigue are common after giardiasis with a rate over 30% in a large Norwegian outbreak in 2004. The trophozoites are coated with a cysteine-rich protein encoded by one of a family of related genes, and expression can be switched from one to another, perhaps contributing to the chronicity of the infection.

### Prevention

The strategies for prevention should be determined by the most prevalent risk factors in specific situations. For travelers to endemic regions, the major risk is from the ingestion of contaminated water. Therefore drinking water should be purified by boiling for 1 minute or by filtration through a pore size of <1  $\mu\text{m}$ . Halogenization with iodine or chlorine requires a prolonged contact time (hours) to inactivate cysts and is not recommended. In daycare centers and for food handlers, the best preventive measure is effective hand washing. In addition, children or workers who are infected should be treated.

### Clinical Features

Most people with giardiasis are symptom-free, but the percentages range from rates of diarrhea no higher than background among children in some highly endemic regions to attack rates of nearly 100% in visitors to endemic regions. Symptomatic patients typically present for evaluation only after several days or even weeks of illness because of the subacute onset. The symptoms of giardiasis typically develop after an incubation period of 1 to 2 weeks and consist of diarrhea that is characterized by loose, foul-smelling stools and abdominal discomfort described as cramping or bloating (Table 1). Fatigue is very common, but fever is unusual and, when present, is mild and occurs only within the first few days. Malabsorption and weight loss are often present. The majority of cases resolve within several weeks, but occasionally the symptoms will last for months in the absence of treatment. The prolonged symptoms are often due to postinfectious irritable bowel syndrome and/or chronic fatigue, especially if not accompanied by weight loss. Relapse is relatively uncommon after effective treatment.

### Diagnosis

The gold standard of diagnosis has been the microscopic evaluation of three separate fecal samples, including concentrated specimens for cysts or, less commonly, trophozoites. The identification of trophozoites is typically associated with symptomatic infection, but cysts may be found in symptom-free persons. Because of the challenges in obtaining three fecal specimens and the interobserver variability in skill at identifying *Giardia*

**TABLE 1** Symptoms of Giardiasis\*

SYMPTOM	AVERAGE (%)
Diarrhea	95
Abdominal cramps	70
Weakness or malaise	70
Nausea	60
Weight loss	50
Anorexia (decreased appetite)	50
Abdominal distention (bloating/distension)	50
Flatulence	50
Vomiting	30
Fever	20

\*The table includes the approximate frequency of the signs and symptoms reported in six studies of symptomatic giardiasis, but it is important to note that there is substantial variability of symptoms among studies.

cysts, antigen detection tests have come into widespread use. The enzyme immunoassays are more commonly used and have high degrees of sensitivity and specificity. A direct fluorescent assay is slightly more sensitive than the enzyme immunoassays and can also detect *Cryptosporidium* species, but it requires the availability of fluorescent microscopy. Polymerase chain reaction (PCR) tests have also been described and are more sensitive but more expensive and not widely available. Some patients have negative workups of stool samples, but *Giardia* trophozoites can be detected in duodenal contents with the string test. The patient swallows a capsule on a string, which is left in situ for 4 hours to overnight. The string is then removed and examined microscopically for trophozoites. Alternatively, endoscopy with sampling of duodenal contents and duodenal biopsy can be used. Endoscopy has the added advantage of being able to detect other possible diagnoses, such as celiac disease or tropical sprue.

### Differential Diagnosis

The diagnosis of giardiasis should be suspected in patients presenting with prolonged (>5–7 days) diarrhea without blood in the stools and no fever. In patients presenting relatively early in the course of illness, the major considerations in the differential diagnosis are other infectious etiologies of diarrhea, particularly *Campylobacter jejuni*, *Salmonella*, *Cryptosporidium*, and *Cyclospora cayatanensis*. Thus patients presenting with compatible symptoms should have stool samples submitted for culture and for microscopic examination for ova and parasites (O and P). Watery diarrhea is uncommon, and bloody stools are not seen with giardiasis; thus these findings should prompt the search for other etiologies.

For patients presenting with more prolonged symptoms, a number of noninfectious illnesses should be added to the differential diagnosis. Irritable bowel syndrome and lactose intolerance are among the more common etiologies and should be considered in patients presenting with diarrhea but no weight loss. Gluten enteropathy, tropical sprue, and, rarely, Whipple's disease are among the noninfectious etiologies of diarrhea accompanied by weight loss.

### Treatment

Patients with symptomatic giardiasis should be treated. The criteria for treatment of patients with asymptomatic giardiasis are not well defined, but in general, patients in regions with low

prevalence or linked with outbreaks should be treated. On the other hand, in settings where the prevalence is high and recurrence rates are high, there is probably no value to treating asymptomatic infection.

The most commonly used agents for treatment of giardiasis are the nitroimidazoles. Metronidazole (Flagyl),<sup>1</sup> tinidazole (Tindamax), and secnidazole (SoloSec)<sup>1</sup> are available in the United States, while ornidazole (Tiberol)<sup>2</sup> is available in other countries (Table 2). These agents are completely absorbed from the gastrointestinal tract and are inactivated primarily by hepatic metabolism. Metronidazole has been available in the United States for decades and has generally been considered the drug of choice for treatment of giardiasis in most situations. More recently, tinidazole has become available and is the only agent available in the United States with a high degree of efficacy when given as a single dose. A meta-analysis of 60 randomized clinical trials for treatment of giardiasis concluded that tinidazole was more effective than metronidazole or albendazole. Metronidazole is mutagenic in bacterial assays and showed some carcinogenic activity in an animal model. However, carcinogenicity in humans has not been documented. Serious adverse reactions to the nitroimidazoles are rare, but nausea and a metallic taste are common and may decrease the compliance of patients with metronidazole. The problem with noncompliance can be addressed by the use of tinidazole or the other agents that can be given as a single dose.

Albendazole (Albenza)<sup>1</sup> is a tubulin inhibitor that was introduced as a broad-spectrum antihelminthic, but it also has good activity against *Giardia* trophozoites. It is generally well tolerated and in areas with endemic helminth infections has the added advantage of antihelminthic activity.

The first trimester of pregnancy poses a special problem because none of the agents have been adequately studied or approved for use during this time. Paromomycin (Humatin)<sup>1</sup> is a nonabsorbed aminoglycoside and is expected to be safe during pregnancy. Therefore it is usually the preferred choice in that setting; however, it is somewhat less effective than other agents. Specialty consultation should be considered for treatment of patients in their first trimester. Metronidazole is used extensively during the second and third trimesters for other indications; thus it can be considered the drug of choice for those patients.<sup>1</sup> Albendazole is known to be teratogenic and should be avoided during pregnancy.

Nitazoxanide (Alinia) has been approved in the United States for treatment of giardiasis (and cryptosporidiosis) and is very well tolerated. However, the somewhat lower efficacy compared with nitroimidazoles and albendazole, along with the requirement for twice daily dosing, limits its role.

Treatment failures are not uncommon but may or may not be due to true drug resistance because in vitro cultures are not routinely performed, and in vitro testing is not standardized. When treatment failure occurs, the patient may respond to the same or an alternative drug. Treatment-refractory cases have been treated successfully with a combination of metronidazole<sup>1</sup> plus quinacrine<sup>2</sup> or albendazole.<sup>1</sup> The most common reason for persistence of symptoms after treatment is due to postgiardiasis irritable bowel syndrome, which can occur in over 30% of patients. Thus it is important to reevaluate stool specimens from patients with symptoms that persist after therapy.

### Diet

Lactose intolerance is quite common while patients have giardiasis and potentially for months thereafter, so lactose ingestion should be moderated or eliminated as needed.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

**TABLE 2** Treatment of Giardiasis

DRUG	DOSE		FREQUENCY	DURATION	EFFICACY (%)
	ADULT	PEDIATRIC*			
Metronidazole <sup>1</sup> (Flagyl)	250 mg	5 mg/kg	tid	5–7 days	90–100
Tinidazole (Tindamax)	2 g	50 mg/kg	Single dose	Single dose	90–100
Secnidazole <sup>1</sup> (Solosec)	1.5 g	30 mg/kg <sup>†</sup>	Single dose	Single dose	90–100
Quinacrine <sup>2</sup> (Atabrine)	100 mg	2 mg/kg	tid	5–7 days	80–100
Furazolidone <sup>2</sup> (Furoxone)	100 mg	1.5 mg/kg	qid	10 days	80–94
Paromomycin <sup>1</sup> (Humatin)	500 mg	8–10 mg/kg	tid	10 days	55–90
Albendazole <sup>1</sup> (Albenza)	400 mg qd	15 mg/kg	Daily	5 days	90–100
Nitazoxanide (Alinia)	500 mg bid	7.5 mg/kg	bid	3 days	70–80

<sup>†</sup>Approved for adults and patients ≥12 years of age.

\*The adult dose is the maximum pediatric dose.

<sup>1</sup>Not FDA approved for this indication.

## HUMAN IMMUNODEFICIENCY VIRUS: TREATMENT AND PREVENTION

Method of

Allison Cormier, MD; and Tyler K. Liebenstein, PharmD

### CURRENT DIAGNOSIS

- National guidelines recommend universal screening for human immunodeficiency virus (HIV) infection for all adult and adolescent patients in all healthcare settings after notification that testing will be done, unless the patient specifically declines testing (opt-out testing). Patients with behavioral risk factors, sexually transmitted diseases, or tuberculosis should be screened annually.
- Revised HIV testing algorithms reflect the increased sensitivity of newer diagnostic assays during early infection, such as fourth-generation HIV-1/2 antigen/antibody combination immunoassays.
- Acute HIV infection is recognized as a variable syndrome including fever, pharyngitis, rash, and arthralgias. As many as one-half of patients may be asymptomatic during seroconversion and early infection.

### CURRENT THERAPY

- Combination antiretroviral therapy (ART) should be offered to all patients with HIV infection, regardless of CD4 helper T-lymphocyte (CD4 T-cell) count.
- Initial ART regimens preferred for most patients include a combination of two nucleoside analogue reverse transcriptase inhibitors (NRTIs) and an integrase strand transfer inhibitor (INSTI), which are often coformulated into single-tablet preparations that can be administered once daily.
- Although ART decisions are often made by providers with specialized training, all providers who care for people living with HIV should be aware of the risk of antiretroviral drug interactions, particularly interactions involving the pharmacokinetic-enhancing agents ritonavir (Norvir) and cobicistat (Tybost).
- All sexually active adult and adolescent patients should receive information about HIV preexposure prophylaxis (PrEP) to reduce the risk of HIV acquisition. Both oral and injectable medication options are available for PrEP.

### Introduction

Remarkable advances in therapeutics, leading to the development of antiretroviral therapy (ART), have transformed human immunodeficiency virus (HIV) infection from an almost universally fatal illness to a chronic disease that can be managed over decades with an enlarging repertoire of treatment options. Further developments in ART have also provided opportunities for preventing HIV infection in high-risk individuals. This chapter provides an overview of the current understanding of HIV pathogenesis and epidemiology and discusses guidelines for the initial evaluation and long-term management of HIV infection in adult patients.

### Pathophysiology

HIV is an enveloped, single-stranded RNA virus belonging to the family Retroviridae. It was recognized as the causative agent of AIDS within 3 years after the initial description of the syndrome in 1981, and ongoing characterization of its molecular biology has provided the identification of multiple targets for drug development. Two types of human immunodeficiency viruses exist: HIV-1 and HIV-2. HIV-1 has worldwide distribution, accounts for most infections outside western Africa, and is the focus of this chapter.

HIV-2 infection is endemic in West Africa and has limited spread outside this area. It should be considered in infections in patients of West African origin or those who have had sexual contact or shared needles with people of West African origin. HIV-2 generally has a longer asymptomatic stage, lower plasma HIV-2 viral loads, and overall lower mortality rate. Approximately 25% to 30% of patients with HIV-2 who do not receive ART will have HIV-2 RNA levels below the rate of detection, and some will also have clinical progression and a decreased CD4 helper T-lymphocyte (CD4 T-cell) count. HIV-2 can progress to AIDS over time. HIV-1 and HIV-2 coinfection may occur and should be a consideration in patients from high prevalence HIV-2 areas. Patients diagnosed with HIV-2 infection should be managed by an HIV specialist.

Genetic heterogeneity of HIV-1 is reflected in categorization of the virus into three groups (M, O, and N) and several subtypes (B, C, D, AE, and CRF01\_AE), some of which have overlapping geographic distribution around the world. Subtype C is prevalent in southern and eastern Africa, China, India, South Asia, and Brazil and accounts for 50% of HIV subtypes, whereas subtype B, the most common subtype in the United States, accounts for 12%.

The HIV viral genome is encoded in single-stranded RNA, packaged in core protein structures, and surrounded by a lipid bilayer envelope that is derived from the cell membrane of the host cell as the virus buds from the cell surface after replication.

This outer viral membrane contains HIV-specific glycoproteins, including gp120 and gp41, which facilitate attachment and entry into host cells through interaction with the cell surface receptor, CD4, and coreceptors CCR5 and CXCR4. CD4 T cells are the predominant host cell affected by HIV; this molecular tropism explains the immune system destruction manifested in chronic HIV infection and provides the rationale for clinical staging of HIV infection using CD4 T-cell counts. After host cell entry, the key enzyme responsible for viral replication is reverse transcriptase, an RNA-dependent DNA polymerase that is packaged within the virion core. This enzyme facilitates conversion of the HIV genome into a double-stranded DNA intermediate molecule. The second key enzymatic step is integration of this intermediate nucleic acid product into the host genome, which is facilitated by the viral protein integrase. Protein synthesis with packaging of new viral particles ensues, utilizing an HIV-specific protease. The integrase inhibitor class of drugs acts by blocking this step of integration.

### Natural History

Within 1 to 4 weeks after the initial HIV infection, seroconversion may be accompanied by a nonspecific, self-limiting illness, often referred to as *acute retroviral syndrome*. This illness has variable manifestations but may include fever, malaise, myalgias, arthralgias, generalized lymphadenopathy, pharyngitis, and rash. The associated rash may be maculopapular, urticarial, or roseola-like. An illness resembling acute infectious mononucleosis syndrome, similar to that caused by Epstein-Barr virus (EBV) or cytomegalovirus (CMV), and aseptic meningitis has been described. Diagnosis of acute HIV infection requires a high index of suspicion, which does not commonly occur unless the patient reports a recent history of high-risk exposure.

During the acute phase of infection, high levels of viremia are present (often exceeding 10 million copies/mL) as HIV becomes widely disseminated throughout the body and the host defenses begin to counteract circulating virus through cell-mediated and humoral (antibody-mediated) immune mechanisms. Antibodies against HIV usually become detectable 2 to 4 months after infection. The initial, high-level viremia plateaus and then begins to decrease as neutralizing antibodies are established. Ongoing replication is partially controlled by the immune response, resulting in a steady-state level of viremia. This virologic level differs from patient to patient and is one of the determinants of the rate of disease progression. A small number of HIV-infected persons are able to control viral replication to levels below the limit of detection, and they tend to have a more benign course of disease. In these patients, designated *elite suppressors* by researchers, HIV replication continues

to occur, and HIV RNA can be isolated from latently infected cells by means of specialized laboratory techniques.

After the establishment of HIV infection and seroconversion, a period of asymptomatic infection ensues, during which patients are free from evidence of immune suppression and opportunistic infections (OIs) are uncommon. This phase of clinical latency lasts a median of 8 to 10 years, based on observational studies from the pre-ART era. Ongoing viral replication leads to a gradual decrease in CD4 T-cell counts.

The symptomatic stage of HIV infection can begin at any time after infection, but clinical manifestations become more likely as the CD4 count decreases farther below the normal range of 800 to 1200 cells/mm<sup>3</sup>. For example, *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia (PJP) usually occurs in patients with a CD4 count less than 200 cells/mm<sup>3</sup> or a percentage less than 10%. CMV retinitis occurs almost exclusively in patients with a CD4 count less than 50 cells/mm<sup>3</sup> or a percentage less than 5%. Mucocutaneous candidiasis (oral thrush), herpes zoster, HIV-associated nephropathy, peripheral neuropathy, tuberculosis, and community-acquired bacterial pneumonia occur with increased frequency at earlier stages of infection and are less reliably predicted by CD4+ T-cell measurement.

### Diagnosis

The current recommended testing algorithm incorporates a fourth-generation antigen/antibody combination HIV-1/2 immunoassay with a confirmatory HIV-1/HIV-2 antibody differentiation immunoassay. The fourth-generation assay detects both HIV-1 and HIV-2 antibodies and HIV p24 antigen. It has increased sensitivity because of its ability to diagnose acute/early infection, because HIV p24 antigen is detected before seroconversion has occurred. If the fourth-generation combination assay is positive, the HIV-1 and HIV-2 antibody differentiation immunoassay both confirms the positive result and determines if the patient is infected with HIV-1 or HIV-2. If the fourth-generation assay is positive but the confirmatory antibody differentiation immunoassay is indeterminate or negative, a plasma HIV RNA level should be obtained.

In facilities where fourth-generation testing is not available, a two-step approach is utilized via enzyme-linked immunosorbent assay (ELISA) to detect HIV antibodies with subsequent confirmation using an HIV-1/HIV-2 differentiation assay. An ELISA can detect HIV IgM and IgG antibodies as early as 3 weeks after virus exposure. This modality has excellent sensitivity and specificity for diagnosing chronic HIV infection; however, diagnosis may be missed in patients with early HIV infection who have not yet had seroconversion. If concern exists for acute/early HIV infection, plasma HIV RNA can be assessed.

False-negative and false-positive tests occur rarely. False-negative screening tests can occur with ELISA-only testing during acute/early HIV infection. This occurs less often using the fourth-generation antigen/antibody assay, which is more sensitive in detecting early HIV infection by identifying the p24 antigen. False-positive screening test results can occur for several non-HIV reasons, including cross-reaction from alloantibodies in pregnant women, autoantibodies from autoimmune diseases or malignancy, and the influenza vaccine. False-positive results in both screening and confirmatory testing are particularly uncommon.

Indeterminate test results occur when the initial screening test is positive and subsequent confirmatory testing is indeterminate or negative. In the event of a positive fourth-generation antigen/antibody test and negative HIV differentiation assay, the detection of p24 antigen would yield a positive result, but the differentiation assay would be negative, as no antibody is present. In all patients with indeterminate test results, a plasma HIV RNA should be obtained, as viremia is present before antibody seroconversion. A detectable plasma HIV RNA level is diagnostic of HIV infection. If HIV RNA is negative, the patient should be reassured that HIV infection is unlikely. A repeat screening test can be repeated after 3 months for further reassurance. If the patient had a recent high-risk exposure, another plasma HIV RNA can be performed in 1 to 2 weeks. All patients with indeterminate testing should be

counseled to avoid activities with potential to transmit HIV to others until evaluation is completed.

### Consent

HIV screening should be voluntary and pursued only after discussion with the patient regarding testing. In the United States, written consent is no longer obligatory in any state, but individual states may have policies regarding documentation of the consent process and related counseling. Confidentiality, access to posttesting counseling, and services to support prompt linkage to HIV care for patients with positive results are important resources in HIV testing settings.

### Screening

Early detection of HIV infection and subsequent initiation of ART can dramatically reduce morbidity and mortality of affected patients. A relatively normal life span is possible in patients in the United States who are diagnosed early in their infection and successfully treated. Such early treatment also can reduce the transmission of HIV. One-time testing is recommended for patients without high-risk factors for HIV exposure in patients 13 to 75 years of age. Pregnant women should be screened for HIV early in their pregnancy, even if they have been screened during prior pregnancies.

In patients with elevated risk of HIV exposure, more frequent testing is recommended. Men who have sex with men (MSM), along with patients who have sex with sexual partners who have HIV or with persons of unknown serostatus may benefit from HIV screening at least every 6 months. This is especially important in patients 13 to 24 years of age because this demographic group has experienced the highest rate of new infections in recent years. Other high-risk groups include patients who use injection drugs as well as sex workers.

### Approach to the Patient with HIV Infection

HIV patient care is an ever-changing field, with routinely updated professional guidelines and new medications. The quality of care received by patients with HIV has been shown to correlate with the healthcare provider's experience and comfort in treating these patients. Referral to an HIV specialist is recommended for new HIV diagnoses, complications of HIV or antiretroviral drugs, and for treatment failure.

All patients with HIV should have a comprehensive history, physical examination, and laboratory evaluation when establishing care. This baseline evaluation can help establish and define the patient's goals and plan of care. In a patient who has already established treatment with ART and presents for initial evaluation with a new healthcare provider, it is important to document the complete antiretroviral history and drug resistance testing results, if available.

Patients with HIV are often faced with many medical, psychiatric, and social issues. These are best addressed through a patient-centered, multidisciplinary approach. In patients with a new diagnosis of HIV, it is important to counsel them regarding HIV infection and assess their understanding of the disease and its transmission. They should also be assessed for readiness to initiate ART, potential high-risk behaviors, mental illness, substance abuse, social support, medical comorbidities, and/or economic factors, because these are potential issues that may impair adherence to ART.

### Antiretroviral Therapy

There are currently six major classes of antiretroviral medications used to treat patients with HIV. Although dozens of such medications are available, only a small selection of agents is currently preferred as initial treatment regimens (Table 1). For most patients, ART includes a combination of two NRTIs plus a third medication from a different class, although two-drug regimens are preferred for some patients.

### When to Initiate Antiretroviral Therapy

Combination ART first became available in the mid-1990s and provided life-saving therapy for millions of patients suffering from HIV and AIDS. Although the early ART regimens were effective in helping patients with AIDS recover, they were also

associated with many toxicities and side effects. In 2006, the U.S. Department of Health and Human Services, the International AIDS Society–USA, and the British HIV Society recommended CD4 counts of 200 cells/mm<sup>3</sup> as the threshold for initiating ART treatment in asymptomatic patients. More recently, the paradigm has shifted toward earlier initiation of ART based on accumulating evidence for the beneficial effects of treatment initiation earlier in the course of infection. Antiretroviral therapies have advanced significantly since their conception, consisting of multiple drug classes, fewer toxicities, less pill burden, and overall improved tolerance. Failure to suppress viral loads on these medications is more likely to result from therapy nonadherence than medication failure.

HIV patients are now achieving normal life spans, and non-AIDS-defining illnesses are becoming more prominent. Cardiovascular, renal, and hepatic disease complications are lower in patients who started ART at higher CD4 thresholds (>350 cells/mm<sup>3</sup>). Earlier initiation of ART is also associated with reduced risk of transmission and improved immune restoration.

### Current Recommendations for Antiretroviral Therapy

ART should be offered to all patients with HIV infection, regardless of CD4 T-cell count. The goal of ART is to prevent morbidity, mortality, and transmission associated with HIV. This is accomplished by maximally inhibiting HIV replication to achieve an undetectable HIV viral load. Based on guidelines from the U.S. Department of Health and Human Services, INSTI-based regimens are currently the first-line recommendation as initial therapy for most patients with HIV based on high rates of virologic suppression and tolerability demonstrated in large clinical trials. Nonnucleoside reverse transcriptase inhibitor (NNRTI) and protease inhibitor (PI) regimens are recommended in certain clinical situations (Table 2). Monotherapy with any antiretroviral drug is not recommended because of increased risk of drug resistance and therapy failure.

### Selection of an Antiretroviral Regimen

ART regimens should be individualized based on a regimen's side-effect profile, pill burden, potential drug interactions, virologic efficacy, cost, and resistance testing results. Before starting ART in any patient with HIV, the following factors must be considered:

- Pretreatment HIV RNA level
- Pretreatment CD4 T-cell count
- HIV genotypic drug resistance testing results
- HLA-B\*5701 status (if planning to use an abacavir-based ART regimen)
- Patient's individual preference
- Anticipated medication adherence

Other factors that are important to consider when choosing an initial regimen include the patient's medical comorbidities (cardiovascular, renal, psychiatric disease), pregnancy or the potential to become pregnant, and coinfections with tuberculosis, hepatitis C virus, and hepatitis B virus (HBV).

The currently recommended ART for most patients includes two NRTIs ("backbone"), abacavir/lamivudine (ABC/3TC [Epzicom]) or either tenofovir alafenamide/emtricitabine (TAF/FTC [Descovy]) or tenofovir disoproxil fumarate/emtricitabine (TDF/FTC [Truvada]), plus an INSTI (see Table 1). Single-tablet regimens coformulated with an INSTI and the NRTI backbone are available. INSTI-based regimens are well tolerated, have convenient dosing, and provide excellent virologic suppression. Regimens including NNRTI or PK-enhanced PIs remain effective but are now only recommended in certain clinical scenarios.

The NRTI combinations of ABC/3TC (Epzicom), TAF/FTC (Descovy), and TDF/FTC (Truvada) are available as fixed-dose combination tablets. The 3TC and FTC components have few adverse effects. The main differences among these combinations involve ABC, TAF, and TDF. The advantages of TAF and TDF include activity against HBV, and HLA-B\*5701 testing is

**TABLE 1** Recommended Initial Regimens for Most People with HIV

GENERIC NAME (TRADE NAME) AND RECOMMENDED ADULT DOSING	SINGLE TABLET REGIMEN?	IMPORTANT POINTS
<b>INSTI + 2 NRTIs</b>		
Bictegravir/emtricitabine/tenofovir alafenamide (Biktarvy)* 50/200/25 mg—1 tablet by mouth once daily	Yes	Bictegravir has been shown to increase serum creatinine from baseline by a median 0.1 mg/dL as a result of inhibition of creatinine secretion, not a true reduction in GFR
Dolutegravir/abacavir/lamivudine (Triumeq) 50/600/300 mg—1 tablet by mouth once daily	Yes	Dolutegravir has been shown to increase serum creatinine from baseline by a mean of 0.15 mg/dL as a result of inhibition of creatinine secretion, not a true reduction in GFR Dolutegravir has a drug interaction with metformin (maximum daily metformin dose is 1000 mg) Must be confirmed HLA-B*5701 negative before starting treatment to avoid abacavir hypersensitivity reaction
Dolutegravir (Tivicay) <sup>†</sup> 50 mg—1 tablet by mouth once daily <i>PLUS</i> Tenofovir alafenamide/emtricitabine (Descovy) 25/200 mg—1 tablet by mouth once daily <i>OR</i> Tenofovir disoproxil fumarate/emtricitabine (Truvada) 300/200 mg—1 tablet by mouth once daily	No	Dolutegravir has been shown to increase serum creatinine from baseline by a mean of 0.15 mg/dL because of inhibition of creatinine secretion, not a true reduction in GFR Dolutegravir has a drug interaction with metformin (maximum daily metformin dose is 1000 mg) Descovy generally preferred over Truvada because of fewer bone and kidney toxicities
<b>INSTI + 1 NRTI</b>		
Dolutegravir/lamivudine (Dovato) 50/300 mg—1 tablet by mouth once daily	Yes	This two-drug regimen should not be used in those with HIV RNA >500,000 copies/mL, HBV coinfection, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available Dolutegravir has been shown to increase serum creatinine from baseline by a mean of 0.15 mg/dL as a result of inhibition of creatinine secretion, not a true reduction in GFR Dolutegravir has a drug interaction with metformin (maximum daily metformin dose is 1000 mg)

\*Biktarvy [package insert]. Foster City, CA: Gilead Sciences, Inc.; 2021.

<sup>†</sup>Tivicay [package insert]. Research Triangle Park, NC: ViiV Healthcare; 2021.

ART, Antiretroviral therapy; GFR, glomerular filtration rate; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; INSTI, integrase strand transfer inhibitor; NRTI, nucleoside analogue reverse transcriptase inhibitor.

Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/adult-adolescent-arv/guidelines-adult-adolescent-arv.pdf> (Table 6).

not required before use. TDF has some association with lower lipid levels compared with TAF, but also may cause decreased renal function and reduced bone mineral density. TAF is associated with less bone and kidney toxicity, and its use is preferred in patients with underlying bone and kidney disease or those at risk for these conditions. The advantage of ABC is that it has less bone mineral loss and less nephrotoxicity than TDF and does not require dose adjustment in patients with renal insufficiency. Potential drawbacks to ABC include an observed association with cardiovascular events in some studies and a hypersensitivity syndrome, necessitating screening for HLA-B\*5701 before treatment initiation.

Once the combination NRTI backbone has been chosen, a third drug from another class must be added to the regimen. Current recommendations for most patients favor the INSTI class because of its high efficacy, fewer side effects, and no significant CYP3A4-associated drug interactions.

Darunavir (DRV [Prezista])–based regimens may still be preferred in certain patients with difficulty maintaining medication adherence, and a high genetic barrier to resistance is favored or in a situation when ART should be initiated before receiving resistance testing results. Darunavir boosted with ritonavir (Norvir) (DRV/r) or cobicistat (Tybost) (DRV/c [Prezcobix]) has a low rate of transmitted PI resistance, a high genetic barrier to resistance, and a low rate of treatment-emergent resistance. A dolutegravir (DTG [Tivicay])- or bictegravir (BIC)-containing regimen (BIC/TAF/FTC [Biktarvy]) is also a consideration for patients in whom it is necessary to initiate ART before receiving resistance testing results because of its high barrier of resistance.

NNRTI-based regimens include efavirenz (EFV [Sustiva]), rilpivirine (RPV [Edurant]), or doravirine (DOR [Pifeltro]) and may be appropriate choices in certain patients with good medication adherence. These medications have a low genetic barrier to resistance. EFV has minimal PK interactions with rifamycins, which

**TABLE 2** Recommended Initial Regimens in Certain Clinical Situations

GENERIC NAME (TRADE NAME) AND RECOMMENDED ADULT DOSING	SINGLE TABLET REGIMEN?	IMPORTANT POINTS
<b>INSTI + 2 NRTIs</b>		
Elvitegravir/cobicistat/tenofovir alafenamide/emtricitabine (Genvoya) 150/150/10/200 mg—1 tablet by mouth once daily OR Elvitegravir/cobicistat/tenofovir disoproxil fumarate/emtricitabine (Stribild) 150/150/300/200 mg—1 tablet by mouth once daily	Yes	Genvoya generally preferred over Stribild because of fewer bone and kidney toxicities Drug interactions with other medications are prevalent with both products because of cobicistat, a CYP3A4 inhibitor
Raltegravir (Isentress HD) 600 mg—2 tablets by mouth once daily OR Raltegravir (Isentress) 400 mg—1 tablet by mouth twice daily PLUS Tenofovir alafenamide/emtricitabine (Descovy) 25/200 mg—1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada) 300/200 mg—1 tablet by mouth once daily	No	Isentress HD generally preferred over Isentress because of once-daily dosing Descovy generally preferred over Truvada (Isentress HD) because of fewer bone and kidney toxicities
<b>NNRTI + 2 NRTIs</b>		
Rilpivirine/tenofovir alafenamide/emtricitabine (Odefsey) 25/25/200 mg—1 tablet by mouth once daily OR Rilpivirine/tenofovir disoproxil fumarate/emtricitabine (Complera) 25/300/200 mg—1 tablet by mouth once daily	Yes	Rilpivirine should only be used if HIV RNA <100,000 copies/mL and CD4 >200 cells/mm <sup>3</sup> Odefsey generally preferred over Complera because of fewer bone and kidney toxicities PPIs contraindicated with rilpivirine H2 blockers may be used once daily but must be spaced 12 hours apart from rilpivirine Should be taken with food
Doravirine/tenofovir disoproxil fumarate/lamivudine (Delstrigo) 100/300/300 mg—1 tablet by mouth once daily OR Doravirine (Pifeltro) 100 mg—1 tablet by mouth once daily PLUS Tenofovir alafenamide/emtricitabine (Descovy) 25/200 mg—1 tablet by mouth once daily	Yes, for Delstrigo	May be taken with or without food Doravirine does not have any restrictions with acid-suppressive medications
Efavirenz/tenofovir disoproxil fumarate/emtricitabine (Atripla) 600/300/200 mg—1 tablet by mouth once daily	Yes	High rates of neuropsychiatric adverse effects (e.g., vivid dreams, depression, suicidal ideation)
<b>PK-enhanced PI + 2 NRTIs</b>		
Darunavir/cobicistat/emtricitabine/tenofovir alafenamide (Symtuza) 800/150/200/10 mg—1 tablet by mouth once daily OR Darunavir/cobicistat (Prezcobix) 800/150 mg—1 tablet by mouth once daily OR Darunavir (Prezista) 800 mg—1 tablet by mouth once daily + Ritonavir (Norvir) 100 mg—1 tablet by mouth once daily PLUS Tenofovir alafenamide/emtricitabine (Descovy) 25/200 mg—1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada) 300/200 mg—1 tablet by mouth once daily OR Abacavir/lamivudine (Epzicom) 600/300 mg—1 tablet by mouth once daily	Yes, for Symtuza	Prezcobix generally preferred over the combination of Prezista and Norvir because of single tablet and potentially fewer GI side effects and drug interactions Drug interactions with other medications are prevalent with both cobicistat and ritonavir because of CYP3A4 inhibition Ritonavir also inhibits and induces several other CYP enzymes Careful attention should be given to manage drug interactions Descovy generally preferred over Truvada because of fewer bone and kidney toxicities If using Epzicom, must be confirmed HLA-B*5701 negative before starting therapy to avoid abacavir hypersensitivity reaction
Atazanavir/cobicistat (Evotaz) 300/150 mg—1 tablet by mouth once daily OR Atazanavir (Reyataz) 300 mg—1 tablet by mouth once daily + Ritonavir (Norvir) 100 mg—1 tablet by mouth once daily PLUS Tenofovir alafenamide/emtricitabine (Descovy) 25/200 mg—1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada) 300/200 mg—1 tablet by mouth once daily	No	Darunavir-containing regimens generally preferred over atazanavir-containing regimens Atazanavir is known to increase serum bilirubin. This generally does not require further workup if the patient is asymptomatic Evotaz generally preferred over the combination of Reyataz and Norvir because of single tablet and potentially fewer GI side effects and drug interactions Drug interactions with other medications are prevalent with both cobicistat and ritonavir because of CYP3A4 inhibition. Ritonavir also inhibits and induces several other CYP enzymes. Careful attention should be given to manage drug interactions Descovy generally preferred over Truvada because of fewer bone and kidney toxicities

CYP3A4, Cytochrome P450 3A4; GI, gastrointestinal; H2, histamine H<sub>2</sub> receptor; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; INSTI, integrase strand transfer inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; PPI, proton pump inhibitor. Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV. **TABLE 3** Recommendations on the Indications and Frequency of Viral Load and CD4 T-Cell Count Monitoring

CLINICAL SCENARIO	VIRAL LOAD MONITORING	CD4 T-CELL COUNT MONITORING
Before initiating ART	At entry into care If ART initiation is deferred, repeat before initiating ART In patients not initiating ART, repeat testing is optional	At entry into care If ART is deferred, every 3–6 months
After initiating ART	Preferably within 2–4 weeks (and no later than 8 weeks) after initiation of ART; thereafter, every 4–8 weeks until viral load is suppressed	3 months after initiation of ART
After modifying ART because of drug toxicities or for regimen simplification in a patient with viral suppression	4–8 weeks after modification of ART to confirm effectiveness of new regimen	Monitor according to prior CD4 count and duration on ART, as outlined below.
After modifying ART because of virologic failure	Preferably within 2–4 weeks (and no later than 8 weeks) after modification; thereafter, every 4–8 weeks until viral load is suppressed. If viral suppression is not possible, repeat viral load every 3 months or more frequently if indicated	Every 3–6 months
During the first 2 years of ART	Every 3–4 months	Every 3–6 months
After 2 years of ART (VL consistently suppressed, CD4 consistently 300–500 cells/mm <sup>3</sup> )	Can extend to every 6 months for patients with consistent viral suppression for greater than or equal to 2 years.	Every 12 months Optional
After 2 years of ART (VL consistently suppressed, CD4 consistently >500 cells/mm <sup>3</sup> )		
While on ART with detectable viremia (VL repeatedly >200 copies/mL)	Every 3 months or more frequently if clinically indicated	Every 3–6 months
Change in clinical status	Every 3 months	Perform CD4 count, and repeat as clinically indicated

ART, Antiretroviral therapy; VL, viral load.

Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/adult-adolescent-arv/guidelines-adult-adolescent-arv.pdf> (Table 4).

makes it an excellent option in patients who require treatment for tuberculosis. EFV has a high rate of central nervous system–related side effects, which lowers its overall tolerability for some patients. RPV has fewer side effects than EFV, but its virologic efficacy is reduced in patients with high baseline HIV RNA and low CD4 T-cell counts. RPV also requires acid for absorption; it is contraindicated with proton pump inhibitors and must be spaced 12 hours apart from histamine 2 receptor antagonists.

More recently, two large, randomized controlled trials showed that a two-drug regimen of DTG plus lamivudine (DTG/3TC [Dovato]) was noninferior to DTG plus TDF/FTC. This two-drug regimen is another potential initial option for most people with HIV, except for patients with pretreatment HIV RNA greater than 500,000 copies/mL, who are known to have active HBV coinfection, or who will initiate ART before results of HIV genotype testing for reverse transcriptase or HBV testing are available.

#### Long-Acting Injectable Antiretroviral Therapy

In 2021, the first complete long-acting injectable ARV regimen, cabotegravir (CAB) and rilpivirine (RPV), Cabenuva, was approved as an option to replace the current ARV regimen in adults with HIV. Once-monthly or every-2-month CAB/RPV intramuscular (IM) injections can be used as an optimization strategy for people with HIV currently on oral ART with documented viral suppression (HIV-1 RNA less than 50 copies per mL) for at least 3 months. Candidates for CAB/RPV long-acting injections should have no baseline resistance to either medication, have no prior virologic failures, should not have HBV infection (unless also receiving an oral HBV active regimen), should not be pregnant or planning to become pregnant, and should

not be receiving medications with significant drug interactions with CAB or RPV. Before initiation of the IM injection, patients should receive oral CAB (Vocabria) and oral RPV (Edurant) for approximately 1 month as an oral lead-in period to assess tolerance to these drugs. CAB/RPV (Cabenuva) injections should be administered by healthcare providers as gluteal IM injections. Administration variances of +/-7 days are allowed. The product is refrigerated and should be brought to room temperature before administration. Unopened vials may remain at room temperature for up to 6 hours. Medication drawn into a syringe may remain in the syringe for up to 2 hours.

#### Monitoring Response to Antiretroviral Therapy

HIV disease progression and response to ART can be monitored via CD4 T-cell count and HIV RNA (viral load). The CD4 T-cell count should be measured before initiation of ART and provides information regarding the patient's immune function and risk of OI. Recommendations for monitoring viral load and CD4 T-cell count are shown in Table 3.

CD4 T-cell counts can be highly variable, and significant change is only considered with 30% difference in absolute count or an increase or decrease in CD4 percentage by 3 percentage points. CD4 T-cell recovery is most rapid in the first 3 months after initiating ART, later followed by more gradual increases. For most patients on ART, adequate response is considered as an increase in CD4 count in the range of 50 to 150 cells/mm<sup>3</sup> during the first year of treatment. Subsequent increases may average 50 to 100 cells/mm<sup>3</sup> per year until a steady-state level is reached. Peripheral blood CD4 T-cell counts in most HIV patients will continue to increase over a decade as long as viral suppression is maintained.

Most individuals will eventually recover CD4 counts within the normal range ( $>500$  cells/mm<sup>3</sup>). For approximately 15% to 20% of patients, especially those who initiate ART at very low CD4 counts ( $<200$  cells/mm<sup>3</sup>), low CD4 counts may persist, which is associated with increased morbidity and mortality. These patients should be evaluated for reversible causes of CD4-positive T-cell lymphopenia, including offending medications, untreated coinfections, and underlying malignancy. In patients with appropriate virologic suppression, the addition of more antiretroviral agents or transitioning to a different ART regimen has not been demonstrated to improve CD4 T-cell recovery.

CD4 T-cell counts should be repeated 3 months after ART initiation to monitor immune reconstitution and can be monitored in many patients at 3- to 6-month intervals for the first 2 years of ART. In virally suppressed patients with consistent CD4 counts between 300 and 500 cells/mm<sup>3</sup> for at least 2 years, CD4 counts can be checked annually. Although ART is recommended for all patients with HIV, patients who remain untreated should have CD4 counts monitored every 3 to 6 months to assess the need for OI prophylaxis.

Viral load functions as a marker for ART response and should be monitored at initiation of therapy and regularly thereafter. The pretreatment viral load can also provide useful information regarding selection of an initial ART. Commercially available HIV-1 RNA assays do not detect HIV-2 viral load. Decreases in viral load following ART initiation are associated with a reduction in risk of disease progression to AIDS or death. Optimal viral suppression is defined as a viral load persistently below the level of detection. Low-level viremia refers to a patient with confirmed detectable HIV RNA less than 200 copies/mL. This may be detected using real-time polymerase chain reaction (PCR) assays and may be predictive of developing viral rebound. Viral rebound, or virologic failure, is considered to occur when a patient with confirmed virologic suppression has HIV RNA greater than or equal to 1000 copies/mL. If virologic suppression occurs and the patient is found to have a single isolated detectable HIV RNA level with return to virologic suppression in subsequent tests, this is referred to as a *virologic blip*. This is not usually associated with virologic failure and does not require a change in ART. Acute illness, stress, and recent immunizations are a few potential causes of virologic blips. A repeat viral load can be rechecked in 3 months to confirm return to appropriate viral suppression.

If a patient has a very high HIV viral load at the time of ART initiation, it may take several weeks for a measurable virologic response to occur. Certain ART regimens may also have slower rates of virologic suppression than others. A patient who has received ART for at least 24 weeks and has not yet had documented virologic suppression should be evaluated for antiretroviral drug resistance.

The use of ART to prevent HIV transmission is called *treatment as prevention* (TasP), also known as *Undetectable = Untransmittable* (U = U). Maintaining HIV RNA levels less than 200 copies/mL with ART prevents HIV transmission to sexual partners. Patients who start ART should use another form of prevention with sexual partners for at least the first 6 months of treatment and until an HIV RNA level less than 200 copies/mL has been achieved. Patients who have HIV and who rely on ART for prevention require high ART adherence because transmission is possible during periods of poor compliance or treatment interruption.

### Treatment Failure

Patients who are receiving ART and do not achieve HIV RNA levels below the lower limit of detection or are shown to have sustained virologic rebound are at risk for developing resistance mutations to their current ART regimen, especially at HIV RNA levels greater than 500 copies/mL. Virologic failure has a strong association with suboptimal medication adherence and drug intolerance/toxicity leading to self-discontinuation of ART.

Some factors that may increase the risk of ART nonadherence include active substance use, neurocognitive impairment, and

mental illness. Unstable housing and other socioeconomic and psychosocial factors can make ART adherence particularly difficult. The patient's inability to afford the medication may lead to intermittent adherence or nonadherence. Some patients will stop taking ART as a result of adverse effects of their regimen. Others may not be able to adhere to a high pill burden or frequency of dosing.

Less common causes of treatment failure include existing or newly developed drug resistance. Patients with HIV-2 or HIV-1/HIV-2 coinfection can have innate resistance to certain ART regimens. Others may have adverse drug-drug interactions with other medications, suboptimal virologic potency, or error in their medication prescription.

If a patient is experiencing virologic failure, it is important to determine the cause because there is potential for choosing a subsequent therapy regimen that promotes better adherence. Management of a patient who is experiencing treatment failure is often complex; consultation with an HIV specialist can prove beneficial.

### Drug Resistance and Resistance Testing

Two types of resistance assays exist to assess viral strains and direct treatment strategies: genotypic and phenotypic. These assays provide useful information in regard to resistance to NRTIs, NNRTIs, PIs, and INSTIs. In some settings, INSTI resistance tests must be ordered separately. In patients with newly diagnosed HIV infection, resistance testing can guide therapy selection to optimize virologic response. Genotypic assays detect drug resistance mutations by sequencing reverse transcriptase, protease, and integrase genes. Interpreting these test results requires knowledge of the mutations selected by different antivirals and the potential for cross-resistance to other drugs. Clinical trials have shown that consultation with HIV specialists regarding drug resistance interpretation improves virologic outcomes.

### Adverse Drug Reactions and Drug-Drug Interactions

Adverse drug reactions to ART are common, especially when first initiating therapy. Generally, reactions such as nausea, fatigue, and headache often resolve within 1 to 2 weeks of starting ART. Severe or persistent adverse drug reactions should prompt consideration of change to a different agent. Each ART drug class has different characteristic adverse drug reactions. Additionally, each individual ART agent carries its own characteristic adverse drug reactions (Table 4). As drug therapies have evolved and new medications discovered, preferred agents have been updated to avoid those that have tended to cause more frequent and severe adverse effects. For example, older agents in the NRTI class (e.g., stavudine [Zerit] and didanosine [Videx]) were commonly associated with hepatic steatosis, lipodystrophy, and insulin resistance. Newer-generation NRTIs, which have much lower rates of these serious adverse effects, have largely supplanted the use of these older drugs.

All providers who care for patients who receive ART should be aware of the possibility of adverse drug-drug interactions of antiretroviral drugs with other medications. The use of the pharmacokinetic-enhancing agents ritonavir (Norvir) and cobicistat (Tybost) in many combination ART regimens can pose serious risks to patients who receive other drugs metabolized through the cytochrome P450 pathway, including numerous anticoagulant drugs and synthetic glucocorticoids. When prescribing or altering one or more drugs in an ART regimen, the potential for drug interactions must be explored. It is critical to carefully review the patient's other medications for potential interactions. If multiple drugs with similar or conflicting metabolic pathways are prescribed, healthcare providers should carefully monitor for appropriate therapeutic efficacy and concentration-related toxicities. Consultation with a pharmacist to evaluate drug interactions is recommended.

**TABLE 4** Monitoring Recommendations for Antiretroviral Toxicity of Selected Drugs\*

DRUG	TOXICITY	MONITORING
<b>NRTIs</b>		
Abacavir (Ziagen)	Liver Abacavir hypersensitivity syndrome	LFTs Screening for HLA-B*5701 (should be confirmed negative before abacavir initiation) Symptoms of abacavir hypersensitivity may include fever, rash, nausea, vomiting, diarrhea, abdominal pain, malaise, fatigue, or respiratory symptoms such as sore throat, cough, or shortness of breath
Emtricitabine (Emtriva)	Minimal toxicity Liver Hyperpigmentation/skin discoloration	Serum creatinine LFTs HBV (before initiation of therapy) Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue emtricitabine. For patients in whom discontinuation of tenofovir is necessary, ensure that an agent active against HBV is administered
Lamivudine (Epivir)	Minimal toxicity Liver	Serum creatinine LFTs HBV (before initiation of therapy) Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue lamivudine. For patients in whom discontinuation of tenofovir is necessary, ensure that an agent active against HBV is administered
Tenofovir (disoproxil fumarate [Viread], alafenamide [Vemlidy])	Renal toxicity (tubulopathy) Decreased bone mineral density Liver	Serum creatinine Urine glucose and protein (before initiation of therapy and as clinically indicated during therapy) Serum phosphorus (in patients with chronic kidney disease) Bone mineral density testing (if history of bone fracture or risk factors for bone loss) LFTs HBV (before initiation of therapy) Tenofovir alafenamide (Vemlidy) is associated with lower rates of bone and kidney toxicity compared with tenofovir disoproxil fumarate Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue tenofovir. For patients in whom discontinuation of tenofovir is necessary, ensure that an agent active against HBV is administered
<b>NNRTIs</b>		
Efavirenz (Sustiva)	Rash Neuropsychiatric symptoms Hyperlipidemia Hepatotoxicity Prolonged QT interval	LFTs Lipid panel (before initiation of therapy and as clinically indicated during therapy) Signs and symptoms of neuropsychiatric effects (e.g., vivid dreams, depression, suicidal ideation)
Rilpivirine (Edurant)	Rash Depression, insomnia, headache Hepatotoxicity Prolonged QT interval	LFTs Lipid panel
Doravirine (Pifeltro)	Nausea Dizziness Abnormal dreams	No specific tests
<b>PIs</b>		
All	GI intolerance, nausea, vomiting, diarrhea Hyperglycemia Insulin resistance Hepatotoxicity Fat maldistribution Hyperlipidemia	Serum glucose LFTs (before initiation of therapy and as clinically indicated during therapy)
Atazanavir (Reyataz)	Indirect hyperbilirubinemia	Bilirubin
Darunavir (Prezista)	Skin rash	Darunavir contains a sulfonamide moiety; Stevens-Johnson syndrome, toxic epidermal necrolysis, acute generalized exanthematous pustulosis, and erythema have been reported Risk of cross-reactivity between darunavir and sulfonamide medications is very low. However, use caution in patients with severe sulfonamide allergies

**TABLE 4** Monitoring Recommendations for Antiretroviral Toxicity of Selected Drugs\*—cont'd

DRUG	TOXICITY	MONITORING
<b>INSTIs</b>		
All	INSTIs typically well tolerated for most patients GI intolerance Insomnia Headache Depression and suicidal ideation (rare, usually in patients with preexisting psychiatric conditions) CPK elevation, muscle weakness, and rhabdomyolysis (primarily reported with raltegravir [Isentress]) Possible association with weight gain	LFTs Serum creatinine (dolutegravir [Tivicay] and bictegravir) CPK (if signs of muscle toxicity)

CPK, Creatinine phosphokinase; GI, gastrointestinal; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; INSTI, integrase strand transfer inhibitor; LFT, liver function test; NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor. Table is not all inclusive.

Modified from Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV. Department of Health and Human Services. Available at: <https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/adult-adolescent-arv/guidelines-adult-adolescent-arv.pdf>.

### Viral Hepatitis Coinfection

Approximately 5% to 10% of patients with HIV in the United States have coinfection with chronic HBV. Disease progression to cirrhosis, end-stage liver disease, and hepatocellular carcinoma is more rapid in these patients. Some antiretroviral toxicities and complications may be attributed to flares of HBV after initiation or discontinuation of ART.

FTC, 3TC, TDF, and TAF<sup>1</sup> are approved for treatment of HIV and are also active against HBV. Discontinuation of these drugs can potentially cause significant hepatic damage resulting from reactivation of HBV. The anti-HBV drug entecavir (Baraclude) has activity against HIV.<sup>1</sup> When entecavir is used to treat HBV in patients with HBV/HIV coinfection who are not taking ART, the drug can select for the M184V mutation, resulting in HIV resistance to 3TC and FTC. When 3TC is the only active drug used to treat HBV in coinfecting patients, 3TC resistance develops in approximately 40% to 90% of patients after 2 to 4 years on 3TC monotherapy.

Before ART is initiated, all patients who test positive for HBV surface antigen (HBsAg) should also be tested for HBV DNA using a quantitative assay. This test should be repeated every 3 to 6 months to ensure effective HBV suppression. In patients with HBV/HIV coinfection, immune reconstitution following initiation of treatment for HIV, HBV, or both can be associated with elevated transaminases.

### Complications

#### Diagnosis and Management of Opportunistic Infections

The widespread availability and use of ART have significantly reduced OI-related mortality in persons with HIV infection. OIs continue to cause considerable morbidity and mortality, however, because of the increasing number of undiagnosed cases of HIV and patients who have known HIV infection but are not on ART or are unable to maintain adherence to ART.

PJP is an infection caused by a ubiquitous fungus, *P. jirovecii*. Most cases occur in patients with an advanced compromised immune system (CD4 count less than 100 cells/mm<sup>3</sup>). The most common manifestations are dyspnea, fever, nonproductive cough, and chest discomfort. Onset of symptoms is usually subacute and progressive over days to weeks. Patients with mild cases may present with normal pulmonary physical examination findings at rest but develop dyspnea, tachycardia, and rales with exertion. Hypoxemia is often present to varying severity. Laboratory findings are

consistent with lactate dehydrogenase levels greater than 500 mg/dL and elevated serum 1,3 β-d-glucan. Chest radiography may show diffuse, bilateral, ground-glass interstitial infiltrates, but chest radiography can appear unremarkable in patients with early disease. In patients with normal chest plain films, computed tomography (CT) of the chest can show underlying abnormalities consistent with PJP. HIV-infected patients, including pregnant women and those on ART, should receive PJP chemoprophylaxis if they have CD4 counts less than 200 cells/mm<sup>3</sup>. Patients who receive pyrimethamine (Daraprim)-sulfadiazine for treatment or suppression of toxoplasmosis do not require additional prophylaxis for PJP. Trimethoprim-sulfamethoxazole (TMP-SMX [Bactrim]) is the first-line prophylactic agent at one double-strength tablet daily (which also confers prophylaxis against toxoplasmosis<sup>1</sup>) or three times weekly. In those who cannot tolerate TMP-SMX, alternative prophylactic options include atovaquone (Mepron), dapsone,<sup>1</sup> dapsone plus pyrimethamine (Daraprim)<sup>1</sup> plus leucovorin,<sup>1</sup> and aerosolized pentamidine (Nebupent).

*Toxoplasma gondii* is a protozoan infection and is associated with reactivation of latent tissue cysts. Patients at greatest risk have CD4 counts less than 50 cells/μL. Clinical disease is rare in patients with CD4 counts greater than 200 cells/μL. In patients with AIDS, the typical presentation of infection is focal encephalitis, including headache, confusion, focal motor weakness, and fever. In the absence of treatment, disease progression may lead to seizures, coma, and death. CT and magnetic resonance imaging (MRI) of the brain may show multiple contrast-enhancing lesions within the gray matter of the cortex or basal ganglia, often with associated edema. HIV-infected patients with toxoplasma encephalitis are usually seropositive for toxoplasma IgG antibodies. Definitive diagnosis requires the combination of clinical presentation, identification of one or more mass lesions via CT or MRI, and detection of the organism in a sample, with brain biopsy being the most preferred method. The therapy of choice includes pyrimethamine plus sulfadiazine plus leucovorin.<sup>1</sup>

Disseminated *Mycobacterium avium* complex (MAC) disease typically occurs in patients with CD4 counts less than 50 cells/mm<sup>3</sup>. Other factors associated with increased susceptibility to MAC disease include HIV RNA levels greater than 100,000 copies/mL, previous OIs, and previous colonization of the respiratory or gastrointestinal tract with MAC. In HIV-infected patients with AIDS who are not on ART, MAC disease usually presents as a disseminated, multiorgan infection. Symptoms may be minimal

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

at first but may include fever, night sweats, weight loss, diarrhea, fatigue, and nonspecific abdominal pain. Laboratory abnormalities may include anemia out of proportion for that expected from HIV alone and an increase in liver alkaline phosphatase. Physical examination or imaging may note nonspecific hepatomegaly, lymphadenopathy, and/or splenomegaly. Diagnosis is based on a combination of clinical symptoms and the isolation of MAC from cultures obtained from blood, lymph nodes, bone marrow, or other sterile sites. Initial treatment should consist of at least two antimycobacterial medications in an effort to prevent the development of resistance. Infectious disease specialists should be consulted regarding treatment. MAC isolates should be tested for susceptibility to clarithromycin (Biaxin) and azithromycin (Zithromax).

*Cryptococcus neoformans* meningitis occurs more commonly in patients with CD4 counts less than 100 cells/ $\mu$ L. It can present as a subacute or acute meningoencephalitis associated with fever, headache, and malaise. Classic meningeal symptoms may be absent. Disseminated disease is usually present when diagnosed in a patient with HIV infection and can involve virtually any organ. Diagnosis of meningitis via cerebrospinal fluid (CSF) often demonstrates elevated opening pressure, elevated protein, low-to-normal glucose, and lymphocytic pleocytosis. Numerous yeast forms may be visualized on Gram stain or India ink preparations of CSF. The CSF cryptococcal antigen (CrAg) is often positive. Serum CrAg may be positive in both meningeal and nonmeningeal involving infections, and its presence can be detected weeks to months before the onset of symptoms. A positive serum CrAg should proceed to lumbar puncture to rule out meningeal disease. Treatment of cryptococcosis occurs in three stages: induction, consolidation, and maintenance therapy.

CMV disease can cause disseminated and localized end-organ damage in HIV-infected patients with suppressed immune states with CD4 counts less than 50 cells/ $\text{mm}^3$ . Clinical disease is usually the result of reactivation of latent infection. Risk factors include not receiving or failing to respond to ART, previous OIs, high level of CMV viremia, and high HIV viral load (>100,000 copies/mL). Retinitis is the most common clinical manifestation of CMV end-organ disease and is often unilateral, but it can progress to bilateral if therapy or immune recovery are not pursued. Retinitis may present with floaters, scotomata, or peripheral visual field defects. Colitis is another manifestation of CMV disease and may be associated with weight loss, abdominal pain, significant diarrhea, and malaise. Hemorrhage and bowel perforation can be life threatening. CMV viremia can be measured via PCR and is usually present in end-organ disease.

Mucocutaneous candidiasis of the oropharynx and esophagus occurs commonly in HIV-infected patients and is often an indication of underlying immune suppression (CD4 count <200 cells/ $\text{mm}^3$ ). Oropharyngeal candidiasis is usually painless and affects the oropharyngeal mucosa and tongue surface. Esophageal candidiasis may be associated with retrosternal discomfort and odynophagia. Oropharyngeal candidiasis is usually diagnosed clinically. Diagnosis of esophageal candidiasis is made based on symptoms, response to therapy, or visualization of mucosal lesions on examination.

Many treatment guidelines recommend initiating ART within 2 weeks for most diagnosed OI. In patients with cryptococcal meningitis and possible tuberculous meningitis, ART should be deferred because of the risks of serious immune reconstitution syndrome outweighing the benefits of ART. In patients with AIDS-associated OI for which no effective therapy exists (e.g., progressive multifocal leukoencephalopathy [PML], cryptosporidiosis, and microsporidiosis), improvement in immune function with ART can potentially improve disease outcomes.

### Neurologic Complications

Both central nervous system disease and peripheral nerve abnormalities are common in advanced AIDS. HIV infection can directly cause distal sensory neuropathy, which may manifest as dysesthesia or hypersensitivity, decreased reflexes, and chronic

neuropathic pain. Inflammatory demyelinating polyneuropathy (e.g., Guillain-Barré syndrome) has known associations with some enteric pathogens and causes ascending motor weakness, typically without sensory involvement. CMV infection may cause polyradiculopathy, transverse myelitis, and encephalitis/ventriculitis in patients with CD4 counts lower than 50 cells/ $\text{mm}^3$ . CMV end-organ disease, including retinitis (a vision-threatening condition), requires prompt diagnosis and initiation of appropriate anti-CMV therapy.

Focal central nervous system lesions can arise from infectious and malignant conditions. Cerebral toxoplasmosis usually occurs in patients with prior exposure to *T. gondii* who develop reactivation disease when the CD4 count is less than 100 cells/ $\text{mm}^3$ . The main differential diagnosis for one or several enhancing brain lesions includes toxoplasmosis and primary central nervous system lymphoma (PCNSL). PCNSL is associated with EBV, and detection of nucleic acid for EBV in CSF carries a high specificity for this condition in the proper radiographic context. PML, a rare and potentially devastating demyelinating condition, is caused by reactivation of the JC virus and can manifest as focal neurologic deficit, seizures, or cognitive dysfunction. *C. neoformans* is a common cause of meningitis in AIDS patients and may manifest with central nervous system mass lesions, pulmonary disease, or gastrointestinal disease. Worldwide, tuberculosis accounts for a large proportion of HIV-associated meningitis cases; less commonly, it can manifest as single or multiple focal lesions (tuberculomas). Neurosyphilis should be considered in patients with unexplained neurologic disease and sexual risk factors.

### Respiratory Complications

Respiratory illnesses are among the most common causes of morbidity in HIV-infected patients. Community-acquired bacterial pneumonia occurs at a significantly higher rate in HIV-infected patients compared with noninfected patients, regardless of CD4 T-cell count, and it is one of the most common reasons for hospitalization. *P. jirovecii* pneumonia (PJP) manifests with fever, cough, and dyspnea. Findings on physical examination and chest radiography can be variable, making the diagnosis difficult in the absence of high clinical suspicion. Elevated lactate dehydrogenase and oxygen desaturation with ambulation can be diagnostic clues. More than 90% of cases occur among patients with CD4 counts lower than 200 cells/ $\text{mm}^3$ . The diagnosis is established by visualization of organisms in induced sputum (sensitivity, 50% to 90%) or in bronchoalveolar lavage specimens (sensitivity, 90% to 99%), most commonly with the use of immunofluorescent staining.

The risk of reactivation of latent TB is increased 100-fold in patients with HIV infection. Patients with HIV infection who are latently infected have a 10% annual risk of developing symptomatic tuberculosis, compared with a 10% lifetime risk among the general population. The risk of reactivation increases with decreasing CD4 T-cell count, and patients with counts lower than 350 cells/ $\text{mm}^3$  are more likely to have atypical radiographic presentations, including middle- and lower-lobe infiltrates without cavitation. Patients with low CD4 T-cell counts are more likely to have extrapulmonary tuberculosis. Diagnostic approaches to tuberculosis in patients with HIV infection are similar to those in patients without HIV infection. Tuberculin skin testing can be used to diagnose latent tuberculosis infection, although the recommended cutoff for a positive test is 5 mm of induration. Treatment of coinfection with *Mycobacterium tuberculosis* and HIV requires consultation with experienced clinicians and pharmacists because of extensive drug-drug interactions among antiretroviral drugs and rifamycins.

### Gastrointestinal Complications

Oropharyngeal candidiasis (thrush) commonly manifests as white plaques on the tongue, palate, or buccal mucosa that are painless and are easily scraped off. Although thrush is typically uncomplicated and easily treatable with topical preparations such as nystatin

(Mycostatin) and clotrimazole (Mycelex troche), in the proper clinical setting it can alert the clinician to the presence of esophageal candidiasis. Esophageal involvement should be suspected in patients with dysphagia and odynophagia; retrosternal chest pain may also be present. Thrush is usually present but is not required for the diagnosis, which is often made on clinical grounds rather than being confirmed with endoscopy. Patients with esophageal candidiasis typically respond after several days of treatment, and 7 to 14 days of antifungal therapy is usually sufficient. For cases not responsive to empiric treatment for candidiasis, referral for endoscopy should be considered. Esophagitis caused by CMV or herpes simplex virus requires a histopathologic diagnosis.

Acute diarrhea, defined as three or more loose or watery stools per day for 3 to 10 days, is common among patients with HIV infection, and more than 1000 different enteric pathogens have been described. Data from a large cohort indicate that the most common pathogens isolated are *Clostridium difficile*, *Shigella* spp., *Campylobacter jejuni*, *Salmonella* spp., *Staphylococcus aureus*, and MAC. Culture of the stool can yield a microbiologic diagnosis in many cases, particularly for acute diarrheal illnesses caused by *Campylobacter*, *Yersinia*, *Salmonella*, and *Shigella* species. Infection with *C. difficile*, the most common bacterial enteric pathogen in the United States for both HIV-infected and HIV-uninfected persons, is diagnosed in most settings by detection of cytotoxin in the stool by enzyme immunoassay (EIA) or PCR, although the more laborious tissue culture is considered the gold standard. Enteric viruses are present in 15% to 30% of HIV-infected persons with acute diarrhea. Definitive diagnosis is not feasible in most clinical laboratories; viral enteritis should be suspected in the setting of community outbreaks because of the high transmissibility of viral pathogens. Treatment is supportive with fluid resuscitation and antimotility agents.

Chronic diarrhea (duration 30 days) was a common manifestation of advanced-stage AIDS in the pre-ART era. Most pathogens that cause acute gastroenteritis can also cause chronic symptoms. Pathogens that should be suspected in cases of chronic watery diarrhea include protozoa such as *Cryptosporidium parvum*, *Isospora belli*, and *Microsporidia* spp. These entities are self-limiting in the absence of severe immunosuppression. In advanced HIV infection, pathogen-specific antimicrobial therapy is infrequently effective, and symptoms commonly do not improve without immune reconstitution in response to ART. *Giardia lamblia* causes watery diarrhea, abdominal bloating, and occasionally malabsorption syndrome, and it can occur at any CD4 T-cell count. CMV infection can affect any segment of the gastrointestinal tract and is a common cause of chronic diarrhea. Diagnosis of gastrointestinal CMV disease is difficult without biopsy. Detection of CMV viremia with PCR does not correlate well with presence of CMV disease in HIV-infected patients, and CMV can be undetectable in serum in patients with extensive gastrointestinal disease.

#### Other Conditions

ART has dramatically increased the survival of individuals living with HIV, and the older adult population with HIV is expanding. There are few clinical trials or studies systematically focused on this cohort. Older adults with HIV may develop comorbidities that can complicate their HIV management. ART-related CD4 T-cell recovery in older patients has been observed to be slower and to be of lower magnitude than in younger patients. Hepatic and renal functions decrease as the body ages and may lead to impaired drug elimination and increased drug exposure in older adult patients.

#### Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a collection of inflammatory disorders often associated with paradoxical worsening of preexisting infectious diseases after initiation of ART. IRIS is usually accompanied by an increase

in CD4 T-cell count and can occur at any CD4 count. It usually occurs in the first 4 to 8 weeks after initiation of ART. Clinical features are often associated with the type and location of the preexisting OI and can be localized or systemic. Patients should continue ART and should receive treatment for the underlying OI as quickly as possible. If the patient's presentation involves paradoxical worsening of a previously diagnosed OI that is already receiving treatment, OI therapy should also be continued. Disseminated MAC accounts for up to one-third of cases of IRIS in the United States. Other important causes of IRIS are tuberculosis, CMV infection, viral hepatitis, and candida infections.

### Management of Human Immunodeficiency Virus in Pregnancy and Women of Childbearing Potential

#### Human Immunodeficiency Virus in Pregnant Women

Every pregnant woman with HIV should be given ART regardless of her immunologic or virologic status in order to improve her health and prevent transmission of HIV to the fetus. Increased perinatal transmission risk exists in pregnant women who experience early HIV infection and high-level viremia. Pregnant women with newly diagnosed HIV infection should start ART as soon as possible to prevent perinatal HIV transmission. The goal of ART is to achieve and sustain viral suppression throughout the pregnancy. Resistance testing should be performed before initiating ART, but therapy may be started before receiving resistance testing results. The ART regimen can be modified at a later date once resistance testing results are available.

Although there originally was a concern for increased risk of neural tube defects (NTDs) with DTG based on preliminary information from a study in Botswana in 2018, the most recent data from this study indicate that there is no longer a significant difference in NTDs with the use of DTG-based regimens compared with non-DTG-based regimens. Therefore, the U.S. Department of Health and Human Services guidelines on the use of antiretroviral drugs during pregnancy recommend DTG as a preferred agent in pregnant women with HIV.

In a patient already taking a regimen containing EFV [Sustiva] who presents for prenatal care during the first trimester and has virologic suppression, EFV can be continued. The risk of fetal NTDs is limited to the first 5 to 6 weeks of pregnancy, and pregnancy is often not recognized before weeks 4 to 6. Unnecessary changes to a patient's ART regimen during pregnancy may result in loss of viral suppression with increased risk of perinatal transmission.

In a pregnant patient with an HIV RNA viral load greater than or equal to 1000 copies/mL (or viral load is unknown) near delivery, IV infusion of zidovudine (Retrovir) during labor is recommended regardless of the patient's antepartum ART regimen or resistance profile. Maternal ART should be continued following delivery. Following delivery, patients should continue to follow up with their HIV healthcare provider as recommended for non-pregnant adults.

Maternal adherence to ART significantly reduces but does not completely eliminate the risk of transmission of HIV in breast milk. Postnatal HIV transmission can occur despite maternal ART adherence, and patients should be counseled to avoid breastfeeding. There have also been reports of mother-to-child transmission of HIV via mothers pre-masticating food and feeding it to their infants.

#### Preexposure Prophylaxis of Human Immunodeficiency Virus Infection

Globally, up to 2 million new HIV infections occur per year. It is estimated that up to 40,000 new HIV infections occur annually in the United States. The highest incidence of new HIV infections occur in MSM, especially among young African American males. For uninfected patients with a high risk of HIV acquisition, pre-exposure prophylaxis (PrEP) is an evidence-based method for preventing infections in those at risk. All sexually active adult

eCrCl, Estimated creatinine clearance; HIV, human immunodeficiency virus; MSM, men who have sex with men; PrEP, preexposure prophylaxis; PWID, persons who inject drugs; STI, sexually transmitted infection.

Modified from Preexposure Prophylaxis for the Prevention of HIV Infection in the United States—2021 Update: A Clinical Practice Guideline. U.S. Public Health Service. Available at: <https://www.cdc.gov/hiv/pdf/risk/prep/cdc-hiv-prep-guidelines-2021.pdf> (Table 1a).

and adolescent patients should receive information about PrEP and its role in preventing HIV acquisition. Clinicians should offer to prescribe PrEP to adults and adolescents whose sexual or injection behaviors and epidemiologic context place them at substantial risk of acquiring HIV infection. Available PrEP options include oral tenofovir disoproxil fumarate-emtricitabine (TDF/FTC [Truvada]), oral TAF/FTC (Descovy), and IM CAB (Apretude) (Tables 5 and 6). Efficacy is dependent on medication adherence; PrEP reduces the risk of acquiring HIV from sex by approximately 99% when taken as prescribed.

Before initiating PrEP, it is important to obtain a brief, targeted sexual and drug use history to identify patients likely to benefit from PrEP. The 2021 PrEP guidelines published by the U.S. Public Health Service recommend a dialogue around The “Five Ps”: *partners*, *practices*, *protection* from sexually transmitted infections (STIs), *past* history of STIs, and *pregnancy* intention. It is important to determine sexual practices with a patient’s main sexual partner, casual partners, or any anonymous partners. A drug history over the prior 6 months should be obtained and include injection drug use and sharing of needles. Clinicians should also briefly screen all patients for alcohol use disorder and the use of illicit non-injection drugs (e.g., amyl nitrite, stimulants) because use of these substances may affect sexual risk behavior. Clinicians should also consider the epidemiologic context of patient sexual practices as the risk of HIV acquisition is determined by both the frequency of specific sexual practices and the likelihood that a sex partner has HIV. Communities and populations that have higher HIV prevalence are more likely to lead to HIV exposure, indicating a greater need for risk-reduction methods (e.g., PrEP).

Patients screened for PrEP must be screened for common bacterial STIs, including serologic testing for syphilis and nucleic acid

amplification tests for gonorrhea and chlamydia. This includes swabs of the oropharynx in patients who participate in oral sex and anal swabs for recipients of anal intercourse. Screening for trichomonas and bacterial vaginosis are not required before initiating PrEP because they lack strong correlation with HIV coinfection.

HIV testing with confirmed results within 1 week before initiating therapy is required to document that patients do not have HIV when they start taking PrEP medications. Plasma HIV testing with a fourth-generation antibody/antigen (Ab/Ag) test should be obtained to confirm that the patient does not have undiagnosed HIV infection. Additional HIV RNA testing should be performed in patients with signs or symptoms of acute HIV infection in the past 4 weeks, those with indeterminate antigen/antibody test results, and patients with high-risk HIV exposure in the preceding 4 weeks. Testing for both HIV Ab/Ag and HIV-1 RNA should be obtained at least every 3 months after oral PrEP initiation or every 2 months when CAB injections are given.

TDF/FTC (Truvada) is generally tolerated well by most patients; however, screening for persons at increased risk of adverse effects should be performed before PrEP initiation. TDF is associated with renal and bone toxicity in some patients; serum creatinine should be measured as TDF/FTC is not recommended for PrEP in patients with creatinine clearance less than 60 mL/min. In patients without reduced kidney function but who have risk factors for developing renal disease, urinalysis to document baseline proteinuria can be obtained for monitoring purposes. A different formulation of tenofovir, TAF (tenofovir alafenamide fumarate), has less association with renal and bone toxicity compared with TDF. In the United States, once-daily TAF/FTC (Descovy) can be

**TABLE 6** Guidance for Cabotegravir Injection Preexposure Prophylaxis Use

CAB, Cabotegravir; HIV, human immunodeficiency virus; MSM, men who have sex with men; PrEP, preexposure prophylaxis; PWID, persons who inject drugs; STI, sexually transmitted infection.

Modified from Preexposure Prophylaxis for the Prevention of HIV Infection in the United States—2021 Update: A Clinical Practice Guideline. U.S. Public Health Service. Available at: <https://www.cdc.gov/hiv/pdf/risk/prep/cdc-hiv-prep-guidelines-2021.pdf>. (Table 1b).

prescribed for PrEP in high-risk MSM and transgender women, particularly those who have bone or renal contraindications to TDF, including those with a creatinine clearance as low as 30 mL/min. CAB (Apretude), administered IM every 2 months, is another option for PrEP in those at risk for renal toxicity because it may be administered irrespective of renal function.

Screening for undiagnosed HBV infection should be performed via hepatitis B surface antigen, hepatitis B core antibody, and hepatitis B surface antibody. If the patient’s serology shows nonimmunity, vaccination against HBV should be pursued, as individuals engaging in high-risk sexual and drug-use behaviors have an increased risk of HBV infection. If the patient’s serology reveals chronic HBV, it must be determined whether the patient requires HBV treatment. TDF (Viread) and TAF (Vemlidy) are first-line treatment choices for chronic HBV and can be used for PrEP<sup>1</sup> and treatment of chronic HBV. In those with chronic HBV who do not require HBV treatment, there is a low risk of HBV flare if TDF or TAF is discontinued.

TDF is also associated with decreased bone density; therefore patients considering PrEP should be screened for osteoporosis risk factors. The greatest amount of bone loss has been associated with the first 6 months of treatment. In patients with known osteopenia or osteoporosis, the risk of acquiring HIV versus further bone loss should be considered. Because of

a lack of clear benefit, neither baseline nor serial dual-energy x-ray absorptiometry (DEXA) scans are recommended before initiation of PrEP or for PrEP monitoring. Because of lower rates of bone and renal toxicity, TAF or CAB should be considered over TDF in patients with significant risk for bone-related complications.

Providers should offer PrEP with TDF/FTC (Truvada) to women seeking to conceive and to pregnant or breastfeeding women whose sexual partner has HIV, especially when the partner’s viral load is detectable or unknown. In patients who are pregnant, the risk of acquiring HIV must be considered against the risk of using antiretroviral medication during pregnancy. The 2021 PrEP guidelines published by the U.S. Public Health Service recommend that providers discuss the risks and benefits of all available alternatives for safer conception. Although each case should utilize shared decision making, generally the potential benefit of preventing HIV transmission to an infant during pregnancy outweighs theoretical risk to maternal or infant health.

### Initiating Preexposure Prophylaxis

The combination tablet of TDF/FTC (Truvada) or TAF/FTC (Descovy) should be taken once daily for a duration of as long as the infection risk continues. It should be dispensed as a 90-day supply and renewed at each 3-month clinic follow-up. Condom use is encouraged while using PrEP. For patients who are

<sup>1</sup>Not FDA approved for this indication.

not willing to use condoms consistently, the Centers for Disease Control and Prevention (CDC) recommends condom use to prevent acquisition of HIV (and other STIs) for the first 7 days after starting oral PrEP if engaging in receptive anal sex and 21 days if engaging in receptive vaginal sex. Common side effects of TDF/FTC and TAF/FTC include nausea and vomiting. These symptoms usually improve and resolve within the first 4 weeks of use.

CAB injections (Apretude) also be used for PrEP and may be especially appropriate for patients with significant renal disease, those who have difficulty with adherence to oral PrEP, and those who prefer injections every 2 months to an oral PrEP dosing schedule. CAB is administered as a 600 mg (3 mL) IM injection at baseline and at 1 month, followed by every 2 months thereafter. CAB injections should be administered in a healthcare setting; they should not be self-administered by patients. In studies, an oral CAB (Vocabria) lead-in phase was utilized before beginning IM injections, but this is not required before initiating CAB injections for PrEP unless patients are especially concerned about side effects with the first dose. Common side effects of CAB injections include injection site reactions, such as pain, tenderness, and induration. Over-the-counter pain medication and/or warm compresses or heating pads can be used if needed to manage injection site pain.

#### Preexposure Prophylaxis Monitoring and Follow-Up

Patients on oral PrEP should have routine follow-up with their prescribing medical provider approximately every 3 months, although some clinicians may wish to schedule contact more frequently at the beginning of PrEP, either by phone or clinic visit. More frequent follow-up should occur for patients with exposures or symptoms of STIs or medication side effects. Patients prescribed CAB for PrEP should return for follow-up visits 1 month after the initial injection and then every 2 months. Recommendations for follow-up screening tests are provided in [Tables 5 and 6](#).

#### Postexposure Prophylaxis of Human Immunodeficiency Virus Infection

The most effective means to prevent HIV infection include preventing exposure to the virus. In the event that an isolated occupational, sexual, or injection drug-related exposure occurs, postexposure prophylaxis (PEP) can be a second line of defense against HIV acquisition.

#### Occupational Exposure

Healthcare personnel include all paid and unpaid persons working in a healthcare setting with potential for exposure to infectious materials such as bodily fluids, contaminated medical supplies, or environmental surfaces. In the occupational setting, prevention of exposures to blood and bodily fluids from infected sources is the key to preventing occupationally acquired HIV infection. The overall risk of becoming infected with HIV after inadvertent exposure to body fluids from an HIV-infected patient is low. It is estimated that the average risk for HIV transmission following percutaneous exposure to HIV-infected blood is 0.3% and after mucous membrane exposure is 0.09%. The average risk of HIV transmission following nonintact skin exposure has not been defined; however, it is estimated to be lower than mucous membrane exposure. Healthcare personnel at the highest risk are those who received an accidental inoculation containing blood from a known HIV-infected source.

#### Initial Laboratory Evaluation

All patients initiating PEP after potential HIV exposure should be tested for HIV antigens and antibodies at baseline before PEP

initiation. If baseline HIV testing indicates existing HIV infection, PEP should not be initiated. Repeat HIV testing should be performed at 4 to 6 weeks and 3 months following the exposure to determine if HIV infection has occurred. Administration of PEP should not be delayed while awaiting the results of HIV testing and can be discontinued if the source patient is found to not have HIV infection. PEP is most effective when taken as soon as possible following exposure.

#### Initiating Postexposure Prophylaxis/Choosing Appropriate Postexposure Prophylaxis Therapy

PEP is most effective when initiated as soon as possible following the exposure incident. If PEP is delayed, the effectiveness of therapy may be significantly reduced if initiated 72 hours or more following exposure. Initiating therapy after 72 hours might still be considered if the exposure is proven to be of an extremely high risk of transmission.

The current recommendation for PEP therapy is TDF/FTC (Truvada)<sup>1</sup> plus RAL (Isentress)<sup>1</sup> or DTG (Tivicay)<sup>1</sup> for 4 weeks. Overall, this regimen has acceptable tolerability, convenient dosing, and minimal drug interactions. In patients with significant underlying renal disease, an acceptable PEP alternative is zidovudine plus lamivudine (Combivir)<sup>1</sup> in addition to RAL or DTG.

PEP regimens include three (occasionally more) antiretroviral medications. Because of the potential for medication-related side effects, it is important to choose a PEP regimen with a lower toxicity profile to improve patient tolerance and encourage completion of PEP therapy.

HIV PEP should be offered to pregnant or breastfeeding healthcare providers based on the same criteria as any other provider with a similar exposure. Risk of HIV transmission from mother to child during acute HIV infection is increased during pregnancy and breastfeeding.

Additional resources regarding PEP are available (e.g., PEpline at <https://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis>; 888-448-4911).

<sup>1</sup>Not FDA approved for this indication.

## INFECTIOUS MONONUCLEOSIS

Method of

Ben Z. Katz, MD

### CURRENT DIAGNOSIS

- The classic triad of acute infectious mononucleosis consists of fever, lymphadenopathy, and pharyngitis.
- The diagnosis of infectious mononucleosis is usually based on the clinical picture, the presence of at least 10% atypical lymphocytes in the peripheral blood, and positive heterophil serology (monospot test).

### CURRENT THERAPY

- In most patients, infectious mononucleosis is self-limited and requires only symptomatic treatment.
- Steroids and antiviral therapy have no place in the therapy of uncomplicated acute infectious mononucleosis in healthy persons.

### Epidemiology and Risk Factors

One must distinguish between the epidemiology of Epstein-Barr virus (EBV) infection and that of infectious mononucleosis (IM), the most common symptomatic manifestation of primary EBV infection. Almost all adults have been infected with EBV. The symptomatology of primary EBV infection varies with the infected person's age at the time, with younger children usually having inapparent or mild infections. In developing countries and in lower socioeconomic groups in industrialized nations, up to 90% of children acquire primary EBV infection by 6 years of age, and IM frequently never develops. In contrast, in higher socioeconomic groups, only 40% to 50% of adolescents have previously experienced EBV infection. From 10% to 20% of susceptible adolescents and adults contract EBV every year thereafter, with IM developing in about half of these patients.

### Pathophysiology

Saliva is the main vehicle for transmission of EBV, a double-stranded DNA herpesvirus. Transmission usually requires direct and prolonged contact with infected oropharyngeal secretions, with salivary exchange being the main mode of transmission. The infection begins with viral replication in oropharyngeal epithelial cells and then spreads to local B lymphocytes, which then disseminate throughout the reticuloendothelial system and induce vigorous T- and NK-cell responses and neutralizing antibodies. The atypical lymphocytes that are produced are mainly suppressor T cells directed against EBV-infected B cells.

It is thought that most of the clinical manifestations of IM are due to these T- and NK-cell responses, which might explain why young children, whose immune responses are incompletely developed, are often asymptomatic with primary EBV infection. It is also possible that viral load determines symptomatology, and, because young adults likely spread more virus via salivary exchange than toddlers, young adults are more likely to be symptomatic. All EBV-seropositive persons shed virus in saliva intermittently throughout their lives. EBV may rarely be spread via blood transfusion or transplantation.

### Clinical Manifestations

IM is usually an acute, self-limited, benign lymphoproliferative disease. EBV is responsible for nearly all heterophil-positive and most heterophil-negative cases. Other causes of heterophil-negative mononucleosis include cytomegalovirus, toxoplasmosis, hepatitis A and B, adenovirus, HIV, rubella, and human herpesvirus 6.

The classic triad of IM consists of fever, lymphadenopathy, and pharyngitis. Other typical findings include lymphocytosis with

atypical lymphocytes and the presence of heterophil antibodies. After a 4- to 6-week incubation period, the illness begins with a 3- to 5-day prodrome of malaise, headache, and fatigue, typically followed in about half of the cases by onset of the triad. Additional symptoms can include anorexia, nausea, vomiting, periorbital or facial edema, and generalized lymphadenopathy, which is usually symmetrical. Splenomegaly occurs by the second or third week of illness in about half of all cases; rarely, splenic rupture can occur, which very rarely may be fatal. Hepatomegaly occurs in 10% to 15%, with hepatitis occurring in about 5% of cases. Up to 20% of patients have a rash that may be erythematous, maculopapular, morbilliform, scarlatiniform, or urticarial, especially if ampicillin or one of its derivatives has been given. Other symptoms can include arthritis and jaundice.

IM is a self-limited disease in nearly all patients. Median illness duration is 16 days.

### Diagnosis

The diagnosis is usually based on the clinical picture, atypical lymphocytosis, and positive heterophil serology. Most adolescents and young adults with IM have most or all of these features, as well as an elevated white blood cell count with a relative lymphocytosis. Atypical lymphocytes generally represent more than 9% to 10% of the white blood cell count. Many infected persons also have mild thrombocytopenia and elevated hepatocellular enzymes. Heterophil antibody positivity is usually measured as a positive monospot test. If IM is suspected and heterophil antibodies are negative, specific titers for EBV, including viral capsid antigen (VCA) IgM and IgG, early antigen (EA), and Epstein-Barr nuclear antigen (EBNA), should be obtained, as well as serologic testing for cytomegalovirus (CMV) and toxoplasmosis, the two most common causes of heterophil-negative infectious mononucleosis. Acute EBV infection is characterized by the presence of IgM and IgG VCA antibodies and EA antibodies and the absence of EBNA antibodies.

### Differential Diagnosis

If liver chemistry values are markedly elevated and antibodies against EBV, CMV, and toxoplasmosis are unrevealing, serology for hepatitis A, B, and C should be measured. If risk factors are present, HIV antibodies should be checked. A throat culture is indicated in patients with pharyngitis or tonsillitis because the tonsillitis of acute IM can be indistinguishable from that of group A streptococcal pharyngitis.

### Treatment

In most patients, IM is self-limited and requires only symptomatic treatment, including bed rest, acetaminophen (Tylenol, 10–15 mg/kg every 4–6 hours), aspirin (10–15 mg/kg every 4–6 hours), or nonsteroidal antiinflammatory agents such as ibuprofen (Advil, 5–10 mg/kg every 6–8 hours). Saline gargles can be useful in treating a sore throat. In severe cases, meperidine (Demerol, 1–1.5 mg/kg every 3–4 hours) may be required.

Although a short, tapering course of corticosteroid therapy (e.g., a Medrol Dosepak<sup>1</sup>) is often prescribed, there is little evidence for its clinical efficacy, and caution is warranted. Infection is ultimately self-limited in nearly all cases, and rare reports of neurologic or septicemic complications after steroid use have appeared. Long-term immune responses following steroid use appear to be normal. Corticosteroid therapy should, however, be considered for the treatment of severe cases of IM associated with hemolysis, respiratory embarrassment, or thrombocytopenic purpura. The use of corticosteroids in atypical or antibody-negative cases is inappropriate because the diagnosis of lymphoma can then be confounded.

Parenteral administration of acyclovir<sup>1</sup> (Zovirax, 10–20 mg/kg IV every 8 hours) to patients with acute IM secondary to EBV reduces the level of oropharyngeal viral replication; however, replication returns to the previously high levels after cessation of treatment, little or no reduction is seen in the number of EBV-infected B cells in the peripheral circulation, and the drug has little or no effect on the clinical course. Acyclovir administered in high doses orally (20 mg/kg, maximum dose of 800 mg qid for 5

<sup>1</sup>Not FDA approved for this indication.

days) is also ineffective. Antiviral therapy is therefore not recommended for acute IM in a normal host.

In immunosuppressed or severely ill patients, however, specific therapy has a role in many cases. For example, etoposide (VePesid)<sup>1</sup>, a drug that reduces macrophage activation, is often used in cases of infection-associated hemophagocytic syndrome. In posttransplant lymphoproliferative disorders, first-line therapy is often a reduction in immunosuppression; other options include rituximab<sup>1</sup> (Rituxan, 375 mg/m<sup>2</sup> IV weekly for 4 weeks). Oral leukoplakia in patients with AIDS responds to oral acyclovir<sup>1</sup> (20mg/kg, maximum dose of 800mg qid for 20 days), whereas a tapering course of steroids (as recommended earlier) may be used for lymphocytic interstitial pneumonitis (see below).

### Monitoring

Quarantine is not indicated. Ampicillin and related drugs should be avoided when treating secondary bacterial complications because of their association with rash in persons with IM. Contact sports should be avoided as long as splenomegaly is still evident because of the rare possibility of splenic rupture, which usually occurs within 3 weeks of onset of IM but has been reported as late as 7 to 10 weeks into the illness.

### Complications

Complications of acute IM can be neurologic (seizures, cranial nerve palsies, aseptic meningitis, encephalitis, optic neuritis, transverse myelitis, infectious polyneuritis [Guillain-Barré syndrome], psychosis, Alice in Wonderland syndrome, or acute cerebellar ataxia), hematologic (hemolytic or aplastic anemia, thrombocytopenic purpura, agranulocytosis, or agammaglobulinemia), cardiac (pericarditis or myocarditis), pulmonary (cough or atypical pneumonia), renal (glomerulonephritis, acute kidney failure, or acute interstitial nephritis), or ophthalmologic (conjunctivitis) in nature. In about 10% of adolescents and young adults, fatigue can persist for 6 months or longer, and many of these patients meet the criteria for chronic fatigue syndrome. Young adults with more severe acute IM and certain predisposing symptoms and laboratory findings are more likely to meet criteria for chronic fatigue syndrome 6 months later.

Rare patients have very high titers of EBV antibodies, and a chronic active EBV infection associated with unusual clinical manifestations such as uveitis or lymphoma can occur. EBV is also associated with lymphoproliferative disorders in persons with underlying abnormal immune systems. These include X-linked lymphoproliferative syndrome, in which affected males usually die of acute EBV infection, and the related infection-associated hemophagocytic syndrome, which is most commonly (about 75% of the time) triggered by EBV and seems to be due to an overly exuberant macrophage response to EBV-infected lymphocytes. Transplant recipients can acquire EBV-associated lymphoproliferative disease that can range from an asymptomatic infection to fatal IM or lymphoma. Finally, although not seen much anymore due to combination antiretroviral therapy, patients with AIDS are susceptible to several serious complications of EBV infection, including lymphocytic interstitial pneumonitis, oral leukoplakia, leiomyosarcoma, and lymphoma.

## INFLUENZA

Method of

Jeffrey A. Linder, MD, MPH

### CURRENT DIAGNOSIS

- Influenza should be considered in any patient with respiratory symptoms between October and May in North America.
- The single most important piece of information when considering a diagnosis of influenza is the community prevalence of influenza.
- During influenza outbreaks, sudden onset of fever and cough has a positive predictive value of about 85%.
- Rapid testing should be done with molecular tests (e.g., reverse transcriptase polymerase chain reaction [RT-PCR]), which have a high sensitivity and specificity.

### CURRENT THERAPY

- The influenza vaccine is the best means of preventing influenza. The inactivated influenza vaccine is recommended for all persons age 6 months and older.
- Influenza vaccination should be prioritized for essential workers and people at high-risk for influenza or COVID-19 complications.
- The antivirals zanamivir (Relenza) and oseltamivir (Tamiflu) can be used for prophylaxis of influenza in unimmunized patients, in close contacts of infected patients, and during institutional outbreaks of influenza.
- Early antiviral treatment should not be delayed and should be used for patients who are hospitalized; have severe, complicated, or progressive illness; or are at higher risk for complications.
- Antivirals may be prescribed within 48 hours of symptom onset for outpatients not at higher risk for influenza complications.

Influenza is a highly contagious viral infection that should be considered in any patient with respiratory symptoms between October and May in North America. Influenza infects 5% to 20% of the population of the United States in a typical year, sickens 3% to 11% of Americans, and is responsible for up to 810,000 hospitalizations and 61,000 deaths per year. Influenza can range in severity from mild illness to life-threatening disease. Those at highest risk of hospitalization, death, or complications from influenza are children younger than 2 years old, adults older than 65 years, people of any age who have underlying medical conditions or immune compromise, and pregnant women.

Information about influenza changes rapidly. Emergence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and associated coronavirus disease 2019 (COVID-19) has complicated influenza diagnosis and management. To care optimally for patients with influenza-like illness during the influenza season, clinicians need to keep abreast of updated recommendations and the current prevalence of influenza and COVID-19 in their community. The influenza vaccine remains the best means of reducing the incidence, severity, and complications from influenza, but antiviral medications and symptomatic treatments have an important role in the prevention and treatment of influenza (Box 1).

### Microbiology

There are two types of influenza viruses, A and B. Influenza A is separated into subtypes based on two surface antigens: hemagglutinin (H) and neuraminidase (N). The predominant circulating strains of influenza in recent decades have been influenza A (H1N1), influenza A (H3N2), and influenza B. Influenza

A (H3N2) subtypes generally cause more severe influenza and are associated with higher mortality than other types. Influenza viruses undergo slight genetic changes from year to year, termed *antigenic drift*. Major changes in surface glycoproteins are termed *antigenic shift* and can result in severe pandemic influenza in a nonimmune population, which happened with an antigenically novel influenza A (H1N1) virus in 2009. Because of antigenic drift, and because immunity to a given type or subtype of influenza provides limited cross-immunity to other types and subtypes, the influenza vaccine needs to be reformulated and administered most years.

Patients contract influenza by being exposed to small- and large-sized respiratory droplets and aerosols from an infected person or contact with surfaces harboring influenza virus. Influenza has a latency of 1 to 4 days before the onset of symptoms. Adults are infectious from the day before symptom onset through approximately day 7 of illness, but immunosuppressed adults and children shed the virus for longer periods. Symptoms generally last from 7 to 14 days.

Beyond the emergence of SARS-CoV-2 in 2019, several other novel, highly pathogenic respiratory viruses—avian influenza A (H5N1), avian influenza A (H7N9), and Middle East respiratory syndrome coronavirus (MERS-CoV)—have case-fatality rates ranging from 35% to 53%. Collectively there have been more than 5000 human cases. These pathogens, if they acquire the ability to be highly transmissible between humans, have the potential to cause pandemic respiratory disease.

## Prevention

Influenza vaccination is between 20% and 90% effective in preventing influenza or complications of influenza. Influenza vaccination is highly cost-effective and can even be cost-saving in high-risk groups. Influenza vaccination is less effective in younger children, in adults older than 65 years, in adults with comorbid conditions, and when there is a poor match between the influenza vaccine and circulating influenza. The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices puts out annual recommendations and supplementary updates on the prevention and treatment of influenza ([www.cdc.gov/flu](http://www.cdc.gov/flu)). The Advisory Committee on Immunization Practices recommends vaccinating all persons 6 months of age and older.

At present in the United States, there are three commonly administered, recommended types of influenza vaccine: quadrivalent inactivated influenza vaccine (IIV4), quadrivalent recombinant influenza vaccine (RIV4), and quadrivalent live attenuated influenza vaccine (LAIV4). The IIV4 (Afluria Quadrivalent, Fluarix Quadrivalent, FluLaval Quadrivalent, Fluzone Quadrivalent, Flucelvax Quadrivalent, Fluzone High-Dose, Fluad Quadrivalent), adjuvant IIV3 (Fluad), and RIV4 (Flublok Quadrivalent) vaccines are administered as an intramuscular injection.

Different products are approved for administration in different lower age limits. A high-dose IIV4 (Fluzone High-Dose Quadrivalent) and an adjuvanted IIV4 (Fluad Quadrivalent) are available for patients aged 65 years or older, who are less likely to respond immunologically to standard inactivated influenza vaccine (IIV). The RIV4 (Flublok Quadrivalent) is only licensed for persons age 18 years or older. The main adverse effect of the IIV is soreness at the injection site. Patients often report a mild immune response of fever, malaise, myalgia, and headache that can last for 1 to 2 days, but rates of most of these symptoms are no different from those in patients who receive placebo injection.

Allergic reactions to egg proteins or other vaccine components (e.g., antibiotics and inactivating compounds) include hives, angioedema, asthma, and anaphylaxis. For patients with egg allergy who have only hives, any otherwise appropriate IIV or RIV can be administered. For patients with more severe reactions to egg or who received treatment for an allergic reaction can also receive any recommended IIV or RIV in an inpatient or outpatient medical setting and observed for at least 15 minutes by a clinician able to recognize and manage severe allergic reactions. The

recombinant influenza vaccine (RIV4; FluBlok Quadrivalent) and cell culture derived quadrivalent (ccIIV4; Flucelvax, Quadrivalent) are considered egg free, but patients who had a severe allergic reaction to a previous dose of an egg-based vaccine should receive ccIIV4 or RIV4 in a supervised inpatient or outpatient setting. Patients who have had severe allergic reaction to influenza vaccine should not receive the vaccine.

Vaccination should be deferred in patients with confirmed or suspected COVID-19 or with any acute febrile illness, but patients with more moderate illness can be vaccinated. Guillain-Barré syndrome was associated with the 1976 swine flu vaccine, but there is no consistent evidence that modern influenza vaccines are associated with Guillain-Barré syndrome.

The LAIV4 (FluMist Quadrivalent) is administered as a nasal spray and is approved for patients ages 2 to 49 years. The LAIV4 is contraindicated in children aged 2 to 4 years with recurrent wheezing or asthma; children who are receiving aspirin or aspirin-containing products; patients with comorbid conditions or immunosuppression; pregnant women; family members or close contacts of severely immunosuppressed patients, who require a protected environment (e.g., hematopoietic stem cell transplant recipients); cerebrospinal leak or cochlear implants; and receipt of oseltamivir (Tamiflu) or zanamivir (Relenza) in the previous 48 hours, peramivir (Rapivab) in the previous 5 days, or baloxavir (Xofluza) in the previous 17 days. The LAIV4 should not be administered to those with severe nasal congestion. Adverse effects of the LAIV4 include runny nose, nasal congestion, headache, sore throat, chills, and tiredness, although these are only slightly more common than in patients receiving placebo. Those receiving the LAIV4 should avoid contact with severely immunosuppressed persons for 7 days.

Patients should be vaccinated in the fall when the seasonal vaccine becomes available, ideally before the end of October. In the event of vaccine shortages, higher-risk patients should receive priority (see [Box 1](#)). Patients should continue to be vaccinated until February and beyond because in the majority of recent influenza seasons the peak has been February or later.

### BOX 1 Influenza Vaccine Recommendations.

- All persons aged  $\geq 6$  months should be vaccinated annually
- Vaccination efforts should prioritize essential workers and people at higher risk of influenza and COVID-19 complications:
  - Age 6 months to 5 years
  - Age  $\geq 50$  years
  - Chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, neurologic, hematologic, or metabolic (including diabetes mellitus) disorders
  - Immunosuppressed
  - Pregnant during the influenza season
  - Age 6 months to 18 years old receiving long-term aspirin therapy and who therefore might be at risk for Reye syndrome
  - Residents of nursing homes and other long-term care facilities
  - American Indians/Alaska Natives
  - Morbidly obese (body mass index  $\geq 40$ )
- Vaccination efforts should also prioritize those likely to transmit influenza to higher risk people:
  - Healthcare personnel
  - Household contacts and caregivers of children aged  $< 5$  years and adults aged  $\geq 50$  years, with particular emphasis on vaccinating contacts of children aged  $< 6$  months
  - Household contacts and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza

Children 6 months to 8 years of age who have not been previously immunized against influenza should be given two doses separated by at least 4 weeks.

## Evaluation

### Community Prevalence of Influenza

In caring for a patient with suspected influenza, the single most important piece of data is the community prevalence of influenza among patients with influenza-like illness. This ranges from near 0% during summer months to approximately 30% during a typical influenza seasonal peak. The prevalence may be higher during a particularly severe outbreak. In the United States clinicians can check the local prevalence of influenza and COVID-19 among patients with influenza-like illness through the CDC ([www.cdc.gov/flu](http://www.cdc.gov/flu)) and their state department of public health.

### History and Physical Examination

Beyond the local prevalence of influenza, the diagnosis of influenza rests on the patient's history. All methods of diagnosing influenza—symptom complexes, clinician judgment, and testing—generally are highly specific but have poor sensitivity. Thus it is important to consider a diagnosis of influenza in any patient with respiratory symptoms during influenza season. Influenza is classically described as the very sudden onset of fever, headache, sore throat, myalgias, cough, and nasal symptoms. Children can also have otitis media, nausea, and vomiting. In differentiating influenza from nonspecific upper respiratory tract infections, it is most useful to consider the circulating prevalence of influenza, the abruptness of onset, and the severity of symptoms. Although COVID-19 and influenza symptoms overlap, COVID-19 may be more likely to include more profound shortness of breath, loss of taste or smell, nausea, vomiting, or diarrhea.

Certain symptom complexes have been shown in trials of antiviral treatment to strongly suggest influenza. For example, in an area with circulating influenza, prior to the emergence of SARS-CoV-2, the acute onset of cough and fever had a positive predictive value as high as 85%. Other studies have shown that clinician judgment performed as well as or better than hard-and-fast symptom complexes or rapid testing.

The physical examination in influenza primarily serves to identify the severity of influenza, complications, and worsening of underlying medical conditions. Clinicians should record vital signs and perform examinations of the ears, nose, sinuses, throat, neck, lungs, and heart for all patients suspected of having influenza.

### Testing

Testing may not be required to make a diagnosis of influenza, but can help differentiate influenza from other respiratory viruses. Treatment for patients at high risk for influenza complications should not wait for test results. Testing may also help inform antiviral use, antibiotic prescribing, site-of-care decisions, and infection control measures. Specimens (nasopharyngeal swab, nasal swab, nasal wash, or nasal aspirate, depending on the particular test) should ideally be collected within 3 to 4 days of symptom onset.

Molecular assays such as reverse transcriptase polymerase chain reaction (RT-PCR) testing are highly sensitive (90% to 95%) and specific. Some can produce results in 15 to 45 minutes, and some can differentiate influenza types and subtypes. RT-PCR should be considered for hospitalized patients, institutional outbreaks, or other situations when clinicians are concerned about false-negative rapid test results. Other nucleic acid amplification tests, which can differentiate influenza from other respiratory pathogens, are becoming more available. The CDC recommends that all hospitalized patients with suspected influenza be tested with a high-sensitivity, high-specificity molecular assay.

Rapid influenza diagnostic tests (RIDTs) are much less sensitive (50% to 70%) and somewhat less specific (90%) than molecular tests. Negative results do not exclude the possibility of influenza, especially if the circulating prevalence of influenza is high (>30%). Some RIDTs can distinguish influenza A from influenza B and can provide a point-of-care result in less than 15 minutes.

In the event of a high prevalence of influenza or a high risk of complications from influenza, empiric antiviral treatment is indicated. Testing may be particularly helpful for hospitalized patients to rule out a need for antibiotics, but antiinfluenza treatment should not be withheld solely on the basis of a negative test result. Chest radiography, cultures, and blood tests are not routinely indicated, but they should be obtained for patients with suspected pneumonia or to identify other suspected complications.

## Complications

Complications of influenza include primary complications, suppurative complications, and worsening of comorbid conditions. Primary complications of influenza include viral pneumonia, which is a feared complication and is likely a main cause of death in pandemic influenza. Other, less common primary complications of influenza include myositis and rhabdomyolysis, Reye syndrome, myocarditis, pericarditis, toxic shock syndrome, and central nervous system disease (e.g., encephalitis, transverse myelitis, and aseptic meningitis). Children can have a severe course with influenza, including signs and symptoms of sepsis along with febrile seizures. Suppurative complications of influenza include bacterial pneumonia, otitis media, and sinusitis. Influenza can cause worsening of comorbid conditions such as asthma, chronic obstructive pulmonary disease, congestive heart failure, and chronic kidney disease.

## Chemoprophylaxis

Antiviral medications can be used to prevent influenza in patients who did not receive the influenza vaccine, cannot receive the influenza vaccine, received the vaccine in the prior 2 weeks (before reliable immunity develops), or in the event of poor matching between vaccine and circulating influenza strains (Table 1). Chemoprophylaxis should also be considered for close contacts of patients with confirmed influenza or for patients with immune deficiency who are unlikely to respond to the influenza vaccine but who are at high risk for having complications from influenza (see Box 1).

Amantadine (Symmetrel) and rimantadine (Flumadine) are not recommended for chemoprophylaxis or treatment because of a high prevalence of resistant influenza A strains. The neuraminidase inhibitors oseltamivir (Tamiflu), and zanamivir (Relenza) are approximately 80% effective in preventing influenza in household contacts of persons with influenza, and more than 90% effective in preventing influenza in institutional settings. Chemoprophylaxis should be taken for 7 days after last known exposure. For hospital or long-term care facility outbreaks, chemoprophylaxis should be taken and for a minimum of 2 weeks or until 1 week after the end of the outbreak. For patients allergic to or unable to respond to the vaccine, chemoprophylaxis should be used for the duration of circulating influenza. The IIV can be given to patients receiving chemoprophylaxis. The LAIV should not be given from 2 days before to 14 days after taking an antiviral medication. Patients who receive the LAIV in this window should be revaccinated at a later date.

## Treatment

The influenza vaccine is the best means of reducing influenza-related morbidity and mortality, but its limitations include production problems, low vaccination rates, and variable effectiveness. Given these limitations, there is an important role in management for influenza-specific antiviral medications (see Table 1). Antiviral medications reduce the duration of influenza symptoms by approximately 1 day, reduce complications requiring antibiotics by 30% to 50%, might decrease hospitalizations, decrease mortality among hospitalized patients, and are cost-effective. Early antiviral treatment, which should not wait

**TABLE 1** Antiviral Agents for the Treatment and Prophylaxis of Influenza.

ANTIVIRAL AGENT	TREATMENT*		PROPHYLAXIS†		COMMENTS
	CHILDREN	ADULTS	CHILDREN	ADULTS	
Oseltamivir (Tamiflu)	Any age‡ Dose for 5 days bid: <1 year: 3 mg/kg per dose; ≤15 kg: 30 mg; 16–23 kg: 45 mg; 24–40 kg: 60 mg; >40 kg: 75 mg	75 mg PO bid for 5 days	3 months to 1 year: 3 mg/kg/day‡ Dose qd: ≤15 kg: 30 mg; 16–23 kg: 45 mg; 24–40 kg: 60 mg; >40 kg: 75 mg	75 mg PO qd	For patients with creatinine clearance < 30 mL/min, oseltamivir adult dosing should be reduced to 30 mg qd for treatment and to 30 mg qod for prophylaxis
Zanamivir (Relenza)	Approved for children ≥7 years; 10 mg (2 inhalations) bid for 5 days	10 mg (2 inhalations) bid for 5 days	Approved for children ≥5 years; 10 mg (2 inhalations) qd	10 mg (2 inhalations) qd	Avoid in patients with chronic lung disease (e.g., asthma, chronic obstructive pulmonary disease)
Peramivir (Rapivab)	≥6 months: One 12-mg/kg dose, up to 600 mg maximum IV over minimum 15 min	≥13 years: One 600-mg IV dose over a minimum of 15 min	NA	NA	For patients with creatinine clearance 30–49 mL/min, the dose should be reduced to 200 mg; For patients with creatinine clearance 10–29 mL/min, the dose should be reduced to 100 mg
Baloxavir (Xofluza)	≥12 years: <80 kg: one 40-mg dose; ≥80 kg: one 80-mg dose	<80 kg: one 40-mg dose; ≥80 kg: one 80-mg dose	≥12 years: <80 kg: one 40 mg dose ≥80 kg: one 80 mg dose	<80 kg: one 40-mg dose; ≥80 kg: one 80-mg dose	For patients within 2 days of illness onset. Avoid in pregnant women or breastfeeding mothers

\*Suspected or confirmed influenza among persons with severe influenza or for persons at higher risk for influenza complications up to 5 days after symptom onset. For outpatients not at higher risk for influenza complications, treatment should be started within 48 hours of symptom onset.

†Prophylaxis should be given for 7 days after last known exposure and for institutional outbreaks for at least 2 weeks or until 1 week after the end of the outbreak.

‡Oseltamivir is approved by the US Food and Drug Administration for treatment in children 14 days and older and prophylaxis in children 1 year and older. Treatment in children <14 days old and prophylaxis in children <1 year old is recommended by the Centers for Disease Control and Prevention and the American Academy of Pediatrics.

IV, Intravenous; NA, not approved; PO, per os (orally).

Adapted from Centers for Disease Control and Prevention. Influenza Antiviral Medications: Summary for Clinicians. Available at <https://www.cdc.gov/flu/professionals/antivirals/index.htm> (accessed July 7, 2022).

for test results, starting up to 5 days after symptom onset can reduce complications for patients who are hospitalized; have severe, complicated, or progressive illness; or are at higher risk for complications (see [Box 1](#)). For outpatients not at higher risk for complications, antiviral treatment must be started within 48 hours of symptom onset.

Oseltamivir (Tamiflu) is taken as a capsule or oral suspension. The dose of oseltamivir should be reduced in patients with renal disease. Adverse effects of oseltamivir include nausea, vomiting, and perhaps behavioral changes. Oseltamivir, oral or enterically administered, is the drug of choice for hospitalized patients and those with severe illness. Zanamivir (Relenza) is taken as an oral inhaled powder and is not recommended for patients with underlying lung or heart disease. Adverse effects of zanamivir include worsening of underlying lung disease and allergic reactions. Amantadine and rimantadine are not recommended because of a high prevalence of resistant influenza A strains.

Peramivir (Rapivab), an intravenous neuraminidase inhibitor, was approved in the United State in December 2014 for patients within 48 hours of symptom onset. Peramivir has been associated with diarrhea, rashes including Stevens-Johnson syndrome, and neuropsychiatric changes.

Baloxavir (Xofluza), a cap-dependent endonuclease inhibitor, is active against both influenza A and B. Baloxavir has been associated with diarrhea. It has the advantage of requiring only one dose.

Antibiotics are generally not necessary, but they should be prescribed to treat suppurative complications of influenza.

Antitussives such as guaifenesin with codeine (Robitussin AC) help coughing patients to sleep at night.  $\beta$ -Agonists, such as albuterol (Proventil)<sup>1</sup>, can help patients with cough, especially if there is wheezing on examination. Analgesics and antipyretics such as acetaminophen (Tylenol) and ibuprofen (Motrin) reduce fever and generally help patients to feel better. Patients should be encouraged to rest and drink plenty of fluids.

Patients with suspected influenza should minimize contact with others to avoid spreading the infection. Use of face masks and hand hygiene can reduce the transmission of influenza.

<sup>1</sup>Not FDA approved for this indication.

## LEISHMANIASIS

Method of

Luigi Gradoni, PhD

### CURRENT DIAGNOSIS

- Infected tissues must be sampled for microscopy demonstration of *Leishmania* organisms in Giemsa-stained impression smears or cultures. Polymerase chain reaction (PCR) detection of *Leishmania* DNA increases diagnostic sensitivity.
- Different tissue samplings are performed depending on the clinical form of leishmaniasis: For visceral leishmaniasis, aspirate or biopsy specimens are obtained from spleen, bone marrow, the liver, or enlarged lymph nodes. For cutaneous and mucocutaneous leishmaniasis, the material is obtained by skin lesion scraping or biopsy.
- Serology is useful when the diagnosis of visceral leishmaniasis proves difficult with other methods.

### CURRENT THERAPY

- The therapy of leishmaniasis relies on a limited number of drugs, most of which are old and relatively toxic. Systemic drug administration requires hospitalization and monitoring of the patient.
- The pentavalent antimony (Sb) drugs sodium stibogluconate (Pentostam)<sup>10</sup> and meglumine antimoniate (Glucantime)<sup>2</sup> are equivalent and used in all clinical forms of leishmaniasis. Dosage is Sb 20 mg/kg/day IM for 21 to 28 days. In cases of uncomplicated cutaneous leishmaniasis, use intralesional administration intermittently over 20 to 30 days.
- Liposomal amphotericin B (Ambisome) is the gold standard for treating visceral leishmaniasis. Dosage: Total dose of 18 to 21 mg/kg IV using one of the following schedules: 3 mg/kg/day on days 1 to 5 and 10; 3 mg/kg on days 1 to 5, day 14, and day 21; 10 mg/kg/day for 2 days.
- Amphotericin B desoxycholate (Fungizone) is used in visceral leishmaniasis<sup>1</sup> and mucocutaneous leishmaniasis. Dosage is 0.5 mg/kg IV every other day for 14 days.
- Other parenteral drugs: Pentamidine isethionate (Pentam 300)<sup>1</sup> is used to treat some forms of New World cutaneous leishmaniasis; dosage is 2 mg/kg IM every other day for 7 days. Paromomycin (aminosidine) sulfate<sup>2</sup> is used for Indian visceral leishmaniasis; dosage is 11 mg/kg/day IM for 21 days.
- Miltefosine (Impavido)<sup>5</sup> is recommended for visceral leishmaniasis therapy in India and Ethiopia and for cutaneous leishmaniasis therapy in Colombia and Bolivia. Dosage is 2.5 mg/kg/day (not exceeding 100 mg/day) PO for 28 days.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>5</sup>Investigational drug in the United States.

<sup>10</sup>Available in the United States from the Centers for Disease Control and Prevention.

### Epidemiology

Leishmaniasis are diseases caused by members of the genus *Leishmania*, protozoan parasites infecting numerous mammal species, including humans. The flagellated forms (promastigotes) are transmitted by the bite of phlebotomine sand flies and multiply as aflagellated forms (amastigotes) within cells of the mononuclear phagocyte system. The diseases range over the intertropical zones of America and Africa and extend into temperate regions of Latin America, Southern Europe, and Asia. About 20 named *Leishmania* species and subspecies are pathogenic for humans, and 30

sand fly species are proven vectors. Each parasite species circulates in natural foci of infection where susceptible phlebotomines and mammals coexist. The epidemiology and clinical manifestations of the diseases are largely diverse, being usually grouped into two main entities: zoonotic leishmaniasis, where domestic or wild animal reservoirs are involved in the transmission cycle and humans play a role of accidental host, and anthroponotic leishmaniasis, where humans are the sole reservoir and source of the vector's infection.

Visceral leishmaniasis (VL) is caused by *Leishmania donovani* in the Indian subcontinent and East Africa (anthroponotic entity) and by *L. infantum* (*L. chagasi*) in the Mediterranean basin, parts of Central Asia, and Latin America (a zoonotic entity with domestic dogs acting as the main reservoir host). Several species of *Leishmania* cause cutaneous leishmaniasis (CL) or mucocutaneous (MCL) leishmaniasis. The most common are *L. major* (rural zoonotic entity) and *L. tropica* (urban anthroponotic entity) in the Old World and *L. mexicana*, *L. braziliensis*, *L. amazonensis*, *L. panamensis*, *L. guyanensis*, and *L. peruviana* (sylvatic zoonotic entities) in the New World.

Globally, 80 Old World and 21 New World countries are endemic for human leishmaniasis, with an estimated yearly incidence of 0.7 million to 1.2 million cases of CL forms and 0.2 million to 0.4 million cases of VL forms. Overall estimated prevalence is 12 million people with a disability-adjusted life years burden of 860,000 for men and 1.2 million for women. The disease affects the poorest people in the poorest countries: 72 are developing countries, of which 13 are among the least developed. The incidence is not uniformly distributed in endemic areas: 90% of CL cases are found in only seven countries (Afghanistan, Algeria, Brazil, Iran, Peru, Saudi Arabia, and Syria), whereas 90% of VL cases occur in rural and suburban areas of five countries (Bangladesh, India, Nepal, Sudan, and Brazil). These figures, however, must be regarded as underestimates; currently, it appears that the global incidence of human leishmaniasis is higher than before, owing to environmental and human behavioral factors contributing to the changing landscape of these diseases.

### Risk Factors

Risk factors for leishmaniasis are primarily associated with geographically and temporally defined human exposure to phlebotomine vectors. In the Old World, colonization and urbanization of desert areas have been identified as the major risk factor for outbreaks of zoonotic CL. Tourists and military personnel are often exposed to *L. major* or *L. tropica* infections in rural or urban endemic settings of North African and Middle Eastern countries. In the New World, the colonization of the primary forest associated with activities of deforestation, road building, mining, and tourism is responsible for the domestication of sylvatic cycles of CL and MCL agents. Increase in density and geographic range of phlebotomine vectors resulting from climate changes, together with the increased mobility of infected pet dogs, has been identified as a cause of northward spreading of zoonotic VL in Europe.

Individual risk factors play a major role in VL disease. Most of the *L. donovani* and *L. infantum* infections are asymptomatic or subclinical in well-nourished immunocompetent persons. Malnourished persons, infants younger than 2 years, and severely immunosuppressed adults are at high risk for acute VL when exposed to infection. Before the era of HAART (highly active antiretroviral therapy), the AIDS epidemics in southern Europe caused more than 2000 HIV and VL co-infection cases among men aged 39 years on average. Other conditions have been reported that influence the clinical outcome of VL, such as immunosuppressive therapies after organ transplantation, corticosteroid and anti-tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) treatments for immunologic disorders, hematologic neoplasia, and chronic conditions of hepatic cirrhosis. However, most acute VL episodes in adults remain unexplained. Other factors associated with impaired immune response to *Leishmania* (e.g., genetic factors) are probably involved.

## Pathophysiology

Ingestion of metacyclic promastigotes inoculated by the vector in the skin is mediated by several types of receptors found in resident macrophages, monocytes, neutrophils, and dendritic cells. *Leishmania* lipophosphoglycan, the most abundant surface glycoconjugate, is the main factor of virulence. Once in the cell phagolysosome, amastigotes survive from hydrolase activity through pH acidification while selectively inhibiting production of reactive oxygen species. Multiplication of parasites, infection of new cells, and dissemination to tissues are contrasted by the host's inflammatory and specific immune responses. Even in most susceptible natural mammal hosts, most infections are efficiently controlled, giving rise to asymptomatic latent infections. Leishmaniasis have typical immunologic polarity: Cure or control are associated with robust cellular immune responses driven by production of interleukin (IL) 12, whereas acute or chronic diseases are characterized by the absence of such responses and the presence of high levels of nonprotective serum antibodies, a condition often associated with high levels of IL-10 production. In spite of this polarity, analysis of cytokine patterns in tissues reveals a less-polar situation, as both  $T_H1$  and  $T_H2$  cytokines were found to be secreted in specimens from tissues infected with CL, MCL, and VL.

## Prevention

There are no human vaccines available for the immune protection against leishmaniasis. Promising data on safety and immunogenicity have been provided for the only *Leishmania* candidate vaccine under development, consisting of the recombinant polypeptide antigen LEISH-F1 with MPL-SE as adjuvant. Preventive measures are thus limited to the individual protection from sand fly bites or to community protection through reservoir control. Individual protection is through the use of repellents or insecticide-impregnated nets. Reservoir control measures are largely diverse, depending on the epidemiologic entity of leishmaniasis. Examples related to zoonotic entities with synanthropic reservoir hosts are the destruction of rodent populations around human dwellings (e.g., to control zoonotic CL due to *L. major*) and the fight against canine infections through the mass use of topical insecticides or drug treatments (e.g., to control zoonotic VL due to *L. infantum*). Early diagnosis and treatment of human cases is the main control measure against anthroponotic entities of VL (*L. donovani*) and CL (*L. tropica*).

## Clinical Manifestations

### Visceral Disease

VL, also known as kala-azar, results from the multiplication of *Leishmania* in the phagocytes of the reticuloendothelial system. In endemic settings, the ratio of incident asymptomatic infections to incident clinical cases varies from 4:1 to 50:1 depending on the epidemiologic type (anthroponotic VL is normally more virulent) and the poverty of the affected country. Classic VL manifests as pallor, fever, and hard splenomegaly; hepatomegaly is less common. Laboratory findings document pancytopenia and hypergammaglobulinemia. The clinical incubation period ranges from 3 weeks (exceptional) to more than 2 years, but 4 to 6 months is average. Patients report a history of fever resistant to antibiotics; on physical examination, the spleen is typically appreciated 5 to 15 cm below the left costal margin. Symptomatic VL is 100% fatal when left untreated.

### Cutaneous Disease

CL results from multiplication of *Leishmania* in the phagocytes of the skin. In the classic course of the disease, lesions appear first as papules, advance slowly to nodules or ulcers, and then spontaneously heal with scarring over months to years. The clinical incubation period ranges from 1 week (exceptional) to several months; lesions caused by *L. major* and *L. mexicana* tend to evolve and resolve quickly, whereas those caused by *L. braziliensis*, *L. tropica*, and dermatropic strains of *L. infantum* can have longer periods of incubation and spontaneous healing.

### Mucosal Disease

MCL results from parasitic metastasis in the nasal mucosal that eventually extends to the oropharynx and larynx. It can develop from CL lesions caused by *L. braziliensis* and *L. panamensis*. Typically, MCL evolves slowly (3 years on average) and does not heal spontaneously.

## Diagnosis

The standard diagnosis method for all forms of leishmaniasis is still the microscopy demonstration of *Leishmania* organisms in Giemsa-stained impression smears or cultures from samples of infected tissues. In general, sensitivity increases when both staining and culture are performed. Polymerase chain reaction (PCR) detection of *Leishmania* DNA on samples further increases the diagnostic sensitivity and also might allow species identification by target DNA sequencing or restriction fragment length polymorphism analysis.

Different tissue samplings must be performed depending on the clinical form of leishmaniasis. For VL, aspirate or biopsy specimens are obtained from the spleen, bone marrow, the liver, or enlarged lymph nodes. Higher diagnostic yields are obtained with spleen aspirates (more than 98%), although bone marrow aspirates (80% to 98% of yield) are usually preferred. For CL and MCL, material is obtained by scraping tissue juice from a nodular lesion or from the edge of an ulcer or by taking punch biopsies of inflamed tissue. Diagnostic yields of about 80% are obtained with impression smears and cultures during the first half of the natural course of the lesion. After that, standard parasitologic diagnosis becomes more difficult and PCR remains the only reliable method.

Serology is useful when the diagnosis of VL proves difficult with other methods. Commercially available dipstick tests using recombinant antigen K39 can be used in decisions for or against treatment. Negative serology results are common in CL and MCL, as well as in VL when patients are severely immunosuppressed.

## Differential Diagnosis

### Visceral Disease

The differential diagnosis depends on the local disease pattern associated with endemic areas. In many of them it includes chronic malaria, disseminated histoplasmosis, hepatosplenic schistosomiasis, typhoid fever, brucellosis, tuberculosis, endocarditis, relapsing fever, and African trypanosomiasis. Other cosmopolitan diseases include syphilis, lymphomas, chronic myeloid leukemia, sarcoidosis, malignant histiocytosis, and liver cirrhosis.

### Cutaneous Disease

A typical history of CL—an inflammatory, slowly developing, and painless skin lesion associated with recent exposure to sand fly bites—can strongly support a clinical diagnosis of disease. However, there is an extensive differential diagnosis, which includes acute or chronic forms of CL. For the former, insect bites, furuncular myiasis, and bacterial tropical ulcers are the most common; for the latter, keloid, lupus vulgaris, discoid lupus erythematosus, and sarcoidosis.

## Treatment

The therapy of leishmaniasis relies on a limited number of drugs, most of which are old and relatively toxic compounds. Systemic drug administration requires hospitalizing and monitoring the patient.

### Pentavalent Antimonials

Organic salts of pentavalent antimony (Sb) are still the mainstay therapy for all clinical forms of leishmaniasis. Two preparations are available that are equal in efficacy and toxicity when used in equivalent Sb doses: sodium stibogluconate (Pentostam),<sup>10</sup> available in English-speaking countries, and meglumine antimoniate (Glucantime),<sup>2</sup> available in Southern Europe and Latin America.

<sup>2</sup>Not available in the United States.

<sup>10</sup>Available in the United States from the Centers for Disease Control and Prevention.

The recommended dosage of Sb is 20 mg/kg/day for 21 to 28 days, given intramuscularly or intravenously. Treatment should be prolonged for 40 to 60 days in areas with documented Sb-resistant VL (e.g., in Bihar State, India). The drugs can be administered intralesionally in cases of uncomplicated CL, intermittently over 20 to 30 days. Systemic toxicity caused by the antimonials relates to the total dose administered and includes anorexia, pancreatitis, and changes on electrocardiography (e.g., prolongation of the QT interval), which can precede dangerous arrhythmias.

### Amphotericin B Drugs

Liposomal amphotericin B (Ambisome) is the current gold standard for VL treatment, being highly effective and nontoxic. However, the high cost of the drug precludes its use in developing countries where leishmaniasis is endemic. Liposomal amphotericin B is given intravenously at the total dose of 18 to 21 mg/kg, with various treatment schedules similarly effective: 3 mg/kg/day on days 1 to 5 and 10; 3 mg/kg on days 1 to 5, 14, and 21; or 10 mg/kg/day for 2 days.

Amphotericin B desoxycholate (Fungizone) is a relatively toxic compound used in Sb-resistant VL<sup>1</sup> and MCL, administered intravenously at the low dosage of 0.5 mg/kg every other day for 14 days. Doses in excess of 1 mg/kg/day commonly result in severe infusion-related side effects (fever, chills, and bone pain) and delayed side effects (toxic renal effects).

### Other Parenteral Drugs

Other parenteral drugs include old second-line drugs whose use is limited. Pentamidine isethionate (Pentam 300)<sup>1</sup> is a toxic compound used to treat some forms of New World CL resistant to Sb therapy and is given intramuscularly at the low dose of 2 mg/kg every other day for 7 days. Treatment in excess of this dosage can result in common side effects such as myalgias, nausea, headache, and hypoglycemia. Paromomycin (aminosidine) sulfate injection<sup>2</sup> (manufactured by Gland Pharma, India, on behalf of Institute of One World Health) is an old aminoglycoside that is being reevaluated as a first-line drug for Indian VL. It is given intramuscularly at the dose of 11 mg base per kg per day for 21 days. Elevation of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) liver enzymes is usually seen during therapy.

### Miltefosine, the First Oral Drug for Leishmaniasis

Miltefosine (Impavido)<sup>5</sup> is a hexadecylphosphocholine originally developed as an anticancer agent. It is the first recognized oral treatment for leishmaniasis and is available in Germany and India. So far, it is recommended for VL therapy in India and Ethiopia and for CL therapy in Colombia and Bolivia. The drug is administered at 2.5 mg/kg/day (not exceeding 100 mg/day) for 28 days. Miltefosine administration does not require the patient to be hospitalized for monitoring. Mild gastrointestinal toxicity may be common. The drug is contraindicated in pregnancy.

### Monitoring

In VL patients, fever recedes by day 3 to 5 of treatment, and well-being returns by the first week. Hematologic indices start to improve during the second week. Hemoglobin, serum albumin, and body weight are the most useful indicators of progress. The spleen tends to normalize 1 to 2 months after the end of therapy, although it can take up to 1 year to regress completely. Parasitologic assessment of cure is not normally necessary. Relapses can occur after apparent clinical cure from 2 to 8 months after treatment has been discontinued.

In CL patients, clinical response to drugs is rapid, but complete reepithelialization of lesions is observed in only one third of patients by the end of 3- to 4-week treatment courses.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>5</sup>Investigational drug in the United States.

## LEPROSY

### Method of

Carolina Talhari, MD, PhD; Maria Lucia Penna, MD, PhD; and Gerson O. Penna, MD, PhD

### CURRENT DIAGNOSIS

- Contact of susceptible person with untreated leprosy cases; travel to or residence in a leprosy-endemic country
- Skin lesion(s) with altered sensation
- Thickened or enlarged peripheral nerve, with sensory loss and/or weakness in the muscles supplied by the nerve
- Presence of acid-fast bacilli in a slit skin smear
- Skin biopsy with the presence of acid-fast bacilli or typical lesions, thereby aiding disease classification

### CURRENT THERAPY\*

#### Paucibacillary Leprosy (6 Months)

Adult (50–70 kg)

- Dapsone: 100 mg daily
- Rifampin (Rifadin)<sup>1</sup>: 600 mg once a month under supervision
- Clofazimine (Lamprene): 50 mg daily and 300 mg once a month under supervision

Child (younger than 10 years)

- Dapsone: 1 mg/kg daily
- Rifampin<sup>1</sup>: 10 mg/kg once a month under supervision
- Clofazimine: 1 mg/kg/day

#### Multibacillary Leprosy (12 Months)

Adult (50–70 kg)

- Dapsone: 100 mg daily
- Rifampin (Rifadin)<sup>1</sup>: 600 mg once a month under supervision
- Clofazimine (Lamprene): 50 mg daily and 300 mg once a month under supervision

Child (under younger than 10 years)

- Dapsone: 1 mg/kg daily
- Rifampin: 10 mg/kg once a month under supervision
- Clofazimine: 1 mg/kg/day

\*As recommended by the World Health Organization (WHO).

<sup>1</sup>Not FDA approved for this indication.

## Epidemiology

Leprosy is a chronic disease caused by *Mycobacterium leprae* that affects skin and nerves, often resulting in physical disabilities. The disease has been found around the world, showing that transmission occurs regardless of climate.

Disease transmission has ceased in nearly all developed nations, most likely because of better nutrition and socioeconomic development. Currently, new autochthonous cases are found in all tropical countries, with India, Brazil and Indonesia having the highest number of cases annually. Some insular countries located in the Pacific and Indian Oceans have the highest rates of new case detection, indicating a high risk of transmission. In 2020, there was a reduction of 27.7% in the global leprosy registered prevalence and 37.1% in the new cases detection rate compared with 2019. According to the World Health Organization (WHO), this decrease is probably caused by less detection and reporting during the coronavirus disease 2019 (COVID-19) pandemic.

In the Gulf region of the United States, mostly in the states of Louisiana and Texas, native cases are still diagnosed. There are armadillos (*Dasyurus novemcinctus*) in the area that have been infected with strains of *M. leprae* found also in autochthonous human cases. This suggests that leprosy might be a regional zoonosis, even though *M. leprae* was introduced into the Americas by Europeans and Africans. There are also records of *M. leprae* infection in armadillos in Central and South America. Furthermore, cases in African chimpanzees raise the possibility that these animals could be helping maintain leprosy transmission in Africa.

The mechanisms of leprosy transmission are not well known because there is no easy way to diagnose infection. It is presumed that in endemic areas, infection is much more frequent than actual disease onset. The incubation period can vary from a few months to more than 10 years, with an average of 2 to 5 years for paucibacillary (PB) leprosy and 5 to 10 years for multibacillary (MB) leprosy.

It is known that MB cases excrete large numbers of viable bacilli through nasal mucus, suggesting that transmission may be by respiratory route; in fact, this is believed to be the main source of transmission. Because *M. leprae* can be eliminated from ulcerated skin lesions, breast milk, urine, and feces, and it remains viable in the environment for many days, especially in humid climates, it is possible to theorize the existence of many different forms of transmission. The role of insects as vectors of bacilli is arguable.

Leprosy cases are not uniformly distributed in a community but tend to form clusters within different geographic regions, villages, or groups of domiciles. In most countries, cases are more common among men, and the 15- to 29-year-old age group tends to present the highest risk of disease. In areas where transmission is decreasing, the incidence tends to be higher among older adults, affecting those who lived during a period with a higher risk of infection.

Until recently, *M. leprae* was the only agent responsible for leprosy. In 2008, a new species called *Mycobacterium lepromatosis* sp. was described in Mexico as responsible for a diffuse form of the disease associated with increased morbidity and mortality. However, the clinical significance of this new entity, both in magnitude and in distribution, as well as particularities of the immune response to this pathogen, are not well known.

## Risk Factors

In endemic areas, the main risk factors are a history of household contact with leprosy cases and low socioeconomic status. It is estimated that home contacts of patients with MB leprosy show a 5 to 10 times increased risk of becoming ill; PB leprosy case contacts present a 2 to 3 times increased risk compared with a group with no history of home exposure. In general, the increased risk between contacts reflects the proximity of these individuals, inside the house, with the potential source of infection. Also important is the sharing of other factors by household members, such as genetic markers, behavior, diet, intercurrent infections, and contextual aspects related to socioeconomic and environmental conditions.

An important fact in leprosy is that, even when living for a long time and in the same house with an untreated MB leprosy patient, most people do not get sick. It is estimated that 90% of

the population have natural defenses against *M. leprae*. Today, there is evidence that susceptibility and resistance to *M. leprae* are genetically determined. The low frequency of genetically determined susceptibility may be the cause of the wide difference between infection and disease that is believed to exist.

Recent studies confirmed the association between risk of incident leprosy and socioeconomic factors as demonstrated by the Norwegian study almost a century ago.

## Prevention

Vaccination with bacille Calmette-Guerin (BCG)<sup>1</sup> reduces the risk of leprosy, with studies showing a variable efficacy of 20% to 80%. The revaccination of household contacts also provides protection, especially against the MB forms of the disease.

Chemoprophylaxis of contacts or high-risk groups with a single dose of rifampin (Rifadin)<sup>1</sup> has been shown to be effective for a period of 2 years. However, although the chemoprophylaxis trials reported a benefit, the relatively short duration of protection indicates functional limitations.

Combined strategies, including the active search for leprosy cases in the communities, integration of rapid diagnostic tests to facilitate the detection of early or asymptomatic cases, as well as both chemoprophylaxis and immunization, is suggested as an active control strategy with a great potential of reducing the incidence of leprosy.

Improving socioeconomic conditions in the general population in endemic areas is also a very effective strategy for disease control. This can be seen when comparing the current epidemiologic situation in the Hawaiian islands with Micronesia or the Marshall islands, where leprosy continues with a high incidence rate.

## Pathophysiology

*M. leprae* is an intercellular microorganism with a specific tropism for skin and peripheral nerve cells. It cannot be cultivated in vitro, but can be inoculated in mouse footpads and armadillos, although growth is quite slow. Active *M. leprae* infection is characterized by a wide clinical range, varying from a disease in which few bacilli are present in the body to one in which a high bacterial load is found in skin lesions.

Upon entering the organism, *M. leprae*, through its pathogen-associated molecular patterns (PAMPs), is recognized by pattern recognition receptors (PRRs) expressed in antigen-presenting cells (APCs), mainly dendritic cells (DCs), macrophages, monocytes, fibroblasts, and Schwann cells. Thus, the innate immune response of the host is initiated, in which a local inflammatory response can eliminate the bacilli, avoiding the disease, or when this does not occur, the innate immunity can regulate the response of host adaptive immunity according to the pattern of cytokines produced by APCs.

In adaptive immunity, the bacilli multiply within macrophages, enter the lymph stream and bloodstream, reach the regional lymph nodes, and from there move on to the organs of the mononuclear phagocyte system. The mycobacterial antigens are then processed and presented by APCs that can be Langerhans cells, DCs, or others from the monocyte-macrophage system that induce the hapten-protein conjugates to link the HLA-DR class II molecules to the CD4 T lymphocytes. In patients in whom there is stimulation of the T-helper 1 cell response, these lymphocytes will produce interferon (IFN)-gamma cytokines, tumor necrosis factor (TNF- $\alpha$ ), interleukin-2 (IL-2), IL-17, IL-1 $\beta$ , and IL-12, which will promote the differentiation of macrophages in epithelioid cells that will undergo a fusion process resulting in giant cells. This inflammatory response will be sufficient to reduce *M. leprae* in the tuberculoid form of leprosy. In the presence of massive tissue infiltration by CD4 T lymphocytes, large production of these cytokines occurs along with the chemokine CXCL-10, leading to edema and tissue inflammation of the leprosy type 1 reaction. The production of TNF- $\alpha$  and IFN- $\gamma$  by Schwann cells will lead to neural damage, which is also more significant in the type 1 reaction.

<sup>1</sup>Not FDA approved for this indication.

On the other hand, in the presence of stimulation of the TH2 subpopulation of T lymphocytes, these will produce the cytokines IL-4, IL-5, IL-6, IL-13, TNF- $\alpha$ , IL-10, and TGF- $\beta$ , the latter two produced by regulatory T lymphocytes (T-regs). TGF- $\beta$ , IL-4, and IL-10 are suppressors of macrophage activation, leading to an insufficient immune cell response to combat the level of *M. leprae* proliferation within the macrophages. This characterizes the more infectious forms of the disease at the lepromatous end of the spectrum. The cytokines IL-4, IL-5, IL-6, and IL-13 activate plasma cells and B lymphocytes, which together with complement activation, will form the immunocomplexes that will trigger leprosy type 2 reactions.

### Clinical Manifestations

Because of the complexity of the parasite-host relation and the variable efficacy of the host's cellular immune response, the clinical manifestations of the disease cross a wide spectrum. This can vary from an isolated nerve lesion or a single skin patch to a systemic disease with the presence of nodules or tubercles, generally on the face. The disease can affect several organs beyond skin and nerves, including eyes, testicles, and kidneys.

Ridley and Jopling, in 1966, proposed a case classification system that takes into consideration clinical, bacteriologic, histopathologic, and immunologic parameters: tuberculoid leprosy (TL), borderline-tuberculoid leprosy (BTL), borderline-borderline leprosy (BBL), borderline-lepromatous leprosy (BLL), and lepromatous leprosy (LL). Indeterminate leprosy (IL) can be considered the first clinical manifestation of the disease. Indeterminate leprosy can resolve spontaneously or evolve into one of the other clinical forms.

### Indeterminate Leprosy

This is characterized by one or more hypochromic macules with imprecise borders and reduced thermal sensitivity, although pain and tactile sensation may be preserved (Figure 1). These may occur as areas of sensory disturbance with no alteration in skin color, sweat glands, or hair growth. Any alteration in nerve function is preliminary, therefore there are no physical disabilities described with this classification. Bacilloscopic readings are negative.

### Tuberculoid Leprosy

This type is characterized by erythematous or hypochromic skin lesions with clear, raised borders (Figure 2). These are limited in number with an asymmetrical distribution and altered thermal sensation. Pain and tactile sensation may also be altered. Reduced perspiration and restricted partial or full alopecia may also be seen. Nerves can be affected intensively, but this usually only happens to a few. Slit skin smear results are negative.

Figure 1 Indeterminate leprosy.

Figure 2 Tuberculoid leprosy in a child.

Figure 3 Borderline-tuberculoid leprosy.

Among children, TL lesions may have the appearance of nodules or tubercles, generally only one on the face, named *nodular benign leprosy of childhood*. Although these lesions tend to regress spontaneously, treatment should continue as per standard ethical practice.

### Borderline-Tuberculoid Leprosy

This form is characterized by lesions similar to those seen at the TL end of the spectrum, although they are more numerous. In general, there are more than five lesions with a diameter of 10 cm or more, less clearly defined borders, and containing possible satellite lesions (Figure 3). These lesions tend to be more symmetrical and several nerves may be affected. However, most patients with this disease type will still have a negative bacilloscopy.

### Borderline-Borderline Leprosy

This is a relatively rare variation, given that it commonly evolves quickly toward the lepromatous pole, often spurred on by reaction episodes. There are usually many foveal lesions (infiltrated plaques with expanding outer borders and well-defined inner borders with apparently normal skin in the middle) (Figure 4). Generally, nerves are intensively affected, and skin smears are almost always positive.

### Borderline-Lepromatous (Virchowian) Leprosy

A wide number of lesions are present with a range of possible clinical manifestations (infiltrations, papules, plaques, foveae, and nodules) that are common to the lepromatous form. However, with this type there is a tendency to see some delimitation

**Figure 4** Borderline-borderline leprosy.

**Figure 5** Lepromatous (Virchowian) leprosy.

between the lesions and areas of healthy skin. Bacilloscopy is positive with a high bacterial load.

#### Lepromatous (Virchowian) Leprosy

This form has the highest bacterial burden of human bacterial infections. Extensive lesions tend to be symmetrical, erythematous, infiltrated, and without clear delineation from normal skin areas. Simple lesions evolve to become papules, tubercles, and nodules that can eventually ulcerate and that are especially full of bacilli (Figure 5). There is diffuse infiltration of the face, with auricular appendages affected in the vast majority of cases and bilateral madarosis also common. Hands and feet may also be infiltrated or showing signs of xerodermia.

LL is a systemic disease that can affect, the liver, spleen, adrenal glands, lymph nodes, eyes, and nose when patients are not treated properly and opportunely. Nasal obstruction can be present with little or no response to vasoconstrictors. Often the nasal cavities will be affected, and the oropharynxes will be full of nasal secretion highly abundant in bacilli. Subsequent nasal dryness can lead to secondary

ulceration and infection with possible perforation and destruction of the nasal septum, resulting in what is commonly referred to as *saddle nose*. With olfactory bulb dysfunction, anosmia will often be the outcome.

Lesions to the palate, lips, gum, and uvula can further compromise the pharynx, nasopharynx, and tonsils. The eyes may show erythema, dryness, dacryocystitis, lagophthalmos, and/or diminished sensation in the cornea. Likewise, iritis and iridocyclitis may be present, so proper intervention is necessary to ensure prevention of early onset of blindness.

The testes may also be directly affected by bacilli, as witnessed by atrophy of the testicular parenchyma and diffuse fibrosis with eventual sterility and alteration of sexual function. When secondary amyloidosis is present, renal insufficiency may result.

#### Variations of Lepromatous Leprosy

##### *Histoid Lepromatous Leprosy (or Wade's Lepromatous)*

This form of leprosy is rare. Nodular lesions are present, well defined, and of varying sizes. These may be round or oval with a reddish or pink color. These lesions contain a large number of bacilli and are normally associated with sulfone resistance. Histiocytes with a spongy appearance are present under histologic analysis.

##### *Diffuse Lepromatous Leprosy*

Described by Lucio, Alvarado, and Latapi, this is a diffuse form of LL, also called *beautiful leprosy* because this form confers a pinkish and healthy appearance to the skin. It is more frequently seen in Mexico and is characterized by the diffuse infiltration of the skin, altered sensation that starts in the hands and feet, loss of eyebrows, and telangiectasias in the face and torso. A mycobacterium was isolated in cases of diffuse lepromatous leprosy (DLL) with Lucio phenomenon, whose DNA cannot be amplified using usual *M. leprae* primers. As a result, a new species has been proposed under the name *M. lepromatosis*.

##### *Pure Neural Leprosy*

This type presents only nerve lesions without any cutaneous patches. The most common nerves affected are the ulnar, tibial, and fibular nerves. The radial, median, facial, trigeminal, and auricular nerves, among others, may also be damaged.

Neuropathic pain is often present spontaneously or when the nerve is palpated, either with or without thickening of the nerve. This can evolve to sensory loss, paresthesia, or muscular atrophy in the corresponding area, in addition to autonomic dysfunction and nerve abscess.

#### Leprosy Diagnosis

The patient is examined to locate any possible skin lesions with diminished sensation and/or areas of sensory alteration that may be caused by compromised peripheral nerves. Lighting must be adequate, and it is important to observe the entire body surface moving from head to toe. Where there are possible signs of disease, thermal, pain, and tactile sensation testing should be done, also looking for areas of alopecia and/or anhidrosis. It must be noted if there is any type of physical disability.

Bacilloscopy consists of collection and examination of skin smears taken from a suspected lesion, both earlobes, and both elbows, and helps classify a patient as PB with a negative examination result or MB when positive.

The bacilloscopic results will generally be negative in the IL, TL, and BTL, which are considered the PB group. Conversely, they tend to be positive in LL, BLL, and BBL, which are considered the MB group.

Ideally, the bacilloscopic reading should be expressed quantitatively as a bacteriologic index (BI) so it is possible to monitor the patient's progress during treatment. In patients with positive bacilloscopy at the time of diagnosis, it is recommended to repeat it at the end of therapy. Smear microscopy is important for differential diagnoses between reactions and relapse.

The histologic examination of a skin biopsy also helps provide a more precise disease classification and can help confirm the diagnosis in cases that are bacilloscopy negative. In

**TABLE 1** Main Differential Diagnosis by Leprosy Forms

INDETERMINATE LEPROSY	TUBERCULOID AND BORDERLINE-TUBERCULOID LEPROSY	BORDERLINE-BORDERLINE, BORDERLINE-LEPROMATOUS, AND LEPROMATOUS LEPROSY
Eczematiditis (Pityriasis alba)	Seborrheic dermatitis	Erythema nodosum
Seborrheic dermatitis	Dermatofitosis	Diffuse (anergic) cutaneous leishmaniasis
Localized scleroderma (morphea)	Granuloma annulare	Cutaneous and mucosal leishmaniasis
Residual hypochromia and achromia	Cutaneous leishmaniasis	Systemic lupus erythematosus and other rheumatologic diseases
Pityriasis versicolor	Discoid lupus erythematosus	Neurofibromatosis (von Recklinghausen disease)
Vitiligo	Pityriasis rosea Gibert	Pityriasis rosea Gibert
Hypochromic nevus	Psoriasis	Congenital syphilis, secondary syphilis, tertiary syphilis
	Sarcoidosis	Cutaneous lymphoma (Mycosis fungoides)
	Secondary syphilis	
	Cutaneous tuberculosis	

IL, there is a nonspecific inflammatory infiltrate, consisting of lymphocytes and sometimes histiocytes, around superficial and deep vessels that affects the cutaneous appendages, especially the neural fillets. The TL and BTL forms are characterized histologically by the presence of granulomas-histiocytes, which differentiate into epithelioid cells, giant cells, and lymphocytes, located around vessels, cutaneous appendages, and nervous fillets. Bacillus research is almost always negative. In BLL and LL forms, the inflammatory infiltrate is characterized by the predominance of foamy or vacuolated histiocytes, with large numbers of bacilli that are isolated or grouped in structures called *globias*.

In regions with limited access to laboratory resources, clinical diagnosis is sufficient to warrant the beginning of the standard leprosy treatment regimen, keeping in mind that this is the only dermatologic disease with altered sensation in lesions. The WHO suggests the classification of cases as either PB or MB based on the number of skin lesions, with MB cases having five or more such patches.

Available serologic testing does not show sufficient accuracy for disease diagnosis or infection. A recent meta-analysis using a fixed model to estimate the association of phenolic glycolipid (PGL)-1 positivity and clinical leprosy demonstrated that PGL-1 does not appear to be a useful test to determine which contacts should receive chemoprophylaxis.

Real-time polymerase chain reaction is available for leprosy and can act as a means of confirmation for diagnosis of PB leprosy cases.

### Differential Diagnosis

Differential diagnoses of leprosy include a variety of skin conditions, given the wide range of clinical manifestations in leprosy. The sensory loss symptomatic of leprosy can also be difficult to determine in children and in other diseases that produce changes in the normal skin characteristics (Table 1).

### Treatment

Leprosy treatment, like tuberculosis treatment, must deal with the resistance of *M. leprae* and its persistence. Single-drug therapy selects drug-resistant bacilli and should be avoided. Therapy duration has, as a target, the reduction of the number of persistent bacilli that could lead to relapses.

Standard multidrug therapy (MDT) with dapsone, rifampin (Rifadin),<sup>1</sup> and clofazimine (Lamprene) for 12 months for MB cases and 6-month MDT with dapsone and rifampin for PB cases has dramatically changed the prognosis for leprosy patients. However, the

evidence is rather weak on the efficacy of this drug regimen, especially regarding the necessary length of time for treatment, both in terms of the proportion of relapse cases and other outcomes, such as physical disability. The use of rifampin once a month was determined for financial reasons, and there is no study comparing this schedule with daily use. For this reason, research on new drugs and treatment regimens continues.

Shorter regimens were used but had shown high relapse rates: daily doses of rifampin<sup>1</sup> and ofloxacin (Floxin)<sup>1</sup> for 4 weeks; single-dose course of rifampin, ofloxacin, and minocycline (Minocin)<sup>1</sup> for single-lesion patients.

Fluoroquinolones (pefloxacin,<sup>2</sup> ofloxacin, and moxifloxacin [Avelox]<sup>1</sup>), macrolides (clarithromycin [Biaxin]<sup>1</sup>), and tetracycline (minocycline)<sup>1</sup> are effective against *M. leprae*. Only rifampin, its derivative rifapentine (Priftin),<sup>1</sup> and moxifloxacin are bactericidal drugs; all others are bacteriostatic.

In cases of intolerance or resistance to dapsone, this can be removed from the drug regimen, and for PB leprosy patients, clofazimine is used instead. For MB leprosy patients, in these cases, minocycline or ofloxacin can be used instead of dapsone, without alteration in treatment duration. When similar intolerance or resistance is related to rifampin, this should be substituted with a daily dose of 400 mg of ofloxacin. This alternate course lasts 6 months for PB leprosy cases and 24 months for MB leprosy cases.

For those who cannot take either dapsone or rifampin, PB leprosy patients can be treated with ofloxacin (400 mg/day) or minocycline (100 mg/day), and clofazimine (50 mg/day) in self-administered doses for 6 months. Similarly, MB patients can use ofloxacin plus minocycline plus clofazimine during the first 6 months of treatment (intensive phase), followed by 18 months with daily doses of ofloxacin or minocycline and clofazimine (maintenance phase).

### Perspectives on the Use of a Uniform Treatment for All Forms, Regardless of Clinical or Laboratory Classification

Despite the success of MDT, the complexity of operationalization of the scheme throughout the healthcare system, the prolonged treatment time, and the difficulty of patient adherence reinforce the need for shorter regimens that can be easily implemented in primary care. Since 2002, the WHO recommended clinical studies to investigate the viability of uniform multidrug therapy (U-MDT) for all leprosy cases, regardless of classification, with 6 months' duration.

The first randomized and controlled study on U-MDT, "Estudo independente para determinar efetividade do esquema Uniforme de MDT de seis doses (U-MDT) em pacientes de hanseníase,

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

(U-MDT-CT-BR),” was performed in Brazil and evaluated the efficacy of daily intake of dapsone plus clofazimine and monthly rifampicin for 6 months for both PB and MB leprosy patients, regardless of classification criteria. Between 2012 and 2018, 14 scientific articles were published from U-MDT-CT-BR; these showed that reduction in the duration of treatment did not increase relapse rates, reaction frequency, or neural damage. The Brazilian study also demonstrated no statistical differences in BI decrease between regular MDT and U-MDT. Moreover, the same study showed that U-MDT reduced *M. leprae*-specific antibodies during and after treatment.

Together with the results from three previous studies performed in China, India, and Bangladesh, U-MDT-CT-BR support the premise that U-MDT is an acceptable option to be adopted in endemic countries to treat leprosy patients in the field worldwide. These studies led the WHO to recommend the addition of clofazimine to PB leprosy treatment in 2019.

A recent study showed the existence of a high susceptibility genetic profile among leprosy patients predisposing to disease recurrence. The authors showed that recurrence or reinfection is not related to time of treatment but rather to individual genetic susceptibility. Additionally, a population-based study for the search for *M. leprae* resistance reported the emergence and transmission of resistant strains in a former leprosy colony located in the Brazilian Amazon. Taken together, these studies demonstrated the need to save the unnecessary use of these drugs and strongly support the decision to adopt the shorter uniform treatment for leprosy.

Dapsone and rifampin resistance have been reported. Although reports of clofazimine-resistant isolates of *M. leprae* are rare, multidrug-resistant leprosy reports are increasing and should be regularly monitored.

### Leprosy Reactions and Control

Over the course of this chronic disease, approximately 30% of the patients develop acute inflammatory episodes called *leprosy reactions*. These reactions can occur before diagnosis as well as during or after MDT treatment. They are commonly grouped into (1) type 1 (reversal) reactions (T1Rs) resulting from vigorous cell-mediated immune response and (2) type 2 reactions (T2Rs), the clinical manifestation of which is frequently erythematous nodosum leprosum (ENL) that comes about mainly from immunocomplex deposits. In patients with BBL and BLL, it is possible to have both reaction types simultaneously. There is also Lucio phenomenon, which is an immune system response with important clinical manifestations. Its physiopathology is not well understood, with abundant infection of *M. leprae* in endothelium, which can lead to thrombosis in the most superficial vessels from immunocomplex deposits with hemorrhaging and cutaneous infarction.

In the literature, a robust association has been demonstrated between bacterial load and the frequency of leprosy reactions. A reaction can be set off by various factors, such as pregnancy, childbirth, vaccinations, puberty, intercurrent infections, stress (physical, psychological, or surgical), use of potassium iodate/iodide (SSKI), and immune reconstruction inflammatory syndrome (IRIS) linked to antiretroviral and/or immune-based therapies.

Those patients who experience leprosy reactions during MDT treatment should continue taking their regimen without modification while also beginning a specific and concurrent treatment for the appropriate reaction type.

#### Type 1 Reaction or Reversal Reaction

Clinically, lesions become more erythematous and infiltrated, and those with previously diminished sensation can become more sensitive to touch. Desquamation may occur, and some lesions may even ulcerate. New lesions can erupt along with edema in the hands, feet, and face, as well general systemic symptoms. These reactions can last for years in some patients. It is important to begin an immediate intervention given that neuritis is the most common, serious, and potentially disabling clinical manifestation of T1R.

The drug of choice for T1R treatment is prednisone (or prednisolone [Millipred]) with a dosage of 1 to 2 mg/kg/day for at least 12 weeks, at which point it can be tapered off until discontinuing the medication around the 24th week.

Alternative drugs for a type 1 reaction include the following:

- Azathioprine (Imuran)<sup>1</sup>: 1 to 2 mg/kg/day, until reaction control
- Cyclosporine (Neoral, Sandimmune)<sup>1</sup>: 5 to 8 mg/kg/day, until reaction control
- Clofazimine: 300 mg to 30 days/200 mg to 30 days/100 mg to 30 days

#### Type 2 Reaction

This occurs in MB leprosy patients, and ENL is the most frequent clinical manifestation of T2Rs. Other variations of T2R are polymorphic erythema and vasculitis.

Clinically, ENL is a systemic condition with the eruption of painful and often symmetrical erythematous nodules on the arms and legs. When deeper, these nodules are more easily palpated than the more visible ones but will often ulcerate. Neuritis is frequent, although it is less aggressive than seen in T1Rs. The systemic impact can produce edema, myalgia, fever, malaise, asthenia, weight loss, cephalgia, iritis, episcleritis, iridocyclitis, glaucoma, epistaxis, arthralgia, and orchiepididymitis with testicular atrophy, glomerulonephritis, chronic renal insufficiency, hepatosplenomegaly, and amyloidosis.

The most common medication used for ENL is thalidomide (Thalomid) in variable dosage, from 100 to 400 mg/day, depending on the severity of the reaction. The distribution of thalidomide is restricted in some countries because of its teratogenic effects. For this reason, it should be given under strict supervision with proper medical, ethical, and legal measures in place.

For ENL associated with neuritis, iritis, orchitis, and/or hand-foot reactions or for women of childbearing age, a course of corticosteroids should be given (prednisone at 1 to 2 mg/kg/day).

In chronic cases and those that are nonresponsive to treatment, it is possible to administer clofazimine along with steroids at the initial dosage of 100 mg three times per day for a maximum of 12 weeks. This should be reduced to 100 mg twice daily for another 12 weeks and finally 100 mg/day for 12 to 24 weeks. Cyclosporine (Neoral, Sandimmune)<sup>1</sup> may also offer some benefit to the patient with serious ENL, as can the association of azathioprine (Imuran),<sup>1</sup> methotrexate,<sup>1</sup> and corticosteroids.

Alternative drugs for a type 2 reaction include the following:

- Azathioprine<sup>1</sup>: 1 to 2 mg/kg/day, until reaction control
- Cyclosporine<sup>1</sup>: 5 to 8 mg/kg/day, until reaction control
- Methotrexate<sup>1</sup>: 15 mg (IM/SC or PO)/week, until reaction control
- Pentoxifylline: (Trental)<sup>1</sup> 1200 mg/day, until reaction control
- Clofazimine: 300 mg to 30 days/200 mg to 30 days/100 mg to 30 days

#### Lucio Phenomenon

Lucio phenomenon can occur in LL patients. The skin lesions can be discrete and limited in number, pinkish or cyanotic, often very painful, and potentially necrotizing and ulcerative. This condition can lead to death. Treatment is based on a course of corticosteroid therapy appropriate for each patient.

#### Differential Diagnosis Between Relapse and Reaction

Relapse rates are very low, whereas reactions are quite frequent, even after completing treatment. Table 2 shows the main differences between reaction type 1 and type 2 relapse. Recently, an *M. leprae* whole-genome sequencing technique was used to discriminate between cases of relapse and reinfection.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Differences Between Reaction Type 1 and Relapse

REVERSAL REACTION	RELAPSE
Generally occurs during course of multidrug therapy or within 6 months of treatment completion	Occurs at least 2 years after treatment completion
Sudden and unexpected onset	Slow and insidious onset
Can be accompanied by fever and malaise	In general, no systemic symptoms present
Old lesions become erythematous, shiny, and infiltrated	Old lesions may present erythematous edges
In general, many new lesions	Few new lesions
There may be ulceration of the reaction lesions	Ulceration may occur on arms and legs in addition to the lesions
Regression with desquamation	No desquamation present
Can quickly affect several nerve trunks, with presence of pain, sensory alteration, and decreased motor function	May affect a single nerve, and functional alterations often take place very slowly
Excellent response to corticosteroid therapy	Does not respond well to corticosteroid therapy
Bacteriologic index stable or decreases	Bacteriologic index increases

### Complications

Leprosy complications are the result of permanent nerve damage. Lesions to the large nerve trunks, such as the ulnar, median, and tibial, cause motor and sensory loss leading to disabilities such as claw hand and footdrop.

The absence of sensation in the hands, soles of the feet, and cornea leaves these areas predisposed to common wounds and pressure ulcers. This reality demands that patients take specific care to avoid ulcers and detect them as soon as possible to prevent secondary infection. In addition, corneal ulcers can result in blindness.

### Acknowledgment

We thank Dr. Anna Maria Salles for the patient pictures.

## LYME DISEASE AND POST-TREATMENT LYME DISEASE SYNDROME

Method of

Carlos R. Oliveira, MD, PhD; and Eugene D. Shapiro, MD

### CURRENT DIAGNOSIS

- Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most common vector-borne infection in both the United States and Europe.
- Early localized Lyme disease is a clinical diagnosis that is based on the presence of a single erythema migrans rash. The rash presents as an expanding circular macule that is often uniformly erythematous but occasionally can have central clearing that gives it the appearance of a target lesion. Erythema migrans usually appears 7 to 14 days after a tick bite (although the bite often is not recognized). If untreated, it persists for about 3 to 4 weeks.
- Early disseminated Lyme disease can present as multiple erythema migrans, cranial nerve palsy, lymphocytic meningitis, radiculomyelitis (Bannwarth syndrome), or carditis.
- Arthritis is the primary manifestation of late Lyme disease. Typically it is an oligoarthritis that most often involves a single knee.
- Patients with no objective signs but only nonspecific symptoms (e.g., arthralgia, myalgia, fatigue, or perceived cognitive difficulties) are highly unlikely to have active Lyme disease as the cause regardless of the result of antibody tests.

- Antibody test results for Lyme disease are usually negative in patients with erythema migrans (single or multiple); therefore testing for antibody generally is only indicated for patients with non-cutaneous manifestations of Lyme disease.
- The IgG antibody test has good sensitivity for patients with Lyme disease  $\geq 4$  weeks after initial infection.
- Tests for antibodies to *B burgdorferi* should use a two-tier procedure, first with a sensitive quantitative test, usually either a whole-cell or C-6 peptide enzyme-linked immunosorbent assay (ELISA); if that result is either positive or equivocal, a more specific test, the Western immunoblot, is done to confirm a positive test result. The presence of antibodies against at least either 2 (for IgM) or 5 (for IgG) proteins of *B burgdorferi* is required for the immunoblot result to be considered positive. Modified two-tier antibody tests, which use a second (different) ELISA assay as the second tier test, have been approved for use by the FDA and are available.
- In patients with symptoms present for 4–6 weeks or longer, Lyme disease should not be diagnosed based on a positive IgM antibody result alone.
- Sensitivity of PCR assays of both blood and CSF are poor because concentrations of *B burgdorferi* in these fluids are low.
- Once serum antibodies to *B burgdorferi* develop, both IgG and IgM antibodies may persist for decades despite adequate treatment; therefore elevated concentrations of antibodies in serum do not necessarily indicate active infection.

### CURRENT THERAPY

- An oral course of doxycycline (Vibramycin)<sup>1</sup> for 10 days or of amoxicillin (Amoxil)<sup>1</sup> or cefuroxime axetil (Ceftin) for 14 days is highly effective for treating early localized Lyme disease.
- A 14-day course of the same antimicrobials also is highly effective in treating multiple erythema migrans and other manifestations of early disseminated Lyme disease, although patients with Lyme meningitis or complete atrioventricular block should be treated either parenterally with ceftriaxone (Rocephin)<sup>1</sup> or cefotaxime (Claforan)<sup>1</sup> or, in some instances, orally with doxycycline.<sup>1</sup>
- A 28-day course of an oral regimen is recommended for the treatment of Lyme arthritis.
- Doxycycline (Vibramycin) is contraindicated in women who are pregnant or are breastfeeding.
- The most effective preventive measure is avoidance of tick-infested areas. If exposure is unavoidable, visual inspection and prompt removal of embedded ticks, use of tick repellents with N, N-diethyl-3-methylbenzamide (DEET), and use of protective clothing have all been found to be modestly effective.
- An infected tick generally must be attached for 36 to 72 hours or longer for there to be a substantial risk of transmission of *B burgdorferi*. If a tick that has been embedded for at least 36 hours is removed, a single dose of doxycycline (Vibramycin) 8.8 mg/kg, maximum 200 mg,<sup>1</sup> given within 72 hours of removing the engorged tick, can be effective in preventing Lyme disease.
- Multiple or prolonged courses of antibiotics have not been shown to be effective and are not recommended for patients with only chronic, subjective symptoms after completing appropriate antibiotic treatment for Lyme disease.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology and Ecology

Lyme arthritis was first described in 1977 when an unusual cluster of children with arthritis in Lyme, Connecticut, was reported. Soon after, Willy Burgdorfer identified the causative bacterial agent, a spirochete that was later named *Borrelia burgdorferi*,

in *Ixodes scapularis*, the deer tick. Lyme disease, the most common vector-borne illness in both the United States and Europe, is transmitted by hard-bodied ticks of the *Ixodes* genus. In the United States, *Ixodes scapularis* (in the East and upper Midwest) and *Ixodes pacificus*, the Western black-legged tick (on the Pacific coast), can be vectors of Lyme disease. More than 90% of all cases in the United States occur in nine states: Connecticut, Maryland, Massachusetts, Minnesota, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. In Europe and in Asia, *Ixodes ricinus* (the sheep tick) and *Ixodes persulcatus* (the tiaga tick) can transmit *B burgdorferi*. *Ixodes* ticks feed once in each of the three stages of their 2-year life cycle: larva, nymph, and adult. There are a number of genomospecies of *Borrelia burgdorferi* sensu lato that cause Lyme disease. In the United States, Lyme disease is almost exclusively caused by *B burgdorferi* sensu stricto, whereas in Europe and in Asia, *Borrelia afzelii* and *Borrelia garinii*, in addition to *B burgdorferi* sensu stricto, are the major causes of Lyme disease.

Lyme disease is a zoonosis. The primary reservoir for *B burgdorferi* are small mammals, such as mice and chipmunks, although birds and other mammals, such as foxes and coyotes, can also serve as reservoirs of the organism. Deer are not a competent reservoir for *B burgdorferi*, but they are important for supporting the life cycle of the deer tick. Ticks are uninfected when they hatch. They can become infected after they feed on an infected animal. The bacteria live in the midgut of the tick, which must remain attached to a host for 36 to 48 hours or longer for the spirochete to travel to the salivary glands so it can be injected into the host. Although ticks may become infected at any stage of the life cycle, nymphs are more likely to transmit the organism. This is because their small size (<2 mm) makes them more difficult to detect than adult ticks. Consequently, nymphal ticks are less likely than are adult ticks to be removed before the organism can be transmitted. The most important risk factor for Lyme disease is exposure to ticks in an area in which the disease is endemic. Most cases of Lyme disease occur in the spring and summer, which correlates with peak activity of nymphal ticks and with frequent outdoor activity of humans.

### Pathophysiology

The pathogenesis of Lyme disease is predominantly driven by the host immune response to the spirochete. During the first stage of infection, after transfer of the organism to the skin, inflammation ensues that leads to an erythematous lesion at the site of inoculation. The spirochete does not produce toxins; however, it can disseminate via the bloodstream or through the lymph vessels. After dissemination, the spirochete can adhere to distal tissues, and an immune-mediated inflammatory reaction at these sites leads to the characteristic clinical manifestations of Lyme disease.

### Prevention

No vaccine is currently available to prevent Lyme disease in humans. The most effective preventive measure is avoidance of tick-infested areas. Tick repellents that contain N, N-diethyl-3-methylbenzamide (DEET) and the use of protective clothing (long sleeves and pants) have been found to be modestly effective at preventing Lyme disease. If exposure is unavoidable, frequent visual inspection with prompt removal of ticks is recommended. In endemic areas, if a nymphal or adult *Ixodes* tick is removed that is partially engorged (has been attached for at least 36 hours), a single dose of doxycycline (Vibramycin)<sup>1</sup> administered within 72 hours of removing the tick can be effective in preventing Lyme disease.

### Clinical Manifestations

The clinical manifestations of Lyme disease can be divided into three stages: early localized disease, early disseminated disease, and late disease. About two-thirds of patients with Lyme disease in the

United States have early localized disease, which is characterized by a single erythema migrans (EM) rash at the site of the tick bite (although the tick bite is recognized in only a minority of cases). The rash starts as an erythematous macule or papule and then expands as an annular macule that is often uniformly erythematous (about two-thirds of cases of EM), although it can have central clearing that gives it the appearance of a classic target lesion. EM usually appears 7 to 14 days (range 3–30 days) after the tick bite and, if untreated, may expand to an average of 15 cm in diameter before resolving after 2 to 4 weeks or longer. The rash may be asymptomatic or it may be accompanied by systemic symptoms such as fever, malaise, headache, stiff neck, myalgia, or arthralgia.

The second most common manifestation of Lyme disease is multiple EM, which accounts for 15% to 23% of the reported cases in the United States. Multiple EM, a manifestation of early disseminated Lyme disease, occurs when the spirochete disseminates via the bloodstream and presents as multiple erythematous round or ovoid macules that are usually smaller than most single EM lesions and are often accompanied by fever and other systemic symptoms. Other manifestations of early disseminated Lyme disease include cranial nerve palsy (especially facial palsy), lymphocytic meningitis, radiculomyelitis, and carditis. Cranial nerve palsies, especially facial nerve palsy, occur more commonly in children and account for approximately 3% to 5% of all cases of Lyme disease. In most cases, facial nerve palsy resolves within 4 to 8 weeks usually leaving minor, if any, obvious residua. Lyme meningitis occurs less frequently (1% to 2% of cases) and typically has a subacute presentation similar to, though often of longer duration, than that of enteroviral meningitis. There is a mononuclear pleocytosis in cerebrospinal fluid. Increased intracranial pressure with papilledema is not uncommon. Neurologic involvement in Lyme disease is more common in Europe and in Asia, presumably because local strains of the bacteria are more neurotropic. Carditis, which is found in fewer than 1% of cases, typically causes various degrees of heart block, which usually is asymptomatic and may be detected only with an electrocardiogram, but may manifest as syncope, dyspnea, or dizziness due to complete heart block. Sudden death due to Lyme carditis has been reported but is very rare.

Arthritis is the main manifestation of late Lyme disease, and in North America accounts for approximately 6% to 8% of reported cases. Lyme arthritis typically is an oligoarthritis that involves a single knee about 90% of the time. Symptoms of arthritis develop 2 to 6 months after the tick bite and present with objective signs of inflammation of the joint. Arthritis typically resolves 2 to 6 weeks after appropriate treatment, although it may persist or recur in 10% to 20% of treated patients.

In Europe and in Asia, uncommon manifestations of Lyme disease include borrelial lymphocytoma, a painless nodule commonly located on the ear, breast, or scrotum; and acrodermatitis chronica atrophicans, a chronic fibrosing skin lesion typically found on the extensor surfaces of the extremities.

### Diagnosis

Early localized Lyme disease is a clinical diagnosis based on a history of potential exposure to ticks in an endemic area and the presence of the characteristic EM rash. Antibodies to the organism typically appear 3 to 4 weeks after the initial infection. Consequently, serologic tests are not indicated in patients with EM because most will not have detectable antibodies. Although more patients with multiple erythema migrans may be seropositive at the time of presentation, a majority will still be seronegative early on. Moreover, detectable antibodies may never develop in patients who are treated early in their courses. In patients with extracutaneous manifestations of Lyme disease, serologic testing is useful in making a diagnosis. Tests for antibodies to *B burgdorferi* should use a two-tier procedure, in which a sensitive quantitative test, usually an enzyme-linked immunosorbent assay (ELISA) against either “whole cell” or C6 peptide antigens of the bacteria, is performed. If the result of the quantitative test is either positive or equivocal, a Western immunoblot is done to confirm the

<sup>1</sup>Not FDA approved for this indication.

specificity of the result. Modified two-tier antibody tests, which use a second (different) ELISA assay as the second tier test, have been approved for use by the FDA. As with most infections, once they develop, elevated concentrations of both IgM and IgG antibodies may persist for decades in symptom-free patients who have been cured of Lyme disease. A positive test result is evidence of prior exposure to the organism and is not evidence of active infection. In addition, false-positive antibody test results are common, especially in patients with a low prior probability of Lyme disease, such as those with chronic nonspecific symptoms such as arthralgia, myalgia, or fatigue, who do not have concomitant objective findings associated with Lyme disease. False-positive IgM test results are especially common. A diagnosis of Lyme disease should rarely be based on a positive IgM test result alone, especially in patients who have had symptoms for a month or longer.

Polymerase chain reaction (PCR) assays can detect the organism in skin biopsies, CSF, blood, or synovial fluid. However, because concentrations of the organism are low in both the blood and the CSF, sensitivity of PCR assays of these fluids is poor. Because the rash is so characteristic and because virtually all patients with Lyme arthritis will have a positive result for IgG antibodies to *B burgdorferi*, such assays rarely are needed to make a diagnosis. The organism can be cultured using special media, but sensitivity generally is poor, and it takes weeks for the organism to grow.

### Differential Diagnosis

The differential diagnosis of Lyme disease depends on the clinical stage of the illness. Single EM may be confused with ringworm, cellulitis, nummular eczema, granuloma annulare or insect bites. Southern tick-associated rash illness (STARI) manifests in a rash identical to EM. However, it occurs at the site of a bite from the lone star tick (*Amblyomma americanum*) and is most common in the south-central United States. The cause of STARI is unknown, but, unlike with Lyme disease, it is not associated with significant extracutaneous manifestations. Multiple EM may look very similar to erythema multiforme. Lymphocytic meningitis occurs with numerous viral infections, most commonly enterovirus. There are many other causes of carditis, including a number of viruses, as well as rheumatologic diseases such as lupus and rheumatic fever. There is substantial variation in how Lyme arthritis presents. Most often it is a subacute arthritis that may mimic rheumatoid arthritis or other more chronic arthritides, with <50,000 white blood cells/mL in the synovial fluid. However, it can present acutely and may mimic acute bacterial arthritis (like that due to *Staphylococcus aureus*), with >100,000 white blood cells/mL in synovial fluid.

### Relapse Versus Reinfection

Resistance of *B burgdorferi* to recommended antimicrobials has not been reported. First-line antimicrobial therapy for Lyme disease is highly efficacious, and bacteriologic treatment failures are very rare. In a study of patients with two or more episodes of EM that occurred years apart, it was shown that the episodes were caused by different strains of bacteria, indicating that reinfection, rather than persistence of the original organism, was the cause of repeated episodes of EM. Reinfection rarely occurs in patients with late Lyme disease, indicating that most such patients are immune. On the other hand, patients with early Lyme disease who are treated may become reinfected from a new tick bite, presumably because the organism was killed before a protective immune response could occur. Persistent or recurrent arthritis does occur in 10% to 20% of patients with Lyme arthritis. So-called antibiotic-refractory arthritis occurs when frank arthritis persists despite two or more courses of antimicrobial treatment. This may be due to either an autoimmune process or slow clearance of antigens of dead organisms. There is no evidence that the cause is failure of the antibiotic to kill the organisms.

### Post-Treatment Lyme Disease Syndrome and "Chronic" Lyme Disease

A small minority of patients with Lyme disease who have completed appropriate treatment may continue to have nonspecific

symptoms, such as fatigue, arthralgia, myalgia, or perceived cognitive difficulties, for weeks or months after completing treatment. These have been termed *post-treatment Lyme disease symptoms* and, if they persist for 6 months or longer and are disabling, they are referred to as *post-treatment Lyme disease syndrome* (PTLDS). It is not clear whether the frequency or the nature of these symptoms in patients with PTLDS is greater than that among the general population. In addition, several placebo-controlled, randomized clinical trials of prolonged courses (6 weeks or longer) of intensive antimicrobial treatment (e.g., with ceftriaxone) in patients with PTLDS have found there was virtually no benefit and substantial risk of adverse side effects of this treatment. Consequently, the Infectious Diseases Society of America, the American Academy of Pediatrics, the American Academy of Neurology, the American College of Rheumatology, and expert professional societies from many European countries do not recommend prolonged treatment with antimicrobials in patients with PTLDS. These patients are distinguished from patients with so-called "chronic" Lyme disease, who have complaints similar to those with PTLDS but who do not have evidence of ever having had Lyme disease. Of course, prolonged antimicrobial treatment is not indicated for these patients, who might better be described as having medically unexplained symptoms. Patients with either PTLDS or "chronic Lyme disease" are best managed by focusing on alleviating symptoms rather than with additional courses of antibiotic therapy. This is because long-term treatment with antibiotics has not been shown to provide benefit and is associated with substantial risks. Managing these patients can be challenging. Ideally, management decisions should be directed by a clinician who can both form a long-term therapeutic relationship with the patient, and who has substantial experience managing medically unexplained symptoms. Clinicians need to be aware that while there is no scientific evidence to support the existence of "chronic" Lyme disease, many of these patients are suffering, and thus, are vulnerable to those who would offer inappropriate and potentially harmful therapies.

### Chemoprophylaxis

A single dose of doxycycline (Vibramycin; 8.8 mg/kg, maximum 200 mg)<sup>1</sup> taken within 72 hours of a deer tick bite was effective in preventing Lyme disease. However, because the risk of Lyme disease after a recognized tick bite is low, prophylaxis generally is not recommended routinely, but only for those at higher risk, such as someone in an endemic area who removes an engorged nymphal stage deer tick.

### Treatment

Antimicrobial treatment of Lyme disease is highly effective and complications are rare (Table 1). The recommendations for treatment are summarized in the table. Antimicrobials that are highly effective and are considered first-line agents to treat Lyme disease orally include doxycycline (Vibramycin)<sup>1</sup>, amoxicillin (Amoxil)<sup>1</sup> and cefuroxime axetil (Ceftin). Amoxicillin (Amoxil) is the preferred agent for women who are either pregnant or breastfeeding. Because the risk of staining of teeth is low, use of doxycycline for ≤21 days of treatment in children <8 years of age is now considered acceptable. Doxycycline (Vibramycin) is the preferred oral agent due to its good activity against other tick-borne illnesses such as human granulocytic anaplasmosis. Although macrolides such as azithromycin (Zithromax),<sup>1</sup> clarithromycin (Biaxin),<sup>1</sup> and erythromycin (EES)<sup>1</sup> are effective for treating early Lyme disease, they may not be as effective as the first-line agents. When parenteral treatment is indicated, ceftriaxone (Rocephin)<sup>1</sup> is the preferred agent because of once-a-day dosing. Alternative antimicrobials such as cefotaxime (Claforan)<sup>1</sup> and penicillin G (Pfizerpen-G)<sup>1</sup> also are highly effective, although penicillin G is rarely used because of frequent dosing due to its short half-life.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Antimicrobials Recommended to Treat Lyme Disease

MANIFESTATION	FIRST-LINE AGENTS	ALTERNATIVE AGENTS	DURATION
Single or multiple erythema migrans, cranial nerve palsy, carditis that is asymptomatic or for which the patient is not hospitalized	Doxycycline (Vibramycin) <sup>1</sup> 4.4 mg/kg/day in 2 divided doses (maximum 100 mg/dose)	Azithromycin (Zithromax) <sup>1</sup> 10 mg/ kg/day in 1 dose (maximum 500 mg/dose)	14 days; for single EM, 10- days of doxycycline or 7–10 days of azithromycin is effective
	Amoxicillin (Amoxil) <sup>1</sup> 50 mg/kg per day in 3 divided doses (maximum 500 mg/dose)	Clarithromycin (Biaxin) <sup>1</sup> 7.5 mg/ kg in 2 divided doses (maximum 500 mg/dose)	
	Cefuroxime axetil (Ceftin) 30 mg/kg PO in 2 divided doses (maximum 500 mg/dose)	Erythromycin (E.E.S.) <sup>1</sup> 12.5 mg/ kg in 4 divided doses (maximum 500 mg/dose)	
Severe carditis, meningitis,* radiculomyelitis	Ceftriaxone (Rocephin) <sup>1</sup> 50–75 mg/kg IV in 1 dose (maximum 2 g/dose)	Cefotaxime (Claforan) <sup>1</sup> 150–200 mg/kg/day IV in 3 divided doses (maximum 2 g/dose) Penicillin G (Pfizerpen) <sup>1</sup> 200,000- 400,000 U/kg/day in 6 divided doses (maximum 4 million U/dose)	14 days; for severe carditis and for meningitis, an oral agent may be used to complete a course of treatment after substantial clinical improvement
Lyme arthritis <sup>†</sup>	Same oral agents used for EM	Same oral agents used EM	28 days

<sup>1</sup>Not FDA approved for this indication.

\*Some experts treat Lyme meningitis with doxycycline (Vibramycin)<sup>1</sup>, administered orally, 4.4 mg/kg/day in 2 divided doses (maximum 100 mg/dose), for 14 days.

<sup>†</sup>Patients with persistent or recurrent arthritis 4 weeks after completing treatment may receive either a second 4-week course of treatment orally or 2 weeks of treatment with a parenterally administered antimicrobial listed above.

For patients with single EM, a 10-day course of doxycycline or a 14-day course of either amoxicillin or cefuroxime is recommended. For multiple EM, cranial nerve palsy (without apparent meningitis) or carditis that is asymptomatic and for which the patient is not hospitalized, a 14-day course of an oral antimicrobial is recommended. For complicated carditis (complete heart block) and for meningitis, a 14-day course of a parental agent is recommended, although there is evidence that 14 days of doxycycline orally may be adequate for treating meningitis. Some experts complete a course of initial parenteral treatment with oral therapy after the patient has improved clinically. Patients with Lyme meningitis should be carefully evaluated for increased intracranial pressure which, if present, should be managed appropriately. There is no evidence that steroids are beneficial for patients with facial palsy due to Lyme disease. For treatment of Lyme arthritis, a 28-day course of an oral antimicrobial is recommended. Nonsteroidal antiinflammatory drugs may be effective for treating the pain and inflammation associated with Lyme arthritis.

## MALARIA

Method of

José D. Suárez, MD; Nestor Sosa, MD, MS; and Laura Naranjo, MD

### CURRENT DIAGNOSIS

- Malaria is endemic in tropical and subtropical areas of Africa, Asia, Oceania, and Central and South America.
- Suspect malaria in returning travelers and recently arrived immigrants from an endemic region with fever, accompanied by headaches, chills, malaise and body aches.
- The microscopic examination of Giemsa-stained thin and thick peripheral blood smears is the standard diagnostic method for malaria.
- Rapid antigen detection tests (RADTs) and polymerase chain reaction (PCR) testing can be used for initial diagnosis, but species confirmation and level of parasitemia require microscopy.

### CURRENT THERAPY

- Treatment selection should be based on *Plasmodium* species involved, geographic area where the infection was acquired, presence of resistance to antimalarial drugs, and disease severity.
- Intravenous (IV) artesunate is the recommended therapy for severe malaria. Alternative treatments are artemether-lumefantrine (Coartem),<sup>1</sup> atovaquone-proguanil (Malarone),<sup>1</sup> or quinine (Qualaquin)<sup>1</sup> plus doxycycline<sup>1</sup> or clindamycin.<sup>1</sup>
- Uncomplicated malaria caused by chloroquine-sensitive *Plasmodium* species can be treated with chloroquine or hydroxychloroquine (Plaquenil). Radical cure of *Plasmodium vivax* and *Plasmodium ovale*<sup>1</sup> requires subsequent therapy with primaquine or tafenoquine (Krintafel).
- Artemisinin combination therapies (i.e., artemether-lumefantrine [Coartem]) are the primary regimens for uncomplicated malaria caused by chloroquine-resistant *P. falciparum* or *P. vivax*.<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

## Introduction

Malaria is an important parasitic disease caused by protozoa of the genus *Plasmodium* (phylum Apicomplexa) and transmitted primarily by the bite of female *Anopheles* mosquitoes.

Malaria remains a formidable health problem, especially in sub-Saharan Africa and in other tropical regions in Southeast Asia, Oceania, and Latin America. The World Health Organization (WHO) estimates that in 2020, there were 241 million cases of malaria and 627,000 malaria deaths worldwide. The WHO and partners had projected a doubling of malaria deaths if the worst-case scenario of service disruptions occurred during the early months of the coronavirus disease 19 (COVID-19) pandemic, but in April 2020, a good response to adapt and implement WHO guidance to maintain essential malaria services during the pandemic was put in place. Nevertheless, an increase of 69,000 deaths was estimated over the previous year, and about two-thirds of these deaths (47,000) were caused by moderated disruptions during the COVID-19 pandemic.

The WHO African Region carries a disproportionately high share of the global malaria burden. In 2020, the region had 95% of malaria cases and 96% of malaria deaths. Children younger than 5 years of age accounted for an estimated 80% of all malaria deaths in the region. The economic losses from the disease, only in Africa, are estimated to reach \$12 billion per year.

In recent years, a significant investment has been made in malaria control and elimination efforts. According to the 2019 WHO World Malaria Report, governments of malaria-endemic countries and international partners invested an estimated \$2.7 billion in 2018. The incidence rate of malaria decreased globally between 2010 and 2018 from 71 to 57 cases per 1000 population at risk; the number of countries with zero or less than 100 indigenous cases also increased in the same period. These advances in malaria control can be explained by the use of long-lasting insecticidal nets, indoor residual spraying programs, rapid diagnostic testing, and access to artemisinin combination therapy (ACT).

## Epidemiology

Most cases of malaria occur in Africa, but cases are reported in other tropical and subtropical regions of Southeast Asia (the Greater Mekong region), Oceania, India, and Central and South America (Figure 1).

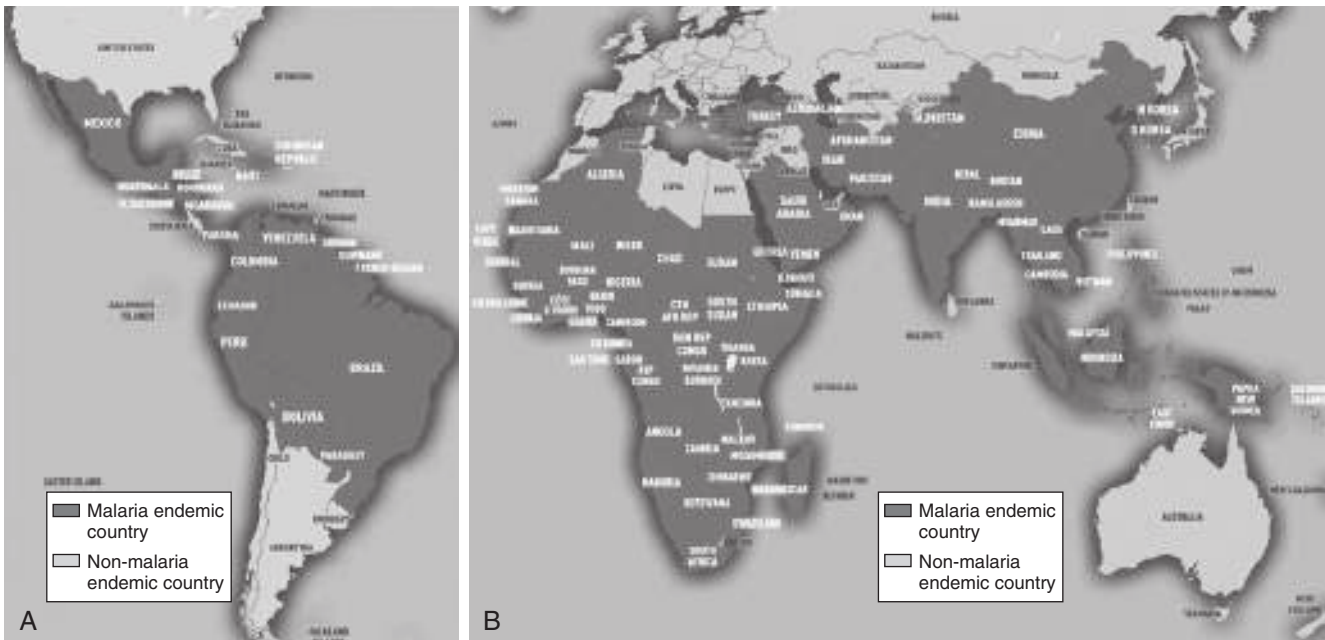

Five different species of *Plasmodia* have been associated with the disease: four human malaria parasites, *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*, and one simian plasmodia of macaque monkeys, *P. knowlesi*, which affects humans in Borneo and peninsular Malaysia.

*P. falciparum* is responsible for the great majority of cases overall, is the most prevalent in sub-Saharan Africa, and it is associated more frequently with the most severe and fatal forms of the disease. *P. vivax* is the most prevalent species in Southeast Asia and Central and South America; *P. ovale* circulates with a very low incidence in Africa, Asia, and Oceania; and *P. malariae* is rare but has been reported worldwide.

The infection is transmitted primarily from person to person via the bite of the female mosquito of the genus *Anopheles*. More than 30 different species of *Anopheles* have been associated with malaria transmission worldwide. Environmental factors, like relative humidity, elevation, and temperature, influence the transmission of malaria in the endemic areas. The highest transmission occurs during the wet or rainy season. Other less common modes of transmission include transmission from mother to child (congenital malaria), blood transfusions, needle sharing, and via solid organ transplants.

Most cases in nonendemic areas are reported in travelers and immigrants arriving from areas with local malaria transmission. Rarely, infected mosquitos can be accidentally transported in airplanes and cause cases in and around airport terminals in non-endemic regions, the so-called *airport malaria*. In the United States, the Centers for Disease Control and Prevention (CDC) reports about 2000 imported malaria cases every year, and it is a nationally reportable disease. Travelers to sub-Saharan Africa have the greatest risk of acquiring the disease. Sixty-nine percent of the cases reported in the United States in 2018 were caused by *P. falciparum*, 9.5% by *P. vivax*, 5.2% by *P. ovale*, and 2.6% by *P. malariae*. Of these cases for which the country of acquisition was known, 85% were acquired in Africa.

One of the greatest challenges for the prevention and treatment of malaria has been the development of drug resistance, especially among *P. falciparum*, but also reported with *P. vivax*. The patterns and geographical distribution of drug-resistant parasites is complex. Resistance to malaria medication continues to be an

**Figure 1** Malaria-endemic countries in the (A) western and (B) eastern hemispheres. Transmission occurs across most of Africa, Central and South America, Southern and Southeast Asia, as well as parts of the Caribbean, Eastern Europe, and the South Pacific. Countries are shaded completely, even if the area of endemicity is only in a small area of the country. (Modified from Centers for Disease Control and Prevention: *CDC Health Information for International Travel 2016*, New York, 2016, Oxford University Press. Public Domain.)

essential consideration when selecting drugs for treatment and chemoprophylaxis.

Since the 1970s, chloroquine resistance in *P. falciparum* has been confirmed in every continent where malaria is endemic, sparing only Mexico, Central America west of the Panama Canal, Haiti, the Dominican Republic, and a few Middle Eastern countries. High-grade chloroquine resistance in *P. vivax* has been reported in Papua New Guinea, the Solomon Islands, India, Myanmar, and Indonesia.

The emergence of resistance of *P. falciparum* to mefloquine (Lariam) has been documented in Myanmar (Burma), Lao People's Democratic Republic (Laos), Thailand, Cambodia, China, and Vietnam. Resistance to sulfadoxine/pyrimethamine (Fansidar)<sup>2</sup> and atovaquone/proguanil (Malarone) has also been reported. The resistance to these drugs has made ACT the treatment of choice for most cases of *P. falciparum* malaria. Unfortunately,

<sup>2</sup>Not available in the United States.

there have been recent reports of clinical failures and resistance to artemisinin derivatives from the five countries of Greater Mekong Subregions: Cambodia, Laos, Myanmar, Thailand, and Vietnam. There is now evidence of the clonal expansion of Pfkclch13 mutations in Rwanda (R561H) and Uganda (C469Y and A675V). However, treatment failure rates in Rwanda and Uganda remain below 10%.

### Parasite Life Cycle

The life cycle of the different species of *Plasmodia* are similar (Figure 2). The sexual cycle occurs in the mosquito, and repeated asexual cycles occur in the human host. The human infection starts when between 10 and 100 sporozoites—present in the salivary glands of the female *Anopheles* mosquito—enter the human host when the insect takes a blood meal. These sporozoites migrate from the dermis, invade the hepatocytes, and differentiate into hepatic schizonts that produce merozoites that later are liberated and invade circulating erythrocytes. *P. vivax* and *P.*

**Figure 2** The malaria parasite life cycle involves two hosts. During a blood meal, a malaria-infected female *Anopheles* mosquito inoculates sporozoites into the human host (1). Sporozoites infect liver cells (2) and mature into schizonts (3), which rupture and release merozoites (4). (In *Plasmodium vivax* and *Plasmodium ovale*, a dormant stage [hypnozoites] can persist in the liver and cause relapses by invading the bloodstream weeks to years later.) After initial replication in the liver via exo-erythrocytic cycle or tissue schizogony (A), the parasites undergo asexual multiplication in erythrocytes via erythrocytic cycle or blood schizogony (B). Merozoites infect red blood cells (5). The ring stage trophozoites mature into schizonts, which rupture, releasing merozoites (6). Some parasites differentiate into sexual erythrocytic stages (gametocytes) (7). Blood-stage parasites are responsible for the clinical manifestations of the disease. The gametocytes—male (microgametocytes) and female (macrogametocytes)—are ingested by an *Anopheles* mosquito during a blood meal (8). The parasites' multiplication in the mosquito is known as the *sporogonic cycle* (C). While in the mosquito's stomach, the microgametes penetrate the macrogametes, generating zygotes (9). The zygotes in turn become motile and elongated (ookinetes) (10) and invade the midgut wall of the mosquito, where they develop into oocysts (11). The oocysts grow, rupture, and release sporozoites (12), which make their way to the mosquito's salivary glands. Inoculation of the sporozoites (1) into a new human host perpetuates the malaria life cycle.

*ovale* preferentially invade younger erythrocytes (reticulocytes); *P. falciparum* invades all types of erythrocytes.

Differences in the duration of these exo-erythrocytic cycles explain the variations in the incubation period of the different species of malaria. The incubation period is 9 to 12 days for *P. knowlesi*, 9 to 14 days for *P. falciparum*, 12 to 17 days for *P. vivax*, and 16 to 18 days for *P. ovale*. *P. malariae* is the most variable with ranges from 18 to 40 or more days.

The erythrocytic cycles of invasion and growth take approximately 24 hours in *P. knowlesi*; 48 hours in *P. falciparum*, *P. ovale*, and *P. vivax*; and 72 hours in *P. malariae*. These differences explain the periodicity of the fever paroxysm seen with the different parasites.

Once in the red blood cells, the merozoites develop into ring forms and mature into trophozoites, schizonts, and finally merozoites that rupture the cells and invade other erythrocytes, repeating and amplifying this erythrocytic asexual phase.

Some of the trophozoites in the red blood cells mature into gametocytes, the cell form that begins the sexual cycle when taken up by the mosquitoes. The sexual cycle takes approximately 1 to 2 weeks within the mosquito. The gametocytes cross-fertilize in the mosquito midgut and become diploid zygotes that form an ookinete, and finally close to 1000 sporozoites that migrate to the salivary glands and can infect another human host.

In *P. vivax* and *P. ovale* infection, parasites may remain latent in the liver as hypnozoites and reactivate after months, or even years, causing relapses of the disease.

### Malaria Immunity

Acquired immunity to malaria is not sterilizing, but it protects against symptomatic and severe disease. It increases with age, number of episodes of the infection, and time spent living in the endemic area.

Several genetic polymorphisms seem to confer resistance to severe *P. falciparum* infection. Its relative increased prevalence in areas that are endemic for malaria demonstrates the natural selection forces of this disease over the human genome. Hemoglobin gene alterations like sickle cell disorders, thalassemia, hemoglobin C, hemoglobin E, and hemoglobin F; blood cell enzyme deficiencies like glucose-6-phosphate dehydrogenase; and certain blood group antigens (Duffy negative and ABO type O) have been associated with relative protection to infection or severe malaria.

Malaria is uncommon in neonates. The presence of fetal hemoglobin (hemoglobin F) and maternal antibodies may, in part, explain this observation.

### Clinical Manifestations

The incubation period ranges from 9 to 40 days and it is influenced by the specific parasite species involved, the immune status of the host, the administration of chemoprophylaxis, and the infecting dose of sporozoites.

After a vague prodromal period of 2 to 3 days, malaria classically manifests as an acute febrile illness with episodes of paroxysms characterized by chills (classically described as “teeth-chattering, bed-shaking chills”), rigor, high temperature ( $\geq 40^{\circ}\text{C}$ ), and profuse sweating, usually followed by fatigue and sleep. Other common symptoms include headache, weakness, insomnia, arthralgia, myalgia, and, less frequently, diarrhea, abdominal pain, or respiratory symptoms.

Individuals with prior immunity and children may present only with fever and headache; infants and very young children may present with irritability and a decrease in food intake.

The malaria paroxysms may recur every 24 hours (*P. knowlesi*), 48 hours (tertian fever in *P. vivax* and *P. falciparum*), or 72 hours (quartan fever in *P. malariae*). In primary infections, this periodicity may take several days to become apparent. The patient may be relatively asymptomatic between these paroxysms.

On physical examination, the patient may exhibit pallor, hepatosplenomegaly and, in severe cases, jaundice, altered mental status, and convulsions. Rash, pulmonary manifestation, and lymphadenopathy are rare.

**TABLE 1** Features of Complicated or Severe Malaria

FINDING	DESCRIPTION
Cerebral malaria	Diminished consciousness, Blantyre Coma Scale score of $\leq 2$ in children, Glasgow Coma Scale score $< 9$ in adults or seizures
Respiratory distress/pulmonary edema	Radiographic evidence, hypoxemia
Hyperparasitemia	$> 2\%$ or $> 100,000/\mu\text{L}$ in low-transmission settings; or $> 5\%$ or $> 250,000$ in high-transmission settings
Severe anemia	$< 5\text{g Hgb}$ or $< 15\%$ Hct
Hypoglycemia	$< 2.2\text{ mmol/L}$ or $40\text{ mg/dL}$
Jaundice/icterus	Clinically evident
Renal failure	Creatinine $> 265\text{ mmol/L}$
Hemoglobinuria	
Metabolic acidosis or hyperlactatemia	$\text{HCO}_3^- < 15\text{ mmol/L}$ or lactate $> 5\text{ mmol/L}$
Shock	SBP $< 70\text{ mm Hg}$ in adults; SBP $< 50\text{ mm Hg}$ in children
Abnormal spontaneous bleeding	

*HCO*<sub>3</sub>, Bicarbonate; *Hct*, hematocrit; *Hgb*, hemoglobin; *SBP*, systolic blood pressure.

### Severe or Complicated Malaria

Nonimmune individuals such as children or travelers to endemic areas or pregnant females may develop more severe manifestations of malaria. Complicated malaria, more commonly associated with *P. falciparum* infection, has been recently reported with *P. knowlesi* and *P. vivax*. The most important clinical and laboratory findings of complicated malaria are listed in Table 1. In parasitemic patients, the presence of any of the clinical or laboratory features of severe malaria represents a medical emergency, and hospitalization, admission into critical care units, and rapid initiation of specific treatment are important. Even in patients with less severe disease, it is advisable to hospitalize all nonimmune individuals during their initial treatment period because of the ability of *P. falciparum* infection to progress in just a few hours to severe and life-threatening complications.

The clinical presentation of complicated malaria may be different in children and adults. Cerebral malaria (see later) is more common in children; multiorgan system involvement is more frequent in adults. Important clues in the physical examination are prostration, deep breathing, a decreased level of consciousness, slow capillary filling, signs of congestive heart failure, hepatosplenomegaly, pallor, and decreased urine output. Mortality rates of complicated or severe malaria range between 15% and 22% in adults and between 8.5% and 10.9% in children.

### Cerebral Malaria

Parasite sequestration in the cerebral microvasculature is associated with a variable and potentially lethal constellation of symptoms that include a decreased level of consciousness, coma, generalized seizures, and/or focal neurologic deficits. Histopathologic findings frequently exhibit the presence of sequestered parasites, ring hemorrhages, perivascular leukocyte infiltrates, and immune-histochemical evidence of endothelial activation. In children with cerebral malaria, intracranial pressure is usually increased. Among those who survive, neurologic recovery can be rapid and complete, but sequelae have been reported in up to 15% of children with cerebral malaria. In patients with malaria who present with neurologic manifestations, it is important to exclude other conditions like meningitis, hypoglycemia, and other causes

of encephalopathy. Fundoscopic examination may be useful, revealing retinal hemorrhages and white exudates suggestive of malarial retinopathy.

### Respiratory Failure/Respiratory Distress Syndrome

Noncardiogenic pulmonary edema is a complication of severe *P. falciparum* malaria, seen more frequently in adults than in children. Sequestration of infected erythrocytes in the lungs is thought to be associated with the production of cytokines, increased vascular permeability, pulmonary edema, dyspnea, hypoxia and progression to acute lung injury, and respiratory distress syndrome. Patients may become hypoxemic and require mechanical ventilation.

### Acute Kidney Injury

Although mild proteinuria and oliguria can be present in uncomplicated malaria, acute renal failure—secondary to decreased renal perfusion, intravascular hemolysis, hemoglobinuria, acute tubular necrosis, and anuria—is a complication of severe malaria. Renal replacement therapy and general support through the critical period is associated with complete recovery of renal function in the majority of patients.

### Malaria During Pregnancy

Malaria during pregnancy, especially in nonimmune primigravida, is associated with increased morbidity and mortality. Pregnant women are particularly vulnerable to *Plasmodium falciparum* infection because red blood cells infected with the parasite can sequester in the placenta and thereby cause adverse fetal effects. The relative immunosuppression of pregnancy and parasite accumulation in the placenta related to its affinity with abundant chondroitin sulfate A (CSA) seem to be contributing factors for this phenomenon. Complications such as premature delivery, intrauterine growth retardation, low neonatal birth weight, increased newborn mortality, and maternal hypoglycemia and pulmonary edema have been reported. Placental malaria during subsequent pregnancies tends to be less severe than in the first pregnancy because of the development of immunity to CSA-binding parasites. The increased risk for acquiring malaria and developing more severe disease persists for at least 60 to 70 days postpartum.

If anti-malarial drugs do not achieve therapeutic levels in the placenta, parasites sequestered there may be released intermittently into the peripheral blood and cause recurrent maternal infection.

### Vertical Transmission

All species of malaria parasite can be transmitted in utero; congenital disease is most often associated with *P. falciparum* and *P. vivax*. Placental infection is a prerequisite for, but does not predict, congenital disease. Placental infection is more common than cord blood parasitemia, which is more common than detection of parasites in the infant's peripheral blood.

### Non-falciparum Malaria

*P. vivax* and *P. ovale* are usually not associated with severe disease, but acute lung injury and splenic rupture may occur. Severe cases of *P. vivax* have been reported in Papua New Guinea and Indonesia, with complications like severe anemia, cerebral malaria, and respiratory distress. Relapses of *P. vivax* and *P. ovale* caused by reactivation of the hypnozoites months or years after the initial infection is another characteristic of these two *Plasmodium* species.

*P. malariae*, the etiology of quartan fever, is associated with very low parasitemia and chronic indolent infection; however, nephrotic syndrome has been reported in young children in endemic areas.

In *P. knowlesi*, the clinical presentation is similar to uncomplicated *P. falciparum* malaria, but approximately 10% of cases may present with daily fever spikes, hyperparasitemia, metabolic acidosis, hepatic and renal dysfunction, respiratory distress, severe anemia, and refractory hypotension.

### Laboratory Diagnosis

The microscopic examination of Giemsa-stained thin and thick peripheral blood smears is the standard diagnostic method for malaria. Thick smears concentrate red cell layers by lysing the

erythrocytes and are used to screen a relatively large amount of blood. Thin smears are used to determine the *Plasmodium* species based on the morphology and characteristics of the circulating forms.

*P. falciparum* infections are characterized by the presence of thin ring forms, frequently positioned at the red cell membrane; multiple infected cells; banana-shaped gametocytes; and the absence of trophozoites and schizonts that are sequestered in the microvasculature. The smears of *P. vivax* and *P. ovale* have thicker rings, ameboid trophozoites, schizonts, and round gametocytes. Erythrocyte enlargement and Schüffner dots are common in *P. vivax* and *P. ovale* but absent in other malaria species. *P. malariae* has characteristic band forms, and *P. knowlesi* rings are similar to *P. falciparum*, but its mature forms and gametocytes are indistinguishable from *P. malariae*.

In addition to direct microscopy, other diagnostic methods, such as rapid antigen detection tests (RADTs), PCR, and serology are used in different settings.

RADTs are increasingly useful, especially in situations in which microscopy is not immediately available. RADTs are immunochromatographic tests that detect *Plasmodium* antigens, like *P. falciparum* histidine-rich protein 2 (PfHRP2) or pan-malarial *Plasmodium aldolase* (PMA). Some of these tests are specific for *P. falciparum* or *P. vivax*, whereas others detect antigens common to several *Plasmodium* species.

The reported sensitivity and specificity of most RADTs are high, frequently around 95% and 99%, respectively. In patients with low parasitemia (less than 100 parasites/ $\mu$ L), the sensitivity decreases.

Even when RADTs are positive, direct microscopy is indicated to confirm the diagnosis to the species level (based on morphology) and to estimate the level of parasitemia. Most RADTs are not useful to evaluate treatment response because they may remain positive for several weeks after successful treatment.

Deletions in the parasite's *pfhrp2* and *pfhrp3* (*pfhrp2/3*) genes renders parasites undetectable by RADTs that are based on histidine-rich protein 2 (HRP2). The WHO recommends that countries with reports of *pfhrp2/3* deletions (Brazil, Democratic Republic of the Congo, Djibouti, Ethiopia, Ghana, Sudan, Uganda, United Republic of Tanzania) or neighboring countries conduct representative baseline surveys among suspected malaria cases to determine whether the prevalence of *pfhrp2/3* deletions causing false-negative RADT results has reached a threshold for a change in RADT (>5% *pfhrp2* deletions causing false negative RADT results).

PCR detects segments of the parasite DNA using amplification. It is very specific and may be useful in very low parasitemia, but it is not yet readily available in most clinical settings where malaria patients are diagnosed.

Serologic tests, like indirect fluorescent antibody (IFA) tests, are not useful for routine diagnosis of acute cases of malaria. Antibody positivity may take several days or weeks to develop. Serology is useful to screen blood donors in transfusion-related cases, to detect infection as part of an evaluation for tropical splenomegaly syndrome (TSS) when parasitemia is below the level of detection for microscopy or RADTs, and to test treated and cured malaria patients.

Other nonspecific clinical laboratory abnormalities frequently detected in patients with malaria are anemia, with decreased hemoglobin and hematocrit, increased lactic dehydrogenase (LDH) levels, and decreased haptoglobin levels. The anemia is normocytic normochromic, but microcytosis is not infrequent, especially in patients with iron deficiency or thalassemia. The white cell count may be increased, decreased, or normal. Platelet counts may be decreased or normal. Mild hyponatremia may be present secondary to inappropriate secretion of antidiuretic hormone, vomiting, or urinary losses.

In severe cases of malaria, hyperbilirubinemia, metabolic (lactic) acidosis, increased creatinine, albuminuria, and hemoglobinuria may be present. Hypoglycemia may occur in patients with malaria. Contributing factors to hypoglycemia are impaired hepatic neoglucogenesis, decreased oral intake, and increased glucose consumption caused by the hypermetabolic state and hyperinsulinemia secondary to drugs like quinine or quinidine.

In African children with malaria, secondary bacterial infection, including bacteremia, is not uncommon.

**TABLE 2** Antimalarial Drugs: Activity and Side Effects

DRUG (TRADE NAME)	ACTIVITY	INDICATION	SIDE EFFECTS	COMMENTS
Chloroquine (Aralen), hydroxychloroquine (Plaquenil)	Blood schizonts (all <i>Plasmodia</i> ) and gametocytes ( <i>P. ovale</i> , <i>P. malariae</i> , <i>P. vivax</i> , <i>P. knowlesi</i> )	Treatment of choice for chloroquine-susceptible <i>Plasmodium</i>	GI symptoms, headache, dizziness, insomnia, visual changes, ototoxicity, retinopathy, and peripheral neuropathy	Safe in children and in pregnant patients
Atovaquone/Proguanil (Malarone)	Blood and tissue schizonts	Chemoprophylaxis and treatment of uncomplicated malaria outside endemic areas (in combination with artesunate <sup>1</sup> or primaquine <sup>1</sup> )*	Headache, cough, GI upset, dizziness, mucosal ulcerations, increased enzymes in LFTs	Safe in children >5 kg of body weight Contraindicated in severe renal dysfunction
Artemisinin derivatives <sup>†</sup> : artemether, artesunate, dihydroartemisinin <sup>‡</sup>	Blood schizonts and gametocytes	Treatment of choice for uncomplicated and severe <i>P. falciparum</i> malaria <sup>1</sup> in endemic areas	GI symptoms, dizziness, headache, neutropenia, increased enzymes in LFTs	Contraindicated in the first trimester of pregnancy
Quinine sulfate (Qualaquin) and Quinidine gluconate <sup>‡</sup>	Blood schizonts of all <i>Plasmodium</i> species, gametocytes of <i>P. vivax</i> , <i>P. ovale</i> , and <i>P. malariae</i>	Treatment of uncomplicated or severe malaria when ACTs are not available or cannot be used (early pregnancy) <sup>1</sup>	Tinnitus, hearing impairment or loss, nausea, headache, dizziness, dysphoria, visual changes, QT prolongation, angina, hypotension, vertigo, vomiting, diarrhea, hypoglycemia	Can be used in the first trimester of pregnancy
Tetracyclines: doxycycline (Vibramycin), tetracycline	Blood schizonts of all <i>Plasmodium</i> species	Chemoprophylaxis of <i>P. falciparum</i> Treatment of chloroquine-resistant <i>P. falciparum</i> and <i>P. vivax</i> <sup>1</sup> in combination with quinine	GI symptoms, dry mouth, stomatitis, photodermatitis, <i>Candida vaginitis</i> , anal pruritus	Contraindicated in children <8 years of age and in pregnant patients
Clindamycin (Cleocin)	Blood schizonts of all <i>Plasmodium</i> species	Severe <sup>1</sup> or uncomplicated malaria <sup>1</sup> in combination with artemisinin derivatives or quinine	GI symptoms (including <i>Clostridium difficile</i> colitis), rash	Not to be used as monotherapy
Mefloquine (Lariam)	Blood schizonts of all <i>Plasmodium</i> species	Chemoprophylaxis of all <i>Plasmodium</i> species <sup>1</sup> Treatment of <i>P. falciparum</i> malaria as part of ACT	GI symptoms, neuropsychiatric symptoms such as anxiety, irritability, paranoia, depression, hallucinations	Violent behavior reported with prolonged use Safe during pregnancy
Primaquine sulfate	Exo-erythrocytic forms (hypnozoites), gametocytes	Chemoprophylaxis of <i>P. vivax</i> -endemic areas <sup>1</sup> Treatment of <i>P. vivax</i> and <i>P. ovale</i> hypnozoites <sup>1</sup> (prevention of relapses or radical cure)	GI symptoms, severe hemolytic anemia in G6PD-deficient patients	Level of G6PD should be checked before primaquine use

\*Not recommended in endemic areas because of resistance to atovaquone.

<sup>†</sup>Used in combination with other agents, ACT is considered the treatment of choice for *P. falciparum* malaria in endemic areas. Available ACT agents include artemether plus lumefantrine (Coartem), which is the only FDA-approved treatment; artesunate plus amodiaquine (Coarsucam)<sup>2</sup>; artesunate plus mefloquine (Artequin)<sup>2</sup>; artesunate plus sulfadoxine-pyrimethamine (Fansidar)<sup>2</sup>; and dihydroartemisinin plus piperazine (Eurartesim).<sup>2</sup>

<sup>‡</sup>Quinidine gluconate intravenous formulation is the only FDA-approved treatment for severe malaria in the United States, but it is no longer available. Cardiac monitoring is recommended during treatment with this drug.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

ACT, artemisinin combination therapy; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; LFTs, liver function tests.

## Antimalarial Drugs

There are multiple drugs used in the treatment and prevention of malaria. Their indication depends on the species involved, availability of the medication, presence of drug resistance, and severity of the disease. Some of the drugs have activity against the erythrocytic phase or asexual forms and are referred to as *blood schizonticides*. Other antimalarial substances kill tissue

or exoerythrocytic parasites in the liver and are called *tissue schizonticides*. Tissue schizonticides prevent disease relapses in patients with *P. vivax* and *P. malariae*. Finally, other drugs demonstrate activity against gametocytes and decrease disease transmission, preventing the sexual stage in the mosquito. See [Table 2](#) for the name, activity, and side effects of the most commonly used antimalarial drugs.

Chloroquine (Aralen) and hydroxychloroquine (Plaquenil) are two of the oldest antimalarial drugs. They are considered blood schizonticides and also have gametocidal activity. They can be used in the prevention and treatment of all *Plasmodium* species in the absence of drug resistance, and they are considered the treatment of choice for *P. vivax*, *P. malariae*, *P. ovale*, and *P. knowlesi*. Unfortunately, chloroquine resistance in *P. falciparum* is widespread, and these drugs are no longer recommended for prevention or treatment, except in limited areas of Central America, the Caribbean, and the Middle East.

The combination of atovaquone/proguanil (Malarone) demonstrates activity against both tissue and blood schizonts and is frequently used in malaria prophylaxis or as part of multidrug regimens with primaquine<sup>1</sup> or artesunate<sup>1</sup> for the treatment of uncomplicated chloroquine-resistant malaria in returning travelers outside endemic areas. The emergence of resistance to the atovaquone component limits its use in endemic areas.

Artemisinin derivatives, like artemether, artesunate, and dihydroartemisinin,<sup>2</sup> have activity against blood schizonts and gametocytes. These substances are originally derived from the Chinese medicinal plant qinghaosu (*Artemisia annua*) and are frequently used in combination with other drugs. The available combinations are collectively referred to as *artemisinin combination therapy* (ACT) and include artemether plus lumefantrine (Coartem, approved by the U.S. Food and Drug Administration [FDA]); artesunate plus amodiaquine (Coarsucam, Arsuamoon),<sup>2</sup> artesunate plus mefloquine (Artequin),<sup>2</sup> dihydroartemisinin plus piperazine (Eurartesim),<sup>2</sup> and sulfadoxina plus pyrimethamine (Fansidar).<sup>2</sup>

ACT is considered the first-line treatment of uncomplicated *P. falciparum* malaria in endemic areas. The recent emergence of *P. falciparum* resistant to ACT in Southeast Asia is compromising the efficacy of these two drug combinations. A recent study demonstrated improved efficacy of a three-drug regimen (dihydroartemisinin plus piperazine plus mefloquine) in areas with artemisinin resistance. Artemisinin derivatives can be used in children and pregnant woman but are contraindicated during the first trimester of pregnancy. Oral monotherapy with artemisinin derivatives is strongly discouraged to prevent the development of resistance.

Quinine sulfate (Qualaquin) is one of the oldest antimalarial drugs and is derived from the bark of the Cinchona tree (*Cinchona calisaya*). Quinine sulfate demonstrates activity against blood schizonts and gametocytes of *P. vivax*, *P. ovale*, and *P. malariae*. It is used in combination with other drugs in severe malaria<sup>1</sup> and for uncomplicated chloroquine-resistant malaria species during pregnancy. Quinine has a narrow therapeutic index and can produce cardiac conduction disturbances (e.g., QT prolongation, angina) and lead to cardiac arrest. Hyperinsulinemic hypoglycemia has been observed in children, older adults and pregnant women. Intravenous (IV) preparations of quinine dihydrochloride and the antiarrhythmic quinidine gluconate were previously used as antimalarial drugs but are no longer available in the United States.

The antibiotics tetracycline and doxycycline (Vibramycin) display activity against blood schizonts; the latter is frequently used in travelers as prophylaxis for chloroquine- and mefloquine-resistant *P. falciparum* malaria. Tetracyclines can be employed in combination with quinine for the treatment of uncomplicated *P. falciparum* malaria and chloroquine-resistant *P. vivax* malaria.<sup>1</sup> These antibiotics should not be used as monotherapy against malaria, and they are contraindicated during pregnancy and for children younger than 8 years of age.

Clindamycin (Cleocin) is another antibiotic that acts as a blood schizonticide for all *Plasmodium* species. It is effective in combination with quinine for the treatment of uncomplicated *P. falciparum* malaria and for chloroquine resistant *P. vivax* when tetracyclines are contraindicated.<sup>1</sup>

Mefloquine (Lariam) is an antimalarial drug that is structurally related to quinine. It has a long half-life and has activity against blood schizonts of all *Plasmodium* species. It is used in prophylaxis of malaria but can be used as an alternative treatment of uncomplicated *P. falciparum* malaria and in combination with primaquine<sup>1</sup> (tissue schizonticide) in cases of chloroquine-resistant *P. vivax* infection. It is generally well tolerated, but central nervous system and psychiatric side effects, such as anxiety, depression, paranoia, hallucinations, and violent behavior, have been reported.

Primaquine is active against tissue or exoerythrocytic forms and gametocytes of malaria parasites. It is indicated in the radical cure of *P. vivax* and *P. ovale*<sup>1</sup> eliminating the hypnozoites and preventing relapses of the disease. Primaquine can be used for prophylaxis in travelers to areas when greater than 90% of the cases of malaria are caused by *P. vivax*.<sup>1</sup> In patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, primaquine administration may cause acute hemolytic anemia. The activity of the G6PD enzyme should be measured before its usage. Primaquine is also contraindicated during pregnancy and breast-feeding, unless the infant has been tested for G6PD deficiency.

Tafenoquine (Arakoda, Krintafel), an FDA-approved antimalarial drug related to primaquine. It is recommended for prophylaxis of all *Plasmodium* species (Arakoda) and as a radical cure of *P. vivax* infection combined with chloroquine only (Krintafel). Like primaquine, tafenoquine should not be used in individuals with G6PD deficiency, during pregnancy, or while breast-feeding.

Lumefantrine is an antimalarial drug used in combination with artemether (as Coartem) in the treatment of uncomplicated *P. falciparum* malaria. It is active against erythrocytic stages of all *Plasmodium* species. Possible serious adverse effects reported with this combination include QT prolongation, bullous eruption, urticaria, splenomegaly, hepatomegaly, hypersensitivity reaction, and angioedema. Artemether-lumefantrine (Coartem) is assigned a pregnancy category C by the FDA, and its use during pregnancy should only be considered when the benefits outweigh the risks.

For specific adult and pediatric dosing regimens, clinical indications, treatment duration, and primary and alternative antimalarial regimens, see [Table 3](#).

### Treatment of Uncomplicated Malaria

The CDC provides advice to healthcare providers on the diagnosis and treatment of malaria and can be reached Monday to Friday, 9 AM to 5 PM EST through the CDC Malaria Hotline (770) 488-7788, or toll free at (855) 856-4713. On off-hours, weekends, and federal holidays, call (770) 488-7100, and ask to have the on-call malaria clinician paged.

For *P. falciparum* or species not identified acquired in areas with chloroquine resistance, there are four regimens: Artemether-lumefantrine (Coartem) is the preferred regimen; alternatives are atovaquone-proguanil (Malarone); quinine plus either doxycycline,<sup>1</sup> tetracycline,<sup>1</sup> or clindamycin<sup>1</sup>; or mefloquine (Lariam). For cases of *P. falciparum* acquired in areas without chloroquine resistance, either chloroquine or hydroxychloroquine can be used. Alternatively, the same drugs used for chloroquine-resistant *P. falciparum* can be used.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Antimalarial Regimens and Dosing by Clinical Diagnosis and Resistance

CLINICAL DIAGNOSIS/ PLASMODIUM SPECIES/ DRUG SUSCEPTIBILITY	DRUG/PRESENTATION	PEDIATRIC DOSE <sup>#</sup>	ADULT DOSE
<b>Primary Regimens</b>			
Uncomplicated malaria/ <i>P. falciparum</i> / chloroquine-sensitive or uncomplicated malaria/ <i>P. malariae</i> or <i>P. knowlesi</i>	Chloroquine phosphate 1 tab = 500 mg (salt) (300 mg of base)	10-mg base/kg PO, then 5-mg base/kg PO at 6, 24, and 48 h. Total 25 mg base/kg	1 g salt (600-mg base) PO, then 500 mg in 6 h, and then 500 mg daily × 2 days. Total dose 2500 mg
	Hydroxychloroquine 1 tab = 200 mg (salt) (155 mg of base)		800 mg salt (620-mg base) PO, then 400 mg daily × 2 days. Total dose 2000 mg
<b>Primary Regimens</b>			
Uncomplicated malaria/ <i>P. falciparum</i> or species not identified Chloroquine resistance or unknown resistance	Artemether/lumefantrine (Coartem) <sup>*</sup> 1 tab = 20 mg/120 mg	The patient should receive the initial dose, followed by the second dose 8 h later, and then 1 dose bid for the following 2 days: 5 to <15 kg: 1 tab per dose 15 to <25 kg: 2 tabs per dose 25 to <35 kg: 3 tabs per dose ≥35 kg: 4 tablets per dose	4 tabs PO in a single dose, then 4 tabs after 8 h, then 4 tabs every 12 h × 2 days
	Atovaquone/proguanil (Malarone) <sup>†</sup> Adult tab = 250 mg/100 mg Pediatric tab = 62.5 mg/25 mg	5 to <8 kg: 2 pediatric tabs PO qd × 3 days 8 to <10 kg: 3 pediatric tabs PO qd × 3 days 10 to <20 kg: 1 adult tab PO qd × 3 days 20 to <30 kg: 2 adult tabs PO qd × 3 days 30 to <40 kg: 3 adult tabs PO qd × 3 days ≥0 kg: 4 adult tabs PO qd × 3 days	4 adult tabs PO in a single dose daily × 3 days
	Quinine sulfate (Qualaquin) 1 tab = 324 mg either:  Doxycycline <sup>1</sup> 100 mg <sup>‡</sup> Tetracycline <sup>1</sup> 250 mg <sup>‡</sup> Clindamycin <sup>1</sup> 450 mg	<b>Quinine sulfate:</b> 10 mg/kg PO tid × 3 days (7 days if Southeast Asia) plus one of the following: <b>Clindamycin:</b> 20 mg/kg/day divided tid × 7 days for children younger than 8 years <i>or</i> <b>Doxycycline:</b> 2.2 mg/kg/bid × 7 days <i>or</i> <b>Tetracycline:</b> 25 mg/kg/day PO divided qid × 7 days	<b>Quinine sulfate:</b> 648 mg PO tid × 3 days (7 days if Southeast Asia) plus <b>Doxycycline:</b> 100 mg PO bid × 7 days <i>or</i> <b>Tetracycline:</b> 250 mg PO qid × 7 days <i>or</i> <b>Clindamycin:</b> 20 mg/kg/day PO divided tid × 7 days
<b>Alternative Regimens</b>			
	Mefloquine <sup>§</sup> 1 tab = 250 mg	15 mg salt/kg (13.7-mg base) PO as initial dose, and then 10 mg salt/kg (9.1-mg base/kg) PO given 6–12 h after initial dose. Total dose: 25 mg salt/kg	750 mg (684-mg base) PO as initial dose, and then 500 mg PO × 1 dose 6–12 h later. <sup>#</sup> Total 1250 mg
<b>Primary Regimens</b>			
Uncomplicated malaria/ <i>P. vivax</i> or chloroquine-sensitive <i>P. ovale</i>	Chloroquine phosphate or hydroxychloroquine plus either primaquine <sup>1</sup> phosphate 1 tab = 15 mg (base) or tafenoquine <sup>1</sup> (Arakoda): 1 tab = 100 mg (Krintafel): 1 tab = 150 mg	<b>Chloroquine phosphate or hydroxychloroquine</b> see doses above <b>Primaquine phosphate:</b> 0.5 mg/kg base PO qd × 14 days <i>or</i> <b>Tafenoquine succinate:</b> 300 mg PO × 1 dose (children ≥16 years)	<b>Chloroquine phosphate:</b> see doses above <b>Primaquine phosphate:</b> 30 mg base = 2 tab PO qd × 14 days <i>or</i> <b>Tafenoquine succinate:</b> <sup>¶</sup> 300 mg PO × 1 dose

**TABLE 3** Antimalarial Regimens and Dosing by Clinical Diagnosis and Resistance—cont'd

CLINICAL DIAGNOSIS/ PLASMODIUM SPECIES/ DRUG SUSCEPTIBILITY	DRUG/PRESENTATION	PEDIATRIC DOSE <sup>#</sup>	ADULT DOSE
<b>Primary Regimens</b>			
Uncomplicated malaria/ <i>P. vivax</i> In case of suspected chloroquine-resistant <i>P. vivax</i>	1. Artemether-lumefantrine (Coartem) <sup>1</sup> plus either primaquine phosphate or tafenoquine	<b>Artemether-lumefantrine:</b> see doses above <b>Primaquine phosphate:</b> see doses above <b>Tafenoquine:</b> see doses above	<b>Artemether-lumefantrine:</b> see doses above <b>Primaquine phosphate:</b> see doses above <b>Tafenoquine:</b> see doses above
	2. 	3. Quinine sulfate <sup>1</sup> plus either doxycycline <sup>1</sup> or tetracycline <sup>1</sup> plus either primaquine phosphate or tafenoquine	<b>Quinine sulfate:</b> see doses above for 3 days <b>Doxycycline or Tetracycline:</b> see doses above <b>Clindamycin:</b> see doses above <b>Primaquine phosphate:</b> see doses above Tafenoquine can be used instead of primaquine in children ≥16 years: 300 mg PO × 1 dose	<b>Quinine sulfate:</b> see doses above for 3 days <b>Doxycycline or Tetracycline:</b> see doses above <b>Clindamycin:</b> see doses above <b>Primaquine phosphate or Tafenoquine:</b> see doses above
	4. Mefloquine plus either primaquine phosphate or tafenoquine	<b>Mefloquine:</b> see doses above <b>Primaquine phosphate:</b> see doses above Tafenoquine can be used instead of primaquine in children ≥16 years: 300 mg PO × 1 dose	<b>Mefloquine:</b> see doses above <b>Primaquine phosphate or Tafenoquine:</b> see doses above
Severe malaria	1. Artesunate IV 110-mg/vial followed by a complete oral course of one of the following: Artemether/lumefantrine <sup>1</sup> Atovaquone/proguanil <sup>1</sup> Quinine <sup>1</sup> plus doxycycline <sup>1</sup>	<b>Artesunate:</b> <20 kg 3.0 mg/kg IV at 0, 12, and 24 h. Continue q24h if unable to take oral medication <b>Atovaquone/proguanil</b> × 3 days (see doses above) <b>Artemether/lumefantrine</b> × 3 days (see doses above) <b>Quinine sulfate:</b> × 3 days (7 days if Southeast Asia) plus <b>Doxycycline:</b> 2.2 mg/kg q12h × 7 days	<b>Artesunate:</b> 2.4 mg/kg IV at 0, 12, and 24 h. Continue q24h if unable to take oral medication <b>Atovaquone/proguanil</b> × 3 days (see doses above) <b>Artemether/lumefantrine</b> × 3 days (see doses above) <b>Quinine sulfate:</b> × 3 days (7 days if Southeast Asia) plus <b>Doxycycline:</b> 100 mg q12h × 7 days

<sup>#</sup>Pediatric dose should not be higher than adult dose.

\*Artemether-lumefantrine: Take with food. Drug of choice in second/third trimester of pregnancy. Recommended by experts in the first trimester but not yet in the official guidelines.

†Atovaquone-proguanil: Take with food; repeat dose if patient vomits within 30 minutes; Not recommended in pregnancy.

‡Doxycycline and tetracycline: Not recommended during pregnancy or in children younger than 8 years of age. Avoid concomitant intake of divalent cations and antacids. The American Academy of Pediatrics now permits less than 21 days for any acute infection for children of all ages.

<sup>§</sup>Mefloquine: Not effective against strains of *P. falciparum* from Southeast Asia.

<sup>¶</sup>Tafenoquine succinate: Must have normal glucose-6-phosphate dehydrogenase activity.

<sup>#</sup>This is an off-label dose.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

Chloroquine or hydroxychloroquine can be used for most cases of malaria caused by *P. ovale* and *P. vivax*, *P. malariae*, and *P. knowlesi*. If these drugs are not available, artemether-lumefantrine (Coartem),<sup>1</sup> atovaquone-proguanil (Malarone),<sup>1</sup> mefloquine (Lariam),<sup>1</sup> or quinine<sup>1</sup> plus either doxycycline,<sup>1</sup> tetracycline,<sup>1</sup> or clindamycin<sup>1</sup> can be used. These regimens can be used for infections where chloroquine-resistant *P. vivax* has been reported (Papua New Guinea, Indonesia, Burma, and certain areas of Central and South America).

To eradicate *P. vivax* and *P. ovale* hypnozoites, patients should also be treated with either tafenoquine (Krintafel)<sup>1</sup> or primaquine phosphate.<sup>1</sup> Tafenoquine can be used in patients 16 years of age or older and is given as a single dose. If primaquine phosphate is used, the CDC recommends a dose of 30 mg (base) by mouth daily for 14 days. Because of reduced efficacy of primaquine in patients over 70 kg, the total dose of primaquine should be adjusted in these patients to 6 mg/kg. This total dose should be given in daily doses of 30 mg for the number of days needed to complete the total dose. As mentioned earlier, quantitative G6PD enzyme activity should be measured before the use of primaquine or tafenoquine.

<sup>1</sup>Not FDA approved for this indication.

## Treatment of Severe Malaria

Patients with severe malaria should be treated promptly. IV artesunate is the treatment of choice regardless of the species involved. Clinicians caring for patients with suspected severe malaria should call the CDC to obtain IV artesunate as part of an expanded-use investigational new drug (IND) protocol (see the CDC contact information provided earlier in this chapter). Oral therapies should be started while waiting for IV artesunate to arrive. The preferred antimalarial drug for interim oral treatment is artemether-lumefantrine (Coartem)<sup>1</sup> because of its fast onset of action. Other oral options include atovaquone-proguanil (Malarone)<sup>1</sup>, quinine<sup>1</sup> plus doxycycline (Vibramycin),<sup>1</sup> and mefloquine (Lariam).<sup>1</sup> Patients on treatment for severe malaria should have one set of blood smears (thick and thin) performed every 12 to 24 hours until a negative result (no *Plasmodium* parasites are detected) is reported.

After the course of IV artesunate is completed, if parasite density is  $\leq 1\%$  (assessed on a blood smear collected 4 hours after the last dose of IV artesunate), and the patient can tolerate oral treatment, a full treatment course with a follow-up regimen must be administered (see Table 3).

## Antimalarial Drugs in Pregnancy

Monitoring the safety of antimalarial drugs and understanding their pharmacokinetics is particularly important in pregnancy because of altered maternal physiology and risks to the developing fetus. The scheme will depend on drug susceptibility, the region where infection was acquired, gestational age, severity of the disease, and drug category.

For infections with chloroquine-sensitive *P. falciparum*, *P. vivax*, *P. ovale*, and *P. knowlesi*, chloroquine or hydroxychloroquine can be used during pregnancy. If resistance to chloroquine is suspected, quinine sulfate<sup>1</sup> plus clindamycin<sup>1</sup> or mefloquine<sup>1</sup> can be used for treatment during the first trimester of pregnancy. Artemether-lumefantrine (Coartem)<sup>1</sup> is the treatment of choice during the second and third trimesters of pregnancy in chloroquine-resistant malaria infections.

Primaquine and tafenoquine should not be given during pregnancy. Pregnant patients with *P. vivax* and *P. ovale* infections should receive chloroquine prophylaxis<sup>1</sup> (300 mg [base] PO once a week) for the duration of the pregnancy to prevent relapses. After delivery, patients with normal G6PD activity should be treated with primaquine or tafenoquine or continue with chloroquine prophylaxis for a total of 1 year. For women who are breast-feeding, infants should be tested for G6PD deficiency and, if found to have normal activity, oral primaquine can be given to the mother. Tafenoquine is not recommended during breast-feeding.

## Treatment of Pediatric Patients

The majority of cases and deaths, especially in sub-Saharan Africa, occur in young children. Prompt diagnosis and therapy initiation are key to prevent complications, like cerebral malaria in young children. Recommended treatment regimens are essentially the same as in adults, with few differences. Weight-based dose adjustments are necessary, and pediatric doses should not exceed those given to adults. Tetracycline and doxycycline should be avoided in children younger than 8 years of age. Tafenoquine is not indicated in those younger than 16 years of age. For complete details on dosing and treatment duration in pediatric patients, see Table 3.

## Prevention of Malaria

Prevention of malaria includes both chemoprophylaxis and measures taken to reduce the number of mosquito bites and vaccines.

Travelers to endemic areas can reduce mosquito bites by using *N,N*-diethyl-meta-toluamide (DEET 10% to 50%) or 7% picaridin-containing insect repellents on exposed skin (applied after sunscreen), wearing permethrin-treated clothing, wearing clothes and footwear that cover as much skin as possible, sleeping under permethrin-treated bed nets, staying in housing with air-conditioning and well-screened areas cleared of mosquitoes, and refraining from outdoor activity during peak *Anopheles* biting hours (from dusk to dawn).

Recommendations for chemoprophylaxis based on the country being visited can be found on the CDC website ([https://www.cdc.gov/malaria/travelers/country\\_table/a.html](https://www.cdc.gov/malaria/travelers/country_table/a.html)).

Several considerations must be taken into account for chemoprophylaxis in travelers to malarial areas. An individualized risk-benefit assessment should be conducted for every traveler, considering not only the region or country to be visited but also the itinerary and duration, specific cities or rural areas, types of accommodations, season (rainy or dry), and type of travel (adventure or business).

It is important to consider that no chemoprophylactic regimen is 100% effective, and other measures to decrease mosquito bites, as described previously, should be considered. If a person develops malaria while taking chemoprophylaxis, that particular drug should not be used as part of the treatment regimen.

The main drugs used for prophylaxis are atovaquone/proguanil, doxycycline, mefloquine, and tafenoquine. Recommended regimens according to the *Plasmodium* species and its pattern of resistance are detailed in Table 4.

Malaria vaccines have been studied primarily in children in endemic areas. In January 2016, the WHO recommended the RTS,S malaria vaccine for pilot introduction in selected areas of three African countries: Ghana, Kenya, and Malawi. The data showed that the vaccine has a favorable safety profile and significantly reduces severe, life-threatening malaria. Therefore on October 6, 2021, the WHO recommended that the RTS,S malaria vaccine be used for the prevention of *P. falciparum* malaria in children living in regions with moderate to high transmission. RTS,S/AS01 (Mosquirix) is a pre-erythrocytic recombinant protein vaccine based on the RTS,S recombinant antigen. It comprises the hybrid polypeptide RTS in which regions of the *P. falciparum* circumsporozoite protein, known to induce humoral (R region) and cellular (T region) immune responses, are covalently bound to the hepatitis B virus surface antigen (S). This recombinant fusion protein (RTS) is expressed in *Saccharomyces cerevisiae* together with free hepatitis B surface antigen (S) to form RTS,S virus-like particles. The formulation contains 25  $\mu\text{g}$  of RTS,S with the AS01 adjuvant system. The first dose of the vaccine is given to children from 6 weeks to 17 months of age. The first dose is given at 5 months of age. The first three doses are administered monthly, and the third should be completed by 9 months of age. The fourth dose should be administered at 15 to 18 months.

Two vaccine candidates are approaching late-stage clinical evaluation: the R21/Matrix-M vaccine targeting the *Plasmodium falciparum* circumsporozoite protein (PfCSP) and the attenuated whole-sporozoite *Plasmodium falciparum* sporozoites (PfSPZ) vaccine.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** Chemoprophylaxis of Malaria

LOCAL RESISTANCE PATTERN	DRUG	PEDIATRIC DOSE	ADULT DOSE
<b>Primary Regimens</b>			
Chloroquine-sensitive <i>Plasmodium falciparum</i>	1. Chloroquine phosphate 1 tab = 500 mg (salt) (300 mg of base)	8.3 mg/kg (5 mg/kg of base) PO 1×/week up to 300 mg (base) max dose. 1–2 weeks before travel, during travel, and for 4 weeks post-travel	500 mg (300-mg base) PO per week. 1–2 weeks before travel, during travel, and 4 weeks post-travel
	2. Atovaquone/proguanil (Malarone)* 1 adult tab = 250/100 mg 1 pediatric tab = 62.5/25 mg	5–8 kg: ½ pediatric tab 9–10 kg: ¾ pediatric tab 11–20 kg: 1 pediatric tab 21–30 kg: 2 pediatric tabs 31–40 kg: 3 pediatric tabs >40 kg: 1 adult tab per day with food 1 day before travel, during travel, and for 7 days post-travel	1 adult tab (250/100 mg) per day with food 1 day before travel, during travel, and 7 days post-travel
<b>Alternative Regimens</b>			
Nonchloroquine-resistant <i>Plasmodium vivax</i>	1. Tafenoquine† (Arakoda) ≥16 years only 1 tab = 100 mg		Before travel to malaria-endemic area (loading regimen): 200 mg once daily × 3 days (starting 3 days before travel) In endemic area (maintenance regimen): 200 mg once weekly (starting 7 days after last loading regimen dose) Post-travel: 200-mg one-time dose (7 days after last maintenance dose)
	2. Doxycycline 1 tab = 100 mg‡	8–12 years: 2.2 mg/kg once/day up to 100 mg/day 1–2 days before travel, during travel, and for 4 weeks post-travel	100 mg PO qd 1–2 days before travel, during travel, and for 4 weeks post-travel
	3. Mefloquine 1 tab = 250 mg§	Weekly dose by weight in kg 5 to <10 kg: 31.25 mg (½ tab) 10 to <20 kg: 62.5 mg (¼ tab) 20 to <30 kg: 125 mg (½ tab) 30–45 kg: 187.5 mg (¾ tab) >45 kg: 250 mg (1 tab) 1–2 weeks before travel, during travel, and 4 weeks post-travel	250 mg (228-mg base) 1 tab PO once per week 1–2 weeks before travel, during travel, and 4 weeks after travel
<b>Primary Regimens</b>			
Chloroquine-resistant <i>P. falciparum</i>	1. Atovaquone/proguanil* 1 adult tab = 250/100 mg 1 pediatric tab = 62.5/25 mg	5–8 kg: ½ pediatric tab 9–10 kg: ¾ pediatric tab 11–20 kg: 1 pediatric tab 21–30 kg: 2 pediatric tab 31–40 kg: 3 pediatric tab >40 kg: 1 adult tab Daily with food 1–2 days before travel, during travel, and for 7 days post-travel	1 adult tab/day with food 1–2 days before travel, during travel, and for 7 days after travel
	<b>Alternative Regimens</b>		
	1. Tafenoquine (Arakoda) 1 tab = 100 mg†	Not approved for malaria prophylaxis in patients <18 years of age	Before travel to malaria-endemic area (loading regimen): 200 mg once daily × 3 days (starting 3 days before travel) In endemic area (maintenance regimen) 200 mg once weekly (starting 7 days after last loading regimen dose) Post-travel: 200 mg one-time dose (7 days after last maintenance dose)
	2. Doxycycline 1 tab = 100 mg‡	8–12 years: 2.2 mg/kg once/day up to 100 mg/day 1–2 days before travel, during travel, and for 4 weeks post-travel	100 mg PO qd Start 1–2 days before travel, during travel, and 4 weeks post-travel
	3. Mefloquine 1 tab = 250 mg§	Weekly dose by weight in kg <9 kg: 5 mg/kg 15–19 kg: ¼ adult dose 20–30 kg: ½ adult dose 31–45 kg: ¾ adult dose >45 kg: adult dose	250 mg (228 mg base) 1 tab PO once per week, 2–3 weeks before travel, during travel, and for 4 weeks post-travel

\* Atovaquone-proguanil: preferred for short trips because of increase adherence.

† Tafenoquine: must have glucose-6-phosphate activity greater than 70% normal on a quantitative test. Preferred for longer trips because of few adverse effects.

‡ Doxycycline: the American Academy of Pediatrics now recommends that doxycycline can safely be administered for short durations (≤21 days) regardless of patient age; this does not apply to malaria prophylaxis because of required duration of dosing.

§ Mefloquine: start 3 weeks ahead, if feasible, to assess for intolerance. This is the current best option for pregnancy.

¶ Not FDA approved for this indication.

## MEASLES (RUBEOLA)

Method of

Jane A. Weida, MD

### CURRENT DIAGNOSIS

- Measles is a highly contagious viral illness with a prodrome of high fever, cough, conjunctivitis, and coryza.
- A pathognomonic antherm (Koplik spots—small clustered white lesions) may appear on buccal mucosa during the prodromal period.
- The incubation period is about 10 days to the onset of fever; the typical rash appears after about 14 days.
- Measles produces a red maculopapular rash beginning on the face and then becoming generalized.
- Patients usually have a history of exposure, particularly of travel to an endemic area or of contact with carriers or non-immunized individuals.

### CURRENT THERAPY

- No specific antiviral therapy is available
- Adequate hydration
- Bed rest
- Antipyretics
- Antibiotics if needed for bacterial complications

## Epidemiology

Before measles vaccines were introduced, measles caused millions of deaths worldwide each year. In the decade before the first measles vaccine was licensed in 1963, there were about 549,000 reported measles cases and 495 deaths annually in the United States. It is estimated that the actual incidence was much higher, possibly 3 to 4 million.

Measles was declared to have been eliminated from the United States in 2000, but outbreaks have occurred since then. As of February 3, 2022, there were no measles cases reported in the United States in 2022. There were 49 cases in the United States in 2021, and there were 13 cases in 2020. Conversely, in 2019 there were 1282 cases of measles in 31 states, the largest outbreak since 1992. The majority of these cases involved people who had not been vaccinated.

Most measles cases are caused by either travel to endemic areas or exposure to carriers or persons who have not been immunized. Travelers with measles continue to bring the disease to the United States. Measles can spread when it reaches an area where groups of people are unvaccinated, including areas where immunity dips below 95%.

Measles continues to be a major problem in many regions of the world. As a result of increased worldwide measles vaccination, reported cases and estimated measles deaths dropped from 2000 to 2016, increased during 2017 to 2019, then decreased again in 2020, possibly related to decreased surveillance as a result of the COVID-19 pandemic. Since 2000, measles deaths worldwide have decreased 94%, and it is estimated that measles vaccination has prevented 31.7 million deaths.

## Risk Factors

Being unvaccinated is the largest risk factor for measles in the United States. Infants who have lost maternal immunity but are too young to be immunized are at higher risk, as are individuals with vitamin A deficiency. Travel to international areas where measles is more common or where there is an outbreak also increases the risk of contracting the disease. If measles is suspected in a patient, a careful travel history should be obtained.

## Pathophysiology

Measles is caused by an RNA respiratory virus of the family *Paramyxoviridae* and genus *Morbillivirus*. It is one of the most highly contagious of the communicable diseases. The virus spreads from person to person via respiratory droplets from coughing or sneezing or via direct contact. Patients are usually contagious from about 4 days before to about 4 days after the rash appears. The fact that the disease is contagious before the onset of symptoms makes quarantining particularly difficult. The incubation period is generally 10 days before the prodrome and 14 days before the onset of the rash, but it may vary from 6 to 21 days.

The virus triggers an aggressive immune response. This leads to a suppression of the immune response to other pathogens, which can make the individual susceptible to secondary infections. This immune suppression can last for a few weeks to a few months, but in some cases, it may last for 2 to 3 years. These individuals may have increased mortality rates, another reason why immunization is so important.

Once a measles infection has cleared, the affected person gains lifelong immunity provided that they remain immunocompetent. Infants are protected by maternal antibodies for about 1 month in the case of an immunized mother and for about 4 months in the case of a mother who had a prior measles infection.

## Prevention

The best way to prevent measles is with measles vaccination. The Centers for Disease Control and Prevention (CDC) recommends measles-mumps-rubella (MMR) vaccination at 12 to 15 months of age, with the second dose at 4 to 6 years of age. Two doses are more than 99% effective. Students at post-high school institutions who are not immune to measles should have two doses of MMR vaccine at least 28 days apart. Adults born during or after 1957 who do not have evidence of immunity should receive at least one dose of MMR vaccine. Adults born before 1957 are assumed to have herd immunity. The vaccine should not be given to pregnant women or immunocompromised individuals.

International travelers should be protected against measles. Infants 6 to 11 months of age who are traveling internationally should receive one dose of MMR vaccine. Children 12 months of age and older should have documentation of two doses of MMR vaccine at least 28 days apart. Adults born during or after 1957

and teenagers without evidence of immunity should have two documented doses of MMR vaccine.

Despite the importance of measles prevention, some parents refuse to vaccinate their children. A study published in the United Kingdom in 1998 claimed to find a link between autism and MMR vaccine. The study was later proven to be erroneous and fraudulent. Subsequent repeated studies have consistently shown that there is no link between vaccines and autism. It is vital for clinicians to educate parents about the importance—which cannot be overstated—of MMR vaccination.

### Clinical Signs and Symptoms

Measles generally presents with a prodrome that includes high fever, malaise, anorexia, conjunctivitis, coryza, and nonproductive cough. Fever may reach over 40°C. Conjunctivitis may include redness, swelling, photophobia, and discharge. Koplik spots, which are small, clustered white spots surrounded by a red ring that appear on the buccal mucosa, are pathognomonic but are not always present.

The measles rash is erythematous and maculopapular. It usually appears first on the face and behind the ears and then spreads to the trunk and extremities. The rash lasts 3 to 7 days. Recovery begins soon after the rash appears.

### Diagnosis

Measles is usually diagnosed clinically, based on the presenting signs, vaccination history, and travel exposure history. Clinical diagnosis can be difficult when the incidence of measles is low. The World Health Organization (WHO) clinical case definition for measles is a person with fever and maculopapular rash and at least one of the symptoms of cough, coryza, or conjunctivitis.

Laboratory findings include leukopenia unless there is a secondary bacterial infection, as well as thrombocytopenia and proteinuria. The most commonly used serologic test is virus-specific immunoglobulin M (IgM) in serum or oral fluid. IgM antibodies may not be detectable until 4 or more days after the rash appears. Viral cultures may be obtained, although measles is technically difficult to culture. Nasopharyngeal swabs may also be obtained for detection of virus by polymerase chain reaction (PCR).

Measles is a reportable illness in the United States; therefore, suspected cases must be reported to the local health department without delay. The CDC recommends that serologic and viral specimens be collected in suspected cases of measles; clinicians can contact their local health department laboratories to find out which specimens to collect.

### Differential Diagnosis

During the prodromal stage, measles can easily be mistaken for other viral upper respiratory illnesses. Although Koplik spots are pathognomonic, they are easy to overlook. Once the rash has appeared, measles can still be mistaken for other illnesses, including erythema infectiosum, infectious mononucleosis, enterovirus, Kawasaki disease, chikungunya, Rocky Mountain spotted fever, rubella, and scarlet fever.

### Treatment

No specific antiviral treatment is available for measles. Treatment is supportive, including rest, adequate fluids, and antipyretics. Patients should be kept on bed rest until they are afebrile. Prompt recognition and treatment of secondary bacterial infections is essential. The WHO recommends the administration of vitamin A<sup>1</sup> to all individuals with measles. The CDC recommends treatment with vitamin A of children with severe cases of measles, such as those who are hospitalized. It is given immediately when the disease is diagnosed and then repeated the following day. In the United States, vitamin A is not routinely given for milder cases of measles.

### Monitoring

Most measles patients do not need hospitalization. For those who do, both standard and respiratory precautions should be initiated. Respiratory precautions should continue for 4 days after onset of rash for healthy children and for the duration of the illness for immunocompromised patients.

For those who have been exposed to measles and are not immune, MMR should be administered within 72 hours of exposure or immune globulin (Ig, GamaSTAN) administered within 6 days of exposure.

### Complications

Complications of measles can occur in up to 40% of patients; complications are highest in the very young, the very old, and those who are malnourished. Often the complications affect the respiratory tract, with pneumonia being the leading cause of death associated with measles. Pneumonia may be caused by a secondary bacterial or viral infection or by the measles virus itself. Otitis media is another common complication. Gastrointestinal complications include diarrhea and stomatitis. Measles keratoconjunctivitis is a common complication, especially in children with vitamin A deficiency.

Rarely, measles can cause severe central nervous system (CNS) complications. About 1 in 1000 cases of measles results in measles inclusion body encephalitis (MIBE), leading to fever, seizures, and progressive neurologic abnormalities seen over weeks to months. Measles causes about 1 to 2 deaths per 1000 as a result of respiratory or neurologic complications. Subacute sclerosing panencephalitis is a rare delayed neurologic complication of measles, occurring in about 1 in 10,000 to 100,000 patients. This fatal complication causes seizures and progressive intellectual and behavioral deterioration about 7 to 10 years following a measles infection.

## METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS

Method of

Elissa Rennert-May, MD, MSc; and John M. Conly, MD

### CURRENT DIAGNOSIS

- Healthcare-associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA) is endemic in many hospital settings. The strains are polyclonal, resistant to many non-β-lactam antimicrobials, and typically cause pneumonia, line-related infection, surgical site infection, bacteremia, and infrequently skin and soft tissue infections.
- Strains of community-associated MRSA (CA-MRSA) have risen exponentially over the past two decades. The strains are clonal, sensitive to many non-β-lactam antimicrobials, harbour multiple virulence factors, and typically cause pyogenic skin and soft tissue infections and occasionally severe necrotizing pneumonia, fasciitis, and multifocal osteomyelitis.
- HA-MRSA infections typically affect patients with multiple comorbidities in the healthcare setting, but CA-MRSA typically affects previously healthy persons.
- It can be difficult to differentiate infectious syndromes due to β-hemolytic streptococci versus CA-MRSA.

<sup>1</sup>Not FDA approved for this indication.

## CURRENT THERAPY

- Methicillin-resistant *Staphylococcus aureus* (MRSA) strains harbor resistance to the  $\beta$ -lactam antimicrobials, including oxacillin, dicloxacillin, cloxacillin<sup>2</sup>, nafcillin, methicillin<sup>2</sup>, and first-, second-, and third-generation cephalosporins.
- Healthcare-associated MRSA (HA-MRSA) strains are typically resistant to macrolides, clindamycin (Cleocin), aminoglycosides, and quinolones (with the exception of delafloxacin [Baxdela]) and are variably resistant to tetracycline and trimethoprim-sulfamethoxazole (Bactrim). They are sensitive to vancomycin (Vancocin) and the lipoglycopeptides, fusidic acid<sup>2</sup>, rifampin (Rifadin)<sup>1</sup>, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro), daptomycin (Cubicin), ceftaroline (Teflaro), and ceftobiprole (Zevtera)<sup>2</sup>.
- Community-associated MRSA (CA-MRSA) strains are resistant to macrolides and quinolones (with the exception of delafloxacin [Baxdela]) but usually are sensitive to aminoglycosides such as gentamicin (Garamycin), clindamycin, (Cleocin) and trimethoprim-sulfamethoxazole (Bactrim)<sup>1</sup>, in addition to vancomycin (Vancocin), the lipoglycopeptides, fusidic acid<sup>2</sup>, rifampin (Rifadin)<sup>1</sup>, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro), daptomycin (Cubicin), ceftaroline (Teflaro), and ceftobiprole (Zevtera)<sup>2</sup>.
- Empiric antimicrobial therapy should be guided by the clinical presentation, and when full sensitivities are available, the antimicrobials may be tailored accordingly.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

## Epidemiology

*Staphylococcus aureus* is one of the most frequently encountered bacteria causing human infections and may be considered as either methicillin-sensitive *S. aureus* (MSSA) or methicillin-resistant *S. aureus* (MRSA). MRSA was first described in 1961 and is resistant not only to the traditional antistaphylococcal  $\beta$ -lactam antibiotics (methicillin<sup>2</sup>, nafcillin, oxacillin, cloxacillin<sup>2</sup>, and dicloxacillin) but also other important  $\beta$ -lactam antibiotics, including the first- to fourth-generation cephalosporins and the carbapenem family, thus eliminating an important class of antibiotics from the clinician's armamentarium. The only  $\beta$ -lactams that have activity against MRSA are the advanced-generation cephalosporin agents ceftaroline (Teflaro) and ceftobiprole (Zevtera)<sup>2</sup>.

MRSA strains acquired in the hospital or other healthcare settings have traditionally been referred to as healthcare-associated MRSA (HA-MRSA), whereas community-associated MRSA (CA-MRSA) has referred to isolates acquired in the community setting and in the absence of traditional hospital or healthcare exposures for at least 1 year (overnight stays in an acute care or long-term care facility, surgery, dialysis, or presence of a central venous catheter). The term *community-onset HA-MRSA* has been used to describe the occurrence of MRSA infection in the setting of the presence of a healthcare exposure within the past year. MRSA has been recognized as a healthcare-associated pathogen since the 1970s and became endemic in hospitals in many countries, including the United States, United Kingdom, and many European countries, with exceptions being Denmark, the Netherlands, Scandinavia, and Canada. For several decades, MRSA was typically considered a hospital pathogen. Novel and virulent MRSA strains arising in the community and not associated with any traditional healthcare exposure risks were first encountered in the late 1990s in the United States, Australia, and some European countries and have since risen explosively on a global basis to become the predominant clone of *S. aureus* associated with community infections. Methicillin resistance among community isolates of *S. aureus* has been reported to be as high as 75% in some

<sup>2</sup>Not available in the United States.

US communities. More recently livestock-associated MRSA (LA-MRSA) has been reported on a global basis, and transmission of these strains from swine, cattle, and horses has been implicated as a source of human infections, particularly in farmers, abattoir workers, and veterinarians.

Specific genetic and molecular distinctions initially distinguished the HA- and CA-MRSA strains (Table 1) and have been used to characterize MRSA strains as likely of community versus health-care origin. The HA-MRSA strains were found to harbor large staphylococcal cassette chromosome (SCC*mec*) types known as SCC*mec* types I, II, or III; to have multidrug resistance to non- $\beta$ -lactam antimicrobials; to have the absence of specific virulence characteristics such as carriage of the Panton-Valentine Leukocidin (PVL) gene; and to have varying multilocus sequence types (ST5, ST239, ST 247, ST250). On the other hand, the CA-MRSA strains have been found to harbor SCC*mec* types IV, V, and more recently VI to XV have been described; to have paucidrug resistance to non- $\beta$ -lactam antimicrobials; to have the presence of specific virulence characteristics such as carriage of the PVL gene, and to have multilocus sequence types ST1, ST8, and ST80. LA-MRSA strains often are nontypeable or harbor SCC*mec* V, have high rates of tetracycline resistance, carry multiple virulence factors, and are most often multilocus sequence types ST398 or ST9. However, over the past few years, healthcare-associated strains have moved into the community and likewise community strains have spread rapidly within hospitals, and the original distinctions between CA-MRSA and HA-MRSA from an epidemiologic perspective have become increasingly blurred. The point of transmission of MRSA is not always possible to identify with certainty, making the classification of CA and HA strains increasingly imprecise.

## Risk Factors

The risk factors for HA-MRSA may be viewed from the perspective of the healthcare environment and patient-specific risk factors. A major risk factor for acquiring HA-MRSA is exposure to a healthcare setting and particularly in hospital or other institutional settings where the prevalence of carriage of MRSA among patients is high. Additional risk factors in the healthcare environment include poor hand hygiene practices among hospital employees, contaminated bedside equipment and surfaces, overcrowding, and reduced healthcare worker-to-patient ratios. Patient risk factors (see Table 1) include aging, multiple comorbidities, receipt of antibiotics within the preceding 3 months, prolonged duration of hospital stay, admission to a long-term care facility or hospital in the previous year, invasive procedures, and the presence of indwelling catheters or other devices. Initial risk groups for CA-MRSA were injection drug users, homeless populations, incarcerated persons, and indigenous peoples. The Centers for Disease Control and Prevention have suggested the five Cs (Figure 1 and Table 2) as contributing factors implicated in the transmission among these groups. The initial risk groups have expanded (Table 3) to include men who have sex with men (MSM), athletes (especially those involved in team and contact sports), military personnel, those with a prior history of abscesses, individuals with chronic skin disorders, individuals with recent antibiotic receipt, underserved urban populations, individuals who have contact with colonized pets or livestock, and veterinary workers. In the drug-using and underserved urban populations, prevalence and social networking studies have identified hospices, shooting galleries, and crack houses as key sites in which CA-MRSA transmission may occur. Recent outbreaks have been reported in hospital nurseries, daycare settings, nursing home workers, schools, and college dormitories. Sexual transmission has been reported, but it may reflect close skin-to-skin genital contact rather than a true sexually transmitted pathogen. CA-MRSA has now become endemic in the general population in many communities, and the elderly and the very young seem to have a predilection for infection, especially if other risk factors are present. Risk groups for LA-MRSA include farmers, their family members and farm hands who are engaged in livestock production (especially swine and cattle), abattoir workers, veterinarians, and veterinary assistants. Recent transmission of strains of LA-MRSA has been reported in the hospital setting as well.

**TABLE 1** General Features Differentiating HA- and CA-MRSA\*

CHARACTERISTIC	HA-MRSA	CA-MRSA
Drug resistance to non- $\beta$ -lactams	Multiresistance	Pauciresistance
Pathogenicity islands	Few	Multiple
Age predilection	Older	Younger
Comorbidities	Multiple	None
Traditional risk factors	Healthcare contact, prolonged hospital stay, poor hand hygiene, contaminated equipment, invasive procedures, medical devices, recent antibiotic use	Crowded community environment, lack of cleanliness, loss of skin integrity, intravenous drug user, homelessness, incarceration, aboriginal, HIV+, contact sports, athletes, military, chronic skin disorder, veterinary worker

\*Features are generalizations only given the appearance of community strains replacing traditional hospital strains in the health care setting and the appearance of typical HA strains in the community setting.

### Pathophysiology

The resistance to the antistaphylococcal  $\beta$ -lactam antibiotics in MRSA strains is imparted by the presence of an altered configuration for a specific penicillin-binding protein (PBP) known as PBP2a in the cell wall of staphylococci. Normally the PBPs would act as a site for the attachment of the active moieties of the  $\beta$ -lactam agent, which then would inhibit further cell wall assembly. The alteration in the configuration of PBP2a occurs as the result of the presence of the SCCmec gene in *S. aureus*, which confers resistance to the  $\beta$ -lactam antibiotics. The origins of the mec gene and its insertion into the SCCmec element are not known with certainty. Once the MRSA strains acquired resistance to the antistaphylococcal  $\beta$ -lactam antibiotics in the healthcare setting, it is not difficult to appreciate how it emerged as a predominant pathogen in the hospital setting over the years, with increasing acuity of illness in the patient populations and increased use of broad-spectrum antimicrobials.

The appearance and rapid spread of CA-MRSA with the clinical impression of more virulent and lethal infections than what had been seen with traditional HA-MRSA strains may be explained by several factors. The SCCmec IV genetic element is very widely distributed among *S. aureus* isolates, which may explain its appearance in multiple settings globally, and these strains appear to have more rapid growth rates than typical HA-MRSA strains, larger numbers of virulence factors, pathogenicity islands, and higher levels of expression of the virulence factors produced. Recently  $\alpha$ -type phenol-soluble modulins were described in strains of CA-MRSA, which are produced at very high levels and are potent lysins of neutrophils. High levels of  $\alpha$ -toxin production by these strains, which act as pore-forming toxins for multiple cell types, may also contribute to their virulence. The vast majority of CA-MRSA strains also produce the genes for PVL and it functions as

a dermonecrotic factor in skin lesions, a potent cell lysis in high concentrations, and a potent inflammatory mediator in lower concentrations. However, there is controversy about the role of PVL as a single predominant virulence factor, because strains of CA-MRSA that have this gene knocked out have demonstrated no difference in pathogenicity in both vertebrate and invertebrate animal models and in human settings when the PVL is not present.

### Prevention

Controlling the spread of HA-, CA-, or LA-MRSA from an infected or colonized person to others in the hospital, family, or community is a key goal of prevention. In the hospital setting, strict adherence to hand hygiene, application of barrier precautions (gloves, gowns, and private rooms) for patients colonized or infected with MRSA, environmental and equipment cleaning, and antimicrobial stewardship are the key preventive strategies. Active surveillance cultures to identify colonized patients and decolonization may be effective in selected settings, but its general application is controversial. In the community setting, practicing hygienic measures including good personal hygiene, consistent hand hygiene, ensuring all draining skin and soft tissue lesions have adequate dressings, not sharing potentially contaminated personal articles, and keeping the household environment hygienic are important. Public health organizations may also contribute to the prevention of CA-MRSA by instituting education programs targeting healthcare providers and individuals in high-risk groups in the community, and by promoting appropriate antimicrobial use. In sports settings, in addition to the basic hygienic measures mentioned previously, avoidance of sharing of towels and other personal items, showering after every practice or tournament, cleaning of communal showering and bathing areas, and cleaning or laundering of equipment after each use are also important.

### Clinical Manifestations

The specific clinical infections associated with MRSA parallel those associated with MSSA. Almost any body site, organ, or appendage may be affected by infections due to *S. aureus*, but there are specific predilections associated with HA- and CA-MRSA. In the hospital or other healthcare setting, the most commonly encountered sites of infection include pneumonia, line-related infection, surgical site infection, bacteremia, and less often skin and soft tissue infections. In the community setting, the most common sites (>80%) are skin and soft tissue infections (furuncles, cellulitis, and soft tissue abscesses) and less commonly severely invasive infections such as necrotizing pneumonia, necrotizing fasciitis, multifocal osteomyelitis/septic arthritis, epidural abscess, pelvic septic thrombophlebitis, and bacteremia with toxic shock syndrome. The skin and soft tissue infections often affect

**TABLE 2** Risk Factor Associations Reported for CA-MRSA Infections

RISK CATEGORIES	FACTOR	DETAILS FROM REPORTS
High-risk populations	Younger and older age	Age distribution in CA-MRSA younger than HA-MRSA High rate of CA-MRSA in children under 2 years CA-MRSA more common in children compared to adults Outbreaks in hospital nurseries Outbreaks in nursing homes with elderly residents
	Indigenous populations: Native or Aboriginal or African American	Aboriginal communities in midwestern United States, Canada, and Australia Alaskan natives More common in African Americans
	Athletes (predominantly contact sports)	Outbreaks on football teams Outbreaks on wrestling team Other competitive sports
	Injection (intravenous) drug users (IVDUs)	San Francisco IVDUs Canadian report of USA300 strain outbreak
	Men who have sex with men (MSM)	CA-MRSA described in HIV+ population of MSM
	HIV+ individuals	Risk associated with overlapping social networks, intravenous drug use, hemodialysis, and CD4 counts <200 reported as independent risks
	Military personnel	3% of US Army soldiers colonized
	Inmates of correctional facilities	Reports of outbreaks in US prisons Two outbreaks (total 10 inmates) in Canada
	Students in elementary schools and college dormitories	Reports of outbreaks in schools and college dormitories
Previous positive MRSA cultures	MRSA carriage Past MRSA infection	Colonized soldiers more likely to get CA-MRSA disease Prior abscess risk factor for CA-MRSA
Medical history	Chronic skin disorder	Dermatologic condition most common underlying medical disorder for CA-MRSA infection Classroom contact of index CA-MRSA case had chronic dermatitis
	Recurrent or recent antibiotic use	Antibiotic use associated with CA-MRSA infection in rural Alaska
Environmental	Homelessness and living in shelters Overcrowding Contact with colonized pet Veterinary workers and family members	Medically underserved populations at higher risk of CA-MRSA Reports of USA300 strain outbreak involving individuals living in shelters or homeless Close contact implicated in jail outbreaks Neonatal intensive care unit transmission Family dog source of recurrent infection Veterinarians working with horses and livestock Family members of animal care workers Small animal veterinarians Swine farmers

CA, Community-associated; HA, healthcare-associated; HIV, human immunodeficiency virus; MRSA, methicillin-resistant *Staphylococcus aureus*.

Adapted from Barton-Forbes M, Hawkes M, Moore D, et al. Guidelines for the prevention and management of community associated methicillin resistant *Staphylococcus aureus* (CA-MRSA): a perspective for Canadian Health Care Practitioners. *Can J Infect Dis Med Microbiol*. 2006;17(suppl C):1B–24B.

young previously healthy patients and are characteristically very painful and pyogenic with an initial black eschar that patients presume was a “spider bite” as the initiating process.

### Diagnosis

The diagnosis of MRSA infections is based on the clinical presentation and the isolation of the causative organism from purulent discharge, sputum, or urine, or from specimens obtained from normally sterile body fluids (joint fluid, abscess or tissue aspirates, and blood). The organism appears on Gram stain as a gram-positive organism in clusters and is usually seen in association with neutrophils and may be either intracellular or extracellular. The organism is very hardy and grows readily on typical media in the microbiology laboratory within 24 to 48 hours. Some laboratories are using rapid agglutination tests to detect the PBP2a protein or polymerase chain reaction (PCR)-based techniques to provide same-day or next-day identification. In settings where no cultures have been obtained or in the setting of toxic shock syndrome where cultures are often negative, the diagnosis

may be difficult and only suspected based on a typical clinical presentation.

### Treatment

MRSA strains harbor resistance to the  $\beta$ -lactam antimicrobials, including oxacillin, dicloxacillin, cloxacillin<sup>2</sup>, nafcillin, methicillin<sup>2</sup>, and first-, second-, and third-generation cephalosporins. The newer advanced-generation cephalosporin antimicrobials ceftaroline (Teflaro) and ceftobiprole (Zevtera)<sup>2</sup> have activity against MRSA strains. The majority of HA-MRSA strains are resistant to macrolides, clindamycin (Cleocin), aminoglycosides, and quinolones (with the exception of delafloxacin [Baxdela]) and are variably resistant to tetracycline and trimethoprim-sulfamethoxazole (Bactrim)<sup>1</sup>, depending on local epidemiologic patterns. They are sensitive to vancomycin (Vancocin) and the lipoglycopeptides such as dalbavancin (Dalvance), telavancin (Vibativ), and oritavancin (Orbactiv) and usually sensitive to fusidic acid<sup>2</sup>, rifampin (Rifadin)<sup>1</sup>, the oxazolidinones linezolid

<sup>2</sup>Not available in the United States

**TABLE 3** Principles of Empiric Treatment of Minor Skin and Soft Tissue Infections (Folliculitis, Furuncles, Small Abscesses Without Cellulitis, Impetigo, Secondarily Infected Lesions Such as Eczema, Ulcers, or Wounds) Where the Etiology Is Unknown But May Include MRSA as a Possibility**Recommendations**

One or more of the following measures may be employed:

- Local therapy using hot soaks, elevation, and dressings as appropriate
- Incision and drainage of furuncles or small abscesses without antimicrobial therapy
- Topical 2% mupirocin ointment (Bactroban) or fusidic acid<sup>2</sup> for impetigo and secondarily infected lesions if local strains are likely sensitive
- Topical antiseptics may be considered
- Antimicrobial therapy is recommended in addition to local measures if one or more of the following is present: multiple sites of infection, evidence of progression, clinical evidence of systemic symptoms and signs, presence of comorbidities, extremes of age, immunosuppression, septic phlebitis, or difficult site for incision and drainage.
- In follow-up, routine screening for colonization of the nares or other body sites is not recommended.

<sup>2</sup>Not available in the United States.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

**TABLE 4** Principles of Empiric Treatment of Non–Life-Threatening Skin and Soft Tissue Infections Other Than Minor Skin Infections Where the Etiology Is Unknown But May Include MRSA as a Possibility**Recommendations**

- Antibiotic choice should be based on the severity of illness at presentation, clinical judgment, and regional susceptibility patterns of strains
- Empiric therapy for CA-MRSA and  $\beta$ -hemolytic streptococci is recommended\*

\*The IDSA guideline suggests to differentiate purulent and nonpurulent cellulitis and reserve empiric therapy for  $\beta$ -hemolytic streptococci only in nonpurulent cellulitis but acknowledges it is an area of controversy. The UK and Canadian guidelines explicitly recommend coverage for  $\beta$ -hemolytic streptococci and do not differentiate cellulitis into different types. The guidelines that exist have not been updated and hence knowledge of local susceptibility patterns is important.

CA, Community-associated; IDSA, Infectious Diseases Society of America; MRSA, methicillin-resistant *Staphylococcus aureus*.

**TABLE 5** Principles of Empiric Treatment of Life-Threatening Infections Where the Etiology Is Unknown But May Include MRSA as a Possibility**Recommendations**

- Include MRSA coverage, regardless of prevalence rates of CA-MRSA in the community
- Include an agent effective against MSSA until susceptibility results become available

CA, Community-associated; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*.

(Zyvox) and tedizolid (Sivextro), and daptomycin (Cubicin). For hospitalized patients where *S. aureus* is considered a possible etiology of any major infectious syndrome, it should be considered as methicillin-resistant until proven otherwise. Empiric choices of vancomycin or lipoglycopeptides such as dalbavancin (Dalvance), telavancin (Vibativ) or oritavancin (Orbitactiv), linezolid (Zyvox) or tedizolid (Sivextro), daptomycin (Cubicin) or advanced-generation cephalosporins such as ceftaroline (Teflaro) or ceftobiprole (Zevtera)<sup>2</sup> should be considered as appropriate to the presenting syndrome. CA-MRSA strains are resistant to macrolides and often quinolones (with the exception of delafloxacin [Baxdela]) but usually are sensitive to aminoglycosides such as gentamicin (Garamycin), clindamycin, and trimethoprim-sulfamethoxazole (Bactrim)<sup>1</sup>, but the resistance patterns vary depending on local resistance patterns. In addition, these strains are sensitive to vancomycin (Vancocin) and the lipoglycopeptides, fusidic acid<sup>2</sup>, rifampin (Rifadin)<sup>1</sup>, linezolid (Zyvox), daptomycin (Cubicin), ceftaroline (Teflaro), and ceftobiprole (Zevtera)<sup>2</sup>. LA-MRSA strains are almost always resistant to tetracyclines; often resistant to quinolones, macrolides, and clindamycin, and variably resistant to aminoglycosides and trimethoprim-sulfamethoxazole. In addition, these strains are sensitive to vancomycin (Vancocin)

and the lipoglycopeptides, fusidic acid<sup>2</sup>, rifampin (Rifadin)<sup>1</sup>, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro), daptomycin (Cubicin), ceftaroline (Teflaro) and ceftobiprole (Zevtera)<sup>2</sup>. Treatment guidelines for MRSA with a focus on the ambulatory setting have been published in Canada, the United Kingdom, and the United States, and provide both empiric choices for common infectious presentations of unknown etiology and definitive treatment once an etiology of MRSA is known. The treatment options for both empiric and definitive use where MRSA is considered or proven are presented in Tables 3 through 6 and represent a constellation of the various guidelines that have been published. A recent randomized controlled trial assessed the efficacy of combination therapy in patients with MRSA bacteremia (vancomycin or daptomycin with flucloxacillin<sup>2</sup>). They found that the number of patients with persistent bacteremia after 5 days was lower in the combination arm. However, due to increased nephrotoxicity in the combination arm the trial was stopped early. Further studies are required to determine the role and benefit of combination therapy for MRSA infections.

<sup>2</sup>Not available in the United States.

**TABLE 6** Guidelines for the Management of MRSA Infections

CLINICAL DISEASE	KEY FEATURES	MANAGEMENT PRINCIPLES	ANTIMICROBIAL CHOICES AND COMMENTS*
<b>Skin and Soft Tissue Infection (SSTI)</b>			
Localized lesion	Infected scratches and minor wounds Insect bites Furuncles Small abscesses Absence of systemic illness	Culture selectively <sup>†</sup> No antibiotic therapy recommended <i>Exceptions: multiple sites of infection, evidence of progression, systemic symptoms and signs, presence of comorbidities, extremes of age, immunosuppression, septic phlebitis, or difficult site for incision and drainage: antimicrobial therapy is recommended in addition to local measures</i> Cover draining lesions Emphasize personal hygiene Close follow-up Return if worsening	Generally not indicated, although some evidence exists for treatment with clindamycin PO or trimethoprim-sulfamethoxazole (Bactrim) <sup>1</sup> PO, in conjunction with incision and drainage for small simple abscesses Topical antibacterial (e.g., mupirocin [Bactroban] or fusidic ointment <sup>2</sup> ) therapy may be considered Systemic antimicrobial therapy indicated if one or more of the following: multiple sites of infection, evidence of progression, systemic symptoms and signs, presence of comorbidities, extremes of age, immunosuppression, septic phlebitis, or difficult site for incision and drainage
Cellulitis (not extensive) or multiple abscesses with minimal or no associated systemic features for oral treatment consideration	Classic features of rubor, dolor, calor, and swelling suggesting cellulitis with or without associated drainage or exudate	Culture site (if purulent or drainage) Drainage of abscess or needle aspiration Oral therapy in older child and adult Appropriate infection control measures Imaging for extent and complications as appropriate Close follow-up Return if worsening	<i>Empiric:</i> Include coverage for β-hemolytic streptococci <sup>¶</sup> Clindamycin (Cleocin) 300–450 mg tid-qid PO for adults and 30–40 mg/kg/day <sup>3</sup> ÷ q6–8h PO for children TMP-SMX (Bactrim) <sup>1</sup> 1–2 DS tab bid PO for adults and 8–12 mg/kg/day (of TMP) ÷ q12h PO for children PLUS coverage for β-hemolytic streptococci (e.g., amoxicillin, cephalixin [Keflex]) Doxycycline (Vibramycin) 100 mg bid PO for adults and 4.4 mg/kg/day mg/kg/day ÷ q12h PO for children** PLUS coverage for β-hemolytic streptococci (e.g., amoxicillin, cephalixin) Delafloxacin (Baxdela) 450 mg bid PO for adults <i>Comment:</i> Recently became the first fluoroquinolone approved by the FDA for MRSA SSTI Linezolid (Zyvox) 600 mg bid PO for adults and 30 mg/kg/day ÷ q8h PO for children, not to exceed 600 mg/dose; for children older than 12 years of age 600 mg bid PO <i>Comment:</i> Linezolid is more expensive than the other options and may not always be readily available depending on the setting <i>Comment:</i> If parenteral therapy considered, see choices for severe SSTI Tedizolid (Sivextro) 200 mg PO/IV once daily for 6 days; safety and efficacy have not been established for children <i>Proven MRSA:</i> As above, based on sensitivity testing If parenteral therapy necessary, see choices for SSTI with systemic features
Cellulitis (severe or rapidly spreading or extensive) or complicated SSTI (deep soft tissue infection, surgical or traumatic wound infection, large or multiple abscesses, or infected ulcers and burns) and/or associated systemic features for parenteral treatment consideration	Classic features of rubor, dolor, calor, and swelling suggesting cellulitis with or without associated drainage or exudate with systemic features of fever, chills, malaise, prostration	Culture (blood if febrile, site if purulent) Hospitalize as appropriate Drainage of abscess or needle aspiration Parenteral therapy Imaging for extent and complications as appropriate Appropriate infection control measures Consultation as indicated	<i>Empiric:</i> Include coverage for β-hemolytic streptococci <sup>¶</sup> Vancomycin (Vancocin) 15–20 mg/kg/dose q8–12h IV for adults and 40–60 <sup>3</sup> mg/kg/day ÷ q6h IV for children <i>Proven MRSA:</i> Based on sensitivity testing Vancomycin 15–20 mg/kg/dose q8–12h IV for adults and 40–60 <sup>3</sup> mg/kg/day ÷ q6h IV for children Clindamycin 600–900 mg q8h IV/IM for adults and 30–40 mg/kg/day <sup>3</sup> ÷ q6–8h IV for children Linezolid 600 mg q12h PO/IV for adults and 30 mg/kg/day ÷ q8h PO/IV for children, not to exceed 600 mg/dose; for children older than 12 years of age 600 mg bid PO/IV Tedizolid (Sivextro) 200 mg PO/IV once daily for 6 days; safety and efficacy have not been established for children Ceftaroline (Teflaro) 600 mg IV q12h for adults; safety and efficacy have not been established for children Daptomycin (Cubicin) 4 mg/kg/dose once daily IV for adults and under investigation in children Dalbavancin (Dalvance) 1000 mg IV followed by 500 mg IV 1 week later for adults; safety and efficacy not established in children Telavancin (Vibativ) 10 mg/kg/dose IV once daily Oritavancin (Orbactiv), given as a single 1200 mg 3-hour infusion; not approved for children Delafloxacin (Baxdela) 300 mg bid IV <i>Comment:</i> Linezolid, tedizolid, daptomycin, ceftaroline, ceftobiprole, <sup>2</sup> dalbavancin, oritavancin and telavancin are more expensive than the other options and may not always be readily available depending on the setting

**TABLE 6** Guidelines for the Management of MRSA Infections—cont'd

CLINICAL DISEASE	KEY FEATURES	MANAGEMENT PRINCIPLES	ANTIMICROBIAL CHOICES AND COMMENTS*
<b>Other</b>			
Sepsis syndrome Bacteremia Native valve endocarditis	Shock Multiple-organ failure May have purpura fulminans Associated SSTI, MSI, and RTI May be complicated by Waterhouse-Friedrichsen syndrome High mortality	Blood cultures Culture any pus or fluid collection Look for primary or secondary focus Imaging for identification of source including echocardiography Consultation as indicated ICU care Imaging: look for occult abscesses, bone infection, or endocarditis Involve surgery and other specialists as needed Infection control measures Parenteral, multidrug therapy Prolonged therapy for endovascular source infections	<i>Empiric:</i> Vancomycin 15–20 mg/kg/dose q8–12h IV for adults and 40–60 <sup>3</sup> mg/kg/day ÷ q6h IV for children Daptomycin 6 mg/kg/dose once daily IV for adults and 4–10 <sup>3</sup> mg/kg/dose once daily for children <sup>1</sup> <i>Comments:</i> Doses of daptomycin of up to 10 mg/kg/dose <sup>3</sup> once daily have been used in adults in this indication Some recommendations have included linezolid in this setting at the doses described above <i>Proven MRSA:</i> As above, based on sensitivity testing. <i>Comment:</i> New IDSA guidelines for the treatment of <i>S. aureus</i> bacteremia are in progress

\*Choice of antimicrobial therapy depends on local susceptibility patterns.

†Patients with risk factors, as a part of an outbreak investigation, patients with slowly responding or recurrent lesions.

‡The IDSA guideline suggests to differentiate purulent and nonpurulent cellulitis and reserve empiric therapy for β-hemolytic streptococci only in nonpurulent cellulitis but acknowledges it is an area of controversy. The UK and Canadian guidelines explicitly recommend empiric coverage for β-hemolytic streptococci and do not differentiate cellulitis into different types. A recent randomized controlled trial in the United States found no significant difference in efficacy between clindamycin and trimethoprim-sulfamethoxazole when used for treatment of uncomplicated skin and soft tissue infections, which were thought to be secondary to either β-hemolytic streptococci or *S. aureus*. Another recent placebo-controlled trial in the United States found that clindamycin or trimethoprim-sulfamethoxazole in conjunction with incision and drainage improved outcomes in patients with simple small abscesses (<5 cm) compared with incision and drainage alone.

<sup>1</sup>Not FDA approved for this indication. Dosing has varied in published reports and specific dosing guidelines are not available.

<sup>2</sup>Not available in the United States.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

\*\*Not recommended for pediatric patients younger than 8 years of age or in pregnancy.

ICU, Intensive care unit; IDSA, Infectious Diseases Society of America; IVIG, intravenous immunoglobulin; MRSA, methicillin-resistant *Staphylococcus aureus*; TMP-SMX, trimethoprim-sulfamethoxazole.

## MUMPS

Method of

Kristen Rundell, MS, MD

## CURRENT DIAGNOSIS

- Parotitis (swelling of the parotid salivary glands): unilateral or bilateral
- Fever
- Headache
- Malaise
- Myalgias
- Anorexia
- Increased serum amylase

## CURRENT THERAPY

- Supportive care
- Warm or cold packs on the parotid
- Analgesics and/or antipyretics (such as acetaminophen [Tylenol] or ibuprofen [Motrin])
- IV fluids or hospitalization for cases of pancreatitis, meningitis, or severe orchitis

### Epidemiology

Mumps is an extremely contagious, self-limiting virus that had disease rates of 99% until the vaccine was introduced in 1967. Since 2006, there have been several outbreaks, in the United States, these usually present in young people and those who are not vaccinated, and have increased transmissibility on college campuses, in close knit communities and large social gatherings. For the United States and Finland, mumps is almost eradicated. For the rest of the world, mumps is still endemic as a result of a vaccination rate of only 61%.

### Pathophysiology

Mumps is a single-stranded RNA virus and a member of the *Paramyxovirus* genus. It is transmitted through respiratory secretions, saliva, and contact with contaminated fomites.

### Prevention

With the high rate of transmission and no antiviral therapy, prevention for mumps relies on community immunity as a result of high vaccine rates. There are two formulations of the mumps vaccine currently available in the United States: the measles-mumps-rubella vaccine (MMR) and the measles-mumps-rubella-varicella vaccine (MMRV, ProQuad). The dosing schedule for children calls for the first dose at age greater than 12 months to 15 months, and the second dose for children greater than 4 years to 6 years of age. For infants aged 6 through 11 months who are traveling internationally, a single MMR vaccine is recommended. These children should be revaccinated with 2 doses of MMR vaccine with the first dose at ages 12 months to 15 months and the second dose at ages 4 years to 6 years. During an epidemic, a single dose for adults born before 1957 is recommended and may be required by some health care professionals. The first dose gives approximately 80% immunity. Persons receiving both doses may still get the mumps virus if there is outbreak or if they travel to an endemic area. To avoid exposure or contraction of the disease during travel, it is suggested that travelers wash hands frequently and use alcohol-based sanitizers to decrease the contraction or spread of disease.

The vaccine is contraindicated for patients who are pregnant or planning to conceive in the 28 days after vaccination. Vaccine administration is also contraindicated for those who have a severe anaphylactic reaction to the vaccine or one of the components, and those individuals who are severely immunocompromised.

### Clinical Manifestations

The incubation period for the mumps virus is 16 to 18 days. At the onset of the illness, patients may develop acute viral infection symptoms of fever, headache, and malaise. The parotitis, swelling of the parotid gland, is the diagnostic hallmark of the mumps virus. This is caused by the infection and inflammation of the parotid ductal epithelium. The swelling may last up to 10 days. Close to 30% of persons may not have this symptom and may be only mildly symptomatic.

### Diagnosis

Diagnosis is made by the history and the constellation of symptoms and physical findings. It is difficult to use IgM to determine active infection, because the response may be short in duration,

delayed, or even absent. PCR testing is available and requires early sampling.

### Differential Diagnosis

Viral infections such as parainfluenza (also in the paramyxovirus genus) coxsackievirus, influenza A, Epstein-Barr, adenovirus, HIV, and cytomegalovirus may present with similar symptoms as mumps. There are also noninfectious etiologies of parotitis, which include salivary stones or tumors, sarcoid, Sjögren's syndrome, and thiazide diuretics.

### Therapy (or Treatment)

Treatment for mumps virus is largely supportive. For complicated cases of pancreatitis, meningitis, encephalitis, and orchitis, patient may need to be hospitalized for additional care. The additional care usually includes fever reduction, analgesia, fluid resuscitation, and treatment of secondary bacterial infections.

### Monitoring

For persons with active mumps, it is suggested that they be isolated from school or work for 5 days after the onset of symptoms. Shedding of virus usually occurs 4 days prior to the onset of symptoms. For this reason, it is difficult to slow down outbreaks of the disease. The last outbreak in the United States was in 2010.

### Complications

Complications from mumps are rare. In children, pancreatitis and hearing loss are the sensorineural complications most often diagnosed. For adolescents and adults the complications are more common and usually more severe. These include aseptic meningitis; orchitis in males, which rarely leads to sterility; oophoritis in females; pancreatitis; and arthritis. Even more uncommon are Guillain-Barré/ascending polyradiculitis, transverse myelitis, facial palsy, interstitial nephritis, and myocardial involvement.

Mumps in pregnancy has been associated with increased fetal loss. There are no known teratogenic effects.

## MYALGIC ENCEPHALOMYELITIS/CHRONIC FATIGUE SYNDROME

Method of

Stephen J. Gluckman, MD

Myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) is an often-misunderstood syndrome that should not be confused with malingering, hypochondriasis, or just fatigue. Patients with ME/CFS are truly suffering from their often-disabling symptoms. It is impossible to successfully treat a patient with ME/CFS unless the clinician believes the patient is genuinely symptomatic. ME/CFS also should not be confused with the isolated symptoms of fatigue. Fatigue is a common patient complaint, whereas ME/CFS has a much lower prevalence.

## Definition

ME/CFS is not a new disease; the syndrome has been described since at least the mid-1700s. However, since that time, it has been mistakenly ascribed to a number of incorrect pathologic and infectious causes. In the past, it has been called *febricula*, *neurasthenia*, *effort syndrome*, *Da Costa syndrome*, *chronic brucellosis*, *chronic Lyme disease*, *chronic Epstein-Barr syndrome*, *total allergy syndrome*, *chronic candidiasis*, and *multiple chemical sensitivity syndrome*. More recently, it has been falsely attributed to infection with xenotropic murine leukemia virus–related virus (XMRV) and related retroviruses, such as murine leukemia virus (MLV). None of these possible causes has proved to be correct.

In 1988, in an attempt to be descriptive rather than to attribute an incorrect etiology to the disease, the term *chronic fatigue syndrome* was coined. Therefore the name is relatively new, but the syndrome is not. The disease is chronic, and fatigue is a cardinal feature, but it is more than being chronically tired. This working case definition was published by the Centers for Disease Control and Prevention and then modified in 1992 by the National Institute of Allergy and Infectious Diseases. In March 2015 the Institute of Medicine (IOM; now the National Academy of Medicine [NAM]) issued an extensive and thorough review of the topic. As a result of this review, they proposed a name change to *systemic exertion intolerance disease* (SEID). This comprehensive report has three major themes: (1) ME/CFS has acquired a great deal of negative connotation with associated misunderstanding and prejudice. The name change to SEID is an attempt to disconnect this disease from past misunderstandings. However, this name change has not caught on. (2) The criteria for diagnosis were greatly simplified, with emphasis on the major features (Box 1). (3) By using the term *disease* and by supplying ample reference support in the document, the IOM unequivocally underscores the very real nature of this malady. The IOM report is by far the most thorough examination of the topic, and it unequivocally supports the validity of this disease.

One note of caution: This case definition is an epidemiologic and research tool and not a strict clinical tool. It is useful for studying the disease. However, some patients do not completely fit this definition. ME/CFS can nonetheless be diagnosed by a knowledgeable clinician who is willing to consider this diagnosis.

Because some immune abnormalities are often seen in these patients, some people have called this *chronic fatigue and immune dysregulation syndrome*. The immune abnormalities seen in ME/CFS patients are mild and differ from patient to patient. Most significantly, these patients are not immunosuppressed or at risk for opportunistic infections.

It has been noted that many of the symptoms of fibromyalgia overlap with ME/CFS, and some clinicians consider fibromyalgia and ME/CFS to be different aspects of the same disease because both often include pain and fatigue. These different names for the same syndrome can be confusing to patients and clinicians, and it is important to explain this when managing patients with ME/CFS.

### BOX 1 Criteria for CFS/SEID

Diagnosis requires that the patient have the following three symptoms:

- A substantial reduction or impairment in the ability to engage in pre-illness levels of occupational, educational, social, or personal activities that persists for more than 6 months and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest
- Postexertional malaise
- Unrefreshing sleep

At least one of the two following manifestations is also required:

- Cognitive impairment
- Orthostatic intolerance

A mention should be made in regard to Long-Haul COVID-19. In this entity, patients have persistent symptoms after recovering from acute COVID-19. There are a number of reasons for persistent symptoms including lingering or permanent organ damage as the result of a severe episode of COVID and/or PTSD related to the trauma of being intubated in an intensive care setting. In addition, COVID-19 triggers typical ME/CFS in some persons.

## Epidemiology

Although chronic fatigue is an extremely common symptom, ME/CFS is not. The former has been noted to have a prevalence of 10% to 25% in a number of studies. However, the point prevalence of ME/CFS has been estimated to be in the range of 0.1%. ME/CFS is overrepresented in young and middle-age women, but it has been described in both men and women and in all age groups.

## Pathophysiology

The cause of ME/CFS is unknown. Much effort has gone into trying to discern an infectious, endocrine, immune, or psychiatric cause, but to date none has been proven. Studies have shown a link between ME/CFS and the presence of certain genes that mediate immune and stress responses. The findings suggest that difficulty managing stress may be linked to the development of ME/CFS. They also suggest that there may not be a single cause of ME/CFS but that there may be a number of stress-related triggers (physical or emotional) in those with a genetic predisposition. This is consistent with the typical course, in which a previously healthy person develops an acute illness that resolves but initiates ME/CFS.

## Clinical Features and Diagnosis

Although there is, as yet, no diagnostic test, the history, physical examination, and laboratory testing are generally very characteristic and allow a clinician to confidently make the diagnosis. The typical story is one of a previously highly functioning person who develops an acute illness or other stressor. The acute problem resolves; however, from that time on, symptoms of ME/CFS are triggered. Despite often-profound symptoms, physical examination is persistently normal, as is laboratory testing. *In fact, if there are significant abnormalities on physical examination or testing, those abnormalities are not consistent with ME/CFS and should be further evaluated.* Symptoms are exacerbated by physical activity. The pre-ME/CFS medical history of the patient is not one of multiple medical problems. Affected patients are typically high-functioning persons who are “struck down” with this disease. Features to emphasize in addition to the case definition noted in Box 1 are included in Box 2.

### BOX 2 Frequent Features of Chronic Fatigue Syndrome

- Sudden onset of fatigue after a relatively common illness or other stressor
- Previously active and healthy person
- Symptoms very sensitive to exacerbation by physical activity
- Normal physical examination and laboratory testing
- Altered sleep
- “Foggy” thought processes
- Lack of progression to organ failure or any significant objective organ abnormality
- Joint and muscle aching without physical evidence of inflammation
- Feverish feeling (sustained elevated temperatures [ $>37.4^{\circ}\text{C}$ ] should prompt a search for an alternative diagnosis because the chronic fatigue syndrome patient is not truly febrile)
- Diffuse aching that is not well localized to joints or muscles, but without erythema, effusion, or limitation of motion
- Muscles that are easily fatigued (however, strength is normal, as are biopsies and electromyograms)
- Occasional mild cervical and/or axillary lymphadenitis (painful lymph nodes [lymphadenia] are a common complaint, but this is not a true lymphadenopathy)

In a patient with a typical history and examination, laboratory testing should be limited (Box 3). Testing for diseases with a low pretest likelihood runs the serious risk of false-positive results. This can result in further testing, diagnostic confusion, and unnecessary treatments. Specifically, the signs and symptoms of ME/CFS are not those of systemic lupus, Lyme disease, cytomegalovirus, bartonellosis, ehrlichiosis, or babesiosis, among others. Serologic testing for these diagnoses is not helpful and can be harmful if the presence of antibodies results in the initiation of unwarranted medications. The presence of antibodies does not mean active disease. The analogy that patients can relate to is to remind them that they likely have antibodies to chickenpox but that they clearly do not have active chickenpox. For similar reasons, neuroimaging without objective clinical findings is not indicated. Although abnormalities can be found, they are nonspecific and of no clinical utility. Tilt-table testing seems to be abnormal in many patients with ME/CFS; however, testing is expensive and uncomfortable, and abnormal results do not alter management. Of course, if history, physical examination, and initial laboratory testing do reveal abnormalities, as noted earlier, further laboratory evaluation should be undertaken to elucidate the cause of the aberration(s).

### Treatment

There is no established cure for ME/CFS, but patients should be counseled that a number of things can be done to manage this often-disabling illness (Box 4). These can be divided into things the clinician should do and things the patient should do.

#### BOX 3 Diagnostic Testing

##### Tests to Perform

- Complete blood count
- Comprehensive chemistry screen
- Thyroid-stimulating hormone
- Perhaps: Cosyntropin (Cortrosyn) stimulation test, sleep study
- Additional testing *only* with specific clinical indications

##### Do Not Routinely Perform

- ANA testing
- Serology for cytomegalovirus, Epstein-Barr virus, *Bartonella*, *Babesia*, *Ehrlichia*, and *Anaplasma*
- MRI, SPECT, or PET scans
- Tilt-table testing

ANA, Antinuclear antibody; MRI, magnetic resonance imaging; SPECT, single-photon emission computerized tomography; PET, positron emission tomography.

#### BOX 4 Therapy of Chronic Fatigue Syndrome

- Educate the patient and his or her support system about the diagnosis of chronic fatigue syndrome. Emphasize the validity of the diagnosis and of the patient's symptoms. Make sure there is an understanding about expectations.
- Aggressively manage specific symptoms of sleep disturbance, pain, and depression.
- Consider cognitive behavioral therapy.
- Emphasize the need for gradual, graded exercise. Give the patient a specific "prescription" for this.
- Avoid the temptation to prescribe antimicrobials, corticosteroids, or other medications with no proven benefit and the potential to do harm.
- Discuss the pros and cons of using unstudied, expensive, or potentially dangerous "alternative therapies."

### Things the Clinician Should Do

To successfully manage ME/CFS, a clinician must believe that the patient is truly symptomatic. Patients with ME/CFS are not malingering. Because they often appear well and have consistently normal objective testing, they often become very defensive about their limitations. They are sensitive to the validity of their symptoms. Not only are they suffering, but also they are blamed for it. Many patients with ME/CFS are partially or totally disabled. Their outward healthy appearance belies the internal sense of ill health. It is common for relatives and colleagues to believe they are malingering. A vicious cycle of frustration, anger, and depression commonly ensues.

As part of establishing the validity of the diagnosis, a clinician should review the history of ME/CFS, emphasizing that this is not a new disease but was originally described centuries ago.

For successful management, the clinician should give the patient enough time, specifically inquire about other diagnoses the patient is concerned about, and explain why they are not correct. The clinician should see the patient at regular intervals.

The clinician should also ensure that the patient has reasonable expectations. Most patients with ME/CFS have not had previous chronic illnesses or significant prolonged limitations. It is often necessary to review the information about ME/CFS with the patient's family and to emphasize that this disabling illness is not volitional.

Although it is generally wise to avoid a discussion about whether the origin of ME/CFS is psychiatric or organic, depression is an expected consequence of any chronic illness. Depression has specific treatments, and it should be aggressively diagnosed and treated. The patient should be told that successful management of depression will help him or her cope with ME/CFS.

If a sleep disturbance exists, it also should be aggressively managed, if necessary, by a sleep specialist. Sleep deprivation makes other symptoms more difficult to deal with.

Chronic pain is very enervating. If pain is prominent, that also should be aggressively managed, often by a pain specialist.

It is important for the clinician to be cautious about ascribing all of a patient's symptoms to ME/CFS. Such patients are, of course, not protected from getting additional, unrelated illnesses. Each symptom should be considered on its own before defaulting it to ME/CFS.

Complementary therapies must be discussed, or the patient might get the impression that the clinician is not comfortable in considering them; this can partially undermine the clinician-patient relationship. Although all are of unproved benefit and often under-terminated risk, "complementary" therapies that are not dangerous (e.g., acupuncture) or expensive are reasonable to consider.

### Things the Patient Should Do

Of the 350 studies that have looked at treatment options for ME/CFS, only cognitive behavioral therapy and graded exercise therapy have been shown to be of possible benefit. In cognitive behavioral therapy, the patient undergoes a series of 1-hour sessions designed to alter beliefs and behaviors that might delay recovery. Although exercise can exacerbate symptoms, deconditioning will also do so. Limiting activity can worsen weakness and depression. The risk of exacerbating symptoms can be reduced by cautiously setting less-ambitious activity/exercise goals. Because many patients with ME/CFS were particularly active before the onset of their illness and are impatient to get their former lives back, they often need strict guidelines to try to prevent overdoing exercise while at the same time getting a clear prescription to exercise. The exercise prescription should be individualized based on the degree of impairment, but it is wise to initially set goals on the low side to avoid exacerbating symptoms. It is important to acknowledge that both CBT and graded exercise are controversial, with several interest groups opposed to these modalities. As for CBT, it is safe and there is nothing to lose. As for exercise, the emphasis should be on very gradual to minimize the risk for exacerbation.

As part of the management of ME/CFS, patients, their families, and, when appropriate, their employers must reframe their expectations. ME/CFS patients have a chronic, disabling illness. Families and others must understand that patients cannot do all that they were able to do before the onset of ME/CFS and that patients cannot “will” the disease away any more than they could will away a more visible disability.

### Things That Should Not Be Done

There are many suggested remedies for ME/CFS. Most are either unstudied or disproved. In particular, treatments that are expensive or potentially harmful should be avoided. There is no role for antimicrobial therapy. There is no role for antiviral therapy, including treatment for retroviruses. There is no role for intravenous immunoglobulin, corticosteroids, special diets, or vitamin treatments.

### Prognosis

The likelihood for complete recovery from ME/CFS is only fair. The disease tends to wax and wane over time, but in only a minority of patients does it completely resolve. If sustained improvement occurs, it is generally over several years. Several features have been associated with a poorer prognosis, including age older than 38 years, more than eight symptoms, duration longer than 1.5 years, less than 16 years of formal education, a history of a dysthymic disorder, and a sustained belief that the disease results from a physical cause.

### Monitoring

Despite the lack of very effective treatment, many patients benefit from regular monitoring of their condition. Knowing they have scheduled visits minimizes the number of crises and emergency visits and allows the patient to reconnect with a validating physician. Follow-up on a quarterly basis is a reasonable interval.

## NECROTIZING SKIN AND SOFT-TISSUE INFECTIONS

Method of

Kalyanakrishnan Ramakrishnan, MD

### CURRENT DIAGNOSIS

- Physical examination of the affected area may detect:
  - Exquisite pain and tenderness out of proportion to local signs of infection.
  - Cutaneous anesthesia, firm woody subcutaneous tissue, edema, and tenderness extending outside involved skin margins, hemorrhage or bullae of the overlying skin, and soft tissue crepitus.
- Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score is useful in diagnosing necrotizing fasciitis. Imaging (computed tomography [CT] or magnetic resonance imaging [MRI] in adults; ultrasonography [US] in children) is usually confirmatory. Imaging should not delay surgery if indicated based on suspicion.

### CURRENT TREATMENT

- Empiric high-dose intravenous polymicrobial antibiotics and surgical debridement remain the cornerstones of initial management of necrotizing skin and soft-tissue infections. Organism-specific antibiotics are continued until resolution of infection and debridement complete (usually 7–14 days).

### Epidemiology

Necrotizing skin and soft tissue infections are rare with an estimated annual incidence of 1000 cases in the United States. These infections may be polymicrobial or monomicrobial. Polymicrobial infections are more common (70%–80%) and generally caused by synergistic activity of aerobes and anaerobes originating from the bowel or genitourinary tracts. They are more prevalent among older and immunocompromised patients, individuals with significant comorbidities, and those with underlying abdominal pathology. These infections typically involve the trunk and perineal regions, and follow penetrating abdominal injuries or surgery, genital or perianal sepsis, or decubitus ulcers. They have a more indolent course and thus are easier to diagnose. Monomicrobial infections (20%–30%) frequently follow minor trauma and are usually caused by group A streptococcus (GAS), occasionally by methicillin-resistant *Staphylococcus aureus* (MRSA), or by clostridia. They are more aggressive, involve the extremities and occur more often in younger healthy individuals. Type 3 infections follow exposure to contaminated fresh or warm seawater or ingestion of raw seafood; organisms responsible include *Aeromonas hydrophila*, *Vibrio vulnificus*, *Mycobacterium marinum*, *Pasteurella multocida*, *Haemophilus* and *Klebsiella* species. Type 4 (fungal) infections generally follow burns or major trauma. Both types 3 and 4 infections are rare, progress rapidly, and have a high mortality rate, especially in immune-suppressed patients.

### Risk Factors

Cardiopulmonary disease, debility, diabetes mellitus, hepatorenal disease, immunocompromised states, obesity, arteriovenous/lymphatic insufficiency, and senescence all increase risk of skin and soft tissue infections by reducing tissue vascularity and oxygenation, increasing fluid stasis and risk of trauma, and decreasing ability to counter infections. Diabetes mellitus and hepatic

cirrhosis favor polymicrobial infections due to staphylococcus and streptococcus species, anaerobes, and gram-negative bacilli. Neutropenia, intravenous drug use, and hot tub exposure promote pseudomonas infection. Human and animal bites cause infections with oral flora, staphylococci, *Pasteurella multocida*, and anaerobes. Poor sanitation and soil contamination propagate clostridial infections. Postoperative infections typically follow wound contamination with microorganisms from the patient during surgery.

### Pathophysiology

Necrotizing skin and soft tissue infections advance rapidly, breaking down and traversing anatomic barriers, initiating extensive destruction of the subcutaneous tissue, fascia, and muscle and damaging the neurovascular bundle, thrombosing the subcutaneous vessels, and causing overlying skin necrosis. Most infections follow a rift in the protective cutaneous barrier due to trauma or increased tissue tension. Necrotizing fasciitis may also result from blunt injuries (bruise, muscle strain) and, occasionally vascular or lymphatic spread from a distant focus of infection. Various toxins expressed by the organisms (GAS and clostridia) display local and systemic effects (platelet aggregation and thrombosis, decreasing phagocytosis, neutrophil function and vascular tone, myocardial inhibition) triggering the systemic inflammatory response syndrome (SIRS) and multiple organ failure.

### Prevention

Preserving cutaneous integrity prevents infection. Abrasions and lacerations should be washed with antibacterial solutions, foreign bodies should be removed, and dead/devitalized tissue excised to minimize infection risk. Preoperative skin cleansing with chlorhexidine/alcohol (Hibiclens) or povidone iodine diminishes rates of superficial and deep incisional infections. Intranasal 2% mupirocin ointment (Bactroban) twice daily with chlorhexidine total body wash daily for 5 days in nasal carriers of MRSA reduces hospital-acquired deep surgical-site infections, as does administering antibiotics (aminopenicillins, a second- or third-generation cephalosporin) 60 minutes before incision, sterile surgical technique, minimal tissue handling, and minimally invasive surgery.

### Clinical Manifestations

Features of inflammation (redness, warmth, swelling, pain) and loss of function characterize necrotizing skin and soft tissue infections. Altered mental status, anorexia, diaphoresis, fatigue, fever, hypotension, nausea, and tachycardia suggest systemic spread of infection. The extremities, trunk, or anogenital regions are usually involved. Induration denotes cutaneous involvement. Patients with necrotizing fasciitis have severe pain disproportionate to the physical findings and rapid progression of infection. Examination reveals cutaneous anesthesia, firm and woody subcutaneous tissue, edema and tenderness extending beyond involved skin, hemorrhage or bullae of the overlying skin, and crepitus (indicates soft tissue gas; seen especially with gas-forming organisms such as clostridia). Tense edema and bullae have high specificity and positive predictive value for necrotizing fasciitis. Fournier gangrene is a form of polymicrobial necrotizing soft-tissue infection involving the loose groin and genital skin, where subcutaneous vessel thrombosis causes extensive tissue loss.

### Diagnosis

Diagnosis is based on a strong clinical suspicion followed by confirmatory laboratory and imaging studies (if time permits), and surgery. Leukocytosis with a marked left shift, elevated C-reactive protein, elevated serum creatinine and creatine phosphokinase (denotes muscle injury), and low serum bicarbonate (suggests acidosis) signify severe infection. The LRINEC score (<https://www.mdcalc.com/lrinec-score-necrotizing-soft-tissue->

[infection](#)) uses six different laboratory parameters (hemoglobin, white blood cell count, C-reactive protein, glucose, creatinine, sodium) to predict risk of necrotizing fasciitis (score  $\geq 6$  suggestive,  $\geq 8$  strongly predictive). White blood cell count ( $< 15,000 \text{ mm}^3$ ) and serum sodium ( $> 135 \text{ mmol/L}$ ) levels alone are useful in ruling out necrotizing fasciitis (99% negative predictive value). Gram stains and cultures of aspirates or tissue biopsies, and blood cultures are valuable for detecting the infecting organisms and systemic spread; contamination may yield false-positive results. Biopsy or debridement typically demonstrates swollen gray soft tissue with undermining of the overlying skin, a brownish and odorous exudate and non-contractile muscle. Imaging (plain x-rays, ultrasonography [US], computed tomography [CT], magnetic resonance imaging [MRI]) may show edema or thickening, fluid collections or free air in the soft tissues. US, CT and MRI are highly sensitive (MRI highest) in detecting deep soft tissue involvement characteristic of necrotizing fasciitis; specificity is lower. US is sufficient in children, whose tissues are thin enough to allow adequate evaluation on imaging. Imaging should not delay debridement, if considered necessary.

### Therapy

Patients with necrotizing skin and soft-tissue infections typically require in-hospital management, because many have underlying unstable comorbid illnesses, systemic sepsis, severe dehydration and acidosis, muscle breakdown, and organ dysfunction. Initial resuscitation may require airway and oxygen support, large-volume rehydration, and invasive monitoring. High-dose intravenous (IV) broad-spectrum antibiotics effective against the usually infecting polymicrobial spectrum of pathogens are commenced, followed by early and aggressive debridement of all necrotic tissue. IV antibiotics are maintained until the patient is afebrile for 48 to 72 hours and tolerates oral intake, debridement is completed and culture results are available. For polymicrobial necrotizing fasciitis acceptable antimicrobial choices include vancomycin plus piperacillin/tazobactam (Zosyn), a carbapenem (meropenem [Merrem], ertapenem [Invanz] or imipenem-cilastatin [Primaxin]), or cefotaxime (Claforan) with metronidazole (Flagyl) or clindamycin (Cleocin). Streptococcal and clostridial infections are treated with penicillin G and clindamycin. Antibiotic options in methicillin-susceptible *S. aureus* infections include nafcillin oxacillin or cefazolin. Options for methicillin-resistant *S. aureus* (MRSA) infections and in penicillin-allergic patients include vancomycin, daptomycin (Cubicin), or linezolid (Zyvox). Antibiotic doses are modified in children. Recommended duration is 7 to 14 days; longer as needed. Doxycycline combined with ciprofloxacin (Cipro) treats *Vibrio vulnificus* infection. Ceftriaxone (Rocephin) or cefotaxime combined with doxycycline is useful in aeromonas infections. Doxycycline is contraindicated in children ( $< 8$  years), as is ciprofloxacin ( $< 17$  years), unless the infection is considered life-threatening. Fungal infections respond well to fluconazole (Diflucan), voriconazole (Vfend) or amphotericin B; the antifungals usually continued for 2 weeks after resolution of symptoms. Debridement/drainage is repeated until all diseased tissue or collections are eliminated and healing begins. Wound vacuum dressings help remove drainage and encourage formation of healing granulation tissue. The tissue defect heals by secondary intention or may require skin grafting or flap closure. Hyperbaric oxygen (3–4 daily treatments at 2–3 atmosphere pressure for 30–90 minutes each) is useful, especially in clostridium-related synergistic infections. Adding intravenous immunoglobulin<sup>1</sup> 0.5–2 g/kg daily for 3 days has shown some success, and is an option in critically ill hemodynamically unstable patients not responding to conventional measures, especially in those with streptococcal toxic shock syndrome. Fournier gangrene is managed along the same principles as above.

<sup>1</sup>Not FDA approved for this indication.

## Monitoring

Patients in shock or with acute respiratory distress syndrome, SIRS, or multi-organ failure are best managed in an intensive care unit and often require invasive monitoring, cardiorespiratory and renal support, and occasionally, endotracheal intubation.

## Complications

Significant disfigurement, limb loss, respiratory and renal failure, and mortality (14%–50%) may eventuate despite timely and appropriate treatment; the mortality influenced by age, extent of infection, degree of biochemical/acid-base imbalance, presence of comorbidities, and treatment delay.

## OSTEOMYELITIS

Method of

Wissam El Atrouni, MD, MSc; John Sojka, MD; Mitchell Birt, MD; and Kim Templeton, MD

### CURRENT DIAGNOSIS

- Osteomyelitis in adults typically occurs as a result of spread from adjacent soft tissues or direct inoculation of bone, such as after trauma or surgery. Hematogenous bacterial seeding leading to osteomyelitis is more common in children than in adults. When it occurs in adults, it is almost exclusively in the spine.
- Open fractures can lead to osteomyelitis due to contamination of bone at the time of injury; even small soft tissue wounds can indicate the presence of an open fracture. Due to the risk of infection, open fractures should be treated emergently.
- Infections around implanted hardware, especially joint arthroplasties or hardware in the spine, require urgent referral. These infections can occur at the time of hardware placement or later due to hematogenous seeding from distant infections. Patients with late arthroplasty infections usually demonstrate new pain in the area of a previously well-functioning joint.
- Diabetes mellitus is one of the more common chronic health conditions that increases the risk of developing osteomyelitis. Osteomyelitis in this population of patients usually occurs in the foot as a result of progressively deepening soft tissue ulcers and secondary infection. These infections are frequently polymicrobial.
- Initial evaluation of patient suspected of having osteomyelitis includes obtaining plain films. However, plain film findings are usually not specific for infection. Additional radiographic modalities, such as magnetic resonance imaging (MRI) scan and/or a variety of nuclear medicine studies, can provide additional information regarding diagnosis and extent of involvement.

### CURRENT THERAPY

- In the absence of sepsis, antibiotics for patients with suspected osteomyelitis are not started until adequate cultures can be obtained, through aspiration or biopsy of the bone or during surgical debridement of the affected area.
- Antimicrobial therapy for osteomyelitis in adults typically lasts 4–6 weeks, while in children it may only be needed for 2–3 weeks, depending on the clinical picture.
- Surgical intervention for osteomyelitis of long bones is indicated for patients with chronic infections, infections adjacent to joint replacements, or to address bone abscesses. Surgery in these instances requires extensive debridement of infected and necrotic bone to remove all microabscesses and then irrigation to dilute any remaining bacterial load.
- Treatment of patients with diabetes-related foot infections and underlying osteomyelitis may require revascularization of the affected limb to decrease the need for amputation.

## Introduction

Normal bone is typically highly resistant to infection. Infections in bone can arise when the host immune system is compromised or there is injury to the bone. Osteomyelitis occurs either due to hematogenous spread, extension from infections in adjacent soft tissues or joints, or as a result of direct inoculation of the bone due to trauma or surgery. Osteomyelitis can lead to devastating outcomes, including amputation or sepsis, if not addressed early, especially in patients with other health conditions.

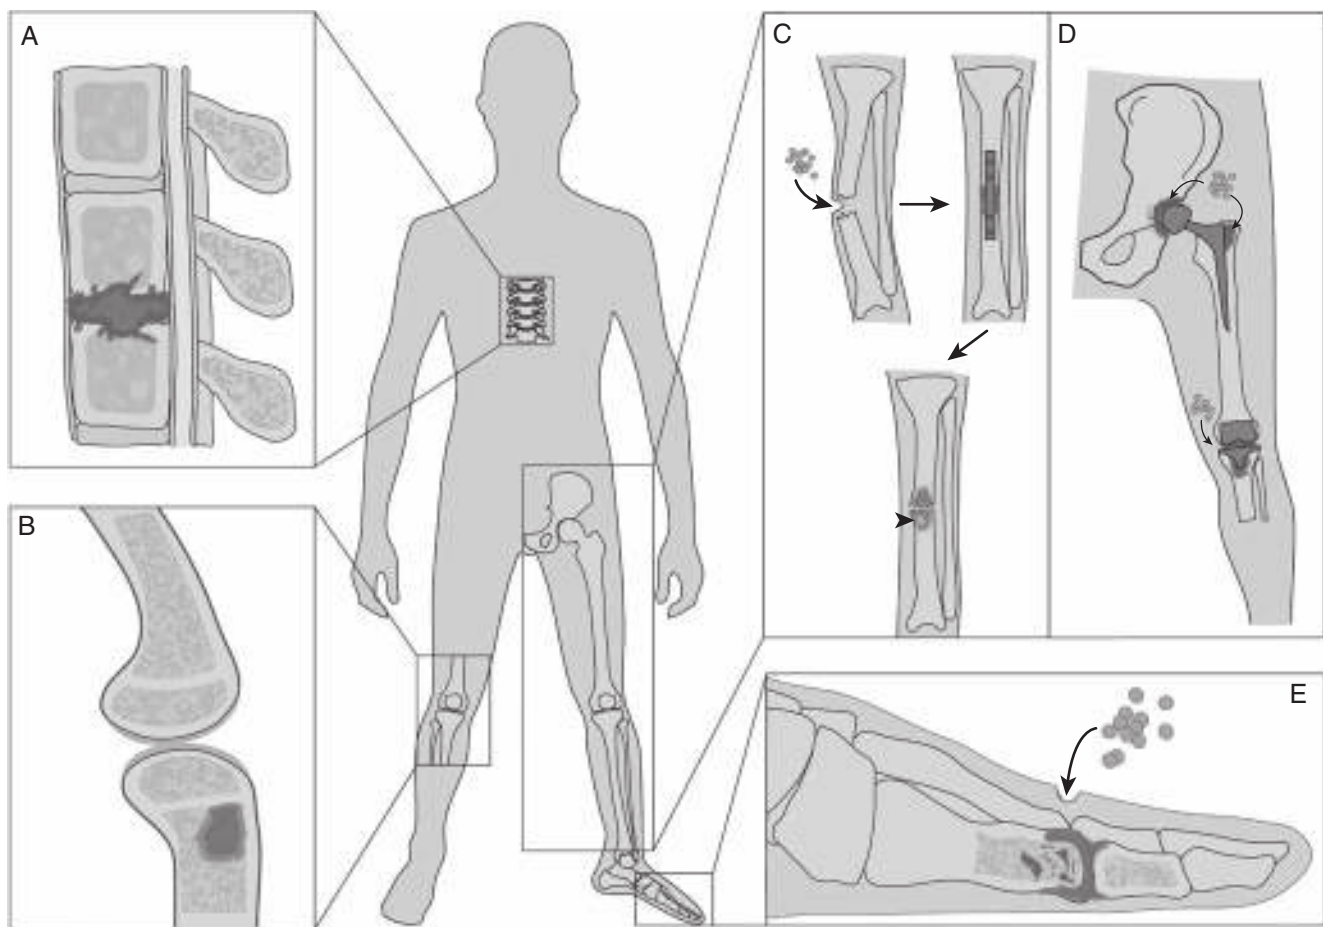

Various classification systems have been developed to describe osteomyelitis. The Lew and Waldvogel classification described the etiology of the infection (in order of decreasing frequency: contiguous focus, vascular insufficiency, or hematogenous); however, this classification system does not guide or indicate the results from treatment. The Cierny-Mader system is based on the location (intramedullary) and extent (localized vs. diffuse) of the infection, as well as the degree of compromise of the patient. Unlike the Lew and Waldvogel classification, the Cierny-Mader (C-M) staging systems correlates with outcomes and can help guide treatment. Mandell et al. recommend considering C-M type 1 as early (intramedullary) hematogenous osteomyelitis, type 2 as early contiguous spread, and types 3 (localized) and 4 (diffuse) as more advanced disease.

Osteomyelitis can be described as acute, usually being present for 2 weeks or less, subacute, and chronic. Chronic osteomyelitis can be more challenging to eradicate due to the development of avascular areas of bone (sequestra) and surrounding bone sclerosis (involucra) that help to wall off the sequestra, making it difficult to adequately address these areas with systemic antibiotics.

## Epidemiology

The incidence of osteomyelitis appears to be increasing, especially among adults. This may reflect better evaluation and diagnostic measures or the increased prevalence of comorbidities, such as diabetes mellitus, or the aging of the population, as the risk increases with age. The reported age- and sex-adjusted annual incidence has been reported to be approximately 24 cases per 100,000 person-years and is higher among men than women.

No similar increased prevalence of osteomyelitis has been identified among children or young adults. However, other demographic differences have been noted. African American children have the highest rates of hospitalization related to osteomyelitis, while the lowest rates are among children of Asian or Hispanic descent. In addition, children who live in households with low median incomes or whose care is covered by private funds or Medicaid are more likely than children from other socioeconomic backgrounds to be hospitalized with acute osteomyelitis.

**Figure 1** A diagram showing three categories of osteomyelitis. A and B, Primary hematogenous (bloodborne) spread of bacteria mainly afflicts the vertebral bodies at all ages or the metaphysis of skeletally immature patients. C and D, Contiguous bone infection is most commonly seen with direct contamination of bacteria in open fractures or joint replacement surgery with prosthetic implants. E, Vascular or neurologic disease associated osteomyelitis most commonly affects the lower extremity. (From Birt MC, Anderson DW, Toby WB, et al: Osteomyelitis: recent advances in pathophysiology and therapeutic strategies, *J Orthop* 14:45–52, 2017.)

### Pathogenesis

Osteomyelitis can occur via hematogenous seeding, direct extension from an adjacent area of infection, or due to inoculation of the bone as a result of trauma or surgery (Figure 1). *Staphylococcus aureus*, in particular, has receptors for fibronectin, laminin, collagen, and sialoglycoproteins that are present in the bone matrix, leading to seeding of the bone and consequent inflammatory reaction. Hematogenous osteomyelitis is more common among children than among adults. In adults, hematogenous osteomyelitis is almost exclusively seen in the spine, resulting from seeding of the disc space from a distant infected site (Figure 2). This can then involve the adjacent vertebral bodies and, with time, result in epidural extension. When hematogenous osteomyelitis occurs in the long bones of children and adolescents, it is almost always in the metaphysis. It is thought that this reflects the circulation in that area, with slowing of bone flow in the terminal capillaries along the area of the physis. In young children, there is connection between the metaphyseal and epiphyseal vessels that can allow infection of the epiphysis and eventually the adjacent joint. This is much less likely to occur in adults.

Bone infections due to trauma are typically related to presence of open fractures. Open fractures usually reflect significant levels of trauma to the bone and secondary soft tissue involvement. Infections can arise in these situations due to direct contamination of the soft tissues and bone with materials from the environment, including clothing, grass, and dirt, with contained bacteria. Open fractures are graded with the system described by Gustilo and Anderson and range from small puncture wounds over the fracture site to soft tissue stripping from the bone to open fractures

with associated vascular injury. This classification system can help in determining the prognosis: patients with higher grade injuries typically have a greater incidence of subsequent infection—up to 50% among patients with concomitant vascular injury. While a small puncture wound over a fracture may seem inconsequential, these wounds usually indicate that bone was exposed at some point and was at risk for bacterial contamination. Open fractures are surgical emergencies and need immediate referral.

Bone infections can develop at sites of prior surgery, especially past surgical sites that include implantation of hardware. Many of these infections are thought to occur during the time of hardware placement. While such infections can occur at the site of any hardware, it is most common among patients who have undergone joint arthroplasty and is one of the most devastating complications of these procedures. The rate of infection after primary joint arthroplasty ranges from 0.3% to 2.4% for total hip arthroplasties (THAs) and 1.0% to 3.0% for total knee arthroplasties. Infection rates are higher among patients who undergo revision surgeries. Patients with infected arthroplasties may present in the first few weeks after surgery or may note onset of new pain in a previously well-functioning joint. The bacteria in these cases not only exist on the surface of the implant but also extend into adjacent bone and soft tissues (Figure 3). Patients with prior surgery of the spine, with or without the placement of hardware, are also at risk of developing late infections in the range of 0.2% to 9%. Suspected infections in areas of prior surgery, especially if implants are in place, require urgent referral.

Osteomyelitis is more likely to occur in patients with serious and/or chronic health conditions, including obesity, malignancy,

**Figure 2** A, Sagittal computed tomography scan demonstrating C6-8 spondylodiskitis. Note the cortical irregularity of the vertebral end plates. There is disc space narrowing and loss of the normal cervical spine curvature. Severe cortical destruction is present due to bacterial infection of the bone and intervertebral disc. B, Sagittal T2 magnetic resonance imaging reveals diffuse T2 signal throughout the vertebral body and disc. Evident is loss of the normal cortical line of the endplates compared to adjacent levels and hyperintensity that extends posteriorly to the soft tissues.

**Figure 3** A, Anteroposterior radiograph of an infected total knee arthroplasty. The radiograph shows resorption of the bone, especially the femur, adjacent to the implant. B, Lateral radiograph of the knee demonstrating lucencies extending posteriorly along the femur and interface between the femur and implant.

immune compromise, substance abuse, and malnutrition. One of the most common of conditions increasing the risk for development of osteomyelitis is diabetes mellitus. An estimated 25% of diabetic patients will develop a foot ulcer at some point in their lifetime, with increased morbidity and mortality, compared to patients with diabetes without foot ulcers. Of these foot ulcers, 20% to almost 60% will harbor underlying osteomyelitis (Figure 4). Infected foot ulcers are the most common risk factor for lower extremity amputations in this population. Diabetic foot ulcers usually start as superficial breaks in the skin or ulcers, which, if they become chronic, are at risk of infection. Infections of foot ulcer in the setting of diabetes are greater among patients with peripheral neuropathy or peripheral vascular disease; these comorbidities can also lead to masking of the signs and symptoms of inflammation,

making a diagnosis of infection more challenging. Superficial infections in diabetic foot ulcers can eventually affect deeper tissues, in some patients progressing to osteomyelitis. Depth of the ulcer, especially in the presence of elevated inflammatory markers, can aid in the diagnosis of osteomyelitis. Involvement of bone can be confirmed with plain films; other imaging modalities, such as magnetic resonance imaging (MRI), white blood cell (WBC) scintigraphy, and 18F-fluorodeoxyglucose (18F) positron emission tomography (FDG-PET)/computed tomography (CT) may be useful in confirming the diagnosis but have variable reported sensitivities and specificities. Treatment of these ulcers and associated infections is multidisciplinary: in addition to administration of antibiotics for culture-confirmed infections and potential surgical debridement of involved tissue, treatment includes local

**Figure 4** Osteomyelitis associated with diabetes/vascular insufficiency. **A**, Anteroposterior radiograph revealing diffuse osteopenia within the fifth toe and subtle cortical disruption along lateral aspect of the proximal phalanx. Note previous amputation of third toe. Patients with loss of protective sensation and poor vascular supply have recurrent or multiple episodes of wound infections that can extend to involve adjacent bone. **B** and **C**, Coronal and axial short tau inversion recovery (STIR) magnetic resonance images. Hyperintense STIR signal along the proximal phalanx and adjacent soft tissues of the fifth toe, consistent with infection and inflammation.

wound care (although evidence of type of wound care is mixed), evaluating and addressing, if needed or possible, peripheral vascular disease; off-loading of the involved portion of the extremity; and appropriate glycemic control.

### Etiology

In children, most cases of acute hematogenous osteomyelitis are caused by a single organism, most commonly *S. aureus*. These cases typically involve the vascular metaphysis of long bones. Coagulase-negative staphylococci can also be an etiology in infants in intensive care with vascular catheters. Other gram-positive cocci include Streptococci: *Streptococcus pneumoniae* in incompletely immunized children, or young children with underlying conditions and *Streptococcus pyogenes* (group A), especially following primary varicella-zoster and *Streptococcus agalactiae* (group B) in neonates. Culture-negative cases occur frequently, and these are usually presumed to be due to *S. aureus* and treated as such. In children 6 to 36 months old, *Kingella kingae*, a gram-negative component of the oral flora, is a major pathogen that causes non-long bone osteomyelitis. *Haemophilus influenzae* type b (Hib) is a rare cause of hematogenous osteomyelitis in young children after the wide implementation of Hib vaccination. Enteric gram-negative bacilli can cause osteomyelitis in infants and children with sickle cell disease. Those with hemoglobinopathies and HIV infection are also at risk for *Salmonella* osteomyelitis.

In adults, hematogenous osteomyelitis primarily presents as vertebral osteomyelitis and is caused by *S. aureus* in more than half of cases in case series in developed countries. The proportion of the cases of hematogenous osteomyelitis due to methicillin-resistant *S. aureus* (MRSA) depends on local epidemiology. Other etiologic organisms include aerobic gram-negative bacilli after genitourinary instrumentation, pyogenic streptococci including group B and C/G in diabetics, viridans and anginosus-group streptococci, enterococci, *Pseudomonas aeruginosa*, coagulase-negative staphylococci in patients with indwelling venous catheters, and injection drug users. In endemic areas, *Brucella* species and *Mycobacterium tuberculosis* should be considered. Disseminated *Mycobacterium avium complex* (MAC) can involve the spine in patients with AIDS. Fungal vertebral osteomyelitis is rare but can occur in people at risk such as individuals who live in endemic areas for dimorphic fungi like *Histoplasma*, *Blastomyces*, and *Coccidioides*; intravenous drug users who can get *Candida* osteomyelitis; and immunocompromised hosts who can develop infections with *Aspergillus*.

Among adults with trauma or open fractures, diabetic and vascular insufficiency foot infections are more likely to develop polymicrobial osteomyelitis with staphylococci, streptococci, enterococci, gram-negative bacilli, and anaerobes (Table 1). After animal or human bites, *Pasteurella multocida*, *Eikenella corrodens*, and oral anaerobic gram-positive cocci are usually identified.

### Clinical Manifestations

Patients with osteomyelitis typically present with pain and tenderness in areas with or without prior injury. They may experience pain with activity but also note pain at rest and that awakens them at night. Symptoms may be acute and localized or gradual onset and nonspecific; the latter may be subtle, making clinical suspicion crucial. There may be noted warmth and erythema, especially in more superficial bones. Patients may also present with fever and other systemic signs of infection. Symptoms of pain at rest and constitutional signs may be interpreted as representing an underlying neoplasm, especially in children, in whom osteomyelitis and Ewing sarcoma often have nearly identical presentations. Patients whose bone infection has involved an adjacent native joint are reluctant to use that joint and have significant pain, even with limited attempts at range of motion. Patients with

**TABLE 2** Medical Treatment of Osteomyelitis

ORGANISM	FIRST CHOICE	ALTERNATIVE
MSSA	Nafcillin, oxacillin or cefazolin	Vancomycin, some add rifampin to nafcillin/oxacillin
MRSA	Vancomycin or daptomycin	Linezolid or levofloxacin + rifampin
Penicillin susceptible <i>Streptococci</i>	Penicillin G, ceftriaxone, or cefazolin	Vancomycin
<i>Enterococci</i> and <i>Streptococci</i> with Penicillin MIC >0.5	Penicillin G, ampicillin with optional gentamicin	Vancomycin with addition of gentamicin

long bone infections, especially children, are reluctant to utilize that extremity, including bearing weight, if the infection involves a lower extremity. Patients with new onset pain in the setting of implanted hardware, especially joint arthroplasties, should be assumed to have an infection until proven otherwise. Patients with vertebral osteomyelitis usually present with unremitting back pain. The diagnosis can be difficult to make, because the symptoms may seem consistent with degenerative changes in the spine and initial plain radiographs prove nondiagnostic. However, continued infections in this area can lead to epidural extension, with neurologic changes that require rapid referral.

### Diagnosis/Confirmation

The clinical diagnosis of osteomyelitis is confirmed by a combination of serum studies, radiographic findings, microbiology or culture results, and pathology, if the patient undergoes surgery. Plain radiographs are an inexpensive initial study; however, their sensitivity in diagnosing osteomyelitis is limited, as the findings of bone loss and periosteal reaction can be attributed to a number of aggressive bone conditions, including neoplasms. In addition, bone loss of approximately 30% to 40% is required before being noted on plain radiographs. MRI provides additional sensitivity and specificity in diagnosis, even in early osteomyelitis, especially if obtained with and without contrast. MRI findings include reduced T1- and heightened T2-weighted bone marrow signals, representing fatty marrow replaced by inflammation. Contrast enhancement patterns can also help to differentiate infection from neoplasia. CT is an alternative to MRI if the latter is not available or the patient is unable to tolerate the examination. CT findings can include gas along fascial plains, decreased density of infected bone, soft tissue masses, and abscesses, as well identifying the course of overlying sinus tracts. Nuclear medicine imaging modalities are more expensive than other imaging options. While in some reports nuclear medicine imaging modalities have been noted to be more sensitive in identifying osteomyelitis, they are less specific, with high false-positive rates. However, they can be useful in imaging areas in which hardware is present, because such metal can significantly limit the details seen on MRI or CT. Nuclear medicine imaging modalities include three-phase Tc99m MDP scan—ideal for bones not affected by underlying conditions, gallium 67 scan (usually performed as sequential bone then gallium scan for comparison), 111-indium radiolabeled WBC scans, or Tc99m sulfur colloid bone marrow scans performed in sequence with WBC scans. These additional imaging modalities are usually used in complicated cases or cases in which the diagnosis is unclear based on other, less expensive tests.

The identification of the infecting organism is crucial to optimal medical management. In cases of presumed osteomyelitis, antibiotics should be withheld until material for culture is obtained, usually via needle aspiration of the area. If the patient requires surgical debridement, tissue can be sent for culture and for pathologic evaluation. Pathology in these instances can help to rule out neoplasia and will demonstrate acute, chronic, or acute on chronic inflammatory cells. Swab cultures of draining sinuses demonstrate poor correlation with adjacent bone cultures, except for *S. aureus*. Material obtained for culture should be sent for both aerobic and anaerobic assessment.

## Treatment

### Medical Treatment

Vertebral osteomyelitis without associated neurologic deficit or nerve compression, and acute hematogenous osteomyelitis in children, are usually treated with systemic antimicrobials without the need for surgical debridement. Most other osteomyelitis syndromes in adults require a combination of medical and surgical treatments to eradicate infection and restore function. A cornerstone of medical therapy for osteomyelitis is identification of the causative organisms in culture. In the absence of associated active soft tissue infection or sepsis, antimicrobials are usually held until adequate cultures are obtained either by aspiration/biopsy or during surgical debridement of the affected bone. Vancomycin (Vancomycin) and beta-lactams including cephalosporins have been used extensively for the treatment of osteomyelitis (Table 2). Although most experience is with intravenous antimicrobials, some data support the use of highly orally bioavailable antibiotics like trimethoprim-sulfamethoxazole (Bactrim)<sup>1</sup>, rifampin<sup>1</sup>, clindamycin, and quinolones. Duration of antimicrobial treatment is generally 4 to 6 weeks based on experimental models and limited prospective studies. Parenteral antimicrobials can be continued outside the hospital using peripherally inserted central catheters (PICCs). In children with hematogenous osteomyelitis, parenteral therapy can be changed to oral when the child is afebrile and able to tolerate oral medications, and duration of therapy as short as 2 to 3 weeks has been reported to be effective.

Fracture site infections following open fractures are treated with debridement, cultures, and organism-directed antimicrobial therapy. Considering that it is common to use or retain fracture fixation devices, long-term oral antimicrobial suppression following induction treatment for 6 weeks is used until fracture healing is documented on imaging. At that point, antimicrobial suppression can be stopped.

Vertebral osteomyelitis treatment might require drainage of associated paravertebral or psoas abscesses by radiology. Duration of antimicrobial therapy might be longer than 6 weeks in patients with undrained abscesses, MRSA infections, or end-stage renal disease. Follow-up at the end of treatment includes assessment of resolution or improvement in pain and in level of inflammation markers in the erythrocyte sedimentation rate C-reactive protein (ESR, CRP) test. A 25% or more reduction in these inflammation markers at the end of therapy is associated with treatment success. Repeat MRI is not routinely recommended and is reserved for patients with failure to improve or worsening symptoms. In 1 to 2 years after successful therapy, spontaneous fusion of the affected vertebral levels usually occurs.

Diabetic foot osteomyelitis management requires evaluation of the vascular supply to the affected area and revascularization is needed in patients with peripheral arterial disease to optimize surgical outcome and minimize need for amputation. Because most of these infections are polymicrobial, use of antimicrobials with anaerobic spectrum of activity is recommended (piperacillin-tazobactam [Zosyn]<sup>1</sup>, ampicillin-sulbactam [Unasyn]<sup>1</sup>, ertapenem

<sup>1</sup>Not FDA approved for this indication.

[Invanz]<sup>1</sup>, cephalosporins with metronidazole [Flagyl], quinolones with metronidazole or clindamycin).

### Surgical Treatment

Surgery is often performed in conjunction with antibiotic treatment in cases of osteomyelitis of long bones, especially in cases of chronic osteomyelitis or in the presence of bone abscesses, typically in cases of chronic osteomyelitis or in the presence of bone abscesses, especially in the presence of implanted hardware. Surgery for osteomyelitis of the spine is usually reserved for patients whose infection does not completely respond to antibiotic treatment or who develop neurologic deficits. Surgical treatment of osteomyelitis of long bones is primarily performed with wide excisional debridement and copious irrigation. The order in which the operations are performed is very important because a large bacterial load can be pushed further into surrounding bone and soft tissues by irrigating before debridement. The adage “the solution to pollution is dilution” accurately describes the intent of copious irrigation at a site of bone infection.

Bacteria identified within bone, either causing a biologic breakdown of the structure of the bone (infection) versus bacteria on or near bone (colonization), are two distinct clinical pictures. The structure of bone is similar to that of sponge; bacteria resulting in osteomyelitis can “hide” in the caverns and nooks of cancellous bone quite readily, leading to small local abscess communities in the bone, bone marrow, and surrounding soft tissues, making it difficult to eradicate them through the host inflammatory response or with systemic antibiotics. In addition, bacteria in these areas may not be exposed to antibiotic agents, WBCs, or irrigation solutions. Therefore, they can exist and multiply until the bone reacts and begins to break down at the site of the infection. Given this analogy, it is understandable that there is the need to irrigate a site of osteomyelitis thoroughly to dilute the bacterial load and then allow antibiotics the opportunity to work to eliminate the remaining pathogens from the infected bone.

To rid the bone of infection, surgeons typically debride bone that is obviously infected and/or necrotic, while healthy bone can and will be removed up to the margin of infected bone to improve the likelihood of healing in the absence of infection. This is critical to the success of the procedure but can lead to large defects. In addition, adjacent soft tissues should be sharply debrided back to healthy, bleeding tissue. As a result, WBCs can come into the area along with antibiotic agents delivered via the healthy, small blood vessels to complete the task of eliminating the bacteria. It is important that tissue removed during these procedures is sent for culture, as well as for pathologic examination.

Debridement involving infected bone with orthopedic implants adjacent to the site can be challenging. These implants and any surrounding necrotic tissue can be colonized by bacteria, often in the form of a surrounding glycocalyx or exopolysaccharide coating that envelops the bacteria. In some patients, this can necessitate the removal of rods, plates, screws, or the components of a joint replacement, as systemic antibiotics are unable to access bacteria housed in this biofilm. Removing the implant results in removal of the glycocalyx and reduces the bacterial load but frequently necessitates subsequent reconstructive surgeries.

Often, with obvious purulent infections, several surgical procedures are required to accomplish the task of bacterial elimination. The initial bacterial load can be so great that even after significant tissue (both bone and soft tissue) has been excised and irrigated, the surgeon cannot confidently close the wound for the completion of the case. Surgical decision making may include a second or third procedure to assess the site and determine the need for further tissue removal and irrigation versus wound closure. When multiple (staged) procedures are performed, wound coverage techniques can help to continue to minimize or eliminate bacteria during the patient’s hospitalization.

A vacuum-assisted closure (VAC) device is one such coverage technique. These devices apply a vacuum or negative pressure environment to the wound with an evenly applied suction level to allow for

continued bacterial debridement while keeping the wound covered during the time that the patient is out of the operating room. The VAC can be applied after the excisional debridement and irrigation procedure has been completed. VACs are typically used in anticipation of a return to the operating room for a second or third procedure.

A wound VAC device is applied to the bed of the wound utilizing three key elements: (1) a sponge substrate (for even application of the suction), (2) a plastic tape to seal the wound edges, and (3) a suctioning device or pump to apply the negative pressure to the wound. Once applied, these devices can continue to promote healthy tissue growth and create a hostile environment for bacteria, thereby limiting bacterial proliferation.

### Conclusion

Patient outcomes after treatment of osteomyelitis have improved over the years with development of new imaging technologies to improve diagnostic accuracy, development of new antibiotics and antibiotic delivery methods, and expanded surgical techniques. Most importantly, treatments, both medical and surgical, are based on a better understanding of the pathogenesis of this infection. However, given the continued increase in prevalence of this condition, we need additional research to better understand the contribution of various risk factors and comorbidities so that we can improve prevention efforts and continue to tailor multidisciplinary interventions.

## PLAGUE

Method of

Nelson Iván Agudelo Higuera, MD; Douglas A. Drevets, MD; and Deidra Bowman, MD

### CURRENT DIAGNOSIS

- Plague should be suspected when a person develops abrupt onset of fever, lymphadenopathy, or sepsis and there is history of a flea bite or possible exposure to an infected animal or person.
- *Yersinia pestis* is an aerobic gram-negative coccobacilli that exhibits bipolar staining with Giemsa, Wright's, and Wayson stains.
- Automated diagnostic systems may misidentify *Y. pestis* as another organism.

### CURRENT THERAPY

- Timely and appropriate management is imperative for a good outcome.
- Despite their toxicities, aminoglycosides are the treatment agents of choice.
- Respiratory droplet precautions should be instituted when pneumonic plague is suspected.
- Postexposure prophylaxis is indicated for close contacts.

Historical descriptions indicate that *Yersinia pestis* probably caused Justinian's Plague (AD 541), which led into the first plague pandemic. The second plague pandemic, also known as the Black Death, began in Central Asia in 1347 and then spread to Europe, Asia, and Africa. It killed an estimated 50 million people. The current (third) plague pandemic began in China and then spread worldwide along shipping routes in 1899–1900. *Y. pestis* is a gram-negative, nonmotile, facultatively anaerobic, non-spore-forming coccobacillus that is approximately 0.5 to 0.8  $\mu\text{m}$  in diameter and 1 to 3  $\mu\text{m}$  in length. Genomic sequencing shows that *Y. pestis* is a recently emerged clone of *Y. pseudotuberculosis*.

### Epidemiology

Plague is a zoonosis for which urban and sylvatic rodents (e.g., rats, prairie dogs, and marmots) are the most important enzootic reservoirs. Additionally, domestic cats and dogs have been linked to human disease. Human plague occurs in North and South America, Asia, and Africa. Recent outbreaks reported to the World Health Organization (WHO) have occurred in the Democratic Republic of Congo (2005, 2006), China (2009), and Peru (2010). Plague is endemic in Madagascar, and between 2004 and 2009, 30% of all human cases worldwide were reported from this country. The largest epidemic in a quarter of a century was identified August 1, 2017, and was contained November 27, 2017. A total of 2417 cases (77% pneumonic) with a 9% case fatality ratio were reported. From 2000 to 2009, a total of 21,725 cases of plague with a 7.4% fatality rate were reported worldwide. The incidence of plague in most of the world is otherwise declining. In 2018, only 5 countries reported cases of plague. In North America, most human cases occur in New Mexico, Arizona, California, Colorado, and Texas. Between 1900 and 2012, 1006 confirmed or probable cases have occurred in the U.S. with over 80% of these attributable to bubonic plague. More information can be found on the WHO and Centers for Disease Control and Prevention websites.

### Modes of Transmission

Most human infections are transmitted from rodent to humans via the bite of an infected flea. Infection also can be acquired by

contact with body fluids from infected animals, such as during field dressing of game or by inhalation of respiratory droplets from animals, particularly cats, or humans with pneumonic plague.

### Bioterrorism Threat

Plague was used as an agent of biowarfare by the Japanese in World War II and was a focus of intensive research and development in the former Soviet Union during the Cold War. Primary pneumonic plague is the most likely form of exposure because of biowarfare or bioterrorism. Recent increases in terrorism worldwide have increased the focus of public health management groups to develop comprehensive statements regarding plague as a biological weapon.

### Pathogenesis and Clinical Syndromes

Transdermal inoculation of bacilli from the bite of an infected flea ultimately leads to infection of the regional lymph nodes in which massive replication of bacteria creates the bubo (derived from the Greek *bubon* or "groin"), a swollen, erythematous, and painful lymph node in the groin, axilla, or cervical region. Bacteremia and septicemia frequently develop and lead to secondary infection of other organs including the lungs, spleen, and central nervous system. Primary pneumonic plague is a rare natural occurrence and results from the inhalation of respiratory droplets containing *Y. pestis* bacilli from another case of pneumonic plague, usually in humans or in cats. Although plague in dogs is rare, human outbreaks have been traced to sick dogs with wildlife exposure. Secondary pneumonic plague results from seeding of the lungs by blood-borne bacteria in the setting of either bubonic or septicemic plague. Septicemic plague also begins with transdermal exposure but manifests as primary bacteremia/septicemia without the bubo. Less common manifestations include meningitis, pharyngitis, and gastroenteritis. In addition, inhalation of respiratory droplets produced by intense manipulation of human corpses or animal carcasses are another potential form of infection. Direct skin contact with infected blood from a corpse or carcass could also result in bubonic plague. Finally, transmission of antimicrobial resistant *Y. pestis* has been documented during outbreaks of pneumonic plague.

Bubonic plague is an acute febrile lymphadenitis that develops 2 to 8 days after inoculation. Inflamed lymph nodes are usually 1 to 6 cm in diameter and painful. Abrupt onset of fever is an almost universal finding and occurs simultaneously with, or up to 24 hours before, the appearance of the bubo. Headache, malaise, and chills are frequent, along with nausea, vomiting, and diarrhea. Most patients are tachycardic, hypotensive, and appear prostrate and lethargic with episodic restlessness. Leukocytosis with a left shift is typical. Complications include pneumonia, shock, disseminated intravascular coagulation, purpuric skin lesions, acral cyanosis, and gangrene. The differential diagnosis of bubonic plague includes tularemia and Group A  $\beta$ -hemolytic streptococcal adenitis with bacteremia.

Symptoms of septicemic plague are similar to those caused by other gram-negative bacteria, and are very similar to those of bubonic plague except that abdominal pain is more common in septicemic plague. Septicemic plague must be differentiated from fulminating septicemia caused by other gram-negative bacteria. Primary pneumonic plague has an abrupt onset of fever and influenza-like symptoms 1 to 5 days after inhalation exposure. Symptoms include shortness of breath, cough, chest pain, and bloody sputum with rapid progression to fulminating pneumonia and respiratory failure. Patients with secondary pneumonic infection show respiratory symptoms in addition to those attributed to the bubo or sepsis. Radiographic findings include patchy bronchopneumonia, multilobar consolidations, cavitations, and alveolar hemorrhage and are not pathognomonic of *Y. pestis*. Plague pneumonia must be differentiated from severe influenza, inhalation anthrax, and overwhelming community-acquired pneumonia.

### Diagnosis

Plague is diagnosed by demonstrating *Y. pestis* in blood or body fluids such as a lymph node aspirate, sputum, or cerebrospinal fluid.

A tentative diagnosis of bubonic plague can be made rapidly with fluid aspirated from a bubo showing gram-negative coccobacilli with bipolar staining. It is important to remember that automated diagnostic systems might misidentify *Y. pestis*. In an outbreak in Colorado, the misidentification of *Y. pestis* as *Pseudomonas luteola* delayed the recognition of the outbreak. *Y. pestis* has also been misidentified as *Y. pseudotuberculosis* with matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF). Serology showing a fourfold rise in antibody titers to F1 antigen or a single titer of more than 1:128 is also diagnostic. Rapid tests using monoclonal antibodies to detect *Y. pestis* F1 antigen in bubo aspirates and sputum have been developed and field tested. The use of mass spectrometry as a more rapid and cost-effective diagnostic tool has also been studied.

### Treatment

The aminoglycosides (gentamicin<sup>1</sup> and streptomycin), the fluoroquinolones (ciprofloxacin [Cipro] moxifloxacin [Avelox] and levofloxacin [Levaquin]) and doxycycline (Vibramycin) are considered first line therapy for all forms of plague with the exception of pneumonic and septicemic plague, in which doxycycline is considered an alternative agent. For plague meningitis, the first line therapy consists of levofloxacin, moxifloxacin, or chloramphenicol. Typical minimal inhibitory concentrations for 90% (MIC<sub>90</sub>) of tested strains for the fluoroquinolones are less than 0.03 to 0.25 µg/mL compared with less than 1.0 µg/mL and less than 1.0 µg/mL to 4.0 µg/mL for gentamicin and streptomycin, respectively, and less than 1.0 µg/mL for doxycycline. Streptomycin (15 mg/kg up to 1 g intramuscularly [IM] every 12 hours) and gentamicin (5 to 7 mg/kg/day intravenously [IV]/IM in one or two doses daily) are the drugs of choice for severe infection. For adults, standard fluoroquinolone dosing includes ciprofloxacin 400 mg IV every 8 hours or 750 mg orally every 12 hours; levofloxacin 750 mg IV/orally daily; and moxifloxacin 400 mg IV/orally daily. Doxycycline is administered starting with a 200 mg loading dose followed by 100 mg IV/orally every 12 hours. Chloramphenicol (25 mg/kg IV/orally every 6 hours) can be used in select circumstances. Antibiotic therapy should be continued for a total of 10 days; some experts will extend the duration of therapy to 14 days when a bacteriostatic agent like a tetracycline is used.

### Prevention and Control

Standard infection control procedures should include a disposable surgical mask, latex gloves, devices to protect mucous membranes, and good hand washing. Hospitalized patients with known or suspected pneumonic plague should be isolated under respiratory droplet precautions for at least 48 hours after appropriate antibiotics are initiated. Patients without respiratory plague can be managed under standard precautions. Pre-exposure prophylaxis is not routinely recommended but can be considered under certain circumstances and for up to 48 hours after the last potential exposure. Postexposure prophylaxis should be given to individuals with close contact (less than 2 meters) with an infectious case or who have had a potential respiratory exposure. The recommended adult antibiotics for prophylaxis are doxycycline or ciprofloxacin in the same doses used for treatment. Postexposure prophylaxis can be given orally and should be continued for 7 days following exposure. Currently, there is no licensed plague vaccine. An encapsulated *Y. pseudotuberculosis*, strain V674pF1, is an efficient live oral vaccine against pneumonic plague in mice. Recently, flea resistance to insecticides such as DDT and Deltamethrin in Madagascar has prompted an immediate need for alternative insecticides to prevent future plague outbreaks.

## POST-ACUTE COVID SYNDROME

Method of

Victor S. Sierpina, MD; Justin Seashore, MD; and Sagar Kamprath, MD

### CURRENT DIAGNOSIS

- *Post-acute COVID syndrome* is defined as symptoms extending 3 weeks to 3 months after the acute disease occurs, and *long-haul COVID* is defined as symptoms persisting beyond 3 months after the infection has resolved.
- Predominant symptoms are new-onset shortness of breath, cough, palpitations, fatigue, and brain fog. Other common symptoms include gastrointestinal disturbances, headache, hair loss, new-onset nondescript pain, depression, anxiety, and posttraumatic stress disorder.
- Results of testing are not part of the current definition as many patients were not tested and are or were asymptomatic carriers.
- The broad spectrum of clinical manifestations of post-acute COVID syndrome should encourage clinicians and medical educators to include it in the differential diagnosis of any of a number of new or worsening complaints.

### CURRENT TREATMENT

- Evidence for optimal management of long-haul COVID may be lacking at this time but is evolving, with best practices being described by multiple professional bodies.
- Multidisciplinary management and rehabilitation are essential to whole-person care.
- Organ- and system-specific care is appropriate and must be prioritized as to serious versus milder long-term problems.
- Self-management and peer support can play important roles and must include shared decision making.
- Appropriate consultation and use of currently established disease-specific and organ-specific practice guidelines are foundational to optimal treatment planning.
- Quality-of-care principles for long-haul COVID include providing access to care, reducing the burden of illness, taking clinical responsibility, offering continuity of care, providing multidisciplinary rehabilitation, conducting evidence-based investigation and management, and continuing further research and development on appropriate and evidence-based clinical services.

<sup>1</sup>Not FDA approved for this indication.

Over the past 3 years, we have endured an ever-changing multimodal disease process, devastating millions of people not only with severe infection but also with mild or asymptomatic forms of the disease. Our understanding and definitions of the spectrum of conditions that encompasses post-acute COVID syndrome and long-haul COVID is an ongoing discovery. It is estimated that 10% to 30% of COVID-infected patients may be left with residual symptoms. With over 500,000 million worldwide known cases and many not reported, untested, or asymptomatic, post-acute COVID syndrome can be expected to affect a huge number of people.

Equally concerning is the puzzling discovery that those with even mild or asymptomatic COVID infections may develop post-acute COVID syndrome. Vaccination is largely protective of severe disease, though the syndrome may still occur in a small number of these patients. Children generally do not experience severe post-acute COVID syndrome, although psychological, mental health, and gastrointestinal symptoms are of increasing concern in this group and are often difficult to dissect from pre-existing conditions.

Some key ongoing questions include the following:

- What is the underlying biology of long-haul COVID?
- How many people become infected with long-haul COVID and who is most at risk?
- What is the relationship between long-haul COVID and other post-infection syndromes?

We endeavor to address these questions, though much further research is needed. We present here a holistic and methodical foundational program that uses minimally invasive procedures and management strategies. This approach will offer patients with post-acute COVID syndrome an improved quality of life with low-risk, cost-effective, common-sense healthcare approaches. The evidence base for this approach is grounded in current best practices but continues to evolve with new knowledge about the course of post-acute COVID syndrome. In parallel, we must guide patients away from high-risk, high-cost invasive therapies that have no proven benefit.

Healthcare professionals must be cognizant of the range of real physical long-term effects of COVID-19 and should address them with clinical discernment, understanding, and empathy. They should be careful not to label all such presentations as related to stress, anxiety, depression, or other psychological epiphenomena. The role of peer support is clearly important to those with post-acute COVID syndrome who may otherwise feel isolated and misunderstood.

### Pathophysiology

COVID-19 is caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and is genetically similar to the severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) coronaviruses that were responsible for the SARS outbreaks earlier in the century. SARS and MERS infections have been found to result in long-term postviral syndromes, some extending a decade or more after the initial disease. Coronaviruses that circulate among humans are usually benign and are responsible for about one-fourth of all common cold illnesses, with a total of seven human coronaviruses in known existence. However, it is likely that bats, a natural animal reservoir, facilitated mutation of the virus in China in late 2019. Another spillover possibility, escape of modified virus from a research laboratory in Wuhan, is still being debated. This novel coronavirus is composed of single-stranded RNA with its envelope surrounded by spike proteins resembling a crown, typically transmitted through respiratory droplets as well as fecal-oral transmission. The incubation period is about 5 days, though some variants such as the Delta variant have a shorter cycle and are potentially followed by 1 week of worsening symptoms that may lead to hospitalization in severe cases. Interferon is a key component that affects the mechanism of viral infection. Higher viral loads and delayed interferon responses are seen in severe infection, and it may be likely that patients most susceptible to

severe disease cannot adequately mount an effective early antiviral response.

The virus attaches to cells via the ACE2 receptor, found in our tongue, nose, throat, stomach, small intestine, liver, brain, kidneys, and lungs. In the lungs, it binds to type 2 alveolar cells, where it replicates. The cells subsequently send a distress signal of cytokines and downregulate the ACE2 receptor, decreasing angiotensin 1 to 9 and angiotensin 1 to 7 (pro-vasodilation and antifibrotic). Angiotensin 1 receptors become more stimulated, which leads to a proinflammatory and profibrotic stage. COVID-19 also favors disordered endothelial function, which contributes to protein accumulation in the alveolar space seen in the “cytokine storm” directly related to capillary leak and the cases of ARDS seen in advanced states of the disease. Unfortunately, this is not only limited to the lungs, but predisposes the entire body system to a prothrombotic state, as seen in cases of stroke and other types of ischemic dysfunction. In this inflammatory state, vascular endothelial and smooth muscle cells produce large amounts of IL-6. This stimulates the acute-phase response, increasing fibrinogen production and favoring clot formation.

COVID-19 remains a complex disease process of the endothelium, and future treatments may focus on antiinflammatory therapies and promoting endothelial homeostasis. Obesity is one of the major risk factors for the cytokine storm as it induces a constant state of low-grade inflammation characterized by acute-phase reactants, reactive oxygen species, and proinflammatory cytokines. However, moderate exercise over time enhances the immune system, mobilizing NK and CD8+ T cells, and overall improves immunosurveillance and lowers inflammation.

### Prevention

Conventional prevention includes the well-known guidelines from the Centers for Disease Control and Prevention (CDC) regarding masking, social distancing, hand washing/avoidance of touching the face, various isolation and quarantine measures, and vaccination. Large droplets are the primary mode of spread, which can be greatly mitigated with widespread mask wearing in addition to adequate ventilation.

Monoclonal antibodies may also be used in acute infection as they bind to the spike proteins of the coronavirus and can reduce the viral load, theoretically reducing the severity of the illness. Immunotherapy continues to evolve as certain formulations are more or less effective against emerging variants.

Given that over 99% of the recent cases in 2022 within the United States were caused by the omicron variant, bamlanivimab<sup>5</sup> and etesevimab<sup>5</sup> (administered together)<sup>5</sup> and REGEN-COV (casirivimab and imdevimab)<sup>5</sup> are not recommended because they have reduced activity against this variant. Paxlovid<sup>5</sup> (nirmatrelvir and ritonavir, approved for Emergency Use Authorization [EUA] by the U.S. Food and Drug Administration [FDA]), sotrovimab<sup>5</sup> (no longer has EUA), remdesivir (Veklury), molnupiravir<sup>5</sup> (Lagevrio, approved for EUA), and most recently bebtelovimab<sup>5</sup> (approved for EUA) are recommended for those with mild-to-moderate COVID-19 who are at risk for progression to severe disease. The monoclonal antibodies leronlimab<sup>5</sup> and tocilizumab (Actemra),<sup>1</sup> which have been efficacious in treating HIV, have been shown to reduce IL-6 levels in COVID-19 and are being further studied. Healthcare providers can consult with the National Institutes of Health’s COVID-19 guidelines to decide whether these therapies are beneficial for individual patients as they are expected to evolve with new variants.

These measures may be used for patients with COVID-19 who are not sick enough to be hospitalized but are at risk for hospitalization because of medical comorbidities such as diabetes, immunosuppression, or obesity. Vaccination along with booster are still recommended for these patients. Access, cost, and administration hurdles impede the availability of immunotherapies worldwide.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

The recent mRNA vaccines offer hope for prevention of infection and transmission, with current projections of 94.5% efficacy in reducing severe disease. Additionally, as new variants occur, these newly developed vaccines continue to protect up to 100% against severe COVID-19 infections. However, it is recommended to continue masking and engaging in social distancing even after vaccination. Some recent reports have indicated that patients suffering with post-acute COVID symptoms found that getting the COVID vaccine relieved these symptoms. The exact mechanism of this is unknown and bears further study but may have to do with clearing residual virus or reducing autoimmune and inflammatory processes.

Rates of anxiety and depression have increased during the pandemic, and this subsequently attenuates the immune system. Managing these appropriately and promptly can improve immunity as well as quality of life. Spending time outside and engaging in physical activity can also help strengthen the immune system and mitigate the cabin fever of COVID-19. Breathing techniques such as resonant breathing, singing, or 4-7-8 breathing can also help increase parasympathetic tone, increase heart rate variability, and decrease stress. At least 7 hours of sleep before vaccination provides a more robust antibody response from the immune system.

Other less proven but widely used methods include use of various supplements such as vitamin C,<sup>1</sup> vitamin D,<sup>1</sup> quercetin,<sup>7</sup> zinc,<sup>1</sup> probiotics,<sup>7</sup> luteolin,<sup>7</sup> melatonin,<sup>7</sup> and other supplements. None of these methods have been proven in prospective trials, but they are widely used, and there is some historical evidence for their utility and mechanisms of action in other coronavirus-like infections such as the common cold. An open discussion with patients regarding the limited evidence for them may be helpful while respecting patient autonomy and desire for agency in selecting self-care strategies in the presence of fear and uncertainty.

Vitamin C remains a potent antioxidant and anecdotally beneficial in several studies. The ongoing Lessening Organ Dysfunction With VITamin C—COVID-19 (LOVIT-COVID) clinical trial (NCT04401150) is assessing high-dose intravenous vitamin C for inpatients with COVID-19. For prevention, one may focus on increasing consumption of foods high in vitamin C such as citrus.

Vitamin D is an important regulator of human immune function and may stimulate the innate immune response to provide front-line protection against infectious agents. On the whole, people are spending less time outside in the sunlight, which hampers the production of the active form of vitamin D. Recently it was noted that higher vitamin D levels correlated with fewer COVID-19 cases and mortality. This could be a result of low vitamin D being a marker of a sedentary lifestyle and thus likely overall health risk. Whether or not one is COVID positive, taking vitamin D may be beneficial in a dose of around 4000 IU daily. There is also evidence that vitamin K<sub>2</sub><sup>1</sup> may be helpful in the absorption of vitamin D, but it should be avoided in patients on blood thinners.

Quercetin is a naturally occurring dietary flavonoid with antiviral properties and may disrupt the infectious mechanism of the coronavirus. It is an antioxidant found in many plant foods including capers, red onions, apples, leafy greens, dill, cilantro, fennel, berries, sweet potato, tomatoes, broccoli, and tea. Quercetin can also be purchased as a supplement. It is often combined with vitamin C to increase absorption and taken up to 500 mg twice a day.

Zinc impairs replication in RNA viruses and may enhance cytotoxicity when used with a zinc ionophore such as quercetin. Long-term zinc supplementation may result in copper deficiency, thus replacing copper is recommended.

N-acetylcysteine,<sup>1</sup> a glutathione precursor, at 600 mg orally twice per day, may help improve oxidative stress and inflammatory response in patients with upper respiratory tract infections. N-acetylcysteine assists the liver in reducing glutathione,

which in turn helps the liver in removing toxins. A case report has noted that glutathione supplementation has improved dyspnea in COVID-19 patients. These may represent a novel treatment approach in blocking nuclear factor kappa B (NF-κB) and attenuating the cytokine storm seen in COVID-19.

Several trials to assess various adaptogens, probiotics, and dietary supplements such as nicotinamide riboside<sup>7</sup> are currently underway as additional therapies for long-haul COVID. Hyperbaric oxygen therapy, montelukast (Singulair),<sup>1</sup> and deupirfenidone<sup>5</sup> are being evaluated to help with COVID-related respiratory complaints. Histamine-1 and histamine-2 antagonists show promise by inhibiting the virus from entering ACE-2-expressing cells. In addition, use of selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) has been associated with reduced risk of intubation or death in COVID-19. As future trials ensue, we may have clearer direction in treating the long-term effects of COVID-19.

### Clinical Manifestations

The multifaceted aspects of long-haul COVID are shown in [Figure 1](#). According to the CDC, the most commonly reported long-term post-acute COVID symptoms are outlined in [Box 1](#).

### Diagnosis

The predominant symptoms leading patients to seek help are focused on new-onset shortness of breath, cough, palpitations, fatigue, and brain fog. Other common symptoms include gastrointestinal disturbances, headache, hair loss, new-onset nondescript pain, depression, anxiety, and posttraumatic stress disorder (PTSD).

*Post-acute COVID syndrome* is defined as symptoms extending 3 weeks to 3 months after the acute disease occurs, and *long-haul COVID* is defined as symptoms persisting beyond 3 months after the infection has resolved. Results of testing are not part of the current definition as many patients were not tested and are or were asymptomatic carriers. Even antibody testing is not entirely reliable as we are unsure of the durability of post-infection IgG results.

Persons with the following risks were two to three times more likely to develop long-haul COVID: persistent cough, hoarseness, headache, diarrhea, loss of appetite, and shortness of breath in the first week.

Persons with more than five symptoms in the first week of illness were four times more likely to develop long-haul COVID than those with fewer symptoms. The five most predictive symptoms of long-haul COVID in the first week of illness were fatigue, headache, shortness of breath, hoarse voice, and myalgia. Long-haul COVID was also more likely to occur in women, older adults, and those with obesity. An autoimmune component may explain the higher rate of post-acute COVID syndrome in women.

Indeed, post-acute COVID syndrome may comprise four or more syndromes rather than one distinct postviral entity, and it may include post-intensive care syndrome, post-viral fatigue syndrome, and long-haul COVID. Symptoms may fluctuate and present in nonlinear and nonsequentially unpredictable ways.

Such conditions have been seen in other post-infectious conditions, largely as a result of the persistence of the immune response, ongoing inflammation, and effects on blood coagulation.

After the Spanish flu of 1918, which killed an estimated 50 million people, late-occurring neurologic sequela included long-lasting brain damage in up to 1 million people. SARS and MERS as well as myalgic encephalomyelitis or chronic fatigue syndrome are other syndromes that share overlapping symptoms with post-acute COVID syndrome.

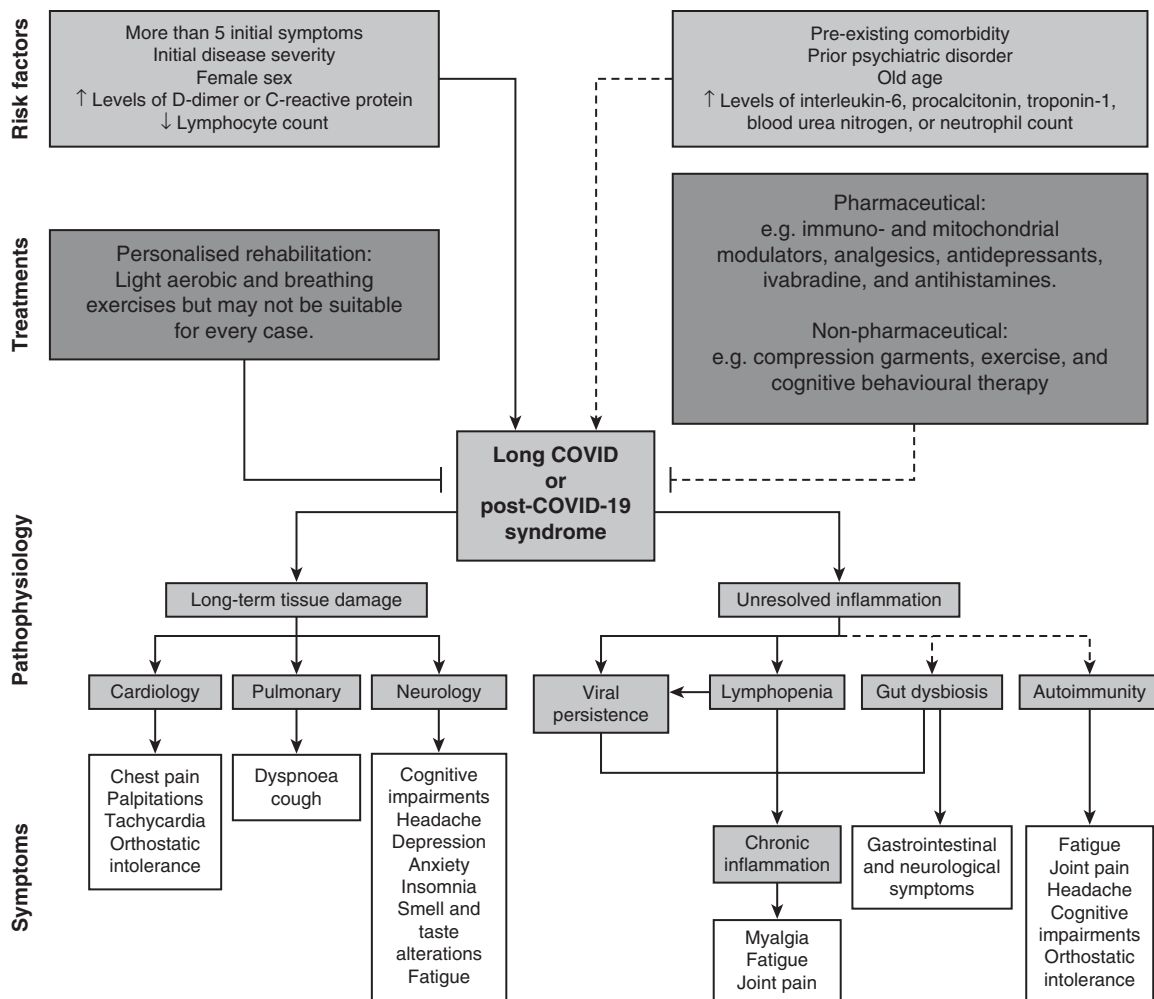

Long-haul COVID is an evolving clinical problem that has important public health and long-term considerations as the pandemic continues and it becomes endemic.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

<sup>5</sup>Investigational drug in the United States.

<sup>7</sup>Available as dietary supplement.

**Figure 1** An overview of the symptoms, putative pathophysiology, associated risk factors, and potential treatments involved in long-haul COVID. Dashed lines represent areas where evidence is relatively lacking compared with the solid lines. (Modified from Yong SJ: Long COVID or post-COVID-19 syndrome: putative pathophysiology, risk factors, and treatments, *Infect Dis (Lond)* 53(10):737–754, 2021.)

## Therapy

Once post-acute COVID syndrome or long-haul COVID is suspected or diagnosed, determining the patient’s baseline status helps organize and systematize clinical interventions. Addressing evolving exacerbations and life-threatening manifestations must take priority. It is important to avoid unproven, high-cost, invasive experimental therapies outside of clinical trials. The general principles of management are described in a monograph by the National Institute for Health and Care Excellence (NICE) (Box 2).

For clinicians, a standardized approach to patients in the initial setting is important. Functional and behavioral assessments are of central importance as the rehabilitation of patients requires management of both. Multidisciplinary teams to direct care and address newly developing symptoms should be utilized when available.

To begin evaluation of the patient with post-acute COVID syndrome, the clinician should perform initial screening with standardized questionnaires including shortness-of-breath scales, such as the University of California, San Diego Shortness of Breath Questionnaire (SOBQ), and activity scales that assess activities of daily living (ADLs) and instrumental activities of daily living (iADLS). Nutritional evaluation (e.g., the subjective global assessment [SGA]), the Generalized Anxiety Disorder 7-Item Questionnaire (GAD-7), the Patient Health Questionnaire-9 (PHQ-9), the International Education Standard-6 (IES-6), and the Impact of Event Scale-Revised (IES-R) are examples of behavioral assessments that can be used to evaluate anxiety, depression, and PTSD along with an ongoing symptoms evaluation. Use of these scales

with each visit allow for individualized evaluations of improvement (Box 3).

Utilizing a multidisciplinary rehabilitation team including physicians, rehabilitation therapists, psychologists, nutritionists, and social workers to review these screenings allows the healthcare provider to develop a personalized, patient-centered approach to care.

Shared decision making with patients is key, given the vast number of symptoms patients may be experiencing. Discussing which are most troubling and limiting to the patient is of importance in goal setting. From this baseline, the healthcare provider can establish plans to address the most severe symptoms initially and determine those that can be readdressed in the future.

Acute COVID-19 presents with a broad range of symptoms, therefore patients recovering from this illness show heterogeneity that may be phenotypic. Some have few or no residual symptoms after the acute infection, while others show sustained symptoms at higher or lesser clinical penetrance.

## Pulmonary

For many, respiratory symptoms may be the predominating indication, therefore a proper pulmonary examination is important. Pulse oximetry, pulmonary function testing, a 6-minute walk test, and chest x-ray are good starting points. Utilization of pulmonary rehabilitation will guide patients through this new sensation of shortness of breath and reduce symptom burden. This aspect of rehabilitation should not be limited to patients with only abnormal pulmonary function testing. Home monitoring with pulse oximetry is recommended. It is also important to eliminate other

### BOX 1 Symptoms Commonly Reported Among Patients with Post-Acute COVID Conditions

- Dyspnea or increased respiratory effort
- Fatigue
- Post-exertional malaise\* and/or poor endurance
- "Brain fog," or cognitive impairment
- Cough
- Chest pain
- Headache
- Palpitations and/or tachycardia
- Arthralgia
- Myalgia
- Paresthesia
- Abdominal pain
- Diarrhea
- Insomnia and other sleep difficulties
- Fever
- Lightheadedness
- Impaired daily function and mobility
- Pain
- Rash (e.g., urticaria)
- Mood changes
- Anosmia or dysgeusia
- Menstrual cycle irregularities

\*Post-exertional malaise (PEM) is the worsening of symptoms following even minor physical or mental exertion, with symptoms typically worsening 12 to 48 hours after activity and lasting for days or even weeks.

From Centers for Disease Control and Prevention: Clinical Care Information for COVID-19. Post-COVID Conditions: Overview for Healthcare Providers. Available at: <https://www.cdc.gov/coronavirus/2019-ncov/hcp/clinical-care.html>.

factors for dyspnea such as smoking, air pollutants, extremes in temperature, or excess exercise.

Several breathing techniques have been offered to help patients deal with breathlessness, improve diaphragmatic breathing, and help normalize lung function (Box 4).

The question of whether to use inhaled bronchodilators remains. A potential practice is to begin a trial with a short-acting agent to be used when symptomatic, and if the patient notes temporary benefit and the need to use it frequently, a long-acting beta agonist plus an inhaled corticosteroid can be considered. COVID-19 is known to induce an inflammatory response, and this may abate symptoms. Step-down therapy should be planned as one would do for asthma.

As pulmonary symptoms such as cough and shortness of breath have predominated presenting concerns in patients with post-acute COVID syndrome, a program at Yale called RECOVERY has been developed that could be a model for approaching pulmonary and other systems (Figure 2).

#### Cardiac

Another key organ affected by COVID-19 infection is the heart. Cardiotoxicity from the infection can cause inflammation of the heart (myocarditis), rhythm disturbances, and damage to the heart muscle (cardiomyopathy). Sudden cardiac death, heart attacks, and heart failure have all been observed, including Takotsubo heart syndrome. Beta blockers and immunotherapy may be indicated.

Cardiac symptoms such as palpitations or increased resting heart rate can be further evaluated with long-term ambulatory cardiac monitoring. A cardiopulmonary exercise test or echocardiogram can assist in delineating cardiac from pulmonary symptoms.

### BOX 2 Management of Post-Acute COVID Syndrome

These recommendations are for healthcare professionals who provide care for patients with ongoing symptomatic COVID-19 or post-acute COVID syndrome in primary care and community settings or in multidisciplinary assessment and rehabilitation services.

#### Self-Management and Supported Self-Management

- Give advice and information on self-management to people with ongoing symptomatic COVID-19 or post-acute COVID syndrome, starting from their initial assessment. This should include the following:
  - Ways to self-manage their symptoms, such as setting realistic goals
  - Who to contact if they are worried about their symptoms or if they need support with self-management
  - Sources of advice and support, including support groups, social prescribing, online forums, and apps
  - How to obtain support from other services, including social care, housing, and employment, and advice about financial support
  - Information about new or continuing symptoms of COVID-19 that patients can share with their family, careers, and friends (see the section on common symptoms of ongoing symptomatic COVID-19 and post-acute COVID syndrome [<https://www.nice.org.uk/guidance/NG188>]).
- Explain that it is not known if over-the-counter vitamins and supplements are helpful, harmful, or have no effect in the treatment of new or ongoing symptoms of COVID-19.
- Support patients in discussions with their employer, school, or college about returning to work or education, for example by having a phased return. For advice on returning to work, follow national guidelines such as the NICE guideline on workplace health: long-term sickness absence and capability to work.

#### Multidisciplinary Rehabilitation

- Assess patients who have been referred to integrated multidisciplinary rehabilitation services to guide management. Include the physical, psychological, and psychiatric aspects of rehabilitation. Ensure that any symptoms that could affect the patient's ability to safely start rehabilitation have been investigated first (see recommendations for multidisciplinary rehabilitation teams [<https://www.nice.org.uk/guidance/NG188>]).
- Work with the patient to develop a personalized rehabilitation and management plan that is recorded in a rehabilitation prescription and includes the following:
  - Areas of rehabilitation and interventions based on their assessment
  - Helping the patient decide and work toward goals
  - Symptom management for all presenting symptoms, for example advice and education on managing breathlessness, fatigue and "brain fog."
- Encourage patients to keep a record or use a tracking app to monitor their goals, recovery, and any changes in their symptoms (see recommendations for follow-up and monitoring [<https://www.nice.org.uk/guidance/NG188>]).

#### Support for Older Adults and Children

- Consider additional support for older adults with ongoing symptomatic COVID-19 or post-acute COVID syndrome, for example short-term care packages, advance care planning and support with social isolation, loneliness, and bereavement, if relevant.
- Consider referral from 4 weeks for specialist advice for children with ongoing symptomatic COVID-19 or post-COVID-19 syndrome.

### BOX 4 Breathing Techniques for Post-COVID Syndrome

About 80% of the work of breathing is done by the diaphragm. After illness or general deconditioning, the breathing pattern may be altered, with reduced diaphragmatic movement and greater use of neck and shoulder accessory muscles. This results in shallow breathing, increasing fatigue and breathlessness, and higher energy expenditure. The “breathing control” technique is aimed at normalizing breathing patterns and increasing the efficiency of the respiratory muscles (including the diaphragm), resulting in less energy expenditure, less airway irritation, reduced fatigue, and improvement in breathlessness. The patient should sit in a supported position and breathe in and out slowly, preferably in through the nose and out through the mouth, while relaxing the chest and shoulders and allowing the tummy to rise. They should aim for an inspiration to expiration ratio of 1:2. This technique can be used frequently throughout the day, in 5–10 minute bursts (or longer if helpful). Other breathing techniques—such as diaphragmatic breathing, slow deep breathing, pursed lip breathing, yoga techniques, Buteyko—are used in strategies to manage patients’ breathing patterns and breathlessness but require specialist advice to identify which technique best suits each patient.

From Greenhalgh T, Knight M, A’Court C, Buxton M, Husain L. Management of post-acute covid-19 in primary care. *BMJ*. 2020;370:m3026.

The appropriate type of testing and therapy for post-COVID cardiac syndrome will need to be determined. Electrocardiogram and rhythm monitoring, echocardiography, cardiac biomarkers, and close clinical observation with directed questions about cardiac function will be required for months and perhaps years. Cardiac biopsy may be needed in select cases as well as special imaging such as cardiac magnetic resonance imaging.

Long-term physiotherapy and ongoing cardiology consultation may be needed. Special consideration to cardiac rehabilitation must be given to patients with post-acute COVID syndrome, and modifying or suspending rehabilitation exercises is indicated for the following:

- Saturation <88% to 93%
- Heart rate <40 beats per minute or >120 beats per minute
- Systolic blood pressure <90 mm Hg or >180 mm Hg

- Body temperature fluctuations >37.2°C
- Respiratory symptoms and fatigue that worsen during exercise and do not alleviate after rest
- Symptoms such as chest tightness or pain, difficulty breathing, severe cough, dizziness, headache, unclear vision, palpitations, sweating, and instability

#### Fatigue

Prevention of deconditioning while considering the risks associated with overexertion can be a balancing act in the patient with post-acute COVID syndrome.

Exercise rehabilitation for athletes and others requires careful titration and personalization as excessive exercise can set back progress. This is also seen in treatment of fibromyalgia and chronic fatigue syndrome in which even slowly graded increases in exercise can cause worsening. It is likely that what we have learned from other conditions such as fibromyalgia and chronic fatigue syndrome, now called *myalgic encephalomyelitis/chronic fatigue syndrome* (ME/CFS), may be transferrable and helpful.

NICE guidelines for these conditions were revised in 2021 and may inform care for patients with post-acute COVID syndrome, but they are still controversial. It is important to consider safe approaches from complementary and integrative medicine, including mind-body therapies, yoga, tai chi, acupuncture, personalized nutritional and fitness prescriptions, and carefully selected supplements, minerals, and vitamins.

A general rule of thumb for rehabilitation of patients with post-acute COVID syndrome is that if a patient feels excessively fatigued the day following exercise, so-called *postexercise malaise*, the program must be backed down to prevent overdoing. Controlled breathing exercises, careful pacing, goal setting, low intensity of exercise, and stress reduction are all critical.

Detailed guidelines on returning to sports activities are provided in the Stanford Hall consensus statement (see references). These guidelines can help address appropriate measures, timing, and rehabilitation of multiple systems (i.e., pulmonary, cardiac, neurologic, psychological, musculoskeletal) and overall exercise rehabilitation for returning to vigorous activities. The risk associated with post-acute COVID syndrome deconditioning is significant and must be considered on returning athletes to activity.

#### Dysautonomia

Providers should be familiar with syndromes such as chronic fatigue syndrome, postural orthostatic tachycardia syndrome, and mast cell activation syndrome. These syndromes are commonly brought up within the post-acute COVID syndrome community.

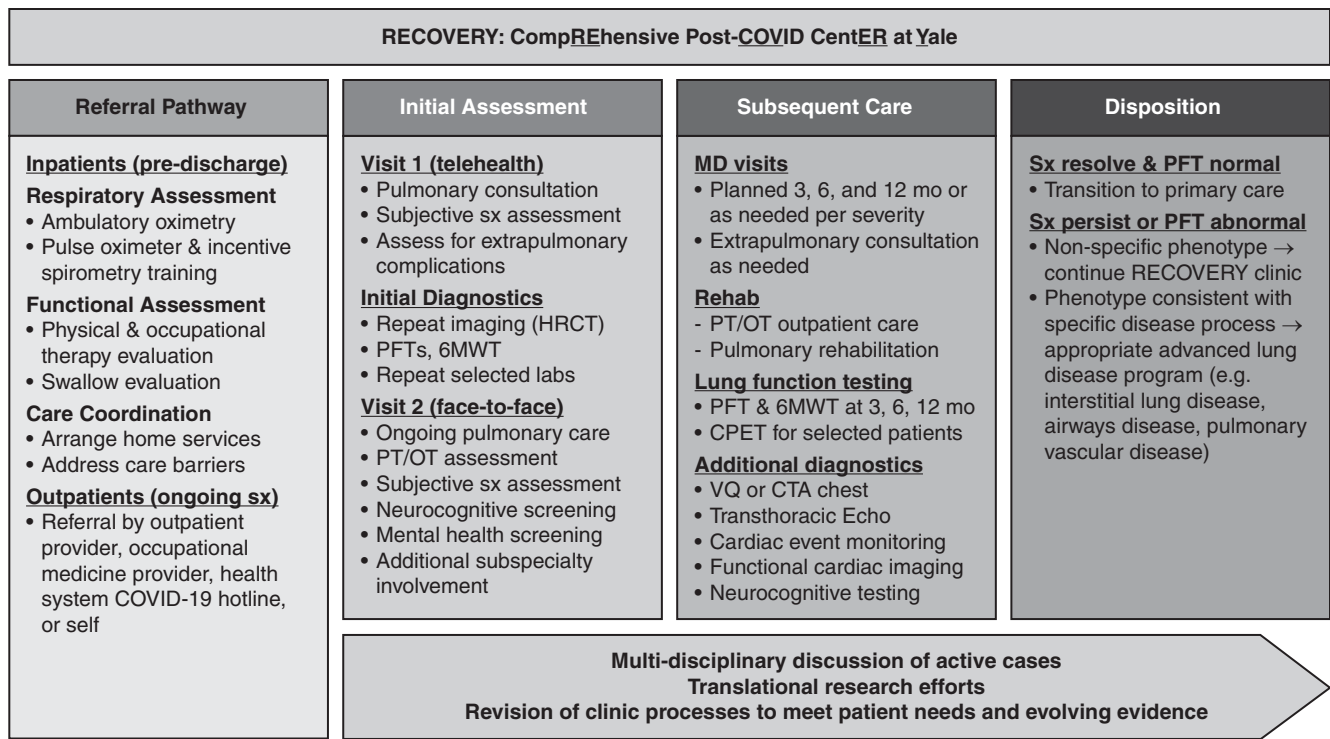

Dysautonomia may be particularly challenging as it presents with rapid heartbeat, anxiety, numbness, dizziness, low blood pressure, and extreme fatigue. Orthostatic intolerance, a postural orthostatic tachycardia (POT)-like syndrome, may be caused by viral or autoimmune damage to the autonomic nervous system. This condition is best managed with established measures such as patient education, maintaining volume and vascular tone, gradually adjusting positional changes, performing structured exercises including isometrics, wearing compression garments, and in some cases using pharmacologic agents to manage palpitations and to retain sodium and fluid. These pharmacologic agents include fludrocortisone (Florinef),<sup>1</sup> midodrine (Proamatine), and others affecting adrenergic surge such as beta blockers, methyl dopa,<sup>1</sup> and clonidine (Catapres).<sup>1</sup>

#### Neurologic

Patients with COVID-19 may suffer severe central nervous system insults resulting in strokes, severe brain inflammation (encephalomyelitis), a multiple sclerosis-like or Guillain-Barré type of demyelination), weakness, numbness, confusion, delirium, memory loss, headache, and psychosis. A complaint of enduring “brain fog” is

<sup>1</sup>Not FDA approved for this indication.

**Figure 2** The RECOVERY Clinic Model. (From Lutchmansingh DD, Knauert MP, Antin-Ozerkis DE, et al.: A clinic blueprint for post-coronavirus disease 2019 RECOVERY: Learning from the past, looking to the future, *Chest* 159(3):949–958, 2021.

common. Some of these problems occur early, and others occur late. They may be difficult to detect in patients in the intensive care unit who are very sick, hypoxemic, or sedated and when magnetic resonance imaging is difficult to obtain. The Mayo Clinic recommends that brain fog be managed like chemobrain including coping strategies and stress relief. Methylphenidate (Ritalin),<sup>1</sup> donepezil (Aricept),<sup>1</sup> modafinil (Provigil),<sup>1</sup> and memantine (Namenda)<sup>1</sup> have been suggested as options. Luteolin,<sup>7</sup> a flavonoid, has some promise of benefit.

Full neuropsychological testing and/or neurologic consultation should be considered in cases in which post-COVID cognitive changes persist. Occupational, physical, and speech/language therapy may play an important role.

Anosmia is another neurologic symptom of COVID and can be quite debilitating, though patients often recover with time. It can lead to loss of appetite, weight loss, and depression. Therapy for persistent anosmia can include olfactory training, which includes repeated sniffing of a set of odorants to speed recovery.

### Mental Health

Mental health support for many will be of importance as patients cope with so many unknowns in their post-COVID world. Sorting out somatic from psychosomatic problems requires clinical acumen, patience, perseverance, and continuity of care. Psychiatric consequences may be severe and related to the immune response and/or from psychological stressors such as social isolation, worries about a potentially fatal illness, concerns about infecting others, stigma of disease, impact on employment, finances, and relationships in general.

The immune response to coronaviruses induces local and systemic production of cytokines, chemokines, and other inflammatory mediators, all of which combine to worsen the burden of preexisting depression, anxiety, PTSD, and other mental health disorders, particularly in female patients.

Mental health issues may end up being one of the most serious, enduring, yet largely hidden impacts seen in the post-COVID

patient; thus management and monitoring must address this domain to maintain a holistic approach. Children and adolescents may be most affected.

Therapeutic trials of holistic, integrative, and functional medicine are appropriate given low harm and potential benefit. These may include antiinflammatory diets, acupuncture, meditation, and selected supplements such as fish oil,<sup>1</sup> magnesium,<sup>1</sup> SAME,<sup>7</sup> valerian,<sup>7</sup> B vitamins,<sup>1</sup> and others.

### Hematologic

Thrombotic sequelae and hypercoagulable states require monitoring and management, and prolonged anticoagulation may be required, especially in those with significant deep venous thromboses or pulmonary or cardiac emboli. Many patients will need transient anticoagulation, though some may require ongoing therapy if clotting abnormalities persist. Endothelial damage is now recognized as a perpetuating factor in post-acute COVID syndrome.

### Gastrointestinal

If diarrhea and other gastrointestinal complaints continue, this likely reflects viral impact on the microbiota. Gastrointestinal symptoms are prominent in affected children. An antiinflammatory diet, Mediterranean-type diet, hypoallergenic elimination diet, or other personalized nutritional strategies should be considered. Optimizing nutritional support for vulnerable older adults and those with continued anosmia and dysgeusia is likewise vital. Though not yet well defined in terms of dosing and speciation, replacing microbiota with food-sourced or encapsulated prebiotics<sup>7</sup> and probiotics is worth considering as a safe and potentially useful strategy in this population. Microbiome changes also affect cognitive and mood function in the central nervous system via the gut-brain axis.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

## Renal

Acute kidney injury during the infectious stage may result in longer-term decreases in glomerular filtration rate and other renal parameters. This is likely to be worse in those already at risk with existing chronic kidney disease, diabetes, or hypertension. Nephrology consultation should be sought in appropriate cases.

## Endocrine

Loss of control of diabetes and even diabetic ketoacidosis has been observed after resolution of acute COVID-19 symptoms, sometimes weeks or months later. New cases of prediabetes and diabetes types 1 and 2 have been reported. COVID-19 may also activate latent autoimmune thyroid disease, resulting in thyroiditis or thyrotoxicosis in the aftermath and resolution of respiratory disease. Risks for osteoporosis may also increase as a result of a multiplicity of factors such as immobilization, inflammation, steroid use, and other lifestyle or dietary factors. Weight gain and inactivity during lockdowns contributed to these conditions as well.

Being alert to the potential for the development or exacerbation of endocrinologic issues will enhance the healthcare provider's ability to respond quickly and appropriately when managing these patients.

## Dermatologic

There is broad range of dermatologic presentations that include rash, chilblains, urticaria, and "COVID-toe," but they are usually self-limiting and not prolonged. They are treated with topical steroids, antihistamines, or oral steroids. Hair loss (telogen effluvium) is a particularly distressing problem from COVID and must be addressed for its emotional and cosmetic impact. It may be short-lived, but if prolonged it must be part of a holistic program of care including dermatologic consultation, particularly if there is an ongoing autoimmune or inflammatory etiology.

## Monitoring

Supportive and rehabilitative care are still the mainstay of treatment for post-acute COVID syndrome. This includes adequate rest, nutrition, immune support, activity modification, mental and cognitive stimulation, stress management, and heart and lung rehabilitation, including supplemental oxygen for some patients. Utilizing standard and evidenced treatments for lung, heart, neurologic, and renal problems is a logical start. Given protracted and relapsing symptoms, it is important to reassure patients that most cases will recover with time and supportive symptomatic care. Registries and post-COVID clinics are needed to track and manage these serious sequelae of COVID-19. Our awareness is the first line of defense. The diffuse and protean manifestations of PCS should motivate our clinicians and medical educators to include it in the differential diagnosis of many other presenting complaints.

Multidisciplinary teams are key to long-term management but are not always easily accessible. Self-care, online, and other forms of support groups have sprung up widely for emotional, social support and peer-led practical advice in managing post-acute COVID syndrome. Much of the knowledge about this syndrome has been brought to public and professional awareness by such peer groups. Further research support in this area will be helpful.

Quality-of-care principles for long-haul COVID include providing access to care, reducing the burden of illness, taking clinical responsibility, offering continuity of care, providing multidisciplinary rehabilitation, conducting evidence-based investigation and management, and continuing further research and development on appropriate and evidence-based clinical services. Given the disproportionate impact of COVID on communities of color, additional attention must be given to social determinants of health, healthcare access, and enhanced research efforts regarding the genetic and racial differences in disease impact, both acute and long-term. Determining phenotypic differences in susceptibility to post-acute COVID syndrome and personalized rehabilitation are key future directions.

## Complications

Understanding of COVID-19 and its potential long-term complications is evolving and offers many opportunities for clinicians and researchers to examine. As with COVID-19 infection itself, long-term complications may broadly affect multiple body systems. Addressing these symptoms starts with recognition.

One persistent neurologic complication that remains of concern is cognitive decline, which many describe as "brain fog." Additional symptoms of neuropathic pain and headaches may require further evaluation by a neurologist.

Myocardial inflammation seen in some COVID-19 infections may lead to future reduced cardiac function, arrhythmias, scarring, or cardiomyopathy. The prevalence currently remains unknown but is a major concern in our younger population and athletes.

Pulmonary complications are common in hospitalized patients who require ventilatory assistance. Our experience in the post-COVID population shows that fibrotic conversion, if it occurs, is rare, but reduction in diffusion capacity may persist. This reduction is a sign of parenchymal disease and should be monitored if patients develop future reductions in lung volumes compared with the standard population.

Hematologic complications such as thrombosis and long-term risk remain unknown, and further study is necessary. For example, it is unknown whether COVID-19 and a thrombosis can be safely considered a short-term event and managed as a provoked clot or if there is a prolonged inflammatory cascade that leaves a sustained risk.

The behavioral health component also remains of utmost importance because so much is not known, and the duration of symptoms is not clear. Management of PTSD, anxiety, and depression for patients with long-term complications should be included in strategies addressing the care of this new and ever-growing at-risk population.

## Acknowledgment

We wish to thank Ms. Julie Trumble of the University of Texas Medical Branch Moody Medical Library for her incredibly diligent work on helping us assemble and keep updated on the literature on this evolving topic with weekly literature reviews in the past year.

## PSITTACOSIS

Method of

Christopher C. McGuigan, MB, ChB, MPH

### CURRENT DIAGNOSIS

- The key to successful management of psittacosis is to consider this diagnosis, particularly in cases of community-acquired pneumonia (CAP), especially given a history of bird contact.
- The typical clinical pictures are of CAP, influenza-like illness, or fever of unknown origin. Psittacosis causes 1% of incident CAP cases. Onset is usually sudden with fever, chills and a prominent headache. Consider this diagnosis in a patient with CAP unresponsive to  $\beta$ -lactam antibiotics.
- Investigation will typically reveal a normal or slightly elevated white blood cell count with a left shift or toxic changes, increase in C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR), mildly abnormal liver function tests, hyponatremia, and mild renal impairment. Chest x-ray may be more abnormal than examination alone would predict.
- Diagnosis can be confirmed with (ideally) paired serum samples: using either the complement fixation test (widely used but unable to differentiate between *Chlamydia* species), or the microimmunofluorescence test, which is specific for individual *Chlamydia* species. Either a single high titer or a fourfold rise in titer using samples collected at least 14 days apart are interpreted as positive. More recently, real-time polymerase chain reaction (rt-PCR) tests are used to detect specific DNA. These can provide a more rapid diagnosis, as well as subspecific genotype.

### CURRENT THERAPY

- Therapy should commence when the diagnosis is suspected on clinical presentation and initial investigation.
- Tetracyclines are the drugs of choice; for example, doxycycline (Vibramycin) 100 mg bid for 10 to 14 days.
- Macrolides are suitable (but probably less effective) alternatives in those intolerant of tetracyclines (e.g., children and pregnant women).
- Notification to health authorities facilitates public health investigation and interventions to reduce transmission and control outbreaks.

Psittacosis is caused by infection with the bacterium *Chlamydia psittaci* (formerly *Chlamydia psittaci*). It is twice as common in men than in women, and mainly affects adults typically aged 40 to 50 years. The main reservoir for psittacosis is birds, particularly psittacine birds (parrots, parakeets, budgerigars and cockatoos), but other bird species and mammals can be infected.

### Risk Factors

The most common etiological factor is exposure to infected birds—especially a new, sick, or dead one—typically a pet or via occupational exposure (e.g., work as a veterinarian, zoo keeper, or poultry-worker). Most cases are sporadic, but outbreaks have occurred associated with pet shops, aviaries, and poultry-processing plants and with mowing lawns in areas with large numbers of psittacine birds. Person-to-person transmission is rare. Ingestion of poultry products is *not* a risk factor.

### Pathophysiology

*C psittaci* infection is via the respiratory tract and is typically thought to be by inhalation of an aerosol of dried feces or other avian secretion. It then either travels via the blood to the liver and

spleen (where it replicates, causing a secondary bacteremia) or directly infects respiratory epithelial cells.

### Prevention

Prevention is aimed at controlling disease or colonization in susceptible host species: usually birds. This is facilitated by import restrictions including quarantine and treatment of suspected infections with tetracycline-impregnated feeds. Notification of health authorities is important for initiating public health investigations and interventions to reduce transmission and control of outbreaks.

### Clinical Manifestations

The incubation period varies from 4 to 14 or more days. The typical presentation of psittacosis is of an influenza-like illness with sudden onset of fever, chills, and prominent headache, with or without rigors. A more gradual onset is also seen. A typically mild, dry cough usually starts later. There may also be diarrhea, pharyngitis, altered mental state, or shortness of breath. Chest examination is usually abnormal, but the findings are often minimal and less prominent than symptoms or x-ray findings would suggest. Pleural effusion is rare.

Patients might present with a fever of unknown origin without obvious respiratory involvement, or the disease can be misdiagnosed as meningitis because of prominent headache, sometimes with photophobia.

The white blood cell count is usually normal or slightly raised, but there is often a left shift or toxic changes. Increases in the C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are common. Mildly abnormal liver function tests, hyponatremia, and mild renal impairment are also common. The cerebrospinal fluid sometimes contains a few mononuclear cells but is otherwise normal. The chest x-ray usually shows more (nonspecific) abnormality than examination findings might predict. The most common finding is lobar consolidation, but bilateral consolidation and interstitial opacities are also common.

Confirmation of diagnosis is more commonly performed using serology. The complement fixation (CF) test is widely used, but cannot differentiate between *Chlamydia* species. A fourfold rise in titer, using samples collected at least 14 days apart, or a single titer of 1:128 or higher, is interpreted as positive, but this test is not widely available. Culture of *C psittaci* is difficult and hazardous. Polymerase chain reaction (PCR) assays have been developed, but are not yet widely available for routine clinical use.

### Diagnosis

Diagnosis is facilitated by eliciting a history of recent bird contact from a patient with a compatible clinical syndrome, most commonly an influenza-like presentation, community acquired pneumonia (CAP), or a fever of unknown origin. The diagnosis should be considered in a patient with CAP and prominent headache, splenomegaly, or failure to respond to  $\beta$ -lactam antibiotics.

### Differential Diagnosis

Differential diagnosis of an atypical CAP, includes infection with *Legionella* species, *Mycoplasma pneumoniae*, or *Chlamydia pneumoniae*.

### Treatment

When the diagnosis is suspected on clinical presentation and initial investigations, empiric therapy should be commenced. Tetracyclines are the drugs of choice, for example doxycycline (Vibramycin) 100 mg bid for 10 to 14 days. Tetracycline treatment usually leads to improvement in symptoms (including fever) within 24 to 48 hours. Macrolides are usually recommended for pregnant women, children, and other patients intolerant of tetracyclines. However, erythromycin (Erythrocin)<sup>1</sup> has been shown to

<sup>1</sup>Not FDA approved for this indication.

fail in situations where a tetracycline was effective, and there are few clinical data on the efficacy of the other agents in this class. Some data suggest that quinolones may be effective. Tetracycline hydrochloride or doxycycline (4.4 mg/kg/d divided into two infusions) may be given intravenously for critically ill patients.

### Monitoring

Symptomatic improvement usually occurs within 24 to 48 hours of starting a tetracycline; typically including reduction of fever.

### Complications

The degree of illness varies from asymptomatic to life threatening. Given appropriate antimicrobial therapy, subsequent case-fatality is less than 1%. Elderly persons and pregnant women are susceptible to more severe illness. Neurologic consequences (e.g., meningoencephalitis) are recognized but rare. Other less-common sequelae include hemoptysis, proteinuria, hepatosplenomegaly, and encephalitis. Cardiac manifestations include relative bradycardia and, rarely, myocarditis, culture-negative endocarditis, and pericarditis. Erythema nodosum and other skin manifestations have also been described. *C. psittaci* has been demonstrated by PCR to be present in ocular adnexal lymphoma (OAL) in parts of Eurasia. Up to one half of such cases respond to antibiotic treatment. However, studies elsewhere suggest that this organism might not commonly play a role in OAL. Recovery with minimal residual deficit is normal.

## Q FEVER

Method of

Didier Raoult, MD, PhD

Q fever is a widespread zoonosis caused by *Coxiella burnetii*, a small, coccoid, strict intracellular gram-negative bacterium. It lives within the phagolysosome of its eukaryotic host cell at very low pH (4.5–4.8). It had previously been classified in the rickettsial family; however, recent phylogenetic data based on study of the 16S rRNA gene sequence have shown that it belongs to *Legionellales* with the *Legionella* species and *Francisella tularensis*.

The bacterium has a sporelike life cycle, which explains its marked resistance to physicochemical agents. In cultures, *C. burnetii* exhibits a phase variation (from virulent phase I to avirulent phase II) caused by a spontaneous chromosome deletion. The avirulent form paradoxically generates high antibody levels in patients, but only patients with chronic infection have high anti-phase I immunoglobulin G (IgG) and IgA antibody titers.

The reservoir of *C. burnetii* is wide, and nearly all tested mammals, birds, and ticks can be infected. Outbreaks have also been reported in association with the birth products of mammals (including ungulates and pets), raw milk, slaughterhouses, and farm work. Laboratory outbreaks have been reported. The disease is prevalent everywhere in the world but in New Zealand and South Pacific Islands, but because its clinical spectrum is wide and nonspecific, the observed incidence is directly related to physician interest in Q fever. A recent outbreak has been observed in the Netherlands.

### Clinical Features

Q fever is a reportable disease in the United States. In humans, infection is symptomatic in only 50% of patients. Most symptomatic patients experience a flulike syndrome lasting 2 to 7 days and consisting of severe headaches and cough; 5% to 10% of infected patients may be sick enough to be investigated. They initially have high fever and one or several of pneumonia, hepatitis, meningoencephalitis, rash, myocarditis, and pericarditis. Routine laboratory investigation commonly shows mildly elevated transaminase levels and mild thrombocytopenia. The local strain may influence the clinical manifestations. In French Guyana, the disease is more commonly symptomatic and severe.

In special hosts such as immunocompromised patients (specifically those with splenectomy), *C. burnetii* can cause endocarditis. In pregnant women it can lead to recurrent miscarriage, low-birth-weight offspring, and prematurity. *C. burnetii* could contribute to the evolution of lymphoma.

In patients with valvular heart disease and those with arterial aneurysms or a vascular prosthesis, it can cause chronic endocarditis or vascular infection in patients in the 2 years following primary infection. The clinical picture is that of a chronic blood culture–negative endocarditis; the modified Duke criteria are of diagnostic value in such cases. It is spontaneously fatal in most cases. Recently, acute endocarditis associated with anticardiolipin antibodies was described. Criteria specifically adapted to Q fever may be used to diagnosed focalized infections. This denomination appears to be more appropriate than “chronic Q fever.”

### Diagnosis

Because Q fever is pleomorphic, the diagnosis is based mainly on comprehensive serum testing in patients with an unexplained infectious syndrome. Liver biopsy may be of diagnostic value, because the typical doughnut granuloma is quasispecific to acute Q fever. Valves obtained at surgery or autopsy can be used for culture, direct immunostaining, and polymerase chain reaction (PCR).

Three serologic techniques are used. Complement fixation lacks sensitivity, and one-third of patients with acute Q fever do not exhibit complement-fixing antibodies within 1 month after onset of the disease. However, a fourfold increase in antibodies to phase II antigen indicates acute Q fever, and antibody levels against phase I that are higher than 1:200 indicate persistent focalized Q fever. Indirect immunofluorescence assay is the reference method. A single titer of 1:200 for IgG antiphase II associated with a titer of 1:50 for IgM is diagnostic of acute infection. IgG antibody levels against phase I that are greater than 1:800 and IgA antibody levels greater than 1:50 are highly predictive of endocarditis or vascular infection. Enzyme-linked immunosorbent assay (ELISA) is useful for diagnosing acute infection in detecting IgM antiphase II.

PCR has recently been developed to detect *C. burnetii* DNA in the sera of patients with Q fever. Real-time PCR using multi-copy gene *IS1111* is the more-sensitive technique. It is positive in the sera of patients with acute Q fever before IgG antibodies to *C. burnetii* become apparent. It is also positive in patients with

untreated endocarditis. Contamination of PCR can occur, and many unconfirmed results are reported in the literature. Detection of patients at risk for endocarditis may be provided by systematic echocardiography in patients with acute Q fever specifically seeking for aortic bicuspidy and serologic follow-up at 3 and 6 months after acute infection. Antiphospholipid antibodies are relatively common during acute Q fever and predictive of endocarditis and deep vein thrombosis.

Use of a positron emission tomography (PET) scanner may help in the diagnosis of endocarditis (and may reveal mycotic aneurysms), vascular infection, and joint infection.

### Treatment

To be active against Q fever, an antibiotic compound has to enter the cell, be effective at an acidic pH (where *C. burnetii* multiplies), and have activity against *C. burnetii*. No antibiotic is bactericidal, but bactericidal activity can be achieved by the addition of hydroxychloroquine (Plaquenil)<sup>1</sup> to doxycycline (Vibramycin).

For acute Q fever, the reference treatment is doxycycline 100 mg orally twice daily for 2 to 3 weeks. Other compounds have been reported to be effective, such as trimethoprim-sulfamethoxazole (TMP-SMX) (Bactrim)<sup>1</sup>, Rifampin (Rifadin)<sup>1</sup> 300 mg twice daily, and ofloxacin (Floxin)<sup>1</sup> 200 mg twice daily. In the case of Q fever in pregnant women, one double-strength TMP-SMX tablet (trimethoprim 160 mg, sulfamethoxazole 800 mg)<sup>1</sup> twice daily until delivery prevents fetal death (Table 1). Patients with acute Q fever and high antiphospholipid antibodies may be treated with hydroxychloroquine<sup>1</sup> until normalization.

Persistent focalized and acute endocarditis should be treated for 18 months to 2 years, and antibody levels should be monitored. Patients with prosthetic valves may be treated for 2 years. Two protocols have been evaluated: doxycycline 200

mg daily combined with ofloxacin<sup>1</sup> 400 mg daily for 4 years to lifetime, and doxycycline combined with hydroxychloroquine<sup>1</sup> for 1.5 to 2 years in an amount to achieve a  $1 \pm 0.20$   $\mu\text{g/mL}$  plasma concentration. Doxycycline serum levels greater than 4.5  $\mu\text{g/mL}$  are associated with a more rapidly favorable outcome. This last regimen is apparently more efficacious in terms of relapse. However, regular ophthalmologic surveillance is critical to detect the accumulation of chloroquine in the retina. Both regimens expose the patient to a major risk of photosensitization.

The combination of doxycycline and hydroxychloroquine for 1 year has demonstrated efficacy in preventing endocarditis. Patients with high-level antiphospholipid antibodies may be treated by the same treatment until normalization of the antibody level.

### Prevention

Prevention depends on avoiding exposure, particularly by pregnant women and patients with valvulopathy. No vaccine is currently available outside Australia.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Treatment

Q FEVER	RECOMMENDED TREATMENT	ALTERNATIVE TREATMENT
Acute	Doxycycline (Vibramycin) 100 mg PO q12h × 14 d	Ofloxacin (Floxin) <sup>1</sup> 200 mg PO q8h <sup>3</sup> × 14 d Cotrimoxazole (Bactrim) <sup>1</sup> 160/800 mg/PO q12h × 14 d
Acute Q fever with high antiphospholipid antibodies	Hydroxychloroquine (Plaquenil) <sup>1</sup> 200 mg PO q8h as long as high antiphospholipid antibodies persist	
Endocarditis	Doxycycline 100 mg PO q12h plus hydroxychloroquine (Plaquenil) <sup>1</sup> 200 mg PO q8h <sup>3</sup> × 18–24 mo	Doxycycline 100 mg PO q12h plus ofloxacin <sup>1</sup> 200 mg PO q8h <sup>3</sup> for 3 y to lifetime
Acute in a patient with a valvular lesion	Same as chronic Q fever for 12 mo	
In pregnancy	Trimethoprim/Sulfamethoxazole (Bactrim) <sup>1</sup> 160/800 mg PO q12h until term	

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

## RABIES

Method of

Alan C. Jackson, MD

### CURRENT DIAGNOSIS

- A history of animal bite or exposure is often absent in rabies acquired in North America.
- Pain, paresthesias, and pruritus are early neurologic symptoms of rabies, probably reflecting infection in local sensory ganglia.
- Autonomic features are common including hypersalivation, gooseflesh, cardiac arrhythmias, and priapism.
- Hydrophobia is a highly specific feature of rabies.
- Paralytic features may be prominent, and the clinical presentation can resemble that of Guillain-Barré syndrome.
- Saliva samples for reverse transcription polymerase chain reaction (RT-PCR) and a skin biopsy should be obtained to detect rabies virus antigen or RNA to make a laboratory diagnosis of rabies.

## CURRENT THERAPY

- Details of an exposure determine whether postexposure rabies prophylaxis should be initiated.
- Wound cleansing is important after potential rabies exposure.
- Active immunization with a schedule of four doses of rabies vaccine (RabAvert or Imovax Rabies) at intervals is recommended. The four-dose series is a new Centers for Disease Control and Prevention (CDC) recommendation and is not yet reflected in the package insert, which calls for five doses.
- Passive immunization (if previously the patient was not immunized) consists of infiltrating human rabies immune globulin (HyperRAB, Imogam Rabies, or KamRAB) into the wound, with the remainder of the 20 IU/kg dosage given intramuscularly.

Rabies is an acute infection of the nervous system caused by rabies virus, which is a member of the family Rhabdoviridae in the genus *Lyssavirus*. Other lyssaviruses have only very rarely caused rabies in locations outside of the Americas.

### Pathogenesis

Rabies virus is usually transmitted by bites from rabid animals. Transmission has rarely occurred through an aerosol route (in a laboratory accident or in a cave containing millions of bats) or by transplantation of infected organs or tissues (e.g., corneas). The virus is in the saliva of the rabid animal and is inoculated into subcutaneous tissues or muscles via a bite.

During most of the long incubation period (lasting 20–90 days or longer), the virus is close to the site of inoculation. The virus binds to the nicotinic acetylcholine receptor at the postsynaptic neuromuscular junction and travels toward the central nervous system (CNS) in peripheral nerves by retrograde fast axonal transport. There is rapid dissemination throughout the CNS by fast axonal transport. Under natural conditions, degenerative neuronal changes are not prominent, and it is thought that the rabies virus induces neuronal dysfunction by mechanisms that are not well understood. Oxidative stress due to mitochondrial dysfunction is thought to play an important role. In rabies vectors, the encephalitis is associated with behavioral changes that lead to transmission by biting. After the CNS infection is established, the virus spreads by autonomic and sensory nerves to multiple organs, including the salivary glands of rabies vectors in which the virus is secreted in saliva.

### Clinical Features

In North America, where the bat is the most common rabies vector for human disease, a history of an animal bite is usually absent, and there may be no known contact with animals. The incubation period is usually between 20 and 90 days, but it occasionally lasts 1 year or longer. Prodromal features are nonspecific and include malaise, headache, and fever, and patients can also have anxiety or agitation. Approximately half of patients experience pain, paresthesias, or pruritus at the site of the wound, which has often healed, and these symptoms likely reflect infection and inflammation involving local sensory ganglia. Approximately 80% of patients with rabies have encephalitic rabies; approximately 20% have paralytic rabies.

In encephalitic rabies, there are characteristic periods of generalized arousal or hyperexcitability separated by lucid periods. Autonomic dysfunction is common and includes hypersalivation, gooseflesh, cardiac arrhythmias, and priapism. Hydrophobia is the most characteristic feature of rabies and occurs in 50% to 80% of patients; contractions of the diaphragm and other inspiratory muscles occur on swallowing. This can become a conditioned reflex, and even the sight or thought of water can precipitate the muscle contractions. Hydrophobia is thought to be caused by inhibition of inspiratory neurons near the nucleus ambiguus.

In paralytic rabies, prominent muscle weakness usually begins in the bitten extremity and progresses to quadriplegia; typically

there is sphincter involvement. Patients have a longer clinical course than in encephalitic rabies. Paralytic rabies is often misdiagnosed as Guillain-Barré syndrome.

Coma subsequently develops in both clinical forms. With aggressive medical therapy, a variety of medical complications develop, and multiple organ failure is common. Survival is very rare and has usually occurred in the context of incomplete postexposure rabies prophylaxis that included administration of one or more doses of rabies vaccine.

### Epidemiology

Worldwide about 60,000 human deaths per year are attributed to rabies. The impact is particularly significant in terms of years of life lost because children are commonly the victims. Most human rabies cases occur through transmission from dogs in developing countries with endemic dog rabies, particularly in Asia and Africa. Travelers to endemic regions may develop rabies after they return home if they have not received effective postexposure rabies prophylaxis after an exposure. In the United States and Canada, transmission of rabies virus occurs most commonly in human cases from insect-eating bats, and often there is no known history of a bat bite or exposure to bats. A bat bite might not be recognized. The rabies virus variants responsible for most human cases are found in silver-haired bats and tricolored bats, and also in Brazilian (Mexican) free-tailed bats. These are small bats. Other rabies vectors in North American wildlife include skunks, raccoons, and foxes, but these species are rarely responsible for transmission to humans. This is likely because postexposure rabies prophylaxis is administered after recognized exposures.

### Diagnosis

Most cases of rabies can be diagnosed clinically or the diagnosis will be strongly suspected, which is particularly important so that appropriate barrier nursing techniques can be initiated to prevent exposures of many health care workers. Some patients are candidates for an aggressive therapeutic approach. A serum-neutralizing titer can be useful for diagnosis in a previously unimmunized person, but a positive titer might not develop until the second week of clinical illness or later, and the result of the test might not be readily available. Detection of rabies virus antigen in a skin biopsy obtained from the nape of the neck using a fluorescent antibody technique is a useful diagnostic test. Detection of rabies virus ribonucleic acid (RNA) in saliva or in skin biopsies using RT-PCR amplification is an important recent advance for rapid rabies diagnosis. Rabies virus antigen can be detected in brain tissue obtained by brain biopsy or postmortem. Negative antemortem diagnostic laboratory tests do not exclude rabies and the tests may need to be repeated on subsequent samples.

### Prevention

After a rabies exposure is recognized, rabies can be prevented with initiation of appropriate steps, including wound cleansing and active and passive immunization. After a human is bitten by a dog, cat, or ferret, the animal should be captured, confined, and observed for a period of at least 10 days; initiation of postexposure rabies prophylaxis is not necessary if the animal remains healthy. The animal should also be examined by a veterinarian prior to its release. If the animal is a stray, unwanted, shows signs of rabies, or develops signs of rabies during the observation period, the animal should be killed immediately, and its head should be transported under refrigeration for a laboratory examination. The brain should be examined via an antigen-detection method using the fluorescent antibody technique and viral isolation using cell culture or mouse inoculation.

The incubation period for animals other than dogs, cats, and ferrets is uncertain; these animals should be killed immediately after an exposure, and the head should be submitted for examination. If the result is negative, one may safely conclude that the animal's saliva did not contain rabies virus; if immunization has been initiated, it should be discontinued. If an animal escapes after an exposure, it should be considered rabid unless information from public health officials indicates this is unlikely, and rabies prophylaxis should be

initiated. The physical presence of a bat might warrant postexposure prophylaxis when a person (such as a small child or sleeping adult) is unable to reliably report contact that could have resulted in a bite.

Local wound care should be given as soon as possible after all exposures, even if immunization is delayed, pending the results of an observation period. All bite wounds and scratches should be washed thoroughly with soap and water. Devitalized tissues should be débrided.

Purified chick embryo cell culture vaccine (RabAvert) and human diploid cell vaccine (Imovax Rabies) are licensed rabies vaccines in the United States and Canada. Other vaccines grown in either primary cell lines (hamster or dog kidney) or continuous cell lines (Vero cells) are also satisfactory and available in other countries. A regimen of four 1-mL doses of rabies vaccine should be given IM in the deltoid area (anterolateral aspect of the thigh is also acceptable in children). The four-dose series is a CDC recommendation and is an update from the five doses recommended in the current package insert. Ideally, the first dose should be given as soon as possible after exposure, but failing that, it should be given regardless of the length of a delay. Three additional doses should be given on days 3, 7, and 14. Pregnancy is not a contraindication for immunization. Live vaccines should not be given for 1 month after rabies immunization.

Local and mild systemic reactions are common. Systemic allergic reactions are uncommon, and anaphylactic reactions may be treated with epinephrine and antihistamines. Corticosteroids can interfere with the development of active immunity. Immunosuppressive medications should not be administered during postexposure therapy unless they are essential. The risk of developing rabies should be carefully considered before deciding to discontinue vaccination because of an adverse reaction. A serum-neutralizing antibody determination is necessary only after immunization of immunocompromised patients. Less-expensive vaccines derived from neural tissues are still used in some developing countries; these vaccines are associated with serious neuroparalytic complications.

Human rabies immune globulin (Imogam Rabies, HyperRAB, or KamRAB) should also be administered as passive immunization for protection before the development of immunity from the vaccine. It should be given at the same time as the first dose of vaccine and no later than 7 days after the first dose. Rabies vaccine and human rabies immune globulin should never be administered at the same site or in the same syringe. The recommended dose of human rabies immune globulin is 20 IU/kg; larger doses should not be given because they can suppress active immunity from the vaccine. After wounds are washed, they should be infiltrated with human rabies immune globulin (if anatomically feasible), and the remainder of the dose should be given IM in the gluteal area. Current updated recommendations by the World Health Organization do not recommend giving the remainder of the dose intramuscularly under certain circumstances. If the exposure involves a mucous membrane, the entire dose should be administered IM. With multiple or large wounds, the human rabies immune globulin might need to be diluted for adequate infiltration of all of the wounds. Adverse effects of human rabies immune globulin include local pain and low-grade fever.

After an exposure, a previously immunized patient should receive two 1-mL doses of rabies vaccine on days 0 and 3, but the patient should not receive human rabies immune globulin.

### Management of Human Rabies

About 30 people have survived rabies, and 29 received rabies vaccine prior to the onset of their disease; there have been many recent survivors in India due to supportive critical care measures, and most have neurological sequelae (see Jackson, 2021). The possibilities for an aggressive approach were reviewed (see Jackson et al., 2003). There was one survivor in Wisconsin in 2004 who did not receive rabies vaccine. It is now doubtful whether the therapy she received played a significant role in her favorable outcome because a similar approach has failed in many cases (see Jackson, 2013), and there are concerns about its scientific rationale (see Zeiler and Jackson, 2016). Palliation is an important alternative approach and may be appropriate for many patients in whom rabies develops (see Jackson, 2021).

### RAT-BITE FEVER

Method of

Jatin M. Vyas, MD, PhD

#### CURRENT DIAGNOSIS

- Exposure to rats is the major risk factor. Transmission can occur with simple contact with infected animals or excreta.
- A maculopapular rash and septic arthritis after initial symptoms of fever or sepsis should raise the suspicion of rat-bite fever.
- Clinicians must maintain a high index of suspicion for this diagnosis.
- Notify microbiology laboratory of clinical suspicion (slow growth, 5%–10% CO<sub>2</sub> microaerophilic conditions, 20% normal rabbit serum media supplementation, and avoidance of sodium polyanethanol sulfonate when collecting blood cultures from the patient).

#### CURRENT THERAPY

##### Bite Site

- Clean and disinfect the bite site.
- Administer tetanus toxoid (tetanus-diphtheria toxoids, Td), if indicated.
- Postexposure rabies prophylaxis (Imovax Rabies) for animal bites should be considered in consultation with local public health authorities, though there are no reports of rat-to-human transmission of the rabies virus.

##### Established and Suspected Cases

- Give intravenous penicillin G at a dose of 1.2 million U/day for 5 to 7 days, followed by oral penicillin (PenVK)<sup>1</sup> or ampicillin (Omnipen)<sup>1</sup> 500 mg qid for an additional 7 days.
- For penicillin-allergic patients, consider doxycycline (Vibramycin)<sup>1</sup> 100 mg IV/PO twice daily or tetracycline (Achromycin)<sup>1</sup> 500 mg PO four times daily.
- *S. moniliformis* can be resistant to gentamicin (Garamycin),<sup>1</sup> tobramycin (Nebcin),<sup>1</sup> ciprofloxacin (Cipro),<sup>1</sup> and levofloxacin (Levaquin).<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

Rat-bite fever (RBF) is a systemic, febrile disease caused by infection with *Streptobacillus moniliformis* or *Spirillum minus*. As the name implies, this infection is transmitted by a rat bite. However, the bacteria can also be transmitted by simple contact with infected rats or even through ingestion of food contaminated with rat excreta. Diagnosis can be difficult, and a high degree of suspicion is necessary to make a correct diagnosis. Recognition and early treatment are crucial, because case fatality is as high as 25% in untreated cases.

### Epidemiology

*S moniliformis* is part of the normal respiratory flora of the rat. From 50% to 100% of healthy wild, laboratory, and pet rats harbor *S moniliformis* in the nasopharynx. *S moniliformis* is also excreted in the urine. *S minus* causes rat-bite fever mostly in Asia, but this organism is found worldwide. *S minus* has been demonstrated in rat conjunctival secretions and blood. Thus rat-bite fever can be transmitted not only from a bite but also through scratches, handling of dead rats, handling litter material, or by contamination of rat excreta.

Although the rat is the natural reservoir and major vector of the disease, *S moniliformis* has also been found in other rodents such as mice, squirrels, gerbils, and weasels. No precise data are available on the true incidence of rat-bite fever because it is not a reportable disease. It appears to be unusual in Western countries, a rarity that might reflect failed diagnosis, empiric treatment of infected bites and scratches caused by animals, or spontaneous recovery.

### Risk Factors

The major risk factor is exposure to rats, either as an occupational hazard for persons such as laboratory workers, veterinarians, or pet shop employees, or for persons who have rats for pets or feed rats to snakes, especially children. Classically, homelessness and lower socioeconomic status were described as major factors, but most cases reported in the last few years have involved pet rats. Thirty percent of patients with rat-bite fever do not report any exposure to rats or other rodents. Therefore the lack of documented exposure does not exclude this diagnosis.

### Pathophysiology

Very little is known about the pathophysiology of *S moniliformis* infections. Presumably, the failure of local control by dendritic cells, tissue macrophages, neutrophils, and other components of the innate immune system results in deeper infection, leading to bacteremia. Studies using histologic analysis have revealed intravascular thrombosis near the port of entry.

### Prevention

The role of prophylactic antibiotics is unknown, but some authors recommend the use of oral penicillin V (PenVK)<sup>1</sup> after documented exposure to rats and a break in the skin. Penicillin V should be given for 3 days at a dose of 2 g per day for adults. Primary prevention should be encouraged for patients with occupational risk by using protective gloves to handle animals or cages.

### Clinical Manifestations

Rat-bite fever is a systemic febrile disease. Classically, following a rat bite and a short incubation of 2 to 10 days, systemic dissemination of the organism is associated with an abrupt onset with intermittent relapsing fever, rigors, myalgias, arthralgias, headache, sore throat, malaise, and vomiting. These symptoms are followed within the first week by the development of a maculopapular rash in 75% of patients. The rash can be pustular, purpuric, or petechial, and it typically involves the extremities, in particular the palms and soles. The bite site typically heals promptly, with minimal inflammation and no significant regional lymphadenopathy.

Following the rash, approximately 50% of infected patients develop an asymmetric migrating polyarthritis, which appears to be exceedingly painful and affects large and middle-sized joints. Joint effusion appears more common in adults. Infection can occur in any tissue. Although most cases of rat-bite fever resolve spontaneously, there have been reports of complications. These include meningitis, endocarditis (including prosthetic valve endocarditis), myocarditis, pericarditis, pneumonia, brain abscess, septic arthritis, DIC (disseminated intravascular coagulation), and infarcts of the spleen and kidneys. The mortality rate in untreated cases is around 10% to 15%, and it rises to more than 50% in the rare cases with cardiac involvement.

Two closely related variants have been described. In Haverrill fever, the organism is transmitted by ingestion of contaminated food. Haverrill fever tends to occur in epidemics and also causes rashes and arthritis, but upper respiratory tract symptoms and vomiting appear more prominent. It is important to note that these patients do not provide a history of exposure to rodents. Sodoku is a rat-bite fever caused by *S minus*; it is common in Japan. The course is more subacute, arthritic symptoms are rare, and if the bite initially heals, it then ulcerates and is associated with regional lymphadenopathy and a distinctive rash. *S minus* cannot be grown using synthetic media, and thus microbiologic diagnosis rests on visualization of these organisms in infected tissues.

### Diagnosis

Diagnosis is difficult and requires a high clinical index of suspicion. The initial symptoms of rat-bite fever are nonspecific, triggering a broad differential diagnosis. Additionally, the fastidious nature of this organism makes isolation from blood cultures difficult. Clinicians should ask about rodent exposure when compatible symptoms are seen in patients. Rat-bite fever should not be ruled out in the absence of bite history, because transmission can occur without a bite, and pet owners or laboratory workers can minimize the significance of the bite, especially in the absence of a local reaction.

No reliable serologic test is available, and the definitive diagnosis requires isolation of *S moniliformis* from the wound, blood, or synovial fluid in patients with septic arthritis. The microbiology laboratory should be specifically notified of any clinical suspicion to enhance the chances of recovering the pathogen.

*S moniliformis* is a highly pleomorphic, nonencapsulated, nonmotile, gram-negative rod, which can stain positively on Gram stain (Figure 1). It is often dismissed as proteinaceous debris because of its numerous bulbous swellings with occasional clumping (*moniliformis*="necklace-like"). It grows slowly and requires a microaerophilic environment with 5% to 10% CO<sub>2</sub> or anaerobic conditions and media supplementation with 20% normal rabbit serum. Cultures can take up to 7 days to turn positive. Some experts recommend holding blood cultures for 21 days to permit sufficient time to grow this organism. *S moniliformis* is also inhibited by sodium polyanethol sulfonate, a common adjunct in most commercial blood culture media at a concentration as low as 0.0125%. *S moniliformis* has been identified using polymerase chain reaction amplification and 16S ribosomal ribonucleic acid (rRNA) sequencing, which shows great promise though it is available at reference laboratories. Fatty acid profiles obtained by gas-liquid chromatography can also be used for identification.

*S minus*, the other etiologic agent of rat-bite fever, is a short, thick, gram-negative, tightly coiled spiral rod that measures 0.2 to 0.5 μm and has two to six helical turns.

### Differential Diagnosis

Differential diagnosis for fever, rash, and polyarthritis is broad. Malaria, typhoid fever, and neoplastic disease can cause relapsing fevers, and the presence of a rash and polyarthritis might suggest viral and rickettsial diseases including Rocky Mountain spotted fever. An asymmetric oligoarthritis

<sup>1</sup>Not FDA approved for this indication.

**Figure 1** Gram stain of *Streptobacillus moniliformis*. Gram stain of growth from anaerobic bottle,  $\times 100$  magnification [microphotography]. Reprinted with permission from Partners' Infectious Disease Images; accessed on August 11, 2016, from <http://www.idimages.org/images/detail/?imageid=373>.

suggests disseminated gonococcal and meningococcal diseases in the context of cutaneous lesions on the palms and soles. Lyme disease, leptospirosis, or secondary syphilis can have a similar clinical presentation. Finally, when classic infectious symptoms such as fever or rash are missing, any causes of polyarthritis, from crystal-induced arthropathies to rheumatoid arthritis, should be considered.

### Treatment

All established cases of rat-bite fever should be treated with antibiotics because of the associated mortality and potential for complications. Intravenous penicillin G at a dose of 1.2 million units per day should be initiated as soon as the clinical diagnosis is made. Empiric therapy is necessary and should not be delayed for laboratory confirmation of this bacterial infection. The intravenous treatment should continue for 5 to 7 days. After treatment with IV penicillin and suitable clinical response, therapy should be continued with oral penicillin (PenVK)<sup>1</sup> or ampicillin (Omnipen)<sup>1</sup> at a dose of 500 mg qid for an additional 7 days. For patients allergic to penicillin, intravenous doxycycline (Vibramycin)<sup>1</sup> at a dose of 100 mg every 12 hours or oral tetracycline (Achromycin)<sup>1</sup> at a dose of 500 mg four times a day can be used.

Streptomycin<sup>1</sup> and cephalosporins including cefotaxime (Claforan)<sup>1</sup> have been reported to be potentially useful. Other antibiotics including azithromycin (Zithromax),<sup>1</sup> erythromycin,<sup>1</sup> carbapenems,<sup>1</sup> aztreonam (Azactam),<sup>1</sup> clindamycin (Cleocin),<sup>1</sup> vancomycin (Vancocin),<sup>1</sup> and nitrofurantoin (Macrochantin)<sup>1</sup> have shown efficacy in vitro, but they lack good clinical correlation to recommend them for routine use. Erythromycin has been associated with treatment failures. Trimethoprim-sulfamethoxazole (Bactrim),<sup>1</sup> polymyxin B,<sup>1</sup> gentamicin (Garamycin),<sup>1</sup> tobramycin (Nebcin),<sup>1</sup> ciprofloxacin (Cipro),<sup>1</sup> and levofloxacin (Levaquin)<sup>1</sup> should not be used because in vitro resistance has been demonstrated.

Typically, the bite site heals promptly. It should be cleaned and disinfected, as is typical for management of other wounds. Tetanus prophylaxis (tetanus-diphtheria toxoids, Td) administration is indicated as required by the patient's immunization record. Rabies prophylaxis (Imovax Rabies) is usually not required for

rodent bite, but consultation with local public health authorities is encouraged. There are no reports of transmission of the rabies virus from rats to humans.

## RELAPSING FEVER

Method of  
Diego Cadavid, MD

### CURRENT DIAGNOSIS

- There are two forms of relapsing fever: epidemic and endemic.
- Epidemic relapsing fever is transmitted from person to person by the body louse *Pediculus humanus*.
- Endemic relapsing fever is transmitted from rodent reservoirs to humans exposed to endemic areas by soft-bodied ticks of the genus *Ornithodoros*.
- The hallmark of relapsing fever is two or more febrile episodes separated by periods of relative well-being.
- The diagnosis is confirmed by visualization of the etiologic spirochetes in thin peripheral blood smears prepared at times of febrile peaks by phase-contrast or darkfield microscopy or light microscopy after Wright or Giemsa staining.

<sup>1</sup>Not FDA approved for this indication.

## CURRENT THERAPY

- The antibiotic of choice for treatment of relapsing fever is doxycycline except in children or pregnant women. In children <8 years of age, erythromycin<sup>1</sup> or oral penicillin is used instead of tetracycline (Table 3).
- Relapsing fever, if severe or complicated with neuroborreliosis, requires treatment with the intravenous antibiotics ceftriaxone or penicillin G (Table 3).
- The louse-borne epidemic form is treated with a single dose, whereas the endemic tick-borne form is treated with multiple doses for at least 1 week (Table 3).
- Antibiotic treatment of relapsing fever results in the Jarisch-Herxheimer reaction (JHR) in as many as 60% of cases, more often in the epidemic than in the endemic forms. It is characterized by the sudden onset of tachycardia, hypotension, chills, rigors, diaphoresis, and high fever. To reduce the risk of JHR, antibiotics should be started between but not at times of febrile peaks.

<sup>1</sup>Not FDA approved for this indication.

Relapsing fever is one of several diseases caused by spirochetes. Other human spirochetal diseases are syphilis, Lyme disease, and leptospirosis. Notable features of spirochetes are wavy and helical shapes, length-to-diameter ratios of as much as 100 to 1, and flagella that lie between the inner and outer cell membranes. The spirochetes that cause relapsing fever are in the genus *Borrelia*. Other *Borrelia* species cause Lyme disease, avian spirochetosis, and epidemic bovine abortion. Table 1 shows the main *Borrelia* species of relapsing fever, their vectors, and an estimate of their geographic ranges. In the United States, relapsing fever was considered a disease endemic only in the West. However, the recent finding of relapsing fever–like *Borrelia* in ticks and dogs in the eastern United States suggests that the risk of relapsing fever may extend into the East.

### Epidemiology

There are two forms of relapsing fever: epidemic transmitted to humans by the body louse *Pediculus humanus* (louse-borne relapsing fever [LBRF]) and endemic transmitted to humans by soft-bodied ticks of the genus *Ornithodoros* (tick-borne relapsing fever [TBRF]). In LBRF, itching caused by skin infestation with lice leads to scratching, which may result in crushing of lice and release of infected hemolymph into areas of skin abrasion.

Louse infestation is associated with cold weather and a lack of hygiene. Migrant workers and soldiers at war are particularly susceptible to this infection. Historically, massive outbreaks of LBRF occurred in Eurasia, Africa, and Latin America, but currently the disease is found only in Ethiopia and neighboring countries. However, immigrants can spread LBRF to other parts of the world.

The main risk factor for TBRF is exposure to endemic areas (Table 1). The risk of infection increases with outdoor activities in areas where rodents nest, like entering caves or sleeping in rustic cabins. *Ornithodoros* ticks are soft-bodied and feed for short periods of time (minutes), usually at night. They can live many years between blood meals and may transmit spirochetes to their offspring transovarially. Infection is produced by regurgitation of infected tick saliva into the skin wound during tick feeding. There are several natural vertebrate reservoirs for TBRF, but most common are rodents (deer mice, chipmunks, squirrels, and rats). In contrast, the body louse *Pediculus humanus* is a strict human parasite, living and multiplying in clothing. Hard-tick-borne relapsing fever (HTBRF) is an emerging infectious disease throughout the temperate zone caused by *Borrelia miyamotoi*. *Borrelia miyamotoi* is a spirochete closely related to the bacteria that cause TBRF. It is more distantly related to the bacteria that cause Lyme disease. First identified in 1995 in ticks from Japan, *B. miyamotoi* has since been detected in two species of North American ticks, the black-legged or “deer” tick (*Ixodes scapularis*) and the western black-legged tick (*Ixodes pacificus*). These ticks are already known to transmit Lyme disease, anaplasmosis, and babesiosis.

### Clinical Diagnosis

Relapsing fever should be suspected in any patient presenting with two or more episodes of high fever and constitutional symptoms spaced by periods of relative well-being. The index of suspicion increases if the patient has been exposed to endemic areas for TBRF or to countries where LBRF still occurs (Table 1). Whereas LBRF is usually associated with a single febrile relapse, TBRF usually has multiple relapses (up to 13). Only about 10% of cases of HTBRF have febrile relapses. In LBRF the second episode of fever is typically milder than the first; in TBRF the multiple febrile periods are usually of equal severity. The febrile periods last from 1 to 3 days, and the intervals between fevers last from 3 to 10 days. During the febrile periods, numerous spirochetes are circulating in the blood. This is called *spirochetemia* and is sometimes unexpectedly detected during routine blood smear examinations. Between fevers, spirochetemia is not observed because the numbers are low. The fever pattern and recurrent spirochetemia are

**TABLE 1** Relapsing Fever *Borrelia* Species Pathogenic to Humans

RELAPSING FEVER	BORRELIA SPECIES	ARTHROPOD VECTOR	DISTRIBUTION OF DISEASE
Endemic	<i>Borrelia hermsii</i>	<i>Ornithodoros hermsi</i>	Western North America
	<i>Borrelia turicatae</i>	<i>Ornithodoros turicata</i>	Southwestern North America and northern Mexico
	<i>Borrelia venezuelensis</i>	<i>Ornithodoros rudis</i>	Central America and northern South America
	<i>Borrelia hispanica</i>	<i>Ornithodoros maroccanus</i>	Iberian peninsula and northwestern Africa
	<i>Borrelia crocidurae</i>	<i>Ornithodoros erraticus</i>	North and East Africa, Middle East, southern Europe
	<i>Borrelia duttoni</i>	<i>Ornithodoros moubata</i>	Sub-Saharan Africa
	<i>Borrelia persica</i>	<i>Ornithodoros tholozani</i>	Middle East, Greece, Central Asia
Epidemic	<i>Borrelia uzbekistan</i>	<i>Ornithodoros pappilipes</i>	Tajikistan, Uzbekistan
	<i>Borrelia miyamotoi</i>	<i>Ixodes</i> spp.	Asia, Europe, North America
	<i>Borrelia recurrentis</i>	<i>Pediculus humanus</i>	Worldwide (recently only in East Africa including immigrants to Europe)

**TABLE 2** Frequent Clinical Manifestations of Tick-Borne Relapsing Fever

SIGN OR SYMPTOM	FREQUENCY (%)
Headache	94
Myalgia	92
Chills	88
Nausea	76
Arthralgia	73

Dizziness	25
Photophobia	25
Neck pain	24
Rash	18
Dysuria	13
Jaundice	10
Hepatomegaly	10
Splenomegaly	6

the consequences of antigenic variation of abundant outer membrane lipoproteins of relapsing fever *Borrelia* species that are the target for serotype-specific antibodies.

The mean latency between exposure to ticks in the endemic form or to lice in the epidemic form and onset of symptoms is 6 days (range, 3–18 days). Because *Ornithodoros* ticks feed briefly and painlessly at night, patients with TBRF may not be able to recall having been bitten by a tick. The clinical manifestations of TBRF and LBRF are similar, although some differences do exist. **Table 2** lists the frequency of the most common manifestations of TBRF. The usual initial presentation is sudden onset of chills followed by high fever, tachycardia, severe headache, vomiting, myalgia and arthralgia, and often delirium. In the early stages, a reddish rash may be seen over the trunk, arms, or legs. The fever remains high for 3 to 5 days, and then it clears abruptly. After an asymptomatic period of 7 to 10 days, the fever and other constitutional symptoms can reappear suddenly. The febrile episodes gradually become less severe, and the person eventually recovers completely. As the disease progresses, fever, jaundice, hepatosplenomegaly, cardiac arrhythmias, and cardiac failure may occur, especially with LBRF. Jaundice is more common at times of relapses. Patients with LBRF are more likely to develop petechiae on the trunk, extremities, and mucous membranes; epistaxis; and blood-tinged sputum. Rupture of the spleen may rarely occur. Multiple neurologic complications can occur as a result of disseminated intravascular coagulation in LBRF and as a result of infection of the meninges and cranial and spinal nerve roots by spirochetes in TBRF. The most common neurologic complications of TBRF are aseptic meningitis and facial palsy. Relapsing fever in pregnant women can cause abortion, premature birth, and neonatal death. Sometimes patients can have nonfebrile relapses, consisting of periods of severe headache, backache, weakness, and other constitutional symptoms without fever that occur at the time of expected relapses. Delirium may persist for weeks after the fever resolves, and, rarely, symptoms may be protracted.

Relapsing fever may be confused with many diseases that are relapsing or cause high fevers. These include typhoid fever, yellow

fever, dengue, African hemorrhagic fevers, African trypanosomiasis, brucellosis, malaria, leptospirosis, rat-bite fever, intermittent cholangitis, cat-scratch disease, and echovirus 9 infection, among others. Relapsing fever *Borrelia* spp. have antigens that are cross reactive with Lyme disease *Borrelia* spp. and inasmuch as the endemic areas of relapsing fever and Lyme disease overlap to some extent, confusion between the two infections can be expected. In fact, the same species of ticks can transmit HTBRF and Lyme disease, although erythema migrans rash is rare in the former and common in the latter.

### Laboratory Diagnosis

Although the pattern of recurring fever is the clue to diagnosing relapsing fever, confirmation of the diagnosis requires demonstration of spirochetes in peripheral blood taken during an episode of fever. The comparatively large number of spirochetes in the blood during relapsing fever provides the opportunity for the simplest method for laboratory diagnosis of the infection, light microscopy of Wright- or Giemsa-stained thin blood smears or darkfield or phase-contrast microscopy of a wet mount of plasma. The blood should be obtained during or just before peaks of body temperature. Between fever peaks, spirochetes often can be demonstrated by inoculation of blood or cerebrospinal fluid (CSF) into special culture medium (BSK-H with 6% rabbit serum available from Sigma) or experimental animals. Enrichment for spirochetes is achieved by using the platelet-rich fraction of plasma or the buffy coat of sedimented blood. In the United States the most common causes of relapsing fever are *Borrelia hermsii* and *Borrelia turicatae*; both grow in BSK-H medium and in young mice or rats. Whereas direct visual detection of organisms in the blood is the most common method for laboratory confirmation of relapsing fever, immunoassays for antibodies are the most common means of laboratory confirmation for Lyme disease. Although serologic assays have been developed for the agents of relapsing fever, these are not widely available and of dubious utility. The antigenic variation displayed by the relapsing fever species means there are hundreds of different “serotypes.” If a different serotype or species is used for preparing the antigen, only antibodies to conserved antigens may be detected. For this reason, a standardized enzyme-linked immunosorbent assay (ELISA) with Lyme disease *Borrelia* as antigen may be the best available serologic assay for relapsing fever. ELISA for *Borrelia burgdorferi* antibodies is routinely done across the United States and Europe. If a positive result for IgM or IgG antibodies is obtained, the Western blot for antibodies to *B burgdorferi* antigens would be expected to discriminate current or past Lyme disease from relapsing fever, as well as from syphilis, another cause of false-positive Lyme disease ELISA results. Other frequent laboratory abnormalities can occur in relapsing fever but are not diagnostic. These include elevated white blood cell count with increased neutrophils, thrombocytopenia, increased serum bilirubin, proteinuria, microhematuria, prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT), and elevation of fibrin degradation products.

### Treatment

Relapsing fever *Borrelias* are very sensitive to several antibiotics, and antimicrobial resistance is rare. **Table 3** summarizes the treatment options for adults and children younger than 8 years. Children older than 8 years can be treated with the same antibiotics as adults, but the doses should be adjusted by weight. Before antibiotics are given, the possibility of causing the Jarisch-Herxheimer reaction (JHR) should be considered (see later). The tetracycline antibiotics are most commonly used for treatment of LBRF and TBRF. The first antibiotic of choice in adults and children older than 8 years is doxycycline (Doryx). In general, shorter treatments are needed for LBRF than for TBRF. Single-dose therapy is usually recommended for LBRF. In contrast, in TBRF even multiple doses of tetracyclines for up to 10 days may fail to prevent relapses, and retreatment can be required. *B. miyamotoi* is susceptible in vitro to doxycycline, azithromycin, and ceftriaxone. Physicians have successfully treated patients infected with *B miyamotoi* with a 2 to 4-week course of doxycycline.

**TABLE 3** Treatment Options for Tick-Borne Relapsing Fever\*

Adults	
Nonsevere forms	
1.	Doxycycline (Doryx oral), 100 mg PO bid for 1–2 wk <sup>†</sup>
2.	Tetracycline (Sumycin), 500 mg PO qid for 1–2 wk
3.	Erythromycin (Erythrocin), <sup>1</sup> 500 mg PO tid for 1–2 wk
Severe forms	
1.	Ceftriaxone (Rocephin), <sup>1</sup> 2 g IV qd for 1–2 wk
2.	Penicillin G parenteral aqueous (Pfizerpen), <sup>1</sup> 4 million U IV q4h for 1–2 wk
Children (≤8 y)	
Nonsevere forms	
1.	Erythromycin suspension oral (EryPed), <sup>1</sup> 30–50 mg/kg/d divided tid for 1–2 wk
2.	Azithromycin oral suspension (Zithromax), <sup>1</sup> 20 mg/kg on the first day followed by 10 mg/kg/d for 4 more days
3.	Penicillin V (Pen-Vee K), <sup>1</sup> 25–50 mg/kg/d divided qid for 1–2 wk
4.	Amoxicillin (Amoxil), <sup>1</sup> 50 mg/kg/d divided tid for 1–2 wk
Severe forms	
1.	Ceftriaxone (Rocephin), <sup>1</sup> 75–100 mg/kg/d IV for 1–2 wk
2.	Penicillin G parenteral aqueous (Pfizerpen), <sup>1</sup> 300,000 U/kg/d given IV in divided doses q4h for 1–2 wk

Abbreviations: IV = intravenous; PO = orally.

<sup>†</sup>Not FDA approved for this indication.

\*The same oral agents are used for treatment of louse-borne (epidemic) relapsing fever but given as a single dose.

<sup>†</sup>In general, treatment for 1 wk is recommended in early/milder cases and for up to 2 wk for more severe cases.

Alternative oral antibiotics to the tetracyclines are erythromycin (E-Mycin)<sup>1</sup>, azithromycin (Zithromax)<sup>1</sup>, amoxicillin (Amoxil)<sup>1</sup>, penicillin<sup>1</sup>, and chloramphenicol (Chloromycetin).<sup>1</sup> However, oral chloramphenicol is not available in the United States. Erythromycin, azithromycin, and penicillin do not appear as effective as the tetracyclines; however, they are recommended for children younger than 8 years and for pregnant women. Amoxicillin is another alternative for young children with early Lyme disease; however, it is ineffective for human granulocytic ehrlichiosis, which sometimes occurs as a co-infection with Lyme disease. *Borrelia miyamotoi* may be resistant to amoxicillin.

Although treatment with antibiotics is usually given orally, they may need to be given intravenously if severe vomiting makes swallowing impractical. If there are symptoms and signs of meningitis or encephalitis without clinical or radiologic signs of increased intracranial pressure, the CSF should be examined to rule out central nervous system (CNS) infection. The finding of elevation of CSF cells and protein demands the use of parenteral antibiotics, such as penicillin G<sup>1</sup> or ceftriaxone (Rocephin).<sup>1</sup> Optimally, antibiotic treatment should be started during afebrile periods when the spirochetemia is low. Starting therapy near the peak of a febrile period may induce JHR, in which high fever and a rise and subsequent fall in blood pressure, sometimes to dangerously low levels, may occur. Dehydration should be treated with fluids given intravenously. Severe headache can be treated with pain relievers such as codeine, and nausea or vomiting can be treated with prochlorperazine (Compazine).

<sup>1</sup>Not FDA approved for this indication.

## Jarisch-Herxheimer Reaction

Antibiotic treatment of relapsing fever causes JHR in as many as 60% of cases. JHR is more common in LBRF than in TBRF. It can also occur in HTBRF. It is characterized by the sudden onset of tachycardia, hypotension, chills, rigors, diaphoresis, and high fever. Patients with JHR have said that they felt as if they were going to die. JHR is caused by the rapid killing of circulating spirochetes 1 to 4 hours after the first dose of antibiotic, which results in the release of large amounts of *Borrelia* lipoproteins in the circulation followed by massive release of tumor necrosis factor and other cytokines. If possible, patients with JHR should be transferred to an intensive care unit for close monitoring and treatment. Over several hours, the temperature declines and the patient feels better. Large amounts of intravenous fluids (0.9% sodium chloride solution) may be required to treat hypotension. Steroids and nonsteroidal antiinflammatory agents have no effect on the frequency or severity of the JHR. One study found that pretreatment with anti-TNF-alpha monoclonal antibody (Humira)<sup>1</sup> suppressed JHR after penicillin treatment for LBRF and reduced the associated increases in plasma cytokines. Death can occur as a result of JHR secondary to cardiovascular collapse in up to 5% of patients with treated LBRF and much less frequently in TBRF.

## Outcome

Complete recovery occurs in 95% or more of adequately treated patients. The prognosis for untreated cases or if treatment is delayed varies. A mortality rate as high as 40% is reported in untreated epidemics of LBRF. Relapsing fever also has a high mortality rate in neonates. Some neurologic sequelae can occur in patients with TBRF complicated with neuroborreliosis.

## Prevention

Prevention of TBRF involves avoidance of rodent- and tick-infested dwellings such as animal burrows, caves, and abandoned cabins. Wearing clothing that protects skin from tick access (e.g., long pants and long-sleeved shirts) is also helpful. Repellents and acaricides provide additional protection. Diethyltoluamide (DEET) repels ticks when applied to clothing or skin, but it must be used with caution. It loses its effectiveness within 1 to several hours when applied to skin and must be reapplied; it is absorbed through the skin and may cause CNS toxicity if used excessively. Picaridin (KBR 3023), which has been used as an insect repellent for years in Europe and Australia, is now available in the United States in 7% solution as Cutter Advanced Repellent (Spectrum Brands). The US Centers for Disease Control and Prevention (CDC) is recommending it as an alternative to DEET. Permethrin Insect Repellent, an acaricide, is more effective than DEET but should not be applied directly to skin. When applied to clothing, it provides good protection for 1 day or more. In LBRF, prevention can be achieved by promoting personal hygiene and by dusting undergarments and the inside of clothing with malathion<sup>1</sup> powder<sup>2</sup> or lindane<sup>1</sup> powder<sup>2</sup> when available. Widespread antibiotic use may be necessary to control epidemics of LBRF, using one or two doses of 100 mg doxycycline<sup>1</sup> given within 1 week of exposure.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States

## RUBELLA AND CONGENITAL RUBELLA

Method of

Dee Ann Bragg, MD

### CURRENT DIAGNOSIS

- Given its clinical overlap with other viral syndromes, suspected rubella infection must be confirmed with laboratory testing.
- Rubella serology or viral polymerase chain reaction (PCR) testing are available options for confirming a suspected diagnosis.

### CURRENT THERAPY

- Rubella infection is largely self-limited with no specific treatment indicated.
- Infection during pregnancy should prompt further evaluation and counseling regarding risks and potential outcomes.
- Treatment of children with congenital rubella syndrome requires a multidisciplinary effort based on individual manifestations.
- Vaccination is essential in reducing the risk of rubella and congenital rubella syndrome.

Rubella typically presents in children and adults as a mild viral illness, but is one of the TORCH infections (toxoplasmosis, other, rubella, cytomegalovirus, herpes) known to cause congenital anomalies. Although vaccination efforts have led to the successful eradication of rubella in the United States, it remains a significant cause of morbidity and death worldwide. Its name is derived from Latin and means “little red.” Initially considered a variant of measles or scarlet fever, rubella was first described as its own entity in the German medical literature in 1814. Thus it is still often referred to as “German measles” in common nomenclature.

### Pathophysiology and Virology

Rubella virus, a single-stranded RNA virus and the only member of the Rubivirus genus, is part of the *Togaviridae* family and is the causative agent of rubella infection. There are 13 recognized genotypes of rubella, each with minor differences in nucleotide sequencing and gene expression. Rubella typically presents as a mild and self-limited illness. During pregnancy, however, it can infect the placenta and disrupt organogenesis by creating systemic inflammation and inhibiting actin assembly. Outcomes of antenatal infection are variable but can include miscarriage, fetal death, and congenital rubella syndrome (CRS).

Multiple factors are involved in the pathogenesis of CRS. Rubella infection can cause necrosis of the chorionic epithelial and endothelial cells. These cells then enter fetal circulation and can incite thrombotic or ischemic lesions in the eyes, ears, brain, and heart. The virus also appears to trigger an immune-modulated upregulation of interferon and cytokines, which can alter the normal development and differentiation of fetal cells.

### Epidemiology

Although rubella is less contagious than other viruses such as influenza or measles, large epidemics are associated with significant morbidity from complications including encephalitis, fetal loss, deafness, and blindness. Norman Gregg, an Australian ophthalmologist, was the first to recognize the teratogenic potential of rubella when in 1941 he noted an unusually high incidence of congenital cataracts after an area outbreak.

Rubella was successfully eradicated from the United States in 2004 due to widespread vaccination efforts, and most sporadic cases since that time have been documented in foreign-born young adults. In endemic areas, annual springtime outbreaks are common. However, sporadic cases can occur year-round in temperate climates. Outbreaks typically affect early school-aged children, and the mean age for an infected host is 5 to 9 years. Because lifelong immunity develops after natural infection, large cyclical epidemics tend to occur every 3 to 8 years as population immunity wanes.

Humans are the only known host of rubella infection, and the virus is transmitted from person to person through respiratory droplets. After transmission, rubella virus replicates in the respiratory mucosa and cervical lymph nodes before entering systemic circulation and spreading to target organs.

### Clinical Manifestations

#### Acquired Rubella

After an incubation period of about 14 days (range, 12–23), a variety of clinical symptoms can appear. These are generally mild, and about 50% of cases are asymptomatic. In children, a skin rash is typically the initial manifestation of rubella. The rash usually appears on the face and then progresses downward from the head to the feet. It lasts about 3 days and is characteristically maculopapular, presenting with small pink non-coalescing papules that are occasionally pruritic. Bathing or showering in hot water tends to make the rash more evident.

Adults more often have a prodromal period of low-grade fever, malaise, and adenopathy lasting 1 to 5 days before the onset of skin findings. Lymphadenopathy may begin up to a week before the rash and can last for several weeks. The postauricular nodes are particularly commonly involved, and posterior cervical or suboccipital nodes may also be affected.

#### Sequelae

Polyarthritides and polyarthralgia are the most common complications of rubella, particularly in adult women, in whom they are seen up to 70% of the time. They appear with such frequency that they are often considered intrinsic to the virus itself rather than complications. Joint symptoms typically present around the same time or just after the onset of the rash. They usually last 3 to 4 days but can remain for up to 1 month. The most commonly affected joints are fingers, wrists, and knees. Chronic arthritis is rarely observed.

Other complications are uncommon but can carry a high degree of morbidity and death. Hemorrhagic events are more likely in children than adults and occur in about 1 in 3000 cases. They manifest as a result of vascular damage or thrombocytopenia. Skin purpura is the most common presentation, but gastrointestinal, cerebral, or intrarenal hemorrhage can occur. Encephalitis occurs in about 1 in 6000 cases, more commonly in adults than children. Rare complications include orchitis, neuritis, progressive panencephalitis, and Guillain-Barré syndrome.

#### Congenital Rubella Syndrome (CRS)

CRS can present transiently with low birth weight, thrombocytopenic purpura, or hemolytic anemia. However, permanent defects are the hallmark of CRS because it classically involves a triad of cataracts, cardiac anomalies, and sensorineural deafness. Of these, hearing loss is the most common and sometimes the only complication observed. Cardiac abnormalities can include patent ductus arteriosus, ventricular septal defect, pulmonary artery hypoplasia, and coarctation of the aorta. Other ocular defects such as glaucoma, retinopathy, and microphthalmia can also occur. Additional manifestations can include microcephaly, intellectual disability, psychomotor retardation, and delayed speech.

Notably, it can take 2 to 4 years for certain neurologic, endocrine, or cardiac abnormalities associated with CRS to manifest. Diabetes mellitus, thyroid disease, autism, and progressive panencephalopathy can all occur as late effects of CRS.

The risk of CRS and its associated congenital defects is greatest when infection occurs in the first trimester. Up to 85% of infants born under these conditions are found to be affected, whereas defects are rare when infection occurs after 20 weeks' gestation.

### Diagnosis

Given its nonspecific nature and similarity to other viral infections, clinical diagnosis of rubella is challenging and largely unreliable. Suspected infection should be confirmed by 1 of 3 diagnostic methods: (1) rubella immunoglobulin M (IgM) serology, (2) a demonstrated rise in rubella virus immunoglobulin G (IgG) between acute and convalescent phases, or (3) detection of rubella virus by PCR.

Among the existing options for laboratory diagnosis, rubella IgM is the most accessible and widely used. However, collection timing is important to consider. Rubella IgM will only be detectable in about 50% of cases on the day of rash appearance but will be present in nearly all cases by 7 to 10 days after the rash. It will then remain positive for 4 to 12 weeks. Importantly, serum IgM testing is most sensitive and specific in the setting of local outbreaks. False-positive results occur more frequently in sporadic cases, and in those instances, additional means of analysis should be performed to confirm diagnosis.

Rubella IgG testing can be used to diagnose acute rubella infection under two circumstances: either (1) a negative rubella IgG during acute infection followed by a positive IgG in the convalescent phase, or (2) a fourfold increase in IgG titer over 10 to 14 days. IgG avidity testing may also be useful. This measures the strength of antigen-antibody binding, which is typically weaker in acute infection and increases over time. Therefore a low avidity index would indicate a more recent infection.

Viral isolation of rubella by PCR is quite valuable for diagnostic confirmation and can be performed on samples obtained from throat or nasopharyngeal swabs. These tests are not as widely available in postvaccination settings and may need to be performed in conjunction with local health departments or national epidemiology centers.

Diagnosis of CRS in infants can similarly be confirmed by one of three methods: (1) rubella IgM detection in serum or cord blood, (2) persistence of rubella IgG >6 months of age (past the time frame of passive maternal immunity), or (3) PCR isolation of rubella virus from respiratory or urinary samples. Because both rubella virus and IgM remain positive for several months in patients with CRS, the time frame for testing is less crucial than in cases of postnatal infection.

### Treatment

There is no specific treatment for rubella and, because acquired cases are generally mild and self-limiting, basic supportive care is recommended. Detection of rubella infection in pregnancies before 18 weeks' gestation should prompt further investigation including maternal-fetal medicine referral, detailed ultrasound examination, support for adverse outcomes including neonatal hospice services, and follow-up examination and screening of the newborn. Maternal infections after 18 weeks can be followed with routine ultrasound monitoring along with newborn evaluation and testing.

### Prevention

#### Rubella Vaccine

The first rubella vaccines became available in 1969, and a number of strains have been developed since that time. Of these, the RA 27/3 vaccine has been the most enduring, and all other strains were discontinued at the time of its introduction in 1979. The RA 27/3 rubella vaccine is a live attenuated virus that is administered in conjunction with measles and mumps as MMR, or with measles, mumps, and varicella as MMRV (ProQuad). Single-antigen rubella vaccine is not available in the United States.

Vaccination against rubella is safe and effective. Adverse events such as fever and rash are mild and are generally attributable to the measles and mumps portions of the vaccines. After a single dose, more than 95% of those vaccinated have serologic confirmation of rubella immunity, with evidence of lifelong immunity in the vast majority of responders. MMR or MMRV is recommended for all children at 12 months of age, followed by a second dose between 4 and 6 years of age. The second dose is generally indicated to stimulate measles and mumps immunity in those who did not respond to the first vaccine. MMR and MMRV are contraindicated in immunosuppression, pregnancy, and in patients with a history of anaphylaxis to neomycin or other vaccine components.

### Preconception Counseling and Prenatal Care

Rubella immunity, defined as serum rubella IgG of 10 IU/mL or greater, should be documented in all women attempting to conceive. MMR vaccine should be given in cases of nonimmunity, and although it is recommended at least 4 weeks before conception, inadvertent vaccination after that time is unlikely to be associated with adverse events. Rubella IgG should likewise be checked in all pregnant females as part of routine obstetric care, and MMR should be administered postpartum to nonimmune women.

### Eradication and Future Goals

Despite widely available effective vaccines and evidence of sustained eradication in the Western Hemisphere, there are still approximately 100,000 cases of CRS annually worldwide. Although some African and Asian nations have introduced routine rubella vaccination, public health efforts have been inconsistent in many developing countries. Dedicated personnel and funding will likely be necessary to decrease rubella incidence and its complications on a global scale.

## SALMONELLOSIS

Method of

Arelis Santana, MD, MPH

### CURRENT DIAGNOSIS

- Nontyphoidal Salmonellae (NTS) represent a significant cause of infectious diarrhea globally.
- Underlying comorbidities, the virulence of the pathogen, and the size of inoculum can affect the severity of the infection.
- The most common clinical manifestation of NTS is self-limited acute gastroenteritis.
- Bacteremia and invasive infections (mycotic aneurysms, aortitis, among others) should be suspected in patients with high-grade fevers and predisposing risk factors (e.g., aneurysms and atherosclerotic disease).
- Diagnosis of NTS infection is confirmed by laboratory isolation of Salmonellae from the stool, blood, or sterile body fluid.

## CURRENT THERAPY

- Treatment for uncomplicated *Salmonella* gastroenteritis is based on supportive care with fluid and electrolyte replenishment.
- Antimicrobial therapy may be warranted for those with severe infection (severe diarrhea, high fever, need for hospitalization) or risk factors for invasive disease.
- Chronic carriage of NTS can occur in less than 1% of patients. Antimicrobial therapy may be of some utility in patients with chronic carriage; however, there is no strong evidence yet supporting its routine use.
- Adequate hand hygiene practices, appropriate food handling, and standard precautions are still the best way to avoid NTS spread.

Salmonellae was named after Dr. Daniel Elmer Salmon, a veterinary pathologist chief of the Bureau of Animal Industry, who helped with the eradication of contagious bovine pleuropneumonia in the United States. His colleague and professor, Dr. Theobald Smith, was the first to isolate *Salmonella choleraesuis* from porcine intestines in 1885. This microorganism can grow in both humans and animals, causing a broad range of clinical manifestations. Clinical presentations comprise gastroenteritis, bacteremia, endovascular infections, localized infections, and chronic carrier state. However, the most common presentation of salmonellosis is uncomplicated gastroenteritis.

### Microbiology

*Salmonella* is a genus of gram-negative bacilli belonging to the family of Enterobacteriaceae. The genus of *Salmonellae* is divided into two species: *enterica* and *bongori*. *Salmonella enterica* is further divided into six different subspecies based on DNA resemblances. Subspecies are also differentiated into serotypes. *Salmonellae* serotypes are designated based on the immunoreactivity of cell surface structures, the O and H antigens. These serotypes are classified using the Kauffmann–White classification scheme. *Salmonella* has more than 2500 serotypes. However, less than 100 have been found to be pathogenic in humans.

*Salmonellae* species are nonspore forming, motile, facultative anaerobes that can measure 2 to 3  $\mu\text{m}$  by 0.4 to 0.6  $\mu\text{m}$  in size. All *Salmonellae* are motile utilizing a flagellum, except for *S. Gallinarum* and *S. Pullorum*. Similar to other Enterobacteriaceae, they can produce acid on glucose fermentation. Most of the species do not ferment lactose and appear white on MacConkey agar plates, except for approximately 1% of them, which can make their identification challenging. Another important feature of identification is that most of the species, except for *S. Typhi*, produce hydrogen sulfide on sugar fermentation, which can be detected on the selective indicator plates.

### Epidemiology

Nontyphoidal *Salmonellae* (NTS) represent a significant cause of infectious diarrhea globally. Approximately, there are 93.8 million cases of gastroenteritis *Salmonella* species and 155,000 deaths per year. According to the Centers for Disease Control and Prevention (CDC), there are approximately 1.35 million illnesses and 420 deaths due to NTS yearly in the United States, with an estimate of 39 cases of salmonellosis for each culture-confirmed case. The *Salmonella* serotypes most frequently isolated are *S. enteritidis*, *S. typhimurium*, and *S. Newport*.

*Salmonellae* can inhabit the intestinal tract and can be found in the feces of humans and animals. These include but are not limited to birds (including poultry), reptiles, and amphibians.

**TABLE 1** Predisposing Factors for Salmonellosis

#### Gastrointestinal

Achlorhydria  
Gastric surgery  
Inflammatory bowel disease

#### Infections

HIV/AIDS (decreased T-cells)  
Bartonellosis  
Malaria  
Schistosomiasis

#### Immune or structural compromise

Age (<6 months, >60 years)  
Lymphoma  
Splenectomy  
Cirrhosis with portal hypertension  
Diabetes mellitus  
Chronic uremia  
Hemolytic anemia (iron overload)  
Sickle cell (bone infarct, autosplenectomy)  
Systemic lupus  
Atheromata, aortic aneurysm

#### Drugs

H2-blockers, proton pump inhibitors  
Antibiotic administration  
Antimotility agents  
Chemotherapy  
Corticosteroids  
Transplant antirejection agents

Infection can occur from the ingestion of animal food products such as undercooked meat, poultry, eggs, and dairy products, or from cross-contamination due to improperly handled food or water. Other possible sources include animal bodies contaminated with *Salmonella*. For example, reptiles can commonly harbor this organism. Also, areas where animals live, such as water tanks and cages, may be contaminated with these organisms and can be potential sources of infection. NTS outbreaks have also been associated with fresh produce, milk, nuts, fruits, and raw vegetables. These products can become contaminated by manure or water and then are distributed.

The emergence of antibiotic resistance in NTS has been on the rise and is currently a global concern as antibiotic treatment options are becoming limited and ineffective. Antibiotic resistance has been associated with the use of antimicrobials in animal feeds. The mechanisms of resistance described in NTS include active efflux pumps to remove antibiotics from inside the cell, hydrolytic enzyme production, mutations in target genes to evade the action of antibiotics, and decreased permeability of the outer membrane, among others.

In the United States, the National Antimicrobial Resistance Monitoring System (NARMS) monitors antibiotic resistance, including *Salmonella*. According to their last report in 2015, approximately 4% of NTS isolates were resistant to five or more antimicrobials, 4.7% of NTS strains were nalidixic acid resistant, 0.4% were resistant to ciprofloxacin, and 2.7% were resistant

to ceftriaxone. Resistance to nalidixic acid is a good indicator of a decreased susceptibility to fluoroquinolones. In summary, resistance rates to fluoroquinolones or third-generation cephalosporins in the United States are not high but warrant careful monitoring.

### Pathogenesis

A combination of factors related to both the pathogen and the host affects the pathogenesis of Salmonella infection and clinical presentation. Underlying conditions and the size of inoculum can affect the severity of the infection. NTS infection commences with the ingestion of organisms in contaminated food or water and usually requires approximately  $10^6$  organisms to produce the disease. However, infants or persons with certain underlying predisposing factors could develop the disease with smaller inoculums. Some of these predisposing risk factors include impaired cellular immunity, achlorhydria, alteration in the intestinal flora and integrity, and the extreme of ages (Table 1). These risk factors can lead to a more severe initial infection and complications such as bacteremia and/or metastatic infection. Gastric acidity is the initial barrier to Salmonellae; therefore, underlying conditions or medications that increase the pH of the stomach can predispose a person to infection. Salmonellae invade by binding to the gastrointestinal mucosa and submucosal lymphoid systems. After the invasion of Salmonella and the translocation of bacterial proteins into the host cell cytoplasm, the intestinal mucosa secretes interleukin-8 (IL-8), a strong neutrophil chemotactic factor. This causes an extensive polymorphonuclear leukocyte infiltration in both small and large intestinal mucosa. Degranulation and release of toxic neutrophils result in damage to the intestinal mucosa, producing diarrhea.

### Clinical Presentation

#### Gastroenteritis

The most common clinical manifestation of NTS is self-limited acute gastroenteritis. The incubation period is usually 6 to 48 hours following the exposure, but more extended incubation periods of up to 7 days have been reported. Symptoms include sudden onset of nausea and vomiting, followed by fever, constitutional symptoms, abdominal pain, and watery diarrhea. On rare occasions, bloody diarrhea can also be present. Symptoms subside within 3 to 7 days in uncomplicated gastroenteritis. In patients with predisposing factors (see Table 1), the clinical illness may be more complex, including bacteremia. Patients with inflammatory bowel disease can have serious complications like toxic megacolon that can potentially be life-threatening.

Higher inoculum of bacteria and virulence of different strains may correlate with the severity of diarrhea and the length of the disease course. The stool can contain polymorphonuclear leukocytes, or occult blood and leukocytosis can also be seen in the complete blood cell count.

#### Invasive Infections

Bacteremia can result as a complication from Salmonella gastroenteritis in up to 5% of the patients, and it should be suspected in patients with high-grade fevers or with predisposing risk factors. Bacteremia can lead to a variety of extraintestinal manifestations such as endocarditis, mycotic aneurysm, hepatic abscesses, or osteomyelitis. *S. choleraesuis* and *S. Dublin* are commonly associated with more invasive infections.

Although these are uncommon, NTS endovascular infection, including aortitis and mycotic aneurysms, should be suspected in patients with high-grade bacteremia or persistent bacteremia, or with pre-existing valvular heart disease, prosthetic vascular graft, or aortic aneurysm.

Intraabdominal infections due to NTS are also rare but can occur as hepatic and/or splenic abscesses, or cholecystitis, more commonly in patients with underlying hepatobiliary abnormalities. Other rare manifestations of invasive disease

are meningitis (more common in infants 1 to 4 months old), pneumonia, and urinary tract infections. Salmonella osteomyelitis is most commonly seen with sickle cell disease, or underlying bone disease.

### Diagnosis

Diagnosis of NTS infection is confirmed by laboratory isolation of Salmonellae from the stool, blood, or sterile body fluid. The definitive diagnosis of NTS gastroenteritis requires the identification in stool culture. Blood cultures should be performed whenever a patient has a prolonged or recurrent fever with NTS gastroenteritis. Endovascular infection should be suspected if there is high-grade bacteremia or persistent bacteremia. If an aortic or vascular infection is suspected, further imaging with computed tomography or magnetic resonance imaging (preferably with contrast angiographic analysis) should be performed.

Additionally, if a localized infection is diagnosed, such as an intraabdominal abscess or osteomyelitis, a body fluid drainage and culture is recommended. Salmonellosis is a nationally notifiable disease for which most states require that isolates of Salmonella be sent for serotyping to the local public health laboratory.

### Treatment

NTS gastroenteritis is usually self-limited; therefore, antibiotics are routinely not recommended for an uncomplicated infection. Antibiotic therapy has been associated with prolonged bacterial shedding and potentially extending carriage.

Supportive care with fluid and electrolyte replenishment, preferably via the oral route, is the mainstay of treatment for Salmonella gastroenteritis. Patients that present with severe dehydration or profuse vomiting should initially receive intravenous fluid repletion and may require hospitalization. Antiemetics such as, but not limited to, prochlorperazine (Compazine) or promethazine (Phenergan) may be helpful for symptom control. Antimotility agents are not recommended as they can increase the risk of complications.

There are specific clinical settings where antimicrobial therapy may be warranted for those with severe disease (severe diarrhea, high fever, need for hospitalization) or risk factors for invasive disease. When antimicrobial therapy is indicated, empiric treatment is started, and it must be tailored to susceptibility data once results are available.

Fluoroquinolones are usually the agents commonly used for adults and adolescents without contraindications to such antibiotics (Table 2). Fluoroquinolones are often avoided in children due to association with the development of cartilage defects. Additionally, note that serious adverse reactions have been associated with fluoroquinolones, including tendonitis, tendon rupture, peripheral neuropathy, and QT prolongation, among others. Other antibiotic options (see Table 2) include trimethoprim-sulfamethoxazole (Bactrim)<sup>1</sup>, amoxicillin<sup>1</sup>, ceftriaxone (Rocephin)<sup>1</sup>, or azithromycin (Zithromax)<sup>1</sup>. For patients with severe infection who cannot tolerate oral intake, intravenous fluoroquinolone or a third-generation cephalosporin such as ceftriaxone<sup>1</sup> is a good option. The duration of antibiotic therapy for NTS gastroenteritis in the absence of bacteremia is 3 to 7 days, depending on clinical response.

In the case of NTS bacteremia without other focal infection or immunocompromised state, 14 days of antibiotics are appropriate. Longer duration of antibiotics of 2 to 6 weeks of antibiotic therapy is recommended in patients with an immunocompromised state, including patients with advanced HIV with CD4 cell counts less than 200 cells/ $\mu$ L and organ transplant recipients in order to prevent a relapse of the infection.

Prolonged antibiotic therapy may be needed in patients with extraintestinal and endovascular infections, and eradication of the infection may require surgical intervention. Focal

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Recommended Antibiotic Therapy for Nontyphoidal Salmonella Infection in Adults

	ANTIBIOTIC	DOSE	DURATION
Severe gastroenteritis	Ceftriaxone (Rocephin) <sup>1</sup>	1–2 g IV daily	3–7 days (Immunosuppressed patients may require longer treatment of 2–6 weeks)
	Cefotaxime (Claforan) <sup>1</sup>	2 g IV Q8h	
	Amoxicillin <sup>1</sup>	1 g PO TID	
	Trimethoprim-sulfamethoxazole Bactrim DS <sup>1</sup>	160/800 mg PO BID	
	Azithromycin (Zithromax) <sup>1</sup>	1000 mg PO on day 1, then 500 mg PO daily	
	Ciprofloxacin (Cipro) <sup>1</sup>	500 mg PO BID or 400 mg IV Q12h	
Bacteremia	Ceftriaxone <sup>1</sup>	2 g IV daily	7–14 days (Immunosuppressed patients may require longer treatment of 2–6 weeks)
	Cefotaxime <sup>1</sup>	2 g IV Q8h	
	Ciprofloxacin <sup>1</sup>	400 mg IV Q12h	
	Trimethoprim-sulfamethoxazole <sup>1</sup>	8–10 mg/kg/day of TMP component IV TID	
	Ampicillin	2 g IV Q4h	
Endovascular infection*	Ceftriaxone <sup>1</sup>	2 g IV daily	6–8 weeks
	Cefotaxime <sup>1</sup>	2 g IV Q8h	
	Ciprofloxacin <sup>1</sup>	400 mg IV Q12h	
	Ampicillin	2 g IV Q4h	
Extraintestinal focal infection**	Ceftriaxone <sup>1</sup>	2 g IV daily	4–6 weeks
	Ampicillin	2 g IV Q4h	
	Ciprofloxacin <sup>1</sup>	400 mg IV Q12h or 750 mg PO BID	

\*Treatment includes antibiotic regimen with surgical intervention.

\*\*Bone and joint infection should be treated for 4–6 weeks along with surgical intervention if clinically indicated.

<sup>1</sup>Not FDA approved for this indication.

infections may require removal of the fluid collection like joint lavage in septic arthritis or abscess drainage if clinically indicated. In addition, graft or prosthetic material removal may be necessary for the eradication of the infection. The duration of the antibiotic course will depend on the infection site (see Table 2).

### Chronic Carriage

Asymptomatic excretion or carriage of Salmonella can occur after NTS infection. This can last up to 5 weeks; however, more extended periods have been reported. Chronic carriage of NTS is defined as excretion of the organism for more than 12 months, identified in stool culture 1 month after illness, followed by repeat positive cultures. Less than 1% of patients develop NTS chronic carriage. Routine follow-up cultures are not recommended after an uncomplicated Salmonella gastroenteritis in immunocompetent patients after the resolution of symptoms. However, in the United States, public health departments may require one or more negative stool cultures for individuals who work in specific settings such as childcare, food preparation, or health care in order to return to work.

An antibiotic course for asymptomatic carriage has not been proved to be effective and may promote resistance; hence, it is not recommended. Antimicrobial therapy may be of some utility in patients with chronic carriage; however, there is no strong evidence yet supporting its routine use.

### Prevention

Prevention of NTS infections involves personal and institutional efforts. Currently, there are no vaccines to prevent NTS infection. Adequate hand hygiene practices and standard precautions

are still the best way to avoid NTS spread. Individuals with the condition should remain out of work until the symptoms of gastroenteritis and diarrhea resolve, especially individuals that work in food handling, childcare, health care, or direct contact with immunosuppressed patients. This approach will decrease the possibility of outbreaks. Cross-contamination can occur when uncooked meat or poultry is being prepared. Therefore, utensils and the cutting board used in the preparation of these should be washed to prevent other foods from contamination.

Additionally, the CDC advises that children less than 5 years old, adults older than 65 years of age, and immunosuppressed individuals should not handle or touch amphibians or reptiles. They also recommend keeping the equipment used to handle reptiles out of the kitchen. The CDC also recommends that live poultry should not be kept inside the house, particularly in areas of food preparation. Also, strict hand hygiene precautions are recommended after touching live fowl. Children under 5 years of age or immunocompromised patients should not handle live poultry.

## SEPSIS

Method of

Rabab Nasim, MD; Jeannina Smith, MD; and Hilary Faust, MD, MS

## CURRENT DIAGNOSIS

### Sepsis

- Evidence of end-organ dysfunction caused by dysregulated inflammatory response from an infection

### Septic Shock

- Persistent hypotension caused by sepsis despite adequate fluid resuscitation (defined as 30 mL/kg)

### Sequential Organ Failure Assessment (SOFA) Score

- Mortality prediction score
- Includes respiratory, cardiovascular, central nervous system, renal, coagulation, and liver dysfunction
- Assessment of severity of sepsis and not diagnosis
- Validated as a predictor of mortality and prolonged ICU stay
- May apply less favorably in certain populations including African American patients

### Quick Sequential Organ Failure Assessment (qSOFA) Score

- Screening tool for organ dysfunction
- May apply less favorably to patients in the emergency department and ICU
- A score >2 prompts for evaluation for sepsis and is used for screening and not diagnosis
  - Altered mental status (Glasgow Coma Scale [GCS] score <15)
  - Respiratory rate >22/min
  - Systolic blood pressure <100 mm Hg

### Supportive Laboratory Findings

- Lactic acidosis ( $\leq 2$  mmol/L)
- Hypoxia ( $PaO_2:FiO_2 < 400$ )
- Hyperbilirubinemia ( $\geq 1.2$  mg/dL)
- Acute kidney injury (creatinine  $\geq 1.2$ )
- Thrombocytopenia ( $< 150,000/\mu L$ )
- Leukocytosis or leukopenia (white blood cell count  $< 4,000$  or  $> 12,000/\mu L$ )
- Elevated erythrocyte sedimentation rate or C-reactive protein

### Supportive Physical Findings

- Altered mental status (GCS score <15)
- Increased capillary refill (>2 seconds)
- Anuria and oliguria (urine output <500 mL/day)
- Tachypnea (respiratory rate >22 breaths/minute)
- Tachycardia (heart rate >90 beats/minute)
- Hypothermia or hyperthermia (temperature >38°C or <36°C)

## CURRENT THERAPY

### Initial 3 Hours of Triage (or Within 1 Hour of Presumptive Diagnosis)

All interventions should be undertaken simultaneously and initiated within 1 hour after making a presumptive diagnosis of sepsis.

- Initiate adequate fluid resuscitation with crystalloid solution (lactated Ringer's preferred to normal saline solution) at 30 mL/kg.
- Obtain blood, urine, and other appropriate cultures (cerebrospinal fluid, abscess drainage, catheter tip, tissue, sputum).
- Administer empiric antimicrobial therapy.
- Perform appropriate imaging studies with urgent source control as indicated and allowed by clinical status; remove potentially infected foreign bodies.

### Subsequent Interventions

- Add norepinephrine (Levophed) as a first-line pressor for persistent hypotension (mean arterial pressure <65 mm Hg) despite adequate fluid resuscitation.
- Initiate therapy with dobutamine (Dobutrex) for inotropic support if there is suspicion of contributory cardiogenic shock.
- Consider therapy with hydrocortisone (Solu-Cortef) for patients with continued hypotension despite adequate fluid resuscitation and vasopressors.
- Maintain glycemic control with a target blood glucose level <180 mg/dL.
- Use unfractionated or low-molecular-weight heparin for prophylaxis against deep venous thrombosis.
- Use a proton pump inhibitor for gastric ulcer prophylaxis.

## Epidemiology

Sepsis and septic shock are leading causes of mortality both globally and domestically. The mortality exists on a continuum, with more modest mortality rates in patients with early sepsis and much higher rates in those with septic shock, in whom 40% to >50% may not survive. Although community-acquired sepsis is more common, hospital-acquired sepsis is associated with higher morbidity and mortality rates. The incidence of sepsis has increased over time, although the overall mortality rate among patients with sepsis has decreased. Studies have shown that sepsis affects all age groups, with older adults and immunocompromised patients being at the highest risk. Indeed, the majority of episodes of sepsis and mortality occur in individuals older than 65 years of age. Rates of sepsis and associated mortality demonstrate differences by demographic group. For example, in the United States, rates are greatest among African American men.

## Etiology

Pneumonia is the leading cause of sepsis followed by abdominal infections, bloodstream infections, and sepsis from a urinary source. The incidence of sepsis is highest during the winter, most likely reflecting increased respiratory viral infections that precede the development of bacterial pneumonia.

## Microbiology

Sepsis can be caused by infection with viruses, bacteria, or fungi. The role of viruses in sepsis has been underappreciated, perhaps because of diagnostic challenges. The coronavirus 19 (COVID-19) pandemic made it clear that viral sepsis can be highly morbid, but a number of common viruses can cause sepsis including influenza and non-influenza respiratory viruses such as parainfluenza viruses, coronaviruses, and adenoviruses.

Common bacterial causes of sepsis include gram-positive pathogens such as *Staphylococcus aureus* and *Streptococcus pneumoniae*. Among gram-negative pathogens, *Escherichia coli*, *Klebsiella* spp., and *Pseudomonas aeruginosa* are most commonly reported. The emergence of resistant organisms, particularly methicillin-resistant *S. aureus* (MRSA) and gram-negative bacteria harboring extended-spectrum  $\beta$ -lactamases, increases the risk of antibiotic failure and attendant mortality. Fungal pathogens may cause sepsis as well. In recent years, non-albicans candida species continue to increase in incidence, particularly among immunocompromised patients.

It is important to note that cultures are often negative in the setting of sepsis. Indeed, nearly 50% of the time, a specific pathogen is not identified. Culture negativity is an independent predictor of death in patients with sepsis. The relative paucity of definitive etiologic pathogens has implications for empiric antimicrobial therapy.

### Definitions

The term *sepsis* is defined as a dysregulated inflammatory response of the body caused by an infection and resulting in end-organ damage. Sepsis was usually fatal in the pre-antibiotic era, and its morbidity and mortality remain substantial. The cardinal finding is organ dysfunction that is unrelated to the primary site of infection. Organ systems affected by sepsis most commonly include the heart, kidney, lung, and central nervous system. Other systems that may be affected include endocrine, hematologic, and gastrointestinal systems.

Uncontrolled sepsis progresses to septic shock, implying a progressively graver degree of illness with associated increasing mortality. Septic shock is persistent hypotension caused by sepsis with either a systolic blood pressure less than 90 mm Hg or a mean arterial pressure (MAP) less than 65 mm Hg and a serum lactate greater than 2 mmol/L despite adequate fluid resuscitation. No single symptom, physical finding, organ dysfunction, or laboratory abnormality serves to make or exclude the diagnosis, although isolation of a microorganism in the setting of such findings is highly suggestive. Increasing numbers of physical findings and other abnormalities correlate with an increasing likelihood of the diagnosis of sepsis.

Typical clinical findings include hypoxia and/or hypercarbia, oliguria, acute kidney injury, poor perfusion, sepsis-induced cardiomyopathy, hyperglycemia or hypoglycemia, thrombocytopenia, anemia, coagulopathy, ileus, acute liver injury, hyperbilirubinemia, acidosis, elevated lactate, edema, hyperthermia or hypothermia, and hypotension.

### Pathophysiology

Infection of the host by a microorganism leads to innate and then adaptive immune activation. This process serves to isolate the site and source of infection. As a consequence, local tissue is often damaged, but eventually the infection is cleared, allowing for repair and regeneration. This process is highly regulated, with a number of different cell types and mediators involved, all in delicate balance between proinflammatory and anti-inflammatory effects. The patient may have few or no symptoms, or there may be systemic evidence of infection.

Sepsis is the failure of localization such that the process becomes generalized and leads to tissue destruction remote from the site of infection. Why the immune system enters this state of dysregulation remains currently poorly understood. Some microbes contribute to this process through the elaboration of pathogen-associated molecular patterns (PAMPs) by the innate immune system, elaboration of toxins (typically by gram-positive organisms) and endotoxins (gram-negative–derived lipopolysaccharide). Immune recognition of these mediators leads to tissue destruction as a result of ischemic insult, direct cytotoxicity, and accelerated programmed cell death including apoptosis, necroptosis, pyroptosis, and ferroptosis. Generation of damage-associated molecular patterns from lytic cell death may further amplify the inflammatory response, leading to increased tissue injury, organ dysfunction, and higher mortality. Genetic predisposition to sepsis and sepsis mortality has long been recognized, with specific genetic loci increasingly identified as risk factors.

The host response is highly heterogenous, making it difficult to predict who will be at a higher risk of developing sepsis or having poor outcomes. An enormous amount of research over the past four decades has elucidated many of the pathways and mediators involved. Tumor necrosis factor- $\alpha$ ; platelet-activating factor; interleukins IL-1, IL-6, and IL-8; eicosanoids; complement pathway proteins; interferons; and nitric oxide are among the biologically active molecules characterized to date. Recent studies using integrated genomics have identified genetic variants more likely to have a pathogenic response to infections. Certain endotypes within sepsis reflecting differential gene expression such as sepsis response syndromes 1 and 2 and the MARS 1 to 4 endotypes are noted to have differential mortality rates and treatment response. These studies provide a platform for future exploration of a “precision medicine approach” to targeted therapeutic intervention in this population to improve sepsis outcomes, but they are not yet clinically relevant.

### Diagnosis

The diagnosis of sepsis ultimately relies on the clinical suspicion of infection in the setting of end-organ dysfunction. The qSOFA screening tool identifies organ dysfunction, which distinguishes uncomplicated infection from sepsis. A constellation of other supportive evidence establishes a greater or lesser likelihood of the presence of sepsis (see the Current Diagnosis box). If clinical suspicion of an underlying infection warrants drawing of culture of body fluids, the diagnosis of sepsis is presumed and justifies the initiation of empiric antibiotics and fluid resuscitation in the setting of hypotension. It is rare that specific microbiologic identification and antibiotic susceptibilities are available to guide initial therapy, therefore sepsis diagnosis relies on careful history taking, a high index of suspicion, and appropriate evaluation for end-organ dysfunction.

### Treatment

#### Screening and Early Treatment

The 2021 guidelines from the Surviving Sepsis Campaign, an international initiative to improve sepsis outcomes, emphasize the importance of early screening and initiation of treatment. Protocolized sepsis resuscitation became common after the success of early goal-directed therapy (EGDT). However, the Australasian Resuscitation in Sepsis Evaluation (ARISE), Protocolised Management In Sepsis (ProMISE), and Protocolized Care for Early Septic Shock (ProCESS) randomized clinical trials did not demonstrate a benefit to EGDT or protocolized sepsis management over “usual standard care,” which may reflect the extent to which EGDT and protocolized resuscitation influenced usual practices. Nevertheless, the mandated introduction of a sepsis bundle including early sepsis identification, initial lactate measurement, cultures, and timely and empiric antimicrobial therapy in the state of New York was associated with reductions in sepsis morbidity and mortality. Based on this, recent recommendations have advocated for performance improvement programs for sepsis, including screening of high-risk acutely ill patients for sepsis and implementation of standard operating procedures for evaluation and treatment, commonly referred to as *sepsis bundles* or *sepsis resuscitation bundles*. The sepsis resuscitation bundle is a combination of evidence-based objectives that must be completed within 1 to 6 hours for patients presenting with severe sepsis, septic shock, and/or elevated lactate, defined as  $>4$  mmol/L (36 mg/dL). Sepsis bundles aim to deliver efficient and effective sepsis care in a timely manner, and studies have shown improved mortality with higher compliance with sepsis bundles.

#### Initial Resuscitation

Sepsis and septic shock are medical emergencies, and it is recommended to begin treatment and resuscitation immediately (within the first 3 hours of triage or within 1 hour of presumed diagnosis). Clinicians should not wait for microbiological

confirmation or evidence of an increasing SOFA score to initiate therapy. For all patients with sepsis and septic shock, recommended treatment includes measuring lactate, obtaining blood cultures, and administering broad-spectrum antibiotics. If the lactate exceeds 2 mg/dL, it should be repeated within 6 hours of presentation. For patients with evidence of septic shock, including hypotension or hypoperfusion as defined by a lactate level  $>4$  mg/dL, it is additionally recommended to give at least 30 mL/kg of intravenous crystalloid solution.

After initial fluid resuscitation of 30 mL/kg in the first 3 hours, fluid status should be reassessed with a goal of resuscitation directed toward a MAP  $>65$  mm Hg, urine output  $>0.5$  mL/kg, or decreasing lactate by 20%.

If hypotension does not respond to the initial 30 cc/kg fluid resuscitation within 6 hours of diagnosis, administration of vasopressors is recommended with a goal of resuscitation directed toward a MAP goal  $>65$  mm Hg. If the initial lactate was elevated, it should be remeasured within 6 hours.

### Choice of Fluid Administered

In patients with septic shock, normal saline solution was previously one of the most common intravenous fluids used for resuscitation. However, recent data have shown the use of normal saline to be associated with increased rates of acute kidney injury, hyperchloremic acidosis, and requirement for renal replacement therapy. Balanced crystalloid solutions like lactate Ringer's solution or Plasma-Lyte A, which have electrolyte compositions more similar to that of plasma, have improved performance over normal saline solution and represent an increasingly used alternative.

Colloids are more effective at volume resuscitation compared with crystalloids in septic shock, although the translation of this finding to improved outcomes remains uncertain. The Saline versus Albumin Fluid Evaluation (SAFE) trial of 4% albumin and the Albumin Italian Outcome Sepsis (ALBIOS) trial of 20% albumin did not show a mortality benefit of using albumin solution for fluid resuscitation compared with crystalloid solution, although decreased mortality was observed in patients with sepsis in the SAFE trial and in septic shock in the ALBIOS trial in post-hoc analyses. The Surviving Sepsis Campaign suggests the use of albumin in patients requiring large volumes of fluid resuscitation based on this data. Data have shown serious adverse events including increased risk of acute kidney injury and mortality with the use of pentastarch or hydroxyethyl starch, both of which should be definitively avoided in sepsis patients.

### Monitoring Treatment Response

Static parameter targets include a central venous pressure of 8 to 12 mm Hg and a central venous oxygenation ( $ScvO_2$ ) greater than 70%. Since the publication of the ProCESS, ARISE, and ProMISE trials, which reported no mortality benefit in association with use of these static measures, dynamic parameters have been emphasized in guidelines such as the Surviving Sepsis Campaign.

Dynamic parameters such as pulse pressure variation, stroke volume variation, respirophasic variation of the inferior vena cava (IVC), and the passive leg-raise test, may be used to guide fluid resuscitation to predict fluid responsiveness and avoid complications such as volume overload and pulmonary edema, particularly in patients who have concomitant heart failure and chronic kidney disease.

Pulse pressure variation is calculated as a difference in systolic and diastolic arterial blood pressure and for mechanically ventilated patients is a good indicator of volume responsiveness. A systematic review of 29 studies reported a higher area under the receiver operating characteristic curve (AUROC) for pulse pressure variation compared with central venous pressure (0.94 vs. 0.55) as an indicator of fluid responsiveness. Stroke volume variation greater than 10% measured by echocardiography is also associated with fluid responsiveness. According to one study, stroke volume variation showed a sensitivity and specificity of 94% each, and another meta-analysis reported that it resulted in shorter length of hospital stay. Point-of-care ultrasonography can be used to assess respirophasic variation in the IVC. Change

in IVC diameter with respiration of 12% to 18% has been associated with fluid responsiveness. Other maneuvers include the passive leg-raising test, which demonstrates similar performance. Although these methods are promising for prediction of fluid responsiveness, none have demonstrated clear superiority or mortality benefit; thus optimal assessment of fluid resuscitation remains an area of active research.

Serial measurement of lactate to determine whether clearance is achieved along with serial assessment of capillary refill time as a marker of perfusion may be useful to guide resuscitation and fluid or vasopressor administration. Some studies have shown the use of serial measurement of lactate and capillary refill time as markers of resuscitation to be associated with less intravenous fluid administration and possible 28-day mortality benefit.

### Vasopressor Support

If there is persistent hypotension despite adequate fluid resuscitation, it is recommended to initiate vasopressor support. Norepinephrine is the first-line agent recommended for septic shock, and addition of vasopressin and epinephrine are recommended as second-line agents. Norepinephrine is superior to dopamine, resulting in a lower risk of mortality and arrhythmias in a large meta-analysis, an effect that is particularly pronounced in patients with cardiogenic shock. Use of low-dose dopamine for renal protection is no longer recommended. Dobutamine is recommended if evidence of hypoperfusion persists after adequate fluid resuscitation and vasopressor administration.

There is clinical uncertainty if there is benefit of early vasopressor initiation with future studies planned to evaluate this question. A MAP goal of  $>65$  mm Hg is appropriate for most patients; patients with chronic hypertension treated with a MAP goal of 80 to 85 mm Hg had lower rates of acute kidney injury requiring renal replacement therapy but higher rates of arrhythmias compared with those treated with a MAP goal of 60 to 65 mm Hg. A subsequent pooled analysis demonstrated increased mortality in patients treated with a higher MAP goal for greater than 6 hours, necessitating an individualized approach.

### Antimicrobial Therapy

National and international quality measures and guidelines recommend immediate empiric broad-spectrum antibiotics for all patients with suspected sepsis. Timely initiation of appropriate antimicrobials is critical as the risk of mortality increases with every hour delay. Inadequate therapy is much more likely in patients with resistant pathogens including MRSA, vancomycin-resistant enterococci (VRE), and resistant gram-negative bacteria, as well as in nosocomial versus community-acquired sepsis. It is less well-appreciated that "overly broad" antimicrobial treatment for sepsis is also associated with an increased risk of poor outcome. A careful review of the history and physical examination and the prior culture results may help with the selection of empiric antimicrobials. The increasing availability of molecular detection methods is hoped to assist in selecting appropriate antimicrobial therapy in the future. This in turn can decrease the time to correct treatment for patients with sepsis and the incidence of multidrug-resistant organisms, *Clostridium difficile* infection, organ failure resulting from ineffective treatment, and deleterious effect on the gut microbiota.

### Source Control

A survey for potential sources of infection should be performed, and early resuscitation efforts should occur concomitantly. Elimination of the source of infection is critical to reversing septic shock. Conditions that require emergent intervention, such as necrotizing fasciitis, cholangitis, and intestinal infarction, should be ruled out within the first 6 hours after presentation. Potentially infected indwelling devices should be removed as soon as possible. Necrotic tissue should be debrided and abscesses drained if either condition is detected. Practitioners must consider the risks and benefits of the specific invasive procedures and the timing of such interventions for each patient individually. Imaging studies

such as computed tomography of the head, chest, abdomen, and pelvis are commonly necessary to assess for potential sources or sequelae of infection. An exception to the mandate to drain or debride infected collections is the presence of infected pancreatic necrosis, in which case a step-up approach including endoscopic and/or percutaneous drainage, preferably delayed by at least 2 weeks, is preferred.

### Biomarkers in Sepsis

The need for a prompt diagnosis and treatment of sepsis has led to intense research into biomarkers for diagnosis and prognostication in sepsis. Over 250 biomarkers have been identified in sepsis, although procalcitonin and C-reactive protein (CRP) remain the principal biomarkers in clinical use. Procalcitonin is a precursor to calcitonin that is often upregulated in sepsis. Data show that the use of procalcitonin is beneficial as a tool to de-escalate antibiotics in patients with sepsis, particularly those with community-acquired pneumonia, rather than as a diagnostic tool. A randomized trial has shown use of procalcitonin to guide discontinuation of antibiotic therapy to be associated with a reduction in 28-day mortality in patients with pneumonia, pyelonephritis, or primary bloodstream infections, suggesting that this may be a useful approach to antimicrobial de-escalation for patients with septic shock. Identifying sepsis biomarkers with superior diagnostic performance to procalcitonin and CRP is an area of active study. Some promising examples include decoy receptor 3, group II phospholipase A2, sCD163, CD64, and heparin-binding protein, but they will require further research and validation before they become available for widespread clinical use.

### Steroid Use

Patients with critical illness can develop absolute or relative adrenal insufficiency. Although absolute adrenal insufficiency is rare, relative adrenal insufficiency caused by hypothalamic-pituitary-adrenal dysfunction may occur in critically ill patients. Administration of low-dose glucocorticoids, typically hydrocortisone 200 to 300 mg in divided doses, has consistently been associated with faster reversal of septic shock. However, the data conflict as to whether there is a mortality benefit associated with steroid use. A large meta-analysis found that there was no overall association of glucocorticoid use with improved mortality, but did find improved 28-day, ICU, and hospital mortality with combined administration of hydrocortisone and fludrocortisone. Subsequent studies have found that response to steroids interacts with underlying endotype, with associated harm in the SRS2 endotype. Thus, steroid administration should be considered on a personalized basis. Steroids should be tapered as soon as vasopressor support is no longer required.

### Conservative Transfusion Threshold

Blood transfusions are immunomodulatory and associated with volume overload. Guidelines recommend limiting red blood cell transfusion to patients with septic shock with a hemoglobin level less than 7 g/dL, which is based on data derived from randomized controlled trials. A large randomized trial of nearly 1000 patients demonstrated no increased mortality with a restrictive strategy using transfusion triggers of hemoglobin <7 g/dL (conservative strategy) versus hemoglobin <9 g/dL (liberal strategy). The restrictive group additionally did not have higher ischemic adverse effects. However, evidence extrapolated from studies of transfusion thresholds in patients with stable cardiovascular disease and post-cardiac surgery patients suggests the use of a transfusion threshold of Hb <8 g/dL in septic patients with known coronary artery disease.

### Nutrition in the Critically Ill Patient

Critically ill patients are in a state of catabolism, and studies have shown that early enteral nutrition, which is defined as within 48 hours of admission to the critical care unit, may decrease the risk of infection, specifically pneumonia, and mortality. However, if there is ongoing shock with MAPs <50 mmHg and escalating

vasopressor support, initiating enteral feeding may theoretically precipitate mesenteric ischemia and nonocclusive bowel necrosis. Enteral nutrition should be initiated only in patients who have been well resuscitated and are on stable levels of vasopressor support.

### Glycemic Control

It is recommended for critically ill patients to have blood glucose target between 140 and 180 mg/dL rather than tighter control with intensive insulin therapy since studies have shown that tighter blood glucose control has no benefit and is associated with increased incidences of hypoglycemia and a higher risk of mortality. More recent data demonstrated that the use of individualized glucose targets based on pre-ICU glycated hemoglobin levels resulted in higher rates of severe hypoglycemia and increased mortality in non-diabetic patients; thus a goal of <180 mg/dL is appropriate for this population.

### Summary

Sepsis remains a life-threatening medical emergency and a leading cause of death in the United States and worldwide. Early recognition and aggressive management are vital to improving outcomes, yet the diagnosis continues to require a high index of suspicion, timely evaluation, and robust clinical judgment. Major challenges include diagnostic uncertainty, low yield of current culture techniques, and antimicrobial overuse and resistance. Improvements in diagnostic and prognostic biomarkers, technologies to identify responsible microbes, identification of biologically-based endotypes, and precision therapies are promising areas for future inquiry and improvement in sepsis care.

## SMALLPOX

Method of

Raul Davaro, MD

### CURRENT DIAGNOSIS

- Human-to-human transmission of variola virus occurs by inhalation of large, virus-containing airborne droplets of saliva from an infected person.
- Before smallpox was eradicated, the disease had a secondary household or close contact attack rate of approximately 60% among unvaccinated individuals.
- There are four main clinical forms of smallpox, each with different characteristics.
- During the smallpox era, the case-fatality rate differed for the different clinical forms, but it was approximately 30% overall in unvaccinated individuals.

### CURRENT THERAPY

- There is no proven treatment for smallpox disease in people sick with smallpox.
- Isolating patients in a negative-pressure room and insuring vaccination is the main course of therapy.

Smallpox is caused by the variola virus (VARV) and is highly infectious by the respiratory route. Susceptible persons have up to a 90% chance of contracting the disease if they are exposed to someone who is infected, and the overall fatality rate is estimated at 30% among those who have not been vaccinated. The VARV is unique among the orthopoxviruses in that it is known to be a sole human pathogen.

The World Health Organization (WHO) declared smallpox eradicated in 1980 and today is the only human disease to be eliminated by the WHO. The eradication of smallpox through vaccination has not eliminated the risk of reintroduction of the infection by the accidental or intentional release of the VARV.

This viral infection, spread by respiratory droplets, continued to have worldwide distribution at the beginning of the 20th century. Because smallpox confers immunity in the survivors of an attack, its persistence depends on the contact of nonimmune persons with infected persons in the initial 2 weeks of acquiring the infection.

The WHO designed an Intensified Eradication Program based on a ring vaccination strategy that began in 1966 and eradicated smallpox from humans in an unprecedented effort in less than 10 years. The last natural case was documented in Somalia in 1977. Routine immunization against smallpox ceased in the United States in 1972 and worldwide in 1980. It was thought that without a human reservoir, the reemergence of this infection would not occur.

Smallpox virus stocks are still available in the United States at the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, and in Russia at the State Center for Virology and Biotechnology in Novosibirsk, Siberia. These stocks are maintained under strict biocontainment measures. In the aftermath of the terrorist attacks on September 11, 2001, and the deliberate distribution of *Bacillus anthracis* afterward, President Bush announced plans to immunize health care workers and first responders against smallpox by 2003. Although the plan fell short of its goals, 40,000 first responders and health care workers were vaccinated by the end of 2003.

### The Agent

Smallpox is a single, linear, double-stranded DNA virus that belongs to the *Orthopoxvirus* genus, family Poxviridae. The poxviruses replicate in the cell cytoplasm. They are brick shaped and measure about 300 by 250 by 200 nm.

### Epidemiology

The natural reservoir of smallpox is the patient suffering from the disease. Smallpox spreads from person to person through droplet nuclei or fine-particle aerosols released from the pharynx of infected persons. Smallpox can also be transmitted by fomites such as clothing and bedding. Smallpox patients are not infectious until the third day of the clinical disease, typically 1 day before the skin eruption. The secondary attack rate of smallpox is 37% to 88% among unvaccinated contacts, depending on many variables.

### Clinical Presentation

Smallpox occurs as either variola major or variola minor (alacrim). Variola major had a mortality rate of 30% compared with 1% for variola minor.

After an incubation period of 10 to 14 days, the illness begins with intense prostration and high fever lasting 4 to 6 days (Figure 1). Headache, photophobia, and vomiting are noted. During the prodrome phase, most patients are bedridden. Around the fourth day, the fever breaks and the patient feels better.

The eruptive phase is signaled by an enanthem involving the buccal mucosa and pharynx and a centrifugal exanthem that begins on the face and forearms. The initial rash is macular and turns pustular in 1 to 2 days. Within 2 days, the papules evolve into vesicles that become cloudy and pustular. Most patients exhibit lesions on their soles and palms. A typical feature of variola is that the exanthem everywhere is in the same state of evolution, unlike the exanthem of chickenpox, in which lesions exhibit all stages of evolution. At the end of days 8 to 10, the skin rash crusts and dries; it takes 3 to 4 weeks from the onset of the disease for all the scabs to fall off. The period of contagiousness ends when the last scab falls off. Scarring and pitting of the skin are common sequelae.

Patients with the hemorrhagic disease develop severe prostration, high fever, abdominal pain, petechiae, and extensive cutaneous ecchymoses. In the malignant or flat form, the lesions fail to progress to the pustular stage. In the hemorrhagic and the malignant forms, death invariably occurs within 1 week.

### Complications

Bacterial infections of the skin and other organs are common. Ocular involvement may result in blindness. Encephalitis (1 in 500 cases of variola major) is a devastating complication.

### Differential Diagnosis (Figure 2)

Many rashes can be confused with smallpox, especially at the outset of the eruption, when the rash is maculopapular. Herpes zoster, chickenpox, herpes simplex, impetigo, scabies, erythema multiforme, and syphilis are some of the conditions that can be confused with smallpox (Box 1). When smallpox was endemic, chickenpox was the most common condition confused with smallpox. The most useful clinical points of smallpox are the following:

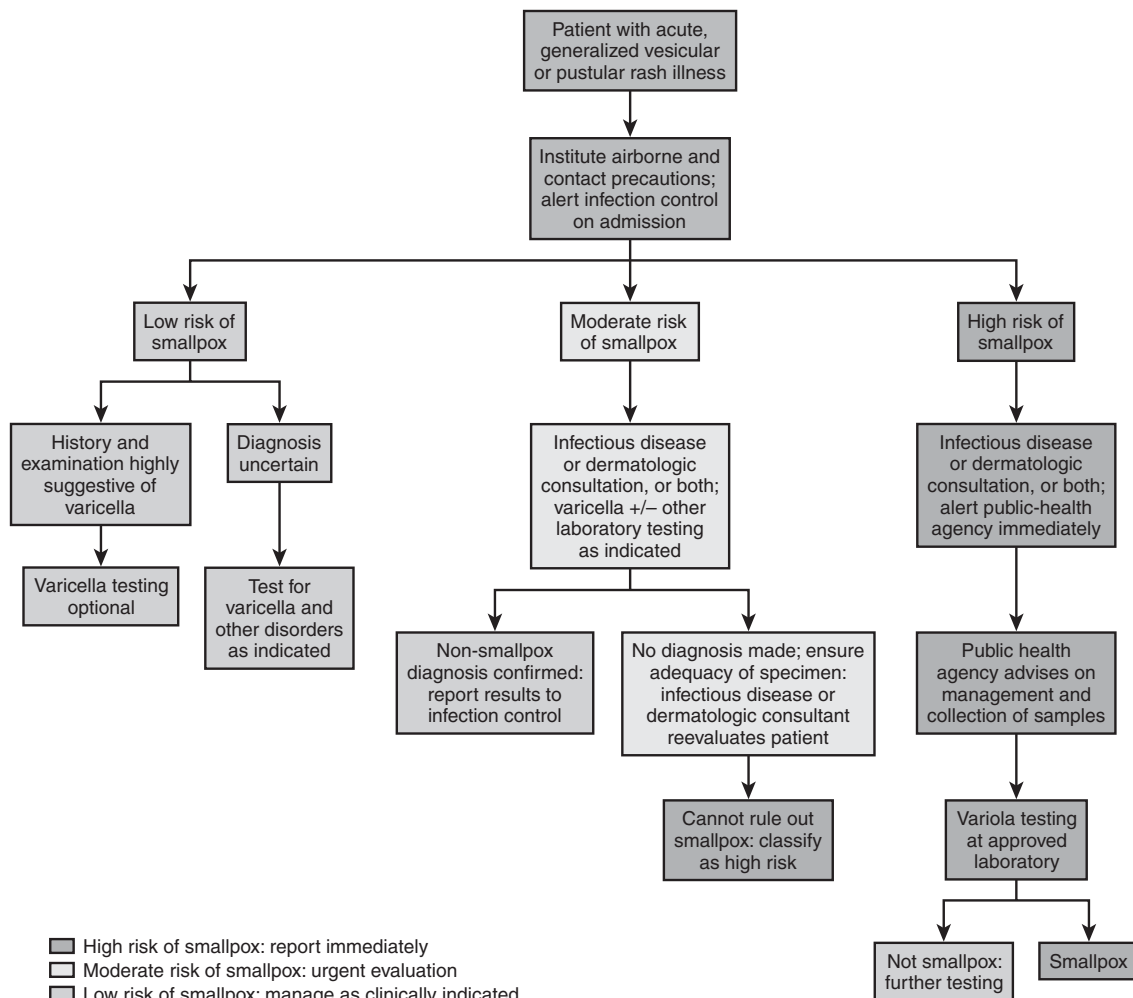

- Centrifugal distribution of the lesions
- All the lesions in the same stage of development
- Progression of the rash from the face to the arms, trunk, and legs
- A severe prodrome phase that lasts 4 days
- In an epidemic, known contact with an active case

### Diagnosis

The identification of a suspected case of smallpox should be treated as an international health emergency. Clinical samples may be collected from vesicular or pustular fluid, blood, tonsillar swabs, and skin biopsy and must be transported to a biosafety

**Maculopapular stage**

- Measles
- Rubella
- Drug eruptions
- Secondary syphilis
- Erythema multiforme
- Scabies, insect bites
- Acne
- Scarlet fever

**Vesicular/Pustular stage**

- Chickenpox
- Disseminated herpes zoster
- Disseminated herpes simplex virus
- Drug eruptions
- Contact dermatitis
- Erythema multiforme (including Stevens-Johnson syndrome)
- Enteroviral infections
- Secondary syphilis
- Acne
- Generalized vaccinia
- Monkeypox
- Impetigo
- Scabies, insect bites
- Disseminated molluscum contagiosum

level 4 facility for processing and testing with real-time polymerase chain reaction (PCR) assays to detect virus DNA.

Lesions of varicella zoster virus (chickenpox, herpes zoster) demonstrate multinucleated giant cells on Tzanck smears; lesions of smallpox do not. Serology or electronic microscopy is not recommended for the diagnosis of smallpox because these modalities cannot distinguish among different orthopoxviruses.

**Treatment**

A suspected case of smallpox should be placed in a negative-pressure room with strict respiratory and contact isolation precautions. Ideally, to minimize the risk of contagion in health care personnel, patients with smallpox should be assisted by providers documented to have been immunized against this condition. Patients with smallpox require careful care of their eyes to avoid complications, and this is accomplished with daily eye rinsing. Patients must receive adequate nutrition and hydration. Skin and soft tissue infections must be treated with an antistaphylococcal  $\beta$ -lactam and, initially pending results of cultures, an antimicrobial with activity against methicillin-resistant *Staphylococcus aureus*. Tecovirimat (TPOXX) is an inhibitor of the orthopoxvirus VP37 envelope wrapping protein and is indicated for the treatment of human smallpox disease in adults and pediatric patients weighing at least 13 kg. The effectiveness of TPOXX for treatment of smallpox disease has not been determined in humans because adequate and well-controlled field trials have not been feasible, and inducing smallpox disease in humans to study the drug's efficacy is not ethical. TPOXX efficacy may be reduced in immunocompromised patients based on studies demonstrating reduced efficacy in immunocompromised animal models. The recommended dosage of tecovirimat in adults weighing at least 40 kg is 600 mg (three 200-mg capsules) taken twice daily orally for 14 days. No adequate and well-controlled studies in pregnant women were conducted; therefore, there are no human data to establish the presence or absence of tecovirimat-associated risk. Common adverse

reactions in healthy adult subjects ( $\geq 2\%$ ) were headache, nausea, abdominal pain, and vomiting.

**Vaccines and Vaccination**

The current smallpox live vaccine, ACAM2000 (Sanofi Pasteur Biologics), is based on the traditional Jenner vaccine (using the related virus, vaccinia) and is administered in a single percutaneous dose. Vaccination after exposure—but before the rash is present—can abort or attenuate the clinical manifestations of the disease. This live vaccine is contraindicated for persons with severe immunosuppression, and newer-generation vaccinations have been developed for these populations. The virus begins growing at the injection site causing a localized infection or “pock” to form. A red, itchy sore spot at the site of the vaccination within 3 to 4 days is an indicator that the vaccination was successful; that is, there is “a take.” A blister develops at the vaccination site and then dries up, forming a scab that falls off in the third week, leaving a small scar. If no evidence of vaccine take is apparent after 7 days, the person can be vaccinated again.

The vaccine causes local and systemic symptoms. There is an eruption at the injection site with redness and pain, systemic symptoms such as fever, and headaches. Swelling and tenderness of regional lymph nodes begin 3 to 10 days after vaccination and can last up to a month.

The Modified Vaccinia Ankara (MVA [JYNNEOS]) was compared with ACAM2000. The immune responses and attenuation of the major cutaneous reaction suggest that this MVA vaccine protected against variola infection.

**Complications**

The vaccine (ACAM2000) is not without risk: it is estimated that pericarditis or myocarditis may develop in 5.7 per 1000 vaccinees. In addition, eczema vaccinatum, generalized vaccinia, progressive vaccinia, and vaccinia encephalitis can also occur (Table 1). The most common complication is inadvertent autoinoculation causing self-limited satellite lesions. Generalized vaccinia results from viremia and may be life threatening in immunocompromised patients. Progressive vaccinia is characterized by necrosis at the inoculation site and distal sites such as bones and internal organs. Progressive vaccinia is often a fatal complication. Myopericarditis was observed with the use of adult vaccines in the United States in 2002 (see Table 1).

**Contraindications to Vaccination**

Persons who are immune compromised or who have severe eczema or who are pregnant should not receive postexposure vaccination against smallpox. However, in the event of exposure to a patient with smallpox, no absolute contraindication is applicable.

**Use in Warfare**

Because natural smallpox has been eradicated, the only possibility of a smallpox outbreak is the deliberate release of smallpox in a population by a nation or a terrorist group to inflict casualties in a civilian population. Preemptive vaccination of first responders and ring immunization of those exposed are the means available to avoid the massive propagation of smallpox. Smallpox stocks have been earmarked for destruction since the eradication of the disease in 1980. Yet, successive meetings of the World Health Assembly have postponed making a final recommendation while the threat of reemergence from elsewhere remains. At its last meeting in September 2018, the Advisory Committee on Variola Virus Research told WHO that live virus is still needed for the development of new antivirals, with split opinions on whether it is needed for diagnostics.

**TABLE 1** Rates of Complications from Vaccinia, According to Vaccination Status and Age<sup>a</sup>

Complications	PRIMARY VACCINATION (N = 650,000)				REVACCINATION (N = 996,000)			
	0–4 Years	5–19 Years	> 20 Years	All Ages	1–4 Years <sup>b</sup>	5–19 Years	> 20 Years	All Ages
Accidental infection	564	371	606	529	198	48	25	42
Generalized vaccinia	263	140	212	242	0	10	9	9
Erythema multiforme	299	87	30	165	73	2	9	10
Eczema vaccinatum	39	35	30	39	0	2	5	3
Postvaccinal encephalitis	15	9	0	12	0	0	5	2
Progressive vaccinia	3	0	0	2	0	0	7	3
Other	222	214	6636	266	18	24	55	39

<sup>a</sup>Data are from a 1968 survey of 10 states. No deaths occurred.

The infection is caused by the gram-positive, spore-bearing bacterium *C. tetani*, the spores of which exist in the soil, in animal feces, and even in the human gastrointestinal tract. Spores remain dormant and viable for several months and are destroyed by autoclaving at 1 atmosphere pressure at 120°C for 15 minutes. When inoculated into human or animal tissues, they transform into motile bacilli in an anaerobic environment that produce a potent exotoxin, tetanospasmin, which produces the manifestations of tetanus. It must be emphasized that tetanus is not transmitted from human to human, and patients do not require isolation.

## Risk Factors

Elderly individuals are at increased risk, as they may not have received adequate immunization or may have waning immunity. Other predisposed groups include immigrants from countries with an unreliable immunization program, immunosuppressed individuals (with HIV infection or receiving immunosuppressive drugs), and intravenous drug addicts. Local factors include wounds with crushed, devitalized tissue or contaminated by dirt or rust, such as open fractures, punctures, and abscesses. However, even scratches, chronic ulcers, or tattooing may cause tetanus. In developing countries, unsafe practices related to termination of pregnancy may cause maternal tetanus; newborn babies born outside of medical facilities are at risk of neonatal tetanus.

## Pathophysiology

Tetanospasmin is a highly toxic protein released by *C. tetani*. It is absorbed into the circulation and reaches the ends of motor axons all over the body, from where it is transported proximally along the axonal cytoplasm to motor nuclei in the brainstem and spinal cord at a rate of 3 to 13 mm/hour. A fragment of the toxin then binds inhibitory interneurons that produce gamma-aminobutyric acid (GABA) and glycine and inactivates synaptobrevin, a protein that is essential for the release of these neurotransmitters from presynaptic vesicles.

The loss of normal inhibition at motor and autonomic neurons results in spontaneous discharge of nerve impulses as well as exaggerated responses to stimuli manifesting as tonic muscle contraction with superadded intermittent muscle spasms. As tetanospasmin reaches the motor nuclei of the shortest motor axons first, muscles innervated by motor cranial nerves are affected first, followed by trunk muscles, and finally the extremities. Autonomic overactivity results in severe tachycardia, swings in blood pressure, profuse sweating, and (rarely) ileus. An exaggerated startle-like response to stimuli with motor and autonomic components is also typical. Generalized spasms may mimic tonic seizures.

## Clinical Manifestations

An attempt should be made to locate the predisposing wound, such as cuts, abrasions, burns, puncture wounds, and other skin lesions. Uncommon causes include needle-sticks in intravenous drug abusers, ulcerated malignant tumors, and chronic middle-ear infection in children (otogenic tetanus). In up to 30% of patients, no site of

## TETANUS

Method of

Dilip R. Karnad, MD

Tetanus is a potentially fatal illness caused by the neurotoxin produced by the spore-bearing anaerobic bacterium *Clostridium tetani*. As the causative organism and its spores are ubiquitous, nonimmune individuals in any part of the world may get tetanus unless they are protected by the highly effective vaccine.

## Epidemiology

As a result of effective universal immunization, tetanus is rare in the developed world. Twenty to 40 cases of tetanus occur annually in the United States and 12 to 15 cases per year have been reported from the United Kingdom in the last 10 years. Although progressively declining in the developing world due to improved immunization coverage, according to WHO figures, more than 500 cases were reported in 2012 from each of these nations: Angola, Bangladesh, Congo, India, and Uganda. While tetanus may affect individuals of all ages, a significant number of cases in developed countries are elderly people who did not receive a primary immunization or lacked the booster dosage needed to maintain protective immunity. In developing countries, most cases are neonates (*tetanus neonatorum*), children who are born to nonimmunized mothers and thus lack transplacentally acquired passive immunity. Infection of the umbilical stump due to poor hygiene results in severe tetanus that has mortality in excess of 60%.

**Figure 1** Typical facial expression with the sneering smile (*risus sardonicus*), wrinkled forehead, narrow palpebral fissures, and “crow’s feet” at the lateral palpebral margins from the tonic contraction of muscles of facial expression in moderate tetanus.

**Figure 2** Spasm of paraspinal muscles, producing the hyperextended opisthotonic posture in severe tetanus.

infection is discovered. The incubation period is the interval between the injury and the onset of symptoms and can range from a few days to a few months (usually 3–21 days). A short incubation period (<7 days) suggests the likelihood of developing severe tetanus; however, a long incubation period does not necessarily indicate a milder disease. The period of onset (the interval between the first symptom and first paroxysmal muscle spasm) is a better predictor of severity: early elective tracheal intubation and mechanical ventilation are usually required if the interval is <48 hours.

### Generalized Tetanus

Initial symptoms include an inability to open the mouth (lock-jaw or trismus), difficulty in chewing and swallowing, and stiffness of neck muscles. The contraction of facial muscles produces the characteristic sneering smile (*risus sardonicus*) (Figure 1). In severe cases, intermittent spasms are provoked by attempts to speak or swallow. Pooled saliva from hypersalivation and dysphagia may trigger cough and laryngeal spasms; if prolonged, these may prove fatal. Rigidity of paraspinal muscles follows, and hyperextension of the spine results in opisthotonus (Figure 2). Finally, proximal muscles of the extremity are also affected. Deep tendon reflexes are always exaggerated and ankle clonus is common. Tonic muscle spasms may affect head and neck muscles and laryngeal muscles, or may be generalized. Paroxysmal spasms occur spontaneously or in response to loud noise, bright lights, or attempts to speak or swallow. Prolonged spasms may compromise breathing.

The Ablett classification is commonly used to grade the severity of tetanus. Grade I (mild) tetanus is characterized by moderate trismus and general spasticity without spasms, dysphagia, or respiratory distress. Grade II (moderate) tetanus has severe trismus, intermittent short spasms, mild tachypnea, and dysphagia. Grade III (severe) tetanus is associated with severe rigidity, prolonged spasms, severe dysphagia, tachypnea, apneic spells, and tachycardia. The presence of additional violent autonomic

**Figure 3** Cephalic tetanus: This 6-year-old child developed mild tetanus 3 weeks after a wound on his right cheek was sutured. He had cephalic tetanus characterized by partial paralysis of the right facial nerve along with overactivity of the unaffected nerve fibers. **A**, Note the overactivity of the facial muscles with a narrow palpebral and prominent nasolabial fold on the same side as the injury. On asking him to shut his eyes tight (**B**), weakness of the orbicularis oculi and other facial muscles on the right side become manifest.

disturbances with persistent or intermittent episodes of severe hypertension and tachycardia alternating with hypotension and bradycardia is classified as Grade IV (very severe) tetanus. Cardiac arrhythmias, peripheral vasoconstriction, and sudden asystole may also occur in very severe tetanus.

Despite the use of antitetanus immune globulin (HyperTET) to neutralize circulating tetanus toxin, the disease may progress for up to 2 weeks as more intraaxonal toxin continues to reach the central nervous system. Manifestations persist for another 2 to 3 weeks before gradually subsiding. During this period, an apparently stable patient is at risk of developing sudden asphyxia due to severe generalized or laryngeal spasms. Patients may develop fever, rhabdomyolysis, and hyperthermia due to excessive muscular activity.

### Cephalic Tetanus

Following injuries to the head or face, in some patients, the toxin reaches the local motor nuclei earlier and produces a combination of partial paralysis and overactivity—more severely affected motor neurons stop functioning while the remaining fibers are overactive and cause muscle spasm (Figure 3).

### Localized Tetanus

In this rare form of tetanus, manifestations are restricted to muscles in the region of the wound. These patients have a good prognosis.

### Diagnosis

*C. tetani* can be isolated from the wound in <30% of cases, and microbiological and other laboratory tests do not help in confirming the diagnosis. The diagnosis is entirely clinical. In an individual with a predisposing injury, the presence of trismus, rigidity of neck, abdominal and paraspinal muscles, and severe hyperreflexia are suggestive. The spatula test is a useful bedside test: A spatula (tongue depressor) is inserted into the mouth to touch the posterior

**TABLE 1** Conditions that Mimic Clinical Manifestations of Tetanus

CLINICAL FEATURE	DIFFERENTIAL DIAGNOSIS
Trismus	Acute tonsillar abscess, temporomandibular joint disease, extrapyramidal reaction to drugs, dental pathology
Neck stiffness	Cervical spine disease; extrapyramidal reaction to drugs such as antipsychotics, antiemetics, or metoclopramide; meningitis; subarachnoid hemorrhage
Abdominal rigidity	Acute abdomen
Dysphagia	Myasthenia gravis, acute bulbar paralysis, rabies
Muscle spasms	Seizures, spasticity due to spinal cord disease, stiff man syndrome

pharyngeal wall. Normally, a gag reflex is activated in an attempt to expel the spatula. In tetanus, severe spasms of the masseters results in the patient biting on the spatula, making it difficult to withdraw—a positive test. In one study, the spatula test was positive in 94% of patients with tetanus and in none without tetanus. The electromyogram shows the continuous discharge of motor units in moderate tetanus and the absence of the normal silent period.

### Differential Diagnosis

While the diagnosis of tetanus is easy in severe tetanus, it may be mistaken for other conditions in its initial stages (Table 1). The spatula test is negative in other conditions causing trismus. Abdominal muscles usually relax after adequate sedation. As in spasticity due to cord compression, deep reflexes are exaggerated; however, the plantar response, which is extensor in spinal cord disorders, is always flexor with tetanus. Unlike seizures or other intracranial diseases, the patient with tetanus is always fully alert and awake.

### Treatment

In patients with life-threatening spasms, prompt, adequate sedation is the first step in management. Patients must be observed in an intensive care unit because the disease may rapidly worsen. They should be nursed in a quiet, dimly lit room in order to keep external stimuli to a minimum—this is difficult in modern intensive care units.

### Neutralization of Toxin

Although unsupported by randomized studies, human tetanus immune globulin (HyperTET) (3000–6000 units) is administered intramuscularly to neutralize the circulating toxin. This does not bind to the toxin that has already entered neurons. There is insufficient evidence favoring intrathecal administration<sup>1</sup> of tetanus immune globulin over the usual intramuscular route, although one randomized study showed a shortening of the course of tetanus. Equine antiserum<sup>2</sup> (10,000–20,000 units) may be administered after skin testing for hypersensitivity. Though rarely used today due to the risk of anaphylaxis or serum sickness, it has the advantage of being administered intravenously.

### Control of Clostridial Infection

Benzylpenicillin (Penicillin G) in a dose of 10 to 12 million units per day is given intravenously for 10 days. In one study, metronidazole (Flagyl) (500 mg every 6 hour for 10 days) was superior to procaine penicillin (Wycillin),<sup>1</sup> presumably because procaine and penicillin are GABA antagonists and may worsen manifestations of tetanus. However, a more recent study showed that a single intramuscular injection of 1.2 million units of benzathine penicillin (Bicillin LA)<sup>1</sup> was as effective as benzylpenicillin or metronidazole. Fortunately, resistance to these antibiotics has not been reported. Debridement

of the infected wound and abscess drainage should be performed after spasms have been adequately controlled.

### Control of Muscle Spasms

Benzodiazepines (diazepam [Valium] or lorazepam [Ativan]<sup>1</sup>) are the preferred drugs and act by enhancing the effect of GABA on its receptor on the postsynaptic membrane, thus potentially antagonizing the effect of tetanospasmin. However, as very little GABA is released in tetanus, large doses (up to 1000 mg/day<sup>3</sup>) of diazepam may be required to achieve adequate sedation and muscle relaxation. Diazepam may be administered intravenously (10–30 mg in 5 mg boluses every 5 minutes)<sup>3</sup> or through a nasogastric tube (10–40 mg every 1 to 2 hours).<sup>3</sup> Barbiturates and chlorpromazine (Thorazine)<sup>1</sup> are alternative agents. Other sedative hypnotic agents such as midazolam (Versed)<sup>1</sup> and propofol (Diprivan)<sup>1</sup> have also been used with good effect. In mild to moderate tetanus, drug doses can be titrated to achieve moderate sedation and control rigidity and spasms without causing respiratory depression. In severe cases, however, spasms may not be controlled despite large doses, increasing the risk of severe central nervous system (CNS) depression. In these patients, heavy sedation combined with neuromuscular blockade and mechanical ventilation is required. In about 10% of cases, benzodiazepines may produce paradoxical excitation instead of sedation; increasing doses make the patient more wakeful, agitated, and delirious, with increased spasms. Discontinuation of diazepam and the use of barbiturates and chlorpromazine may prevent the need for paralysis and mechanical ventilation. Pancuronium (Pavulon),<sup>1</sup> vecuronium (Norcuron),<sup>1</sup> and rocuronium (Zemuron)<sup>1</sup> are often used for neuromuscular blockade. Atracurium (Tracrium)<sup>1</sup> could also be used but may have unfavorable cardiovascular effects. Intravenous and intrathecal baclofen (Lioresal Intrathecal)<sup>1</sup> have been used in some case.

### Airway Management

Tracheostomy or endotracheal intubation is required in moderate and severe tetanus to prevent respiratory failure due to laryngeal spasm and aspiration of oropharyngeal secretions. In most developing countries, elective tracheostomy is performed early in severe tetanus. In countries with superior intensive care facilities, heavy sedation, neuromuscular blockade, endotracheal intubation, and mechanical ventilation are preferred, with tracheostomy being reserved for those who need prolonged ventilation.

### Control of Autonomic Disturbances

With good intensive care, mortality due to respiratory failure has been drastically reduced. Autonomic dysfunction is now the major challenge in patients with severe tetanus; it is common even in sedated and paralyzed patients. Various measures to control autonomic fluctuations include intravenous fluid loading, oral and parenteral beta-blockers, alpha-blockers, centrally acting sympatholytics such as clonidine (Catapres)<sup>1</sup> or dexmedetomidine (Precedex),<sup>1</sup> and epidural or spinal bupivacaine (Marcaine).<sup>1</sup> More recently, infusion of dexmedetomidine has been used by some authors. Many patients may develop sudden asystole, possibly due to sudden parasympathetic discharge, catecholamine-induced myocardial damage, or sudden loss of sympathetic drive. Consequently, the use of long-acting antiadrenergic drugs should be avoided. Increasing the level of sedation itself is also effective, to a significant extent.

The agent most frequently used for autonomic dysfunction is intravenous magnesium sulfate.<sup>1</sup> A randomized controlled trial in Vietnamese patients showed that magnesium sulfate did not decrease mortality, ICU stay, or the need for mechanical ventilation but did reduce the dose of sedatives and neuromuscular blocking drugs required. This study used a loading dose of 40 mg/kg over 30 minutes, followed by intravenous infusion of 2 g/hour in patients >45 kg and 1 to 5 g/hour in patients ≤45 kg. Infusion was titrated to maintain serum magnesium levels between 2 and 4 mmol/L.

### Other Measures

Continuous muscle hyperactivity and spasms greatly increase caloric requirements. Most patients require nasogastric tube

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>1</sup>Not FDA approved for this indication.

feeding because of trismus and dysphagia. A catabolic state similar to sepsis may develop in very severe tetanus. Consequently, patients lose up to 15% of their body weight during the illness. Good nursing care is essential to prevent pressure sores, deep vein thrombosis, stress ulcers, and aspiration pneumonia. Urinary catheterization is required in most patients as urinary retention is common and distension of the urinary bladder may provoke spasms and autonomic overactivity. All patients should be started on a primary immunization schedule against tetanus.

### Complications

Respiratory failure may occur due to laryngeal obstruction, prolonged spasm of respiratory muscles, aspiration pneumonia, or sedative drugs. Severe spasms may result in tongue-bite, compression fractures of midthoracic vertebrae, rhabdomyolysis, myoglobinuria, and renal failure. Rarely, patients may develop acute respiratory distress syndrome (ARDS) either due to tetanus itself or as a result of secondary bacterial sepsis. Cardiac arrhythmias and sudden asystole are common in patients with autonomic dysfunction. Acute myocardial infarction may occur in elderly patients with underlying coronary artery disease due to sympathetic overactivity. Deep vein thrombosis and pressure sores are preventable complications. The overall mortality ranges from 40% to 60% in countries with inadequate health care facilities. With good intensive care, mortality as low as 10% is reported in some series. Mortality is higher in neonates, the elderly, and patients with a short incubation period and period of onset.

### Prevention

Adsorbed tetanus toxoid (Tt), derived from formaldehyde-treated tetanus toxin, is extremely effective in inducing active immunity. It is available as a single-antigen preparation or in combination with diphtheria toxoid as pediatric diphtheria-tetanus toxoid (DT) or adult tetanus-diphtheria (Td), and with both diphtheria toxoid and acellular pertussis vaccine as DTaP (Infanrix, Tripeadia) or Tdap (Adacel, Boostrix) (lower-case alphabets indicate lower doses of antigens). Pediatric vaccines (DT and DTaP) contain identical amounts of tetanus toxoid as adult vaccines, but three to four times as much diphtheria toxoid. The usual schedule for primary immunization in children <7 years consists of four doses of DTaP or DT at age 2, 4, 6, and 15 to 18 months. A booster dose is recommended at 4 to 6 years of age. In individuals aged 7 years or older, three doses of the adult formulation are administered; the second dose is given 4 to 8 weeks after the first, and the third dose after another 4 to 6 months. Further booster doses are needed every 10 years to maintain antibody titers above the protective level of 0.1 IU/mL.

After administration of Tt to individuals with wounds, protective titers of antibody are achieved after at least 2 weeks. Consequently, passive immunization with 250 units of human tetanus immune globulin (HyperTET) or 1500 units of equine antitetanus serum<sup>2</sup> administered intramuscularly is needed to confer protection during these initial few weeks. This is especially required in individuals with tetanus-prone wounds who have not received at least three doses of tetanus toxoid in the past. Previously unimmunized individuals with clean, minor, nontetanus prone wounds do not need any passive immunization, but should receive active immunization. Passive immunization is not necessary in those who have received three or more doses of the toxoid. These individuals should receive a dose of Tt (or Td) if more than 10 years have elapsed since the last booster dose and they have nontetanus prone wounds or if >5 years have elapsed after the booster dose and they have a tetanus-prone wound. In countries where neonatal tetanus is common, primary immunization of women during pregnancy has been advocated as a public health program to prevent neonatal tetanus.

## TICKBORNE RICKETTSIAL DISEASES (ROCKY MOUNTAIN SPOTTED FEVER AND OTHER SPOTTED FEVER GROUP RICKETTSIOSES, EHRLICHIOSES, AND ANAPLASMOSIS)

Method of

Robert Wittler, MD

### CURRENT DIAGNOSIS

- Early diagnosis of Rocky Mountain spotted fever (RMSF) and other tickborne rickettsial diseases is made clinically. RMSF should be considered in the setting of fever, headache, rash, and a history of possible tick exposure. The rash is not always present and typically occurs 2 to 4 days after the onset of fever.
- Diagnostic laboratory tests for rickettsial diseases, particularly RMSF, are usually not helpful in making a timely diagnosis during the initial states of illness.
- Tickborne rickettsial diseases can be confirmed by polymerase chain reaction (PCR) during the acute stage if readily available (whole blood for ehrlichiosis and anaplasmosis and skin biopsy or whole blood for RMSF) or at later stages by subsequently demonstrating a fourfold increase between acute and convalescent (ideally 2 to 4 weeks apart) serum immunoglobulin G (IgG) indirect immunofluorescence antibody titers. PCR of whole blood for RMSF has low sensitivity, although sensitivity increases in patients with severe disease.
- Typical findings of ehrlichiosis and anaplasmosis include fever, headache, malaise, leukopenia, thrombocytopenia, and elevated serum transaminases. Rash is often not present.

### CURRENT THERAPY

- Treatment of choice for all tickborne rickettsial diseases in patients of all ages (including children less than 8 years of age) is doxycycline (Vibramycin).
- The dose for doxycycline is 100 mg twice daily (intravenously [IV] or orally depending on severity of illness) for adults. For children weighing <45 kg,<sup>1</sup> the recommended dose is 2.2 mg/kg/dose IV or orally twice daily.
- Delay in recognition and appropriate treatment is the most important factor associated with death from RMSF. Empiric treatment within 5 days of the onset of symptoms with doxycycline is the best way to prevent morbidity and death. Treatment decisions should never be delayed while awaiting laboratory confirmation, nor should treatment be discontinued solely on the basis of a negative test result with an acute-phase specimen.
- Although optimal duration of therapy has not been well studied, a common treatment course for RMSF and ehrlichiosis is at least 3 days after the patient defervesces (typically the minimum total course is 5–7 days) or longer for severe illness. Anaplasmosis should be treated for 10 days to provide appropriate therapy for possible coinfection with *Borrelia burgdorferi*.

- Historically chloramphenicol has been recommended for the treatment of RMSF during pregnancy based on adverse effects of older tetracycline drugs (but not specifically doxycycline). Although there is limited evidence, doxycycline has not been associated with teratogenicity or maternal hepatic toxicity during pregnancy, and doxycycline has been used successfully to treat tickborne rickettsial disease in several pregnant women without adverse effects.
- Chloramphenicol is not an alternative treatment for human monocytic ehrlichiosis (HME) or HGA. Chloramphenicol treatment of RMSF has been associated with a greater risk of death compared with doxycycline treatment.
- Limited case report data suggest that rifampin<sup>1</sup> can be used as an alternative to doxycycline for the treatment of confirmed (RMSF ruled out) mild anaplasmosis during pregnancy or with documented tetracycline allergy.

<sup>1</sup>Not FDA approved for this indication.

Tickborne rickettsial diseases in humans often share clinical features but are epidemiologically and etiologically distinct. In the United States included diseases are (1) Rocky Mountain spotted fever (RMSF) caused by *Rickettsia rickettsii*; (2) other spotted fever group (SFG) rickettsioses, caused by *Rickettsia parkeri* and *Rickettsia* species 364D; (3) *Ehrlichia chaffeensis* ehrlichiosis, also called human monocytic ehrlichiosis (HME); (4) other ehrlichioses, caused by *Ehrlichia ewingii* and *Ehrlichia muris*-like agent; and (5) anaplasmosis, caused by *Anaplasma phagocytophilum*, also called human granulocytic anaplasmosis (HGA). The reported incidence of tickborne rickettsial diseases has increased in the United States. Tickborne rickettsial diseases, especially RMSF, continue to cause severe illness and death in otherwise healthy adults and children, despite the availability of effective antibiotic therapy. SFG rickettsioses (including RMSF), ehrlichioses, and anaplasmosis are nationally notifiable diseases in the United States. Providers report potential cases to state or local health departments. In 2010, the reporting category of RMSF was changed to spotted fever rickettsiosis, as serology does not readily distinguish RMSF from other SFG rickettsioses.

### Epidemiology

Tickborne rickettsial pathogens are maintained in natural cycles involving domestic or wild vertebrates and ticks. The epidemiology of each disease reflects the geographic distribution and seasonal activities of the tick vectors and the natural vertebrate hosts, as well as the human activities resulting in tick exposure. Although cases have been reported in every month, most cases occur during April to September, coincident with peak levels of tick host-seeking activity.

RMSF is the rickettsiosis in the United States that is associated with the highest rates of severe and fatal outcomes. The case-fatality rate in the preantibiotic era was ~25%. Current case-fatality rates are estimated at 5% to 10%. From 2008–2012, the estimated average annual incidence from passive surveillance of SFG rickettsioses was 8.9 cases per million persons. Reported annual incidence has increased during the past two decades. The highest incidence occurs in persons aged 60 to 69 years, and the highest case-fatality rate is among children aged <10 years. Additional epidemiologic risk factors for fatal RMSF include age ≥40 years, alcohol abuse, and glucose-6-phosphate dehydrogenase deficiency. From 2008 to 2012, 63% of reported SFG rickettsiosis cases came from Arkansas, Missouri, North Carolina, Oklahoma, and Tennessee. SFG rickettsiosis has been reported from all the contiguous 48 states and the District of Columbia.

In the United States, the tick species most frequently associated with transmission of *R. rickettsii* is the American dog tick, *Dermacentor variabilis*, which is found primarily in the eastern, central, and Pacific Coast regions. The Rocky Mountain wood tick, *Dermacentor andersoni*, is associated with transmission in the western United States. Larval and nymphal stages of most *Dermacentor* spp ticks usually do not bite humans. Adult *D. variabilis*

and *D. andersoni* ticks bite humans, but the principal hosts are deer, dogs, and livestock.

The brown dog tick, *Rhipicephalus sanguineus*, which is located throughout the United States, is an important vector in parts of Arizona and along the United States–Mexico border. All stages (larvae, nymphs, and adults) of *Rh. sanguineus* bite humans and can transmit *R. rickettsia*. Domestic dogs are the preferred host. On Arizona tribal lands, the warm climate and proximity of ticks to domiciles (tick-infested dogs) provide a suitable environment for *Rh. sanguineus* to remain active year-round, resulting in cases of RMSF in Arizona every month of the year.

*Rickettsia parkeri* is transmitted by the Gulf Coast tick, *Amblyomma maculatum*. *R. parkeri* rickettsiosis cases have not been documented in children, and no fatal cases have been reported. The first confirmed case of Rickettsia species 364D was in 2010 and likely transmitted by the Pacific Coast tick, *Dermacentor occidentalis*. All reported cases have been from California.

The average annual incidence of ehrlichiosis from 2008 to 2012 was 3.2 cases per million persons, with the most common cause being *E. chaffeensis*. The highest incidence is in persons aged 60 to 69 years. The case fatality rate is ~3% and is highest among children aged <10 years, adults aged ≥70 years, and immunosuppressed persons. *E. chaffeensis* is transmitted to humans by the lone star tick, *Amblyomma americanum*, which is the most commonly encountered tick in the southeastern United States, with a range that extends into areas of the Midwest and New England. Arkansas, Delaware, Missouri, Oklahoma, Tennessee, and Virginia have the highest reported incidence. The white-tailed deer is an important natural reservoir for *E. chaffeensis*, and most cases occur during May to August.

The principal vector for *E. ewingii* ehrlichiosis is also *A. americanum*. Cases have primarily been reported from Missouri. No fatal cases of *E. ewingii* ehrlichiosis have been reported. *Ehrlichia muris*-like agent (EML) has recently been recognized as a human pathogen. Reported cases have been from Minnesota and Wisconsin. The blacklegged tick, *Ixodes scapularis*, is an efficient vector for EML in experimental studies. EML agent DNA has been detected in *I. scapularis* collected in Minnesota and Wisconsin but has not been detected in *I. scapularis* from other states.

The incidence of human anaplasmosis during 2008–2012 was 6.3 cases per million persons. Incidence is highest in the northeastern and upper midwestern states, and the geographic range seems to be expanding. The case fatality rate is <1%. *I. scapularis* is the vector for *Anaplasma phagocytophilum* in the northeastern and midwestern United States, whereas the western blacklegged tick, *Ixodes pacificus*, is the principal vector along the West Coast. The seasonality is bimodal, with the first peak June–July and a smaller peak in October, corresponding to the emergence of the adult stage of *I. scapularis*. *I. scapularis* also transmits *Borrelia burgdorferi* (Lyme disease), *Babesia microti* (babesiosis), *Borrelia miyamotoi* (tickborne relapsing fever), and deer tick virus (a cause of tickborne encephalitis). Simultaneous infections with *A. phagocytophilum* and *B. burgdorferi* or *B. microti* have occurred.

### Pathophysiology

The agents causing RMSF, ehrlichiosis, and anaplasmosis are all obligate intracellular pathogens, but the target host cells they infect and subsequent pathology vary by organism.

*R. rickettsii* is transmitted from the tick to humans via a painless bite, which often goes unrecognized. The organism resides in the salivary gland of the tick and is passed during acquisition of a blood meal. *R. rickettsii* can be transmitted as early as 10 to 24 hours after tick attachment. When transmitted to a human host, *R. rickettsia* localize and multiply in vascular endothelial cells, and, less commonly, underlying smooth muscle cells of small and medium vessels, resulting in vasculitis. The vasculitis is the underlying mechanism for most of the clinical features and laboratory abnormalities of RMSF. Injury to the vascular endothelium results in increased capillary permeability, microhemorrhage, and platelet consumption. Late-stage complications of pulmonary edema (acute respiratory distress syndrome) and cerebral edema are consequences of the microvascular leakage.

*E chaffeensis* predominantly infects monocytes and tissue macrophages and replicates in cytoplasmic vacuoles called morulae. Unlike RMSF, direct vasculitis and endothelial injury are rare in human monocytic ehrlichiosis. Frequent pathologic findings include granuloma formation, myeloid hyperplasia, and megakaryocytosis in the bone marrow. The severe pathology and multiorgan involvement in severe and fatal HME in immunocompetent patients is believed to be due to dysregulation of the host immune response that leads to tissue damage and eventually multiorgan failure. *E ewingii* has a predilection for neutrophils, and morulae can be observed in granulocytes of the blood, cerebrospinal fluid (CSF), and bone marrow.

*A phagocytophilum* is found predominantly in neutrophils in the peripheral blood and tissues from infected individuals. *A phagocytophilum* has the unique ability to selectively survive and multiply within cytoplasmic vacuoles (morulae) of polymorphonuclear cells by delaying their apoptosis. Infection with *A phagocytophilum* induces a systemic inflammatory response, which is believed to be the mechanism for tissue damage. Pathologic findings with human granulocytic anaplasmosis include normocellular or hypercellular bone marrow, erythrophagocytosis, hepatic apoptosis, focal splenic necrosis, and mild interstitial pneumonitis and pulmonary hemorrhage.

### Clinical Manifestations

A detailed history should include information about known tick bites or activities that might be associated with tick exposure. Unrecognized tick bites are common. A history of a tick bite within 14 days of illness onset is reported in only 50% to 60% of RMSF cases and 68% of ehrlichiosis cases. Absence of a tick bite should never dissuade providers from considering tickborne rickettsial disease in the appropriate clinical context. Contact with pets, especially dogs, and a history of tick attachment or recent tick removal from pets can be useful in assessing human tick exposure.

Tickborne rickettsial diseases commonly have nonspecific clinical signs and symptoms early in the course of disease. Although there is overlap in the clinical presentations of tickborne rickettsial diseases, the frequency of certain associated signs and symptoms (e.g., rash and other cutaneous findings) and typical laboratory findings differ by pathogen and assist providers in developing a differential diagnosis, beginning appropriate antibacterial treatment, and ordering confirmatory diagnostic tests.

Symptoms of RMSF typically begin 3 to 12 days after the bite of an infected tick or 4 to 8 days after discovery of an attached tick. The incubation period is generally shorter ( $\leq 5$  days) in patients who develop severe disease. Initial symptoms are often nonspecific and include the sudden onset of fever, chills, malaise, and myalgia. Clinical suspicion for RMSF should be maintained in cases of nonspecific febrile illness and sepsis of unclear cause, particularly during the spring and summer months.

The classic triad of fever, rash, and reported tick bite is present in only a minority of RMSF patients during the initial presentation to health care; therefore it is crucial not to wait for development of this triad before considering a diagnosis of RMSF and beginning treatment. A rash typically occurs 2 to 4 days after the onset of fever; however, many patients initially seek medical care before the rash. In one large series of patients with RMSF, 88% of patients had a rash, but only 49% had a rash in the first 3 days. Children more frequently have rash (97%) and develop the rash earlier. The rash typically begins as small, blanching macules on the ankles, wrists, or forearms that then spreads to the palms, soles, arms, legs, and trunk, usually sparing the face. The generalized petechial rash appears later (day 5 or 6) and is indicative of advanced disease. An inoculation eschar is rarely present with RMSF. In addition to rash, the most frequent clinical findings at any point in the illness are fever (99%), headache (91%), and myalgia (82%).

The total white blood cell count is typically normal or mildly increased with RMSF, and increased numbers of immature neutrophils are often present. Thrombocytopenia, slight elevations of AST or ALT, and hyponatremia might be present, particularly as the disease advances. Laboratory values cannot be relied on

to guide early treatment decisions because they are often within or slightly deviated from normal reference values early in the course. When CSF is obtained, a lymphocytic (less commonly neutrophilic) pleocytosis can be present, along with a moderately elevated CSF protein. CSF glucose is generally normal.

*R parkeri* rickettsiosis is a milder illness compared with RMSF; no severe manifestations or death has been reported. Symptoms develop a median of 5 days (range, 2–10 days) after the bite of an infected tick. The first manifestation in nearly all patients is an inoculation eschar, which generally is nonpruritic, nontender or mildly tender, and surrounded by an indurated, erythematous halo and occasionally a few petechiae. Shortly after the onset of fever (0.5–4 days later), a nonpruritic maculopapular or vesicopustular rash develops in 90% of patients. The rash primarily involves the extremities and trunk and in ~half of patients involves the palms and soles. Headache (86%) and myalgia (76%) are common. Laboratory findings include modest elevation of hepatic transaminases (78%), mild leukopenia (50%), and thrombocytopenia (40%).

Few patients with *Rickettsia* species 364D have been reported, so the full clinical spectrum has yet to be described. It does appear to be relatively mild and characterized by an eschar or ulcerative skin lesion with regional lymphadenopathy. Fever, headache, and myalgia occur, but rash has not been a notable feature.

Symptoms of *E chaffeensis* ehrlichiosis typically occur a median of 9 days (range, 5–15 days) after an infected tick bite. Fever (96%), headache (72%), malaise (77%), and myalgia (58%) are common. Abdominal pain, vomiting, and diarrhea can occur, particularly in children. Rash (maculopapular, petechial, or diffuse erythema) occurs in approximately one-third of patients and is more frequent in children. The rash occurs a median of 5 days after illness onset and can involve the palms and soles. Neurologic manifestations are present in ~20% of patients. Characteristic laboratory findings in the first week include leukopenia, thrombocytopenia, and elevated levels of hepatic transaminases. *Ehrlichia ewingii* and *Ehrlichia muris*-like agent ehrlichiosis have similar clinical and laboratory features as *E chaffeensis* ehrlichiosis, although rash and gastrointestinal symptoms are less common.

Symptoms of human granulocytic anaplasmosis typically occur 5 to 14 days after an infected tick bite. Fever (92%–100%), headache (82%), malaise (97%), and myalgia (77%) are common. Rash is present in <10% of patients, and central nervous system involvement is rare. Laboratory findings are similar to ehrlichiosis.

### Diagnosis

Early diagnosis and initiation of treatment of tickborne rickettsial diseases is based on clinical and epidemiologic findings, as rapid confirmatory assays are often not available or reliable to guide treatment decisions early in the clinical course. Confirmatory diagnostic tests are serologic assays, nucleic acid detection, immunostaining of biopsy tissue, blood-smear microscopy, and culture.

Assays using paired acute and convalescent sera (ideally collected 2–4 weeks apart) are the standard for serologic confirmation. Assays are insensitive during the first week of rickettsial infection. After 7 days of illness, the sensitivity increases. Assays are highly sensitive 2 to 3 weeks after illness onset. Early therapy with doxycycline may diminish or delay the development of antibodies in RMSF.

A diagnosis of tickborne rickettsial diseases is confirmed with a  $\geq$ fourfold increase in antibody titer in patients with a clinically compatible acute illness. A single IgG antibody reciprocal titer  $\geq 64$  is supportive of, but not confirmatory for, the diagnosis. In the United States, *R rickettsia*-reactive IgG antibody reciprocal titers  $\geq 64$  can be found in 5% to 10% of the population who do not acutely have RMSF. Some laboratories also perform assays for IgM antibodies. However, because of the lower specificity of IgM compared with IgG assays, IgM titers should not be used as a stand-alone method for diagnosis.

PCR amplification of DNA from whole blood specimens collected during the acute stage of illness is particularly useful for confirming *E. chaffeensis*, *A. phagocytophilum*, *E. ewingii*, and EML agent infections due to the tropism of those organisms for circulating cells. PCR detection of *R. rickettsia* in whole blood is less sensitive, as low numbers of rickettsiae typically circulate in the blood in the absence of advanced disease. Tissue specimens such as a skin biopsy are a more useful source of SFG rickettsial DNA compared with blood samples. Doxycycline treatment decreases the sensitivity of PCR. Obtaining blood before treatment is recommended to decrease false-negative results.

Immunostaining of a skin punch biopsy is useful for diagnosing RMSF with 100% specificity and 70% sensitivity. Microscopic examination of blood smears or buffy-coat preparations during the first week of illness may reveal leukocyte morulae in patients infected with *E. chaffeensis* or anaplasmosis, although it is relatively insensitive, and accuracy is dependent on having experienced microscopists. Culture is the reference standard for microbiologic diagnosis, but the agents that cause tickborne rickettsial diseases require cell culture techniques that are not widely available.

### Differential Diagnosis

The differential diagnosis of fever and rash is broad, and during the early stages of illness tickborne rickettsial diseases can be indistinguishable from many viral exanthams, particularly in children. In addition to viral infections, conditions that should be considered include meningococemia, Kawasaki disease, secondary syphilis, disseminated gonococcal infection, bacterial endocarditis, scarlet fever, leptospirosis, typhoid, drug eruptions, Stevens-Johnson syndrome, toxic shock syndrome, and thrombotic thrombocytopenic purpura.

### Treatment

Doxycycline is the drug of choice for treatment of all tickborne rickettsial diseases in patients of all ages and should be initiated immediately in persons with signs and symptoms suggestive of rickettsial disease. Treatment decisions should never be delayed awaiting laboratory confirmation. Multiple studies have noted a delay in appropriate treatment of tickborne rickettsial diseases, particularly after the fifth day of illness for RMSF, to be a significant potentially preventable risk factor for severe disease, increased mortality rates, and long-term sequelae. Because of the nonspecific signs and symptoms of tickborne rickettsial diseases, concomitant empiric treatment for other conditions in the differential diagnosis should be administered (e.g., treatment with ceftriaxone for meningococemia).

The recommended dose of doxycycline is 100 mg twice daily (IV or oral) for adults and 2.2 mg/kg twice daily (IV or oral) for children weighing <45 kg.<sup>1</sup> Oral therapy is appropriate for patients with early-stage disease who can be treated as outpatients. The recommended duration of therapy for RMSF and ehrlichiosis is at least 3 days after fever resolves and until evidence of clinical improvement is noted; typically, the minimum total course is 5 to 7 days. Severe or complicated disease could require a longer course. HGA should be treated for 10 days to provide appropriate therapy for possible coinfection with Lyme disease.

The use of doxycycline to treat children with suspected tickborne rickettsial disease should no longer be a subject of controversy. The American Academy of Pediatrics and CDC recommend doxycycline as the treatment of choice for children of all ages with suspected tickborne rickettsial disease. Doxycycline used at the recommended dose and duration for RMSF in children aged <8 years, even after multiple courses, has not resulted in tooth staining or enamel hypoplasia.

Chloramphenicol in the past was used as an alternative drug for treating RMSF. However, chloramphenicol has been associated with a higher risk of death compared to patients treated with a tetracycline; in vitro evidence indicates that chloramphenicol is

not effective treatment for ehrlichiosis or anaplasmosis. Chloramphenicol is no longer available in the oral form in the United States, and the IV form is not readily available at all institutions.

Chloramphenicol has been recommended for the treatment of RMSF during pregnancy based on adverse effects of older tetracycline drugs (but not specifically doxycycline). Although there is limited evidence, doxycycline has not been associated with teratogenicity or maternal hepatic toxicity during pregnancy, and doxycycline has been used successfully to treat tickborne rickettsial diseases in several pregnant women without adverse effects.

Rifamycins demonstrate in vitro activity against *E. chaffeensis* and *A. phagocytophilum*. Case reports document favorable outcomes in small numbers of pregnant women treated with rifampin for anaplasmosis. Rifampin<sup>1</sup> could be an alternative for treatment of confirmed mild anaplasmosis (RMSF ruled out) during pregnancy or documented allergy to tetracycline-class drugs. Rifampin is not acceptable treatment for RMSF or potential coinfection with *B. burgdorferi*.

Treatment of symptom-free persons seropositive for tickborne rickettsial disease is not recommended, regardless of past treatment, because antibodies can persist for months to years after infection.

### Monitoring and Complications

Fever with tickborne rickettsial diseases typically subsides within 24 to 48 hours when treated with doxycycline in the first 4 to 5 days of illness. Lack of a clinical response within 48 hours of early treatment with doxycycline could indicate the illness is not a tickborne rickettsial disease, and alternative diagnoses or coinfection should be considered. Severely ill patients may require >48 hours of treatment before clinical improvement is noted. Patients with mild disease treated on an outpatient basis need close follow-up to ensure they are responding appropriately.

Patients with evidence of organ dysfunction, severe thrombocytopenia, mental status changes, or the need for supportive therapy should be hospitalized. Other considerations for hospitalization include the likelihood and ability to take oral medication and existing comorbid conditions, including the patient's immune status. Infection with RMSF and to a somewhat lesser extent HME are most likely to have a severe disease or death. Severe, late-stage manifestations of RMSF include meningoen- cephalitis, acute respiratory distress syndrome (ARDS), acute renal failure, arrhythmia, and seizures. Severe manifestations of HME include ARDS, shock-like syndromes, renal failure, hepatic failure, coagulopathies, and hemorrhagic complications.

Severe or life-threatening manifestations are less frequent with anaplasmosis than with RMSF or HME. Predictors of a more severe course of anaplasmosis include advanced age, immunosuppression, comorbid medical conditions, and delay in diagnosis and treatment. Confirmed *A. phagocytophilum* coinfection has been reported in <10% of patients with Lyme disease. Response to treatment can provide clues to possible coinfection with Lyme disease or babesiosis. If the clinical response to treatment with doxycycline is delayed, coinfection or an alternate infection should be considered. Conversely, if Lyme disease is treated with a beta-lactam antibiotic in a patient with unrecognized *A. phagocytophilum* infection symptoms could persist.

### Prevention

The best prevention for all the tickborne rickettsial diseases is to avoid tick bites, perform regular tick checks on humans and pets, and promptly remove attached ticks. Longer periods of tick attachment increase the probability of transmission of tickborne diseases. Repellents and protective clothing can reduce the risk for tick bites. Products containing 20% to 30% N,N-Diethylmeta-toluamide (DEET) effectively repel ticks and can be applied directly to the skin. DEET is not recommended for use on infants younger than 2 months. Permethrin-treated or -impregnated clothing can significantly reduce tick bites. Prophylactic treatment is not recommended in persons who have had recent tick bites and are well.

## TOXIC SHOCK SYNDROME

Method of

Alwyn Rapose, MD

### CURRENT DIAGNOSIS

- Clinical diagnosis: High index of suspicion when there is a combination of fever, rash—initially erythematous followed by desquamation, hypotension, and multiorgan injury.
- There needs to be a thorough search for a focus of infection like retained foreign body or tampon, deep-seated abscess or peritonitis, necrotizing fasciitis, or postoperative wound infection.
- Blood cultures and deep tissue cultures (from the site of the suspected infection) are recommended in all cases.

### CURRENT THERAPY

- Aggressive fluid resuscitation.
- Broad antibiotic coverage initially, followed by deescalation to target the organism identified in cultures.
- Intravenous immunoglobulin may help in patients who fail to respond to standard care.

## Introduction

Toxic shock syndrome (TSS) is an acute illness, which as the name suggests is caused by a toxin, and the patient presents with hypotension (shock) and multiorgan involvement (syndrome). It was initially described in children with *Staphylococcus aureus* infection, but a similar syndrome is associated with *Streptococcus* infections as well as clostridial infections in children and adults. Different toxins—acting either directly or via different cytokine pathways—have been implicated in the pathogenesis of the disease. TSS carried a high mortality risk (40% to 60% in streptococcal TSS). However, early recognition and aggressive interventions have resulted in much improved outcomes in the era of modern medicine.

## Historical Aspects

A review of the medical literature indicates this was first described in 1978 when J. Todd and colleagues reported a collection of seven cases in children. In the early years following its description, a majority of cases were seen in young menstruating women who used tampons, with the onset of illness within a few days of onset of their menstrual period. A large number of investigators evaluated tampons, contraceptive sponges, sanitary pads, and other medical and surgical materials and as the medical community became more familiar with this syndrome, there was a decrease in tampon-associated TSS and an increased incidence of nonmenstrual TSS associated with respiratory infections, necrotizing skin infections, deep-seated abscesses, and postoperative infections including gynecologic surgeries.

TSS is classically associated with *S. aureus* infection. The clinical features included fever, skin rash, hypotension, and multiorgan involvement with various combinations of respiratory, renal, and hepatic injury. Similar features following infection with *Streptococcus pyogenes* (group A *Streptococcus* [GAS] as well as other streptococci) resulted in a description of streptococcal toxic shock-like syndrome (TSLS). In patients with complications of medical or spontaneous abortions and infection with *Clostridium species* similar clinical features were seen along with very high mortality, and this condition was also included when describing TSS.

## Pathogenesis

The *S. aureus* isolates from patients with menstruation-related TSS revealed a toxin that was first called toxic shock syndrome toxin 1 (TSST-1). Since then, however, multiple other toxins associated with *S. aureus* (enterotoxins B-F) have been described to be associated with TSS. Similarly, streptococcal exotoxins (A, B, and C)—superantigens—are potent activators of T lymphocytes and can also directly cause high fever (pyrotoxins) and shock, as well as tissue damage.

These bacterial toxins induce production of tumor necrosis factor (TNF $\alpha$ ), interferons (IFN $\gamma$ ), interleukins (IL-1, IL-2), and other cytotoxins by human monocytes and lymphocytes that result in a cascade of proinflammatory cytokines (cytokine storm). These cytokines are responsible for fever, damage to vascular endothelium resulting in tissue injury, as well as the loss of intravascular volume and hypotension.

In contrast, clostridial infection is associated with direct tissue damage by secreted clostridial toxins.

## Clinical Features

The surveillance case definition developed by the Centers for Disease Control and Prevention (CDC) included five clinical criteria: Fever, rash, hypotension, and involvement of three or more organ systems. The rash usually subsided with desquamation, which is the fifth clinical criterion. The patient may have prodromal symptoms like myalgia, arthralgia, and headache. Fever associated with a diffuse erythematous skin rash (sheets of erythema) involving the face trunk and extremities is rapidly followed by hypotension, decreased urine output, and features of septic shock (Figures 1 through 3). Detailed history taking and a thorough clinical examination is essential to determine the focus of infection—either menstrual tampon, retained foreign body, necrotizing infection in a closed space (fasciitis), postoperative wound infection, or, more recently described, peritonitis-associated TSS. Subtle differences between TSS and TSLS have been described. Clostridial infection following septic abortion or other gynecologic surgery is associated with severe abdominal and pelvic pain, uterine tenderness (endometritis), and a foul-smelling vaginal discharge. A delay in diagnosis and intervention results in a rapid progression of systemic involvement. A cytokine storm in the lungs can result in respiratory complications like acute respiratory distress syndrome (ARDS), and there can be acute renal injury secondary to hypotension or toxin-induced acute interstitial nephritis, shock liver, and in severe situations, altered mental status. In the recovery phase, the erythematous rash subsides with desquamation.

**Figure 1** Diffuse erythematous rash on the trunk.

**Figure 2** Diffuse erythematous rash on the lower extremity.

**Figure 3** Diffuse erythematous rash on the upper extremity.

### Management

Early diagnosis, rapid intervention with intravenous (IV) fluids, IV antibiotics as well as IV immunoglobulin (IVIG)<sup>1</sup> in some circumstances, along with supportive therapy like mechanical ventilation in patients with respiratory failure and dialysis for patients with severe renal injury, are key to survival in patients with TSS. Patients in circulatory shock are treated in an intensive

<sup>1</sup>Not FDA approved for this indication.

care unit with inotropic agents such as norepinephrine (Levophed) and vasopressin (Pitressin) to provide pressor support. A multidisciplinary team, including intensivists, infectious disease specialists, pulmonologists, and nephrologists, is required for the management of these patients because they often develop respiratory failure and acute renal injury.

Removal of the focus of infection—be it an infected tampon, retained products of conception, surgical drainage of deep-seated abscess, aggressive debridement in patients with necrotizing fasciitis, or postoperative wound infection—is an essential component in the management of TSS.

Blood cultures should be obtained at presentation, and tissue cultures should be obtained at the time of surgery. Ascitic fluid cultures are essential in cases with suspected peritonitis.

Patients should be initially treated with aggressive IV fluid resuscitation along with antibiotic combinations that will provide broad coverage against *Staphylococcus*, *Streptococcus*, and anaerobic organisms. Vancomycin (15 to 20 mg/kg every 12 hours) along with a carbapenem (meropenem [Merrem] 1 g every 8 hours, imipenem [Primaxin] 500 mg every 6 hours, or ertapenem [Invanz] 1 g every 24 hours), or vancomycin along with piperacillin-tazobactam (Zosyn 4.5 g every 6 to 8 hours) (though there has been reported a higher risk of nephrotoxicity with this compared to the combination of vancomycin with carbapenem) is often the first choice for broad coverage. These antibiotics need dose adjustments based on a patient's renal function. In addition, antibiotics like clindamycin (600 to 900 mg every 8 hours) and linezolid (Zyvox 600 mg every 12 hours) are included because of their direct antitoxin effect (suppress toxin production and accelerate phagocytosis). These antibiotics do not need renal dose adjustments. When the patient is on vancomycin, there should be close monitoring of vancomycin troughs or vancomycin area under the curve, as well as creatinine, to optimize vancomycin dosage and reduce the risk of nephrotoxicity. If linezolid is used, vancomycin will not be required. Newer agents like ceftaroline (Teflaro 600 mg every 12 hours) also provide coverage against methicillin-resistant *S. aureus* (MRSA). The results of microbiology cultures help guide the final antibiotic choice (deescalation of antibiotics). If an infection is caused by a *Streptococcus* species, and no *S. aureus* is identified, vancomycin/ceftaroline can be discontinued and IV penicillin (12 to 24 million units per day as a continuous infusion or in six divided doses) combined with clindamycin is recommended. The duration of antibiotic therapy depends on the patient's clinical response. IVIG<sup>1</sup> has been used in patients who are failing standard therapy. It probably acts by providing antiinflammatory mediators and antibodies against some of the toxins and superantigens and has been shown to improve survival especially in TSS.

### New Research and Developments

Newer antibiotics recently approved for use in skin and skin structure infections, including dalbavancin (Dalvance), oritavancin (Orbactiv), delafloxacin (Baxdela), and omadacycline (Nuzyra), have great coverage against *S. aureus*, including MRSA and *Streptococcus*. However, these have not been approved for use in TSS.

There is ongoing research into the development of immunological agents (monoclonal antibodies and vaccines) that can target toxins and other superantigen-induced cytokine pathways. These nonantibiotic therapies have the potential to block the toxin-induced shock without the side effects commonly associated with antibiotic use.

## TOXOPLASMOSIS

Method of

Carlo Contini, MD

### CURRENT DIAGNOSIS

- The diagnosis of *Toxoplasma gondii* infection mostly relies on serologic detection of specific IgM and IgG antibodies.
- Specific IgM antibodies with low IgG (IgG-avidity testing) are consistent with recent infection in immunocompetent persons. Positive IgG antibodies in the absence of IgM in healthy persons indicate past infection and resistance to reinfection.
- Amniocentesis and polymerase chain reaction (PCR)-based analysis on amniotic fluid (AF) [past 18 weeks' gestation] are useful to establish a certain or presumed seroconversion in pregnancy and to determine whether the infection was transmitted to the offspring.
- IgM, IgA, or both at birth indicate probable congenital infection.
- Serologic testing is not useful for the diagnosis of TE in AIDS patients, who should instead undergo computed tomography (CT) or magnetic resonance imaging (MRI), cerebrospinal fluid (CSF)-*T.gondii* DNA PCR testing, or demonstration of tachyzoites by histology.
- Serologic screening is helpful in identifying transplant patients at risk, especially seronegative recipients with seropositive donors, and can help in establishing the diagnosis by showing seroconversion. Serologic follow-up combined with PCR after allogeneic hematopoietic stem cell transplantation (HSCT) is recommended in all patients at risk for toxoplasmosis.

### CURRENT THERAPY

- All immunocompetent patients, as well as nonpregnant women with acute toxoplasmosis presenting with lymphadenitis and fever, generally do not require specific antimicrobial treatment because the infection is self-limited and usually subclinical.
- Pyrimethamine (Daraprim) plus sulfadiazine<sup>1</sup> plus folinic acid (Leucovorin)<sup>1</sup> is the standard and preferred regimen against toxoplasmosis. It is recommended for acute *T gondii* infection in immunocompetent adults with acute illness; pregnant women who acquire the infection after 18 weeks' gestation or in whom fetal infection is documented (positive PCR-AF); and immunosuppressed patients, including AIDS patients. Patients who do not tolerate the standard regimen should be given alternative drugs such as clarithromycin (Biaxin),<sup>1</sup> azithromycin

(Zithromax),<sup>1</sup> atovaquone (Mepron),<sup>1</sup> and dapsone.<sup>1</sup>

- Trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim)<sup>1</sup> has been shown to have efficacy similar to pyrimethamine-sulfadiazine and may be used as an alternative if patients do not have sulfa allergy and pyrimethamine is not tolerated or is not available.
- Oral spiramycin (Rovamycin)<sup>2</sup> is the drug most often used in the prenatal therapy of congenital toxoplasmosis (before 18 weeks of gestation) because of high concentration in placenta without crossing it and of its relative lack of toxicity compared with the teratogenic effects of pyrimethamine. Spiramycin is more efficacious when administered early after maternal seroconversion.
- TMP-SMX<sup>1</sup> should be given as a prophylaxis to HIV-positive patients who have CD4<sup>+</sup> cell counts that are less than 100/mm<sup>3</sup> and IgG *T gondii* antibodies and who are not already receiving a PCP prevention regimen, as well as to patients with active toxoplasmosis, transplant patients, and workers after accidental laboratory exposure.
- In ocular toxoplasmosis, corticosteroid therapy, if given, should be always monitored to prevent severe tissue destruction.
- Universal prophylaxis with TMP/SMX in allo pre-HCTSP patients should be implemented by all transplantation programs.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not commercially available in the United States.

*Toxoplasma gondii* is a ubiquitous protozoan parasite that is extremely widespread and of great medical importance, infecting all mammalian cells and responsible for human and veterinary diseases. It was initially described in Tunisia by Nicolle and Manceaux (1908) in the tissues of the rodent gundi (*Ctenodactylus gundi*) and later in Brazil by the microbiologist Alfonso Splendore (1908) in the rabbit. Its identification was rapidly followed by the recognition that it was a human pathogen. In this regard, the Italian bacteriologist Castellani (1914) was probably the first to describe a *T gondii*-like parasite in smears of blood and spleen from a 14-year-old Singhaiese boy who died of a disease characterized by severe anemia, fever, and splenomegaly. However, it was not until the 1960s and 1970s that the parasite was identified as a coccidian and the cat recognized as the definite host.

*Toxoplasma* belongs to the phylum *Apicomplexa*, which contains many other protozoan pathogens of human and veterinary importance, such as *Plasmodium* spp. (malaria), *Cryptosporidium* spp. (cryptosporidiosis), and *Eimeria* spp. (poultry coccidiosis).

Disease can occur through acute infection after recent contact with *T gondii* cysts or oocysts or through endogenous reactivation. Primary infection is usually subclinical, but in some patients cervical or occipital lymphadenopathy or ocular disease is present. Infection acquired during pregnancy can cause severe damage to the fetus if *Toxoplasma* crosses the placental barrier, and it causes abortion or congenital birth defects if the mother becomes infected for the first time shortly before or during pregnancy.

In patients with AIDS and others who are immunocompromised, reactivation of latent disease can cause life-threatening encephalitis. Ocular infection by *Toxoplasma* is a major cause of retinochoroiditis in several geographic areas in both immunocompetent and immunocompromised persons. Due to the heterogeneous parasitologic outcomes and limited immunological data, the role of aging in toxoplasmosis evolution remains poorly understood.

### Epidemiology and Risk Factors

Toxoplasmosis is a cosmopolitan zoonotic disease that has important implications for public health because it affects one-third of the world's population. It is also a significant veterinary pathogen that can infect many species of warm-blooded animals. *T gondii* is one of the world's most successful parasites, in part because of its ability to infect and persist in most warm-blooded animals. In general, the prevalence in animals is much higher than that in humans. In China, among the major animals monitored,

pigs were the most frequently infected by *T gondii*, reaching 70% in some areas and farms. This high *T gondii* prevalence increases the risks of human infection through meat consumption, because pork is the main meat Chinese people consume. Among other meat-producing animals, sheep and chickens have also high *T gondii* infection rates, and economic losses caused by abortions and other diseases from sheep toxoplasmosis are predicted to be huge in the forthcoming decades.

In humans, the incidence of positive serology for *Toxoplasma* varies greatly around the world and is influenced by different cultures. In Colombia, approximately half of the women of child-bearing age have *T gondii* antibodies, and the clinical disease in congenitally infected children is more severe than in Europe. In humans, seroprevalence of *T gondii* infection rises with age; does not vary greatly between sexes; and is lower in cold regions, hot and arid areas, and at high elevations. Prevalence rates, which range worldwide from <10% to >60%, are thought to depend on food production and harvesting practices, water treatment, environment, climate, and exposure to soil or sand. In the United States, the seroprevalence of *T gondii* appears to be declining. Seroprevalence in Europe is high, up to 54% in southern European countries; it decreases with increasing latitude to 5% and 10% in northern Sweden and Norway, respectively. As is the case of most other protozoa, the prevalence of *Toxoplasma* is higher in Africa, South America, and in developing areas of the world. In Brazil, there is a higher prevalence of *T gondii* infection among male patients (79.0%) than among female patients (63.4%), according to data obtained from a blood bank.

The sexual cycle of *T gondii* occurs in felines. The estimated seroprevalence for *T gondii* in domestic cats (*Felis catus*), worldwide, is 30% to 40%. Most feline infections occur postnatally through ingestion of infected tissue cysts or rarely oocysts, although congenital infections occur. Tens of millions of unsporulated oocysts may be released in the feces of a single cat in a day, depending on the stage of *T gondii* ingested. These sporulate in 1 to 21 days and are highly infectious to the parasite's intermediate hosts (asexual cycle), which include almost any warm-blooded animal, such as birds, humans, and sea otters.

Sporulated oocysts are very resistant to environmental conditions and to disinfectants; however, they are killed within 1 to 2 minutes by heating to 55°C to 60°C, and the risk of infection is reduced by deep-freezing meat (−12°C or lower) before cooking.

Feline infections are typically subclinical. Common symptoms of *T gondii* infection in cats can include fever, ocular inflammation, anorexia, lethargy, abdominal discomfort, and neurologic abnormalities. Occasionally, pneumonia, liver damage, and loss of vision develop. Why only some cats show symptoms is not known.

Identification of locally prevalent risk factors is critical for health education, and it is generally important for policy. The most important recognized factors influencing the risk of *T gondii* infection are having a cat or a dog, doing household work, having a lower education level, having poor hygiene habits, eating raw vegetables, and working in contact with soil.

Most people are infected inadvertently, and thus the specific route of transmission usually cannot be established. Contact with this obligate intracellular protozoan can occur through the ingestion of oocysts containing sporozoites or cysts containing bradyzoites in contaminated food or water. The major risk factors for *T gondii* exposure are directly related to exposure to cats and more specifically to cat feces, which represent the source of ingestion of sporozoites from the environment. Because cats are the primary host for *T gondii*, cats in the house or stray cats in and around the house or property are considered a primary risk factor for acquiring this parasite during pregnancy. Moreover, any job or activity that puts a pregnant woman in direct contact with soil, sand, or materials such as fruit, vegetables, or drinking water that could have been contaminated by cat feces puts her at risk for being infected. In this setting, rain and surface water can transport infectious oocysts into drinking water supplies and irrigation waters. Coprophagous insects that can contaminate food

and fertilizer also contribute to the spread of oocysts. Climate plays an indirect role in allowing better (in the case of moist and hot climate) or worse (in the case of dry and cold climate) survival of oocysts in the environment.

Consumption of undercooked meat of secondary hosts such as pigs and sheep is also a major route of transmission of the disease to humans. The ingestion of undercooked or raw meat during pregnancy is also an important risk factor, because the tissue can contain *T gondii* cysts that, unless destroyed by cooking or by food-preparation practices, could infect a pregnant woman. Heating at 60°C to 100°C for 10 minutes, freezing at either −10°C for 3 days or −20°C for 2 days, or irradiation at doses of 75 to 100 kilo rad is sufficient to kill tissue cysts. Tissue cysts are also killed by gamma irradiation at a dose of 1.0 kGy, but irradiation of meat has not been approved in the European Union (EU). Neither cooking in a microwave oven nor chilling at 5°C for 5 days is sufficient to kill tissue cysts.

The risk of infection rises also in women who taste meat when preparing meals or who eat raw or undercooked beef, lamb, or other meats, but not pork. Eating raw horsemeat imported from non-EU countries can expose consumers to high inocula of highly virulent atypical *T gondii* strains, which can cause a life-threatening primary infection or severe congenital toxoplasmosis with atypical outcome. Transmission during breast-feeding or direct human-to-human transmission other than from mother to fetus (discussed later in the chapter) has not been recorded. Drinking unpasteurized milk and consuming milk products also correlates with increased risk of infections. Although oral transmission is considered the main route of infection, it does not explain the common occurrence of toxoplasmosis in a variety of hosts, such as herbivorous animals, birds, and wild rodents. In this regard, *T gondii* infection has been discovered in particular ticks (i.e., *Haemaphysalis longicornis*) that could serve as a reservoir for secondary toxoplasmosis transmission to other common hosts, if ingested. Other routes are transplacental infection of the fetus, transfusion of white blood cells, and organ transplantation from a seropositive donor to a seronegative recipient.

It is not uncommon for health care professionals, laboratory workers, pet lovers (especially cat owners), butchers, cooks (those handling raw meat), veterinarians, and farmers to acquire acute toxoplasmosis.

Finally, an interesting hypothesis suggested that toxoplasmosis may be transmitted from infected men to noninfected women during unprotected sexual intercourse, resulting in the most dangerous form of disease, the congenital toxoplasmosis. *T gondii* tachyzoites in fact, are present in the seminal fluid and tissue of the testes of various animals including humans.

Dogs can also have a role in the transmission of toxoplasmosis as a mechanical vector by rolling in foul-smelling substances and by ingesting fecal material. Unlike in cats, *T gondii* does not replicate in the dog's gut and no cysts are shed. In areas where dogs and cats are plentiful, immunocompromised persons and pregnant women should be warned of the possibility of acquiring *T gondii* from dogs, as well as from soil contaminated by cats. People should be encouraged to wash their hands after contact with soil, dogs, or cats, as well as before eating.

### Pathophysiology

Disease can occur through acute infection after recent contact with *T gondii* cysts or oocysts or through endogenous reactivation. After ingestion, the sporozoites or bradyzoites invade the intestinal epithelium and differentiate to tachyzoites, which disseminate in the blood and replicate within the new host. The parasite translocation into the blood stream may be a possible consequence of localized intestinal inflammation and enteropathy generated by the parasite, which collectively results in impaired integrity of the intestinal mucosa and gut-blood barrier. Transport of the parasite via the bloodstream can occur intracellularly within dendritic cells or monocytes or as a free tachyzoite. Certain *Toxoplasma* surface antigens aid in the interaction between the tachyzoite and the host cell. One is the perforin-like protein 1 (PLP-1) forming pores in the

host cell membrane after binding, as well as playing a role in egress. The success of *Toxoplasma* as a widespread pathogen is due to the effortlessness with which it can be transmitted among the intermediate hosts. Once inside a host, the parasite develops powerful tools to modulate its host cell and to develop into a chronic infection, undergoing bradyzoite development that can evade the host's immune system as well as, in contrast with acute toxoplasmosis, all known antitoxoplasmic drugs.

Host protection from *T gondii* results from a complex cell-mediated immune response involving inflammatory cells, lymphocytes and macrophages, and cytokines. Inoculum size, parasite virulence (strain), genetic background, time of infection (congenital versus postnatal contamination), and sex also contribute to affect the course of infection in human beings and animal models of toxoplasmosis. In particular, the *T gondii* genotype affects its replication rate, migration, and tendency to differentiate to bradyzoites, virulence, and epidemiologic pattern of occurrence. Type II genotypes (most strains isolated from AIDS patients and newborns with congenital disease) and type III genotypes (mostly isolated from animals) are generally less virulent and more cystogenic compared with type I genotypes (also found in congenital disease). Ocular toxoplasmosis in humans is associated with type I but not type II or III genotypes.

Other than the three major *Toxoplasma* clonal lineages designated as types I, II and III, which are only predominant in Europe and North America (mostly type 2 strain), there are highly polymorphic strains referred to as atypical in South America and Africa, termed Africa 1, 2, and 3.

Genetic background also plays a significant role in increased susceptibility to *T gondii* in humans; HLA-DQ3 appears to be a genetic marker associated with susceptibility to development of TE in patients with AIDS. The mechanisms by which *T gondii* invades host cells and forms an intracellular niche have been extensively reviewed, and several aspects of this process are directly relevant to immunity and pathogenesis. During invasion, three successive waves of proteins are secreted from parasite organelles, (the micronemes, dense granules, and rhoptries) into the host cell. Rhoptry proteins are the major virulence factors of *T gondii* and are located in different parts of the host cells. Blocking the cell intrinsic defense mechanisms of the host lets *T gondii* invade, parasitize, and proliferate in the host successfully. These proteins can alter host cell function and inhibit the immune response directed toward the parasite.

During infection in the intermediate host, *T gondii* undergoes stage conversion between the rapidly dividing tachyzoite that is responsible for acute toxoplasmosis and the slowly replicating, encysted bradyzoite stage. This process of tachyzoite-bradyzoite interconversion is central to the pathogenesis and longevity of infection. In normal conditions, the tachyzoite stage is thwarted by the prompt and efficient interferon- $\gamma$ -dependent cell-mediated immune response, which eventually kills off the majority of the disseminating tachyzoites before eventually entering the persistent form, the bradyzoite. Bradyzoites are encysted within various tissues, most notably the brain but also muscle, eye, and lung, and are infectious to another intermediate host or the cat if eaten. Cell-mediated immune mechanisms thus play a major role in the control of *T gondii* infection because the parasite is exclusively localized intracellularly.

After infection, *T gondii* evokes a powerful and persistent T-helper-1 (Th1) response (dendritic cell activated) together with neutrophils, inflammatory monocytes, and macrophages. The response is characterized by production of proinflammatory cytokines, including interleukin (IL)-12, INF- $\alpha$  and tumor necrosis factor (TNF)- $\alpha$ , which, together with other immunologic mechanisms, protect the host against rapid replication of tachyzoites and subsequent pathologic changes. The outcome of toxoplasmic infection depends on a balance between proinflammatory (IL-12, TNF- $\alpha$ ) and downregulatory (IL-10, IL-27) cytokines that suppress parasite proliferation and control the inflammatory response, respectively.

## Clinical Presentation in the Immunocompetent

Acute acquired toxoplasmosis has traditionally been considered an oligosymptomatic and self-limited infection in previously healthy patients. The typical clinical presentation of acute *T gondii* infection is a short flulike or mononucleosis-like illness that includes prolonged fever, headache, persistent enlarged but firm lymph nodes (rarely painful but initially tender) unattached to the overlying skin, and, occasionally, myalgia and gastrointestinal symptoms that rarely need treatment. Other infectious or non-infectious diseases cause similar symptoms and should always be included in the differential diagnosis: mononucleosis, cat scratch disease, tuberculosis, primary HIV infection, sarcoidosis, metastatic cancer, and lymphoma. In these cases, serologic testing is the initial and primary method of diagnosis.

Lymph node biopsy should be reserved for when *Toxoplasma* serology is uncertain and all other infectious serologic investigations are negative. Hepatomegaly and hepatitis with a moderate increase in liver enzyme levels (a 5- to 10-fold elevation) are common. Lymphocytosis and atypical lymphocytes are other laboratory hallmarks of toxoplasmosis. The spleen appears to be involved early in toxoplasmosis, but palpable splenomegaly is uncommon.

Pneumonia as well as myocarditis, polymyositis, or encephalitis are rarely described in immunocompetent hosts.

Although malaria and dengue are the most common causes of fever in travelers, toxoplasmosis should be considered in the differential diagnosis of fever, particularly in travelers with nonspecific symptoms such as fatigue, fever, headache and lymphadenopathy.

Latent toxoplasmosis is characterized by the lifelong presence of cysts of the parasite in different host tissues, including the nervous system, and by the presence of anamnestic *T gondii* immunoglobulin (Ig) G antibodies in the serum. Long considered asymptomatic, latent toxoplasmosis might increase the risk of schizophrenia and Parkinson's disease; influence human personality and behavior; impair psychomotor performance and increase the risk of suicide (suicide rates have been shown higher in countries with greater *T gondii* prevalence, regardless of national wealth or gross domestic product), traffic accidents, and the probability of the birth of male offspring. Recent studies have also hypothesized that *T gondii* is a risk factor for increasing aggressiveness as well as a murder behavior in women.

Higher rates of *T gondii* seropositivity have been reported for several psychiatric conditions affecting neurotransmitters, especially dopamine, that are implicated in the emergence of psychosis and behavioral *Toxoplasma*-induced abnormalities and in inducing brain inflammation by the direct stimulation of inflammatory cytokines in the central nervous system. Also, there is increasing evidence for a prominent role of immune dysregulation in psychosis and bipolar disorders. Accumulating evidence suggests that a permeabilized gut-blood barrier is present in psychiatric disorders, as demonstrated through studies of microbial translocation and microbiome sequencing that seem to indicate an actively dysbiotic environment in subsets of individuals with psychiatric disorders. RhD phenotype seems to play an important role in the strength and direction of association between latent toxoplasmosis and personality and intelligence.

Toxoplasmosis should also be regarded as an epilepsy risk factor. Epileptogenic mechanisms are probably multifactorial (direct lodgment of parasite, direct modulation of neuronal functions, abnormalities in GABA, role of calcium, etc.), etc. Recently, it was suggested that chronic latent neuroinflammation caused by the parasite may be responsible for the development of several neurodegenerative diseases manifesting with the loss of smell. Olfactory dysfunction reported in Alzheimer's disease, multiple sclerosis, and schizophrenia was frequently associated with the significantly increased serum anti-*T gondii* immunoglobulin G antibody levels.

In addition to above-mentioned manifestation, several recent studies performed in human and animal models have demonstrated that latent or acute toxoplasmosis is associated with

reproductive organs disorders, infertility, sperm abnormalities, behavioral changes, and neurological disorders in pregnant women and other people.

A meta-analysis also suggested chronic toxoplasmosis as a possible risk factor for type 2 diabetes mellitus. However, more accurate studies are needed to better understand this association.

A very important aspect that has emerged in recent years concerns the possible occurrence of toxoplasmosis in patient receiving biotherapies, particularly anti-TNF- $\alpha$  agents for the treatment of rheumatologic diseases and other conditions that need biotechnological drugs. *Toxoplasma* serology should be performed in patients before treatment with TNF- $\alpha$  antagonists is initiated, and patients should be advised to avoid situations that increase risk of exposure to *Toxoplasma*.

### Clinical Presentation in Immunocompromised Patients

The presence of latent bradyzoite cysts, along with the ability of bradyzoites to revert into the active and rapidly growing tachyzoites that can result in often fatal injury, explains the high incidence of acute toxoplasmosis often observed in immunocompromised persons. In immunocompromised hosts and in patients with AIDS, the central nervous system (CNS) is the site most typically affected by infection, and toxoplasmic encephalitis (TE) is the most common manifestation, which typically consists of single or multiple brain lesions. In individuals with AIDS and a CD4 T-cell count  $<100$  cells/ $\mu$ L, the incidence of TE is 28% in seropositive patients not taking prophylaxis. Ocular and pulmonary diseases are the most common extracerebral sites of infection. For *Toxoplasma*, various mechanisms have been proposed for CNS entry, including the so-called "Trojan horse" mechanism, whereby an infected immune cell crosses the BBB, bringing the intracellular parasite with it. TE is also the third most common condition associated with AIDS in Brazil, still accounting for high mortality and morbidity rates despite free access to antiretroviral therapy (ART). However, as in transplant patients or those with malignant hemolymphopathies or solid tumors, other organs such as the lungs or eyes may be involved. Most of these cases result from reactivation of latent infection, although reinfection with a different *T gondii* strain in the transplanted organs can also occur. Although the mortality rate of pulmonary toxoplasmosis was high before the advent of ART, patients with AIDS and recipients of bone marrow transplants are also at risk for development of pulmonary toxoplasmosis, especially patients with very low CD4 cell counts. The clinical manifestations are nonspecific and are similar to those of *Pneumocystis jirovecii*.

In immunocompromised patients with suspected pulmonary toxoplasmosis, conventional staining is the most appropriate method to diagnose for experienced microbiology laboratories, whereas *T gondii*-specific PCR may be useful for laboratories with less experience in parasitology.

The predictive value of elevated blood levels of lactate dehydrogenase is of uncertain value. Patients with TE typically present with headache, confusion, altered mental status, and motor weakness. Focal neurologic deficits or seizures, weakness, sensory abnormalities, cerebellar signs, and neuropsychiatric manifestations are also common. Fever is usually, but not reliably, present. Accompanying nausea or vomiting usually indicates elevated intracranial pressure. Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the brain typically shows multiple contrast-enhancing lesions, often with associated edema. These should be distinguished from other infectious or noninfectious CNS diseases in the course of AIDS.

In immunocompromised patients, the infection can disseminate rapidly and manifests with nonspecific symptoms such as fever and malaise. It can affect a number of organs, including the brain, cerebellum (an uncommon presentation), eye, liver, and lungs, as well as skeletal muscle, bone marrow, bladder, and spinal cord. Cardiac toxoplasmosis can occur during the course of multivisceral dissemination. However, in patients with AIDS, it is usually asymptomatic and found only at autopsy, typically in the setting of widely disseminated infection. Acquired toxoplasmosis with

cutaneous involvement can also occur in the pediatric population, particularly in immunocompromised patients after stem cell transplantation. Early diagnosis and treatment of this life-threatening opportunistic infection may improve patient outcomes.

### Toxoplasmosis of the Eye

Ocular toxoplasmosis is the major cause of visual impairment in high *T gondii* endemic regions of the United States and Europe, where it accounts for 30% to 50% of the infectious posterior uveitis. Toxoplasmosis can affect the retina and the underlying choroid, causing retinochoroiditis, the most common manifestation of ocular toxoplasmosis, which consists in an acute focal-necrotizing retinochoroiditis often adjacent to an old chorioretinal scar. Although the inner retina is the primary site of infection, vitreous, choroid, and sometimes sclera are secondarily affected. Many lesions are self-limiting and heal, forming characteristic unilateral or bilateral pigmented scars in the retina, where *Toxoplasma* cysts are found. Ocular lesions can recur in adolescence and adulthood, even after treatment in infancy. The severity of the disease is mainly a function of the parasite genotype and the host's immune status. Diagnosis in immunocompetent patients is based on the findings of typical ocular manifestations, including eye pain and decreased visual acuity, and may be confirmed by biologic tools applied to intraocular samples for antibody detection (local synthesis of specific antibodies), although PCR is becoming more widely available for direct identification of the parasite DNA in the vitreous and aqueous humor, especially with new methods of detection that can improve its sensitivity. When the clinical symptoms first manifest in immunocompetent patients, the intraocular inflammatory response may reduce the parasitic burden in the aqueous humor and vitreous, thus decreasing the amount of target DNA for PCR amplification. Secretory IgA antibodies in tears have been suggested as a reliable marker of acute ocular toxoplasmosis. Symptoms and signs in immunocompromised patients do not distinguish ocular toxoplasmosis from other ocular infections in HIV, including tuberculosis, *P jirovecii* pneumonia, and CMV retinitis. Toxoplasmic chorioretinitis appears as raised yellow-white, cottony lesions in a nonvascular distribution, unlike the perivascular exudates of CMV retinitis. Vitreal inflammation is usually present, in contrast to ocular toxoplasmosis in immunocompetent patients. Up to 63% of AIDS patients with *Toxoplasma* chorioretinitis have concurrent CNS lesions.

### Maternal Infection and Congenital Toxoplasmosis

Infection with *T gondii* is particularly dangerous for pregnant women because it can lead to the transplacental passage of the parasite from the circulation of the primarily infected mother. Successful pregnancy involves an elegant equilibrium in organizing the immune system at the fetal-maternal and uteri milieu resulting in tolerance (TH2) of the fetus and defense (TH1) against the pathogenic agents. The placenta also plays an important role in trans-placental transmission, as it is a natural barrier to protection of the fetus against infectious agents and also a target tissue for parasite multiplication. In fact, the placental barrier is more efficient to inhibit the tachyzoites transmission at the beginning of gestation, but becomes more permeable at the end of pregnancy.

As tachyzoites bypass the placental blood barrier and invade the fetal organs, they propagate and compromise the embryonic developmental process.

During pregnancy, the prevalence of toxoplasmosis increases throughout the second and third quarter of gestation; simultaneously, progesterone and 17 $\beta$ -estradiol also increase and can aggravate or reduce parasite reproduction. Infection of the placenta is a prerequisite for congenital transmission. More than 60% of infected pregnant women do not experience any symptoms or signs, and the clinical features, when present, are the same as in other immunocompetent persons.

Currently, congenital toxoplasmosis is the second most common intrauterine infection and remains a public health problem throughout the world. The global annual incidence of congenital

toxoplasmosis has been estimated to be 190,100 cases (95% credible interval, CI: 179,300–206,300). This is equivalent to a burden of 1.20 million DALYs (95% CI: 0.76–1.90). High burdens are seen in South America and in some Middle Eastern and low-income countries. The risk of transmission of *T gondii* to the fetus ranges from 0.6 to 1.7 per 1000 pregnant women.

According to Massachusetts Department of Health (United States), about 1 case of congenital toxoplasmosis occurs for every 10,000 live births. Moreover, from 4,000,000 live births each year in the United States, 400 have acquired congenital toxoplasmosis. This rate is markedly higher for other developing countries. In France, about 300 cases are reported each year to the National Reference Center. The frequency of transmission and severity of disease are inversely related.

The development of possible consequences depends on many factors, including the degree of parasitemia in the mother, the maturity of the placenta, the age of the fetus, and immunologic maturity. Early maternal infection (first trimester) can cause severe congenital toxoplasmosis and can result in death of the fetus in utero and spontaneous abortion. Clinical manifestations of congenital toxoplasmosis observed in infancy are numerous and include jaundice, rash, hepatosplenomegaly, anemia, thrombocytopenia, hydrocephalus, microcephalus, intracranial calcifications, convulsions, psychomotor and mental retardation, chorioretinitis, microphthalmia, blindness, strabismus, visual and auditory inflammatory disorders, cardiovascular abnormalities, and pains. All these signs and symptoms are included in the general workup of suspected congenital TORCH infections: toxoplasmosis, other (syphilis, varicella-zoster, parvovirus B19, HIV infection, listeriosis, hepatitis B, Zika virus), rubella, cytomegalovirus, and herpes. The classic triad of bilateral chorioretinitis, hydrocephalus, and cerebral calcifications is exceptional.

Fetal infection at the second trimester results in milder complications, which include splenomegaly, hepatomegaly, cerebral calcifications, pneumonitis, anemia, epilepsy, thrombocytopenia-induced petechiae, rash, and retinochoroiditis. When maternal infection occurs during the third trimester, most of neonates (more than 80%) are asymptomatic; however, retinochoroiditis and neurologic deficits in newborn who may be at high risk for seizures, mental retardation, or delay in growth, as well as in early adulthood, might be developed if these newborns are not treated appropriately in early age. In multiparous women, the risk of infections has been shown twice as high as in nulliparas.

The clinical course of the disease in a child with congenital toxoplasmosis is not influenced by whether the mother showed any clinical symptoms of the disease or was entirely asymptomatic. Infants born to women infected simultaneously with HIV and *T gondii* should be evaluated for congenital toxoplasmosis, considering the increased risk of reactivation of parasitemia and disease in these mothers.

### Diagnosis in the Immunocompetent

In immunocompetent persons, confirmation of acute infection can exclude other potentially more serious etiologies. In other clinical settings where *Toxoplasma* infection can result in severe sequelae, the interpretation of laboratory findings poses significant challenges. The parasite can in fact be present in acute, chronic, latent, or reactivated form. Thus, discrimination of these forms is often crucial in understanding clinical relevance. A schematic diagnostic pathway that can be followed for the diagnosis of toxoplasmosis is shown in Figure 1. Methodical serologic screening for *T gondii* IgG and IgM antibodies in adult symptomatic immunocompetent persons, in pregnant women as early in gestation as possible (preferably in first trimester), and in seronegative women each month or trimester thereafter is optimal. Such screening allows detection of seroconversion and early initiation of treatment.

The laboratory tests used most commonly for initial investigation are serologic, targeting detection of IgG, IgM, and IgA specific for *T gondii* by available commercial kit. In addition to confirming infection, these tests can aid in determining prognosis,

influence management, and assist in monitoring response to treatment. Typically, acute-phase IgM appears first about 1 to 2 weeks after infection, closely followed by IgA and IgE. Generally, IgM peaks at about 2 months. The time at which immunoglobulins can no longer be detected is highly variable depending on the test employed, usually about 6 to 9 months. In a small minority of cases IgM can persist at high levels for up to 18 months or for years, leading to an inaccurate assessment of when the exposure occurred. This circumstance can be problematic because congenital toxoplasmosis can occur if the mother was infected during her pregnancy, and it is thus important to ascertain in which trimester of pregnancy the infection occurred. IgA antibodies are considered to be a marker of acute toxoplasmosis as their kinetics are faster than those of IgM antibodies; however, they can also persist for more than a year, and their detection, together with IgM detection, strongly suggests neonatal infection. IgE serology is highly specific in pregnant women but has low sensitivity, remaining detectable for less than 4 months after infection; moreover, it is not useful in samples from newborns.

To date, an IgM test is still used by most laboratories to determine if a patient has been infected recently or in the distant past, but confirmatory testing (double sandwich or capture IgM-ELISA [enzyme-linked immunosorbent assay] kits and the immunosorbent agglutination assay [IgM-ISAGA]) should always be performed owing to the difficulties in interpreting a positive IgM test result for the relatively high incidence of false-positive results (due to the rheumatoid factor and antinuclear antibodies in some IgM-IFA tests). Thus, a positive IgM test result in a single serum sample can be interpreted as a true-positive result in the setting of a recently acquired infection, a true-positive result in the setting of an infection acquired in the distant past, or a false-positive result. IgM levels decline more rapidly than IgG antibodies, which typically reach maximal levels at about 4 months, then decline to a lower level over the next 12 to 24 months but persist for decades. Elevated IgG levels confirm if a patient has been exposed to the parasite, but they do not differentiate between a recent or past exposure, because IgG persists at a low level throughout the life of the patient. The absence of IgG antibodies in early pregnancy indicates that women are at risk for acquiring toxoplasmosis.

The most commonly used tests for the measurement of IgG antibody are the Sabin-Feldman dye test (still considered the gold standard diagnostic test; it measures primarily IgG antibodies to *T gondii*, but it requires viable *Toxoplasma* organisms), the ELISA, the IFA, and the modified direct agglutination test. Other immunological methods, including chemiluminescence assays (CLIA), enzyme-linked fluorescence assay (ELFA), and immunochromatographic test (ICT), have been developed to improve the ability of diagnosis of *T gondii* infection.

Depending on the method used, the avidity tests currently available (serum IgG avidity test and immunosorbent agglutination assays [ISAGA]) are helpful primarily to rule out that a patient's infection occurred within the prior 4 to 5 months and that the fetus is not at risk for congenital toxoplasmosis. The avidity test that shows low IgG values in a recent *T gondii* infection is most important when only a single serum sample is available at the time when critical decisions must be made. A major problem with this test is that the maturation of the IgG response after a primary *Toxoplasma* infection varies considerably among patients; in fact, low-avidity results can persist for as long as 1 year, and substantial numbers of patients have borderline or equivocal results. These equivocal cases require that in addition to a more careful interpretation of all laboratory test results in conjunction with other clinical findings, other serologic methods should then be undertaken in serology reference laboratories. Recently, a growing number of studies have demonstrated the potential advantages of chimeric or synthetic peptide antigens (EC2 (containing MIC1 and MIC2 antigenic regions) and EC3 (containing M2AP, GRA3 and GRA7 antigenic regions) for the serological diagnosis of toxoplasmosis.

The employment of polymerase chain reaction (PCR) to identify *T gondii* DNA in amniotic fluid (AF) obtained by

First-level *T. gondii* Diagnostic TestDetection of serum anti-*T. gondii* IgM and IgG in first trimester

- If IgM and IgG negative: absence of specific immunity; mother prophylaxis, monthly serologic control\*
- If only IgG is detected: infection likely took place 6–12 months before or before pregnancy; immunity
- If only IgM is detected: initial phase seroconversion of false IgM positivity†
- If IgM and IgG are detected: possible recent infection; consider a more thorough workup (reference laboratory) to try to determine the time of infection in the mother‡

## Second-level Diagnostic Test

## IgG avidity assay

- If negative (high avidity): infection occurred 3–5 months before testing
  - If positive (low avidity): probable recent *T. gondii* infection; repeat serology 3 weeks after the first sample; start spiramycin, ecographic surveillance
- Try to establish a certain or presumed seroconversion in pregnancy and to determine whether the infection was transmitted to the product of conception.

## Third-level Diagnostic Tests (further maternal and fetal assessment)

## In the mother

Detection of *T. gondii*-specific DNA by PCR-AF at 18 weeks of gestation§

- If positive: the fetus has been infected; consider starting treatment and monthly fetal ultrasound examination to detect abnormalities; start pyrimethamine-sulfadiazine¶
- If negative: fetus unaffected; *T. gondii* has not crossed the placental barrier; continue spiramycin¶
- Parasite isolation on tissue culture: mouse inoculation\*\*

## In the newborn

Detection of serum anti-*T. gondii* IgM and IgA††

- If IgM and/or IgA are present at birth: probable congenital infection
- If IgM and/or IgA are not present at birth: monthly control

## Western blot assay of serum IgG and IgM from mother-baby pairs‡‡

- If positive: confirmation of early postnatal diagnosis; therapy and serological control§§
- If negative: monthly control for the first 3 months

**Figure 1** A schematic diagnostic pathway for the diagnosis of toxoplasmosis. \*No treatment is required. †Repeat the tests weekly to detect the appearance of IgG antibodies to confirm the seroconversion. ‡Given that IgM may persist for several months, try to date the beginning of infection through education and counseling to guide the prenatal diagnosis of the patient. §PCR sensitivity is significantly higher for infections occurred between the 17th and 21st week of gestation. ¶If ecographic abnormalities, consider abortion. ¶A negative PCR cannot completely rule out congenital infection; consider follow-up through ultrasounds and continue prophylaxis with spiramycin (Rovamycine) until delivery and neonatal testing. \*\*For confirmation of PCR results; however, they are complex, expensive, and relatively insensitive. ††Limitations because IgA antibodies may persist for several months and are not always produced. ‡‡This test is not widely used mainly because of its technical complexity and high price. §§Administer pyrimethamine (Daraprim)-sulfadiazine therapy and serologic controls after cessation of therapy and every 6 months for the first 2 years.

amniocentesis at 18 weeks and later represents a milestone in the early diagnosis of intrauterine *T. gondii* infection, thereby avoiding the use of more invasive procedures on the fetus. Sensitivity and specificity of PCR may even increase when performed on AF samples obtained from the sixteenth week of pregnancy onward. The specificity and positive predictive value of PCR on AF samples is close to 100%, although different protocols influence its sensitivity and specificity. PCR is generally carried out with various gene targets, of which the most widely used is the 35-fold repetitive gene *B1*. Following it, several multicopy targeting genes including 18S rRNA-, P30-, *B1*-genes, 529-bp repeat fragment or the AF146527 element have been used for the detection of *T. gondii* in different biologic samples. In particular, PCR with the 529-bp RE gene is 10–100 times more sensitive than the *B1* gene.

Results of studies indicated that loop-mediated isothermal amplification (LAMP) and real-time-PCR using AF and CSF are more sensitive and specific methods in congenital infection and immunocompromised patients, respectively, and could be used for early diagnosis of infection and also in follow-up after treatment. Moreover, LAMP on cord blood or whole blood is highly

sensitive, specific, and easy to perform, as it doesn't require expensive equipment.

However, a definitive correlation between the number of *Toxoplasma* organisms in AF and the severity of congenital infection has not yet been demonstrated. PCR should be considered for pregnant women (without a contraindication for the procedure) with positive diagnostic serology or highly suggestive of an infection because of ultrasonographic abnormalities in the fetus acquired during gestation or shortly before conception. If the PCR-AF test result is negative, the fetus should be unaffected, presumably because *T. gondii* has not yet crossed the placental barrier even if it is theoretically possible that fetal infection can occur later in pregnancy from a placenta that was infected earlier in gestation. Samples obtained by cordocentesis, funipuncture, or periumbilical fetal blood sampling should not be used, because fetal risk of contamination with maternal blood is higher than with amniocentesis, and cordocentesis is less sensitive.

In the newborn, diagnosis of infection is based on detection of serum anti-*Toxoplasma* IgM and IgA antibodies that do not cross the placenta, unlike maternal IgG antibodies. Better results are obtained if the ISAGA method is used. Maternal IgG antibodies

present in the newborn can reflect either past or recent infection in the mother and require serologic follow-up of the newborn for the 1st year of life until the complete disappearance of these antibodies. A negative *T gondii*-specific IgG test result at 1 year of age essentially rules out congenital toxoplasmosis. Detection of IgG in oral fluid appears to be a promising tool for monitoring infants with suspected congenital toxoplasmosis.

Detection of specific IgA antibodies appears to be more sensitive than detection of IgM antibodies for establishing infection in the newborn, because these antibodies may be present when there is no *T gondii*-specific IgM, and the converse can also occur. However, transmission of maternal IgM or IgA antibodies can occur during the birth process. Because of the relatively brief half-life of IgM and IgA, positive tests for these antibodies usually must be confirmed by repeat testing at 2 to 4 days of life in the case of IgM antibodies and at 10 days of life for IgA antibodies.

Evaluation of infants with suspected congenital toxoplasmosis should always include ophthalmologic examination, electroencephalogram, hearing test, blood tests, non-contrast CT scanning or ultrasound of the brain, and examination of CSF. Although CT scanning is the first-line diagnostic method used in the United States to detect CNS abnormalities caused by toxoplasmosis, ultrasound can be used as an alternative diagnostic method to avoid the effects of radiation in the neonatal period. Ultrasound is recommended for women with suspected or diagnosed acute infection acquired during or shortly before gestation. This technique can reveal fetal abnormalities, including hydrocephalus, brain or hepatic calcifications, splenomegaly, and ascites. Because most infants do not show signs of toxoplasmosis at birth, a negative ultrasound does not rule out the possibility of infection and might need to be followed by a CT scan for confirmation, because ultrasound results can vary depending on the examiner and technology used. Newborns thus need a thorough examination after birth and follow-up blood tests during the first year of life.

### Diagnosis in the Immunocompromised

In immunocompromised persons and AIDS patients with TE, indirect serologic methods widely used in immunocompetent patients are unreliable because they fail to produce significant titers of specific antibodies. Although incidence of TE among HIV-infected persons directly correlates with the prevalence of anti-*T gondii* antibodies, the absence of IgG antibody makes a diagnosis of toxoplasmosis unlikely, but not impossible. Anti-*Toxoplasma* IgM antibodies are usually absent. CSF findings are normal or show nonspecific alterations such as lymphocytic pleocytosis and discrete CSF hyperproteinorrachia.

In clinical practice, the diagnosis of TE is presumptive and mainly based on clinical presentation, imaging, and laboratory test results. Imaging includes CT or MRI, preferably with gadolinium contrast, and shows isodense or hypodense single or multiple lesions with a mass effect, taking up the contrast dye in a ringlike or nodular manner in more than 90% of cases. However, as neither CT nor MRI can reliably distinguish CNS infections, such as toxoplasmosis, from lymphoma in HIV-1-positive patients, the use of FDG-PET has been shown to offer better sensitivity to noninvasively differentiate cerebral toxoplasmosis and other infectious diseases from primary CNS lymphoma. Laboratory results include the presence of serum-specific *T gondii* IgG antibodies. Diagnosis is also made from an objective response, on the basis of clinical and radiographic improvement, to specific anti-*T gondii* therapy in the absence of a likely alternative diagnosis. In general, the occurrence of low CD4<sup>+</sup> T-cell count (less than 150–200/mm<sup>3</sup>) and the presence of *T gondii* IgG antibody is habitually accepted as being a good predictor of TE reactivation, although less than 6% of TE patients show negative tests. If the suspected diagnosis of toxoplasmosis is correct, clinical or radiographic improvement should become evident by more than 50% within 7 to 14 days. If symptoms persist, a brain biopsy should be performed. This should be considered in immunocompromised patients with presumed CNS toxoplasmosis with a single MRI

lesion, absence of IgG antibodies, or an unsatisfactory clinical response to specific anti-*T gondii* treatment.

Diagnosis of TE is crucial because other brain diseases—such as CNS lymphoma, bacterial abscess, progressive multifocal leukoencephalopathy, viral or fungal encephalitis, neurotuberculosis, cytomegalovirus encephalitis, and focal lesions caused by fungi (*Cryptococcus neoformans*, *Aspergillus* spp., and *Nocardia* spp.)—could share similar clinical and CT scan signs. In general, no imaging technique is completely specific. Thallium single-photon emission computed tomography (SPECT) and positron emission tomography (PET) can be useful in distinguishing toxoplasmosis or other infections from CNS lymphoma. CNS lymphoma has greater thallium uptake on SPECT and greater glucose and methionine metabolism on PET than neurotoxoplasmosis or other infections.

Definitive diagnosis of TE is made by pathologic examination of brain tissue obtained by open or stereotactic CT-guided brain biopsy, although there is morbidity and even death associated with the biopsy procedure. Tachyzoites are demonstrated on hematoxylin and eosin stains or immunoperoxidase staining, which can increase diagnostic sensitivity, or by Giemsa on cyto-centrifuged CSF samples. Toxoplasma organisms must be distinguished from other intracellular organisms such as *Histoplasma*, *Trypanosoma cruzi*, and *Leishmania*.

Since the turn of the twenty-first century, molecular techniques have allowed significant improvement and have been shown to be an important diagnostic tool in laboratory diagnosis of TE. Their use is principally appropriate for immunocompromised patients because these techniques are not affected by the immunologic status of the host. PCR-based assays, in particular, have been shown to be rapid, sensitive, and specific enough to be used as a front-line test for detecting CSF *T gondii* DNA in most patients with CNS infection, thus avoiding invasive and expensive brain biopsy procedures. However, results usually are negative once specific anti-*Toxoplasma* therapy has been started. Moreover, parasite levels in blood and CSF may be very poor in some patients and cause difficulties in interpreting the PCR product. For this reason, a number of quantitative real-time PCRs with specific *T gondii* genome sequence have been developed in the last decade and used in patients with AIDS and CNS damage with different rates of sensitivity and specificity. In this setting, the recent sensitive and specific real-time PCR technique targeting the 529-bp repeat fragment of the *AF146527* element repeated 300 times in the genome of *T gondii* has been demonstrated to exactly quantify the parasite load, allowing correlation with clinical symptoms and impact of treatment. Moreover, the use of real-time PCR with primers targeting the genes *SAG4* and *MAG1* (located in the bradyzoites) and *SAG1* (located in tachyzoites) has shown to be useful to identify relapses of TE in patients in whom the use of PCR with *B1* gene failed to detect DNA, in AIDS patients and other immunocompromised patients especially, when prophylaxis or treatment has been started.

Diagnosis of TE in AIDS patients can also be supported by demonstration of intrathecal antibody production based on detection of oligoclonal bands in CSF with antibody-specific index (ASI) and affinity-mediated immunoblot (AMI) techniques. This approach has also been shown to discriminate TE from other opportunistic CNS infections in AIDS.

In non-AIDS-immunocompromised patients, regular PCR follow-up of allogeneic hematopoietic stem-cell transplant (allo-HSCT) patients could guide preemptive treatment and improve outcome.

### Treatment

An ideal treatment for toxoplasmosis should achieve therapeutic, systemic brain and eye concentrations to be effective in the organs where the majority of disease occurs and should be active against both the acute replicating tachyzoite and latent bradyzoite stages of the parasite. However, current treatments are only capable of suppressing the rapidly dividing tachyzoite stage of the organism. The main goal of treatment is to interrupt

the replication of the parasite and prevent further damage to the organs involved. Nonpregnant immunocompetent patients with acute toxoplasmosis plus lymphadenitis generally do not require antimicrobial therapy because the infection is self-limiting and usually subclinical. Chronic lymphadenopathy accompanied by fever and marked weakness can be cured with specific therapy. Patients whose *T gondii* infection occurred during laboratory accidents or blood transfusions need specific treatment. Pregnant women must be treated to reduce the risk and severity of congenital infection. Immunocompromised patients, including patients with AIDS and transplant recipients, should always be treated with antitoxoplasmic agents. For eye disease, treatment usually includes anti-*Toxoplasma* agents plus systemic corticosteroids. The most important treatment and prophylactic regimens for the therapy of toxoplasmosis are shown in [Tables 1 and 2](#).

The folate synthesis pathway being the best-known therapeutic target against *Toxoplasma*, the main enzymes targeted by pharmaceuticals are the dihydropteroate synthase and dihydrofolate reductase. Since the dihydropteroate enzyme is not found in mammalian cells, it provides a specific target against *Toxoplasma*. The standard pyrimethamine (Daraprim) and trimethoprim (Trimex)<sup>1</sup> are the most widely used dihydrofolate reductase inhibitors. Pyrimethamine, however, is more effective than trimethoprim and is usually administered in conjunction with a dihydropteroate synthase inhibitor (sulfonamide compounds such as sulfadiazine and sulfamethoxazole).

First-line therapy for acquired toxoplasmosis in both immunocompetent and immunodeficient patients consists of the synergistic combination of pyrimethamine and sulfadiazine. Pyrimethamine plus sulfadiazine<sup>1</sup> plus folinic acid (Leucovorin)<sup>1</sup> to prevent hematologic toxicity is the preferred regimen. Azithromycin (Zithromax)<sup>1</sup> or atovaquone (Mepron)<sup>1</sup> may be used as alternate therapy in combination with pyrimethamine or sulfonamides for the treatment and prophylaxis of toxoplasmosis when first-line therapy is contraindicated. Both compounds have been shown to be partially effective against tissue cysts in experimental studies. More recently, however, the search for new and efficient pharmacologic treatments directed against proliferating tachyzoites or the tissue cyst of *Toxoplasma* is under intense and frequent evaluation.

### Treatment During Pregnancy

Management of maternal and fetal infection of *T gondii* varies considerably between different countries and even centers in the same country. According to the European Multicentre Study on Congenital Toxoplasmosis (EMSCOT) data, which suffer from the lack of a large-scale controlled clinical trial, treatment for the fetus should be started immediately (within 3 weeks of infection) after diagnosis of recently acquired maternal infection. This has been shown to significantly reduce sequelae and to have a beneficial effect when therapy is begun soon after birth. Later treatment has been shown to have no effect.

The macrolide antibiotic spiramycin (Rovamycin)<sup>2</sup> is prescribed immediately after diagnosis of maternal infection in most centers in Europe and the United States, and there has been no evidence that this drug is teratogenic. Spiramycin does not cross the placenta but is concentrated in the placenta and protects the fetus from contact with the parasite. It has been estimated to reduce the incidence of vertical transmission of *T gondii* by about 60%. It is used 1 g every 8 hours in many EU countries, especially France, and in Asia and South America and does not seem to have any fetal effects, although a small percentage of women have developed gastrointestinal side effects.

Spiramycin should be continued as prophylaxis until delivery, along with periodic ultrasound examination, because the placenta could have been infected earlier in gestation.

In the case of positive PCR-AF at or immediately after 18 weeks' gestation, or with high probability of fetal infection acquired late in the second trimester (after 18 weeks) or during the third trimester of gestation (because of ultrasound abnormalities), and in women who cannot undergo amniocentesis, the spiramycin regimen should be replaced with the drug combination of sulfadiazine<sup>1</sup> and pyrimethamine plus folinic acid (Leucovorin).<sup>1</sup> This treatment strategy varies in some U.S. and European centers. Folinic acid prevents the toxicity of pyrimethamine without activity against *Toxoplasma*. This combination therapy is used only after confirmed or strongly suspected fetal infection and is never administered in the first trimester of pregnancy due to its teratogenic and hematological adverse effects, in addition to symptoms of nausea in the mother.

Throughout the pregnancy, therapy with pyrimethamine in conjunction with folinic acid should be continued to prevent hematologic toxicities, along with monitoring of blood cell counts and rigorous periodic ultrasound examination. Because spiramycin does not readily cross the placenta, it is not reliable for the treatment of infection in the fetus. In the absence of clinical and laboratory signs suggestive of congenital toxoplasmosis, therapy is not indicated in infants, but it is necessary to inform the specialist and to plan, with the specialist, periodic clinical and serologic controls. In symptomatic infants, the combination of pyrimethamine plus sulfadiazine plus leucovorin is recommended. The duration of this treatment is not specifically defined, but it must be continued for up to a year, possibly alternating cycles of antifolate for 4 weeks with spiramycin cycles of equal duration.

### Ocular Toxoplasmosis

In immunocompetent patients, *Toxoplasma*-related chorioretinitis is usually a self-limited infection and generally may resolve spontaneously in a period of 4 to 8 weeks. However, treatment is recommended for lesions within the vascular arcades, adjacent to the optic disk, or larger than 2 optic disk diameters to reduce the chance of vision loss. In general, pyrimethamine, sulfadiazine<sup>1</sup> plus folinic acid<sup>1</sup>, and corticosteroids form the most common drug combination currently used to treat ocular toxoplasmosis. Patients may also be treated with TMP-SMX,<sup>1</sup> which appears to be a safe and effective substitute for pyrimethamine, sulfadiazine, and folinic acid, or with azithromycin<sup>1</sup> or intravitreal clindamycin (Cleocin)<sup>1</sup> and prednisone for 4 to 6 weeks. Pyrimethamine plus azithromycin is another drug combination that is similar to the standard treatment and can be considered an acceptable alternative treatment for sight-threatening ocular toxoplasmosis. *Toxoplasma* retinochoroiditis in immunocompromised patients requires immediate treatment. Atypical presentations also warrant treatment.

Recurrent toxoplasmic retinochoroiditis, probably related to the rupture of the dormant retinal cyst or *Toxoplasma* circulating in peripheral blood, remains a major health crisis and can be associated with severe morbidity if the disease extends to structures critical for vision, including the macula and optic disk. Severe morbidity can also occur if there is damage to the eye from inflammation or if there are complications such as retinal detachment or neovascularization. In patients with frequent recurrences, the rate of recurrent toxoplasmic retinochoroiditis can be significantly reduced by long-term intermittent treatment with TMP-SMX 160 mg/800 mg (Bactrim DS)<sup>1</sup>, with one tablet administered three times a week as a prophylactic regimen. Intravitreal clindamycin<sup>1</sup> injection and possibly steroids may be an acceptable alternative to the classic treatment in ocular toxoplasmosis. It can offer the patient more convenience, a safer systemic side effect profile, greater availability, and fewer follow-up visits and hematologic evaluations. Although research has identified wide variation in practices regarding the use of corticosteroids, a recent Cochrane review did not identify evidence from randomized controlled trials for the role of corticosteroids in the management of ocular toxoplasmosis. The question of foremost importance, however, is

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not commercially available in the United States.

**TABLE 1** Treatment Regimens for Toxoplasmosis

PATIENTS	DRUG OF CHOICE	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION	ADVERSE EFFECTS
Acute infection in <i>T gondii</i> seropositive pregnant patients with undocumented fetal infection	Spiramycin (Rovamycin) <sup>2</sup>	1000 mg PO q8h (without food)	Throughout pregnancy or until fetal infection is documented	Mild GI disturbances, possible skin eruptions
Acute infection in a pregnant patient with documented fetal infection (positive PCR-AF)	Pyrimethamine (Daraprim) <sup>*</sup> <i>plus</i>	Loading dose, 50 mg PO q12h × 2 d, then 50 mg PO daily	Throughout pregnancy; avoid before 18th wk of gestation because of high risk of teratogenesis	Pyrimethamine is a potential teratogen (kidney and heart malformation) and should be used only after the first trimester
	Sulfadiazine <sup>1</sup> <i>plus</i>	Loading dose 75 mg/kg PO, then 50 mg/kg q12h (max 4 g daily) 10–20 mg PO daily	Throughout pregnancy; do not administer before 18th wk of gestation <sup>†</sup>	Sulfadiazine can cause crystal-induced nephropathy <sup>‡</sup>
	Folinic acid (Leucovorin) <sup>1</sup>		During and for 1 wk after pyrimethamine use	Complete regimen: rash, fever and dose-dependent myelosuppression; weekly monitoring of blood cell counts
Congenital infection in the infant	Pyrimethamine <i>plus</i>	Loading dose 2 mg/kg PO daily × 2 d; then 1 mg/kg PO daily × 2–6 mo; then 1 mg/kg tiw	1 y	Same as above
	Sulfadiazine <sup>1</sup> <i>plus</i>	50 mg/kg PO q12h	1 y	
	Folinic acid <sup>1</sup>	10 mg/kg PO tiw	During and for 1 wk after pyrimethamine use	
Acute <i>T gondii</i> infection in adult immunocompetent patients and in pregnant patients infected > 6 mo before conception	Treatment not recommended or, if acutely ill: Pyrimethamine <i>plus</i>	Loading dose 200 mg PO daily in 2 divided doses, then 0.5–1 mg/kg/d (max 50 mg/d; 75 mg (if >60 kg)	4–6 wk, or 1–2 wk after resolution of symptoms	Same as above
	Sulfadiazine <sup>1</sup> <i>plus</i>	1000–1500 mg PO q6h	During and 1 wk after pyrimethamine use	
	Folinic acid <sup>1</sup>	5–20 mg PO tiw		
Chorioretinitis in immunocompetent patients	Pyrimethamine <sup>5,1</sup> <i>plus</i>	200 mg loading dose, then 50–75 mg PO daily	1–2 wk after resolution of symptoms	
	Sulfadiazine <sup>5,1</sup> <i>plus</i>	1000–1500 mg PO q6h	1–2 wk after resolution of symptoms	
	Folinic acid <sup>1</sup> <i>plus</i>	5–20 mg PO tiw	During and for 1 wk after pyrimethamine use	
	Prednisone	1 mg/kg daily in 2 divided doses	Until resolution of signs and symptoms	
<i>Alternatives</i>				
	TMP-SMX (Bactrim) <sup>1</sup> <i>or</i>	160–800 mg q12h	6 wk	Skin rash, fever, leukopenia, thrombocytopenia, hepatotoxicity; also available as an IV formulation
	Azithromycin (Zithromax) <sup>1</sup> alone <i>or</i> associated with pyrimethamine <i>or</i> Intravitreal clindamycin (Cleocin) <sup>1</sup> -dexamethasone (Decadron)	500 mg/d	5 wk	Not reported
		One injection 1–400 mcg	Not reported	Not reported
<i>For untreatable cases only</i>				
	Photocoagulation	Not usually done	Not reported	Not reported

*Continued*

**TABLE 1** Treatment Regimens for Toxoplasmosis—cont'd

PATIENTS	DRUG OF CHOICE	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION	ADVERSE EFFECTS
Immunocompro-mised patients and patients with TE <sup>1</sup>	Pyrimethamine <i>plus</i>	Loading dose 200 mg PO, then 50–75 mg PO daily	At least 4–6 wk after signs and symptoms resolve	Same as above
	Folinic acid <sup>1</sup> <i>plus either</i> Sulfadiazine <i>or</i> Clindamycin <sup>1,†</sup> <i>plus</i> Prednisone	10–20 mg PO or IV or IM daily (max 50 mg daily) 1000–1500 mg PO q6h 600 mg PO or IV q6h (max 1200 mg q6h) 1 mg/kg daily in 2 divided doses	During and for 1 wk after pyrimethamine use At least 4–6 wk after signs and symptoms resolve Until improvement of edema or mass effect related to focal lesion	Rash, fever, diarrhea, hepatotoxicity Fever, rash, diarrhea, hepatotoxicity
	<i>Alternatives</i> TMP-SMX <sup>1</sup> alone <i>or</i>	5 mg/kg TMP PO or IV q12h (max 15–20 mg/kg/d)	Same as above	Same as above
	Pyrimethamine <i>plus</i> folinic acid <sup>1</sup> <i>plus one of the following:</i>	Same as above abovepyrimethamine and folinic acid doses 500 mg PO q12h	Same as above	Same as above
	Clarithromycin (Biaxin) <sup>1</sup>		At least 4–8 wk after resolution of signs and symptoms	
	Atovaquone (Mepron) <sup>1</sup>	750 mg PO q6h 1200–1500 mg PO daily	Not reported	Atovaquone can increase LFTs and skin rash Take with a meal to enhance absorption
	Azithromycin <sup>1</sup>	100 mg PO daily	Not reported	
	Dapsone <sup>1</sup>	750 mg PO q6h	Not reported	
	Atovaquone (Mepron) <sup>1</sup> alone or with sulfadiazine	1000–1500 mg PO q6h	Not reported	
	Acute infection in patients with <i>T gondii</i> and HIV infection <sup>**</sup>	Spiramycin <sup>2</sup> (as for immunocompetent pregnant women)	1,000 mg PO q8h (without food)	Throughout pregnancy or until fetal infection is documented

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not commercially available in the United States.

\*Take with food to minimize gastrointestinal adverse effects.

<sup>†</sup>This might change in some European countries.

‡Should be taken on an empty stomach with adequate water.

<sup>‡</sup>Take both for 3 weeks followed by 1 week off; repeat for 3 or 4 cycles.

§After initial phase of therapy, maintenance therapy must be continued as long as the patient remains immunocompromised.

¶Clindamycin can be used instead of sulfadiazine in patients intolerant to sulfonamides.

\*\*Amniocentesis should be avoided because of the risk of transmitting HIV infection to the fetus.

Abbreviations: GI, gastrointestinal; LFT, liver function test; PCR-AF, polymerase chain reaction testing of amniotic fluid; TMP-SMX, trimethoprim-sulfamethoxazole.

whether they should be used as adjunct therapy (that is, in addition) to antiparasitic agents. There is no evidence to support that one antibiotic regimen is superior to another, so choice needs to be informed by the safety profile. Intravitreal clindamycin with dexamethasone<sup>1</sup> seems to be as effective as systemic treatments. There is currently level I evidence that intermittent trimethoprim-sulfamethoxazole prevents recurrence of the disease.

### Toxoplasmosis in Immunosuppressed Patients

With the advent of the ART, the natural course of HIV infection has markedly changed, and opportunistic infections including toxoplasmosis have declined and changed in presentation, outcome, and incidence. However, TE is a major cause of morbidity and mortality, especially in resource-poor settings, and it is a common neurologic complication in some countries despite the availability of ART and effective prophylaxis. The initial therapy of choice in TE patients consists of the combination of pyrimethamine, which is able to penetrate the brain parenchyma efficiently even in the absence of inflammation, plus sulfadiazine or clindamycin<sup>1</sup> plus folinic acid.<sup>1</sup>

Adjunctive corticosteroids should be administered when clinically indicated only for treatment of a mass effect associated

with focal lesions or associated edema and for a short time because of their potential immunosuppressive effects. Patients receiving corticosteroids should be closely monitored for the development of other effects, including CMV retinitis and tuberculosis. Anticonvulsants should be administered to patients with a history of seizures, but should not be administered prophylactically to all patients. Drug interactions between anticonvulsants and antiretroviral agents should be carefully evaluated, and doses should be adjusted according to established guidelines. The preferred alternative regimen for patients unable to tolerate or who fail to respond to first-line therapy is pyrimethamine plus clindamycin<sup>1</sup> plus leucovorin.<sup>1</sup> Common clindamycin toxicities include fever, rash, nausea, diarrhea (including pseudomembranous colitis or diarrhea related to *Clostridium difficile* toxin), and hepatotoxicity. Other alternative regimens shown in Table 1 are active in the treatment of TE and may be used in sulfa-intolerant patients or those who have not responded to treatment, although their relative efficacy compared with the previous regimens is unknown.

The combination of atovaquone (Mepron)<sup>1</sup> with either pyrimethamine or sulfadiazine has demonstrated utility for the treatment of acute TE in patients with a Karnofsky Performance Status Score greater than 30, which combines the

**TABLE 2** Prophylaxis Regimens for Toxoplasmosis

PATIENTS WHO SHOULD RECEIVE PROPHYLAXIS	DRUG OF CHOICE*	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION
Primary prophylaxis for immunocompromised patients, including advanced pregnant HIV-positive women (CD4 <sup>+</sup> count < 100 cells/mm <sup>3</sup> and <i>T gondii</i> IgG positive)	First choice: TMP-SMX (Bactrim) <sup>1</sup>	1 DS tab 160–800 mg PO daily	For life or until immunoreconstitution has occurred <sup>†</sup>
	<i>Alternatives</i>		
	Pyrimethamine (Daraprim) <sup>1</sup> <i>plus</i>	50–75 mg/wk	
	Dapsone <sup>1</sup> <i>plus</i>	50 mg/d	
	Folinic acid <sup>1</sup> <i>or</i>	25 mg/wk	
	Pyrimethamine-sulfadoxine (Fansidar) <sup>1</sup> <i>plus</i>	1 tab twice weekly	Same as above
	Folinic acid <sup>1</sup> <i>or</i>	25 mg/wk	Same as above
Atovaquone (Mepron) <sup>1</sup>	1,500 mg PO daily	Same as above	
Secondary prophylaxis for immunocompromised patients after primary or induction treatment	Same regimen used in the acute phase: TMP-SMX <sup>1</sup>	Half doses of those used in the acute phase 2.5 mg/kg TMP PO or IV q12h, max 15–20 mg/kg/d	For life or until immunoreconstitution has occurred <sup>†</sup>
Prophylaxis in adults receiving heart, lung, or liver transplant, especially in the case of a seropositive donor (D +) and seronegative recipient (R –) <sup>‡</sup>	First choice: TMP-SMX <sup>1</sup>	80 mg TMP/400 mg SMX (1 tab single-strength Bactrim) twice daily	For 6 wk after transplant
	<i>Alternative</i>		
	Pyrimethamine <sup>1</sup> <i>plus</i>	50–75 mg PO daily	Same as above
	Folinic acid <sup>1</sup>	5–10 mg PO daily	During and for 1 wk after pyrimethamine use
Prophylaxis in adults receiving bone marrow and allogeneic stem cell transplants <sup>§</sup>	First choice: TMP-SMX <sup>1</sup>	Same as above <sup>¶</sup>	For more than 6 mo
	<i>Alternatives</i> <sup>¶</sup> : Pyrimethamine <sup>1</sup> <i>plus</i> Clindamycin (Cleocin) <sup>1</sup> <i>plus</i> Folinic acid <sup>1</sup>	Not standardized	Not reported
Prophylaxis for accidental laboratory exposure and blood transfusions	Pyrimethamine <sup>1</sup> <i>plus</i> Sulfadiazine <sup>1</sup> <i>plus</i> Folinic acid <sup>1</sup>	Same as for acute infection* <sup>**</sup>	2 wk

<sup>1</sup>Not FDA approved for this indication.

\*For side effects, see Table 1.

<sup>†</sup>In patients with AIDS, primary and secondary prophylaxis are generally discontinued when the patient's CD4<sup>+</sup> cell count has returned to more than 200 cells/μL and HIV PCR peripheral blood viral load has been reasonably controlled for at least 6 months following ART.

<sup>‡</sup>Preemptive antiparasite treatment should be considered for all symptomatic, seropositive, immunocompromised patients in whom toxoplasmosis is suspected.

<sup>§</sup>There are no clear recommendation for anti-*T gondii* prophylaxis in allogeneic stem cell transplantation, because the optimal regimen has not yet been determined. INot specifically codified.

<sup>¶</sup>Alternative regimen in sulfonamide-allergic patients.

<sup>\*\*</sup>Presumptive therapy should be given with the same dosages as for acute infection and monitored serologically for several months after the exposure or until seroconversion is noted; that is, testing immediately after the exposure, weekly for at least 1 month, and at least monthly thereafter. Seroconversion can occur despite presumptive therapy. Although presumptive therapy typically prevents disease or at least substantial morbidity, it does not necessarily prevent infection.

Abbreviations: ART, highly active retroviral therapy; PCR, polymerase chain reaction; TMP-SMX, trimethoprim-sulfamethoxazole.

ability to work, to undertake normal activities without external assistance, and to take care of personal needs. Acute therapy should be continued for at least 6 weeks, if there is clinical and radiologic improvement. This should be followed by maintenance therapy (lifelong secondary prophylaxis), usually with the same regimen that was used in the acute phase but at half doses (see Table 2).

Recent findings indicate that daily pyrimethamine-based maintenance therapy is likely more efficacious in preventing TE relapse compared with intermittent therapy. Moreover, the likelihood of relapse associated with pyrimethamine-based therapy in patients with HIV and TE decreased after the introduction of HAART

<sup>1</sup>Not FDA approved for this indication.

to approximately 11%. Relapse may thus affect a patient's disease severity and prognosis, increase utilization of health care resources, and result in additional health care expenditure. Currently, maintenance treatment should be continued for the life of the patient or until underlying immunosuppression has ceased (immune reconstitution resulting from ART). Adult and adolescent patients appear to be at low risk for recurrence of TE when they have successfully completed initial therapy, remain asymptomatic with respect to signs and symptoms, and have a sustained (i.e., more than 6 months) increase in their CD4<sup>+</sup> T-lymphocyte counts to greater than 200 cells/ $\mu$ L on ART. AIDS patients with CD4<sup>+</sup> T-cell counts less than 100/ $\mu$ L and IgG *Toxoplasma* antibody should receive primary prophylaxis for toxoplasmosis. Fortunately, the same daily regimen of one double-strength tablet of TMP/SMX (Bactrim DS) used for *Pneumocystis jirovecii* prophylaxis provides adequate primary protection against toxoplasmosis. Secondary prophylaxis for toxoplasmosis may be discontinued in the setting of effective ART and when CD4<sup>+</sup> T-cell counts increase to more than 200/ $\mu$ L for 6 months.

Prophylaxis and treatment measures of disease in bone marrow transplant recipients as well as in those receiving organ transplantation are shown in Table 2. Universal prophylaxis with TMP/SMX in allo pre-hematopoietic cell transplant seropositive recipients (HCTSP) should be implemented by all transplant programs. Preemptive treatment with routine blood PCR monitoring is an option if prophylaxis cannot be used.

### T gondii Infection During Pregnancy in HIV-Positive Women

Immunocompromised women with chronic infection do rarely transmit the parasite to the fetus, resulting in congenital infection. This includes women with AIDS, as well as those on immunosuppressive treatment. Vertical transmission occurs in up to 4% of cases, particularly when the CD4<sup>+</sup> count is less than 100/mm<sup>3</sup>. The risk of transmission is low when the CD4<sup>+</sup> count is greater than 200/mm<sup>3</sup> (see Table 2).

Consideration should be given to screening all immunosuppressed women for evidence of maternal *T gondii* serologic status to establish an early diagnosis of reactivation. Seropositive women with low CD4 counts should receive TMP-SMX (Bactrim)<sup>1</sup> to prevent reactivation of *Toxoplasma*. Because of reports of congenital toxoplasmosis in mildly or moderately immunosuppressed women, it is recommended that immunocompromised women not infected with HIV and women who are infected with HIV and who have CD4 counts less than 200/mm<sup>3</sup> be treated with spiramycin (Rovamycin)<sup>2</sup> for the duration of the pregnancy. A nonpregnant woman who has been diagnosed with an acute *T gondii* infection should be counseled to wait 6 months before attempting to become pregnant. Each case should be considered separately in consultation with an expert.

Detailed ultrasound examination of the fetus specifically evaluating for hydrocephalus, cerebral calcifications, and growth restriction should be done for HIV-1-infected women with suspected primary or symptomatic reactivation of *T gondii* during pregnancy.

### Prevention

Strategies for the primary prevention of toxoplasmosis in pregnant women and in immunosuppressed patients with negative serology are shown in Box 1.

### Screening

Secondary prevention by serologic monitoring of seronegative pregnant women should be closely connected with detailed primary prevention. Routine toxoplasmosis screening programs for pregnant women have been established in France, Austria, and Brazil. In France, guidelines recommend that nonimmune pregnant women be tested monthly throughout pregnancy to detect seroconversion to *Toxoplasma* infection. In the United States, routine serologic screening is not performed. In Italy, serologic screening is recommended to prevent congenital toxoplasmosis as

part of the antenatal care protocol (TORCH). Serologic screening of women should begin before conception, with follow-up monthly tests during pregnancy to detect seroconversion. This is the basis for the French screening program and the Austrian Toxoplasmosis Prevention Program, which recommend routine serologic testing. Treatment is recommended if one of the tests suggests definite or probable primary maternal infection.

### Vaccine

Vaccination is one of the most efficient strategies to prevent and control the spread of toxoplasmosis by immunization of humans and animals (the source of infection). To date, there is much debate about whether a human vaccine is feasible. Costs, target population, method for testing the vaccine, and risks associated with the vaccine are important factors affecting development of the vaccine. Much of the work has been focused on SAG1, a surface antigen expressed on tachyzoites, in attempts to induce protective immune response when introduced to the host with various adjuvants. SAG1 is primarily involved in adhesion, signal transduction, invasion, material transport and host immune responses. Thus, this protein may be crucial for both the diagnosis of *T gondii* infection and the ability to immunize against this parasite.

In general, a simpler route to prevent human disease would be to vaccinate animals (cats and intermediate hosts) that are responsible

#### BOX 1

#### Strategies for the Primary Prevention of Toxoplasmosis in Pregnant Women and in Immunosuppressed Patients With Negative Serology

- Check immunity to toxoplasmosis. If the patient has no protection (absence of anti-*Toxoplasma* IgG), take direct or indirect prophylactic measures against cats, food, and water.
- Universal prophylaxis with TMP/SMX<sup>1</sup> in all pre-HCTSP patients should be implemented by all transplant programs. Preemptive treatment with routine blood PCR monitoring is an option if prophylaxis cannot be used.
- Avoid contact with food (including unwashed fruit or vegetables) or water potentially contaminated with cat feces. Wash before consuming.
- Avoid any job or activity that requires contact with dirt, soil, or other material potentially contaminated with cat feces (e.g., gardening or handling cat litter). Wear gloves when gardening or handling cat litter.
- Keep cats inside. Do not adopt or handle stray cats. Do not feed cats raw or undercooked meat but only canned or dried commercial food or well-cooked food. Do not obtain a new kitten or cat during pregnancy.
- Disinfect the cat litter box with near-boiling water for 5 minutes before handling.
- Wash hands thoroughly after contact with raw meat.
- Kitchen surfaces and utensils that have come in contact with raw meat should be washed.
- Avoid ingesting raw or dried meat, raw eggs, or unpasteurized milk.
- Avoid eating raw oysters, clams, or mussels.
- Protect foods from flies, cockroaches, and other insects.
- Avoid touching the eyes or face or any mucous membrane during or immediately after preparing food.
- Cook meat thoroughly. Pork, lamb, beef, veal, and poultry should be cooked until the meat reaches 80°C in the center.
- Refrain from skinning animals.
- Avoid children's sandboxes.
- Avoid contact with stray dogs (xenosmophilia); if this is not possible, wash your hands after contact.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

for transmission to humans, as demonstrated using a live attenuated vaccine developed for the prevention of chronic infection in sheep. However, it cannot be used in humans because of the risk of reversion to a pathogenic form. Vaccine development to prevent feline oocyst shedding is ongoing, mostly involving live vaccines. More recently, *T gondii* dense granule proteins including GRA-6, a secretory vesicular organelle that produces proteins that participate in the modification of the parasitophorous vacuole, have been shown to be suitable as possible DNA vaccines for immunity against toxoplasmosis. Recombinant rhoptry effector protein 54 (ROP54) plasmid has demonstrated to provide partial protection against acute and chronic toxoplasmosis. Finally, aspartic protease 1 (Asp 1) has also shown to play an essential role in the *T gondii* lifecycle, thus being a potential vaccine candidate against toxoplasmosis.

In summary, the immune evasive nature and complex life cycle of *T gondii* has made the design of immunotherapeutics aimed at providing complete protection, a discouraging challenge. Generally, vaccine studies thus far have shown that multi-antigenic formulations confer better protection than single-subunit vaccines.

## TYPHOID FEVER

Method of

Tamilarasu Kadhiraan, MD

### CURRENT DIAGNOSIS

- Typhoid fever typically manifests as an undifferentiated acute febrile illness.
- Soft splenomegaly, normal or low white blood cell count, and elevated liver enzymes are subtle diagnostic pointers.
- Blood culture, drawn before antibiotic administration, is the most useful investigation.
- Consider presumptive treatment in appropriate epidemiologic settings.

### CURRENT THERAPY

- Intermediate susceptibility and resistance to fluoroquinolones are widespread among *Salmonella enterica* Typhi.
- High-dose fluoroquinolones are suboptimal for treating such infections.
- Azithromycin (Zithromax)<sup>1</sup> is the preferred drug for uncomplicated typhoid fever.
- Ceftriaxone (Rocephin)<sup>1</sup> is preferred for treating hospitalized and seriously ill patients.
- Extensively drug-resistant (XDR) typhoid fever, which is resistant to ceftriaxone and fluoroquinolones, is an emerging threat.

<sup>1</sup>Not FDA approved for this indication.

Typhoid fever is a bacteremic infection caused by the gram-negative bacillus *Salmonella enterica* serovar Typhi. *S enterica* Paratyphi also causes an illness clinically indistinguishable from typhoid fever. Humans are the only known host of *S enterica* Typhi, and it is transmitted by ingestion of contaminated food or water. Improvement in sanitation and hygiene led to the elimination of typhoid fever from the developed world long before the advent of antibiotics. On the other hand, in parts of the world lacking sanitation, it continues to be an important cause of febrile illness despite the availability of effective antibiotics.

### Epidemiology

Typhoid fever is endemic in the developing world, especially the South and South East Asian countries of India, Nepal, Pakistan, Bangladesh, Vietnam, and Indonesia. Annual incidence in endemic settings is typically more than 100 cases per 100,000 population, and it predominantly affects children and young adults. Apart from sick persons with typhoid fever, convalescent carriers and asymptotically infected food handlers (long-term carriers) are the sources of infection. Potential vehicles of infection include food or water consumed from roadside eateries, ice cubes and ice cream made from contaminated water, and raw vegetables and fruits. In contrast, most cases of typhoid fever in developed countries are imported by travel, especially to the Indian subcontinent.

### Pathogenesis and Clinical Features

Following ingestion, the bacilli invade and multiply in the small-intestinal lymphoid tissue before entering the bloodstream. This primary bacteremia leads to widespread seeding of the reticuloendothelial system and intestinal lymphoid tissue, where the infection is amplified and spills over into the circulation. Onset of symptoms usually coincides with this secondary bacteremia. Interestingly, unlike other gram-negative bacteremic infections, septic shock develops relatively late in the course of illness, and the infection can be eminently cured by oral antibiotic therapy.

**BOX 1** Complications of Typhoid Fever**Abdominal**

Paralytic ileus  
 Intestinal hemorrhage  
 Intestinal perforation  
 Secondary peritonitis  
 Symptomatic liver dysfunction  
 Acalculous cholecystitis

**Extra abdominal**

Encephalopathy  
 Cerebellar dysfunction  
 Myocarditis  
 Osteomyelitis and soft tissue abscesses  
 Multiorgan dysfunction syndrome  
 Hemophagocytic syndrome  
 Hemolysis  
 Glomerulonephritis

**Long-term**

Gallbladder cancer

Nonetheless, it should be emphasized that any delay in initiating antibiotic therapy increases the risk of complications (Box 1).

During the first week, temperature gradually increases in a step-ladder fashion. Localizing symptoms are usually minimal. Anorexia, lassitude, and malaise are often marked. Headache and vomiting are common; however, a supple neck helps rule out meningitis. Abdominal symptoms such as constipation, loose stools, and abdominal pain are not infrequent, but they are nonspecific and often overlooked. Soft, tender enlargement of liver or spleen is seen in about half the patients. Rose spots and relative bradycardia, though classic, are rare. When the infection goes untreated, hypertrophied lymphoid tissue of the Peyer's patches can ulcerate toward the end of the second week, resulting in torrential gastrointestinal bleeding, small intestinal perforation, and secondary bacterial peritonitis. Patients with severe illness can present with a muttering delirium described as *coma vigil*. Untreated typhoid fever often resolves spontaneously in about 4 to 6 weeks. However, the risk of death is high (>10%), and relapses are frequent. Many patients excrete *S. enterica* Typhi in feces and urine during convalescence (convalescent carriers), and some of them continue to excrete beyond 1 year (long-term carriers).

**Current Pattern of Antimicrobial Susceptibility**

Since 1990, a sea change has occurred in the antimicrobial susceptibility of *S. enterica* Typhi in endemic countries and elsewhere. Unregulated use of fluoroquinolones initially led to the emergence of *S. enterica* Typhi strains with decreased susceptibility. These strains had a subthreshold increase in minimal inhibitory concentration (MIC) that was not detected by conventional disk-diffusion testing. Hence, resistance to nalidixic acid (NegGram)<sup>2</sup> (a quinolone) was often used as a surrogate marker for such strains. Currently, determination of MIC is recommended to identify fluoroquinolone susceptibility. Most infections in endemic countries are now caused by *S. enterica* Typhi with intermediate susceptibility or resistance to fluoroquinolones. Not surprisingly, this change is reflected in far-away geographic locales such as the United States and the United Kingdom. Of late, sporadic instances of resistance to azithromycin and third-generation cephalosporins have been reported. Notably, an ongoing outbreak of extensively drug-resistant (XDR) *S. enterica* Typhi with extended-spectrum  $\beta$ -lactamase-mediated resistance to third-generation cephalosporins has been reported in the Sindh province of Pakistan. In 2019, two-thirds of *S. enterica* Typhi isolates from Karachi, Pakistan, were resistant to third-generation

cephalosporins. Travel-associated XDR-typhoid cases have been reported from several countries in the Europe and North America.

**Diagnosis**

Clinical features are nonspecific, and laboratory testing is essential to confirm a diagnosis of typhoid fever. A soft splenomegaly, absence of leukocytosis, mild leukopenia, and modest elevation of transaminases are subtle pointers to a diagnosis of typhoid fever. Blood culture drawn early in the illness before initiation of antibiotics is often fruitful and is the gold standard for the diagnosis of typhoid fever. The time-honored Widal test, which detects agglutinating antibodies to somatic and flagellar antigens of *S. enterica* Typhi, adds little to decision making. Initial enthusiasm about rapid serologic tests such as Typhidot and Tubex TF has not been confirmed in community-based studies. None of these tests are sensitive enough to rule out typhoid. In a patient who has non-localizing acute febrile illness lasting more than 5 to 7 days in a suggestive epidemiologic setting (residence in or travel to endemic area; outbreaks), it is prudent to treat presumptively for typhoid fever, after reasonably ruling out competing diagnoses such as malaria, dengue, leptospirosis, and rickettsial infection.

**Treatment**

Fluoroquinolones (ciprofloxacin [Cipro] or ofloxacin [Floxin]<sup>1</sup> 7.5 mg/kg twice a day for 5–7 days) were unparalleled in efficacy for treating fully susceptible *S. enterica* Typhi strains. However, their use was associated with frequent treatment failures, prolonged defervescence, and higher rates of complications in nalidixic acid-resistant *S. enterica* Typhi (NARST) infections. Given the widespread emergence of reduced susceptibility, fluoroquinolones are no longer considered the drug of choice. Several alternatives have been evaluated in randomized, controlled trials for treating uncomplicated typhoid fever caused by NARST (Table 1). Ease of oral administration, proven efficacy, and safety (under FDA review) make azithromycin (Zithromax)<sup>1</sup> a good first choice for uncomplicated typhoid fever. In hospitalized seriously ill patients and treatment failures, parenteral ceftriaxone (Rocephin)<sup>1</sup> is preferred. Usually, it takes about 4 to 7 days for defervescence after the initiation of antibiotics.

Recently, combining oral azithromycin (500 mg qd) with ceftriaxone (2 g qd) for inpatient or cefixime (Suprax)<sup>1</sup> (400 mg qd) for outpatient treatment was found to shorten the fever clearance time by about 7 hours, and fewer patients had persistent bacteremia on Day 3 (17% vs 4%). This clinical trial had certain limitations, and I do not recommend using a combination of antibiotics to treat typhoid fever. Despite in vitro susceptibility, aminoglycosides and first- and second-generation cephalosporins are not effective clinically for treating typhoid fever. Azithromycin (20 mg/kg qd for 7 days)<sup>3</sup> and meropenem (Merrem<sup>1</sup>; 20 mg/kg tid for 14 days) are the only options currently available for the treatment of XDR-typhoid. Antipyretics should be used for symptom relief; ibuprofen (Motrin; 10 mg/kg every 6 hours) is superior to acetaminophen (Tylenol; 12 mg/kg every 6 hours). However, ibuprofen should be avoided when dengue fever is a possibility. A soft, low-residue diet is traditionally advised to prevent intestinal perforation. Such a practice, however, is not founded on scientific evidence. Treatment of *S. enterica* Paratyphi infection is identical to that of *S. enterica* Typhi infection.

**Prevention**

Sustained improvement in sanitation and access to safe drinking water are essential to control typhoid fever in endemic areas. Avoiding potentially contaminated food and beverages and being vaccinated before travel decrease the risk of typhoid fever among travelers (see the article on travel medicine). Mass administration of the Vi polysaccharide vaccine (Typhim Vi, Typherix [outside United States]) has been found to confer herd immunity and is a potential tool for the control of typhoid fever in endemic settings.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>2</sup>Not available in the United States.

**TABLE 1** Outcomes of Alternative Treatments for Nalidixic Acid–Resistant *S enterica* Typhi (NARST) Infection Evaluated in Randomized, Controlled Trials

DRUG	DOSAGE	FEVER CLEARANCE TIME (MEDIAN OR MEAN)	RATE OF TREATMENT FAILURE	RELAPSE RATE	COMMENTS
High-dose ofloxacin (Floxin) <sup>1</sup>	10 mg/kg <sup>3</sup> bid × 7 d	8.2 d	36%	<1%; insufficient data	Not recommended
Gatifloxacin (Tequin) <sup>2</sup>	10 mg/kg qd × 7 d	4.4 d	9%	3%	Serious concerns about dysglycemia; resistance emerging in Nepal
Azithromycin (Zithromax) <sup>1</sup>	10–20 <sup>3</sup> mg/kg qd × 7 d	4.4 d	9%	<1%; insufficient data	Effective in XDR-typhoid. Unproven in complicated typhoid fever
Cefixime (Suprax) <sup>1</sup>	10 mg/kg <sup>3</sup> bid × 7 d	5.8 d	27%	9%	High cost; not recommended
Ceftriaxone (Rocephin) <sup>1</sup>	60 mg/kg qd × 7 d	2.8 d	7%	7%	Experts suggest treatment for 10–14 d

## VARICELLA (CHICKENPOX)

Method of

Martha Riese, MD

### CURRENT DIAGNOSIS

- Historically, varicella has been diagnosed clinically. Symptoms include a pruritic vesicular rash, fever, malaise, abdominal pain, and anorexia.
- Polymerase chain reaction (PCR) testing is available for confirmation of the diagnosis. An open vesicular lesion is swabbed for specimen collection.

### CURRENT THERAPY

- For immunocompetent individuals 1 to 12 years of age, treatment is supportive.
- Acyclovir (Zovirax) or valacyclovir (Valtrex) treatment is used to reduce the severity of symptoms and/or risk of complications in those who are younger than 1 year or older than 12 years of age, pregnant women, or for those who are immunocompromised.
- Postexposure prophylaxis with the varicella vaccine (Varivax)<sup>1</sup> is recommended for healthy patients exposed to the virus who do not have evidence of immunity or previous vaccination.
- Varicella zoster immunoglobulin (Varizig) administration is recommended for high-risk individuals with exposure history.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Varicella infection is caused by the varicella zoster virus (VZV) and is commonly known as chickenpox. This virus is highly contagious and spreads rapidly. Varicella exhibits a seasonality with infections being more common in the winter and spring. Individuals living in tropical climates are typically affected at an older average age than those living in more temperate climates. Historically, prior to the availability of vaccinations, greater than 90% of people were seropositive for varicella by adolescence in temperate areas and less than 5% of adults remained susceptible.

The economic and healthcare burden of varicella is significant. In 1995, the varicella virus vaccine (Varivax) became licensed and available in the United States, beginning an era of reduced morbidity and mortality from the virus. Since the addition of the varicella virus vaccine into the vaccination schedule in the United States in 1996, the overall incidence of the disease has decreased by approximately 92%, and varicella-related deaths have declined by 94%. However, even with the availability of the vaccine and its proven effectiveness at reducing the overall burden of disease,

there are still many industrialized countries that have not incorporated it into their national vaccination programs.

### Risk Factors

The only risk factor for infection with varicella is exposure to the virus. Adults, immunocompromised patients, infants, and pregnant women are at greatest risk for complications. Specifically, pregnant women, newborns, and the fetus are at high risk for complications.

Following the resolution of the primary infection, the virus remains dormant in the sensory nerve ganglia and can be reactivated at a later time, causing herpes zoster (shingles).

### Pathophysiology

The VZV is a double-stranded DNA virus from the Herpesviridae family. The illness is spread by respiratory droplets or direct contact with open vesicular lesions. The virus enters through the respiratory system, mucosa, or conjunctiva. The incubation period is typically 10 to 21 days. The virus replicates in the regional lymph nodes of infected individuals and then is spread throughout the body.

Varicella infection typically confers lifelong immunity, but secondary infections in immunocompetent individuals have been documented on rare occasions. It is thought that subclinical reinfection is common.

### Prevention

A live-attenuated varicella virus vaccine, Varivax, has been available since 1995. Currently, in the United States, a two-shot series is recommended for all children and adults who do not have evidence of immunity. The two-shot series of Varivax is more effective than a single dose of the vaccine at preventing infection and complications. A single dose of the vaccine has been shown to prevent infection and reduce the risk of complications, but to a lesser degree than when two shots are administered.

Evidence of immunity is defined as appropriately timed administration of the varicella vaccine, laboratory confirmation of disease, history of diagnosis of varicella or herpes zoster confirmed by a healthcare provider, or birth in the United States before 1980 (although birth prior to 1980 should not be considered sufficient evidence for healthcare workers, pregnant women, or the immunocompromised).

The United States follows the routine childhood vaccination schedule recommended by the Advisory Committee on Immunization Practices (ACIP). In keeping with that schedule, Varivax is recommended for initial administration to healthy children between the ages of 12 and 15 months. The second dose is recommended between ages 4 and 6 years. For children who receive the vaccine series between age 7 and 13 years, the minimum required interval between doses is 3 months. For adolescents over age 13 who have not been previously vaccinated, the first dose should be administered and the second dose should be given 4 to 8 weeks later. The second dose may still be given if more than 8 weeks have lapsed between doses without the need to repeat the series. The varicella vaccine can be safely administered with other vaccines during childhood.

Varicella postexposure prophylaxis with Varivax<sup>1</sup> and/or the varicella zoster immune globulin (Varizig) is recommended to people exposed to active disease who do not have evidence of immunity. The varicella vaccine should optimally be administered to these individuals within 3 to 5 days of exposure to the virus. If the time from exposure exceeds 5 days, the vaccine is still recommended. These individuals should be encouraged to receive the second dose at the appropriate dosing interval.

For individuals without evidence of immunity who are at the highest risk of severe varicella infection and complications, varicella zoster immune globulin may be given following exposure to active disease. The immune globulin should be given within 10

days of exposure for high-risk patients. Patients given the varicella immune globulin should be evaluated for eligibility of future immunization with the varicella vaccine. If they are deemed eligible, an interval of 5 months should lapse prior to the administration of the varicella vaccine.

Varicella immunoglobulin can also be considered for those with contraindications to the varicella vaccine. Contraindications to the varicella vaccine include patients who are pregnant or might be pregnant, malignant neoplasms affecting the bone marrow or lymphatic system, those receiving prolonged immunosuppressive therapy (>2 weeks), moderate or severe concurrent illness, family history of congenital hereditary immunodeficiency, receipt of blood products within the past 3 to 11 months, or history of anaphylactic reaction to gelatin, neomycin, or other components of the vaccine.

### Clinical Manifestations

Varicella infection is typically self-limited, with healthy children often having less severe disease than infected adults. Infections often start with a prodrome of fever, chills, malaise, abdominal pain, and pharyngitis that is followed by the appearance of the vesicular pruritic rash on an erythematous base. The lesions have been described as having a “dewdrop on a rose petal” appearance (Figure 1). The rash typically appears on the scalp, face, trunk, and extremities. Lesions may also appear on the mucous membrane of the cornea, conjunctiva, oropharynx, respiratory tract, and vagina. Following the initial prodrome, the first crop of lesions appears as erythematous macular lesions. The lesions commonly transition to papules, then to clear, fluid-filled vesicles, and the vesicles eventually crust over, usually in 1 to 2 days. New crops of lesions continue to appear throughout the course of the illness over approximately 4 to 5 days, ranging between 1 and 7 days. The presence of lesions in different stages is highly characteristic of varicella infection (Figure 2) and helps differentiate the clinical findings of chickenpox from smallpox. Individuals are infectious approximately 1 to 2 days before the onset of the rash until all lesions are crusted over and no new lesions are forming. The stage of the illness when the open vesicles are present is considered to be highly contagious.

Breakthrough infections in previously immunized patients have been documented. These are infections occurring at least 6 weeks following immunization and result from inadequate immunity to the virus. The course of the breakthrough infections in these patients is often shorter and milder with less than 50 lesions. Lesions may not progress to vesicles and or have the typical appearance, potentially making the diagnosis more challenging.

### Diagnosis

Historically, the diagnosis of varicella has been based on typical clinical findings. When diagnosing varicella, the history and physical exam are of paramount importance. Noting the characteristics of the rash, including onset and evolution, are helpful in the diagnostic process. The disease is usually self-limiting. An atypical presentation or rash can make the diagnosis based on clinical symptoms difficult. The use of PCR testing is available for confirmation of the diagnosis. An open vesicular lesion is swabbed in order to collect the specimen to be tested. Other sources such as cerebrospinal fluid, blood, saliva, tissue biopsy, and throat swabs may also be used for PCR testing.

### Differential Diagnosis

The differential diagnosis of a varicella infection can include hand, foot, and mouth disease; atopic dermatitis; eczema herpeticum; guttate psoriasis; impetigo; viral exanthem; allergic reactions; shingles; and smallpox. Herpes zoster typically presents unilaterally in a dermatomal pattern. Smallpox has been eradicated from natural transmission, but infection via bioterrorism or laboratory exposure must be considered if a suspicious rash is present. The rash seen with smallpox is typically more uniform in appearance and follows a more significant prodrome of symptoms.

<sup>1</sup>Not FDA approved for this indication.

**Figure 1** A, “Dewdrop on a rose petal”; a thick-walled vesicle with clear fluid forms on a red base. B, The vesicle becomes cloudy and depressed in the center (umbilicated); the border is irregular (scalloped). C, A crust forms in the center and eventually replaces the remaining portion of the vesicle at the periphery.

**Figure 2** The disease starts with lesions on the trunk (A) and then spreads to the face (B) and extremities.

### Treatment

Treatment of varicella infection in healthy children older than 1 year and less than 12 years is symptomatic. Treating fever, malaise, and pharyngitis with ibuprofen or acetaminophen can improve patient comfort. Avoidance of salicylate use is important to reduce the risk of Reye syndrome.

Treatment of adults and children over the age of 12 years involves symptomatic care and antiviral medications such as acyclovir (Zovirax) and valacyclovir (Valtrex). Valacyclovir is more bioavailable and therefore recommended as the first-line treatment. Dosing for valacyclovir is 20 mg/kg up to a maximum of 1000 mg per dose, given three times daily for 5 days. Acyclovir can also be used as treatment, and the recommended dosing for individuals greater than 40 kg is 800 mg five times daily for 5 days. For children over 2 years of age and individuals less than 40 kg, liquid suspension acyclovir (200 mg/5 mL) is dosed 20 mg/kg every 6 hours for 5 days. The maximum dose of acyclovir is 3200 mg daily. If antiviral treatment is deemed necessary it should be started as soon as possible, ideally within 24 hours of rash onset.

For infants less than 12 months of age and immunocompromised individuals, IV antiviral medications are recommended. For adults, dosing of IV acyclovir is 10 to 15 mg/kg every 8 hours for 7 to 10 days. IV acyclovir for infants less than 12 months of age or immunocompromised children is 30 mg/kg/day divided every 8 hours for 7 to 10 days. Ideal body weight should be used to calculate the dosing regimen. With symptomatic improvement, absence of fever for 24 hours, and absence of new lesion development, switching to oral antiviral medication can be considered. For affected individuals with renal impairment, renal dose adjustments are recommended.

Pregnant women with any pulmonary involvement, including upper respiratory symptoms, should be treated with antivirals.

### Complications

Approximately 1 in 1000 children with varicella infection will suffer from severe complications. Complications related to

varicella infection include pneumonia, secondary bacterial skin or soft tissue infections due to *Staphylococcus aureus* or *Streptococcus pyrogenes*, encephalitis, cerebellitis, hepatitis, and even death. Severe complications occur more commonly in immunocompromised individuals, children younger than 1 year, those older than 12 years, adults, and newborns born to mothers that were infected with varicella. Neonates are most susceptible to a severe, even life-threatening disease if the mother develops varicella infection within 5 days prior to delivery or 2 days following birth.

Reye syndrome is another complication that has been associated with varicella infection. This illness presents with symptoms of nausea, vomiting, headaches, excitability, confusion, combativeness, and often progresses to a coma. An association with salicylate administration to febrile children was found to increase the risk of Reye syndrome. Children should not be given salicylates, including aspirin, due to this risk.

Congenital varicella can result in abnormalities of the brain, limbs, and eyes, as well as scarring of the skin and low birth weight. Children with mothers infected during the first and second trimesters have a greater risk of developing congenital varicella syndrome than those infected during the third trimester. Infections during the third trimester increase the risk of disseminated varicella. Infants born to mothers who were infected during pregnancy have an increased risk of developing herpes zoster (shingles) during the first few years of life.

### Herpes Zoster

#### Vaccination

Herpes zoster infections are caused by a reactivation of the latent VZV that has been dormant in the sensory nerve ganglia of individuals who were previously infected with varicella. Patients over the age of 50 or those with a decreased amount of cell-mediated immunity appear to be most susceptible to herpes zoster. Herpes zoster infection typically only affects one side of the body and is distributed within a single dermatome. Disseminated zoster, or disseminated shingles, is characterized by a widespread rash that is not localized to a single dermatome.

There are two vaccines available to help prevent herpes zoster (shingles). Shingrix, a recombinant zoster vaccine, is the currently preferred vaccine and is recommended for individuals over the age of 50 years. Shingrix is given as a two-dose series with doses separated by 2 to 6 months apart. The second vaccine, Zostavax (zoster vaccine live), is a single-dose live-attenuated virus that has been available since 2006 and is approved to prevent shingles in patients  $\geq 50$  years of age. Currently, Zostavax has a recommendation from the Centers for Disease Control and Prevention (CDC) for administration to immunocompetent patients who are 60 years of age or older. Zostavax is safe for use in healthy individuals over the age of 60 who are allergic to Shingrix, who prefer Zostavax, or who do not have access to the Shingrix vaccine.

The Shingrix vaccine is preferred over Zostavax as it confers greater efficacy of herpes zoster prevention as well as fewer occurrences of postherpetic neuralgia (PHN)<sup>1</sup>. Shingrix provides

<sup>1</sup>Not FDA approved for this indication.

a longer duration of protection. Patients who have had shingles in the past, have had Zostavax previously, or those who are uncertain if they have previously had varicella should still receive the Shingrix vaccine series if they otherwise meet the administration criteria.

### Treatment

Treatment of acute herpes zoster with antiviral medication is recommended to aid in diminishing symptoms of the shingles rash, including severity and duration, as well as prevent new lesion formation and decrease viral shedding. Treatment is also thought to potentially decrease the risk of developing PHN.

Dosing regimens for immunocompetent adults include valacyclovir (Valtrex) 1000 mg three times daily for 7 days; famciclovir (Famvir) 500 mg three times daily for 7 days; or acyclovir (Zovirax) 800 mg five times daily for 7 days.

Children who are 11 years of age or younger or those who are immunocompromised with an acute herpes zoster infection should be treated with IV acyclovir 30 mg/kg/day divided every 8 hours for 7 to 10 days. Immunocompromised patients with disseminated herpes zoster should be treated with IV acyclovir therapy. Dosing is 10 mg/kg every 8 hours for 7 days. Ideal body weight should be used to calculate the dose for obese patients.

Treatment has been shown to be most effective if initiated within the first 72 hours of symptom onset. Initiating treatment past 72 hours in immunocompetent adults is recommended if new lesions are still appearing. There is limited evidence available on the efficacy in initiating treatment past 72 hours in immunocompetent patients if new lesions are no longer appearing. Immunocompromised adults should be treated with antiviral medication as soon as possible even if 72 hours have lapsed since the onset of the illness.

Pregnant women should also receive early initiation of treatment regardless of the number of lesions present. Acyclovir is preferred for use in pregnant women; recommended dosing is 800 mg five times daily for 7 days.

### Postherpetic Neuralgia

PHN can occur following herpes zoster infection. Symptoms of PHN include severe pain in the area of previous zoster infection even after the rash has resolved. PHN can last for a few days or up to several years. Tricyclic antidepressants, pregabalin (Lyrica), and gabapentin (Neurontin) have the most research to support their use in the reduction of pain from PHN. Some evidence supports the use of topical capsaicin (Zostrix) and lidocaine patches (Lidoderm) in the treatment of herpes zoster. Acetaminophen and nonsteroidal antiinflammatory agents are commonly used, though studies of their effectiveness is limited.

## WHOOPING COUGH (PERTUSSIS)

Method of

Raul Davaro, MD

### CURRENT DIAGNOSIS

- Pertussis, also known as whooping cough, is an acute respiratory tract infection that has increased in incidence in recent years.
- The diagnosis depends on clinical signs and laboratory testing. Both culture and polymerase chain reaction testing can be used to confirm the diagnosis; serologic testing is not standardized or routinely recommended.

### CURRENT THERAPY

- Macrolide antibiotics such as azithromycin are first-line treatments to prevent transmission; trimethoprim/sulfamethoxazole is an alternative in cases of allergy or intolerance to macrolides.
- Current immunization recommendations in the United States consist of administering five doses of the diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine to children before 7 years of age and administering a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) booster between 11 and 18 years of age.

Pertussis is a respiratory infection caused by *Bordetella pertussis*, a gram-negative, pleomorphic aerobic coccobacillus. Infection due to *B. pertussis* affects persons of all ages, with a clinical presentation ranging from a relatively mild-cough illness to a severe illness with pneumonia, seizures, encephalopathy, respiratory failure, and/or death.

Prior to the introduction of whole-cell pertussis vaccines in the United States during the 1940s, the annual number of reported cases often exceeded 200,000. The introduction of childhood pertussis vaccines dramatically altered the epidemiologic landscape of pertussis, with reported cases declining to a nadir of just over 1000 (0.47/100,000 population) by the mid-1970s. However, despite substantial declines in disease since the prevaccine era, pertussis remains a significant health problem worldwide, with incidence increasing in several countries in recent years.

### Epidemiology

Pertussis is highly contagious and is transmitted via aerosolized droplets through close contact during coughing or sneezing. Studies have identified household members as the source in 75% of cases in infants, mothers being the likely source in almost one-half of these cases. Pertussis shows no seasonality transmission.

During 2000–2016, 339,420 pertussis cases were reported. The majority were in white (88.2%) and non-Hispanic (81.3%) persons, 9.9% were hospitalized, and 0.1% were fatal; however, differences existed by age. Infants had the highest incidence (75.3/100,000 population), accounting for 88.8% of death.

The resurgence of pertussis, probably due to several reasons, including vaccine-driven selection, increased disease awareness and testing, improved diagnostics, and waning immunity.

### Transmission

Pertussis is highly contagious and can spread rapidly from person-to-person through contact with airborne droplets. The human nasopharynx can be densely colonized with both

commensal bacteria and pathogens, including *B. pertussis*. Infected individuals aerosolize pertussis-containing droplets by coughing or sneezing. Persons with pertussis are most infectious during the mucous producing stage and the first 2 weeks after cough onset.

Pertussis is considered far more contagious than polio, smallpox, rubella, mumps, and diphtheria. Studies showed that one infected person can transmit *B. pertussis* to as many as 12 to 17 other susceptible individuals, while polio and smallpox can be transmitted to 5 to 7, rubella 6 to 7, mumps 4 to 7, and diphtheria 6 to 7 susceptible individuals.

### Microbiology and Pathophysiology

*Bordetella* are small gram-negative, aerobic, nonsporulating coccoid rods. *B. pertussis* infection and disease occur after four important steps: (1) attachment, (2) evasion of host defenses, (3) local damage, and (4) systemic manifestations.

Filamentous hemagglutinin (FHA) and fimbriae (FIM) are two major adhesins and virulence determinants for *B. pertussis*. They are required for tracheal colonization, are highly immunogenic, and are components of certain acellular pertussis vaccines. However, there is likely redundancy in the adhesion role of *B. pertussis* proteins, and it has been suggested that virulence factors such as pertactin (PRN) may mediate attachment in the absence of FHA. Pertussis toxin (PT) also acts as an adhesion and has specific recognition domains for human cilia. Evasion of host defenses occurs primarily through adenylate cyclase toxin (ACT) and PT. PT targets the innate immune system of the lung by inactivating or suppressing G protein-coupled signaling pathways. Through this mechanism of action, PT delays the recruitment of neutrophils to the respiratory tract and targets airway macrophages to promote *B. pertussis* infection.

### Immunity

Immunity to pertussis, acquired either from natural infection or through vaccination, is not lifelong. It has been estimated that natural pertussis infection yields 3.5 to 30 years of protection, the estimated protection obtained from the whole-cell pertussis vaccine is 5 to 14 years, and that from the acellular vaccine is 4 to 7 years.

### Clinical Symptoms

Pertussis symptoms begin 7 to 10 days after exposure. The disease is characterized by three stages: catarrhal stage, consisting of symptoms indistinguishable from a minor upper respiratory tract infection; paroxysmal stage, named for its characteristic cough consisting of intermittent, sudden bursts of cough, followed by whoop on inspiration and posttussive emesis (the paroxysms of cough are rapid and numerous, occurring up to 15 times in a 24-hour period); and convalescent stage, when paroxysms wane in number and severity. Patients are most contagious during the catarrhal stage. The paroxysmal stage usually lasts 1 to 6 weeks but can be as long as 10 weeks. Almost 80% of adults with confirmed pertussis have an illness involving a cough of at least 3 weeks' duration, and 27% still had a cough after 90 days.

Although symptoms can be prolonged, there is no evidence for chronic infection or long-term carriage of *B. pertussis*. Paroxysms can recur with subsequent respiratory illnesses months after initial illness and are not associated with recurrent isolation of *B. pertussis*. Adolescents and adults frequently have diseases that may not be recognized as pertussis. Whoop is uncommon, but paroxysms of cough and posttussive emesis are common manifestations. A study of adolescents and adults with prolonged cough illness found that 13% to 20% had infections with *B. pertussis*. Pertussis leads to the hospitalization in older children and adolescents in only about 1% to 7% of those affected. Among adults, people older than 65 years are at the highest risk of pertussis hospitalization. Complications also are uncommon in adults,

occurring in about 5%, but can include syncope, rib fractures, pneumonia, and otitis media.

Among immunized patients, especially adolescents and adults, a prolonged cough may be the only manifestation of pertussis. A number of studies have documented that between 13% and 32% of adolescents and adults with an illness involving a cough of 6 days' duration or longer have serologic evidence of infection with *B. pertussis*.

### Diagnosis

A positive culture of nasopharyngeal secretions (preferably an aspirate) on selective Regan-Lowe medium is the gold standard for the diagnosis of pertussis. PCR is a rapid test and has excellent sensitivity. However, PCR tests vary in specificity. It is recommended to obtain culture confirmation of pertussis for at least one suspicious case when there is suspicion of a pertussis outbreak. PCR may provide accurate results for up to 4 weeks. After the fourth week of cough, the amount of bacterial DNA in the nasopharynx rapidly diminishes, which increases the risk of obtaining false-negative results. PCR assay protocols that include multiple target sequences allow for speciation among *Bordetella* species.

### Treatment

Antimicrobial therapy administered during the catarrhal stage may ameliorate the disease. Antimicrobial therapy is indicated before test confirmation if the clinical presentation is suggestive of pertussis or the patient is at high risk of severe or complicated disease (e.g., is an infant). The duration of treatment for pertussis and postexposure prophylaxis (PEP) is 5 days. After the paroxysmal cough is established, antimicrobial agents have no effect on the course of illness but are recommended to limit the spread of organisms to others. The resistance of *B. pertussis* to macrolide antimicrobial agents has been reported, but rarely. Penicillins and first- and second-generation cephalosporins are not effective against *B. pertussis*.

Trimethoprim-sulfamethoxazole (Bactrim)<sup>1</sup> is an alternative for patients older than 2 months who cannot tolerate macrolides or who are infected with a macrolide-resistant strain, but studies evaluating trimethoprim-sulfamethoxazole as treatment for pertussis are limited (Table 1).

Hospitalized young infants with pertussis should be managed in a setting/facility where these complications can be recognized and managed urgently. Exchange transfusions or leukapheresis have been reported to be life-saving in infants with progressive pulmonary hypertension and markedly elevated lymphocyte counts.

### Prevention

In the United States, all vaccines available for preventing pertussis are acellular pertussis formulations combined with tetanus and diphtheria toxoids. Five doses of pertussis-containing vaccine (DTaP [Daptacel, Infanrix]) are recommended prior to entering school: four doses of DTaP before 2 years of age and one dose of DTaP before school entry. Adolescent and adult formulations, known as Tdap vaccines (Adacel, Boostrix), contain reduced quantities of diphtheria toxoid and some pertussis antigens compared with DTaP. A single dose is recommended universally for people 11 years and older, including adults of any age, in place of a decennial tetanus and diphtheria vaccine (Td). Booster doses of Tdap are not recommended for any group of people except pregnant women. The Centers for Disease Control and Prevention (CDC) recommends the use of PEP with antimicrobials in persons at high risk of developing severe pertussis and those who will have close contact with those at high risk of developing severe pertussis.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Pertussis Treatment

ANTIBIOTIC	DOSING	COMMENTS
Azithromycin (Zithromax)	Children: 10 mg/kg/day for 3 days, or 10 mg/kg on day 1, then 5 mg/kg/day on days 2 through 5 Adults: 500 mg/day for 3 days, or 500 mg on day 1, then 250 mg/day on days 2 through 5	Preferred therapy due to ease of use and tolerability. Preferred agent for infants younger than 1 month Prolongation of the QT interval
Clarithromycin (Biaxin)	Children: 7.5 mg/kg twice daily for 7 days Adults: 500 mg twice daily for 7 days	Fewer adverse effects than erythromycin, but typically more than azithromycin Prolongation of the QT interval CYP3A4 inhibitor; use with caution with other CYP3A4 medications
Erythromycin, delayed release (Ery-Tab)	Children: 40 to 60 mg/kg/day in three or four divided doses for 7 to 14 days Adults: 666 mg three times per day for 7 to 14 days	Gastrointestinal adverse effects limit use Risk of hypertrophic pyloric stenosis in infants CYP3A4 inhibitor; use with caution with other CYP3A4 medications
Trimethoprim/sulfamethoxazole	Children: 8/40 mg/kg/day divided into two doses for 14 days Adults: one double-strength tablet (160/800 mg) twice daily for 14 days	May be effective for those with intolerance to macrolide antibiotics Caution in pregnancy; contraindicated in infants younger than 2 months, or in mothers breastfeeding infants younger than 2 months

CYP, Cytochrome P450.

## YELLOW FEVER

Method of

Lucius M. Lampton, MD

### CURRENT DIAGNOSIS

- Yellow fever is a historically important mosquito-borne Flavivirus with high morbidity and mortality.
- Travel to yellow fever–endemic areas in Sub-Saharan Africa and tropical Central and South America is the essential risk factor.
- Symptoms may include abrupt onset of fever, relative bradycardia, headache, and, if severe, jaundice, hemorrhage, and multiorgan failure.
- Diagnosis is with viral culture and serologic tests.
- Although infectious disease experts consider it improbable that yellow fever outbreaks will return to the continental United States, this reemerging disease is threatening to become more prevalent and deadly in tropical South America and Africa. Travel-related cases should be anticipated in the United States and its territories, as well as the possibility of brief episodes of local dissemination in areas bordering the Gulf of Mexico, where the vector, the *Aedes aegypti* mosquito, can be found.

### CURRENT THERAPY

- Prevention is key and accomplished by vaccination and mosquito avoidance and control.
- Supportive care is the only treatment.

### Epidemiology

Yellow fever is one of the great epidemic diseases of tropical Africa and the Americas. It receives its appellation “yellow” from the symptom of jaundice, which appears in severe disease, and it is caused by an RNA virus, specifically a Flavivirus (a family name derived from yellow fever, with *flavus* Latin for yellow), that is held in natural reservoirs by forest monkeys and spread to people via mosquitoes. The disease, termed an acute hemorrhagic fever, infects humans, all species of monkeys, and certain other small mammals and is transmitted among its hosts by several species of mosquitoes.

There are three types of yellow fever infection: urban, jungle, and intermediate. In urban or classical yellow fever, human-to-human spread occurs by the bite of the *A. aegypti* mosquito, which breeds in urban unpolluted water and bites principally in the daytime. Reinvasion of this mosquito in Central and South America has occurred beginning in the 1970s owing to increases in breeding sites resulting from urbanization and the collapse of vector control efforts. In jungle or sylvatic yellow fever, which was first recognized in 1933, the disease is perpetuated by enzootic infection of mammals, usually monkeys, disseminated by several different mosquitoes: in South America via the *Haemagogus* and *Sabethes* spp.; in East Africa via *Ae. africanus*; and in West Africa via a variety of species of *Aedes*. Human infection arises by jungle exposure to these mosquitoes. In intermediate or savannah yellow fever, which commonly occurs in Africa, the virus disseminates from mosquitoes to humans residing or working in areas bordering jungles. This cycle also involves spread of the virus from monkey to human or from human to human via the bite of a mosquito.

Yellow fever, also termed Yellow Jack, the Saffron Scourge, fièvre jaune, Bronze John, and Black Vomit (the Spanish name is vómito negro), is the deadliest arthropod virus ever to emerge in the Americas. Both the molecular taxonomic research of viral

strains and the annals of history reveal an African origin. Most authorities assert it was introduced to the new world by *A. aegypti*-infested slave ships voyaging from West Africa, with its first recognition in the Americas occurring in Yucatan, Mexico, in 1648 (although research suggests the disease was present in the Americas as early as 1498). Over the next two and a half centuries, yellow fever erupted with regularity in American and European port cities, with hundreds of thousands of deaths, earning the virus deserved recognition as one of the worst plagues the world had ever seen. Two of the most significant North American epidemics occurred in Philadelphia in 1793 and in the Mississippi Valley in 1878. American epidemics were the result of the introduction of the mosquito vector and infected humans along routes of trade, especially sea and river ports and rail lines, with particular virulence associated with the Gulf region where *A. aegypti* resided. Early attempts at control focused on quarantine and sanitary measures. The devastation associated with American epidemics was an important impetus in the nation's early public health and sanitation movements for the creation of city, state, and national boards of health.

Although two 19th-century physicians, Josiah Nott and Carlos Juan Finlay, suggested the mosquito was the infectious agent for yellow fever, it was not until 1900 that the work of the US Army Commission in Cuba under Major Walter Reed established that the vector of the urban form of this disease was the *A. aegypti* mosquito, with its viral cause not established until after 1928. Max Theiler developed an attenuated vaccine strain in 1937, which was recognized with a Nobel Prize. In what is acknowledged as one of the most successful campaigns in history against infectious disease, mosquito eradication efforts and this vaccine effectively controlled and eliminated urban yellow fever in the Americas and the West Indies, with the last large outbreak occurring in the continental United States in New Orleans in 1905. However, the disease persisted in its jungle form in forest areas in Africa and South America. Vaccine administration remains incomplete in endemic areas, and outbreaks periodically recur. As well, mosquito eradication efforts in both the Americas and Africa have recently slackened, with the resulting resurgence of *A. aegypti* into nearly all of the tropical American countries, placing this region at extraordinary risk for urban outbreaks. While only travel-related cases have been documented in Asia, theoretic anthroponotic dissemination could also take place there in the many areas where the urban vector resides.

Official statistics suggest the incidence of yellow fever fluctuates, with 90% of the 200,000 annual cases reported in Africa. However, authorities warn that these statistics considerably underestimate (owing to underreporting) the true magnitude of epidemics, which field studies estimate as 50 times greater. A frightening prospect associated with failing mosquito control in urban habitats is the potential reemergence of yellow fever similar to the recent rapid resurgence of dengue, which is also transmitted by the vector *A. aegypti*. Experts contend that one of the most profound mysteries of tropical medicine is that this dangerous virus has not emerged more frequently where a susceptible, unimmunized human population and the vector density coexist. However, since the 1980s, a resurgence of yellow fever has been seen across South America and Africa, which augurs potential risk for the United States. While yellow fever outbreaks remain unlikely in the United States, travel-related cases should be expected, as well as the possibility of brief urban cycle transmission in the American Southeast.

The 2015–2020 outbreaks in Brazil and Africa portend ominously that yellow fever appears to be moving from its typical rural setting toward urban areas. A large urban outbreak in Angola, which began in December 2015 and subsequently spread to the Democratic Republic of the Congo, resulted in 962 confirmed cases and 393 deaths and included multiple travel-related cases appearing in nonendemic areas internationally such as China. The outbreak in Brazil was first recognized in December 2016, with more than 2251 confirmed cases and 772 deaths noted as of June 1, 2019, including two dozen travel-related

cases. This upsurge of human cases, which is the highest observed in the Americas for decades, reflects the spread into densely populated metropolitan areas, such as Rio de Janeiro and Sao Paulo, which in the past were not considered at risk for transmission. This outbreak has impacted not only Brazil but six other American countries: Bolivia, Colombia, Ecuador, French Guiana, Peru, and Suriname. In the current outbreak, all human cases have been linked only to *Haemagogus* and *Sabethes* mosquitoes.

In response to yellow fever's reemergence in Africa, the World Health Organization (WHO) launched the Yellow Fever Initiative in 2006, vaccinating in mass campaigns more than 105 million people in West Africa and attempting to secure a global vaccine supply. In 2017, the Eliminate Yellow Fever Epidemics (EYE) strategy was initiated with more than 50 partners supporting 40 at-risk countries in the Americas and Africa to prevent, detect, and contain global outbreaks. By 2026, it is projected that 1.38 billion people will be vaccinated against the disease. In March 2018, Brazil's health minister announced that all of the country's 78 million people will be targeted in a large-scale vaccination campaign.

Yellow fever remains the most dangerous arbovirus ever to inhabit the Western Hemisphere. Despite ongoing vaccination and mosquito control efforts in endemic areas, sylvatic and intermediate transmission cycles persist and appear to be expanding toward urban spread. Public health leaders encourage clinicians to utilize heightened suspicion and awareness for the virus, especially among travelers to tropical areas. Recent yellow fever outbreaks underscore boldly the potential threat this disease poses for the international community.

### Risk Factors

Travel to yellow fever-endemic areas in Sub-Saharan Africa and tropical Central and South America, between the 15th parallel north and the 15th parallel south, is the essential risk factor.

### Pathophysiology

Yellow fever virus has three types or cycles of transmission: urban, jungle (sylvatic), and intermediate (savannah). In urban yellow fever, the virus is spread by the bite of an *A. aegypti* mosquito infected about 2 weeks previously by feeding on a person with viremia. In jungle (sylvatic) yellow fever, the virus is transmitted by various forest canopy mosquitoes that acquire it from wild primates and then disseminate it to humans who are visiting or working in the jungle. Incidence of the disease is highest during months of peak temperature, rainfall, and humidity in South America and during the late rainy and early dry seasons in Africa. In the intermediate (savannah) cycle, which is most common in Africa, transmission of the virus to humans results from humans living or working in jungle border areas, with the virus spread from monkey to human or from human to human by mosquitoes. Humans infected with the virus are infectious to mosquitoes (what is termed being "viremic") shortly before the onset of illness and up to 5 days after onset. Yellow fever is not transmissible by contact, only via a vector's bite.

### Prevention

Yellow fever is a mosquito-borne infection that can be prevented by mosquito avoidance and vaccination. Recovery from yellow fever imparts lifelong immunity against the virus.

Mosquito control is an essential component of any strategy to prevent the spread of yellow fever. Before the development of the vaccine and after the mosquito was proven as the vector, eliminating mosquito-breeding sites and decreasing exposure to *A. aegypti* mosquitoes proved successful in ending yellow fever outbreaks in North America and also in the building of the Panama Canal. Today, it remains critical not only to reduce the number of mosquitoes through larvicides and insecticides but also to limit mosquito bites through the use of house screening, mosquito netting, the wearing of protective attire, and the use of insect repellants such as diethyltoluamide (DEET). During jungle outbreaks, mosquito elimination is impractical and evacuation is essential

until individuals are immunized and mosquitoes controlled. To prevent further mosquito transmission during outbreaks, infected patients should be isolated in well-screened rooms sprayed with insecticides.

Immunization is the most effective and reliable way to prevent yellow fever in areas in which it is endemic. Live attenuated yellow fever virus vaccine (17D strain) (YF-VAX) should be given (0.5 mL subcutaneously every 10 years) at least 10 days before travel to endemic areas in Africa and Central and South America. A single dose of vaccine gives greater than or equal to 99% protection and confers lifelong immunity. (Although required by some countries, a booster dose of the vaccine is not medically needed.) Although infection is uncommon in most of the endemic areas, vaccination is legally required for entry into many of these countries. The typically well-tolerated vaccine is contraindicated in pregnant women, in individuals with concurrent febrile illness or compromised immunity, and in infants younger than 6 months. If infants aged 6 to 8 months cannot avoid travel to a high-risk location, parents should discuss immunization with their physician, since the vaccine is usually not offered until the age of 9 months. In the United States, the vaccine is given only at US Public Health Service-authorized Yellow Fever Vaccination Centers. The International Certificate of Vaccination is valid for 10 years from 10 days after immunization or immediately after reimmunization.

After the 2016 outbreaks depleted global vaccine supplies, experts suggested as a dose-sparing strategy the utilization of a fractional dose of the vaccine among children 2 years of age or older and among nonpregnant adults.<sup>3</sup> In an observational study, a one-fifth dose of the vaccine induced seroconversion in 98% of recipients. In the 2018 and 2019 outbreaks, mass vaccination campaigns have utilized primarily fractional dosing.

### Clinical Manifestations

Yellow fever is characterized by the swift onset of fever, rigors, myalgias, headache, nausea, and vomiting. With an incubation period lasting 3 to 9 days, the illness is typically biphasic, with a two-stage course during which the pulse slows and kidney involvement occurs along with bleeding disorders. Between 5% and 50% of the cases are so mild they are inapparent. In those cases recognized, the pulse is usually rapid initially but by the second day becomes slow for the degree of fever (Faget sign). A tendency to bleed may be seen early in the disease. Often, the face is flushed, with facial edema and conjunctival injection. Restlessness, irritability, and leukopenia are also common. In most cases, this initial period of mild infection resolves after 1 to 3 days, occasionally longer, and the illness concludes with rapid recovery and no sequelae. However, approximately 15% of those infected progress further into the moderate to severe phases. In these cases, the falling fever and remission of symptoms 2 to 5 days after onset are only transitory, and a deadly phase soon begins with renewal of malignant symptoms. This stage of the illness, called intoxication, is marked by the fever returning, and although the pulse remains slow, the blood pressure drops, with resultant renal failure. The flushed face is replaced by a dusky pallor, with swollen, bleeding gums and a pronounced hemorrhagic tendency with telltale black vomit (one of the disease's monikers and classic symptoms) and melena. The skin and eyes may appear yellow (jaundice), the symptom that gave rise to the disease's popular name. (However, this jaundice is generally a symptom of convalescence more than acute disease.) Liver and renal failure (which may progress to acute tubular necrosis) and epigastric tenderness with hematemesis and gastrointestinal hemorrhage often occur. There may be oliguria, albuminuria, disseminated intravascular coagulopathy, backache, dizziness, ecchymoses, myocarditis, agitated delirium, intractable hiccups, seizures, coma, and multiple organ failure. During recovery, bacterial superinfections, particularly pneumonia, may occur.

In terminal cases, death usually transpires within 7 days of onset and is rare beyond 10 days of illness. In patients with

intoxication (malignant yellow fever), a 30% to 60% mortality may be seen, with survival depending on the quality of supportive management. At autopsy, the kidneys, liver, heart, and spleen appear to be the organs most impacted by the disease.

### Diagnosis

Yellow fever is suspected in patients in endemic areas or returning from them if they develop classic clinical features such as sudden fever with relative bradycardia and jaundice. Mild infection often escapes recognition by the patient or clinician. Complete blood count, urinalysis, liver function tests, coagulation studies, viral blood cultures, and serologic tests should be done. Leukopenia with relative neutropenia is common, as are thrombocytopenia, prolonged clotting, and increased prothrombin time. Bilirubin and aminotransferase levels may be elevated acutely and for several months. Albuminuria, which occurs in 90% of patients, may reach 20 g/L. This finding helps differentiate yellow fever from viral hepatitis. In malignant yellow fever, hypoglycemia and hyperkalemia may occur terminally.

Diagnosis is confirmed by viral culture, serology, the identification of viral antigens and virus-specific immunoglobulin M (IgM) and neutralizing antibodies in serum by several rapid diagnostic methods, or detecting characteristic midzonal hepatocyte necrosis at autopsy. Suspected or confirmed cases must be quarantined and health departments notified. Needle biopsy of the liver during illness is contraindicated because of high risk of hemorrhage.

### Differential Diagnosis

Mild yellow fever appears clinically like a broad expanse of other infections presenting with similar symptoms, including dengue, viral hepatitis, malaria, typhus, Q fever, typhoid, Rift Valley fever, leptospirosis, drug-induced syndromes, and toxic causes. Yellow fever may be distinguished from malaria by the findings of conjunctival suffusion or relative bradycardia. The other viral hemorrhagic fevers, which include dengue, Lassa fever, Marburg disease, Ebola, Crimean-Congo hemorrhagic fever, and Bolivian and Argentine hemorrhagic fevers, usually present without jaundice. As well, albuminuria is a reliable hallmark of yellow fever that allows its differentiation from other causes of viral hepatitis.

### Treatment

Since no antiviral therapy is currently available, treatment is supportive, focused on aggressive symptom management designed to correct the acid-base imbalance and electrolyte abnormalities caused by emesis, heart failure, and renal derangements. Placement in an intensive care unit is recommended. Transfusions of blood, fresh-frozen plasma, and vitamin K<sup>1</sup> may be utilized with hemorrhagic symptoms. As well, a proton pump inhibitor, H<sub>2</sub> blocker, and sucralfate (Carafate)<sup>1</sup> can be helpful as prophylaxis for gastrointestinal bleeding and should be considered in all hospitalized patients. Antipyretics, oxygen, vasopressors, and IV hydration may also be helpful. Avoidance of sedatives and drugs metabolized hepatically is prudent, and medication dosing should be adjusted in the face of declining renal function. Antibiotic therapy for secondary bacterial sepsis is often necessary during the recovery period. Owing to the increased risk of bleeding, avoidance of aspirin and other nonsteroidal antiinflammatory drugs, such as naproxen and ibuprofen, is recommended.

### Complications

The majority of those infected with yellow fever will be asymptomatic or experience only mild disease with total recovery. The mortality rates in tropical America range from 45% to 75%, compared with less than 30% in Africa. This difference suggests genetic factors play a role in the course of the illness, as well as the viral strain. The convalescence of a yellow fever patient is usually prolonged and varies from patient to patient. Although uncommon, late death (weeks after the acute illness) can occur

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>1</sup>Not FDA approved for this indication.

as a result of cardiac complications or renal failure. Profound asthenia and fatigue usually last for 1 to 2 weeks, but in some cases can last many months. Jaundice and the elevation of liver enzymes have been known to last an extended period (several months) during convalescence. Survival of an attack imparts life-long immunity against subsequent infection.

## ZIKA VIRUS DISEASE

Method of

Scott Kellermann, MD, MPH; and Rick D. Kellerman, MD

Zika virus is a mosquito-borne flavivirus. In 1947, in a quest to solve the dilemma of yellow fever, researchers at the East African Research Institute, Uganda placed a caged rhesus macaque in the nearby Zika Forest. The monkey developed a fever and from its serum was isolated a transmissible agent that was first described as Zika virus in 1952. Initially, Zika virus, borne by arboreal mosquitoes such as *Aedes africanus*, infected wild primates and rarely infected humans, even in highly enzootic areas. Results of serologic and entomologic investigations suggest that Zika virus had an extensive geographic distribution in Africa and Asia earlier than 2007. However, fewer than 20 cases in humans were reported before 2007, and all had mild, self-limiting clinical manifestations. Within less than a decade, Zika went from a poorly known virus causing sporadic human infections in Africa and Asia to a nearly pandemic neurotropic virus with active circulation detected in more than 87 countries and territories. After its original identification, the first major Zika outbreak, outside of Africa, took place in 2007 on Yap Island with approximately three-fourths of the population over the age of three suspected to be infected. In 2013–2014, an outbreak affecting an estimated 30,000 people occurred in French Polynesia. Other isolated outbreaks followed. In 2015–2016, a major outbreak occurred in Brazil and other South American, Central American, and Caribbean countries. The first locally transmitted cases on the United States mainland were reported in 2016. As Zika virus migrated from Africa to Asia, the Asian lineage of the virus emerged. Strikingly, all Zika virus strains responsible for human outbreaks to date belong to the Asian lineage. The Zika virus appears to have mutated in character while expanding its geographical range, transforming from a localized endemic, mosquito-borne infection producing only a mild illness to a disease causing explosive outbreaks linked with neurological disorders including

Guillain-Barré syndrome and microcephaly. Estimates are that, between October 2015 and January 2016, approximately 1.5 million Brazilians were infected by Zika with 3,500 cases of microcephaly reported within the three poorest states of Paraíba, Pernambuco, and Bahia. The strain of Zika virus most closely related to the one that emerged in Brazil was originally isolated from patient samples in French Polynesia. In all probability, Zika virus arrived in Brazil in 2014 during the Confederation Cup, when Tahiti's soccer team and its supporters visited a variety of Brazilian venues.

In November 2016, the World Health Organization declared that “The Zika virus and associated consequences remain a significant enduring public health challenge requiring intense action but no longer represent a public health emergency of international concern.”

The incidence in the Americas and the world has significantly waned since 2017. Since 2019 there have been no confirmed reports of mosquito transmission of Zika virus in the continental United States or its territories.

## Epidemiology

Zika virus is transmitted by the daytime-active *Aedes* mosquitoes, such as *A. aegypti* and *A. albopictus*. With the exception of West Nile virus, which is predominantly spread by culex-species mosquitoes, the arboviruses reaching the Western Hemisphere have all been transmitted by *Aedes* mosquitoes. Millennia ago, North African villagers began storing water in their dwellings, giving arboreal *A. aegypti* a ready medium for depositing their eggs—domestic water-containing vessels. The hatched mosquitoes then fed on humans, evolving into an entirely new maintenance cycle of human–*A. aegypti*–human transmission. Now, thousands of years later, the worst effects of this evolutionary cascade have been seen in the repeated emergence of arboviruses in human ecosystems.

The distribution of *A. aegypti* is more extensive now than ever recorded, extending across all continents including North America. Although *A. aegypti* has likely maintained an intermittent presence in the United States for approximately 375 years, its distribution has been assumed to be limited by cold temperatures to boundaries roughly southward of the average 10°C winter isotherm. However, *A. aegypti* has been found in a Capitol Hill neighborhood of Washington, DC, and genetic evidence suggests they survived at least four consecutive winters in the region. It is assumed that *A. aegypti* mosquitoes are capable of adapting for persistence in a northern climate.

Another significant Zika virus vector is *Aedes albopictus*, commonly known as the Asian tiger mosquito, named for its white striped legs. *A. albopictus* is of medical importance due to its aggressive daytime human-biting behavior and ability to vector many viruses, including dengue, La Crosse, and West Nile.

Most significantly, pregnant mothers may vertically transmit the virus to the developing fetus, potentially resulting in microcephaly. Zika virus has been isolated in semen and vaginal secretions. Male to female as well as female to male sexual transmission of the Zika virus has been reported. Blood transfusions have been a source of transmission outside of the United States. The blood supply in the United States is tested for Zika virus.

The Zika pandemic is an example of a “perfect storm” in which a new American subclade emerged from the Asian lineage of the virus and was introduced into a uniformly susceptible population that had not been previously exposed to Zika virus. Zika has followed a pattern of dispersion analogous to chikungunya, spreading pandemically from west to east. Both viruses now encircle the globe. It appears that both viruses migrated from East Africa to Asia. There is a similar striking movement of Zika and chikungunya from Asia into the Pacific Islands and then to the Americas. Analogous ecological factors might be responsible for their similar spread and may be a key to understanding effective prevention strategies.

## Risk Factors

The risk of Zika virus infection for pregnant women is pronounced because of the potential link to microcephaly of the

infant. The risk is greatest if the infection is early in pregnancy. There is no evidence that pregnant women are more susceptible to Zika virus infection or that the disease is more severe during pregnancy. Although the transmission of Zika virus is most commonly due to the bite of an infected mosquito, transmission has also been documented through sexual contact, blood transfusion, laboratory exposure, and both intrauterine and intrapartum transmission. The CDC reports that although Zika virus has been found in breast milk and possible Zika virus infections have been identified in breastfeeding babies, Zika virus transmission through breast milk has not been confirmed. Based on what is known about similar arbovirus infections, once a person has been infected and developed antibodies to Zika virus, they are likely to be protected from a future Zika infection. Based on currently available evidence, once the virus has cleared from the blood of a Zika-infected woman, she is not felt to be at future risk for having a child with a Zika-related birth defect.

### Pathophysiology

The Zika virus is a member of the Flaviviridae virus family, which includes dengue, yellow fever, West Nile, and Japanese encephalitis viruses. Zika is a single-stranded, positive-sense RNA virus that has been fully sequenced. It is one of many arthropod-borne arboviruses. Monkeys are the common vertebrate host of the virus. Arboviruses oftentimes have complex natural transmission cycles involving mammals, birds, and blood-feeding arthropod vectors.

Until recently, only a few arboviruses have caused clinically significant human diseases. These include mosquito-borne alphaviruses such as chikungunya and flaviviruses such as dengue and West Nile. The most historically important of these is the yellow-fever virus, the first recognized viral cause of deadly epidemic hemorrhagic fever.

### Prevention

Population-based mosquito control measures are recommended to prevent the spread of Zika virus. Although yellow fever has historically been prevented entirely by aggressive mosquito control, in the modern era vector control has been problematic because of the expense, logistics, public resistance, the development of resistance to the pesticides used and their collateral adverse effects on humans. Although a chemical war against the vector may provide short-term control, programs for improving urban infrastructure and environmental sanitation with a stable supply of potable water would offer more durable results. Among the best preventive measures against Zika virus are house screens, air conditioning, and removal of yard and household debris and containers that provide mosquito-breeding sites, luxuries often unavailable to impoverished residents of crowded urban locales where such epidemics take their greatest toll. Releasing mosquitoes that are sterile or genetically modified to die before they can reproduce is being investigated. Research funded by the Bill and Melinda Gates Foundation has demonstrated the efficacy of Wolbachia in preventing mosquitoes from transmitting viral diseases such as dengue, Zika, chikungunya, and yellow fever.

Because of the association between Zika virus infection and microcephaly in fetuses, the United States Centers for Disease Control and Prevention (CDC) should be consulted for travel guidelines when pregnant women or women considering pregnancy are traveling to affected countries. In some cases, travel may need to be postponed. The CDC website at <https://wwwnc.cdc.gov/travel/page/zika-information> (Figure 1) contains valuable information regarding areas of the world where risk of exposure to Zika virus is possible. Women who are considering becoming pregnant should consult with their physicians for preconception counseling.

The CDC recommends that women who have had Zika virus exposure through travel or sexual contact and do not have ongoing risks for exposure should wait at least 8 weeks from date of diagnosis, symptom onset (if symptomatic), or last possible

exposure before attempting to conceive. During this waiting period, either abstinence should be practiced or barrier contraception with condoms should be used. The 8-week waiting period may decrease the risk of maternal-fetal transmission of the Zika virus.

Zika virus typically remains in the semen for longer periods of time than other body fluids. Accordingly, the CDC recommends waiting at least 3 months from date of diagnosis, symptom onset (if symptomatic), or after the last possible exposure before attempting conception with their partner. During this waiting period, either abstinence should be practiced or barrier contraception with condoms should be used. The recommendation to wait at least 3 months for asymptomatic men is based on the length of time the Zika virus RNA has been detected in semen. The median and 95 percentile for the time until the loss of Zika RNA detection are 42 days and 120 days, respectively, for semen compared to 15 days and 41 days, respectively, for serum and 11 days and 34 days, respectively, for urine. The longest duration of detection of Zika RNA in semen is 370 days, although shedding of infectious Zika virus is believed to be limited to the first few weeks after the onset of illness. There is a lack of evidence that the risk of sexual transmission differs in symptomatic and asymptomatic men.

Between 2015 and July 2018, 52 cases of confirmed sexual transmission of Zika virus infection had been reported in the United States. The longest period from symptom onset in the index case to potential sexual transmission to a partner was between 32-41 days; most reports are of much shorter intervals.

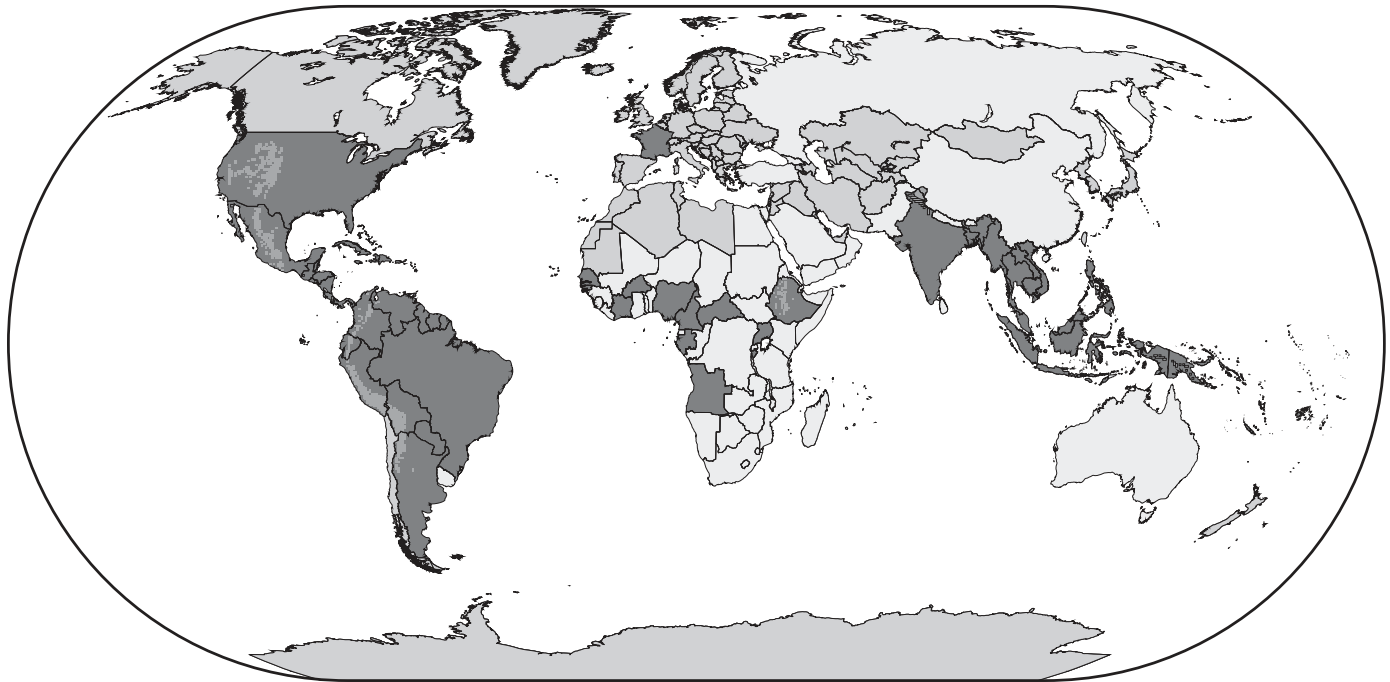

Recommendations for men with possible Zika virus exposure whose partners are pregnant are advised to consistently and correctly use condoms during sex or abstain from sex for the duration of the pregnancy.

Documented reports of sexual transmission have primarily involved transmission from a man to a woman; however, transmission has also been documented from a man to another man and from a woman to a man. If a couple has a female partner and only she travels to an area with risk of Zika, the couple should consider using condoms or not having sex for at least 2 months after the female partner returns, even if she doesn't have symptoms. Pregnant women and men and women who are considering parenthood and who have visited or are considering traveling to areas at risk should consult their physician and reference the CDC website for travel alerts and pregnancy counseling recommendations.

Avoiding mosquito bites is important for disease control (Table 1). There are hundreds of insect repellants sold in the United States. These insect repellants have different ingredients, diverse concentrations of ingredients, and various combinations of ingredients. Furthermore, various species of mosquitoes may be differentially repelled by different repellants. Though research is limited, the *Aedes aegypti* and *Aedes albopictus* mosquitoes seem to be most effectively repelled by products that contain at least 25% DEET (N,N-diethyl-m-toluamide), 30% Oil of Lemon Eucalyptus, or 20% picaridin. When applied appropriately, these ingredients may repel mosquitoes for approximately 7 hours and seem to be safe when used during pregnancy. Products with lower concentrations of DEET, Oil of Lemon Eucalyptus, and picaridin are much less effective. Products containing IR3535, 2-undecanone, and products made from natural plant oils such as citronella, lemongrass oil, cedar oil, rosemary oil, cinnamon oil, and geraniol seem to be ineffective against Zika-transmitting mosquitoes. Insect repellents can be used with sunscreen, but the sunscreen should be applied first.

Additional protection from mosquito bites can be achieved by treating outer clothing with permethrin. Permethrin, a derivative of *Chrysanthemum cinerariifolium*, is an insect repellent and insecticide. Though it is poorly absorbed and rapidly inactivated permethrin should not be applied directly to the skin and it should not be used on underclothing. The Environmental Protection Agency (EPA) recommends that clothes treated with permethrin should be washed separately from clothes that are not treated. If washed together, underclothing may absorb permethrin into

World Map of Areas with Risk of Zika

**Map Legend**

- Country or territory with current Zika outbreak<sup>1</sup>
- Country or territory that has ever reported Zika cases<sup>2</sup> (past or current)
- Areas with low likelihood of Zika infection because of high elevation (above 6,500 feet/2,000 meters)
- Country or territory with mosquito<sup>3</sup> but no reported Zika cases<sup>2</sup>
- Country or territory with no mosquitoes that spread Zika

<sup>1</sup>No areas are currently reporting Zika outbreaks  
<sup>2</sup>Locally acquired, mosquito-borne Zika cases  
<sup>3</sup>*Aedes aegypti*

the fabric which may increase the risk of absorption through the skin. Permethrin-treated clothing will retain repellent activity through multiple washes. The EPA indicates there is no evidence that exposure to permethrin results in adverse effects for pregnant or nursing mothers or adverse developmental effects in their children. Permethrin is listed as pregnancy category B. It can be used on the outer clothing of children older than 2 months of age.

At present no Zika vaccines are available, although Phase 1 and Phase 2 studies are underway, several DNA and mRNA vaccine platforms appear promising.

**Clinical Manifestations**

The incubation period for Zika virus is estimated to be 3 to 12 days. Serosurvey results from the Yap Islands indicate that only 19% of persons who were infected had symptoms that were attributable to Zika virus. Common symptoms were macular or papular rash (90% of patients), fever (65%), arthritis or arthralgia (65%), nonpurulent conjunctivitis (55%), myalgia (48%), headache (45%), retro-orbital pain (39%), edema (19%), and vomiting (10%). The rash is generally maculopapular and pruritic. Fever, when present, is generally short-term and low-grade. Rarely, immune thrombocytopenia purpura has been linked to Zika. In more than 60 years of observation, severe disease requiring hospitalization is uncommon and case fatality is low.

**Diagnosis**

In a “pure” Zika epidemic, a diagnosis can be ascertained on clinical grounds. However, dengue and chikungunya have similar

**TABLE 1** Prevention of Mosquito Bites

- Remove yard debris (e.g., old tires) and containers that collect water and may provide mosquito breeding sites.
- Wear long-sleeved shirts, long pants, and socks. Tuck pants into socks.
- Apply permethrin to outer clothing.
- Use window screens.
- Use mosquito netting at night if sleeping quarters are not screened.
- Use mosquito netting when children less than 2 months of age—before they can use mosquito repellants—must go outside.
- Apply mosquito repellents directly to exposed skin. When applying mosquito repellants to the face, spray it on the hands, then rub it in. Avoid the eyes and mouth.
- Do not allow young children to apply mosquito repellants themselves. Children who rub mosquito repellent into their own skin are prone to putting their hands into their mouths or touching their eyes.
- Adults should apply mosquito repellent on children by putting the repellent on their own hands and rubbing it into the child’s skin.
- To limit the total amount of mosquito repellent that might be absorbed, do not apply to skin under clothing or on skin that is broken (i.e., cuts, rashes).
- Do not use mosquito repellents near food. Wash hands before eating or drinking.
- Wash off mosquito repellent from the skin when it is no longer needed.
- At the end of the day, wash treated skin with soap and water.

clinical presentations and have been epidemic in the Americas, confounding the clinical diagnosis.

The CDC website should be consulted for Zika virus testing recommendations for women who are symptomatic or asymptomatic during pregnancy. Instructions for testing can be found at <https://www.cdc.gov/zika/hc-providers/types-of-tests.html>.

Cross-reaction with related flaviviruses (e.g., dengue and yellow-fever viruses) is common, complicating the immunologic interpretation of infection. Physicians who deliver an infant suspected of suffering the effects of maternal Zika virus infection should consult the CDC to discuss blood, placental, and umbilical cord sampling. Clinicians should be alert to brain and eye defects in an infant, which might prompt suspicion of prenatal Zika virus infection. These findings might provide a signal to the reemergence of Zika virus, which is particularly important in geographic regions lacking ongoing comprehensive Zika virus surveillance. Zika virus infection is a nationally notifiable disease.

### Differential Diagnosis

Differential diagnosis encompasses a wide variety of other viral diseases such as dengue, chikungunya, Mayaro virus disease, Ross River fever, Barmah Forest disease, o'nyong-nyong disease, and Sindbis fever. In addition, the CDC lists group A streptococcus, leptospirosis, malaria, rickettsia, rubella, measles, parvovirus, enterovirus, and adenovirus in the differential diagnosis.

### Treatment

At present, there is no treatment or vaccine for Zika virus disease. Because symptoms are usually absent or mild, most acutely infected patients do not access the medical system and treat themselves symptomatically. Antiviral medication is ineffective. The mainstays of management are bed rest and supportive care. When multiple arboviruses are co-circulating, testing for a specific viral diagnosis, if available, can be important in anticipating, preventing, and managing complications.

Although the Zika virus has not been associated with hemorrhagic fever, it is probably best to avoid aspirin and nonsteroidal antiinflammatory medications due to their association with hemorrhagic fever syndromes and death when taken for the treatment of similar viruses. The use of aspirin should be avoided in children due to the risk of Reye syndrome. Guidelines for women considering pregnancy and having concerns regarding Zika can be found at the CDC website here: <https://www.cdc.gov/pregnancy/zika/women-and-their-partners.html>.

Because of the rapidly evolving knowledge about the Zika virus, clinicians are encouraged to freely consult the CDC and WHO websites for clinical guidance.

### Monitoring

Pregnant women should be asked about their travel history. Currently the WHO recommends anomaly ultrasound investigations at 18 to 20 weeks' gestation to identify, monitor, or exclude fetal brain abnormalities, particularly microcephaly, for all pregnant women living in areas with ongoing Zika virus transmission. Guidelines for monitoring pregnant females with a potential exposure to Zika virus can be found at [https://www.cdc.gov/mmwr/volumes/66/wr/mm6629e1.htm?s\\_cid=mm6629e1\\_w](https://www.cdc.gov/mmwr/volumes/66/wr/mm6629e1.htm?s_cid=mm6629e1_w).

### Complications

The major complication of Zika virus disease is the potential risk of microcephaly as a result of vertical transmission. Amniocentesis has been used to detect the presence of Zika virus in amniotic fluid of women who had ultrasound confirmation of microcephalic fetuses. The virus has been isolated in the brains of newborns and miscarried fetuses. It is unclear whether there may be contributory factors to the development of microcephaly such as nutritional and environmental factors or concomitant infection with other microorganisms. Other fetal findings have included intracranial calcifications, orbital calcifications, and microphthalmia. It does not appear that the proportion of birth defects differs among mothers who experience symptoms versus those who are asymptomatic.

The U.S. Zika Pregnancy and Infant Registry (USZPIR) conducted a study of 6799 live-born infants from pregnancies with laboratory evidence of confirmed or possible Zika virus infection born between December 1, 2015 and March 31, 2018. The results of the study found that 4.6% had Zika-associated birth defects. In a subgroup of pregnancies with a positive nucleic acid amplification test (NAAT) for Zika virus infection, the percentage was 6.1% of live-born infants. Among infants with any Zika-associated birth defect, one-third had more than one defect reported. Among the subgroup with NAAT-positive results, Zika-associated birth defects were reported with exposures throughout pregnancy but were more prevalent among infants born to mothers with exposure early in pregnancy. Approximately two-thirds of pregnant women in this cohort reported asymptomatic infections. The microcephaly may be subtle. Children may have a craniofacial disproportion and abnormal cranial shape. The fontanelles may be closed or very small and the sutures may be uneven or overlapping. In addition to microcephaly, a phenotypic spectrum has been identified in congenital Zika syndrome. Neurologically, there may be changes in motor activity, severe muscle hypertonia, feeding difficulties, and excessive and inconsolable crying. Musculoskeletal problems include joint immobility, hand and finger contractures, feet contractures and malposition, deep and multiple dimples over joints, abnormal palmar creases and generalized arthrogryposis. Skin on the scalp and other areas of the body may be redundant. Brain imaging may show calcifications, abnormal gyral patterns, enlarged ventricles, and marked decreases in the volume of gray and white matter. The corpus callosum may be thin or absent. The brainstem and cerebellum may be underdeveloped. Seizures, especially in infants between 3 and 6 months of age, may develop and children may exhibit visual problems, hearing loss, and impaired growth. Children exposed to Zika virus in utero who do not have overt signs of Zika virus-associated clinical manifestations or abnormal neuroimaging may have a higher risk of neurodevelopmental delay. The viruses' strong affinity for neural cells may cause neurologic damage that only becomes apparent as children age. Although the full range of birth defects and disabilities associated with Zika virus disease remains to be fully delineated, neural tube defects do not seem to be associated. It is unclear whether infants and children who contract Zika in infancy or early childhood may develop neurologic complications.

Retrospective data from the French Polynesia Zika virus outbreak from October 2013 to April 2014 indicate a close association with Guillain-Barré syndrome. Of the 42 patients diagnosed with Guillain-Barré syndrome, 41 (98%) had anti-Zika virus IgM or IgG, and all (100%) had neutralizing antibodies against Zika virus compared with 54 (56%) of 98 in the control group.

Much still needs to be learned about Zika virus and its geographic spread, transmission, teratogenicity, and long-term complications, including the potential for late onset symptoms in adulthood in previously asymptomatic individuals. A larger issue still to be elucidated in the emergence of Zika and other novel infectious diseases is the role played by urban crowding, ease of international travel, and human encroachments into complex ecosystems.

## ACUTE FACIAL PARALYSIS

Method of

Steven L. Meyers, MD

### CURRENT DIAGNOSIS

- Typical cases of acute facial paralysis are diagnosed based on examination and do not require additional evaluation.
- All patients with acute facial paralysis should have a complete neurologic and head and neck examinations.
- The presence of atypical features such as a slowly progressive course, failure to improve, recurrent attacks, or other neurologic findings should prompt additional evaluation with computed tomography (CT) or magnetic resonance imaging (MRI) of the head and a specialist consultation.

### CURRENT THERAPY

- Steroid therapy, such as prednisone<sup>1</sup> 60–80 mg daily for 7 days, initiated within 3 days of onset of the facial paralysis, increases the chances of recovery
- The use of antiviral therapy remains controversial without strong evidence of benefit, but valacyclovir (Valtrex)<sup>1</sup> 1000 mg three times daily for 7 days may be beneficial in patients with severe paralysis.
- Eye care with artificial tears, ophthalmic ointments at night, and eye protection should be used in patients with severe facial paralysis.

<sup>1</sup>Not FDA approved for this indication.

Acute facial nerve paralysis, or Bell's palsy, is a common disorder manifesting with the acute to subacute onset of unilateral paralysis of the muscles of facial expression. The Scottish physician Sir Charles Bell described cases of facial paralysis due to trauma in the 1800s, and the idiopathic condition carries his name today. However, there are many possible causes of facial paralysis, and each patient requires a careful history and complete neurologic examination to exclude these possibilities.

### Epidemiology and Risk Factors

The annual incidence rate is between 13 and 34 cases per 100,000 population. All age ranges can be affected, but persons between the ages of 15 and 40 years are most commonly affected. Diabetics, pregnant women in the third trimester, and women in the immediate postpartum period are at increased risk. There is no gender, race, or geographic predilection.

### Pathophysiology

The seventh cranial, or facial, nerve arises from the pontomedullary junction and runs in close proximity to the eighth cranial nerve to the internal auditory meatus. The nerve then runs

through the bony fallopian canal before exiting the skull at the stylomastoid foramen. The labyrinthine portion of the fallopian canal is very narrow, and it is postulated that swelling of the nerve results in compression in this region.

Three branches arise from the facial nerve within the fallopian canal. The greater petrosal nerve arises from the geniculate ganglion, passes to the pterygopalatine ganglion, and eventually supplies innervation to the lacrimal and palatine glands. The second branch is the nerve to the stapedius muscle in the middle ear. The final branch is the chorda tympani, which supplies taste sensation from the anterior two thirds of the tongue.

The pathophysiology of Bell's palsy is uncertain, but a viral cause is the most commonly accepted hypothesis. Many different viruses have been associated with facial paralysis, with herpes simplex virus (HSV) having the strongest evidence. HSV-1 DNA has been detected by polymerase chain reaction assay in endoneural fluid in patients with Bell's palsy undergoing facial nerve decompression.

Herpes zoster is another virus associated with facial nerve paralysis. Herpes zoster oticus (Ramsey Hunt syndrome) is diagnosed when vesicles are seen in the external auditory canal or on the auricle. Other viruses implicated include cytomegalovirus, Epstein-Barr virus, adenovirus, rubella, mumps, influenza B, and coxsackievirus.

The histopathology of the facial nerve supports an inflammatory etiology with findings similar to those seen in herpes zoster infection. The perineurium is edematous, with diffuse infiltration of inflammatory cells between nerve bundles and surrounding the intraneural vessels.

### Clinical Manifestations

The clinical presentation of Bell's palsy is typically dramatic and very stereotypical. Pain behind the ear in the region of the mastoid can precede the onset of weakness by hours to days. Weakness of the muscles of facial expression on one side progresses over a period up to 48 hours. Progression over more prolonged periods raises the possibility of a neoplasm affecting the nerve. The degree of weakness can range from quite subtle to complete paralysis of all muscles of facial expression. Typical features include inability to close the eye, sagging of the eyelid, loss of the nasolabial fold, and inability to wrinkle the forehead muscles. Sparing of the forehead muscles suggests a central or upper motor neuron lesion because these muscles receive bilateral innervation. Additional symptoms that may be reported include hyperacusis caused by paralysis of the stapedius muscle, loss of taste in the anterior tongue due to involvement of the chorda tympani, and decreased tearing due to dysfunction of the parasympathetic innervation of the lacrimal gland. However, most patients actually report increased tearing from the affected eye owing to diminished blinking.

### Diagnosis and Differential Diagnosis

There is no specific diagnostic test for Bell's palsy. The diagnosis is based on a typical history and examination. Atypical features mandate a search for other causes. A slowly progressive course, parotid gland mass, or involvement in selected branches of the facial nerve can suggest neoplastic compression. Vesicles over the ear or internal auditory canal suggests herpes zoster infection. Patients should be asked about preceding fevers, rashes, and arthralgias, which can prompt evaluation for Lyme disease. However, in the absence of

**BOX 1** Differential Diagnosis of Acute Facial Nerve Paralysis**Idiopathic**

Idiopathic cases account for 65%

**Infectious**

## Common

- Herpes zoster
- Herpes simplex
- Borreliosis

## Uncommon

- Lyme disease
- Epstein-Barr virus
- Human immunodeficiency virus
- Tuberculosis

## Rare

- Acute otitis media
- Chronic otitis media

**Trauma**

## Temporal bone fractures

Penetration wounds

**Neoplasm**

## Parotid

- Metastases
- Schwannoma
- Cholesteatoma

**Metabolic and Toxic**

## Diabetes

- Thyroid disease
- Alcoholism
- Carbon monoxide poisoning (rare)

**Other**

- Sarcoidosis
- Multiple sclerosis
- Sjögren syndrome

these features, routine serologic testing is not recommended. Sarcoid is a rare cause of usually bilateral facial paralysis. The onset of facial paralysis in the setting of head injury, particularly in the presence of ipsilateral hearing loss, should prompt imaging of the skull base to rule out a temporal bone fracture (Box 1).

**Treatment**

Treatment of Bell's palsy can be divided into three categories: general medical therapy, specific medical therapy, and surgical therapy. General medical care includes proper eye care. Reduced blinking and inability to completely close the eye increases the risk of corneal abrasion and ulceration. Artificial tears and ophthalmic ointments can prevent these complications. Patients should be instructed to use proper eye protection to prevent injuries. Facial muscle massage and facial nerve stimulation have no evidence to support their use.

**Medical Therapy**

Specific medical therapy includes glucocorticoid and antiviral medications. Glucocorticoid therapy has been demonstrated to be effective in both meta-analyses and randomized trials. The two largest trials of glucocorticoid and antiviral therapy demonstrated benefit for steroids but no benefit for antiviral therapy when used either alone or in combination with steroids. Treatment in these trials was begun within 72 hours of onset of paralysis and consisted of relatively high-dose prednisolone (Millipred)<sup>1</sup> 50 to 60mg daily for 10 days. Antiviral therapy evaluated included acyclovir (Zovirax)<sup>1</sup> 400mg five times daily for 10 days and valacyclovir (Valtrex)<sup>1</sup> 1000mg three times daily for 7 days, neither of which showed benefit.

<sup>1</sup>Not FDA approved for this indication.

Smaller, lower-quality studies have suggested a benefit of combining antiviral therapy with glucocorticoids, particularly in patients with more severe baseline dysfunction.

**Surgical Therapy**

Surgical decompression of the facial nerve is not recommended. A 2011 Cochrane review and a 2001 review by the American Academy of Neurology both found no good evidence supporting this treatment modality. Only two small randomized studies showed no differences in outcome between surgical and medical therapy.

**Monitoring and Complications**

The overall prognosis of Bell's palsy is favorable. In one study of untreated patients, 85% showed signs of recovery within 3 weeks. Ultimately, 71% experienced complete recovery and an additional 13% were felt to have only slight residual weakness. The degree of weakness at onset is an important prognostic indicator: 94% of patients with incomplete paralysis experienced complete recovery. The absence of any improvement, no matter how small, at 3 to 4 months should raise concern regarding the diagnosis and lead to a search for alternative etiologies.

Motor nerve conduction studies, or electroneurography, can be used to help predict prognosis in selected patients. Patients with incomplete lesions that have an excellent prognosis do not require further evaluation. Motor nerve conduction studies involve stimulating the facial nerve electrically and recording muscle responses with surface electrodes over appropriate muscles. The amplitude of the evoked muscle response on the affected side at 10 days can be compared with the unaffected side, giving an estimate of the degree of axonal loss. A 90% drop in amplitude predicts less than complete recovery, and loss greater than 98% predicts significant residual weakness and synkinesis.

In severe cases of facial paralysis, attention to good eye care as previously discussed is important to prevent eye damage and vision loss.

During recovery from severe nerve injury, axonal regrowth may be misdirected, resulting in synkinesis. Voluntary activation of one muscle group can cause activation of other muscles. Attempts at blinking can result in twitching of the mouth, or smiling can cause involuntary blinking. Misdirection of autonomic fibers can result in the syndrome of "crocodile tears," involuntary lacrimation while eating.

Recurrent attacks of facial paralysis on the ipsilateral or contralateral side occur in up to 15% of patients even after many years. Additional recurrences are quite rare, being reported at a rate between 1% and 3%.

## ALZHEIMER'S DISEASE

Method of

Katarzyna Wilamowska, MD, PhD; and Janice Knoefel, MD, MPH

### CURRENT DIAGNOSIS

- There is insufficient evidence on benefits versus harms in screening for cognitive impairment in older adults (Category I).
- Diagnosis of Alzheimer's disease (AD) is clinical, but consider referral to dementia specialist if there are ambiguous findings.

### CURRENT THERAPY

- There is no known cure or disease-slowing treatment for AD.
- Acetylcholinesterase inhibitors and NMDA receptor antagonists temporarily improve day-to-day function but do not slow the progression of neuronal cell death.
- Behavioral symptoms of AD are best treated with psychosocial interventions; use pharmacology as a last resort.
- Caregiver training and support is extremely important; it will impact the health of patient and caregiver alike.
- High caregiver burden can result in early institutionalization and poor patient outcomes.

Alzheimer's disease (AD) is considered the most common (60%–80%) individual cause of major neurocognitive disorders (NCDs), previously denominated as dementia. As of 2021, more than 1 in 9 (11.3%) Americans aged 65 or older are living with AD. By 2050, the number of Americans living with AD will double to a projected 12.7 million.

AD is not a result of normal aging (Table 1). There is no cure and, after a prolonged debilitating disease process, AD is fatal. Although we continue to learn more about the pathophysiology of AD, it is known to have indolent asymptomatic deposition of abnormally folded extracellular amyloid- $\beta$  (A $\beta$ ) and clumping tau proteins in the brain that may precede symptoms by more than 20

years. As the disease progresses, amyloid plaques, neurofibrillary tangles, and brain inflammation develop, culminating in neuronal cell death. Research is not yet able to accurately predict the appearance of cognitive symptoms based on these processes.

As with many disorders listed in the DSM-5, dementia carries with it a stigma that may lead patients, family, and friends to avoid or reject the diagnosis. Conversely, a patient with AD, due to the cognitive impact of the disease, may not be aware of their deficits. Diagnosis of AD is often delayed (especially in unbefriended older adults) until the inability for self-care, usually seen as reduction in instrumental activities of daily living (IADLs), brings the patient to the attention of medical professionals.

### Screening

Screening for cognitive impairment in older adults continues to be controversial. The US Department of Veterans Affairs, the Canadian Task Force on Preventive Health Care (CTFPHC), the National Institute for Health Care and Excellence (NICE), and the Royal Australian College of General Practitioners (RACGP) recommend against screening for cognitive impairment of asymptomatic older adults. The European Federation of Neurological Societies (EFNS) has no recommendations for asymptomatic individuals, and the US Preventive Services Task Force (USPSTF) states that the current evidence is insufficient to assess the balance of benefits and harms of screening for cognitive impairment in older adults. However, all these organizations encourage screening, work-up, and referrals for cognitive impairment in patients where memory or other cognitive concerns are detected by the patient, knowledgeable informant, or medical practitioner.

On the other hand, the International Association of Gerontology and Geriatrics (IAGG) recommends screening for cognitive impairment of patients with known risk factors for dementia. The Gerontological Society of America (GSA) and the Alzheimer's Association recommend regular screening for cognitive impairment through the Medicare Annual Wellness Visit with coverage for "detection of cognitive impairment" approved by Medicare since 2011.

### Risk Factors and Prevention

The strongest risk factors for AD are unmodifiable: age and genetics.

AD is not a normal part of aging, and aging alone does not cause AD. The percentage of Americans with AD increases with age, with the prevalence of AD in those aged 65 to 74 at 5.3%, 75 to 84 at 13.8%, and 85 or older at 34.6%.

**TABLE 1** Examples of Changes With Normal Aging vs. Alzheimer's Disease

COGNITIVE DOMAIN AFFECTED	NORMAL AGING	ALZHEIMER'S DISEASE
Learning and Memory	Sometimes forgetting names or appointments but remembering them later.	Forgetting important dates or events. Asking for the same information over and over.
Executive Function	Occasional error in balancing a checkbook, omission of a recipe ingredient, taking the wrong turn while driving, making a bad decision once in a while.	Difficulty completing daily tasks, trouble driving to a familiar location, managing a budget, or remembering rules to a favorite game. Poor judgment when dealing with money; victim of financial fraud. Less attention to personal grooming.
Complex Attention	Misplacing things occasionally but able to find them by retracing their steps.	Putting items in unusual places, losing things, unable to retrace steps to find them, may accuse others of stealing.
Language	Sometimes having trouble finding the right word.	Trouble following or joining a conversation. May struggle with vocabulary: word finding, calling things by the wrong name.
Perceptual-motor	Vision changes related to cataracts, glaucoma, age-related macular degeneration.	Difficulty reading, judging distances, determining color/contrast. No longer knows how to use daily household objects (e.g., hairbrush, TV remote, phone)
Social Cognition	Sometimes feeling weary of work, family, and social obligations. Developing very specific ways of doing things and getting upset at change in routine.	Decreased participation in hobbies, social activities, work projects, or sports. Changes in mood and personality; confused, suspicious, depressed, fearful, or anxious. Easily upset.

Several identified genes increase the risk of AD, and people with a first-degree relative (parent or sibling) with AD have a 2.5 lifetime risk of developing AD compared with the general population. AD with mendelian family history is rare and is more likely in early-onset Alzheimer's disease (EOAD, symptom onset before age 65). Of families with EOAD, 86% have a mutation in one of three causative genes: PSEN1 (chromosome 14, most frequent), APP (on chromosome 21, important in trisomy 21 populations), and PSEN2 (chromosome 1, extremely rare).

In late-onset AD, APOE-ε4 gene has the strongest impact on risk but by no means is a guarantee of disease development. In fact, recent research suggests lifestyle modifications can decrease the impact of this vulnerability gene marker. Of note, studies of racial or ethnic backgrounds on AD development are inconclusive and, at best, illustrate nonbiologic determinants of health.

Modifiable risk factors include optimizing cardiovascular health, preventing brain cell injuries, decreasing harmful substance exposure, and promoting protective behaviors.

Optimizing cardiovascular health involves controlling hypertension while monitoring for and correcting adverse effects such as cerebral hypoperfusion or falls, controlling hyperlipidemia and diabetes with appropriate treatment, and encouraging smoking cessation.

Preventing brain cell injury starts in early life with consistent helmet use, and with counseling and treatment of substance-use disorders. Treatment of obstructive sleep apnea can prevent injury to brain cells.

The lifetime dose of over-the-counter and prescribed medications with potent anticholinergic action have been shown to increase risk for dementia. Reduction and/or cessation in the use of these medications must be encouraged. Frequently implicated are 1st generation antihistamines, overactive bladder antimuscarinics, muscle relaxants, and tricyclic antidepressants.

Protection includes ameliorating sensory impairment (vision and hearing loss), treating mood disorders, encouraging a healthy diet and exercise, and enhancing brain plasticity in cognitive and social functions. All these behaviors have a transient effect that diminishes once the intervention is abandoned.

## Diagnosis

### Diagnostic Criteria

Diagnosis of dementia involves meeting the diagnostic criteria for an all-cause major neurocognitive disorder, which necessitates:

- Evidence of cognitive decline from previous functional and performance baseline in a **minimum of two cognitive domains** (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition)
- Cognitive deficits interfere with patient's ability of independent function
- Deficits cannot be better explained by delirium, affective disturbances, or another disorder

AD diagnosis is clinically classified as **probable AD** or **possible AD** dementia. Core clinical criteria for probable AD dementia are:

- Insidious onset
- Clear-cut history of worsening cognition
- Initial and most prominent cognitive deficits in one of the categories:
  - **Amnesic presentation:** Most common. Presents with impairment in learning and recall of recently learned information. Deficits in other cognitive domains should be present.
  - **Nonamnesic presentation:**
    - **Language presentation:** Deficits in word-finding, but deficits in other cognitive domains should be present.
    - **Visuospatial presentation:** Deficits are in spatial cognition, including object agnosia, impaired face recognition, simultanagnosia, and alexia. Deficits in other cognitive domains should be present.
    - **Executive dysfunction:** The most prominent deficits are impaired reasoning, judgment, and problem solving. Deficits in other cognitive domains should be present.

The diagnosis of probable AD dementia should *not* be applied when there is evidence of other major neurocognitive disorders such as vascular dementia, Lewy body dementia, frontotemporal dementia, primary progressive aphasia, or other active neurologic disease (e.g., Parkinson's disease), nonneurologic comorbidity, or medication use causing substantial cognitive effect (see differential diagnosis section).

Possible AD dementia diagnosis is applied in circumstances of atypical disease course that fulfills the above core diagnostic criteria or in an etiologically mixed presentation.

### Differential Diagnoses

The diagnosis of AD must be differentiated from other states of altered cognition (Table 2). Furthermore, in older adults, the presence of delirium, postoperative cognitive dysfunction, post-COVID-19 "brain fog," mild cognitive impairment, or new onset anxiety or mood disorder may be a first sign of future development of major neurocognitive disorder and should trigger closer follow-up.

- **Delirium:** Develops over a short period of time (hours or days), with change from baseline involving fluctuating levels of attention and awareness throughout the day. Level of activity may range from hyperactive to hypoactive (often underdiagnosed), or mixed. Delirium may be incited by acute infection, change in medical condition, substance intoxication or withdrawal (e.g., drug abuse, over-the-counter or prescribed medications), toxin exposure, or multiple etiologies. Resolution may be acute with correction of underlying cause, but symptoms may persist for weeks or months.
- **Postoperative cognitive dysfunction:** Develops after receiving anesthesia. Although multifactorial in origin, it is thought to be triggered by the immune/inflammatory response to surgery. Typically affects cognitive domains of learning and memory, and executive function. Resolution typically within 6 months.
- **Post-COVID-19 "brain fog":** Develops after COVID-19 infection of any severity, including asymptomatic positive tests. Current presumed etiologies include multifactorial delirium, viral-induced immune and inflammatory response, SARS-CoV-2-induced coagulopathy, and direct viral invasion of CNS. Some cases resolve within days or weeks; others have been persistent and may indicate a new cognitive baseline for the patient. There is some emerging evidence of hypometabolic lesions of the brain that can be visualized with PET scanning.
- **Mild cognitive impairment (MCI):** Insidious onset of symptoms of **minor** neurocognitive disorder where cognitive impairment **does not** interfere with ability to function independently. May affect any cognitive domain and presage development of major neurocognitive disorder. Symptoms may not progress and does not resolve unless substance/medication induced.
- **Anxiety or mood disorder:** Onset often insidious but may be acute. If new onset of anxiety or depression occurs, it may be the first symptom of a major neurocognitive disorder. Rather than a new onset of mental disorder such as bipolar or attention-deficit/hyperactivity disorder (ADHD), consider chronic undiagnosed disorder with atypical presentation or "new" presentation due to loss of compensatory mechanisms. Resolution depends on appropriate recognition and cognitive/pharmacologic treatment.
- **Substance use disorder:** Onset may be acute or progressive. Etiology is typically from chronic use but may be brought to medical attention due to discontinuation or overdose. Substances typically indicated are alcohol, stimulants, marijuana, and opioids. Impacts primarily to executive function, memory, and learning domains. Complete resolution of symptoms can occur with prolonged abstinence from substance and correction of nutritional deficiencies, but masked vascular dementia (VaD) may be present as sequelae of chronic substance use. Cannot exclude that presence of neurocognitive changes incited substance use disorder.
- **Major neurocognitive disorders that are not Alzheimer's disease:** all are progressive and do not resolve. Treatment varies with category and can, in fact, worsen cognitive and behavior.

**TABLE 2** Differential Diagnosis of Major Neurocognitive Disorder Due to Alzheimer's Disease

COGNITIVE DISORDER	ONSET	ETIOLOGY	CHARACTERISTICS SPECIFIC TO DISORDER	TIME TO RESOLUTION
Delirium	Acute	Multifactorial	Fluctuating levels of attention and awareness	Days, weeks, months
Postoperative cognitive dysfunction	Immediately after anesthesia	Multifactorial Immune/inflammatory response to surgery	Memory and executive function domains most effected	Typically within 6 months
Post-COVID-19 "brain fog"	Positive COVID-19 infection	Multifactorial Viral-induced inflammation Viral-induced coagulopathy Viral invasion of CNS	May affect any cognitive domain	Weeks, months, or persistent
Mild cognitive impairment (MCI)	Insidious	Multifactorial May be reversible if due to substance or medication intoxication Amnesic most common	May affect any cognitive domains; not severe enough to interfere with independent function	Resolves after substance/medication cessation, or persistent
Anxiety or mood disorder	Chronic or new onset	If new onset, consider prodromal neurocognitive disorder or atypical presentation of previously undiagnosed anxiety/mood disorder	Depression: "Pseudodementia" may appear to affect multiple cognitive domains, but upon closer evaluation cognition changes are due to depression Anxiety: suspiciousness, restlessness, insomnia, fearfulness	May improve with combination of cognitive therapy and appropriate medications; recalcitrant disorders may benefit from ECT
Substance use disorder	Progressive due to use, or acute due to overdose or cessation of substance	Alcohol-related brain damage Chronic stimulant use disorder Chronic marijuana use disorder Chronic opioid use disorder	Memory and learning Executive function domains most commonly affected May have VaD component	May improve with cessation of substance and/or repleting nutritional deficiencies, or persistent
<b>Major neurocognitive disorders</b>				
Alzheimer's Disease (AD)	Insidious, most common individual cause of dementia	Misfolded amyloid- $\beta$ and tau protein deposition leading to neuronal death	Short-term memory loss, language, visuospatial, or executive function most impacted	Progressive
Lewy Body Dementia (LBD): umbrella term for dementia with Lewy bodies and Parkinson's disease dementia	Insidious or pseudoacute in the setting of sleep deprivation	Misfolded $\alpha$ -synuclein (Lewy bodies) deposition in substantia nigra and cortex leading to degradation of dopaminergic neurons	Visual hallucinations, REM sleep disorders; may have bradykinesia, rigidity, or gait changes (see Parkinson's disease chapter) Very sensitive to neuroleptic medications	Progressive
Frontotemporal lobar degeneration (FTLD)	Insidious, symptoms develop earlier in life than AD	Tau and TDP-43 protein inclusions in frontal and temporal lobes Most common cause of dementia in people younger than 60	Behavioral, personality, language changes; memory typically preserved in early disease May have worsening symptoms when treated with cholinesterase inhibitors or NMDA antagonists	Progressive
Vascular dementia (VaD)	Step-wise progression	Cardiovascular risk factors, strokes, infarcts	May affect any cognitive domains; focal findings or gait/balance changes on examination	Progressive
Mixed dementia	Insidious, increases with age	Commonly a combination AD and VaD but can have LBD components	Mixed characteristics of component disorders	Progressive

ral outcomes if misdiagnosed. For brevity, only the most common major neurocognitive disorders are listed in full detail.

- Vascular dementia (VaD): Presentation may affect any cognitive domain, although executive function domain deficits tend to be favored, while memory is initially preserved. Onset of impairment is often abrupt. Patient with cardiovascular risk factors. Physical examination findings are focal in

nature (but may be subtle) and often include motor function difficulties, especially slow gait or poor balance. Five percent to 10% of all dementias are of vascular etiology alone.

- Lewy body dementia (LBD): An umbrella term for neurocognitive disorders due to misfolded  $\alpha$ -synuclein deposition including Dementia with Lewy Bodies (DLB) and Parkinson's disease dementia (PDD). Presentation characteristic

of REM sleep disturbances (acting out dreams), visual hallucinations, and marked visuospatial impairment. Parkinsonian motor symptoms may or may not be present at time of diagnosis (see chapter on Parkinson's disease). Patients in this group are often exquisitely sensitive to neuroleptic medications. Five percent of all patients with dementia are of DLB etiology alone.

- **Frontotemporal lobar degeneration (FTLD):** Group of disorders that includes behavioral variant FTLT, primary progressive aphasia, Pick's disease, corticobasal degeneration, and progressive supranuclear palsy. Degenerative changes involve tau and TDP-43 protein inclusions preferentially in frontal and temporal lobes leading to marked atrophy. Presentation encompasses marked changes in personality and behavior and/or difficulty producing or comprehending language. Symptoms may worsen when treated with anti-Alzheimer's medications.
- **Mixed:** Presents as a combination of component neurocognitive disorders with AD, VaD, and, to a lesser degree, LBD. Increases in likelihood with age, with highest likelihood in 85 years and older age group. Over 50% of people with dementia have evidence of more than one type of pathology.
- **Other diagnoses to consider:** traumatic brain injury, chronic traumatic encephalopathy syndrome, prion disease, Huntington's disease, human immunodeficiency virus (HIV) infection, neurosyphilis, cryptococcosis, brain tumor, subdural hematoma, normal-pressure hydrocephalus, hypoxia secondary to heart failure, hypothyroidism, hypercalcemia, hypoglycemia, temporal arteritis, systemic lupus erythematosus, hepatic or renal failure, metabolic conditions, epilepsy, and multiple sclerosis.

## Diagnostic Evaluation

### History

Focused history is needed from the patient and at least one knowledgeable informant. Current cognitive and functional difficulties should be discussed, as well as fluctuation of symptoms. Behavior linked to stress, fatigue, or being away from a patient's normal surroundings should also be understood and may clue clinician into treatment needs.

A thorough medication review should be performed with focus on adverse medication effects, goals of care, and deprescribing where possible. Supplements, over-the-counter medications, and herbal remedies need to be evaluated in a nonjudgmental fashion. Reviewing current and past substance use at the same time may reveal more information than if asked separately.

Timeline of the start of functional decline generally precedes presentation to provider by several years. This may be elicited by asking about anecdotes that may have seemed funny or odd at the time (e.g., "Remember when Mom was making her specialty dish and forgot part of the recipe?" or "Remember when Dad took a long time to drive home, even though he was 5 minutes away?"). Any medical illnesses or conditions that may have triggered the decline should be elucidated (e.g., "Mom has never been the same since that infection last year" or "Dad woke up one morning and couldn't see out of his right eye, but he didn't mention it until a few weeks later and it doesn't bother him").

Neurocognitive disorders expose the affected individual to multiple safety concerns, and these must be discussed to detect current problems and to plan for the future. Triggers for further evaluation include "close calls" for motor vehicle accidents, falls, getting lost, or locked out.

### Cognitive Status Examination

Although qualitative impressions of cognitive status are helpful in raising suspicions, quantitative evaluation of cognitive status is needed. No single screening tool evaluates all of the cognitive domains: learning and memory, executive function, complex attention, language, perceptual-motor/visuospatial skills, and social cognition. With the limited time of a primary care visit, one is compelled to leverage previsit and office waiting times for questionnaires completed by patient and informant prior to visit, as well as some in-clinic screening tools that may be administered by a medical assistant, nurse, or medical provider (Table 3). These screening tools may aid in the clinical decision making of the provider but need to be interpreted with caution. For example, there may be cases where the patient passes a cognitive screen but fails an entire cognitive domain within the screen, warranting further evaluation.

The Alzheimer's Association "Alzheimer's Disease Pocketcard" mobile app has interactive links to many of the tools listed in this

**TABLE 3** Brief List of Self-Administered and Office Screening Tools for Evaluation of Suspected Major Neurocognitive Disorders and Caregiver Burden

TOOL	PREVISIT OR TIME TO ADMINISTER IN OFFICE	PREFERRED PERSON TO ANSWER	COGNITIVE DOMAINS EVALUATED	DESCRIPTION
IADL	Previsit / <5 min	Patient	Executive function, apraxia, agnosia	Independent activities of daily living
ADL	Previsit / <5 min	Patient	Executive function, apraxia, agnosia	Activities of daily living
AD8	Previsit / <5 min	Informant	Memory, executive function, apraxia, agnosia	Good at eliciting early cognitive changes in a variety of dementias; asks informant about judgment, less interest in hobbies, repeats things, trouble using tools, forgets month or year, finances, trouble remembering appointments or daily things
GPCOG	Previsit / <5 min	Patient and Informant	Memory, executive function, aphasia	Recall, orientation, recent news recall; patient questionnaire is paired with an informant questionnaire that asks about memory, finances, wordfinding, ADLs
Short (16 qs) or full (26 qs) IQCODE	Previsit / >10 min	Informant	Memory, executive function, apraxia, agnosia	Asks informant about changes in cognitive function, physical function, patient personality, and behavior
Mini-Cog	<5 min	Patient	Memory, executive function, apraxia	3-item recall plus clock drawing
MIS	<5 min	Patient	Memory	4-item recall

**TABLE 3** Brief List of Self-Administered and Office Screening Tools for Evaluation of Suspected Major Neurocognitive Disorders and Caregiver Burden—cont'd

TOOL	PREVISIT OR TIME TO ADMINISTER IN OFFICE	PREFERRED PERSON TO ANSWER	COGNITIVE DOMAINS EVALUATED	DESCRIPTION
SLUMS	6–10 min	Patient	Memory, executive function, aphasia, apraxia, agnosia	Orientation, 5-item recall, math, animals, attention, clock, figures, story
MOCA: may require extra training and licensing	6–10 min	Patient	Memory, executive function, aphasia, apraxia, agnosia	Small trails B, copy figure, clock, naming, verbal fluency, 5-word recall, similarities, orientation, attention
Trail making tests (TMT)	<5 min	Patient	Executive function	Older patients with a TMT-A $\geq$ 54 seconds or a TMT-B $\geq$ 150 seconds have a threefold (CI 95% 1.3–7.0) increased risk of performing poorly during driving
Zarit Burden Interview	Previsit /22 questions	Caregiver	Measures perceived social, physical, financial, and emotional burden	Higher scores indicate greater caregiver burden
Revised Memory and Behavior Problems Checklist	Previsit /24 questions	Caregiver	Focused and caregiver reactions to problematic behaviors in patients with dementia	Higher scores indicate greater caregiver burden

chapter and is available for free on iTunes and GooglePlay, or [alz.org/hcps](http://alz.org/hcps) where it can be accessed as a web app.

### Physical Examination

The neurologic examination should attempt to rule-out Alzheimer's dementia with findings indicative of other major neurocognitive etiologies. Asymmetry in sensation/motor/strength is suggestive of vascular dementia. Tremor and bradykinesia hint at Parkinson's disease syndromes. Abnormalities of eye movement in vertical gaze may signify progressive supranuclear palsy. Peripheral neuropathy, although most likely secondary to diabetes, may indicate B12 deficiency, hypothyroidism, alcoholism, or neurosyphilis.

### Laboratory Testing

Reversible or treatable causes of neurocognitive impairment may be revealed by testing complete blood count (CBC), electrolytes including blood glucose, renal function, liver function, thyroid function, syphilis, HIV, and vitamins B12 (cobalamin), B9 (folate), B1 (thiamine), and D (calciferol).

If EOAD is suspected based on family history and early age of presentation, consider genetic counseling prior to testing for PSEN1, PSEN2, or APP. There is currently no clinical benefit to testing for the APOE-e4 gene.

### Neuroimaging

Although neuroimaging research continues to move forward on deterministic brain matter changes and correlation to the development of major neurocognitive disorders, these findings do not yet promise diagnosis from neuroimaging alone. At present, there is some controversy as to whether clinical neuroimaging is needed in routine cognitive workups, but we recommend routine brain magnetic resonance imaging (MRI) to rule out stroke, vascular dementia, tumors, or normal pressure hydrocephalus, and perhaps rule in FTLD with focal cortical atrophy.

Of note: There can be significant crossover in presentation between FTLD and AD. As such, Medicare provides conditional reimbursement for a positron emission tomography (PET) for brain amyloid.

### When to Refer

Ultimately, the diagnosis of AD in the primary care setting is done clinically after ruling out the above-mentioned differential

diagnoses, with more ambiguous cases referred to dementia specialists: geriatricians, geriatric psychiatrists, neurologists, or neuropsychologists. If finding a specialist nearby proves difficult, consider directing your efforts to the closest Alzheimer's Disease Research Center (ADRC).

### Treatment Counseling

Alzheimer's disease is a life-altering diagnosis. Although many patients have heard of AD, they may not know of the progressive debilitation ahead of them. While the patient is decisional, planning and future decisions may be reassuring to both patient and families. It is essential to discuss protection of themselves, their assets, and their wishes pertaining to current and future management of financial, legal, and medical concerns.

### Caregiver Support

On average, a person diagnosed with AD survives 4 to 8 years after diagnosis; some may live 20 years. The progressive dependence of patients with AD brings to focus the importance of their caregivers. More than 11 million Americans provide care for people with dementia. They provide emotional support, assist in household tasks and personal care, provide health and medical care at home, navigate healthcare systems, serve as surrogate decision makers, arrange services of community-based organizations, and provide needed information during patient visits.

Eighty-three percent of caregivers are family, friends, and unpaid caregivers, often undertaking this role on the foundation of love or obligation to the care recipient. Most begin this role without adequate training or support. This is not without cost: caregivers report physical, emotional, and financial strain, with 1 in 4 finding it difficult to take care of their own health. Increased caregiver burden correlates with decreases in care recipient quality of life, hastens placement, and increases risk of hospitalization and mortality. (See Table 3 for tools to evaluate caregiver burden.)

### Management of Cognitive Symptoms

Until June 2021, Food and Drug Administration (FDA)-approved medications for treatment of AD would only ameliorate symptoms, not alter the progression of the disease. There are two classes of these medications: acetylcholinesterase inhibitors (AChEIs) and NMDA-receptor antagonists (Table 4).

**TABLE 4** FDA-Approved Medications for Treating Cognitive Symptoms of Alzheimer's Disease\*

	<b>DONEPEZIL (ARICEPT)</b>		<b>RIVASTIGMINE (EXELON)</b>		<b>GALANTAMINE (RAZADYNE)</b>	<b>MEMANTINE (NAMENDA)</b>	<b>COMBINED MEMANTINE-DONEPEZIL (NAMZARIC)</b>
Stage of AD	Mild to moderate	Moderate to severe	Mild to moderate	Mild to moderate	Mild to moderate	Moderate to severe	Moderate to severe
Mechanism	Acetylcholinesterase inhibitor (AChEI)					NMDA receptor antagonist	Shared characteristics of component medications
Route of administration	Tablet ODT (orally disintegrating tablets)	Tablet	Oral capsules Oral solution	Patch	Tablet XR tablet Oral solution	Tablet Oral solution	XR tablet
Doses	5 mg, 10 mg ODT: 5 mg, 10 mg	10 mg, 23 mg	1.5 mg, 3 mg, 4.5 mg, or 6 mg Oral sol: 2 mg/mL	Patch 4.6 mg/24hr (9 mg rivastigmine) Patch 9.5 mg/24hr (18 mg rivastigmine)	4 mg, 8 mg, 12 mg Oral sol: 4 mg/mL XR: 8 mg, 16 mg, 24 mg	5 mg, 10 mg Oral sol: 2 mg/mL XR: 7 mg, 14 mg, 21 mg, 28 mg	XR: 7 mg–10mg, 14 mg–10 mg, 21 mg–10 mg, 28 mg–10 mg
Target daily dose	10 mg	23 mg	6 mg BID	9.5 mg/24 hours once daily	Tabs: 12 mg BID XR: 24 mg QD	10 mg XR: 28 mg	28 mg–10 mg
Renal impairment	No dose adjustment	No dose adjustment	May be able to tolerate lower doses	No dose adjustment	Do not exceed 16 mg/day; none if CrCl < 9 mL/min	5 mg BID XR: 14 mg	14 mg–10 mg
Hepatic impairment	Use with caution	Use with caution	May be able to tolerate lower doses	No dose adjustment	Do not exceed 16 mg/day	Use with caution	Use with caution
Frequency	Once daily	Once daily	BID	Daily	Varies	Once daily in evening	Once daily in evening
Minimum interval between dose increases	4–6 weeks between 5 mg and 10 mg	at least 3 months at 10 mg before increasing to 23 mg	2 weeks	4 weeks	4 weeks	1 week	1 week
Administration cautions		23 mg tablet should not be split, crushed, or chewed because this may increase its rate of absorption	Should be taken with meals	The patch should be replaced with a new one every 24 hours. The same site should not be used within 14 days.	Should be taken with meals	XR: do not divide, crush, or chew	Do not divide, crush or chew
Most common adverse effects	Nausea, diarrhea, insomnia, vomiting, muscle cramps, fatigue, and anorexia May cause bladder outflow obstructions		Nausea, vomiting, anorexia, dyspepsia, and asthenia	Nausea, vomiting and diarrhea	Nausea, vomiting, diarrhea, dizziness, headache, decreased appetite, and weight decreased. May cause bladder outflow obstructions.	Dizziness, headache, confusion, and constipation	Headache, diarrhea, dizziness May cause bladder outflow obstructions

\*See chapter text for aducanumab commentary.

AChEIs increase the available acetylcholine between neuronal synapses, enhancing neurotransmission. These medications are most effective in mild to moderate AD. Donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne) are AChEIs currently approved by the FDA. Historically, the first FDA-approved medication for treating AD was tacrine, but this was withdrawn later due to hepatotoxicity.

NMDA-receptor antagonists function by inhibiting the excitation of NMDA receptors by the neurotransmitter glutamate, preventing influx of  $Ca^{2+}$ . This inhibition has the effect of both decreasing excitotoxicity of the neurons involved (reducing symptoms) and restoring the amyloid- $\beta$  induced  $Ca^{2+}$  imbalance (potential neuroprotective role).

A new class of medications became available to select patients in 2021: monoclonal antibodies directed against amyloid. The first of this class was aducanumab (Aduhelm), a recombinant human immunoglobulin gamma 1 (IgG1) monoclonal antibody directed against aggregated soluble and insoluble forms of amyloid beta. As the accumulation of amyloid beta plaques in the brain is part of the AD disease process, there is hope that aducanumab could provide clinical benefit.

In June 2021, aducanumab was granted accelerated approval by the FDA for the treatment of any stage of Alzheimer's disease. This decision was met with strong backlash due to an independent advisory committee's near-unanimous vote to reject the drug due to lack of clinical efficacy and concerns for safety. By July 2021, aducanumab indications were narrowed to patients with mild cognitive impairment due to AD or mild AD. As of April 2022, Centers for Medicare and Medicaid has restricted coverage to clinical trials for aducanumab.

Although numerous vitamins and supplements have been studied in prevention and treatment of cognitive behaviors in Alzheimer's disease, the evidence of benefit is inconclusive and not subject to FDA scrutiny.

Multiple studies have shown aerobic exercise has a positive overall effect on cognitive function and may even slow the progression

of Alzheimer's disease. Cognitive stimulation (engagement in a range of activities aimed at general enhancement of cognitive and social functioning) has also been shown to have beneficial effects on cognitive function, while music-based therapies and psychological treatment can improve symptoms of anxiety, depression, and quality of life in those suffering from AD. Cognitive training (guided practice of standard tasks designed to engage particular cognitive functions with a range of difficulty levels to suit the individual's level of ability) has been shown to provide a few months of benefit to cognitive function.

### Management of Behavioral Symptoms

Behavioral symptoms in AD are the most common reason for acute care appointments, emergency room visits, or psychiatric admissions in persons with major neurocognitive disorders. Although admittedly more difficult to implement, the most effective treatment is nonpharmacologic.

Some behavior disturbances are induced by brain changes due to AD. In early stages of the disease, these are repetition, wandering, and refusing assistance. In moderate AD, pacing, agitation, antisocial or oversexualized behavior, resistance to care, and aggression can be common. Lastly, in late AD, resistance to care and repetitive vocalizations such as moaning or screaming may appear. The disease process notwithstanding, the most common cause of new behavioral symptoms is an environmental trigger, either internal (e.g., infection, pain) or external (e.g., new housing, change in caregivers or daily routine). To manage the behavior, the trigger must be identified.

Patient-centered and adaptive dementia communications skills are key to solving most behavioral symptoms of AD: making eye contact before speaking, using simple language, speaking slowly and clearly, communicating empathy through actions (smiling), asking only one question at a time, and allowing adequate time for the patient to respond (Table 5).

Although it is appropriate to consider anxiolytics and antidepressants in the treatment of anxiety and depression

**TABLE 5** Initial Treatment of Common Behavioral Symptoms in Alzheimer's Disease

BEHAVIORAL SYMPTOM	CONSIDERATIONS	TREATMENT	FOLLOW-UP	CAUTION
Agitation	Change in patient's environment (most common cause)	If possible, remove the new trigger. If not, caution 3–4 week adjustment period.	1–2 weeks	Reassure caregiver and allow for more frequent contact.
	Lack of caregiver training/knowledge	Provide in office training on redirection, reassurance, de-escalation. Alzheimer's Association offers free online classes on Living with Alzheimer's for Caregivers.	1–2 weeks	Evaluate for caregiver strain as this will have lasting impact on both caregiver and patient health and may lead to early institutionalization of patient.
	Unreported pain	Acetaminophen 500 mg daily. Can slowly scale up to 1000 mg BID. Use the lowest effective dose.	3–4 weeks	Medication review of other APAP containing medications; contraindicated in concurrent hepatic illness
	Infection	Determine source and treat appropriately	After treatment	Many common antibiotics can trigger behavioral issues; review Beers criteria and use with caution
Anxiety	Drug reaction	Review medications with Beers criteria	1–2 weeks	Due to lower renal and hepatic clearances, drug effect may last longer than expected
	Start at half of recommended adult dose, and taper slowly.	Cognitive behavioral therapy, anxiolytics	3–4 weeks	Avoid benzodiazepines or sedative-hypnotics
Depression	Start at half of recommended adult dose, and taper slowly	Cognitive behavioral therapy, antidepressants	3–4 weeks	

Continued

**TABLE 5** Initial Treatment of Common Behavioral Symptoms in Alzheimer's Disease—cont'd

BEHAVIORAL SYMPTOM	CONSIDERATIONS	TREATMENT	FOLLOW-UP	CAUTION
Restlessness/pacing	Ensure proper use of assistive devices or walking buddy	Create an environment that encourages safe walking or other forms of exercise. If patient no longer mobilizes, consider fidget blanket.	At next visit	
Anorexia/cachexia	Due to AD progression: may have lost cognitive domains to prepare food, remember mealtimes, execute coordinated chew/swallow control.	Optimize social supports, deprescribe medications which interfere with eating, provide appealing food and feeding assistance.	At next visit	Avoid appetite stimulants or high-calorie supplements. Do not recommend percutaneous feeding.
Insomnia	Wake-sleep cycle inversions are common in AD; patients have good sleep, just not at hours expected by caregiver	May be corrected with cognitive behavioral therapy, bright light exposure during waking hours, increasing daytime activity, replacing caffeine with decaf, trial of melatonin. <sup>7</sup>	At next visit	Avoid benzodiazepines or sedative-hypnotics
Aggression	See all agitation sections above	Apply all nonpharmacologic interventions possible. As last resort consider AChEI, then antipsychotics/anticonvulsants	1–2 weeks	Avoid benzodiazepines

<sup>7</sup>Available as dietary supplement.

associated with AD, the treatment of agitation and aggression is more nuanced. It is in these cases that we should strive for excellent individualized psychosocial care. Unfortunately, there are times when the patient's agitation and aggression can be extremely distressing to the caregiver and when the medical provider is asked for a prescription. If this is the case for your patient, consider an AChEI as the initial prescription because this medication has been shown to have benefits for apathy, delusions, and purposeless motor behaviors. If a patient has been on a maximal dose of an AChEI for some time and now has new behavioral symptoms, deprescribing should be considered because it may be that the AChEI action has outlived its usefulness.

If AChEI are unsuccessful, antipsychotics (given in order of trial: quetiapine [Seroquel],<sup>1</sup> risperidone [Risperdal],<sup>1</sup> olanzapine [Zyrexal]<sup>1</sup>) or anticonvulsants (given in order of trial: carbamazepine [Tegretol],<sup>1</sup> valproate [Depakene]<sup>1</sup>) should be carefully considered, starting at half the adult dose and titrating slowly to effect or lack of tolerance to adverse reactions. Thorough documentation of behavioral issues triggering prescription, and deprescription trials should be maintained for these medications. There is a strong national movement to decrease use of antipsychotics in dementia care, especially in nursing homes.

### Monitoring

AD is a progressively debilitating neurocognitive disorder with the patient slowly losing the ability to accurately report symptoms or concerns and being increasingly dependent on the care of others. The Reisberg Functional Assessment Staging (FAST) scale was designed to reflect the progressive activity limitations of AD and has been well validated since its initial publication in 1988. Key points of the FAST scale are (1) the

scale progresses through all steps in sequence, therefore out of sequence changes should trigger work-up for non-AD causes; and (2) when a patient reaches stage 7, the patient is eligible for hospice benefits.

In addition to monitoring the patient's health and well-being, special attention must be paid to the caregiver's needs, signs of caregiver burn-out, and if, despite all best efforts of the caregiver, the patient requires a higher level of care than can be provided in the current care setting.

<sup>1</sup>Not FDA approved for this indication.

## BRAIN TUMORS

Method of  
Ryan Merrell, MD

### CURRENT DIAGNOSIS

- Subacute to chronic onset of generalized and/or focal neurologic symptoms should alert the physician to order neuroimaging to investigate the possibility of a brain tumor.
- Magnetic resonance imaging (MRI) is preferable to computed tomography (CT) for imaging tumors.
- A biopsy or resection is necessary to diagnose a primary brain tumor or a metastatic tumor of unknown primary origin. The diagnostic yield is increased with a resection.
- Neuroimaging suggestive of meningioma does not require a tissue diagnosis and in many cases can be followed closely with serial neuroimaging.
- If a primary central nervous system (CNS) lymphoma is suspected, corticosteroids should not be given unless absolutely necessary in order not to confound the biopsy diagnosis.

### CURRENT THERAPY

- Surgical resection is preferred for patients with most types of brain tumors as long as the resection does not leave the patient with permanent neurologic deficits.
- Whole-brain radiotherapy and stereotactic radiosurgery are the primary treatment modalities for patients with metastatic brain tumors.
- Surgical resection is preferred for patients with large or symptomatic meningiomas that are surgical accessible and in patients who can tolerate surgery.
- Patients with gliomas are treated with fractionated radiotherapy alone or in combination with chemotherapy.
- Patients with primary CNS lymphoma are treated with high-dose methotrexate<sup>1</sup> alone or in combination with other chemotherapy drugs.

<sup>1</sup>Not FDA approved for this indication.

Brain tumors are categorized as metastatic or primary. The incidence and prevalence of metastatic tumors outweigh those of primary tumors up to 10:1. Lung and breast carcinoma make up the majority of metastatic tumors, largely because of their increased prevalence in the population compared with other tumors. Melanoma is a less prevalent malignancy but has a high propensity to metastasize to the brain. Meningioma is usually a benign tumor that is found most often in the fourth through sixth decade, with a female-to-male ratio of 2:1. Gliomas are primary brain tumors that are categorized as high-grade gliomas or low-grade gliomas. High-grade gliomas usually affect patients in the fifth and sixth decades and older, whereas low-grade gliomas usually affect patients in the third and fourth decades. Primary CNS lymphoma is a rare tumor that usually affects patients in the sixth decade and older.

There are very few identifiable risk factors for brain tumors. The histology of the primary neoplasm confers the risk of brain metastases because lung cancer, breast cancer, and melanoma are more likely to metastasize to the brain, whereas colorectal, ovarian, and prostate cancers are less likely to metastasize to the brain. Past exposure to ionizing radiation and a family history of a genetic cancer syndrome are the only known risk factors for primary tumors. Despite much press, cell phone use has not been irrefutably shown to be a risk factor for brain tumors. Immunocompromise such as human immunodeficiency virus (HIV) infection is a well-known risk factor for primary CNS lymphoma.

Brain tumors manifest with the subacute or chronic onset of generalized symptoms such as confusion, headaches, seizures, and nausea or focal symptoms and signs such as visual field deficit, loss of language, unilateral weakness, sensory neglect, or difficulty walking. There are no symptoms or signs specific to any brain tumor because the anatomic location of the tumor in the brain dictates the presentation. These symptoms and signs should prompt neuroimaging with MRI. MRI has largely replaced CT for evaluating brain tumors, although CT serves as a quick screening modality and must be used in patients who have contraindications to MRI. Radiographic features on MRI can predict the type of tumor but cannot accurately confirm the pathology. A tissue diagnosis through a biopsy or surgical resection is necessary to confirm the pathology, except in patients with metastatic tumors with a known primary tumor. The differential diagnosis of mass lesions in the brain includes abscess, demyelinating lesion, inflammatory disease, and other infections such as toxoplasmosis and cysticercosis.

A biopsy or surgical resection provides the definitive diagnosis of the tumor. For most tumors, a resection is preferred when safely possible because the greater amount of tissue obtained avoids the sampling error that can occur with a biopsy. Additionally, maximal surgical debulking can provide significant relief of symptoms. The goal of surgery for all brain tumors is to provide a maximal resection while leaving the patient free of permanent neurologic deficits. Metastatic brain tumors are classified according to the cell of origin. Primary brain tumors are classified according to the World Health Organization (WHO) classification system. Additional molecular classification that can provide prognostic and therapeutic information is often obtained on select primary brain tumors. Oligodendroglioma is a primary brain tumor that has well-characterized chromosomal deletions on the short arm of chromosome 1 and the long arm of chromosome 19 (1p/19q codeletion) that have been shown to predict improved survival and increased sensitivity to treatment. Similarly, O-6-methylguanine-DNA-methyltransferase (MGMT) promoter methylation is a marker that predicts improved survival and may predict improved response to treatment in high-grade glioma.

A major challenge to treating brain tumor is to find drugs that cross the blood-brain barrier. Many chemotherapy drugs used to treat systemic tumors are too large or hydrophilic to cross the blood-brain barrier. Treatments designed to circumvent the blood-brain barrier have only been modestly successful to date.

### Metastatic Tumors

Metastatic brain tumors are the most common brain tumors, with as many as 170,000 new cases diagnosed in the United States each year. Metastatic tumors can occur with or without evidence of a primary neoplasm. Findings on brain MRI suspicious for a metastatic tumor should prompt an investigation for a primary malignancy with body imaging (Figure 1). The discovery of a systemic mass that can be biopsied might avoid a brain biopsy or resection in select patients. Occasionally, after an extensive evaluation, no evidence of a primary tumor is found. About 50% of patients have a single metastasis, and the rest have multiple tumors. In general, prognosis is poor, but some patients with less-aggressive primary tumors (melanoma, breast, non-small cell lung carcinoma) can achieve long-term survival. This is particularly true for tumors with targetable mutations such as BRAF in melanoma and epidermal growth factor receptor and anaplastic lymphoma kinase in non-small cell lung cancer. Additionally, immunotherapy has had significant impact in melanoma and other tumors. Clinical trials are evaluating whether treatment with targeted drugs can allow delaying radiotherapy in select patients.

Tumors can metastasize to the nervous system through infiltration of the cerebrospinal fluid (CSF), a process termed *leptomeningeal carcinomatosis* or *carcinomatous meningitis*. Symptoms suggesting leptomeningeal carcinomatosis include altered mental status, headaches, loss of vision, double vision, slurred speech, difficulty swallowing, and lower extremity pain and weakness. Brain MRI can show enhancement of the meninges, and CSF

**Figure 1** Contrast-enhanced magnetic resonance image shows a multiple enhancing mass with surrounding edema at the gray–white junction, suggesting a metastatic tumor.

from lumbar puncture shows low glucose and elevated protein with malignant cells. A lumbar puncture is not necessary to confirm the diagnosis in a patient with a known primary malignancy and characteristic clinical presentation and MRI findings. The prognosis is poor, on the order of weeks to months. Patients with lymphoma and breast cancer might realize longer survival.

Several factors determine the approach to treatment of metastatic tumors. The age, comorbidities, functional status, degree of neurologic impairment, and extent of the systemic disease determine whether surgery is indicated. Solitary metastases and large symptomatic tumors in patients with multiple tumors are generally resected in patients who are good surgical candidates. Whether a patient undergoes surgical resection or not, radiotherapy is the mainstay of treatment for metastatic tumors.

The two approaches to radiotherapy are whole-brain radiotherapy and stereotactic radiosurgery. In whole-brain radiotherapy, a dose of radiation is fractionated into several treatment sessions and given to the entire brain. In stereotactic radiosurgery, a high dose of radiation is given only to areas of brain involved with tumor and often in one treatment session. The effectiveness of whole-brain radiotherapy versus stereotactic radiosurgery has not been established in large randomized trials. Whole-brain radiotherapy is more suited for patients with multiple metastases or large tumors (more than 3 cm diameter). Stereotactic radiosurgery is indicated for patients with fewer than four metastases, for smaller-volume tumors (less than 3 cm diameter), and for radioresistant tumors such as melanoma. Whole-brain radiotherapy has the advantage of treating the visible and undetectable tumors, but it carries a risk of delayed neurotoxicity that often manifests as cognitive impairment. Recent studies have shown that this cognitive toxicity can be lessened through whole brain radiation with hippocampal sparing and addition of the drug memantine during radiation. Stereotactic radiosurgery has the advantage of local control by treating the visible tumors and carries less risk of delayed neurotoxicity. Stereotactic radiosurgery can be repeated if new tumors develop in areas of brain not previously radiated. The disadvantage of stereotactic radiosurgery is the potential for new tumors to develop in areas of brain not treated.

**Figure 2** Contrast-enhanced magnetic resonance image shows a homogeneously enhancing mass arising from the dura, with the typical appearance of a meningioma.

Treatment of leptomeningeal carcinomatosis involves chemotherapy or radiotherapy. Chemotherapy is often administered directly into the spinal fluid (intrathecal), usually through a ventricular (Ommaya) reservoir. Alternatively, chemotherapy can be given systemically. Common chemotherapeutic agents include methotrexate (Methotrexate PF),<sup>1</sup> cytarabine (Cytarabine PF),<sup>1</sup> and thiotepea.<sup>1</sup> Radiotherapy is usually only used as a salvage treatment after chemotherapy failure or for bulky disease.

### Meningiomas

Meningiomas are the most common primary brain tumor, accounting for more than 32% of all tumors. Meningiomas arise from the arachnoid cap cells. They are often discovered incidentally when a patient undergoes neuroimaging for symptoms that are unrelated to the meningioma. The radiographic appearance of meningiomas is one of the most specific of all brain tumors and allows a confident diagnosis without the need for a confirmatory biopsy (Figure 2). The most common radiographic mimicker is a metastatic tumor to the meninges, but usually a patient in this circumstance has a known history of malignancy. Small meningiomas may be followed with serial imaging. Meningiomas that correlate with neurologic deficits or tumors that have grown significantly over time should be treated.

Surgical resection is the preferred treatment if it can be safely accomplished, but it should be avoided in the elderly. Meningiomas are graded WHO I to III; 90% are grade I (benign), and grade III (anaplastic) are the most aggressive and likely to recur. Complete resection is curative in most cases, but some meningiomas recur. If recurrent tumors are large or symptomatic, surgery is the preferred treatment if possible. Radiotherapy, either fractionated or stereotactic radiosurgery, can be used postoperatively to treat residual tumor or to treat tumors that cannot be resected. Meningiomas have an intermediate response to radiotherapy, and grade III tumors often show minimal response.

There is no defined chemotherapy for meningiomas, although several drugs are being actively investigated. Immunotherapy is also being investigated.

**TABLE 1** World Health Organization Classification of Common Gliomas in Adults

SUBTYPE	WORLD HEALTH ORGANIZATION GRADE
<b>Low-Grade Gliomas</b>	
Astrocytoma	II
Oligodendroglioma	II
Oligoastrocytoma	II
<b>High-Grade Gliomas</b>	
Anaplastic astrocytoma	III
Anaplastic oligodendroglioma	III
Anaplastic oligoastrocytoma	III
Anaplastic ependymoma	III
Glioblastoma	IV

### Gliomas

Gliomas consist of astrocytomas, oligodendrogliomas, and ependymomas, in decreasing order of prevalence. It was once thought that these tumors derived from mutations of normal glial cells, but it is increasingly recognized that gliomas derive from brain tumor progenitor cells. Glioblastoma is the most malignant glioma and accounts for 60% to 70% of all gliomas. Gliomas are classified by the glial cells from which they originate and the histologic features that give them a grade according to the WHO classification (Table 1). Grade III and IV tumors are high-grade gliomas, and grade II tumors are low-grade gliomas. Grade I glioma (pilocytic astrocytoma) is rarely seen in adults. A maximal surgical resection that leaves the patient with minimal neurologic deficits is the preferred initial treatment for all grades of gliomas.

### High-Grade Gliomas

Most high-grade gliomas are glioblastoma or anaplastic astrocytoma (WHO grade III); anaplastic oligodendroglioma and anaplastic ependymoma are less common. The brain MRI often shows a ring-enhancing mass centered in the white matter surrounded by edema and causing mass effect (Figure 3). A maximal surgical resection that leaves the patient without permanent neurologic deficits is the goal in high-grade glioma. A maximal resection, younger age, and good performance status are favorable prognostic factors. Methylation of the MGMT promoter correlates with improved survival. High-grade gliomas are aggressive, incurable tumors; the median survival for glioblastoma is 14 to 18 months and for anaplastic astrocytoma is 2 to 2.5 years. The isocitrate dehydrogenase 1 (IDH 1) mutation is less commonly seen in high grade gliomas and correlates with improved survival.

Treatment of high-grade glioma is based on the histology of the tumor. The standard treatment of glioblastoma consists of fractionated radiotherapy given over 6 weeks with temozolomide (Temodar), an oral chemotherapeutic drug. Temozolomide is given 1 month after the completion of radiotherapy, usually for 6 cycles. Tumor progression occurs on average around 7 months after the original diagnosis for glioblastoma (Table 2). There is no consensus on treatment of anaplastic gliomas, although this is being clarified by two ongoing clinical trials (CATNON and CODEL). Patients with anaplastic astrocytoma are usually treated with 6 weeks of radiotherapy alone followed by adjuvant temozolomide. Patients with glioblastoma and anaplastic astrocytoma are usually treated with 6 months of temozolomide, although some practitioners will treat glioblastoma patients with up to 12 months of temozolomide. Tumor treating fields (TTF) therapy is a cap-like device worn on a shaved scalp. TTF delivers radiofrequency pulses to the tumor. Based on the results of a large randomized clinical trial, TTF were approved to add on to the standard therapy of radiation with temozolomide for newly diagnosed glioblastoma.

**Figure 3** Contrast-enhanced magnetic resonance image shows a ring-enhancing mass with surrounding edema with the typical appearance of glioblastoma.

**TABLE 2** Common Chemotherapy for Gliomas

GENERIC NAME	TRADE NAME	DOSE
Temozolomide	Temodar	75 mg/m <sup>2</sup> daily during radiotherapy, 150–200 mg/m <sup>2</sup> after radiotherapy on 5 d per 28 d schedule 50 mg/m <sup>2</sup> daily or 75 mg/m <sup>2</sup> 3 wk on, 1 wk off, for recurrent high-grade glioma
Bevacizumab	Avastin	10 mg/kg every 2 wk

Careful consideration should be given to neuroimaging findings suggesting tumor progression within the first 3 to 6 months after radiotherapy because these changes can reflect radiation necrosis (pseudoprogression) rather than true tumor progression.

In the setting of tumor progression, salvage chemotherapy is the mainstay of treatment. Bevacizumab (Avastin), a drug that inhibits blood vessel formation around tumors, is the most common drug that is given at tumor recurrence. Despite showing improvement in progression free survival and symptom control, bevacizumab has never been shown to increase overall survival. Temozolomide given in low dose daily and lomustine (CeeNU) are other approaches for recurrent high-grade glioma. TTF can also be used in the recurrent setting if not used at initial diagnosis. Experimental chemotherapy through a clinical trial is a common option used in recurrent high-grade glioma. Current clinical trials are evaluating targeted therapies and many types of immunotherapy. Occasionally, surgical resection is indicated to improve symptoms, but it has not been shown to improve survival. Surgical resection has been employed more in recent years for clinical trials that require resection of tumor with the local implantation

**Figure 4** Fluid-attenuated inversion recovery (FLAIR) magnetic resonance image shows a nonenhancing tumor abutting the cerebral cortex with the typical appearance of a low-grade glioma. The tumor proved to be a grade II oligodendroglioma.

of a treatment such as immunotherapy. Focused radiation such as stereotactic radiosurgery has not been shown to affect survival.

Anaplastic oligodendroglioma is usually treated with radiation followed by chemotherapy, either PCV (procarbazine [Matulane],<sup>1</sup> CCNU [Lomustine], vincristine<sup>1</sup>) or temozolomide while anaplastic ependymoma is usually treated with radiotherapy alone. Anaplastic oligodendrogliomas with chromosomal 1p/19q codeletions carry better prognosis and response to treatment.

#### Low-Grade Gliomas

Despite being lower-grade tumors, low-grade gliomas are not benign. The natural history is that patients with low-grade gliomas ultimately progress to high-grade glioma. Low-grade gliomas account for about 15% of all primary brain tumors. Low-grade gliomas are more likely to manifest with seizures than high-grade gliomas. The brain MRI often shows a nonenhancing mass with involvement of white matter and sometimes abutting the cerebral cortex (Figure 4). As in high gliomas, a maximal surgical resection confers a survival advantage in low-grade gliomas. Prognosis varies considerably by tumor histology: Patients with astrocytoma live 5 to 10 years after diagnosis, whereas patients with oligodendroglioma live 10 to 15 years after diagnosis. The isocitrate dehydrogenase I (IDH 1) mutation correlates with improved survival. This mutation is seen in the majority of patients with low-grade glioma.

The results of a randomized clinical trial revealed superior progression free survival and overall survival in patients with low-grade gliomas treated with radiation followed by adjuvant PCV.

In the absence of a head-to-head clinical trial of PCV with temozolomide, many clinicians would use temozolomide in place of PCV because temozolomide is better tolerated. Therefore radiation followed by PCV<sup>1</sup> or temozolomide has become the standard of care for all patients with low-grade gliomas. It still common practice to take a watch and wait approach in select patients with newly diagnosed low-grade glioma who have had

<sup>1</sup>Not FDA approved for this indication.

**Figure 5** Contrast-enhanced magnetic resonance image shows a homogeneously enhancing mass near the surface of the ventricle, suggesting primary central nervous system lymphoma.

a gross total resection. Clinical trials evaluating IDH inhibitors are ongoing. When patients with low-grade gliomas have findings on neuroimaging that suggest progressive tumor, a surgical resection or biopsy is often conducted to alleviate symptoms and to establish the grade of the tumor. Patients with low-grade gliomas that progress to high-grade glioma are treated similarly to patients with de novo high-grade glioma but with consideration to previous treatments.

#### Primary Central Nervous System Lymphoma

Primary CNS lymphoma is a rare non-Hodgkin lymphoma that affects the brain, eyes, meninges, and spinal cord and accounts for about 5% of all brain tumors. This tumor is associated with the immunocompromised state, but it has a significant incidence in the immunocompetent. The characteristic radiographic appearance suggests but does not confirm the diagnosis (Figure 5). If primary CNS lymphoma is suspected, corticosteroids should not be given unless they are necessary to reduce increased intracranial pressure. This is because corticosteroids are directly cytotoxic to lymphoma cells, which can confound the tissue diagnosis. Occasionally, the diagnosis can be obtained through CSF testing, but a brain biopsy is often necessary.

Surgical resection has no role in treating this tumor because lymphoma is sensitive to chemotherapy and radiotherapy. The exception is in large tumors causing significant mass effect. Staging tests are necessary to rule out a systemic lymphoma that has metastasized to the CNS. Despite being incurable, primary CNS lymphoma is a more treatable tumor, and many patients live 5 years or longer after diagnosis.

Primary CNS lymphoma is treated with intravenous or intrathecal chemotherapy with or without radiotherapy. Methotrexate<sup>1</sup> is the principal drug used either alone or in combination with other chemotherapy drugs. High doses of methotrexate (3.5–8 g/m<sup>2</sup>)<sup>3</sup> must be used to overcome the blood-brain barrier. Owing to the

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

potential for renal toxicity, high-dose methotrexate must be given in a setting where kidney function can be carefully monitored (usually the inpatient setting). Some patients with compromised renal function or aversion to hospital stays may not be good candidates for high-dose methotrexate and should be treated with alternative chemotherapy treatments.

Radiotherapy was previously used as an initial treatment, but it is associated with profound cognitive impairment, especially in patients older than 60 years. However, more recent approaches have used lower doses of radiotherapy combined with chemotherapy with less neurotoxicity reported. Opinion is divided about the use of radiotherapy. Chemotherapy can also be used as a salvage treatment. Besides methotrexate, other commonly used chemotherapy drugs include cytarabine,<sup>1</sup> etoposide (Toposar),<sup>1</sup> rituximab (Rituxan),<sup>1</sup> procarbazine (Matulane),<sup>1</sup> and temozolomide (Temodar).<sup>1</sup> In younger patients, an increasingly used treatment at the time of relapse is high-dose chemotherapy with autologous stem cell transplantation. This approach is increasingly being investigated in the newly diagnosed setting. Newer drugs that are being used for salvage therapy include lenalidomide (Revlimid)<sup>1</sup> and ibrutinib (Imbruvica).<sup>1</sup>

## GILLES DE LA TOURETTE SYNDROME

Method of

Alonso G. Zea Vera, MD; Steve W. Wu, MD; and Donald L. Gilbert, MD

### CURRENT DIAGNOSIS

- Multiple motor tics and one or more phonic tics have been present for some time during the illness, although not necessarily concurrently.
- The tics may wax and wane in frequency but have persisted for more than 1 year since the first tic onset.
- Onset occurs before 18 years of age.
- The disturbance is not caused by the direct physiologic effects of a substance or a general medical condition.

### CURRENT THERAPY

- Educate the patient and family about tics, their waxing and waning course, and its natural history. Long-term reductions in tics may occur in the late teens, irrespective of pharmacologic therapy.
- If necessary, provide information to educate teachers and classmates to reduce social impairment.

- Assess for the presence of comorbidities including attention-deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), anxiety, mood problems, learning problems, and behavior problems.
- Consider nonpharmacologic and pharmacologic treatment for the most impairing symptoms first. Tics do not always need to be treated, and other comorbidities may be more impairing.
- Treatment of ADHD, OCD, anxiety, mood problems, learning problems, and behavior problems should follow evidence-based guidelines and may require specialty evaluation (neurology, psychiatry, and psychology). Stimulants are not contraindicated in patients with Tourette syndrome.
- Comprehensive Behavioral Intervention for Tics could be considered in motivated families and can be offered even if tics are not impairing. Families should be counseled about the time and effort required and the scarcity of trained providers in some areas. Patients who are very young or have severe untreated comorbidities may not be able to participate in this therapy.
- Alpha-agonists are the most common first-line medications used in the treatment of tics and are particularly beneficial for patients with comorbid ADHD. Commonly used second-line medications include topiramate (Topamax)<sup>1</sup> or baclofen (Lioresal).<sup>1</sup> Dopamine receptor antagonists are usually restricted to severe and refractory cases.
- Monitor the benefits and side effects at regular intervals. Counsel parents that tics fluctuate and that brief worsening of symptoms is common. Brief exacerbations do not necessarily require a change in therapy.
- Do not begin treatment with more than one central nervous system drug simultaneously, and avoid changing medication regimens too fast. Start one medication, wait 2 to 4 weeks, and then reassess all symptoms before starting the next medication.
- Maintain stable dosing during the school year; consider tapering medications in the summer.
- Consider weaning tic-suppressing medications in the middle to late teen years if tics are well controlled.

<sup>1</sup>Not FDA approved for this indication. Tourette syndrome (TS) is a neuropsychiatric illness characterized by multiple motor and phonic tics that persist for longer than 1 year (see the Current Diagnosis box). Transient tics have been reported in up to ~25% of children from kindergarten to sixth grade. However, the prevalence of TS is closer to 0.3% to 1.5% of the population, and boys are three to four times more likely to be affected than girls. The prevalence of tic disorders is even higher in children with intellectual disabilities.

## Clinical Manifestations

Tics are sudden, recurrent, nonrhythmic, patterned movements (i.e., motor tics) or vocalizations (i.e., phonic tics; also called *vocal tics*). Tics are fragments of normal behavior that present out of context and are not goal-directed. What separates tics from normal actions is their exaggerated character in intensity, frequency, and repetition. Tics usually follow a somatotopic distribution, with tics being more frequent in the eyes, face, neck, phonic muscles (i.e., phonic tics), and shoulders compared with the trunk and extremities.

Tics can be divided into simple or complex tics. Simple tics are brief and involve a single muscle or small group of muscles. Common simple motor tics include eye blinking, facial grimace, head jerk, and shoulder shrug. Common simple phonic tics include throat clearing, sniffing, and coughing. Complex tics can be a series of simple tics or a seemingly purposeful coordinated sequence of actions or sounds. Examples of complex motor tics include jumping, touching, or copropraxia (i.e., performing obscene gestures). Examples of complex phonic tics include echolalia (i.e., repeating others' words), palilalia (i.e., repeating their own words), or coprolalia (i.e., utterance of foul language). Simple tics are more frequent than complex tics.

The possibility of developing coprolalia or copropraxia often causes significant distress in patients and families. These phenomena are commonly considered a core symptom of TS by the general population leading to names like *the cursing disease*. This perception has been fueled by inaccurate and exaggerated portrayals of people with TS in the media. Coprophenomena is only present in 10% to 20% of patients.

Tics have a characteristic waxing and waning pattern. Patients frequently report the resolution of old tics (although they may recur later) and the appearance of new tics. Tics tend to be exacerbated by stress, anxiety, excitement, anger, fatigue, and acute illnesses. Parents often notice more tics when the child is bored or unoccupied with an activity. On the contrary, tics are often diminished during focused mental or physical activities, and they usually do not affect activities of daily living, occupational activities, or recreational activities. Although tics are commonly reported to be absent during sleep, studies using polysomnography have shown that they may persist during it.

Patients with tics often describe an uncomfortable sensation preceding the tics, known as a premonitory urge, that remits once the tic is performed. This urge can be described as a physical sensation (i.e., itch or pressure) in a specific body area or a general ill-defined feeling. The majority of older children and adults report premonitory urges associated with at least one of their tics. However, younger children are less likely to report it. It is unclear if this is caused by the absence of an urge or the lack of awareness of the urge. Some young children that deny urges may report that their tics are “painful,” even with mild tics. Further questioning may reveal that the pain appears shortly before the tic and disappears after the tic, suggesting a premonitory urge.

Tics can often be suppressed, although only momentarily, leading to the misinterpretation that tics are voluntary actions. The ability to suppress tics improves with age. Patients frequently report that the premonitory urge worsens when suppressing their tics and that the release of the tic brings relief. Some patients report a “rebound effect” with many tics occurring after a prolonged period of tic suppression. For example, some children who suppress their tics in school report an increased frequency of tics when they get home.

A natural course has been described in TS. The onset of tics is usually between 4 and 8 years of age. Children often present with motor tics first, followed by the development of phonic tics. Tic severity usually increases in the later elementary school years and early adolescence and decreases by late adolescence and early adulthood. Most TS patients have minimal tics or may “out-grow” their tics when they become adults. However, a minority of patients may continue to have bothersome tics throughout life.

### Comorbidities

About 85% of patients with Tourette syndrome have at least one psychiatric comorbidity and ~60% have 2 or more. The most common comorbidities are obsessive-compulsive disorder (~65%; OCD) and attention deficit and hyperactivity disorder (~55%; ADHD). Anxiety, mood disorders, and sleep problems are also common. ADHD symptoms frequently are present before tic onset, but OCD symptoms are more likely to appear after the onset of tics. TS patients should be screened for these conditions regularly.

### Diagnosis

TS is a primary tic disorder diagnosed based on clinical criteria (see Current Diagnosis box) listed in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). Other primary tic disorders include *provisional tic disorder*, *persistent (chronic) motor or vocal tic disorder*, *other specified tic disorder*, and *unspecified tic disorder*. The diagnosis depends on correctly recognizing that the abnormal movements are tics through a careful history and physical examination. Laboratory and imaging studies can be used to rule out other conditions but are rarely needed. Sometimes tics are interpreted as a symptom of a different condition. Coughing or sniffing tics may be attributed to

asthma, chronic cough, or allergies. Blinking tics could lead to the diagnosis of poor vision or dry eyes.

Secondary tics, those caused by an underlying condition, are rare. Causes of secondary tics include drug-induced movement disorders, structural lesions (i.e., trauma, tumors), and a variety of neurodevelopmental and neurodegenerative disorders. Complex or atypical cases with multiple comorbidities or multiple abnormalities identified on a general or neurologic examination should be referred for specialist consultation.

Tics may resemble other movement disorders, such as stereotypy, chorea, ballism, dystonia, and myoclonus. Stereotypies are repetitive, simple movements that start before 3 years of age, are suppressible, and usually occur when a child is excited. Chorea consists of a sequence of random, continual, involuntary, nonpurposeful, nonrhythmic movements. Choreic movements often flow from one body part to another. Ballism is a large-amplitude choreic movement affecting the proximal limb. Myoclonus is an involuntary, sudden, shocklike movement. Chorea, ballism, and myoclonus cannot be volitionally suppressed. Dystonia is produced by overflow of motor contractions, leading to abnormal postures, and its twisting movements typically are slower than tics.

An important mimic of TS is *functional ticlike disorder*. This is a subtype of functional movement disorder characterized by ticlike behaviors. Although previously considered uncommon, a large increase of this phenotype was reported during the coronavirus 2019 (COVID-19) pandemic. In contrast with TS, it more commonly presents with an abrupt onset of ticlike behaviors in adolescents and young adults, with a preponderance in female patients. Functional ticlike behaviors involve the arms or trunk more than the face, interfere more with voluntary actions, are less suppressible, and are more suggestible. Other functional neurologic symptoms can be present. The diagnosis of functional ticlike disorder is challenging because it can also present in patients with TS, and the characteristics of these two conditions may overlap. Evaluation by a specialist is recommended in these cases.

A controversial diagnosis that includes tics as a core symptom is pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). PANDAS criteria include an abrupt onset or exacerbation of tics or obsessive-compulsive symptoms in prepubertal children after documented group A  $\beta$ -hemolytic streptococcal (GABHS) infections. PANDAS criteria imply an immunologic etiology for tics triggered by GABHS infections, similar to Sydenham chorea. However, PANDAS is not associated with arthritis, carditis, or nephritis and is not thought to be a rheumatic disease.

Several factors have contributed to the controversy in PANDAS. Both tics and GABHS infections are common in childhood, therefore separating a causal from an incidental relationship is challenging. The definition of *abrupt* exacerbation is also unclear because TS is characterized by a waxing and waning pattern, and exacerbations can present after infectious and non-infectious triggers. An elevated GABHS serologic titer (i.e., anti-streptolysin O, and anti-DNase B) are commonly used to prove the temporal association of tic exacerbation and a recent GABHS infection. However, prospective studies have shown that these titers can remain elevated for many months without evidence of an acute infection, making them unreliable markers of recent infections.

Large prospective studies, using serial throat cultures and serologic testing, compared patients with TS or OCD and patients meeting the PANDAS criteria. These studies found similar frequencies of exacerbations and exacerbations associated with GABHS infections in both groups. Most exacerbations in both groups were not related to GABHS infections. More recent studies evaluating the association between GABHS infections with onset and exacerbations of tics in patients with chronic tic disorders also failed to show a relationship. As a result, it has been suggested that patients meeting the PANDAS criteria represent a subgroup of patients with TS or OCD, and the proposed immunologic link between GABHS infections and tics has been questioned. Testing patients with tics for GABHS in the absence of symptoms of an acute infection is not recommended.

**TABLE 1** Therapy for Tics in Tourette Syndrome

MEDICATION	STARTING DOSE	TITRATION	GOAL DOSE
Clonidine (Kapvay) <sup>1</sup>	0.05 mg qhs	0.05 mg every 3–7 d	0.05–0.1 mg tid
Clonidine patch (Catapres-TTS) <sup>1</sup>	Catapres TTS-1 weekly*	Weekly as needed	Catapres TTS-1, TTS-2, or TTS-3 weekly*
Guanfacine (Intuniv) <sup>1</sup>	0.5 mg qhs	0.5 mg every 3–7 d	1–4 mg divided bid
Baclofen (Lioresal) <sup>1</sup>	10 mg qhs	10 mg every 3–7 d	40–90 mg/d divided bid/tid
Clonazepam (Klonopin) <sup>1</sup>	0.5 mg qhs	0.5 mg every wk	1–2 mg bid
Topiramate (Topamax) <sup>1</sup>	25 mg qhs	25–50 mg weekly	50–100 mg bid
Pimozide (Orap)	1 mg qhs	1 mg every 3–5 d	1–4 mg/d divided daily or bid
Haloperidol (Haldol)	0.25–0.5 mg qhs	0.25–0.5 mg every 5–7 d	1–4 mg/d divided daily or bid
Fluphenazine (Prolixin) <sup>1</sup>	0.5 mg qhs	0.5 mg every 3–5 d	1–4 mg/d divided daily or bid
Risperidone (Risperdal) <sup>1</sup>	0.5 mg qhs	0.5 mg every 3–5 d	1–4 mg/d divided daily or bid
Ziprasidone (Geodon) <sup>1</sup>	20 mg qhs	20 mg every wk	20–80 mg/d divided daily or bid
Aripiprazole (Abilify)	1 mg qhs	1 mg every wk	1–20 mg daily or divided bid
Botulinum toxin type A (Botox) <sup>1</sup>	Not applicable	Not applicable	30–300 units in one or more focal sites, injected once every 3 mo

\*The system areas are 3.5 cm<sup>2</sup> (Catapres TTS-1), 7.0 cm<sup>2</sup> (Catapres TTS-2), and 10.5 cm<sup>2</sup> (Catapres TTS-3), and the amount of drug released is directly proportional to the area.

<sup>1</sup>Not FDA approved for this indication.

## Treatment

The first step in treating TS is educating the patient, parents, and other adult caregivers. Parents, teachers, and other adult caregivers are discouraged from telling the child to stop ticcing because this produces emotional anxiety that may worsen the tics. Educational materials for teachers aim to promote a conducive environment for the child at school. The patient is encouraged to openly talk about his or her tics to classmates to promote understanding and minimize bullying. However, if bullying is present, it should be addressed with the school. Comorbidities should be considered early in the treatment of TS. Although tics are often the most noticeable symptom, other symptoms like inattentiveness, hyperactivity, obsessive or compulsive behaviors, depression, and anxiety may be more impairing to the patient. Untreated comorbidities can also worsen the severity of tics and hamper its treatment.

Not all patients with tics need tic-suppressing treatment. The decision to start treatment depends on the level of impairment caused by tics, which may not correlate with objective markers of tic frequency or severity. Younger children are usually less bothered by their tics, even if they are frequent. However, adolescents may find tics more disruptive, even if infrequent. Treatment should be considered when there is functional interference, social interference, pain, or classroom or occupational disruption. Occasionally, parents request treatment preemptively (i.e., even if tics are not causing impairment) because of fear that the tics may worsen or result in bullying in the future. Preemptive treatment is generally not recommended for TS. Finally, it is important to keep in mind that tic-suppressing treatment rarely stops tics completely. The goal of treatment is to decrease tics to a level that is not impairing.

Initial treatment of tics consists of pharmacotherapy, psychotherapy, or a combination of both. Clinical trials enrolling patients with TS are usually small and show small effect sizes. A recent systematic review found that comprehensive behavioral intervention for tics (CBIT) had the highest level of confidence in the evidence with an effect size similar to medications. In CBIT, patients learn to increase self-awareness of tics and premonitory urges and to perform antagonistic movements. CBIT effects can persist months to years after concluding therapy, and it has been recommended in highly motivated families given the lack of side effects, even if tics are not impairing. However, CBIT is limited by the amount of effort and time required as well as the

scarce availability of trained providers in some areas. Very young patients or patients with severe untreated comorbidities may be unable to complete the program.

Because TS is a chronic, nonfatal disorder, it is prudent to start pharmacotherapy with medications that carry the least side effects. The most commonly used tic-suppressing medications belong to two classes:  $\alpha_2$ -adrenergic agonists and dopamine receptor blocking agents (Table 1). Because of their favorable side-effect profile,  $\alpha_2$ -adrenergic agonists are usually the first-line treatment. Clonidine (Catapres; Kapvay)<sup>1</sup> and guanfacine (Tenex; Intuniv)<sup>1</sup> have shown benefits in both tics and ADHD symptoms, making them an excellent choice in patients with comorbid ADHD. The main side effects are sedation and lightheadedness caused by mild hypotension. Sedation is more common with clonidine. The clonidine patch (Catapres-TTS)<sup>1</sup> may produce less peak sedation, but it commonly produces local skin irritation.

Among tic-suppressing medications, dopamine receptor blocking agents have the higher effect size and confidence in the evidence. However, they are associated with severe side effects including acute akathisia, dystonic reactions, tardive dyskinesia, cognitive blunting, acute anxiety with somatizations and school refusal, sedation, weight gain, metabolic syndrome, and QT prolongation. Some experts recommend baseline electrocardiograms, weight, blood pressure, fasting glucose, and lipid profile with follow-up monitoring every 3 months to detect drug-induced metabolic syndrome. Diet modification, routine exercise, or pharmacologic therapy may be needed. Dopamine receptor antagonists are usually restricted to the most severe cases and managed in specialty clinics.

Other medications used for tics with limited evidence include topiramate (Topamax)<sup>1</sup> and baclofen (Lioresal).<sup>1</sup> These can be used as second-line agents. The decision to use these medications can also be guided by comorbidities (i.e., using topiramate in patients with comorbid migraines). Medications used for refractory patients include botulinum toxin type A (Botox)<sup>1</sup> and tetrabenazine (Xenazine).<sup>1</sup> Finally, deep brain stimulation has emerged as a potential therapy for medically refractory patients.

The importance of effectively treating comorbid conditions cannot be overstated. The frequently held concern that ADHD

<sup>1</sup>Not FDA approved for this indication.

stimulant therapy may worsen tics may lead families to avoid these medications, even if indicated. The landmark Treatment of ADHD in Children with Tics study and subsequent meta-analyses showed that children treated with methylphenidate (Ritalin) had, on average, reduced tic severity, contrary to the belief that stimulants exacerbate tics. The presence of tics is not an absolute contraindication to the use of stimulants in ADHD. However, if symptoms of OCD, anxiety, or autism spectrum disorder are present, ticcing or compulsions may escalate on stimulants. If a patient has done well for months to years on stimulants for ADHD before an exacerbation of tics, it usually is not necessary to discontinue stimulants.

### Complications

Patients with TS have a poorer quality of life, more suicidal thoughts, and more difficulties with school and work. TS patients also have a higher frequency of self-injurious behaviors, which can be tic-related or not. Most patients with TS (~60%) report pain associated with one of their tics during their lifetime. A recent study also found a higher frequency of cervical spine disorders in adult patients with TS. Although rare, in severe cases tics have resulted in serious complications such as vertebral artery dissection or spinal compression.

### Summary

TS is a complex neuropsychiatric illness that may need pharmacologic and nonpharmacologic therapies. Cooperation among the primary care physician, neurologist, psychiatrist, and psychologist is imperative for the comprehensive care of severely affected patients. If a patient has mild tics and few or no comorbid symptoms, pharmacologic therapy may not be needed. However, if the tics are severe in the presence of many neuropsychiatric symptoms, it is reasonable to refer patients to specialists.

## INTRACEREBRAL HEMORRHAGE

Method of

Ronda Lun, MD; and Dar Dowlathshahi, MD, PhD

### CURRENT DIAGNOSIS

- Intracerebral hemorrhage is a medical emergency; immediate imaging must be obtained in anyone with acute onset focal neurologic deficits.
- Noncontrast computed tomography (CT) is the gold standard; CT angiography can be helpful for prognostic factors and to rule out underlying vascular malformations.
- Obtain magnetic resonance imaging (MRI) +/- MR venogram (MRV) if etiology of bleed is unclear.

### CURRENT THERAPY

- Ensure the airway is protected because level of consciousness could deteriorate rapidly.
- Medical treatment:
  - Hemostasis by correcting coagulopathies
  - Blood pressure (BP) lowering
- Surgical treatment:
  - Posterior fossa decompression for cerebellar hemorrhages
  - Extraventricular drainage for hydrocephalus
  - Evacuation of hematoma may be necessary as a life-saving measure

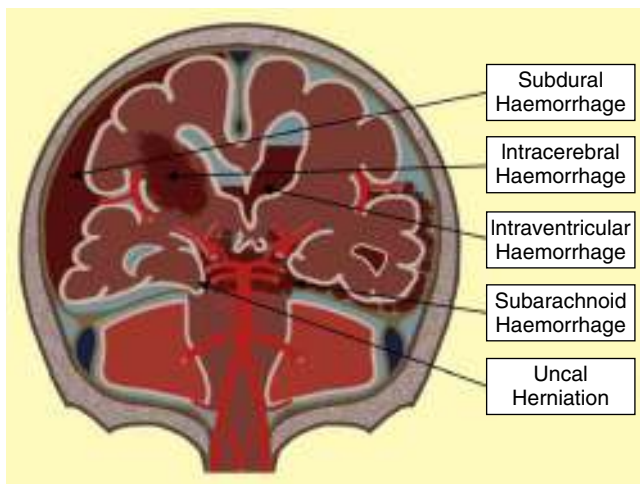

### Introduction

Intracranial hemorrhage (ICH) refers to bleeding within the skull in any intracranial compartment (i.e., subdural, subarachnoid, epidural, or intraparenchymal) (Figure 1). However, the term is commonly used for intraparenchymal hemorrhages specifically, which will be the focus of this chapter. ICH can be further categorized as “spontaneous” or “secondary,” with the latter inferring that there is an underlying lesion (i.e., vascular malformation, tumor) or alternative explanation (i.e., trauma) for the bleed (Table 1). Spontaneous ICH is synonymous with hemorrhagic stroke, referring to spontaneous intraparenchymal bleeding in the absence of identifiable secondary causes. It represents 10% to 15% of all strokes and is the second most common subtype after ischemic strokes. Although its incidence has been increasing in recent years, likely as a result of the aging population and increased use of antithrombotic medications, long-term outcomes from ICH have remained largely unchanged, with mortality rates of 50% at 1 year, and loss of functional independence in almost 75% of patients.

### Pathophysiology

ICH occurs when an arterial intracranial blood vessel bursts and a hematoma is formed as a result of accumulation of extravasated blood. The hematoma then causes mass effect with compression of adjacent healthy brain tissue, causing neuronal dysfunction and cell death from cytotoxic edema. Hematoma expansion (HE) occurs in up to 1/3 of patients with ICH in the first 6 hours and is a potentially targetable surrogate outcome for improving survival and preventing disability. The risk for hematoma expansion is greatest at within 3 hours after symptom onset, and the predicted probability of HE is inversely associated with time, although delayed expansion after 24 hours can rarely be encountered. Concurrent with the cessation of active bleeding, vasogenic edema will develop and peak over the next 2 to 7 days. Extension of the blood into the ventricular system may cause acute hydrocephalus because of obstruction of venous outflow. Even small volumes of HE are associated with an increased risk for adverse outcomes; the development of a teaspoon of new parenchymal hemorrhage is associated with quadruple the odds of mortality, and the development of even 1 mL of new ventricular hemorrhage has been shown to be associated with increased risk of disability and death. Ultimately, increased intracranial pressure from the mass effect may cause supratentorial herniation, midline shift, and secondary brain injury.

Location of ICH is a helpful predictor in determining the underlying pathogenesis of the ICH. Chronic hypertension is the most common risk factor responsible for subcortical and infratentorial hemorrhages, such as those in the basal ganglia, thalamus, brainstem, and cerebellum. The pathogenesis of hypertensive hemorrhages is attributed to chronic exposure to high pressures in the branching arterioles from major intracranial vessels, resulting in lipohyalinosis of the small arterioles. These relatively fragile vessel walls may then rupture and result in ICH. On the contrary, lobar hemorrhages

**Figure 1** Types of intracranial hemorrhage. From Zebian B, Critchley G: Spontaneous intracranial haemorrhage. *Surgery (Oxford)* 2015; 33(8):363–368.

**TABLE 1** Spontaneous vs Secondary Causes of ICH

SPONTANEOUS ICH	SECONDARY ICH
Hypertensive vasculopathy	Vascular malformations (dural arteriovenous fistula, arteriovenous malformation, cavernous malformation, capillary telangiectasias)
Cerebral small vessel disease	Cerebral venous thrombosis
Cerebral amyloid angiopathy	Hemorrhagic conversion of ischemic infarct
	Moyamoya disease
	Septic emboli/mycotic aneurysm
	Brain tumors
	Vasculitis (infectious, systemic autoimmune disease, primary CNS)
	Reversible cerebral vasoconstriction syndrome
	Drugs/toxins (cocaine, amphetamines)

and convexity subarachnoid hemorrhages in adult patients over the age of 55 are often attributed to cerebral amyloid angiopathy. This disease process is characterized by the deposition of abnormal amyloid beta proteins in the small to medium-sized vessels of the brain, resulting in weakened vascular integrity over time, which increases the risk for arterial rupture. Amyloid-related hemorrhages typically spare the deep gray matter and brainstem, reflecting the distribution of amyloid deposits, most of which are detected only on MRI sequences sensitive for blood byproducts (see Diagnosis section). They are thought to represent clinically silent cerebral microbleeds and are an important risk factor to recognize for increased risk for recurrent ICH.

Although this chapter focuses on arterial ICH, it is important to recognize that bleeding from a ruptured venous blood vessel may occur rarely and that venous hemorrhages are not considered a subtype of ICH. However, it needs to be ruled out as a potential secondary etiology for parenchymal hemorrhage because the treatment and prognosis are drastically different. Counterintuitively, the mechanism by which venous hemorrhages occur is caused by formation of thrombus in the venous drainage of the brain, leading to buildup of intracranial pressure and blockage of cerebral spinal fluid

(CSF)/blood outflow from the brain. The backlog of pressure leads to venous infarction, petechial hemorrhage, and ICH. In any patient with a lobar ICH of unknown origin or ICH that crosses typical arterial territories, immediate neuroimaging with CTV or MRV should be pursued to rule out underlying cerebral venous sinus thrombosis as the ultimate culprit.

### Clinical Manifestations

Neurologic deficits caused by ICH are sudden in onset, but unlike its ischemic stroke counterpart—where stroke deficits are maximal at onset—neurologic signs and symptoms attributed to ICH tend to worsen with time. As the hematoma expands, patients can rapidly deteriorate, resulting in decreased level of consciousness and requiring intubation. Initial clinical manifestations vary depending on hemorrhage location. The most frequent location for ICH related to chronic hypertension is within the basal ganglia, more specifically the internal capsule/thalamus/putamen/pons. Thus the most common symptomatology includes hemiplegia, hemi-body sensory loss, dysarthria, ataxia, and visual field loss. Cortical bleeds are most frequently associated with cerebral amyloid angiopathy and may clinically manifest with aphasia, apraxia, and hemianopia, in addition to the symptomatology mentioned previously. Epileptic seizures may be seen either at the onset of disease or later, as a manifestation of cortical irritation from blood/scar tissue. Headaches, nausea, vomiting, and decreased level of consciousness are common in the context of increased intracranial pressure (ICP) but may result from other mechanisms such as brainstem compression, development of hydrocephalus, or herniation.

### Diagnosis

ICH is a medical emergency. The development of acute neurologic deficits should immediately raise concern for stroke, thus rapid assessment and management are crucial. Initial assessment should prioritize the ABCs of resuscitation—airway, breathing, and circulation—before proceeding with assessment for neurologic deficits. The most commonly used rapid stroke assessment scale is the National Institute of Health Stroke Severity (NIHSS) scale, which can be found in Table 2. However, another frequently used clinical assessment tool is the Glasgow Coma Scale (GCS), which is often used to assess indications for intubation in the context of decreased level of consciousness. A threshold of GCS 8 or less is used as an indication for intubation. Immediate neuroimaging should be obtained to confirm the diagnosis and rule out other diseases that may present in a similar manner, including ischemic stroke and subarachnoid hemorrhage. The noncontrast CT scan is the gold standard for emergent assessment of ICH. Administration of CT iodinated contrast to facilitate CT angiography may be pursued to look for active contrast extravasation (known as the *spot sign*) and to investigate for underlying lesions such as tumor or vascular malformations. Emergent MRI may be used as the initial imaging modality in select centers, although more commonly MRI is obtained in a delayed fashion to investigate the etiology of the bleed. Useful MRI sequences include T2\* susceptibility-weighted images (SWI) or gradient-echo (GRE) sequences, which are sensitive for the detection of deoxyhemoglobin, a byproduct of blood. Additional pursuit of imaging such as CTV or MRV should be considered when there is clinical or radiologic suspicion for CVST. Catheter angiography may be pursued when diagnostic suspicion for underlying vascular malformation is high and no etiology for the ICH can be found.

### Therapy

Treatment of ICH is composed of a combination of medical and surgical approaches and generally follows two important principles. During the acute period, stabilizing the hematoma and decreasing the risk for hematoma expansion is crucial and may be achieved through hemostasis and blood pressure (BP) control. Secondly, addressing mass effect and its downstream complications may be done through surgery and osmolar therapies.

**TABLE 2** NIHSS Stroke Scale

CATEGORY	SCORE/ DESCRIPTION
1a. Level of consciousness (awake, drowsy, comatose, etc.)	0 = alert 1 = drowsy 2 = stuporous 3 = coma
1b. LOC questions (month, age)	0 = answers both correctly 1 = answers one correctly 2 = incorrect
1c. LOC commands (open/close eyes, make fist/let go)	0 = obeys both correctly 1 = obeys one correctly 2 = incorrect
2. Best gaze (eyes open and tracks)	0 = normal 1 = partial hemianopia 2 = complete hemianopia 3 = bilateral hemianopia (blind)
3. Visual fields (introduce visual stimulus to all 4 visual field quadrants)	0 = normal 1 = minor 2 = partial 3 = complete
4. Facial paresis (show teeth, raise eyebrows and squeeze eyes shut)	0 = normal 1 = minor 2 = partial 3 = complete
5a. Motor arm (left) 5b. Motor arm (right) (elevate arm to 90°)	0 = no drift 1 = drift 2 = can't resist gravity 3 = no effort against gravity 4 = no movement X = untestable (joint fusion or limb amputation)
6a. Motor leg (left) 6b. Motor leg (right) (elevate leg 30°)	0 = no drift 1 = drift 2 = Some effort against gravity 3 = no effort against gravity 4 = no movement X = untestable (joint fusion or limb amputation)
7. Limb ataxia (finger-nose, heel-shin)	0 = no ataxia 1 = present in one limb 2 = present in two limbs
8. Sensory (pinprick to face/arm/trunk/leg)	0 = normal 1 = partial loss 2 = severe loss
9. Best language (naming, fluency, reading)	0 = no aphasia 1 = mild to moderate aphasia 2 = severe aphasia 3 = mute
10. Dysarthria (evaluate speech clarity by repeating listed words)	0 = normal articulation 1 = mild or moderate slurring of speech 2 = near unintelligible or worse X = intubated or other physical barrier
11. Extinction and inattention	0 = no neglect 1 = partial neglect (visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral stimulus in one sensory modality) 2 = profound hemi-attention or extinction to more than one modality

### Emergency Medical Treatment

The two mainstays of medical treatment in ICH are hemostasis and BP control. Hemostatic abnormalities may not only cause ICH but potentially worsen outcomes if not corrected. Patients with known coagulation factor deficiency or platelet disorders should have replacement of the appropriate factor(s). Patients with significant

thrombocytopenia should be considered for platelet transfusion. Those taking vitamin K antagonists (i.e., warfarin) with elevated international normalized ratio (INR) should have their INR corrected rapidly. Either fresh frozen plasma (FFP) or prothrombin complex concentrates (PCC) may be used, although PCC may be superior in achieving a faster INR normalization rate than FFP and is the preferred agent. Vitamin K (phytonadione) needs to be given concurrently because of the short half-life of PCC; the onset of action of vitamin K starts approximately 2 hours after administration and will continue to peak over the next 12 to 14 hours. Other hemostatic factors such as rFVIIa are not currently recommended, although there are ongoing clinical trials evaluating its efficacy in patients presenting in an early time window from symptom onset. Patients taking direct-oral anticoagulants (DOACs) may be eligible for specific reversal agents, such as idarucizumab (Praxbind) for dabigatran (Pradaxa) and andexanet alfa (Andexxa) for factor Xa inhibitors (such as rivaroxaban [Xarelto], edoxaban [Savaysa, Lixiana],<sup>1</sup> or apixaban [Eliquis]). If andexanet alfa is not available, some clinicians may choose to use PCC to reverse factor Xa inhibitors if there is biochemical evidence of activity at time of presentation or confirmed recent ingestion. Patients taking antiplatelet agents prior to development of their ICH should not routinely receive platelet transfusion if their platelet count is normal because it has been found to be harmful rather than beneficial.

Elevated BP is frequently encountered in acute ICH as a result of a variety of physiologic responses. However, high BP is a major risk factor for developing hematoma expansion and thereby worse outcomes after ICH. For patients presenting with systolic blood pressure (SBP) between 150 and 220, lowering the SBP to <140 mm Hg is safe and may be effective for improving functional outcomes at 3 months. However, more aggressive BP lowering may be associated with increased risk for renal insufficiency, and therefore the potential benefit achieved from BP reduction should be balanced with feasibility and maintenance of systemic perfusion pressure to all organs. For those presenting with severely elevated SBP (>220 mm Hg), lowering to 140 mm Hg is practically challenging and may be harmful, thus many clinicians may choose to target a BP that is 25% lower than the patient's initial SBP instead.

### Inpatient Medical Treatment

Medical treatment of ICH should be continued beyond the emergency setting to prevent further complications during hospitalization. Maintenance of normoglycemia and normothermia should be standard of care because hyperglycemia and hypothermia have both been associated with poorer long-term outcomes. Universal dysphagia screening before initiation of an oral diet should be implemented to reduce the risk of aspiration pneumonia, a common complication during the first weeks of hospitalization. To mitigate the risk for urinary tract infections, indwelling foleys should not be inserted without appropriate clinical indication. All patients should have intermittent pneumatic compression devices for prevention of venous thromboembolism (VTE) beginning the day of hospital admission. Once the patient has been deemed clinically and radiologically stable, the patient may be transitioned to a pharmacologic agent for VTE prophylaxis. Osmolar therapies such as hypertonic saline<sup>1</sup> and mannitol (Osmitol) should be considered in patients with concern for increased intracranial pressure, but these are considered temporizing measures until definitive surgical intervention.

### Surgical Management

Although the evidence for indications and timing of surgical treatment of ICH remains somewhat controversial, surgery is often indicated for cerebellar hemorrhages, intraventricular extension, and hydrocephalus. Because of the limitations in room for expansion in the posterior fossa, it is generally accepted that any cerebellar hemorrhage with brainstem compression and/or hydrocephalus and/or neurologic deterioration should have immediate surgical decompression. A threshold of 3 cm in the diameter of the hematoma is

<sup>1</sup>Not FDA approved for this indication.

commonly used for consideration of surgery. On the contrary, the evidence for supratentorial and deep hemorrhages is much less robust. Hematoma evacuation with decompressive craniotomy/craniectomy may be considered a life-saving measure in deteriorating patients; however, its efficacy for prevention of functional disability has not been well established. In patients with intraventricular hemorrhage causing hydrocephalus and deteriorating level of consciousness, extraventricular drainage (EVD) should be considered. There is limited evidence for irrigation of extraventricular drains with alteplase (Activase)<sup>1</sup> and its use is not routinely recommended based on the current level of evidence. Other surgical interventions such as minimally invasive clot evacuation have demonstrated promising results, and research in this field is active and ongoing. A summary of therapeutic options for ICH are outlined in Table 4.

### Monitoring

ICH patients should be cared for in a dedicated stroke or intensive care unit wherever possible, as this has been shown to be associated with better outcomes. Frequent vital sign checks, neurologic assessments with validated scales such as GCS and NIHSS, and continuous cardiopulmonary monitoring should be part of the standard treatment plan. BP monitoring is especially crucial because it is the only therapy that has the potential to improve functional outcomes; thus hypertensive patients should have repeat BP checks every 15 minutes until the desired BP target is achieved and maintained for 24 hours. Electroencephalogram (EEG) monitoring should be considered in any patient who has persistent unexplained decreased loss of consciousness (LOC) caused by frequent subclinical seizures in ICH patients. Continuous monitoring of ICP is not universally indicated but may be considered in patients with evidence of tentorial herniation, significant intraventricular hemorrhage (IVH), hydrocephalus, or decreased level of consciousness (i.e., Glasgow Coma Scale [GCS] of  $\leq 8$ ).

### Complications

#### Prognostication

ICH patients typically present very severely (i.e., decreased LOC, debilitating deficits), and recovery in ICH tends to be much slower than its ischemic stroke counterpart. It is a devastating disease with limited treatment options, and a vital role for the clinician is providing accurate prognostication to family members/patients. The most widely used prognostication tool is the ICH score, which was initially developed to predict 30-day mortality but has since then been validated to predict long-term mortality up to 1 year (Table 3). Other prediction scores include the FUNC score, originally developed to predict the chances of meaningful functional recovery (see Table 3), although its use is less widely implemented. It is generally recommended that prognostication should be deferred to at least 48 to 72 hours after time of presentation to optimally assess the patient's clinical trajectory and to allow time for radiographic stability to ensue.

#### Acute Neurologic Deterioration

Acute neurologic deterioration is associated with increased risk for long-term disability and mortality and may result from hematoma expansion, seizures, increasing mass effect, development of ventricular hemorrhage, and cerebral herniation. Approximately 1/5 patients will experience early neurologic deterioration. Antiepileptic medications should not be initiated unless a clinical seizure is witnessed or suspected and confirmed with EEG. Important inpatient complications were discussed under "Therapy: Inpatient Medical Treatments."

#### Long-Term Complications

The long-term sequelae of ICH include physical disability, cognitive impairment, mood disorders, localization-related epilepsy, and increased risk for recurrent ICH. There may be an increased risk for ischemic stroke in patients with a history of ICH caused by avoidance of antithrombotic medications. Important predictors for recurrent ICH include microhemorrhages detected on MRI,

**TABLE 3** Glasgow Coma Scale

RESPONSE	SCALE	SCORE
Eye opening response	Eyes open spontaneously	4 points
	Eyes open to verbal command	3 points
	Eyes open to pain	2 points
	No eye opening	1 point
Verbal response	Oriented	5 points

**TABLE 5** Summary of Therapies in the Treatment of ICH

<b>MEDICAL TREATMENT OPTIONS</b>	
Hemostasis	<p>Known coagulation factor deficiency: replacement of appropriate factors</p> <p>Vitamin-K antagonist related ICH: Fresh frozen plasma (FFP) or prothrombin complex concentrates Vitamin K</p> <p>DOAC related ICH: Idarucizumab (Praxbind) for dabigatran (Pradaxa) Andexanet alfa (Andexxa) for rivaroxaban (Xarelto), edoxaban (Savaysa, Lixiana),<sup>1</sup> or apixaban (Eliquis) Consider using FFP if andexanet alfa is not available</p> <p>Antiplatelet related ICH: Do not give platelet transfusion</p> <p>Ongoing trials for rFVIIa: not currently recommended</p>
Blood pressure control	<p>SBP between 150–220 mm Hg: Lowering SBP to 140 mm Hg is safe and may improve functional outcomes Be aware of maintenance of systemic perfusion pressures to other organs (i.e., kidneys)</p> <p>SBP &gt;220 mm Hg: Lowering SBP is still indicated, although practically challenging to 140 mm Hg. Consider lowering SBP by 25% reduction</p>
<b>SURGICAL TREATMENT OPTIONS</b>	
Decompressive surgery	<p>Posterior fossa/cerebellar hemorrhages: Surgery is indicated for any cerebellar hemorrhage with brainstem compression and/ or hydrocephalus and/ or neurologic deterioration Threshold of 3 cm in hematoma diameter for surgical intervention</p> <p>Supratentorial/deep hemorrhages: Surgery may be considered a life-saving measure in deteriorating patients but does not improve functional outcomes</p>
Extraventricular drainage	<p>Indicated for patients with hydrocephalus and decreased level of consciousness</p> <p>Irrigation with alteplase (Activase)<sup>1</sup> is not currently indicated</p>
Minimally invasive surgery	Not currently indicated
<b>PREVENTION OF SECONDARY INJURY AND COMPLICATIONS</b>	
Monitoring	<p>Dedicated stroke unit or intensive care unit with neuroscience expertise</p> <p>Frequent vital sign checks (including blood pressure), neurologic assessments, and continuous cardiopulmonary monitoring if on continuous IV antihypertensives</p> <p>EEG should be considered for decreased level of consciousness</p> <p>Continuous intracranial pressure monitoring may be considered for transtentorial herniation, significant intraventricular hemorrhage (IVH), hydrocephalus, or decreased level of consciousness</p>
Glucose	Maintenance of normoglycemia is recommended
Temperature	Maintenance of euthermia is recommended
Seizure control	Antiepileptics should be considered in those with clinical seizures. It is not routinely recommended as prophylaxis
Dysphagia	Dysphagia assessment needs to be performed before initiation of oral diet to prevent aspiration pneumonia
Urinary tract infection	Foley catheters should not be routinely used
Venous thromboembolism	Intermittent pneumatic compression devices are indicated on first day of hospitalization

<sup>1</sup>Not FDA approved for this indication.

uncontrolled hypertension, prior lacunar stroke, older age, and ongoing anticoagulation therapy, although it is still an ongoing, active area of research. Patients with ICH who require long-term anticoagulation (i.e., atrial fibrillation, mechanical heart valves, hypercoagulable disorders) should be assessed by a neurologist or thrombosis specialist to optimize risk factor control and the risk for future ICH should be weighed against the need for antithrombotic therapy.

## Prevention

### Primary Prevention

Hypertension is the major modifiable risk factor for hemorrhagic strokes. Uncontrolled hypertension accounts for approximately 74% of ICH worldwide, and treatment of hypertension is effective as both primary and secondary prevention. Use of antithrombotic

medication is another modifiable risk factor for ICH. For patients who require long-term anticoagulation for atrial fibrillation or venous thromboembolism, direct oral anticoagulants (DOACs) carry a much lower risk for ICH than warfarin and should be first line therapy unless patients have a specific indication otherwise (i.e., valvular atrial fibrillation, mechanical valve). Patients should not be on antiplatelet agents without appropriate clinical indication because chronic antiplatelet therapy is a known risk factor for ICH.

### Secondary Prevention

Hypertension is not only an important risk factor for ICH but is also implicated in other cardiovascular diseases. Treatment of hypertension is effective for attenuating the risk for recurrent hemorrhagic strokes and prevention of ischemic strokes. For patients at a high risk for cardiovascular events who previously

experienced an ICH, recent research has shown that antiplatelet therapy may be resumed without an increased risk of recurrent ICH. The decision to start anticoagulants after an ICH, however, is not as clear cut and will depend on the balance of risk for ICH occurrence and clinical indications for requiring anticoagulation. Important factors to consider include the suspected etiology of ICH, control of risk factors prior to the last ICH, age/comorbidities, and patient preference. Lastly, statin therapy is not currently indicated for primary or secondary prevention of intracerebral hemorrhage. Traditionally lower levels of low-density lipoprotein (LDL) have been associated with increased risk for ICH, but research is ongoing to better understand this relationship.

## ISCHEMIC CEREBROVASCULAR DISEASE

Method of

Alvaro Cervera, MD, PhD; and Geoffrey A. Donnan, MD

### CURRENT DIAGNOSIS

- Early recognition of stroke is crucial to transport patients to hospitals with dedicated stroke units.
- Advanced neuroimaging allows the use of reperfusion therapies with a prolonged time window.

### CURRENT THERAPY

- Admission to a stroke unit is the most effective and widely available resource for the majority of patients.
- Thrombolysis and thrombectomy have revolutionized the management of acute stroke, greatly improving the outcome.

Treatment of ischemic stroke has improved significantly in the past few years, and mortality and disability rates owing to this condition have decreased. The management of patients in stroke units and the demonstration of the efficacy of thrombolysis and thrombectomy have been crucial in this achievement. Control of vascular risk factors has decreased the number and severity of events. However, recent studies have found an increased incidence of ischemic stroke in the young. Improved management has included high-quality rehabilitation, which has to start early to improve the recovery (i.e., functional independence) of stroke survivors. The multidisciplinary management of stroke can be improved with specific educational programs aimed at increasing awareness of stroke in the general population and among professionals. The concept of “Time is Brain” has great value in emphasizing that stroke is an emergency. Because the window for the available time-dependent treatments is very narrow, avoiding delay is the major goal in the prehospital phase of acute stroke care. Therefore it is important to transport all stroke patients as soon as possible to the closest hospital with a stroke unit. In rural or remote areas with no stroke unit facilities, telemedicine has proven to be a valid alternative.

## Prevention

Lifestyle modification can be a major contributor to reducing the risk of ischemic stroke. Strategies to achieve this protection include avoiding smoking and excessive alcohol consumption, keeping a low/normal body mass index, practicing regular exercise, and having a diet low in salt and saturated fat, high in fruits and vegetables, and rich in fiber. In addition, a Mediterranean diet supplemented with nuts is associated with a decreased risk of vascular events. There is no need to add vitamin supplements to the diet because they have no impact in stroke prevention.

Regular assessment of vascular risk factors (e.g., hypertension, diabetes, and hypercholesterolemia) is important because their control can reduce significantly the incidence of vascular events. In the case of blood pressure, this can be done with diet and pharmacologic therapy, aiming at normal levels of 120/80 mm Hg. After an ischemic stroke, blood pressure should be lowered even in patients with normal blood pressure. Diabetes should be managed with lifestyle modification and pharmacologic therapy as required, and blood pressure needs to be more tightly controlled in these patients (<130/80 mm Hg). The best antihypertensive treatments for diabetics are angiotensin-converting enzyme inhibitors or angiotensin receptor antagonists. Hypercholesterolemia should be managed with lifestyle modification and a statin. After a noncardioembolic ischemic stroke, high-dose statins are beneficial in all patients for secondary prevention.

Postmenopausal hormone replacement therapy should be avoided for the primary or secondary prevention of stroke because it can increase the risk of new vascular events. Other strategies to prevent stroke include the treatment of obstructive sleep apnea with continuous positive airway pressure breathing.

## Antithrombotic Therapy

Low-dose aspirin<sup>1</sup> can be used for the primary prevention of stroke in women or of myocardial infarction in men. Nevertheless, its effect is very small, and it cannot be recommended on a population-wide basis. Aspirin is beneficial for the prevention of stroke in patients with asymptomatic carotid stenosis.

In patients with atrial fibrillation, the CHA2DS2-VASc score (Table 1) is used to decide whether to use anticoagulation. If the score (<https://www.mdcalc.com/chads2-score-atrial-fibrillation-stroke-ris>) is 2 or more, treatment with oral anticoagulants is indicated. With a score of 1, the decision should be made according to the presence of risk factors, risk of bleeding, and patient choice. If the score is 0, there is no need to start antithrombotic treatment, neither antiplatelets nor

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Prevention of Stroke in Patients With Atrial Fibrillation

CHA2DS2-VAS SCALE	
RISK FACTOR	SCORE
Congestive heart failure	1
Hypertension	1
Age $\geq 75$	2
Age 65–74	1
Diabetes mellitus	1
Stroke or transient ischemic attack	2
Vascular disease	1
Female sex	1

anticoagulants. All patients with stroke or transient ischemic attack (TIA) should be anticoagulated, unless strictly contraindicated. Patients with valvular atrial fibrillation require anticoagulation with warfarin, aiming at an international normalized ratio (INR) of 2.0 to 3.0. Patients with prosthetic heart valves should also receive warfarin, and the target INR depends on the prosthesis type. In nonvalvular atrial fibrillation, the treatment options include warfarin (INR 2.0 to 3.0) or a direct oral anticoagulant (dabigatran [Pradaxa], apixaban [Eliquis], rivaroxaban [Xarelto], and edoxaban [Savaysa]). The direct oral anticoagulants are associated with a decreased risk of intracranial hemorrhage when compared with warfarin. Dabigatran (150 mg, twice daily) and apixaban (5 mg, twice daily) have shown to be superior to warfarin in stroke prevention. The dose of the direct oral anticoagulants needs to be adjusted depending on age, renal function, and/or weight.

After an ischemic stroke, all patients should receive anti-thrombotic therapy. Antiplatelet agents are the first choice unless anticoagulation is required. The most effective regimen is clopidogrel (Plavix) or aspirin plus dipyridamole (Aggrenox). However, low-dose aspirin is a reasonable alternative. During the first 3 weeks after a minor stroke or TIA, the combination of aspirin plus clopidogrel can be more effective in reducing ischemic events than clopidogrel alone, although the evidence is scarce. However, dual antiplatelet treatment is not recommended in the long term, except if there is an association with unstable angina or non-Q wave myocardial infarction, or if there has been a recent stenting. Anticoagulation is usually indicated for secondary prevention if the stroke cause is cardioembolic and in specific situations, such as aortic arch atheroma or fusiform aneurysms of the basilar artery. However, level 1 evidence is lacking for these approaches.

### Management of Carotid Stenosis

In patients with asymptomatic carotid stenosis ( $\geq 60\%$ ), surgery is indicated only if the risk of stroke is high. Endarterectomy is the treatment of choice if the stenosis is symptomatic (i.e., has been associated with an ipsilateral stroke or TIA), and severe (70% to 99%). Surgery should be performed in centers with a perioperative complication rate of less than 6% and as soon as possible after the last ischemic event.

Endarterectomy may be indicated for certain patients with moderate stenosis (50% to 69%), although it should be performed only in centers with a perioperative complication rate of less than 3% to be effective. In cases of symptomatic carotid lesions, angioplasty plus stenting is a reasonable alternative, mainly in patients younger than 70 years old. If stenting is performed, a combination of clopidogrel and aspirin is required immediately before the procedure and for at least 1 month after to prevent stent thrombosis.

In patients with intracranial atheromatosis and stroke recurrences, intensive medical treatment is the preferred option. Angioplasty and stenting are not recommended.

### Management of Patent Foramen Ovale

The presence of a patent foramen ovale (PFO) is associated with cryptogenic stroke in the young. There is evidence that in selected patients with stroke or TIA (<60 years of age, non-lacunar stroke, and exclusion of other causes of stroke) the percutaneous transcatheter closure of the PFO is associated with a significant reduction of new vascular events, although with more frequent atrial fibrillation postprocedure, usually transient. Otherwise, there is no evidence indicating that anticoagulation is more effective than antiplatelets for stroke prevention in patients with PFO.

### Management of Acute Ischemic Stroke

All stroke patients should be treated in a stroke unit, because this is associated with a reduction of death, dependency, and the need for institutional care. This effect is present in all stroke patients, irrespective of gender, age, stroke subtype, and stroke severity. Patients with stroke should have a careful clinical assessment, including a neurologic examination. The use of a stroke rating scale, such as the National Institutes of Health Stroke Scale (NIHSS), provides important information about the severity of stroke.

Urgent cranial computed tomography (CT) is mandatory after an ischemic stroke before starting any therapy. Alternatively, magnetic resonance imaging (MRI) or CT perfusion (CTP) can be performed, providing additional information about the selection of patients for mechanical thrombectomy within 6 to 24 hours from symptom onset. However, there is not enough evidence to recommend its routine use in the acute stroke setting.

For the detection and early management of the medical complications of stroke, neurologic status, pulse, blood pressure, temperature, and oxygen saturation should be monitored. Similarly, serum glucose levels need to be monitored and hyperglycemia needs to be treated with insulin accordingly. Normal saline is recommended for fluid replacement during the first 24 hours after stroke. If the patient has a fever, treatment with paracetamol (acetaminophen) may be used while sources of infection are being sought. Reducing blood pressure is recommended only in patients with extremely high blood pressure or when indicated by other medical conditions. Blood pressure should be lowered gradually, avoiding abrupt changes.

### Thrombolysis

All patients suffering an ischemic stroke within 4.5 hours of onset should receive thrombolytic treatment, with intravenous tissue plasminogen activator (tPA [Activase]) unless contraindicated, because it is effective in improving stroke outcome (Box 1). It is very important to start treatment as soon as possible, because pooled analysis has demonstrated that earlier treatment results in a better outcome. Thrombolysis with tPA is effective in all different population subgroups, including the very elderly, even with significant comorbidities. The therapeutic window can be extended up to 9 hours from onset when using advance imaging, such as perfusion-diffusion MRI or CTP. This approach has also been shown to be effective in wake-up strokes. Tenecteplase (TNKase)<sup>1</sup> is an alternative treatment to tPA, with the advantage of being administered in a single bolus (0.25 mg/kg).

### Endovascular Thrombectomy

Mechanical thrombectomy using stent retrievers, in addition to thrombolysis, is more effective in improving outcomes than thrombolysis alone in anterior circulation strokes and a large artery occlusion, with a time window of up to 6 hours. This

<sup>1</sup>Not FDA approved for this indication.

**BOX 1** Treatment of Acute Ischemic Stroke: Intravenous Administration of Tissue Plasminogen Activator

- Infuse 0.9 mg/kg (maximum dose 90 mg) of tissue plasminogen activator (tPA [Activase]) over 60 min, with 10% of the dose given as a bolus over 1 min.
- Admit the patient to a stroke unit for monitoring. Perform neurologic assessment and blood pressure measurement every 15 min during the infusion, every 30 min thereafter for the next 6 h, and then hourly until 24 h after treatment. Administer antihypertensive medications to maintain systolic blood pressure  $\leq 180$  mm Hg and diastolic  $\leq 105$  mm Hg.
- If intracranial hemorrhage is suspected, discontinue the infusion and obtain an emergency computed tomography scan.
- Obtain a follow-up computed tomography scan at 24 hours before starting anticoagulants or antiplatelet agents.

treatment is also effective when there are contraindications for intravenous thrombolysis. In a recent meta-analysis of five major trials (MR CLEAN, ESCAPE, REVASCAT, SWIFT PRIME, and EXTEND IA), endovascular thrombectomy led to significantly reduced disability at 90 days compared with control (odds ratio 2.49), with a number needed to treat of 2.6. All subgroups of patients benefit from this effect. Therefore, health authorities have to implement access to thrombectomy within a reasonable time frame in a network, including stroke centers.

There is recently published evidence indicating that therapeutic window could be extended significantly when using multimodal imaging to select patients who have marked penumbra. Thus, the DAWN trial showed that patients with ischemic penumbra could benefit from thrombectomy up to 24 hours since symptom onset, in comparison with standard care. This result was replicated by the DEFUSE 3 trial, although it included patients up to 16 hours from onset. In **Box 2**, there is a simplified algorithm for the use of reperfusion therapies in acute ischemic stroke.

In large urban areas, mobile stroke units can significantly improve the management of acute stroke patients. These specialized units are ambulances equipped with CT scans and staff expert in acute stroke care. The use of mobile stroke units is associated with a faster thrombolytic treatment and a better functional outcome in comparison with the standard of care (transferring patients to emergency services). Also, these mobile units could facilitate a faster access to endovascular thrombectomy.

### Antithrombotic Drugs

All ischemic stroke patients should receive a low dose of aspirin daily. This can be started as soon as possible in patients who have not received reperfusion therapies, but always within 48 hours after onset. However, in patients who received thrombolysis, aspirin should be delayed for 24 hours. The use of other antiplatelet agents during the acute phase of stroke cannot be recommended based on available evidence. Similarly, early administration of unfractionated heparin, low-molecular-weight heparin, or heparinoids is not indicated in patients with acute ischemic stroke.

### Treatment of Stroke Complications

Brain edema develops between the second and fifth day after stroke onset and is the cause of early deterioration and death. In the case of a malignant infarction of the middle cerebral artery, the mortality rate is 80%. In patients younger than 60 years, with this pattern of cerebral infarction, hemicraniectomy has been effective in reducing mortality and severe disability, as shown in the pooled analysis of the DECIMAL, DESTINY, and HAMLET trials. Decompressive hemicraniectomy is also effective

**BOX 2** Reperfusion Therapies in Acute Ischemic Stroke

- Symptom onset between 0 and 4.5 h:
  - No contraindications for thrombolysis.
    - Perform CT scan.
    - Administer IV tPA (Activase).
    - Perform multimodal imaging (this could be done beforehand if it does not delay treatment with IV tPA).
    - Mechanical thrombectomy (MT): if occlusion of intracranial internal carotid artery or middle cerebral artery (segment 1, M1), NIHSS score  $\geq 6$ , no pre-morbid disability (mRS 0–1), and ASPECTS of  $\geq 6$ . Groin puncture within 6 h of symptom onset.
  - Contraindications for thrombolysis:
    - Perform multimodal imaging.
    - Proceed to MT: if occlusion of intracranial internal carotid artery or middle cerebral artery (M1), NIHSS score  $\geq 6$ , no pre-morbid disability (mRS 0–1), and ASPECTS of  $\geq 6$ . Groin puncture within 6 h of symptom onset.
- Symptom onset between 4.5 and 9 h or wake-up stroke:
  - Perform multimodal imaging.
  - If no contraindications for thrombolysis, administer IV tPA (Activase) if significant penumbra according to EXTEND or WAKE-UP trials.
  - Proceed to MT if significant penumbra according to DAWN or DEFUSE 3 trials (this varies depending on age, NIHSS, and size of infarct core).
  - Standard medical management if no criteria for thrombolysis or MT.
- Symptom onset between 9 and 24 h:
  - Perform multimodal imaging.
  - If occlusion of the intracranial internal carotid artery, middle cerebral artery (M1), or both.
    - Proceed to MT if significant penumbra according to DAWN or DEFUSE 3 trials (this varies depending on age, NIHSS, and size of infarct core).
    - Otherwise, standard medical management.
- Other circumstances:
  - MT could be a reasonable option in selected cases with distal occlusion of the middle cerebral artery (M2 or M3).
  - MT is a reasonable therapeutic option for selected patients with occlusion of the anterior cerebral arteries, vertebral arteries, basilar artery, or posterior cerebral arteries.
  - Selected patients could benefit from MT even with pre-morbid conditions (mRS > 1), ASPECTS < 6, or NIHSS score < 6.

*ASPECTS*, Alberta stroke program early CT score; *CT*, computed tomography; *IV*, intravenous; *mRS*, modified Rankin Scale; *NIHSS*, National Institutes of Health Stroke Scale; *tPA*, tissue plasminogen activator.

in reducing mortality in patients older than 60 years, although the rates of severe disability are very high. Surgery needs to be performed within 48 hours after symptom onset. Surgical decompression is also indicated in the case of large cerebellar infarctions that compress the brainstem.

Stroke-associated infections require appropriate antibiotics, but prophylactic administration is discouraged. Venous thromboembolism is a frequent complication after stroke, but its incidence can be reduced with appropriate hydration and graded compression stockings. If the risk of deep venous thrombosis or pulmonary embolism is high, the use of subcutaneous heparin or low-molecular-weight heparin is beneficial. Early mobilization is an effective way of preventing complications, such as aspiration pneumonia or pressure ulcers. Anticonvulsants are administered only to prevent recurrent seizures but are not used prophylactically.

In the case of urinary incontinence, specialist assessment and management are recommended. Dysphagia is common after stroke and is associated with a higher incidence of medical complications and increased mortality. Malnutrition also predicts a poor functional outcome and increased mortality, and it is important to assess the swallowing capacity and the nutritional status of the patient.

Rehabilitation should be started after admission to the stroke unit. The optimal timing of first mobilization is unclear, but mobilization within the first few days appears to be well tolerated. However, very early mobilization can be associated with a worse outcome, as shown in the AVERT trial. An early, lower-dose, out-of-bed activity regimen is preferable to very early, frequent, higher-dose intervention. It is important to assess cognitive deficits and depression during the patient's hospital stay, because this may require specific intervention, although evidence about the type is lacking.

## MIGRAINE

Method of

Natalia E. Murinova, MD

### CURRENT DIAGNOSIS

- Migraine is a primary headache disorder with severe one-sided headache associated with nausea, vomiting, and/or light and sound sensitivity.
- Migraine is highly prevalent: it affects more than 1 billion people worldwide. It is highly disabling and constitutes the second leading cause of years lost to disability.
- The coronavirus 2019 (COVID-19) pandemic is a sensitive time for migraineurs because of an increase in stressors, heightened anxiety, and changes in daily life that often trigger new or worsening migraine.

### CURRENT THERAPY

- Acute treatment of migraine
  - Nonspecific
    - Acetaminophen; nonsteroidal antiinflammatory drugs (NSAIDs); antiemetics
  - Specific migraine medication classes
    - FDA approved for acute treatment of migraine with or without aura in adults
    - Triptans, serotonin (5-HT<sub>1B</sub>, 5-HT<sub>1D</sub>, 5-HT<sub>1F</sub>) receptor agonists
    - Ditans, oral serotonin (5-HT<sub>1F</sub>) receptor agonists
    - Gepants, oral calcitonin gene-related peptide (CGRP) receptor antagonist
- Preventive treatment of migraine
  - Nonspecific therapies
    - Beta blockers; tricyclic antidepressants; antiepileptics; N-methyl-D-aspartate (NMDA)
  - Specific therapies
    - Anti-CGRP medications
    - Onabotulinumtoxin A (Botox) injections

### Definition

Migraine is a primary headache disorder that does not have any known structural cause. International Headache Society (IHS) criteria define *migraine* and explain the clinical variability seen in patients.

The headache episode in migraine as defined by the IHS has at least two of four defining features: (1) one-sided, (2) pulsating, (3) moderate to severe, and (4) aggravated by movement, along with at least one of two associated features: (1) nausea and/or vomiting and (2) light and sound sensitivity. In its most common form, migraine is an episodic recurrent headache lasting 4 hours or longer per episode if left untreated. The frequency varies from rare episodes to everyday headache.

In its more malignant forms, migraine is chronic, daily, nonstop pain with rare or no pain-free time. There is significant clinical variability: unilateral location and pulsating pain is present in around 50% of migraine sufferers. Most patients are disabled from pain; environmental oversensitivity to light, sound, and smell; inability to function; and often transient cognitive dysfunction such as difficulty with concentration. There is a subset of migraine with aura, most commonly the visual symptoms associated with fully reversible visual changes that can mimic transient ischemic attack or stroke.

Many healthcare providers fail to recognize migraine because they default to the most classic migraine presentation with visual aura with unilateral, pulsating pain with nausea and vomiting. Because migraine can manifest in different ways, this makes diagnosis more challenging. If a patient presents to a healthcare provider with recurrent moderate-to-severe headaches, migraine diagnosis should be considered. In general, most migraine experts consider a headache a migraine unless there is a warning sign or some atypical feature. However, there are a number of neurologic disorders that mimic migraine. For example, stroke can present with migraine-like headache. The majority of people with “sinus headache” can also suffer from migraine. For patients’ safety, other causes of headache and other neurologic disorders must be ruled out. The clinical presentation differs from person to person, and we should consider migraine diagnosis as a possibility in anyone with recurring, disabling headaches and impaired function.

### Epidemiology

Migraine affects more than 1 billion people worldwide. In the United States, migraine affects more than 45 million adults, encompassing 18% to 23% of women and 6% to 9% of men. Onset can occur as early as 5 years of age, and prevalence peaks in young people, but it can occur at any age. Although migraine can be transient, migraine affects people during their most productive

years of life. The Global Burden of Disease (GBD) Study 2016 measured how disabling various disorders are across the world and assessed how disorders affect disability-adjusted life years (DALY). In GBD 2016, migraine was the second-most disabling disorder, after low-back pain. In one study, 88% of patients diagnosed with sinus headache had migraine.

### Risk Factors

Migraine is most commonly seen in young white women with a family history of migraine. There are many risk factors that can be cumulative for a given individual who presents with migraine. Lifestyle factors that lead to migraine include high-stress work, nutrition (high-carbohydrate diet), physical inactivity, and chronic stress. Therefore, a young person with genetic susceptibility to migraine with stress at work, physical inactivity, poor nutrition, and sleep deprivation has an increased risk for developing migraine. It is estimated that in 1 year, up to 3% of episodic migraine cases become chronic. Risk factors for migraine chronicity are obesity, acute medication overuse, caffeine overuse, stressful life events, depression, and sleep disorders. Comorbid conditions often seen in migraine include anxiety, depression, and insomnia, and these conditions have a bidirectional effect.

### Pathophysiology

Although migraine was once considered exclusively a disorder of the blood vessels, compelling evidence has led to the realization that a migraine represents a highly choreographed interaction between major inputs from both peripheral nervous system and the central nervous system (CNS), with the trigeminovascular system and the cerebral cortex among the main players. Migraine was initially thought to be a purely vascular disorder, but it is understood that migraine involves the neurotransmitter calcitonin gene-related peptide (CGRP). The pain of a migraine attack seems to be caused by the release of CGRP in the dura mater, which results in vasodilation and inflammation. Studies have shown that if CGRP is given intravenously to migraine sufferers, most of them have a migraine episode in the next few hours.

### Diagnosis and Workup

The main questions are whether the patient presents with headache that meets migraine criteria and whether he or she needs neuroimaging (Table 1). We diagnose migraine using IHS criteria (<https://ichd-3.org/1-migraine/>). Migraine is divided into two major subtypes. Migraine without aura is the most common, characterized by a headache with severe unilateral pain, photophobia, phonophobia, and functional impairment. Migraine with aura is most commonly characterized by reversible visual changes that precede and sometimes accompany the migraine pain. The success of migraine treatment depends on making the correct diagnosis. This requires a careful headache history as many patients diagnose themselves with sinus headache, tension-type headache, or another type of headache. Identifying classic symptoms has a high probability of accurate diagnosis. The headache pattern should distinguish migraine from other primary headaches (tension or cluster headache). The clinical history and neurologic examination target must exclude secondary headache that can present as migraine. In most patients, the diagnosis is made using their history and IHS criteria. Diagnostic imaging is not indicated in otherwise healthy migraine patients with normal neurologic examination. Patients with “red flags” such as abnormalities during the neurologic examination, fever, unintentional weight loss, history of cancer, transplant, or immunodeficiency need further workup with neuroimaging. Which kind of neuroimaging should be performed is a common question. Magnetic resonance imaging (MRI) of the brain with and without contrast is the preferred imaging modality.

### Treatment

Pharmacologic treatment includes acute treatment, used for management of acute exacerbations, and preventive treatments that have shown efficacy in decreasing migraine attacks in the long term. Preventive medications are taken daily for at least several

**TABLE 1** Precision Questions Helpful in Migraine Diagnosis

1. Is this a new kind of headache?	New headache needs further history, make sure this is not a migraine mimic.
2. Use “red flag” questions such as, “Do you have any other condition such as cancer?”	“Red flag” questions are used to exclude secondary headache
3. How many total headache days do you have per month? Lump all headache days.	Total headache days >15 days per month are suggestive of chronic migraine.
4. How long do your headaches last with no treatment?	Duration of headache without therapy should be more than 4 hours for migraine diagnosis. With shorter duration, consider other diagnoses, such as trigeminal autonomic cephalgia.
5. What associated symptoms do you have?	For migraine, look for associated nausea, light and sound sensitivity.
6. How many days per month do you use an acute therapy for any pain?	Medication overuse headache is commonly seen with chronic migraine, and any medication use for any pain can cause this.

months, sometimes years, to reduce the severity and frequency of migraines before they start.

The treatment strategy for migraines has shifted from using mostly nonspecific pain medications such as aspirin and acetaminophen to migraine-specific therapies such as triptans, ditans, and gepants, and other treatments such as neuromodulation (Table 2; Boxes 1 to 3).

### Acute Treatment

#### Mechanism of Acute Migraine Medications

Migraine pain is considered to be caused by dura mater release of CGRP, with subsequent vasodilation and neurogenic inflammation. Triptans and ergots are agonists of serotonin 5-HT<sub>1D</sub> receptors, and their activation prevents CGRP release. Agonism at 5-HT<sub>1B</sub> receptors results in vasoconstriction, which opposes the action of CGRP. Ditans are selective nontriptan oral serotonin (5-HT<sub>1F</sub>) receptor agonists, which are thought to stop plasma protein release by action of the trigeminal ganglion. 5-HT<sub>1F</sub> receptors are not present in vessels. Ditans also inhibit trigeminal nucleus caudalis. Gepants such as ubrogepant (Ubrovelvy), rimegepant (Nurtec ODT), and atogepant (Qulipta)<sup>1</sup> are oral CGRP receptor antagonists.

The American Headache Society (AHS) guideline for acute treatment in 2015 summarized evidence-based assessment of acute treatments for migraine: “The specific medications—triptans and dihydroergotamine (nasal spray [Migranal], inhaler<sup>5</sup>) are effective (level A),” whereas “effective nonspecific medications include acetaminophen, NSAIDs, opioids (butorphanol nasal spray)<sup>1</sup> [not recommended], sumatriptan/naproxen (Treximet), and the combination of acetaminophen/aspirin/caffeine (e.g., Excedrin Migraine)” also have level A evidence. “Ergotamine tartrate (Ergomar) and other forms of dihydroergotamine, ketoprofen (Orudis),<sup>1</sup> intravenous and intramuscular ketorolac (Toradol),<sup>1</sup> flurbiprofen (Ansaid),<sup>1</sup> intravenous magnesium (in migraine with aura),<sup>1</sup> and the combination of isometheptene compounds codeine/acetaminophen,<sup>1</sup> tramadol/acetaminophen (Ultracet),<sup>1</sup> prochlorperazine (Compazine),<sup>1</sup> droperidol (Inapsine),<sup>1</sup> chlorpromazine (Thorazine),<sup>1</sup> and metoclopramide (Reglan)<sup>1</sup> are probably effective (level B).”

It is important to educate patients on the appropriate use of acute therapy because medication overuse headache (MOH) can develop. This is defined as the presence of headache while taking

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

**TABLE 2** Migraine Treatment by Severity and Phenotype

	CLINICAL MIGRAINE PHENOTYPE	STRATEGY	MEDICATION
Increasing migraine severity	Mild to moderate	Acetaminophen NSAID	Acetaminophen (Tylenol) <sup>1</sup> 1000 mg Naproxen sodium (Aleve) <sup>1</sup> 220–660 mg Ibuprofen (Motrin) 800 mg
	Moderate to severe	NSAID + triptan + anti-nausea  Triptan (5HT <sub>1B</sub> agonist, 5HT <sub>1D</sub> agonist) Ditan (5HT <sub>1F</sub> agonist) Gepant (CGRP antagonist)	Naproxen (Aleve) 440 mg + ondansetron (Zofran) <sup>1</sup> 8 mg ODT + triptan later for rescue if necessary  Sumatriptan (Imitrex) (6 mg SQ injection, 20 mg nasal solution, 25 mg, 50 mg, and 100 mg oral tablet) Zolmitriptan (Zomig) (2.5 mg, 5 mg nasal solution, oral tablet, oral disintegrating tablet [ODT]) Rizatriptan (Maxalt) (5 mg, 10 mg oral tablet, ODT) Naratriptan (Amerge) (1 mg, 2.5 mg PO tablet) Eletriptan (Relpax) (20 mg, 40 mg PO tablet) Almotriptan (Axert) (6.25 mg, 12.5 mg PO tablet) Frovatriptan (Frova) (2.5 mg PO tablet) Lasmiditan (Reyvow) 50 mg, 100 mg, 200 mg PO tablet Ubrogepant (Ubrelyvy) 50 mg, 100 mg PO tablet Rimegepant (Nurtec ODT) 75 mg oral disintegrating tablet
	Severe attack difficult to treat and refractory migraine		Triptan + NSAID + anti-nausea drug Gepant + NSAID + anti-nausea drug Ditan + NSAID + anti-nausea drug  Ketorolac (TORADOL) <sup>1</sup> IM 60 mg Indomethacin <sup>1</sup> oral or rectal Prochlorperazine (COMPAZINE) <sup>1</sup> 5 mg, 10 mg Dexamethasone <sup>1</sup> or prednisone <sup>1</sup>

### BOX 1 First-Line Acute Therapy of Migraine

Naproxen (Aleve)<sup>1</sup> 440 mg plus ondansetron (Zofran)<sup>1</sup> 8-mg ODT plus triptan later for rescue if necessary

#### Triptans

Sumatriptan (Imitrex) 6-mg SQ injection; 20-mg nasal solution; 25-mg, 50-mg, and 100-mg oral tablet

Zolmitriptan (Zomig) 2.5-mg, 5-mg oral tablet, ODT; nasal spray

Rizatriptan (Maxalt) 5-mg, 10-mg oral tablet, ODT

Naratriptan (Amerge) 1-mg, 2.5-mg oral tablet

Eletriptan (Relpax) 20-mg, 40-mg oral tablet

Almotriptan (Axert) 6.25-mg, 12.5-mg oral tablet

Frovatriptan (Frova) 2.5-mg oral tablet

#### Ditans

Lasmiditan (Reyvow) 50-mg, 100-mg, 200-mg oral tablet

#### Gepants

Ubrogepant (Ubrelyvy) 50-mg, 100-mg oral tablet

Rimegepant (Nurtec ODT) 75-mg ODT

ODT, Oral disintegrating tablet.

any acute medications for any pain, even if not headache related, more than 15 days per month. MOH is often difficult to treat and is medication- and procedure-refractory. We strongly recommend monitoring days per month of acute medication use and setting a limit on maximum monthly use. An electronic headache diary app, such as MigraineBuddy (<https://migrainebuddy.com/>), can be helpful in documenting headache days and medication use.

An oral nonopioid analgesic, such as naproxen (Aleve),<sup>1</sup> is often adequate for acute treatment of mild to moderate migraine without nausea or vomiting. Migraine-specific agents should be considered when migraine episodes are moderate to severe. The acute

### BOX 2 Steps for Acute Treatment for Migraine Headache

Step 1: Choose options that are not known to lead to medication overuse headache (MOH).

- Antiemetics: Ondansetron (Zofran)<sup>1</sup> (tablet, dispersible tablet), prochlorperazine (Compazine)<sup>1</sup> (tablet, suppository), promethazine (Phenergan)<sup>1</sup> (tablet, suppository), metoclopramide (Reglan).<sup>1</sup>

- Natural supplements/herbs: Feverfew tea,<sup>7</sup> Boswellia,<sup>7</sup> magnesium.<sup>7</sup>

- Anesthetic: Lidocaine nasal spray.<sup>1</sup>

- Neuromodulation: Cefaly (supraorbital stimulation), Gammacore (vagal nerve stimulation), SpringTMS (transcranial magnetic stimulation), Relivion (external combined occipital and trigeminal neurostimulation)

Nonmedication options: Rest, ice, meditation, biofeedback, distraction, essential oils.<sup>7</sup>

Step 2: NSAIDs, longer acting are generally considered less likely to lead to MOH.

- Diclofenac (tablet,<sup>1</sup> capsule,<sup>1</sup> powder), ketorolac,<sup>1</sup> naproxen,<sup>1</sup> ibuprofen.

Step 3: Limit any acute medications to 1 to 2 days per week to avoid MOH such as triptans.

- Triptans: Sumatriptan (Imitrex) (tablet, nasal spray, injection), rizatriptan (Maxalt) (tablet, dispersible tablet), eletriptan (Relpax), zolmitriptan (Zomig) (tablet, dispersible tablet, nasal spray), almotriptan (Axert), frovatriptan (Frova), naratriptan (Amerge).
- Ergotamines: Dihydroergotamine DHE 45 injection, Migranal nasal spray

<sup>1</sup> Not FDA approved for this indication.

<sup>7</sup> Available as dietary supplement.

**Level A Therapies, Established as Effective and FDA Approved for Episodic Migraine (EM)**

Antiepileptic drugs (AEDs): Topiramate (Topamax) (caution if low weight or history of kidney stones), divalproex sodium (Depakote) (caution of weight gain), sodium valproate (Depakene).

Beta blockers: Propranolol (Inderal), timolol (Blocadren), metoprolol (Lopressor) (the only medication level A that is not FDA approved).

**Specific Preventive Migraine Therapies FDA Approved for EM and CM**

Anti-CGRP monoclonal antibodies: Erenumab-aooe (Aimovig), fremanezumab-vfrm (Ajovy), galcanezumab-gnlm (Emgality)

Gepants: Rimegepant (Nurtec ODT)

Neuromodulation devices: Cefaly (supraorbital stimulation), Gammacore (vagal nerve stimulation), SpringTMS (transcranial magnetic stimulation)

**Level B Therapies, Probably Effective for EM, not FDA Approved for EM**

Antidepressants: Amitriptyline, venlafaxine (Effexor XR)

Beta blockers: Atenolol (Tenormin), nadolol (Corgard)

**Level C Therapies, Possibly Effective for EM, not FDA Approved**

Calcium channel blockers and ACE inhibitors: Verapamil (Calan), lisinopril (Prinivil)

AEDs: Carbamazepine (Tegretol)

Beta blockers: Pindolol (Visken)

Antihistamines: Cyproheptadine (Periactin)

Angiotensin receptor blockers: Candesartan (Atacand), clonidine (Catapres)

migraine-specific pharmacotherapies include triptans, ergotamines, ditans, and gepants.

Many acute therapies are effective only for some patients and can cause significant side effects. Patients who do not respond to one triptan may respond to another triptan or a different mode of administration of the same triptan. Note that triptans are contraindicated in patients with vascular risk factors. Treatments include the following:

- Sumatriptan (Imitrex) (6 mg SQ injections; 20-mg nasal solution; 25-mg, 50-mg, and 100-mg oral tablet)
- Zolmitriptan (Zomig) (2.5-mg, 5-mg nasal solution; oral tablet or oral disintegrating tablet)
- Rizatriptan (Maxalt) (5-mg, 10-mg oral tablet; or oral disintegrating tablet)
- Naratriptan (Amerge) (1-mg, 2.5-mg oral tablet)
- Eletriptan (Relpax) 20-mg, 40-mg oral tablet
- Almotriptan (Axert) (6.25-mg, 12.5-mg oral tablet)
- Frovatriptan (Frova) (2.5-mg oral tablet)

Dihydroergotamine (D.H.E. 45, Migranal) should be considered in patients who are refractory to triptans, although they have the same vascular disease contraindication.

- Dihydroergotamine (D.H.E. 45, 1 mg SQ or IV; Migranal 0.5-mg/nasal spray)

A number of new agents became available in 2020.

- New acute migraine treatment: Ditans and gepants

The one approved ditan is lasmiditan (Reyvow), which is an oral serotonin (5-HT<sub>1F</sub>) receptor agonist. The gepants approved for acute migraine treatment are ubrogepant (Ubrovelvy) and rimegepant (Nurtec ODT), which are oral CGRP receptor agonists. These drugs were approved by the U.S. Food and Drug Administration (FDA) in 2020 for acute migraine treatment with and without aura in adults.

**Ditans for Acute Migraine Treatment**

Ditans are the only group of medications known to selectively bind serotonin 1F receptor (5-HT<sub>1F</sub>) on the trigeminal neurons. Ditans

do not cause vasoconstriction via the serotonin 1B receptor on blood vessels as triptans do, therefore they are not contraindicated in patients with known vascular risk factors. A majority of patients in clinical studies had at least one cardiovascular risk factor, only a few of the subjects had ischemic heart disease, and none had ischemic events attributed to lasmiditan during the trial within 48 hours. To date, no clinical trials are available that have compared lasmiditan to other acute headache treatments. The most common side effects in clinical trials were dizziness, paresthesias, and sedation. Cognitive changes and confusion were also reported. Lasmiditan can cause impaired driving ability, and there is a drug warning against driving and operating machinery for at least 8 hours after taking this drug. It is important to mention this to the patient. Because of the CNS action, other concomitant CNS depressants should be avoided. Caution is also advised with heart rate-lowering medications. It is not known if ditans can cause serotonin syndrome.

There is no available evidence that supports limiting the use of ditans with selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) because of concerns for serotonin syndrome. However, given the seriousness of serotonin syndrome, caution is warranted, especially in a patient taking other medications or supplements. No data for pregnancy and breastfeeding are available at this time. Treatments include the following:

- Lasmiditan (50-mg, 100-mg, or 200-mg PO as a single dose; maximum: One dose in 24 hours)

**Gepants for Acute Migraine Treatment**

Gepants are the only group of oral medications known to selectively bind and antagonize CGRP receptors. Gepants do not cause vasoconstriction because they do not bind to serotonin 1B receptors on blood vessels as triptans do, therefore they are not contraindicated in patients with known vascular risk factors. CGRP levels tend to increase with migraine, and patients with migraine injected with CGRP develop migraine within 4 hours. No clinical trials are available that have compared gepants with other acute headache treatments. Gepants are well tolerated, and the most commonly reported side effect compared with placebo is nausea in ubrogepant trials. Because gepants are metabolized via the CYP3A4 enzyme system in the liver, coadministration with strong inhibitors of CYP3A4 such as ketoconazole and CYP3A4 inducers such as rifampin should be avoided. No data for pregnancy and breastfeeding are available at this time. Treatments include the following:

- Ubrogepant (50 to 100 mg PO as a single dose; may repeat once based on response and tolerability after ≥2 hours)
- Rimegepant (75 mg PO as a single dose; maximum: 75 mg/24 hours)

**Neuromodulation Therapies for Migraine**

There are currently several FDA-approved neuromodulation devices for use in migraine, all of which use noninvasive stimulation to modulate brain function. All are considered to have nonsignificant risks and are generally well tolerated by patients. Neuromodulation can be used for acute treatment of migraine. These devices generally require patient payment, although they are generally free of charge for veterans or military active duty.

- Remote electrical neuromodulation (REN) device
- External trigeminal neurostimulation (eTNS) device, Cefaly device
- Single-pulse transcranial magnetic stimulation (sTMS) device
- External vagal nerve stimulation (VNS) device (GammaCore)
- External combined occipital and trigeminal neurostimulation (eCOT-NS) device (Relivion)

**Preventive Treatment**

There is emphasis on prevention of migraine attacks for many patients because acute therapy is often less effective in more severe cases. Consider preventive treatments for patients who are disabled by migraine, missing work, using the emergency department for headache treatment, have five or more migraine days per month, or are prone to overusing acute medications. Preventive treatments

should also be considered for patients with serious medical problems such as heart disease or stroke.

Healthcare providers should consult the American Academy of Neurology (AAN)/AHS guidelines. All guidelines were consistent in their treatment recommendations for first-line use. All rated topiramate, divalproex/sodium valproate, propranolol, and metoprolol as having the highest level of evidence. Treatments include the following:

#### Level A: Effective

- Divalproex (Depakote ER)/sodium valproate (Stavzor) 500 to 1000 mg/day
- Metoprolol (Lopressor)<sup>1</sup> 25 to 200 mg/day
- Petasites (butterbur)<sup>7</sup> 50 to 75 mg bid
- Propranolol (Inderal) 40 to 240 mg/day
- Timolol (Blocadren) 10 to 15 mg bid
- Topiramate (Topamax) 25 to 200 mg/day

#### Level B: Probably effective

These medications should be considered for patients requiring migraine prophylaxis

- Amitriptyline (Elavil)<sup>1</sup> 10 to 150 mg/day
- Fenopropfen (Nalfon)<sup>1</sup> 200 to 600 mg three times a day
- Feverfew<sup>7</sup> 50 to 150 mg bid; 2.08 to 18.75 mg three times a day for MIG-99 preparation
- Ibuprofen (Advil, Motrin)<sup>1</sup> 200 mg twice a day
- Ketoprofen (Orudis)<sup>1</sup> 50 mg three times a day
- Magnesium<sup>1</sup> 600 mg/day
- Naproxen (Naprosyn)<sup>1</sup>/naproxen sodium (Anaprox DS)<sup>1</sup> 500 to 1100 mg/day or naproxen sodium 550 mg twice a day
- Riboflavin (Vitamin B2)<sup>7</sup> 400 mg/day
- Venlafaxine (Effexor ER)<sup>1</sup> 150-mg extended release/day
- Atenolol (Tenormin)<sup>1</sup> 25 to 100 mg/day

#### Anti-Calcitonin Gene-Related Peptide Monoclonal Antibodies for Preventive Treatment

Since 2018, CGRP receptor antagonist monoclonal antibodies (mAbs) have been FDA approved for preventive treatment of both episodic and chronic migraine: erenumab-aooe (Aimovig), galcanezumab-gnlm (Emgality), fremanezumab-vfrm (Ajovy), and eptinezumab-jjmr (Vypti). The first three are intended for self-injection at home. Before covering, most medical insurances require trial of at least three classes of preventive therapies with highest level of evidence including beta blockers (propranolol or timolol), antiseizure medications (divalproex sodium or topiramate), and tricyclic antidepressants or SNRIs. They are effective in about one-third of patients with migraine with super-responders, have a low side-effect profile, and do not interact with any medications. They are not indicated during pregnancy or breastfeeding because of lack of evidence. Treatments include the following:

- Erenumab-aooe (Aimovig) 70 mg, 140 mg SQ once a month self-administered by the patient
- Fremanezumab-vfrm (Ajovy) 225 mg SQ monthly, or 675 mg every 3 months (quarterly), which is administered as three consecutive subcutaneous injections of 225 mg each
- Galcanezumab-gnlm (Emgality) 240 mg (two consecutive subcutaneous injections of 120 mg each), once as a loading dose, followed by monthly doses of 120 mg injected subcutaneously

#### Gepant Anti-Calcitonin Gene-Related Peptide Receptor Antagonists for Migraine Prevention

Atogepant (Qulipta) was approved in 2021 for prevention of migraine at doses from 10 mg to 60 mg a day. Rimegepant (Nurtec ODT) received additional FDA approval for migraine prevention in 2021 at the dose of 75 mg every other day.

#### Chronic Migraine Treatment

Patients with chronic forms of migraine are especially difficult to treat. They are prone to chronic MOH. *Overuse* is defined as

taking acute medication 15 or more days per month for nonopioid analgesics (including aspirin, NSAIDs, and acetaminophen) and 10 or more days per month for triptans, ergotamines, opioids, and combination analgesics. People can develop MOH at much lower levels of regular medication use. Healthcare providers should ensure that patients are aware of the risk of MOH and limit medication use well below these levels. We recommend not using acute medication more than 1 to 2 days per week on average, and this includes all acute medications. Neuromodulation is a great option for management of acute exacerbation in patients with chronic migraine because daily use does not lead to rebound and worsening headaches. Always consider preventive medications and lifestyle changes in patients with chronic migraines because acute medications cause MOH when used 15 or more days per month.

MOH often leads to clinically refractory migraine. Taking acute medications to abort migraine attacks more than 10 days per month can lead to increased neuronal excitability, depletion of central serotonin production, and increased release of CGRP. Clinical observation suggests that both preventive and acute treatment for the primary headache usually fail unless the offending medication or medications that caused MOH are discontinued.

Treatments for chronic migraine include the following:

- Topiramate (Topamax)<sup>1</sup> 25 to 200 mg/day
- OnabotulinumtoxinA (Botox)<sup>1</sup> 155-unit injections by a healthcare provider every 3 months
- Erenumab-aooe (Aimovig)<sup>1</sup> 70 mg, 140 mg SQ once a month self-administered by the patient
- Fremanezumab-vfrm (Ajovy)<sup>1</sup> 225 mg SQ monthly, or 675 mg every 3 months (quarterly), which is administered as three consecutive subcutaneous injections of 225 mg each.
- Galcanezumab-gnlm (Emgality)<sup>1</sup> 240 mg (two consecutive subcutaneous injections of 120 mg each) once as a loading dose, followed by monthly doses of 120 mg injected subcutaneously
- Atogepant (Qulipta) 10 to 60 mg daily orally<sup>1</sup>

#### Monitoring

Primary care providers should consider regular follow-up of their patients every few months or more frequently until patients are stable and have gained therapeutic success. We recommend adding multimodal therapy at each visit, and this can include exercise, sleep therapy, nutrition therapy, stress reduction, supplements, and pharmacotherapy reevaluation. We use the visits to address migraine comorbidities, especially anxiety and sleep. With regular monitoring, the medication dose can be optimized for maximum efficacy and the fewest possible side effects. Acute pharmacotherapy escalation in patients who are not optimally controlled can backfire and lead to development of MOH. When a patient experiences significantly worsening headache on 15 or more days per month and has a history of migraine, acute medication frequency of use must be assessed. MOH may resolve after the acute medication is discontinued; however, in many patients with comorbid anxiety and insomnia, more treatment should be considered. In patients with MOH, we should consider preventive therapy and neuromodulation therapy. Compliance with medication therapy can be improved by education offered by caring healthcare providers and establishing therapeutic alliance with patients by using motivational interviewing skills.

<sup>1</sup>Not FDA approved for this indication.

## CURRENT THERAPY

- Acute attacks of MS are treated with high-dose corticosteroids and, in severe cases, plasma exchange. These therapies facilitate time to recovery but do not prevent future relapses.
- Disease-modifying therapies (DMTs) reduce the number of new attacks and new MRI lesions. To date, there are no curative treatments.
- There are many distinct and effective DMT choices approved for CIS, RRMS, and SPMS with activity (ongoing clinical attacks and/or new MRI lesions).
- The single approved therapy for PPMS is ocrelizumab (Ocrevus). Treatment for RIS remains uncertain with trials ongoing.
- Medications vary in their mechanism of action, efficacy, side-effect profile, and mode of delivery. DMT choice should be individualized considering the patient's age, severity of MS, presence of comorbidities, family planning, and patient preference. Insurance coverage plays a role given the substantial cost of these medications.
- Novel MS medications, including further oral medications, and infusion-based monoclonal antibodies are currently under scientific evaluation.

Multiple sclerosis (MS) is an autoimmune inflammatory demyelinating disease of the central nervous system (CNS) that affects approximately 1 million people in the United States alone.

### Risk Factors

Women are at least twice as likely to develop of MS as are men. Other known risk factors for development of MS include ethnicity, genetic background, and socioeconomic and environmental exposures. Persons of European ethnicity, particularly those born and reared in extreme northern or southern latitudes, are particularly susceptible to MS, although recent data suggest that African Americans may have a more severe clinical course. Genetic susceptibility is associated with the *HLA-DRB1* major histocompatibility allele as well as interleukin-2 and interleukin-7 receptors. Low serum vitamin D levels are associated with an increased risk of development of MS and may influence the severity of its clinical course. The association between MS and infection with Epstein-Barr virus (infectious mononucleosis) has been studied extensively. A recent large longitudinal study of U.S. military recruits strengthened this association by demonstrating that Epstein-Barr infection preceded the development of MS in those who were subsequently diagnosed with MS. Further, the risk of developing MS was increased 32-fold after Epstein-Barr infection but was not increased by other viruses such as cytomegalovirus. Given Epstein-Barr infection is very common and MS quite uncommon, this suggests that exposure to the virus may be necessary but insufficient for developing MS. Comorbid chronic vascular diseases, including hypertension, obesity, and mood disorders complicate and worsen MS disease course. Cigarette smoking is associated with an increased risk for development of MS and likely is associated with an increased severity and clinical course, including that of cognitive impairment.

### Pathophysiology

The etiology and pathophysiology of MS as a whole remains uncertain. However, most evidence supports an inflammatory demyelinating disease induced by environmental factors in a genetically susceptible host. Animal studies including experimental allergic encephalomyelitis and Theiler murine encephalomyelitis virus also point to an autoimmune inflammatory demyelinating etiology, most likely associated with viral infection. Studies that suggested chronic cerebrospinal vascular insufficiency has an important association with MS have been refuted.

## MULTIPLE SCLEROSIS

Method of

Caitlin Jackson-Tarlton, MD; and B. Mark Keegan, MD

## CURRENT DIAGNOSIS

- Multiple sclerosis (MS) is an autoimmune demyelinating disease of the central nervous system (CNS).
- The McDonald criteria, the most widely used diagnostic criteria, incorporate a patient's symptoms, physical examination, magnetic resonance imaging (MRI) findings, and when applicable, cerebrospinal fluid (CSF) analysis and other ancillary tests.
- The core MS phenotypes are relapsing and progressive MS. Diagnosis of relapsing-remitting multiple sclerosis (RRMS) requires recurrent episodes of acute CNS demyelinating attacks (also referred to as *relapses* or *flares*). Clinically isolated syndrome (CIS), a single demyelinating episode and often first attack of MS, may meet McDonald criteria for RRMS based on MRI and CSF results.
- Primary progressive multiple sclerosis (PPMS) is heralded by progressive neurologic impairment from disease onset in the absence of any preceding attacks. Secondary progressive multiple sclerosis (SPMS) is progressive disease following a history of relapsing MS.
- Radiologically isolated syndrome (RIS) is the presence of CNS demyelinating lesions on MRI in a patient lacking symptoms and physical examination findings typical of demyelination. RIS and CIS not meeting McDonald criteria may later develop into definite MS requiring clinical and radiologic monitoring.

**Figure 1** Magnetic resonance image showing brain T<sub>1</sub> gadolinium-enhancing lesions (A) and T<sub>2</sub> thoracic spine (B) typical of multiple sclerosis.

Pathophysiology likely varies among individual patients with MS. Four distinct pathologies in active demyelinating MS lesions have been described. Pattern 1 displays marked macrophage infiltration without humoral abnormalities. Pattern 2 shows distinct humoral abnormalities with complement activation and immunoglobulin (Ig) deposition. Pattern 3 involves primary oligodendrocyte degeneration and early loss of myelin-associated glycoprotein. Pattern 4 reveals oligodendrocyte dystrophy in periplaque white matter. Early studies suggest that there could be a therapeutic advantage with different therapies for different types of demyelinating disease.

### Prevention

Currently, there is no known way to prevent the development of MS. Patients with a single clinical attack of demyelination and abnormal magnetic resonance imaging (MRI) (“high-risk” clinically isolated syndrome) have a delayed onset to MS diagnosis with immunomodulatory therapy; however, there is no evidence to support that this prevents the eventual development of MS.

### Clinical Manifestations

The clinical course of MS is varied. Approximately 85% of patients present with a relapsing-remitting course. This entails an acute impairment within the CNS, depending on the area of inflammation. A demyelinating cause of a focal neurologic symptom is suggested by an onset over hours to days, with a plateau of impairment over a few weeks. Symptoms then improve either spontaneously or with the use of corticosteroids over a number of days to weeks or longer. Following this, however, symptoms might not completely resolve. Inflammation within the optic nerve (optic neuritis) is heralded by painful, unilateral, central monocular visual deficit (central scotoma). Symptoms of brain stem dysfunction include binocular diplopia, sensory deficits unilaterally on the face and contralaterally on the arm and leg, significant dysarthria, and vertigo. Cerebellar dysfunction is seen with pure ataxia that is typically unilateral. Spinal cord inflammation is indicated by a distinctive, usually gradually rising sensory level of deficit that commonly is accompanied by bowel and bladder impairment and paraparesis or quadriparesis, depending on a thoracic versus cervical level of the lesion.

Progressive forms of MS include secondary progressive multiple sclerosis (SPMS) and primary progressive multiple sclerosis

(PPMS). These are heralded by a slow (months to years) but steady and insidious, progressive neurologic deficit, usually a progressive myelopathy of upper motor neuron gait disorder with spasticity, neurogenic bladder and bowel impairment, and progressive weakness. Occasionally, patients with progressive MS have insidious cerebellar ataxia or dementia in isolation or in association with the myelopathy. SPMS is diagnosed when a patient has had a prior history of at least one clinical attack (relapse) with improvement in the past followed by more than 1 year of progressive neurologic disease. PPMS is diagnosed with progressive CNS disease consistent with MS and typical MRI brain or spinal lesions from onset without any prior relapse, often with cerebrospinal fluid (CSF) or visual evoked potential abnormalities that support the diagnosis.

### Diagnosis

The diagnosis of MS is formalized by the continually revised McDonald criteria. Criteria must only be applied to individuals presenting with a syndrome typical for demyelination, and alternative diagnoses must be considered and excluded. A diagnosis of relapsing-remitting multiple sclerosis (RRMS) entails having two or more clinical attacks (relapses) in the accompaniment of objective clinical evidence of two or more lesions or by evidence of one lesion with additional MRI criteria required. Patients with a single clinical attack, clinically isolated syndrome (CIS), who have two or more MRI lesions with both the presence of MRI gadolinium-enhancing lesions (indicative of acute MS lesions) and non-gadolinium-enhancing lesions (indicative of prior MS lesions) or who have CSF-specific oligoclonal bands are diagnosed with RRMS.

Progressive MS is diagnosed when there is progressive CNS disease characteristic of MS for at least 1 year and abnormal brain or spinal cord MRI findings with or without CSF-specific oligoclonal bands (Figure 1). Occasionally, visual-evoked potentials and somatosensory-evoked potentials are used to further document dissemination of MS within the CNS. Serologic investigations are done primarily to rule out MS mimickers depending on and directed by any accompanying systemic symptoms and the clinical setting in individual patients. These may include autoantibodies (aquaporin-4-IgG and myelin oligodendroglial protein-IgG), antinuclear antibodies (ANA for lupus), erythrocyte sedimentation rate, anti-cardiolipin antibodies, vitamin B<sub>12</sub>, Lyme serology, and chest imaging for CNS sarcoidosis.

## Differential Diagnosis

Other CNS demyelinating diseases can mimic relapsing or progressive MS. Acute disseminated encephalomyelitis (ADEM) is an acute, typically monophasic, and postinfectious CNS inflammatory demyelinating disease. It may be severe; however, if recurrent episodes are separated by at least 3 months, a diagnosis of RRMS is by far more likely.

Neuromyelitis optica is an autoimmune disease with severe acute attacks but is relatively restricted to the optic nerves and spinal cord. Other brainstem and deep cerebral structures, such as the area postrema, cerebral white matter, and hypothalamus, can also be affected by neuromyelitis optica. Brain MRI findings are usually not consistent with MS, at least early on in the disease, and a specific water channel autoantibody (aquaporin-4-IgG) is found in most cases.

Clinical syndromes of CNS demyelination with inflammatory myelopathies, inflammatory optic neuritis, and ADEM with serologic presence of antibodies to myelin oligodendroglial protein (MOG-IgG) are increasingly recognized. Optic neuritis may be further mimicked by acute ischemic optic neuropathy. This condition is typically painless, occurs suddenly, and occurs in patients with advanced age and preexisting vascular risk factors.

Progressive myelopathies that mimic PPMS or SPMS include a compressive myelopathy (e.g., cervical spondylosis, disc disease, or neoplastic infiltration); nutritional deficiencies (e.g., vitamin B<sub>12</sub> or copper deficiency); infectious causes (e.g., HTLV1); genetic causes (e.g., adrenoleukodystrophy); paraneoplastic disease (e.g., CRMP-5 auto-antibodies); or a vascular progressive cause (e.g., dural arteriovenous fistula).

## Treatment

Acute demyelinating MS attacks (relapses) may be treated with high doses of corticosteroids. These may be given orally or intravenously; however, high doses of corticosteroids are necessary and are superior to low doses. For example, a typical regimen is intravenous methylprednisolone (Solu-Medrol) 1000 mg once daily for 3 to 5 days without oral corticosteroid tapering doses. The oral equivalent to this intravenous regimen is prednisone 1000 to 1250 mg orally once daily for 5 days with no oral corticosteroid taper afterward. Gastrointestinal intolerance occurs in some patients, and concomitant use of stomach-protecting agents such as proton pump inhibitors may be recommended. Typical acute corticosteroid side effects include insomnia, irritability, and increased appetite. There are rare but well-known associations with avascular hip necrosis and acute psychosis. Chronic corticosteroid side effects such as diabetes mellitus, cataracts, osteoporosis, adrenal suppression, weight gain, and cushingoid habitus are more associated with chronic corticosteroid use and not short courses of steroids.

Generally, only MS attacks that are associated with functional impairment (vision loss, diplopia, motor weakness, and ataxia) are treated because clinical recovery is hastened, but final clinical recovery is not found to be altered by this therapy. Rarely, patients have very severe acute attacks of MS or other demyelinating disease that does not improve with use of high-dose corticosteroids. In these rare patients, the use of plasma exchange (seven exchanges over approximately 14 days) is recommended. Approximately 45% of patients experience functional recovery within 1 month following plasma exchange. Side effects of plasma exchange therapy include paresthesias related to hypocalcemia, anemia, thrombocytopenia, or complications of central venous access that is required for many patients. Intravenous immunoglobulin (Gammagard)<sup>1</sup> has not yet been shown to improve severe clinical attacks of demyelinating disease.

The goal of chronic immunomodulatory therapy for MS is a reduction in clinical attacks of MS (somewhere between 30% and 60%, depending on the agent) and a reduction in new inflammatory MRI lesions (somewhere between 40% and 90%, depending

on the agent). Patients and healthcare professionals should realize that the medications are specifically for reduction in relapse-related disease and do not provide a cure or any symptomatic benefit.

Chronic parenteral therapy for RRMS includes the use of type 1  $\beta$  interferons (IFN- $\beta$ 1), glatiramer acetate (Copaxone), natalizumab (Tysabri), alemtuzumab (Lemtrada), ocrelizumab (Ocrevus), and ofatumumab (Kesimpta) (Table 1). Alternatively, oral therapies can be used and include teriflunomide (Aubagio), sphingosine-1-phosphate (S1P) receptor modulators, and the fumarates. The S1P receptor modulators include fingolimod (Gilenya), siponimod (Mayzent), ozanimod (Zeposia), and ponesimod (Ponvory). Dimethyl fumarate (Tecfidera) was the first fumarate available. More recently, diroximel fumarate (Vumerity) and monomethyl fumarate (Bafiertam) have been approved. Cladribine (Mavenclad) is an oral medication for treatment-resistant disease as a second-line therapy. The FDA product label for most of these parenteral and oral therapies have recently been updated to specifically include CIS and SPMS with activity (ongoing relapses or new MRI lesions) as approved indications for their use. Cladribine is not recommended for CIS because of its side-effect profile. Ocrelizumab is approved for treatment of all clinical courses of CNS demyelinating disease including CIS, RRMS, SPMS with activity, and PPMS course.

The side-effect profile is well known for traditional injectable agents such as interferons and glatiramer acetate (see Table 1), and they have been safely used for many years. The safety profile for oral therapies seems satisfactory, but their long-term side-effect profile is still being assessed. For fingolimod, first-dose monitoring for 6 hours is required to assess heart rate and rhythm, and occasional patients have developed progressive multifocal leukoencephalopathy (PML). Additional S1P receptor modulators have been developed with similar but distinct receptor binding in an effort to improve the side-effect profile. As a result, siponimod has fewer cardiac side effects requiring first-dose cardiac monitoring only in select circumstances. It does, however, require CYP genotyping before initiation because of genetic differences in drug metabolism. Ponesimod requires first-dose cardiac monitoring in some individuals but does not require genetic testing. Ozanimod does not require genetic screening or cardiac monitoring although there is a theoretical risk of serotonin syndrome and use of monoamine oxidase inhibitors is not recommended.

Teriflunomide may be associated with liver disease and teratogenicity. Dimethyl fumarate is associated with flushing and gastrointestinal discomfort, and rare patients have developed PML when taking this medication. Diroximel fumarate, a structurally similar drug, showed improved gastrointestinal tolerability compared with dimethyl fumarate in a clinical trial. Monomethyl fumarate, the active metabolite of dimethyl fumarate and diroximel fumarate, was not studied in a trial specific to patients with MS but was approved based on mechanism of action and safety data when studied in healthy individuals.

Highly active MS therapy may be indicated with natalizumab, alemtuzumab, or ocrelizumab if first-line medications are intolerable, if therapeutic response is suboptimal (continued MS attacks or marked ongoing and new inflammatory disease on MRI despite therapy), or when a concerning clinical onset (severe attack with multiple lesions and incomplete recovery) occurs.

Natalizumab is clearly associated with the development of PML (progressive multifocal leukoencephalopathy), a severely impairing and often fatal opportunistic brain infection caused by reactivation of the dormant JC virus. In North America, natalizumab is only available through the Tysabri Outreach: Unified Commitment to Health (TOUCH) prescribing program. Risk factors for PML in natalizumab-treated patients include the presence and index value of JC virus serum antibody (JCV-Ab), duration of therapy of at least 2 years, and history of prior immunosuppressive medication therapy (e.g., methotrexate, azathioprine). Seropositivity of MS patients for JC virus antibody is over 55%. Seroconversion rate from JC virus Ab negativity to positivity is approximately 2% to 5% per year, and false-negative results

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Approved Immunomodulatory Therapy for Multiple Sclerosis

MEDICATION	DOSING	SIDE EFFECTS	MONITORING	ADDITIONAL INFORMATION
Interferon $\beta$ 1a (Avonex)	30 $\mu$ g IM injection every week	Flulike symptoms (fever, chills, arthralgias, myalgias, and headaches), elevated LFTs, anemia, leukopenia, thrombocytopenia, depression, localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level at baseline, at 3 months, at 6 months $\times$ 2 years, and then annually Thyroid function cascade on initiation of therapy	Premedication with acetaminophen can ameliorate postinjection flulike symptoms Pregnancy: can continue until the time of conception Compatible with breast-feeding
Interferon $\beta$ 1a (Rebif)	22- $\mu$ g or 44- $\mu$ g SC injection three times per week	Flulike symptoms (fever, chills, arthralgias, myalgias, headaches), elevated LFTs, anemia, leukopenia, thrombocytopenia, depression, localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level at baseline, at 3 months, at 6 months $\times$ 2 years, and then annually Thyroid function cascade on initiation of therapy	Premedication with acetaminophen can ameliorate postinjection flulike symptoms Pregnancy: can continue until the time of conception Compatible with breast-feeding
Peginterferon $\beta$ 1a (Plegridy)	125 $\mu$ g SC every 2 weeks	Flulike symptoms (fever, chills, arthralgias, myalgias, headaches), elevated LFTs, anemia, leukopenia, thrombocytopenia, depression, localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level at baseline, at 3 months, at 6 months $\times$ 2 years, and then annually Thyroid function cascade on initiation of therapy	Premedication with acetaminophen may ameliorate postinjection flulike symptoms Pregnancy: can continue until the time of conception Compatible with breast-feeding
Interferon $\beta$ 1b (Betaseron, Extavia)	250- $\mu$ g SC injection every other day	Flulike symptoms (fever, chills, arthralgias, myalgias, headaches), elevated LFTs, anemia, leukopenia, thrombocytopenia, depression, localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level at baseline, at 3 months, at 6 months $\times$ 2 years, and then annually Thyroid function cascade on initiation of therapy	Premedication with acetaminophen can ameliorate postinjection flulike symptoms Pregnancy: can continue until the time of conception Compatible with breast-feeding
Glatiramer acetate (Copaxone)	20-mg SC injection daily or 40-mg SC injection three times per week	Injection-site reactions (erythema, edema, pruritus, pain), transient chest pain, palpitations, facial flushing, anxiety, shortness of breath	None	Pregnancy: can continue until the time of conception, or in select circumstances may continue during pregnancy Compatible with breast-feeding
Fingolimod hydrochloride (Gilenya)	0.5 mg PO once daily	Headache, flulike symptoms, diarrhea, back pain, liver enzyme elevations, cough, hypertension, macular edema, and infections (disseminated varicella and herpes, rare cases of PML, opportunistic bacterial and fungal infections), increased risk of skin cancer; may cause a decrease in pulmonary function New FDA labeling required, investigating unexplained deaths occurring during treatment with fingolimod	CBC with differential, AST, ALT, and bilirubin at baseline and periodically thereafter Serology for VZV-IgG to determine immunity; if negative, vaccinate; if live attenuated vaccine, give at least 4 weeks before initiation Latent infection screening (HIV, hepatitis, TB) in those at high risk Fundus examination at baseline and in 3 to 4 months for macular edema, repeated annually in those with diabetes mellitus or uveitis or if visual symptoms develop ECG, HR, and BP before first dose; first dose must be monitored for 6 hours for HR reduction and BP changes; 6-hour monitoring following oral dose must be repeated for patients who discontinue therapy for $\geq$ 2 weeks Periodic skin examinations	Should not be used in patients with recent MI, unstable angina, stroke, TIA, second- or third-degree AV block, CHF, SSS without cardiac pacing, or QTc $>$ 500 ms, or with class Ia or III antiarrhythmic drugs Overnight continuous ECG monitoring recommended for those with preexisting cardiac or cerebrovascular disease; recurrent syncope; severe, untreated OSA; use of $\beta$ blockers; or prolonged QTc Pregnancy: discontinue 3 months before conception Caution for redemonstration of severe inflammatory disease on discontinuation Not compatible with breast-feeding

Siponimod (Mayzent)	Requires oral titration; the recommended maintenance dosage for most is 2 mg PO once daily The recommended maintenance dosage in patients with a CYP2C9*1/*3 or CYP2C9*2/*3 genotype is 1 mg PO once daily Contraindicated in CYP2C9*3/*3 genotype	Herpes infection, upper respiratory infection, fungal skin infection, hypertension, macular edema; may cause a decrease in pulmonary function	CYP2C9 genotype determination CBC with differential, AST, ALT, and bilirubin at baseline and then periodically Serology for VZV-IgG to determine immunity; if negative, vaccinate; if live attenuated vaccine, give at least 4 weeks before initiation Latent infection screening (HIV, hepatitis, TB) in those at high risk Fundus evaluation (OCT) at baseline and then annually for those with diabetes and uveitis or if visual symptoms develop Recent ECG (within past 6 months) and baseline BP	Concomitant use of moderate or strong CYP3A4 inducers (e.g., modafinil, efavirenz [Sustiva]) is not recommended for patients with CYP2C9*1/*3 and CYP2C9*2/*3 genotype Should not be used in patients with MI, unstable angina, stroke, TIA, or class III/IV CHF in the past 6 months or in patients with second- or third-degree AV block or in those with SSS unless the patient has a pacemaker First-dose monitoring is recommended for patients with certain preexisting cardiac conditions; initial monitoring procedures must be repeated for interruption of treatment of $\geq 4$ consecutive doses Pregnancy: discontinue 3 months before conception Unknown if rebound disease occurs with discontinuation, as seen in fingolimod Not compatible with breast-feeding
Ponesimod (Ponvory)	Requires oral titration; maintenance dose is 20 mg PO once daily	Herpes infection, upper respiratory infection, fungal skin infection, hypertension, macular edema, increased rate of cutaneous malignancies; may cause a decrease in pulmonary function	CBC with differential, AST, ALT, and bilirubin at baseline and then periodically Serology for VZV-IgG to determine immunity; if negative, vaccinate; if live attenuated vaccine, give at least 4 weeks before initiation Latent infection screening (HIV, hepatitis, TB) in those at high risk Fundus evaluation (OCT) at baseline and then annually for those with diabetes and uveitis or if visual symptoms develop Recent ECG (i.e., within past 6 months) and baseline BP Periodic skin examinations	Should not be used in patients with MI, unstable angina, stroke, TIA, or class III/IV CHF in the past 6 months or in patients with second- or third-degree AV block or those with SSS unless the patient has a pacemaker First-dose monitoring is recommended for patients with certain preexisting cardiac conditions; initial monitoring procedures must be repeated for interruption of treatment of $\geq 4$ consecutive doses Pregnancy: discontinue 3 months before conception Unknown if rebound disease occurs with discontinuation, as seen in fingolimod Not compatible with breast-feeding
Ozanimod (Zeposia)	Requires oral titration; maintenance dose is 0.92 mg PO once daily	Herpes infection, upper respiratory infection, fungal skin infection, hypertension, macular edema; may cause a decrease in pulmonary function	CBC with differential, AST, ALT, and bilirubin at baseline and periodically thereafter Serology for VZV-IgG to determine immunity; if negative, vaccinate; if live attenuated vaccine, give at least 4 weeks before initiation Latent infection screening (HIV, hepatitis, TB) in those at high risk Fundus evaluation (OCT) at baseline and then annually for those with diabetes and uveitis or if visual symptoms develop Recent ECG (within past 6 months) and baseline BP	Should not be used in patients with MI, unstable angina, stroke, TIA, or class III/IV CHF in the past 6 months or in patients with second- or third-degree AV block or those with SSS unless the patient has a pacemaker Do not use in severe untreated OSA or with concomitant use of an MAOI Cardiac monitoring and genetic testing not needed Pregnancy: discontinue 3 months before conception Unknown if rebound disease occurs with discontinuation, as seen in fingolimod Not compatible with breast-feeding
Teriflunomide (Aubagio)	7 mg or 14 mg PO once daily	Diarrhea, abnormal LFTs, nausea, alopecia, hepatotoxicity, may cause significant birth defects if used during pregnancy, hypertension, TB reactivation, peripheral neuropathy, can worsen psoriasis, hypophosphatemia, transient acute renal failure, hyperkalemia	CBC at baseline, 6 months, and then annually AST, ALP, and bilirubin monthly for 6 months and then annually Latent infection screening (HIV and hepatitis) in those at high risk Tuberculin skin test and pregnancy test (women of childbearing potential) at baseline BP at baseline and then periodically	Do not use in severe hepatotoxicity, pregnancy, or with concomitant leflunomide use Prolonged half-life: recommend removal by activated charcoal or cholestyramine when required Pregnancy: teratogenic, accelerated washout recommended before conception (including if fathering a child), or if unexpectedly pregnant while on the medication Not compatible with breast-feeding

Continued

**TABLE 1** Approved Immunomodulatory Therapy for Multiple Sclerosis—cont'd

Dimethyl fumarate (Tecfidera)	120 mg PO twice daily for 1 week, then 240 mg PO twice daily	Flushing, abdominal pain, nausea, diarrhea, infection (rare cases of PML, disseminated herpes), lymphopenia, hepatotoxicity	CBC with differential at baseline and then every 6 to 12 months; if lymphopenia occurs, monitor more frequently; may need to discontinue AST, ALT, ALP, and bilirubin at baseline Latent infection screening (HIV, hepatitis, TB) in those at high risk	Discontinue in sustained lymphopenia ( $<0.5 \times 10^9/L$ ) as increases risk of infections including PML or LFT elevation ( $>20\times$ upper limit of normal or jaundice) Pregnancy: can continue until the time of conception Not compatible with breast-feeding
Monomethyl fumarate (Bafiertam)	95 mg PO twice daily for 1 week, then increase to 190 mg PO twice daily	Flushing, infection, lymphopenia, abdominal symptoms but generally less than dimethyl fumarate, hepatotoxicity	CBC with differential at baseline, at 6 months, and then annually AST, ALT, ALP, and bilirubin at baseline Latent infection screening (HIV, hepatitis, TB) in those at high risk	Pregnancy: can continue until the time of conception Not compatible with breast-feeding
Diroximel fumarate (Vumerity)	231 mg PO twice daily for 1 week, then increase to 462 mg PO twice daily	Flushing, infection, lymphopenia, abdominal symptoms but generally less than dimethyl fumarate	CBC with differential at baseline, at 6 months, and then every 6 to 12 months AST, ALT, ALP, and bilirubin at baseline Latent infection screening (HIV, hepatitis, TB) in those at high risk	Improved gastrointestinal intolerance Pregnancy: can continue until the time of conception Not compatible with breast-feeding
Ocrelizumab (Ocrevus)	300 mg IV once followed by a 300-mg dose 2 weeks later, then 600 mg IV every 24 weeks	Infusion reactions (~34%), respiratory tract infections, herpes infections, neutropenia, reduced immunoglobulins Possible increased risk of cancer including breast cancer; follow standard cancer screening	Rule out active hepatitis and latent TB before first dose; consult liver specialist if history of hepatitis before first dose Immunoglobulins at baseline and then annually	Do not administer if signs of infection; delay until infection resolves. If IgG $<150$ mg/dL or 150 to 500 mg/dL with recurrent infections, consider IVIg replacement Administer vaccines $>6$ weeks before ocrelizumab infusions; live and live-attenuated vaccines not recommended until B-cell counts recover after discontinuation Pregnancy: washout per drug label is 6 months preconception, but based on pharmacokinetics, many MS experts allow conception 1 to 2 months after last dose Enters breastmilk but in very low levels; can consider continuing given low risk to the infant
Ofatumumab (Kesimpta)	Initial dosing: 20 mg SC injection at weeks 0, 1, and 2 Subsequent dosing: 20 mg SC injection every 4 weeks starting at week 4	Injection reactions most common within 24 hours of the first injection Respiratory tract infections, herpes infections, neutropenia, reduced immunoglobulins	Rule out active hepatitis and latent TB before first dose Immunoglobulins at baseline and then annually	Do not administer if signs of infection; delay until infection resolves. If IgG $<150$ mg/dL or 150 to 500 mg/dL with recurrent infections, consider IVIg replacement Administer live and live-attenuated vaccines $>4$ weeks and inactivated vaccines $>2$ weeks before initiation; live and live-attenuated vaccines not recommended until B-cell counts recover after discontinuation Pregnancy: washout per drug label is 6 months preconception Unknown if it enters breastmilk; consider on an individualized basis

Natalizumab (Tysabri)	300 mg IV once every 4 weeks	Urticaria and anaphylaxis, headache, arthralgias, nausea, depression, infections (urinary tract, pneumonia, herpes simplex or reactivation) Rare hypersensitivity reactions can occur and are often associated with antibodies against natalizumab; if occurs, DMT switch is required	Baseline JCV Ab serologic study every 6 months while JCV negative; if JCV seropositive, consider another DMT If conversion occurs while on drug, strong consideration should be given to switching DMT with interim close monitoring; extended dosing interval of 6 to 8 weeks can be considered, but long-term a switch is recommended If PML is suspected, discontinue immediately, PLEX to remove the drug, MRI head with and without gadolinium with diffusion-weighted imaging; CSF for JCV PCR	Risk of PML may be greater in patients with prolonged therapy and those previously treated with immunosuppressive medications; prescribing professional requires TOUCH enrollment Pregnancy: washout per drug label is 3 months, but in select circumstances can be continued until week 30 to 32 (resume shortly after delivery), often with extended interval dosing, and with hematologic monitoring of the newborn Caution for redemonstration of severe inflammatory disease on discontinuation Enters breastmilk but in very low levels; can consider continuing given low risk to the infant
Alemtuzumab (Lemtrada)	IV infusion over 4 h x two treatment courses First course: 12 mg/day on 5 consecutive days Second course: 12 mg/day on 3 consecutive days 12 months after the first treatment course	Infusion reactions with anaphylaxis; rarely MI, stroke, cervicocephalic artery dissections Autoimmune thyroid disorders, immune thrombocytopenia, antiglomerular basement membrane disease Malignancies including thyroid cancer, melanoma, lymphoproliferative disorders Opportunistic infections (PML, herpes, varicella, and other viral, bacterial, and fungal infections)	CBC with differential; serum creatinine; urinalysis with urine cell counts at baseline, then monthly; and TSH at baseline and then every 3 months until 48 months after last dose ALT, AST, bilirubin at baseline and then periodically until 48 months after last dose Serology for VZV-IgG to determine immunity; if negative, vaccinate; if live attenuated vaccine, give at least 6 weeks before initiation Ensure no infections (HIV, hepatitis, TB) before treatment Baseline and yearly skin and cervical examinations	Contraindicated if HIV positive Premedicate with high-dose corticosteroids, and give herpetic prophylaxis at time of first dose, continuing for at least 2 months or until CD4+ lymphocyte count is >200 cells/ $\mu$ L, whichever occurs later Complete all necessary immunizations at least 6 weeks before initiation No live-virus vaccines after a course of alemtuzumab Pregnancy: conception can occur 4 months after last dose Not compatible with breast-feeding
Cladribine (Mavenclad)	Two treatment courses (1.75 mg/kg per treatment course); one course per year for a total of 2 years Treatment course is divided into 2 treatment weeks separated by 4 weeks: each treatment week consists of 4 to 5 days on which a patient receives a single daily dose (dose depending on body weight)	Anemia, thrombocytopenia, lymphopenia, upper respiratory tract infection, headache, hypersensitivity reaction, may increase risk of malignancies	CBC 2 and 6 months after the start of each treatment course and then annually thereafter Ensure no infections (HIV, hepatitis, TB) before treatment Serology for VZV-IgG to determine immunity; if negative, vaccinate, if live attenuated vaccine, give at least 4 to 6 weeks before initiation If lymphocyte count at month 2 is <200 cells/mL, hold cladribine, monitor monthly until month 6, and then administer herpes prophylaxis Follow standard cancer screening guidelines	Contraindicated in infections (HIV, active hepatitis, TB), current malignancy, pregnant women, and women and men of reproductive potential who do not plan to use contraception during dosing and for 6 months after the last dose in each treatment course Administer live-attenuated or live vaccines at least 4 to 6 weeks before starting; avoid vaccination with live-attenuated or live vaccines during and after treatment Pregnancy: teratogenic, contraception can occur 6 months after treatment Breast-feeding can be considered 10 days after treatment

Ab, Antibody; ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; AV, atrioventricular; BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood count; CHF, congestive heart failure; CSF, cerebrospinal fluid; DMT, disease modifying therapy; ECG, electrocardiogram; FDA, U.S. Food and Drug Administration; HR, heart rate; HIV, human immunodeficiency virus; IgG, immunoglobulin G; IV, intravenous; IVIg, intravenous immunoglobulin G; JCV, JC virus; LFTs, liver function tests; MI, myocardial infarction; MAOI, monoamine oxidase inhibitor; MRI, magnetic resonance imaging; OCT, optical coherence tomography; OSA, obstructive sleep apnea; PCR, polymerase chain reaction; PLEX, plasma exchange; PML, progressive multifocal leukoencephalopathy; PO, by mouth; PPD, purified protein derivative; SC, subcutaneously; SPMS, secondary progressive multiple sclerosis; SSS, sick sinus syndrome; TB, tuberculosis; TIA, transient ischemic attack; TOUCH, Tysabri Outreach: Unified Commitment to Health; TSH, thyroid-stimulating hormone; VZV-IgG, varicella zoster virus immunoglobulin G.

are rare (less than 3%). Currently, no cases of PML have been found in patients persistently seronegative for JCV antibodies. Risk prevalence estimation after 2 years of treatment in JCV Ab-positive patients ranges from 1:250 for those without a history of immunosuppression to 1:90 in those with a history of prior immunosuppressive therapy. Evidence is emerging for extending the dosing interval to every 6 to 8 weeks in select individuals as a strategy to lower the risk of PML but maintain drug efficacy.

Ocrelizumab (anti-CD20 B cells; humanized form), an every-6-month infusion, is approved for relapsing MS and is the only therapy approved for PPMS. Initial clinical trials of ocrelizumab showed an increased rate of breast cancer in patients treated with ocrelizumab compared with those on placebo or interferons. As such, the FDA-approval label recommends advising patients regarding a potential increased malignancy rate and that patients follow standard breast cancer screening guidelines. More recently, long-term follow-up safety data from several clinical trials, including open-label extension periods, were published and showed no increased risk of malignancy, including breast cancer, compared with matched reference MS and general populations. Ofatumumab is another anti-CD20 B-cell-depleting monoclonal antibody that has a similar risk profile to ocrelizumab but is given monthly through an autoinjector. Alemtuzumab is a monoclonal antibody (anti-CD52; T and B cells) for RRMS with major safety precautions that include development of autoimmune thyroid disease, immune thrombocytopenia, and rarely antiglomerular basement membrane disease.

Mitoxantrone is a chemotherapy agent that is approved for SPMS, but given its severe side-effect profile (acute and delayed cardiotoxicity, acute myelogenous leukemia), it is rarely used today. Daclizumab (Zinbryta) (anti-CD25, IL-2 receptor) was withdrawn voluntarily because of case reports of an association with presumably immune-mediated encephalitis.

Available, although limited, evidence suggests that autologous bone marrow transplantation with stem cell delivery is a promising therapy for select patients with MS. It appears that individuals most likely to benefit are young, are ambulatory, have recent disease onset, and have ongoing disease activity despite having tried first- and second-line agents. Risks are “front-loaded” and include the adverse effects resulting from cytotoxic agents (nausea, mucositis, and alopecia) and myelosuppression (infection and hemorrhage). Late toxicity includes engraftment syndrome, infertility, infection, myelodysplastic syndromes, and secondary autoimmune disorders. Several large randomized controlled trials are ongoing to supplement existing evidence.

The mechanism of action of most DMTs is to modulate the immune system. This can have important implications on timing of vaccine delivery (see Table 1) and vaccine response. Immunization status should be discussed early, and generally patients should be encouraged to update their vaccines as per public health guidelines. Administration of non-live vaccines is considered safe in patients with MS including those taking a DMT, although response may be diminished with specific DMTs such as anti-CD20 B-cell-depleting agents. If a patient is experiencing an acute MS relapse, vaccination should be deferred until after symptoms resolve or plateau. If a patient has recently received a course of steroids, it is recommended to wait 6 weeks before vaccinating if possible. The inactivated seasonal influenza vaccine and non-live coronavirus 2019 (COVID-19) vaccines are recommended in all patients with MS. Guidelines regarding the number and timing of COVID-19 vaccinations are continuously changing as the understanding and epidemiology of COVID-19 evolves. Currently, consideration should be given to vaccination against COVID-19 before initiation of anti-CD20 B-cell-depleting agents and S1P receptor modulators as both have been shown to impair vaccine response. The Centers for Disease Control and Prevention (CDC) recently recommended Shingrix, a recombinant non-live vaccine against herpes zoster, to immunocompromised individuals older than 18 years of age, such as those with MS on immunosuppressing DMTs. Live and live-attenuated vaccines should be avoided in persons with MS if possible. When needed, administration should be done before initiation of DMT, with

timing dependent on the specific agent used (see Table 1). For instance, immunity against varicella zoster should be confirmed before initiating an S1P receptor modulator given reports of disseminated varicella on fingolimod. This requires a live vaccination series to be completed at least 1 month before beginning the S1P modulator to allow time for the vaccine to take effect.

### Monitoring

Most, if not all, MS patients should be followed by a neurologist at least occasionally. Recommendations for clinical assessment range from 6 to 18 months, depending on clinical activity of relapses and disability. The ideal scheduling of repeat brain MRI scans is controversial and varies depending on MS clinical activity and whether medications are initiated, changed, or discontinued, but general recommendations are every 1 to 2 years.

### Complications

MS is one of the main causes for impairment at a young age and trails only acute trauma. Often patients need gait assistance when impairment becomes more severe. This includes the use of a single gait aid, such as a cane or walking stick, or an ankle-foot orthosis for symptomatic foot drop. Dalfampridine (Ampyra) is a potassium channel blocker that has been shown to improve walking speed. Contraindications include a history of seizures and moderate to severe renal impairment.

Spasticity associated with upper motor neuron weakness in the lower extremities may be treated with an active daily exercise program directed by physical therapists and physiatrists. Judicious use of baclofen (Lioresal) is helpful (starting at 5 mg three times daily by mouth, with no more than a maximum of 80 mg per day). Baclofen side effects include drowsiness and liver enzyme elevations. Some patients with significant lower extremity weakness are assisted in their gait by the leg support provided by spasticity, and if spasticity is reduced pharmacologically, this can in fact worsen their gait. Alternatives to baclofen include tizanidine (Zanaflex) and clonidine (Catapres). For focal spasticity, botulinum toxin (Botox) injection can be used. Gabapentin (Neurontin)<sup>1</sup> can be helpful as an adjuvant therapy, particularly in those with neuropathic pain or for monotherapy in those who failed baclofen and/or tizanidine. Oral cannabinoids<sup>1</sup> have favorable evidence for patient-reported symptoms of spasticity, spasms, and central pain. Benzodiazepines have antispasticity properties but are not typically first line because of side effects and potential for dependency. Dantrolene (Dantrium) has been shown to be effective but is rarely used because of hepatotoxicity.

Patients often experience symptoms of neurogenic bladder dysfunction. This includes symptoms of urgency and urge-related incontinence. Bladder stimulants such as caffeine must be avoided. Patients with this symptom should be investigated for completeness of bladder emptying. If there is severe impairment in bladder emptying, urinary catheterization often is recommended. If bladder emptying is complete or only mildly impaired (<100 mL postvoid residual), use of medications such as oxybutynin (Ditropan) or tolterodine (Detrol) may be recommended for urge-related symptoms. These anticholinergic medications can cause confusion and should be used with caution in older adults or those with cognitive dysfunction. Mirabegron (Myrbetriq) may be preferable in such situations as it selectively acts as a beta-3 adrenergic receptor agonist to relax the detrusor smooth muscle. Regardless of drug choice, ongoing monitoring of bladder emptying is recommended. Some patients require formal urodynamic evaluation for complex bladder symptoms.

Constipation is a common symptom that may exacerbate neurogenic bladder symptoms. Treatment includes physical exercise, dietary fiber supplementation, and hydration. Stool softeners, pro-motility agents, bulking agents, or enemas may be required. Sexual dysfunction can occur in men and women including reduced libido either with or without difficulty achieving erection and/or orgasm.

<sup>1</sup>Not FDA approved for this indication.

Management may include nonpharmacologic and pharmacologic strategies similar to those used in non-MS-related sexual dysfunction.

Fatigue is a common MS-related symptom. A complete sleep history to ensure appropriate sleep hygiene is imperative. This includes initiating sleep promptly, maintaining sleep throughout the night, and awakening feeling refreshed. Encouragement of a formal exercise program to facilitate restful sleep and daytime vigor is important. Obstructive sleep apnea, restless leg syndrome, and other parasomnias must be ruled out as additional contributing factors to fatigue. If sleep hygiene is entirely normal and late afternoon fatigue remains a problem, pharmacologic therapy for MS-related fatigue can proceed. Medications that can be considered for debilitating MS fatigue that does not respond to nonpharmacologic management include amantadine hydrochloride (Symmetrel),<sup>1</sup> modafinil (Provigil),<sup>1</sup> armodafinil (Nuvigil),<sup>1</sup> amphetamines (including methylphenidate [Ritalin]<sup>1</sup>), and fluoxetine (Prozac).<sup>1</sup> None of these medications have FDA approval specific to MS fatigue. The benefit of these medications remains unproven, and their use is often limited by their side-effect profile.

Neuropathic pain and other uncomfortable sensations can occur in MS. Neuropathic pain agents such as gabapentin (Neurontin),<sup>1</sup> pregabalin (Lyrica),<sup>1</sup> duloxetine (Cymbalta),<sup>1</sup> and tricyclic antidepressants (TCAs) are frequently used. Paroxysmal attacks of sensory (Lhermitte phenomenon and trigeminal neuralgia) and motor (painful tonic spasms) symptoms can cause discomfort and interfere with function. Both sensory and motor symptoms are typically very sensitive to low-dose carbamazepine (Tegretol).<sup>1</sup>

Mood disorders such as anxiety and depression are prevalent in MS. Treatment includes nonpharmacologic management such as cognitive-behavioral therapy, and medications may be warranted in some patients. Pseudobulbar affect, uncontrollable episodes of laughter or crying, may occur. If this symptom is bothersome to the patient, dextromethorphan/quinidine (Nuedexta) is approved for this indication. Selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and TCAs have been used off-label for pseudobulbar affect.

MS is a common CNS inflammatory demyelinating disease with heterogenous presentation and prognosis. CIS, RRMS, and active SPMS are treated with corticosteroids to hasten resolution of acute relapses and chronic immunomodulatory medications to reduce the number of future clinical attacks and new MRI lesions. Ocrelizumab is the only medication approved for PPMS. Symptomatic care is important in these patients, including the treatment of gait disorder, spasticity, neurogenic sphincter dysfunction, fatigue, paroxysmal symptoms, neuropathic pain, and mood disorders.

<sup>1</sup>Not FDA approved for this indication.

## MYASTHENIA GRAVIS

Method of

Taylor B. Harrison, MD; and William P. Roche, MD

### CURRENT DIAGNOSIS

- Myasthenia gravis (MG) is an autoimmune disorder that affects the neuromuscular junction, resulting in fatigable skeletal muscle weakness.
- Diagnosis may be based on clinical history and exam in combination with identification of autoantibodies (Ach-R Abs) or abnormalities on electrodiagnostic testing.
- Myasthenic crisis, defined by respiratory failure, can stem from respiratory or oropharyngeal weakness. It may develop abruptly and typically occurs in the setting of illness, change in medications, or early in the disease course.

### CURRENT THERAPY

- Mild symptoms can respond well to anticholinesterase inhibitors such as pyridostigmine (Mestinon).
- A wide range of medications may be used to treat MG, including steroids, nonsteroidal immunosuppressants, as well as intravenous immunoglobulin<sup>1</sup> and plasmapheresis. Thymectomy may be considered in patients with acetylcholine receptor antibodies.
- It is important to recognize that certain medications may worsen MG.
- Myasthenic crisis is a medical emergency, and patients should be treated in the intensive care unit with close respiratory monitoring and possibly intubation. Intravenous immunoglobulin<sup>1</sup> and plasmapheresis are treatment options for myasthenic crisis.

<sup>1</sup>Not FDA approved for this indication.

## Epidemiology

Myasthenia gravis (MG) is the most common acquired disorder of neuromuscular transmission, with an incidence of 8 to 10 per million annually. The prevalence is 150 to 250 per million, reflecting the disease's low mortality rate. An estimated 700,000 people are living with MG worldwide, with between 36,000 to 60,000 living in the United States.

There exists a bimodal age distribution with two peaks of incidence: the first peak in the second to third decades of life, and a second peak in the seventh to eighth decades. Women predominate in early-onset MG (defined by onset <50 years of age) whereas men predominate with late-onset disease (>50 years of age).

## Risk Factors

MG is associated with thymoma: approximately one-third of patients with thymoma will develop myasthenia, and 10% of myasthenic patients have a thymoma. Certain HLA subtypes, which are known to predispose to autoimmune disorders in general, also increase the risk of MG. Other autoimmune disorders are present in about 15% of myasthenic patients, most commonly thyroiditis, followed by systemic lupus erythematosus and rheumatoid arthritis. A small percentage of patients may have a myasthenia-myositis overlap syndrome (Tables 1 and 2).

## Pathophysiology

To understand the pathophysiology, a review of normal physiology is needed. In normal muscle contraction, an action potential (AP) travels down a motor nerve to the presynaptic axon

**TABLE 1** Medications That May Exacerbate or Precipitate MG

Black box warnings:
Telithromycin (Ketek) <sup>2</sup>
Fluoroquinolones (ciprofloxacin [Cipro], moxifloxacin [Avelox], levofloxacin [Levaquin])
Drugs to avoid:
D-penicillamine (Cuprimine)
Checkpoint inhibitors (ipilimumab [Yervoy], pembrolizumab [Keytruda], nivolumab [Opdivo])
Quinine
IV Magnesium
Use only with caution:
Macrolidess (erythromycin, azithromycin [Zithromax], clarithromycin [Biaxin])
Aminoglycosides (gentamycin [Garamycin], neomycin, tobramycin)
Procainamide (Pronestyl)
Desferrioxamine (Desferal)
Beta blockers (propranolol, metoprolol [Lopressor], carvedilol [Coreg])
Statins (atorvastatin [Lipitor], pravastatin [Pravachol], rosuvastatin [Crestor], simvastatin [Zocor])

<sup>2</sup>Not available in the United States.

**TABLE 2** Suggested Medication Monitoring

MEDICATION	SUGGESTED MONITORING
Azathioprine (Imuran)	CBC, LFTs weekly for the first month then monthly to every 3 months
Cyclosporine (Sandimmune)	Monthly CBC, LFTs, renal function monthly for 3 months then quarterly Periodic trough level Blood pressure checks
Cyclophosphamide (Cytoxan)	CBC (attention to neutrophil count), electrolytes and renal function, LFTs, UA every 2–4 weeks
Eculizumab (Soliris)	CBC, renal function, LFTs
IVIg (Gammagard)	Renal function monthly, with repeated dosing maybe every 3 months
Methotrexate (Trexall)	CBC, LFTs monthly initially, then at stable dose at least every 3 months
Mycophenolate mofetil	CBC every 2 weeks for first month, then monthly to quarterly
Plasma exchange	Blood pressure and serum calcium
Prednisone	Weight and blood pressure Periodic potassium and HgbA1c Bone density test Periodic eye exam
Rituximab (Rituxan)	CD 20 counts may be considered but varies among providers
Efgartigimod (Vyvgart)	Evaluate the need to administer age-appropriate immunizations (live attenuated or live vaccines) according to immunization guidelines before initiation of a new treatment cycle

CBC, Complete blood count.

terminal. At the axon terminal, the AP triggers voltage-gated calcium channels to open, causing calcium influx. Calcium influx causes synaptic vesicles containing acetylcholine to fuse with the cell membrane, resulting in exocytosis of acetylcholine into the synaptic cleft. Acetylcholine diffuses across the synaptic cleft and binds with nicotinic acetylcholine receptors (AChRs) on the cell membrane of the muscle fiber. The AChRs are ligand-gated ion channels that, once opened, allow cation influx, generating an end plate potential (EPP). When the EPP reaches a threshold value, it triggers voltage-gated sodium channels in the postsynaptic membrane to open, resulting in further cation influx and membrane depolarization, resulting in a muscle fiber AP and muscle fiber contraction. Excess acetylcholine is then broken down by the enzyme acetylcholinesterase (AChE) in the synaptic cleft.

The safety factor is an important concept in understanding the muscle fatigability of MG. The safety factor is the ratio of postsynaptic EPP generated by a quantity of acetylcholine to the threshold required to generate an all-or-none muscle fiber AP and thus muscle fiber contraction. In the healthy state, more acetylcholine is released than is needed to generate a muscle fiber AP. In myasthenia the safety factor is lower, and sufficient acetylcholine may not be released to generate successive APs with repeated contractions. Exercise will result in insufficient neuromuscular transmission over time because of this reduction in safety factor, and as muscle fibers fail to reach threshold to generate an AP, fatigable weakness ensues.

MG is caused by antibodies targeting antigens of the postsynaptic membrane of the neuromuscular junction. In myasthenia gravis, the normal action of acetylcholine at the postsynaptic muscle cell membrane is disrupted by one of several antibody-mediated mechanisms. Most commonly, antibodies are formed against the AChR itself. These AChR antibodies interrupt normal transmission by cross-linking the receptors causing increased turnover or complement-mediated degradation or by inducing conformational changes in the channel, keeping acetylcholine from activating the channel. Other antibodies have been found to cause MG, including antibodies against muscle-specific kinase (MUSK), lipoprotein-related protein 4 (LRP4), or agrin. The postsynaptic cell membrane is folded into secondary synaptic folds, increasing the surface area of the cell membrane, and AChRs are organized in clusters at the peaks of these folds (adjacent to the nerve axon terminal). MUSK, LRP4, and agrin are proteins that participate in AChR clustering on these peaks. Antibody-mediated disruption of the function of these proteins causes reduced AChR concentration on the postsynaptic membrane with reduced safety factor, resulting in a myasthenia phenotype.

Some patients do not have antibodies that are detectable by current serologic testing. These patients are presumed to have antibodies against components of the postsynaptic membrane that have not yet been identified.

### Prevention

Although there is no recognized prevention for developing myasthenia, exacerbations (myasthenic crises) are preventable by avoiding certain drugs. In particular, beta blockers, some antibiotics (aminoglycosides, fluoroquinolones, and macrolides), and chelating agents (penicillamine [Cuprimine]) should be avoided in myasthenic patients (see Box 1). Statins should be used cautiously and only at the lowest effective dose.

### Clinical Manifestations

Patients with MG will present with weakness of the extraocular, bulbar, axial, or limb muscles. The most characteristic feature of the weakness seen in myasthenia is fatigability; that is, the tendency of a muscle to get weaker with repeated use. Thus, when thinking about weakness from MG, it is important to get a sense of whether the patient's symptoms are exacerbated by exercise, or demonstrate a diurnal fluctuation (with the most typical pattern being weakness that is worse at the end of the day).

Ocular symptoms (ptosis and diplopia) are the first symptoms of myasthenia in approximately 60% of patients, and in 15%

to 20% of all myasthenic patients, weakness remains limited to the eye muscles (so-called “ocular myasthenia”). Patients will complain of a drooping eyelid or binocular double vision (that improves with closing one eye) that frequently fluctuates throughout the day or with activity. On physical examination, these patients have ptosis or limitations in extraocular movements that are triggered or exaggerated by sustained upgaze for 60 seconds (so-called “upgaze paresis”). The extraocular manifestations are rarely symmetric, and the ptosis is very often more significant on one side.

Weakness of the limbs tends to be symmetric and usually affects proximal more than distal muscles. Patients will frequently complain of reduced ability to perform repetitive actions of the proximal muscles, such as lifting an arm to comb hair or climbing stairs. On physical examination, fatigability can be demonstrated by having the patient activate the deltoids (arm abduction) or iliopsoas (hip flexion) either against gravity for 2 minutes or against examiner resistance for 5 repetitions of 5 seconds each. Typically, myasthenic patients with weakness of these muscle groups will have a significant decrement in strength between the first repetition and the last. Similar maneuvers can be performed using whichever muscle groups are affected, according to the patient’s complaints.

Bulbar weakness manifests as difficulty with speech (dysarthria) or swallowing (dysphagia). These symptoms may also be fatigable; for example, patients may notice more difficulty enunciating toward the end of the day or at the end of a speech, or more trouble swallowing toward the end of a meal or when eating chewy foods such as steak. If shortness of breath is present, it typically improves moving from a supine to sitting position, which helps with diaphragm excursion. Strength of sniff and cough can be easily assessed at the bedside, and weakness of neck flexion may indicate risk for diaphragmatic weakness.

Sensation is not affected in MG. If a patient has sensory loss, static weakness that does not fluctuate with exercise, or other neurologic symptoms aside from weakness, this should prompt the examiner to consider an alternate diagnosis. Deep tendon reflexes are normal in myasthenia gravis.

## Diagnosis

It is important to understand the proper diagnostic algorithm for MG, which is based on the combination of clinical history, examination findings, presence of autoantibodies, and results of electrodiagnostic testing. In the setting of a good clinical history and positive examination findings, the presence of pathologic autoantibodies is likely sufficient to confirm the diagnosis. When the clinical history or examination is suggestive but autoantibodies are not present, electrodiagnostic testing is important to confirm a suspected diagnosis, particularly if immunosuppressive or interventional therapies are considered.

Bedside tests to support a diagnosis include the ice pack test and edrophonium. Placement of ice over a ptotic eyelid may lead to clinical improvement, as cool temperature slows down the breakdown of Ach in the synapse due to slowed action of AchE. Edrophonium (Enlon, previously marketed as Tensilon) is a short-acting AchE inhibitor may be used to help confirm a clinical diagnosis. It is best used if the patient has ptosis or extraocular paresis because there is less subjectivity in assessing improvement. Edrophonium is given intravenously (IV) with 0.1 mL of a 10 mg/mL solution administered initially as a test to assess tolerance, and if no unwanted effects are noted, the remainder of the drug is injected and the patient is observed for a clinical response. If a cholinergic reaction occurs, which may include bradycardia or hypotension, then administer 0.5 mg atropine IV.

Laboratory evolution of autoantibodies is standard of care in patients with suspected MG. In generalized MG, Ach-R Abs are generally present in up to 85% of affected individuals with generalized MG. Ach-R Abs may include blocking, binding, as well as modulating antibodies. Of those patients with generalized

MG who are seronegative for Ach-R Ab, approximately 30% to 40% are seropositive for MUSK antibodies. In ocular MG, where symptoms are limited to ptosis or binocular diplopia, only about 15% are seropositive for autoantibodies, and if present, those autoantibodies are Ach-R ab. The vast majority are seronegative and require further evaluation for confirmation of the diagnosis.

Electrodiagnostic testing for a disorder of neuromuscular transmission includes slow repetitive nerve stimulation (RNS). A stimulator is used to depolarize a motor nerve (resulting in an all-or-none nerve AP) and generate a muscle twitch recorded as a compound motor action potential (CMAP). A train of stimuli (between 4 to 6) are performed at a rate of 3 to 5 per second. In MG the dysfunction at the postsynaptic muscle membrane results in some muscle fibers not achieving depolarization sufficient to cause an all-or-none muscle fiber AP, and the size of the overall CMAP (from multiple muscle fibers) is reduced. The threshold for abnormality is a CMAP decrement of >10%, generally between the first and fourth stimuli. If a baseline study at rest is normal, the patient is asked to exercise the muscle for 1 minute, and the study is repeated at 1-minute intervals to assess for the development of decrement. It should be noted that the sensitivity of RNS is increased with the presence of fatigable weakness on examination, because the clinical correlate of a decrement is weakness. Aside from distal hand muscles, trapezius or facial muscles such as nasalis can be studied.

Single fiber electromyography looks for “jitter” or loss of synchronization of individual muscle fibers innervated by a single anterior horn cell in the spinal cord. This is the most sensitive electrodiagnostic test for MG.

## Differential Diagnosis

The differential diagnosis for diplopia and ptosis includes cranial nerve palsies: oculomotor (cranial nerve III), trochlear (cranial nerve IV), and abducens (cranial nerve VI). Horner’s syndrome may also cause ptosis due to weakness in Mueller’s muscle, although other signs such as anisocoria (unequal pupils) that is worsened in the dark is present. Thyroid eye disease may cause any of these symptoms as well. The differential diagnosis for appendicular weakness without sensory loss includes myopathy, pure motor neuropathy, anterior horn cell disease, or a central nervous system pathology involving the motor pathways. These causes of weakness result in static rather than fluctuating weakness.

The main differential diagnosis for fatigable weakness as seen in MG is the Lambert-Eaton myasthenic syndrome (LEMS). LEMS is caused by antibodies against voltage-gated calcium channels on the presynaptic neuromuscular junction and may be paraneoplastic (small cell carcinoma of the lung) or autoimmune. MG and LEMS can be differentiated by the presence of postexercise facilitation of reflexes (after 10 seconds of sustained exercise), as well as antibody and electrodiagnostic testing.

## Therapy

Overall, the treatment goal is to achieve freedom from symptoms or functional limitations, recognizing that patients may still have some weakness of some muscles (this is known as minimal manifestation status). Mainstays of treatment include anticholinesterase inhibitors, as well as oral steroids, and a variety of immunosuppressants, as well as intravenous immunoglobulin (IVIG),<sup>1</sup> and plasmapheresis may be used. Broadly, medical therapy can be classified as symptomatic or disease-modifying, the latter with an immunomodulatory effect targeting the underlying disease pathophysiology.

It should be noted that there exists wide variation in therapeutic approaches, and there are limited head-to-head data comparing individual medications. Current treatments, as well as advances

<sup>1</sup>Not FDA approved for this indication.

in clinical care, have significantly improved the mortality rate of MG and outcomes of myasthenic crisis.

### Symptomatic Therapy

Pyridostigmine (Mestinon) is an AchE inhibitor that increases the amount of acetylcholine in the synaptic cleft by slowing its breakdown by AchE and should be considered as initial therapy. Onset of action is typically within 30 minutes, with benefit generally lasting 3 to 4 hours. As such it is initially dosed 60 mg 3 times daily by mouth and may be increased to 120 mg every 3 to 4 hours while awake, with the total dose typically not exceeding 480 mg/d. It does not penetrate the central nervous system, and most side effects are gastrointestinal. Side effects may include nausea, vomiting, abdominal cramping, diarrhea, sweating, blurred vision, or muscle twitching and cramps. Anticholinergic agents such as glycopyrrolate (Robinul) 1 mg or hyoscyamine sulfate (Levsin)<sup>1</sup> 0.125 mg with each pyridostigmine dose can usually treat these muscarinic side effects effectively. Data suggest that MUSK Ab–positive patients may have a lesser response to acetylcholinesterase therapy when compared with ACH-R–seropositive patients. In the setting of ocular myasthenia, there appears to be more of response in ptosis when compared with diplopia.

### Corticosteroids

Corticosteroids, typically prednisone,<sup>1</sup> are a mainstay of immunotherapy and used when pyridostigmine alone does not achieve an adequate treatment response. Two general approaches exist, using either a low-dose or high-dose regimen. Decisions may be dictated by the severity of weakness, presence of significant bulbar dysfunction, or comorbid conditions (such as diabetes). A “low-dose” approach is used with milder disease and includes initiation of 10 to 20 mg daily, and increasing by 5 mg orally weekly to a lower target dose (generally 40–60 mg/d). Oral high-dose (1 mg/kg/d) steroid therapy may be used with moderate-severe weakness and generally has a latency of 2 to 4 weeks before onset of benefit with maximal benefit in 5 to 6 months. It is important to recognize that early clinical deterioration is possible (reported up to 50%) approximately 7 to 10 days after treatment initiation, generally when steroids are dosed at 1 mg/kg/d or higher. In those patients for whom high-dose therapy is introduced, concomitant treatment with either IVIG or plasma exchange (PLEX), discussed herein, may provide protection against early clinical deterioration.

For a patient who has achieved the treatment goal of minimal manifestation on a particular dose of steroids, it is important to consider weaning the dose to reduce side effects. A common approach is a slow taper decreasing 5 mg/d per month on alternate days, with a slower taper once a total dose of 10 mg daily is achieved. Many patients can be maintained on low doses of steroids.

Some patients have an inadequate response to steroids or intolerable side effects or are unable to taper because of recurrence of symptoms. These patients are typically treated with alternative, steroid-sparing, immunomodulatory therapies. Some patients with comorbidities that limit steroid dosing are started on steroids and nonsteroidal immunosuppressant medications concurrently.

### Thymectomy

Thymectomy is considered standard of care for those with thymoma, which is present in approximately 15% of patients with generalized MG. A recent study supports thymectomy in Ach-R Ab–positive patients with at least moderately severe disease. Thymectomy patients demonstrated improved outcomes compared with placebo, required less steroids, fewer required steroid-sparing immunosuppressants, and experienced fewer hospitalizations. Thymectomy is controversial for mild symptoms, purely ocular disease, older age (>60 years), and there exist various surgical

approaches. It is considered standard of care to pretreat with IVIG or PLEX before surgery if patients are symptomatic.

### Other Immunomodulatory Therapies

Azathioprine (Imuran)<sup>1</sup> is a purine analogue that inhibits nucleic acid synthesis, as well as T- and B-cell proliferation. It is a commonly used steroid-sparing immunosuppressant that is considered first-line and has shown efficacy in a randomized clinical trial. Azathioprine allows reduced steroid dose, reduces relapse rate, and prolongs duration of remission. Treatment is generally started at 50 mg daily, increasing by 50 mg every 1 to 2 weeks to approximately 150 to 200 mg daily (2–3 mg/kg/d), generally in split doses. Onset of action is estimated at 4 to 8 months, and therapy requires regular blood count and liver function monitoring. Side effects include a flulike illness at initiation (reported in up to 10% to 20%, requires cessation), leukopenia, and transaminitis. Thiopurine methyltransferase enzyme testing can be performed, if available, before starting to identify patients at high risk of bone marrow suppression (although monitoring of blood counts is favored by many practitioners).

Intravenous immunoglobulin (IVIG, Gammagard)<sup>1</sup> has been shown to improve weakness in MG. Its mechanism of action is unclear although presumed to stem from neutralizing circulating pathogenic autoantibodies. A dose of 2 g/kg spread over 5 days is a common algorithm for initial treatment, although in patients who previously tolerated it, IVIG could be given as 1 g/kg/d over 2 days. Onset of action is typically within the first week, and benefit may be sustained for 3 to 4 weeks after treatment. Side effects include headache (sometimes severe and related to aseptic meningitis), thrombosis because of increased serum viscosity, and renal failure. Avoidance of sucrose-containing products may decrease risk of renal failure. Slowed infusion rates may help avoid decompensation of heart failure. Patients on maintenance dosing may receive IVIG 1 g/kg every 3 to 4 weeks.

Mycophenolate mofetil (Cellcept)<sup>1</sup> inhibits guanosine nucleotide synthesis that is needed for B and T lymphocytes. Although there have been two negative randomized clinical trials, there are several retrospective reports supporting efficacy and consensus expert opinion is that it remains a treatment option. It is started at 500 mg twice daily and titrated to 1000 to 1500 mg twice daily. Side effects include nausea, vomiting, diarrhea, and leukopenia. It has teratogenic potential and should not be used in pregnancy.

Cyclosporine (Sandimmune)<sup>1</sup> is a calcineurin inhibitor that has suppressed inflammatory cytokines and has multiple effects on T-cell function. It is initiated at approximately 3 mg/kg daily as a twice-daily split dose and may be titrated up to 5 mg/kg/d with a target trough level <300 ng/mL. Onset of action is approximately 2 to 3 months. Side effects include hirsutism, hypertension, clinically significant nephrotoxicity, and increased cancer risk (including dermatologic cancers). Cyclosporine level may be affected by multiple drug interactions, and concomitant medications should be reviewed.

Methotrexate (Trexall)<sup>1</sup> is a folate antimetabolite that may be dosed orally or subcutaneously. A typical oral dose is initiated at 10 mg weekly and titrated to 15 to 25 mg orally once a week. It is recommended that the patient take folate<sup>1</sup> supplementation of approximately at least 1 mg daily. Side effects include stomatitis (folate supplementation may help prevent this), bone marrow suppression, as well as interstitial lung disease (rare). It is important to note that methotrexate is a known teratogen and should be avoided in women of child-bearing potential.

<sup>1</sup>Not FDA approved for this indication.

Plasmapheresis or PLEX removes plasma from the circulation and replaces it, typically with albumin, with the net effect of removing pathologic autoantibodies and inflammatory cytokines. Typically five exchanges are performed over a period of 1 to 2 weeks, and benefit is typically observed by the third exchange. PLEX requires placement of a vascath or (if to be used as a maintenance therapy) a permacath. When used as a maintenance therapy, 1 to 2 exchanges are typically performed, at variable intervals, as frequently as weekly. There is a risk of deep venous thrombosis or line infection. Hypotension may occur because of citrate-induced hypovolemia, and it may be associated with hypocalcemia. ACE inhibitors need to be held 24 hours because of bradykinin-related vasodilation.

Rituximab (Rituxan)<sup>1</sup> is a CD20 antibody that has been evaluated in a randomized controlled trial, the results of which are pending. There exists retrospective data to support efficacy, particularly in MUSK Ab patients who have failed initial therapy. It is dosed 325 mg/m<sup>2</sup> weekly for 4 weeks, although it can also be dosed 1 g/m<sup>2</sup> with a second dose 2 weeks later. Dosing may be repeated at 6-month intervals. Side effects include infusion-related symptoms including pruritis, headache, hypotension, nausea, and chills. Rituximab may additionally result in leukopenia, anemia, or thrombocytopenia. Infusion-related symptoms can be pretreated with acetaminophen and diphenhydramine.

Eculizumab (Soliris) is a complement inhibitor that was FDA approved for AchR Ab generalized myasthenia gravis in 2017. It is dosed at 900 mg weekly for 4 weeks, followed by 1200 mg for the fifth week and thereafter 1200 mg every 2 weeks. Generally only mild infusion reactions are reported, typically managed by pretreatment acetaminophen and diphenhydramine, although there is risk for severe meningococcal infection. Meningococcal immunization is recommended before treatment initiation.

Cyclophosphamide (Cytoxan)<sup>1</sup> is typically reserved for treatment-refractory patients. It may be administered orally with a daily dose ranging from 1.5 to 5 mg daily. Potential side effects of oral cyclophosphamide include cystitis as well as bladder cancer, leading many treating physicians to use IV pulse dosing. A common approach for pulse dosing is 1 gm/m<sup>2</sup> monthly for 6 months (less toxic). Onset of action with pulse dosing is relatively quick, generally about 1 month.

Efgartigimod (Vyvgart) is a neonatal Fc receptor blocker, which was FDA-approved for AChR Ab generalized myasthenia gravis in 2022. It has a novel mechanism of action that effectively reduces IgG levels, including levels of pathogenic autoantibodies. As such, efgartigimod has been likened to “plasma exchange in a bottle.” It is administered intravenously at a dose of 10 mg/kg weekly for a total of four treatments (a treatment cycle) and, depending on response, repeat cycles may be given after 8 weeks. Side effects include infusion reaction, headache, and respiratory and urinary tract infections. If a patient has an active infection at the time of a cycle, it is recommended that the treatment cycle be delayed.

### Treatment Considerations in Pregnancy

Pregnancy and postpartum status have been reported to be triggers for worsening of myasthenia. Ideally, prepregnancy planning allows for optimization of clinical status to improve pregnancy outcomes. These patients require expert multidisciplinary care through the postpartum period. In pregnancy the treatment of choice is pyridostigmine, with steroids being the immunosuppressant of choice. Azathioprine<sup>1</sup> and cyclosporine<sup>1</sup> are relatively safe in expectant mothers who are not satisfactorily controlled or cannot tolerate corticosteroids. IVIG<sup>1</sup> and PLEX may also be treatment options.

Transient neonatal myasthenia may affect the newborn infant. This is difficult to predict and requires close attention for signs after delivery. Neonatal critical care support should be readily available for these infants.

### Monitoring

After a diagnosis of MG is confirmed, additional testing or monitoring is indicated. The frequency of clinical assessment should be dictated by the severity and nature of the patient's symptoms, as well as the impact of the disease on function. Patients with MG should be managed in concert with a neurologist. Refractory MG is defined by symptoms that affect function and are unchanged or worse after corticosteroids and at least two other immunosuppressive agents used in adequate doses for adequate duration. Patients meeting criteria for refractory MG should be referred to a physician or medical center with expertise in MG.

Computed tomography of the chest should be performed to screen for thymoma. Assessment of thyroid function is important. If immunomodulatory medications are used for disease control, TB screening should be performed.

Pulmonary and swallowing dysfunction may be encountered. Pulmonary function testing should be performed for patients with symptomatic generalized MG, particularly if there are complaints of dyspnea. Speech therapy referral for a swallow evaluation should be performed if there is concern for dysphagia.

Periodic laboratory monitoring is required with use of immunomodulatory medications, which may vary depending on the specific medication used. Suggested tests and monitoring algorithms are detailed in Box 2.

### Complications

The most severe complication of MG is myasthenic crisis, which is defined by worsening of weakness requiring intubation or noninvasive ventilation. Myasthenic crisis may be seen in up to 20% of patients at some point in disease course. Myasthenic crisis is most commonly encountered in the setting of concomitant illness, change in medications, or early in the disease course because maximum weakness occurs in the first year of the disease in 66% of patients. Respiratory failure can result from respiratory muscle weakness, oropharyngeal weakness, or a combination of both. It is important to recognize that new respiratory or swallowing complaints can quickly escalate, and patients with these complaints should be quickly assessed. One can assess diaphragm strength by the force of a strong sniff or cough; patients should be able to count to 20 after a deep breath. Staccato speech or dyspnea that precludes speaking in full sentences is of high concern for myasthenic crisis. Spirometry with forced vital capacity <2 L or negative inspiratory force of <40 cm H<sub>2</sub>O should be sent to the hospital for further evaluation. Assessment of swallowing function by speech therapy and possible modified barium swallow should be considered in the context of dysphagia for solids and liquids.

IVIG and PLEX have comparable outcomes for the treatment of patients with moderate-to-severe weakness. The response to PLEX may be more predictable than IVIG in severe MG exacerbations, and retrospective data suggests PLEX may be more effective than IVIG in myasthenic crisis. PLEX, however, may be associated with more complications, as well as longer hospital stay and associated hospital costs.

## NEUROFIBROMATOSIS (TYPE 1)

Method of

Jason E. Marker, MD, MPA

### CURRENT DIAGNOSIS

- Neurofibromatosis type 1 (NF1) can be diagnosed by physicians based on well-defined diagnostic criteria that can be met with a careful history and physical exam.
- Additional testing may be needed in some cases (including genetic testing) to confirm the diagnosis or to provide information that will be important for both short- and long-term management.
- NF1 has important genetic underpinnings, can have extremely variable expression within families, and will evolve in its need for medical intervention throughout the lifetime of the patient.

### CURRENT THERAPY

- There is no treatment for NF1. However, there are many therapies for both the common and uncommon manifestations and complications of the condition.
- Many therapies are similar to those used for non-NF1 patients with the same symptoms. However, there are some manifestations where unique therapies are needed, and physicians need to know the difference between these.
- Proper monitoring of the patient aids in the identification of treatable symptoms and allows opportunities for anticipatory guidance and counseling.
- There are several emerging therapies related to the heritability of NF1 that are important for patients of childbearing age to be aware of.

### Introduction and Epidemiology

Neurofibromatosis encompasses three distinct genetic entities: NF1, neurofibromatosis type 2 (NF2), and schwannomatosis. Because NF1 is so much more common (incidence of 1:1900 to 1:3000 livebirths) than NF2 (incidence of 1:25,000 to 1:33,000 livebirths) and schwannomatosis (incidence of 1:40,000 to 1:1.7M livebirths), when the word *neurofibromatosis* is used (or the older name, Von Recklinghausen disease), it is generally referring to NF1. NF1 is the primary topic of this chapter.

NF1 is an autosomal dominant genetic disorder and is progressive in that its clinical manifestations evolve over the lifespan. About half of the cases of NF1 are familial and the remainder are the result of new, spontaneous mutations. Life expectancy is reduced by 5 to 15 years and is related to the severity of the clinical manifestations, the emergence of malignant tumors, and excess hypertensive and vascular disease risk. There is no predilection based on race, ethnic origin, or country of birth.

### Risk Factors

NF1 is an autosomal dominant condition and affects 50% of the offspring of parents where one parent is affected, making family history the primary predictable risk factor. Advanced paternal age increases the likelihood of a de novo mutation. Eighty percent of newly occurring mutations are believed to come from the paternally derived chromosome.

### Pathophysiology

NF1 is the result of mutations in the *NF1* gene (chromosome 17q11.2) that codes for the protein neurofibromin. Neurofibromin is a protein in the GTPase-activating family that stimulates

the Ras pathway for tumor suppression. Loss of neurofibromin results in “de-suppression” of tumor growth within susceptible tissues. Although genetic penetrance in NF1 is complete, NF1 is highly variable in its expression (even within families). This is because germline mutations must be coupled with somatic mutations in order for symptoms to manifest clinically.

Several thousand distinct *NF1* mutations have been identified. Many small mutations have demonstrated no genotype-phenotype correlation, while some individuals (1% to 5% of NF1 patients) will have complete loss of the 1.4 to 1.5 Mb of the *NF1* gene and are quite severely affected. Due to the large size of this gene, mutations in the *NF1* gene occur more often than in any other human gene.

Somatic and germline (rare) mosaicism occurs and can result in phenotypically unaffected offspring who could later transmit the mutated gene to their own children. Also, some individuals with neurocognitive symptoms have been found to have haploinsufficiency (heterozygous for a pathogenic variant with an intact second allele).

### Prevention

There is no specific prevention for any of the clinical manifestations of NF1. Due to its variable expression, some individuals will simply be more or less affected. To the extent that having a diagnosis of NF1 *could* cause academic challenges, interpersonal hardships, and social isolation, robust anticipatory guidance throughout the lifespan can help these individuals develop proper support systems and personal resilience, preventing some of the morbidity of the disease.

Affected individuals of child-bearing age now have the option of genetic testing of fertilized eggs to select unaffected eggs for implantation. This is an emerging prevention strategy.

### Clinical Manifestations

There are a number of clinical manifestations of NF1. Because of the variability of expression of the *NF1* gene, these manifestations may be variably present in any affected individual. The following section on diagnosis will discuss how these clinical manifestations fit into the diagnostic criteria for NF1.

*Café-au-lait spots* are flat, irregularly shaped, uniformly hyperpigmented macules that appear during the first year of life and then increase in number through childhood. These macules are present in 95% of adults with NF1 but tend to fade and become more indistinct later in life. Among the general population of individuals who do not have NF1, 15% will have one to three café-au-lait macules.

*Freckling* (primarily in areas of skin apposition like the axillae and inguinal folds) is distinct from café-au-lait macules as the freckles are smaller, more clustered, and generally appear later in childhood than the café-au-lait macules.

*Lisch nodules* are tan-colored hamartomas of the iris. Lisch nodules do not affect vision and may be seen with simple ophthalmoscopy (although the use of a slit lamp will help identify small nodules and distinguish them from iris nevi). These nodules are seen in up to 90% of adults with NF1, but fewer than 10% of children under 6 years old.

*Neurofibromas* present as several types of lesions with variable characteristics, risk of pathology, and symptomatology. Cutaneous peripheral neurofibromas are benign peripheral nerve sheath tumors that are generally soft, mobile, and fleshy. They may be dermal or epidermal on a broad or pedunculated base. These neurofibromas are nontender, are usually more common on the trunk, and can number from a few to thousands. Cutaneous peripheral neurofibromas do not degenerate into malignant peripheral nerve sheath tumors (MPNSTs). Plexiform peripheral neurofibromas can be superficial or deep inside the body. They tend to be more diffuse and involve plaques and tangles of abnormal tissues that can grow into a complex mass. On whole-body scanning, 50% of patients with NF1 will have at least one plexiform neurofibroma. Large plexiform neurofibromas can create symptoms by compressing nearby structures and, unlike cutaneous neurofibromas, they have the capacity to degenerate into MPNSTs. Nodular neurofibromas are firm and rubbery. Unlike the cutaneous neurofibromas, they

are sometimes tender, often deeper and usually less mobile. They are not as invasive as the plexiform neurofibromas but can undergo degeneration into MPNSTs.

*Optic pathway gliomas* (OPGs) occur in 15% of children younger than 6 (but rarely in older individuals) and can grow anywhere along the optic tracts. Most individuals are asymptomatic, but advanced tumors can affect vision or even upset the normal function of the hypothalamus with growth rate variations and premature or delayed puberty.

*Orthopedic abnormalities* are primarily long-bone dysplasias and pseudoarthroses. Anterolateral bowing of the tibia (usually unilateral) in infants and young children can easily go undetected until a pathologic fracture develops at the onset of ambulation. One half of fractures occur during the toddler years. Long-bone pseudoarthrosis has a male predisposition (1.7:1) and NF1 accounts for 50% to 70% of all long-bone pseudoarthroses. Other orthopedic findings in NF1 patients may include short stature (13% have a height less than 2 standard deviations below the mean), scoliosis (10% to 15% of NF1 patients are affected), sphenoid wing dysplasia (leading to facial asymmetry), osteoporosis, and macrocephaly.

*Neurologic abnormalities* encompass cognitive defects and learning disabilities as well as the risk of seizures. Although profound intellectual disability is rare (the likelihood of having an IQ <70 is similar to the general population), 81% of NF patients will have some impairment in one or more areas of cognitive functioning. While less than half of NF1 patients have a specific learning disability, more than half will have some amount of neuropsychological impairment, including speech articulation problems, AD/HD, or impairment of executive functioning. Seizures occur twice as often in patients with NF1 (prevalence 4% to 6%) as in the general population and can be of any type and occur at any age.

*Other manifestations of concern:* Rarely, other central nervous system (CNS) neoplasms develop. CNS astrocytomas usually arise during childhood and, when not an incidental finding on a scan being done for another purpose, may present with symptoms of increased intracranial pressure. Rare brainstem gliomas are usually symptomatic at presentation. Malignant peripheral nerve sheath tumors are highly malignant tumors that can arise from a preexisting plexiform or nodular neurofibromas. The lifetime risk of developing an MPNST in a patient with NF1 is 5% to 13% and most commonly occurs in teenagers and young adults. MPNSTs are usually diagnosed when a plexiform or nodular neurofibroma goes through a period of pain, change in consistency, and rapid growth. Hypertension, including hypertension as early as childhood, is common among NF1 patients. Although rare, renal neurovascular lesions can be the cause, and NF1 patients with hypertension should be evaluated for renal artery stenosis. Macrocephaly, congenital heart disease (primarily pulmonic stenosis and mitral valve defects), cerebrovascular dysplasia, and increased incidence of irritable bowel syndrome and constipation have been observed, more commonly in individuals with NF1, though not fully studied.

## Diagnosis

The diagnosis of NF1 can be made reliably by a primary care team, but a multidisciplinary team of subspecialists is often involved in the long-term care of these individuals, including during the diagnostic phase. A comprehensive history (including a detailed family history) and examination should be undertaken. Additional testing or referral, as indicated by the initial evaluation, should be pursued to clarify the diagnosis, seek findings amenable to treatment, and facilitate proper anticipatory guidance and patient/family education.

The US National Institutes of Health (NIH) Consensus Conference in 1997 (with minor revisions in 2021) set forth the following diagnostic criteria for NF1:

At least two of the following clinical features must be present to make the diagnosis of NF1:

- Six or more café-au-lait macules greater than 5 mm (prepubertal) or greater than 15 mm (postpubertal) in longest diameter
- Two or more neurofibromas of any type (or a single plexiform neurofibroma)

- Freckling in the axillary or inguinal regions
- Optic pathway glioma
- Two or more Lisch nodules or two or more choroidal abnormalities (see below)
- A distinctive bony lesion (sphenoid dysplasia or a long-bone dysplasia with or without pseudoarthrosis)
- A heterozygous pathogenic NF1 variant allele fraction of 50% in apparently normal tissue (like WBCs)

A child with ONE of the above clinical findings AND a first-degree relative with NF1 based on these criteria meets diagnostic criteria for NF1.

These criteria are both sensitive and specific, and are met by 97% of NF1 patients by the age of 8 years (100% by the age of 20 years). Nearly half of individuals with a new sporadic mutation fail to meet these criteria by the age of 1 year. Therefore, in an infant with one clinical feature, close observation is needed to determine if other criteria will be met. If, by the age of 4 years, only one criterion is met, referral for a genetic diagnosis may be warranted if not already obtained.

Other specific testing may be needed to make the diagnosis, to determine the extent of involvement of the disorder, or to decide on treatment. These include the following:

- **Dermatologic evaluation:** If the identification of café-au-lait spots, whether café-au-lait spots meet diagnostic criteria, or the identification of criteria-meeting freckling is in question, referral to Dermatology may be needed. Likewise, the spectrum of neurofibromas is broad and a dermatologist may be needed to properly identify these lesions.
- **Lisch nodules:** Although occasionally seen with the naked eye or through an office ophthalmoscope, formal ophthalmologic consultation is recommended to look for small Lisch nodules and to assess for optic disk findings suggestive of OPGs or increased intracranial pressure. Choroidal abnormalities seen on optical coherence tomography/near infrared imaging (OCT/NIR) fall into this same diagnostic category.
- **Optic pathway gliomas:** Ophthalmologic evaluation is recommended as noted earlier. Brain MRI imaging is not recommended for asymptomatic patients with normal ophthalmologic evaluations.
- **Orthopedic abnormalities:** Plain radiographs of long bones or CT imaging of craniofacial bones may be needed to identify the diagnostic findings in these areas.
- **Neurologic abnormalities:** Because new focal seizures could be the result of a new intracranial neoplasm, neuroimaging is warranted with any new seizure activity.
- **Other manifestations of concern:** MPNSTs are best differentiated from benign plexiform or nodular neurofibromas by positron emission tomography (PET) scan. Evaluating for renal artery stenosis in individuals with new onset hypertension (including children) is indicated.
- **Genetic counseling and testing:** Genetic testing is usually reserved for cases where the diagnosis remains in question following a thorough history, examination, and nongenetic testing. Additionally, genetic testing may be indicated for family members of the affected individual. Knowing that expression is extremely variable, preconception, embryonic preimplantation, or prenatal (amniocentesis or chorionic villi sampling) testing for individuals in families with NF1 should be considered.

## Differential Diagnosis

Because of the well-established diagnostic criteria and availability of genetic testing, the differential diagnosis of NF1 is limited. As noted at the outset, NF2 and schwannomatosis are lumped together with NF1 under the general diagnosis of neurofibromatosis. Schwannomatosis is a complex regional pain syndrome with some common underlying pathophysiology but no overlapping symptoms and unrelated genetics. NF2 will be discussed briefly in the discussion to come.

*Legius syndrome* includes café-au-lait macules, axillary freckling, and macrocephaly. It does *not* include neurofibromas or CNS tumors, however. Like NF1, Legius syndrome is an autosomal dominant disorder for loss of a tumor suppressor protein, but it affects an entirely different gene.

*Constitutional mismatch repair-deficiency syndrome* (CMMR-D) is a rare autosomal recessive condition that results in café-au-lait macules (and occasionally axillary freckling and Lisch nodules). Unlike in NF1, individuals with CMMR-D are at risk for hematologic malignancies in infancy and childhood, brain tumors (primarily glioblastomas) in mid-childhood, and colorectal cancer in adolescence and young adulthood. Rhabdomyosarcomas and optic pathway gliomas may occur rarely in CMMR-D.

NF2 is caused by the NF2 gene on chromosome 22, which encodes for the tumor suppressor protein merlin (or schwannomin), which is a functionally different protein than that produced by NF1. Key differences between NF1 and NF2 include the following points about NF2:

- Few or nonexistent café-au-lait macules
- No Lisch nodules
- No risk of MPNSTs
- Spinal root tumors are schwannomas in NF2 (neurofibromas in NF1)
- No cognitive impairment
- High prevalence of bilateral acoustic schwannomas and resulting hearing loss in 90% to 95% of patients by the age of 30 years
- 60% to 80% have cataracts
- Presence of meningiomas

*Noonan syndrome* is characterized by short stature and may include café-au-lait macules that may meet the size and number criteria for NF1. Sometimes, the facial features of Noonan syndrome can overlap with the appearance of NF1. However, the webbed neck of Noonan syndrome and the association with pulmonic stenosis are not part of NF1. Although the Ras signaling pathway is involved in Noonan syndrome, the underlying genetics are entirely different.

### Surveillance and Therapy

In 2020, the FDA approved oral selumetinib (Koselugo), a first-of-class kinase inhibitor, for pediatric patients 2 years of age and older with NF1 who have symptomatic, inoperable plexiform neurofibromas. The research that led to this approval showed statistically and clinically significant decreases in the size of these neurofibromas, as well as the pain and disability that often accompanies them. It remains unclear whether selumetinib treatment decreases the likelihood of malignant transformation of plexiform neurofibromas into MPNSTs. Similar medications are currently under study at this time.

The following areas of surveillance should be undertaken. Where research or expert opinion suggests a proper frequency, it is listed, although shared decision making with the patient/family as well as communication with your medical colleagues will be required to develop appropriate timelines. Therapeutic options are listed here for many of the common issues NF1 patients face, while the management of less common complications is outlined in the next section.

- Yearly examination of the skin for new neurofibromas and any signs of change within an existing neurofibroma should be done. Especially when nodular or plexiform neurofibromas exist (those at risk of malignant transformation), any history of rapid change or new pain should be evaluated thoroughly. A PET scan can distinguish between benign and malignant lesions. Referral to surgical and/or dermatologic colleagues should be made regarding these nodular or plexiform neurofibromas (for biopsy and management decisions) and should be strongly considered for all but the most clear and superficial cutaneous neurofibromas.
- Cutaneous neurofibromas that develop pruritus are often not responsive to antihistamines, although the itching is often improved by the use of gabapentin (Neurontin)<sup>1</sup>.

- Yearly blood pressure measurement, even in children and young adults, should be done. Once the diagnosis of essential hypertension is made following testing that excludes the diagnosis of renal artery stenosis, blood pressure should be controlled following standard blood pressure goals and treatment algorithms. Hypertension that becomes hard to control may prompt an evaluation for pheochromocytoma, a rare finding in NF1.
- Growth tracking of weight, height, and head circumference should be done through childhood and adolescence in the usual manner. Additionally, any signs of premature or delayed puberty should be evaluated further. Growth and pubertal abnormalities should prompt an age-appropriate endocrinology referral for additional testing (serum, urine, and/or neuroimaging) and treatments based on these results.
- Neurodevelopmental and academic assessment should be undertaken, involving family members and school personnel when appropriate. Individuals who develop neuropsychiatric and academic problems should undergo formal neurodiagnostic testing, and any identified diagnoses should be treated. These treatments are no different than those used for non-NF1 individuals who carry the same neuropsychiatric diagnosis. Neuroimaging is not indicated in the evaluation of neuropsychiatric conditions unless neurologic deficits exist.
- NF1 patients who develop seizures are treated with the usual seizure management algorithms following neuroimaging to look for new intracranial pathologies. An electroencephalogram (EEG) is not indicated for asymptomatic individuals.
- Evaluation for skeletal changes including scoliosis, facial asymmetry, or long bone abnormalities should be performed yearly during childhood and adolescence, and then at the typical wellness visits into young adulthood (with prompting in these older ages to report any changes that are noticed between visits). Any abnormalities that are encountered should prompt additional imaging and referral to subspecialty care.
- Women with NF1 develop osteoporosis at an earlier age than their non-NF1 peers and should undergo earlier screening in accordance with this fact and with other standard risk factors they may have. When diagnosed, this osteoporosis is treated like it would be for any other patient.
- For unclear reasons, women with NF1 have an increased risk of breast cancer, especially women under the age of 40 (at the age of 70, the risk approximates that of the general population). These are usually invasive ductal carcinomas (the most common type overall) and are managed in the usual way, although these patients need both earlier education about, and screening for, breast cancer.
- Formal ophthalmologic evaluation for visual screening, slit lamp and intraocular examination should take place yearly at least through adolescence, usually in the context of a comprehensive examination. Lisch nodules are nonpathologic and no treatment is needed, but any signs of elevated intracranial pressure or optic disc pathology warrant further testing and management. The optimal frequency of MRI surveillance of an optic pathway glioma is unknown but should be based on symptomatology, size, and rate of progression.
- Brain MRI is not recommended as a routine screening test. It may be a part of the initial diagnostic workup but should not need to be repeated for asymptomatic patients who are otherwise receiving comprehensive surveillance. Of note, “NF-associated bright spots” may be seen on MRI imaging, and the data are inconclusive on the relationship between these spots and any pathologic process. These spots often resolve spontaneously by late childhood. Increased brain volume may be observed but is not definitively tied to any NF1 symptoms.
- Whole body MRI screening or MRI of nonbrain areas of potential concern (such as visible but stable and asymptomatic plexiform or nodular neurofibromas) is not recommended by most authorities. Likewise, screening PET scanning is not recommended.

<sup>1</sup>Not FDA approved for this indication.

## Management of Complications

The previous section outlines the surveillance of and treatment for most of the common concerns for patients with NF1. Rarely, more significant complications present themselves. These are listed here along with their management plan.

- Symptomatic cutaneous neurofibromas that are cosmetically unacceptable, painful, itchy, or disfiguring will sometimes need to be managed. Once it is clear that the lesions in question are truly simple cutaneous neurofibromas, they may be removed in any manner, including by excision, cryotherapy, laser, or electrodesiccation.
- Symptomatic plexiform neurofibromas that have not degenerated into MPNSTs that are deemed in need of management or removal should be managed by a multidisciplinary team of surgeons and oncologists who are familiar with this type of tumor. These invasive tumors require nonstandard operative approaches and consideration of emerging chemotherapeutic agents.
- MPNSTs are often due to a co-mutated *SUZ12* gene (which lies contiguous to *NF1*). Individuals with large or complete deletions of the *NF1* gene (those who are generally more severely affected) are at an increased risk of this complication. MPNSTs are usually managed by surgeons and oncologists familiar with NF1 and often involve surgical excision with adjunctive radiation and possibly emerging chemotherapeutic agents.
- Optic pathway gliomas are most commonly found to be low-grade pilocytic astrocytomas. As such, they are often sensitive to the standard oncologic treatments for that type of tumor—but when to observe and when to proceed to treatment is controversial.
- Because the bony architecture of pathologic skeletal lesions is inherently abnormal in these patients, the risk of complications from corrective treatments is higher than in non-NF1 patients. Your local orthopedic colleagues need to be aware of this and obtain tertiary care backup when needed. Amputation is often the best long-term plan for long bone lesions.
- Refractory hypertension in the absence of renal artery stenosis that is ultimately found to be the result of pheochromocytoma should be managed by a multidisciplinary team experienced in the management of this diagnosis. It is managed in the same manner as non-NF1 patients with a pheochromocytoma.
- Short stature is often correctible with growth hormone therapy. However, this treatment is not often used because it compounds the inherent protumorigenic nature of NF1. In extreme cases of short stature when growth hormone is used, clinicians need to be alert to the evolution and potential malignant degeneration of new or existing tumors.
- NF1 patients are at a high risk of psychosocial issues arising from the symptoms they may experience from their NF1, its lack of treatability, and its genetic underpinnings. These symptoms may affect relationship building and reproductive decisions. Extra professional support may be needed, particularly during adolescence.

Although pregnancy is not a “complication” of NF1, its management can certainly be complicated by the diagnosis. Pregnant NF1 patients have increased morbidity (but not mortality) due to hypertensive and vascular complications. These complications should be anticipated and managed by an appropriately trained medical team. Genetic counseling should be recommended, ideally prior to conception, and steps taken to ensure proper evaluation and surveillance for the newborn.

## NONMIGRAINE HEADACHE

Method of

Stephen Ross, MD

### CURRENT DIAGNOSIS

- Evaluation/diagnostic tests should be considered for any patient with headache who also has “red flags” (see [Table 2](#)).

### CURRENT THERAPY

- Specific therapy for secondary cause of headache should be initiated when identified.
- Symptomatic therapy for headache should be selected based on the headache phenotype.

## Evaluation and Diagnosis

Gathering of a thorough history (including headache history, see [Table 1](#)) and physical examination facilitates two principal goals of headache management:

1. To determine the need for diagnostic studies to evaluate for potential secondary contributors. The more “red flags” ([Table 2](#)) the patient has, the more you must consider this. Depending on the differential diagnosis, evaluation may include brain and/or cervical spine imaging, spinal tap, and blood studies. Specific treatment can be initiated for some identified secondary contributors (e.g., intracranial hypertension or meningitis).
2. To discern dominant headache phenotype ([Figure 1](#)) in order to guide symptomatic treatment

The two forms of secondary headache therapy include specific treatment that addresses underlying etiology—for example, antibiotic for bacterial meningitis, and symptomatic treatment, which is selected based on the dominant headache phenotype. Often headache phenotypes can be segregated into one or more of the following four themes: migrainous (covered in the chapter Migraine Headache), tension-type, cluster-like (trigeminal autonomic cephalalgia [TAC]), and neuralgia. The symptomatic treatment mirrors that used for the parallel primary headache disorders (see the following).

**TABLE 1** Headache Characteristics

Is there more than one type?	Location/radiation	Is there any positional component?	Anything that triggers it?	Any pattern to occurrence? (e.g., always 1 hour after going to bed; or every Spring)
When was the onset?	What does it feel like? (e.g., throbbing, pressure, burning)	Are there any associated features? (e.g., nausea, photophobia, ptosis, lacrimation)	Anything that relieves it?	What treatments have been tried so far? Response to these?
Duration	Frequency	Intensity along with ramp	Any family history of this?	Any change with Valsalva?

**TABLE 2** Headache Red Flags

Onset after age 50 years	“Thunderclap” onset of pain	Positional exacerbation	Onset with recent malignancy, nontrivial head trauma or seizures	Persistent or unexplained vomiting
Worst headache of life	Marked change in pain pattern	Precipitated by Valsalva maneuvers	Unexplained fever	Meningeal signs
First headache of life	Unusual associated features (blindness, diplopia, confusion, weakness)	Lack of response to abortive medications	Significant blood pressure elevation	Abnormal neurologic examination

**Migraine**

Throbbing  
Unilateral  
Mod-severe  
Nausea  
Photophobia  
Phonophobia  
Aura

**Tension-type**

Pressing  
Bilateral  
Mild-moderate

**Trigeminal Autonomic Cephalalgia**

Unilateral  
Orbital/temple  
Severe  
Ptosis, lacrimation, rhinorrhea, nasal congestion  
Restlessness

**Neuralgiform**

Electric/stabbing  
Unilateral  
Severe  
Triggered by innocuous stimuli

**Headache Type and Therapy**

For anyone with headache presentation, the first step in evaluation (history and physical) is to discern potential primary versus secondary source of the pain. If there is concern for possible secondary etiology, diagnostic studies should be considered. Symptomatic treatment is similar for primary and secondary etiologies but varies according to the pain phenotype (Table 3). General principles are to start low-dose treatment then titrate up if needed to control pain (understanding that often it can take 3 to 4 weeks before you see benefit of preventive treatments). If the pain is not adequately controlled despite maximum dose or treatment is not tolerated, then consider moving on to a second-line treatment. If there has been some (but not enough) improvement with the first treatment, then a second treatment can be added. If there has been no improvement with the first treatment, taper off the first while adding the second treatment.

**Tension-type headache** is experienced by almost everyone at some point in their lives. Most do not seek medical evaluation but rather self-manage. Diagnostic criteria are listed in Table 4. The presence or absence of “emotional tension” does not define this condition. Many individuals experience tension-type headache who are not “stressed” and do not have anxiety or depression. If a person is experiencing “stress” or is anxious, this can act as a trigger for tension-type headache, as well as the other primary headache conditions. Tension-type headache has both episodic and chronic forms. Chronic is defined as having symptoms  $\geq 15$  days/month for greater than 3 months.

**Treatment of Tension Headache**

Generally start with physical modalities/relaxation techniques (e.g., local heat, massage, analgesic cream) and/or as needed acetaminophen 325 mg or nonsteroidal antiinflammatory drugs (NSAIDs; e.g., ibuprofen 200 mg, aspirin 325 mg, naproxen 220 mg, diclofenac 50 mg). If this is inadequate, titrate the dose (e.g., acetaminophen 325 mg up to 1000 mg, ibuprofen 200 mg up to 800 mg) and/or referral for additional physical/cognitive modalities (e.g., physical therapy, myofascial release therapy, biofeedback therapy, cognitive behavioral therapy). FDA-approved preventive treatments are lacking. If preventive treatment is needed consider a tricyclic antidepressant (e.g., amitriptyline [Elavil]<sup>1</sup> starting with 10 mg or 25 mg at bedtime, titrating up to 150 mg if needed/tolerated). Allow 3 to 4 weeks to assess efficacy before titration to the next dose. Prescreen

**Figure 1** Headache phenotypes.<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Symptomatic Headache Treatment

MIGRAINOUS	TENSION-TYPE	CLUSTER-LIKE	NEURALGIA
See chapter Migraine Headache	Heat, massage, analgesic cream	Sumatriptan, zolmitriptan <sup>1</sup> , oxygen	Carbamazepine, oxcarbazepine <sup>1</sup>
	Acetaminophen, NSAID	gammaCore	Topiramate <sup>1</sup> , gabapentin, baclofen <sup>1</sup>
	Physical modalities	Verapamil <sup>1</sup>	Gamma-knife surgery
	Relaxation techniques	Galcanezumab	Microvascular decompression surgery
	Amitriptyline <sup>1</sup>	Topiramate <sup>1</sup> , lithium <sup>1</sup>	
	Venlafaxine <sup>1</sup> , tizanidine <sup>1</sup> , baclofen <sup>1</sup>	For select types—Indomethacin <sup>1</sup>	

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** International Headache Society Criteria for Tension-Type Headache

At least 2 of these 4 characteristics:	Both of the following:
Bilateral location	No nausea or vomiting
Pressing or tightening (non-pulsating) quality	No more than one of photophobia or phonophobia
Mild or moderate intensity	
Not aggravated by routine physical activity such as walking or climbing stairs	

with electrocardiogram (ECG) and monitor for side effects. Once you reach 100 mg, check amitriptyline blood level and repeat ECG. Alternatives could include venlafaxine [Effexor]<sup>1</sup> starting 37.5 mg or 75 mg (two to three times per day or once per day if using the long-acting form) titrating if needed to 225 mg, tizanidine (Zanaflex)<sup>1</sup> starting with 4 mg ½ pill two to three times per day titrating if needed to 2 pills three times per day, baclofen (Lioresal)<sup>1</sup> starting with 5 mg or 10 mg tid titrating if needed up to 20 mg qid, mirtazapine (Remeron)<sup>1</sup> starting with 7.5 mg or 15 mg qhs titrating if needed up to 45 mg.

**Cluster Headache (Trigeminal Autonomic Cephalgia)**

Cluster headaches have three main contrasts to migraine: (1) briefer duration, (2) more likely to have associated ipsilateral autonomic features, and (3) more likely to have agitation/activation during the attack (Box 1). The most common TAC subtype is cluster headache, but even this is 100 times less prevalent than migraine.

A second type of TAC is paroxysmal hemicrania. This has the same diagnostic criteria as cluster headache with one exception, duration. Paroxysmal hemicranias last 2 to 30 minutes.

A third type of TAC is hemicrania continua. This is a unilateral daily constant pain with exacerbations of pain intensity associated with autonomic/activation features similar to cluster headache.

**Treatment of Cluster Headache**

Triptans or high-flow oxygen are first-line abortive treatments. Preference is given to faster acting agents (e.g., sumatriptan [Imitrex] 6 mg SC injection/20 mg nasal<sup>1</sup> or zolmitriptan [Zomig]<sup>1</sup> 5 mg nasal; these may be repeated again in 1 to 2 hours if needed but have a maximum of two doses in a 24-hour period). Oxygen is best administered by nonrebreather face mask at 6 to 12 L/min for 7 to 15 minutes. An alternate abortive treatment is gamma Core, a noninvasive vagus nerve stimulator that may be administered to the anterior neck as a set of three 2-minute stimulations. Other options include IM dihydroergotamine (D.H.E. 45)

<sup>1</sup>Not FDA approved for this indication.

**BOX 1** International Headache Society Criteria for Cluster Headache

At least five attacks
Severe unilateral orbital, supraorbital, and/or temporal pain lasting 15–180 min
Either or both of the following:
1. At least one of the following symptoms or signs, ipsilateral to the headache:
• Conjunctival injection and/or lacrimation
• Nasal congestion and/or rhinorrhea
• Eyelid edema
• Forehead and facial sweating
• Miosis and/or ptosis
2. A sense of restlessness or agitation
Occurring with a frequency between one every other day and 8 per day
Not better accounted for by another diagnosis

or 1 mL of 4% intranasal lidocaine<sup>1</sup>. Short-term preventives can include oral steroids or occipital nerve blocks.

First-line preventive treatment is short-acting verapamil<sup>1</sup> starting at 40 to 80 mg oral tid titrating if needed to 480 mg (total daily dose, although there are studies taking the dose up to 720 mg/day<sup>3</sup>). An effective alternative is galcanezumab (Emgality) given as three consecutive 100-mg SC shots each month while cluster headache is active. This is a monthly self-injection that blocks one of the neurotransmitters (calcitonin gene-related peptide [CGRP]) that propagates messages along the pain pathways. Third-line considerations are topiramate (Topamax)<sup>1</sup> or lithium<sup>1</sup>. For refractory cases consider referral to a specialty headache center for sphenopalatine ganglion stimulator.

Paroxysmal hemicranias and hemicrania continua both respond absolutely to indomethacin (Indocin)<sup>1</sup> (25 mg PO tid with meals, if no improvement after 1 week titrate to 50 mg tid, if no improvement after 1 week titrate to 75 mg tid<sup>3</sup>, if no improvement after 1 week consider an alternate etiology).

**Neuralgia**

Neuralgia can be experienced in both primary and secondary headache disorders. An example of this is trigeminal neuralgia that can be primary/idiopathic or secondary (e.g., multiple sclerosis inflammation of the nerve). Neuralgia is often expressed as burning, electric shock, or jolts.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

\*Most of the treatments discussed in this chapter are considered off-label, non-FDA-approved use.

## Treatment of Neuralgia

First-line symptomatic treatment for trigeminal neuralgia includes carbamazepine (Tegretol) 100 mg bid titrating up to 1200 mg/day (monitoring level and metabolic panel) or oxcarbazepine (Trileptal)<sup>1</sup> 150 to 300 mg bid titrating up to 2400 mg/day. Second-line agents can include baclofen (Lioresal)<sup>1</sup>, pregabalin (Lyrica), gabapentin (Neurontin), topiramate (Topamax)<sup>1</sup>, and lamotrigine (Lamictal)<sup>1</sup>. For refractory cases consider referral for Gasserian ganglion percutaneous techniques, which are deep face injections typically performed by pain management. Other treatment options include gamma-knife treatment or microvascular decompression performed by neurosurgeons.

<sup>1</sup>Not FDA approved for this indication.

## OPTIC NEURITIS

Method of

Heather E. Moss, MD, PhD; and Tanyatuth Padungkiatsagul, MD

### CURRENT DIAGNOSIS

- Vision is impaired, including visual acuity, visual field, and/or color perception.
- Patients typically have eye pain that is worse with eye movement.
- There is a relative afferent papillary defect if only one eye is affected.
- The anterior optic nerve has a normal appearance in two-thirds of affected patients.

### CURRENT THERAPY

- Consider IV methylprednisolone (Solu-Medrol, 1 g/day IV for 3 days) followed by oral steroids (1 mg/kg per day for 11 days).
- Avoid low-dose oral steroid monotherapy, as this is associated with a higher relapse rate.
- If brain MRI or blood testing suggest a high-risk, clinically isolated syndrome, consider disease-modifying therapy to delay progression to Multiple Sclerosis (MS) or Neuro-myelitis optica (NMO).
- If the clinical features suggest NMO spectrum disorder (NMOSD) optic neuritis, consider IV methylprednisolone and plasma exchange therapy.
- If the patient's history and testing suggest MS-, NMOSD-, or recurrent myelin oligodendrocyte glycoprotein (MOG)-IgG-associated disease, consider treatment for these conditions.

## Epidemiology

The incidence of optic neuritis is approximately 1 to 5 in 100,000. Though it typically affects women in their fourth decade of life, 1 in 4 patients are male, and patients have been reported ranging from the first to seventh decades of life. Optic neuritis occurs worldwide in persons of various ethnicities.

Optic neuritis can be classified as a clinically isolated syndrome or in association with a disease such as multiple sclerosis (MS) or neuromyelitis optica spectrum disorder (NMOSD). NMOSD is clinically distinguished by more frequent involvement of the optic nerves and spinal cord and less involvement of the brain than MS and by distinct pathophysiology. A recently identified distinct classification is myelin oligodendrocyte glycoprotein (MOG)-immunoglobulin G (IgG)-associated optic neuritis. Approximately half of patients with optic neuritis as a clinically isolated syndrome develop MS. A small percentage develop NMOSD.

## Risk Factors

A diagnosis of a disease associated with optic neuritis, such as MS or NMOSD, increases the risk of developing optic neuritis. In one study, more than 70% of patients with MS and 100% of patients with neuromyelitis optica (NMO) had unilateral optic neuritis at some point. Patients with recurrent MOG-IgG-associated disorder (MOGAD) flares or persistent elevated serum MOG-IgG may be at risk for recurrent optic neuritis.

## Pathophysiology

Most optic neuritis occurs as a result of inflammation causing demyelination of the ganglion cell axons that compose the optic nerve. This is thought to be an immune-mediated process.

## Prevention

Disease-modifying therapies have been shown to reduce risk of neurologic relapses in patients with MS or NMOSD. These therapies presumably also decrease the risk of MS-, NMOSD-, or recurrent MOG-IgG-associated optic neuritis because optic neuritis is a common relapse syndrome in these conditions.

## Clinical Manifestations

A typical optic neuritis patient experiences acute or subacute loss of vision characterized by decreased visual acuity, visual field loss, and/or color vision loss, accompanied or preceded by pain in the affected eye that is worse with eye movements. However, 8% of patients do not have pain. Other symptoms include positive visual phenomena in 30% of patients. Other signs include a relative afferent papillary defect in cases where one eye is affected and a mildly swollen optic nerve head in approximately one-third of patients. Optic neuritis in NMOSD is more likely to have bilateral involvement and severe visual impairment. The spectrum of MOG-IgG-associated optic neuritis is being defined with initial case series describing a higher prevalence of and more severe optic nerve head swelling than MS- or NMOSD-associated optic neuritis.

The natural history of clinically isolated optic neuritis includes resolution of pain 3 to 5 days after onset and nadir of vision 7 to 14 days after onset. Spontaneous improvement in vision is typically evident within 3 weeks, and almost 70% of affected patients recover 20/20 visual acuity even in the absence of treatment. MOG-IgG associated optic neuritis also usually has a favorable final visual outcome. Optic neuritis associated with NMOSD tends to have less spontaneous recovery of vision and early recognition is important due to benefits of early treatment.

## Diagnosis

The diagnosis is based on the clinical presentation. Where there is uncertainty, magnetic resonance imaging (MRI) of the orbits, including fat-saturated sequences (T2 and T1 with and without gadolinium contrast), can help visualize inflammation in the retrobulbar optic nerve. Changes on MRI involving the chiasm or more than 50% of the optic nerve are suggestive

of NMOSD optic neuritis. MOGAD optic neuritis also has distinct imaging features, including peripoptic nerve sheath enhancement.

Optic neuritis is often associated with other demyelinating syndromes, most commonly MS. Therefore it is important to screen for historical and current neurologic impairment through history and examination. MRI and/or and cerebrospinal fluid analysis documenting evidence of dissemination in time and space is diagnostic of MS in patients with clinically isolated optic neuritis. In addition, for patients not meeting criteria for MS at time of presentation with clinically isolated optic neuritis, MRI of the brain has been shown to be an important prognostic indicator for development of MS. MRI of the brain showing 0, 1, or more than 3 lesions typical for MS is associated, respectively, with a 25%, 60%, and 78% risk of progression to clinically definite MS.

Less commonly, optic neuritis is associated with other demyelinating syndromes such as NMOSD. This should be considered in patients with severe vision loss, bilateral involvement, or history of prior optic neuritis or transverse myelitis. A serum antibody, aquaporin-4 (AQP-4)-IgG, has been identified as a pathologic agent in this disorder. Testing for this is commercially available with a published sensitivity and specificity of 63% and 99%, respectively. Positive testing for AQP4-IgG in a patient with optic neuritis is diagnostic of NMOSD per published consensus criteria. A serum MOG-IgG is commercially available and aids in the identification of MOGAD optic neuritis.

### Differential Diagnosis

Other diagnostic considerations in a patient with unilateral painful vision loss without explanatory pathology evident on ophthalmic examination include other optic neuropathies such as those due to sarcoidosis, lupus, vasculitis, neoplastic, vascular, and infectious causes. Atypical features for optic neuritis such as systemic symptoms, history of cancer, pain that persists beyond 2 weeks, progressive vision loss beyond 14 days, no spontaneous improvement in vision, retinal hemorrhages, cotton-wool spots, or macular exudates should prompt diagnostic evaluation for etiologies other than optic neuritis.

### Treatment and Monitoring

The Optic Neuritis Treatment Trial (ONTT) was a randomized trial comparing placebo, oral prednisone, and IV methylprednisolone (1 g/day IV for 3 days) followed by oral prednisone (1 mg/kg per day for 11 days) for acute optic neuritis. IV steroids hastened recovery of vision without affecting final visual outcome compared with placebo treatment. Treatment with low-dose oral prednisone alone (1 mg/kg/day for 14 days) was associated with an increased risk of relapse compared with placebo treatment. The 15-year follow-up results, published in 2008, demonstrated persistence of visual recovery. Studies have demonstrated non-inferiority of high-dose oral steroids (1250 mg prednisone/day for 3 days) to IV methylprednisolone with regards to vision recover following acute optic neuritis.

Many clinicians offer IV or high-dose oral steroid treatment to hasten visual recovery. Monotherapy with low-dose oral prednisone should be avoided. Regardless of the decision to treat or not with steroids, all patients should be monitored closely. Continued progression of vision loss, failure to spontaneously recover vision, or persistent pain should prompt additional diagnostic workup as well as consideration for additional IV steroid therapy for atypical optic neuritis. If this is not effective, plasma exchange has been reported as an effective acute therapy for atypical optic neuritis including NMOSD optic neuritis.

In patients with acute optic neuritis and NMOSD or acute optic neuritis on the NMO-spectrum, treatment with plasma exchange or rituximab (Rituxan)<sup>1</sup> should be considered to improve functional visual outcome.

In patients with a clinically isolated syndrome, consideration should be given to institution of disease-modifying therapy for MS based on the type and number of lesions on brain MRI and oligoclonal bands in cerebrospinal fluid. Several clinical trials have shown an association between early treatment with MS therapies and decreased incidence of progression to clinically definite MS in patients with a recent clinically isolated syndrome and clinically silent lesions on brain MRI.

In patients who meet diagnostic criteria for either MS or NMOSD, consideration should be given to treating the underlying disease. Eculizumab (Soliris) has shown to reduced risk of relapse and increased remission rate in AQP-4-IgG-positive NMOSD. Decisions regarding chronic therapy following MOGAD optic neuritis are currently based on recurrence and persistently elevated serum antibody titers.

### Complications

Though more than 70% of patients with optic neuritis recover objectively normal visual acuity, many have residual subjective visual disturbances. These often worsen or recur in heat, which is known as Uhthoff's phenomenon.

Complications of steroid therapy include insomnia, agitation, and stomach irritation. Long-term side effects of steroid treatment for this condition are rare owing to the brief period of treatment. Complications of disease-modifying therapies for MS-, NMOSD-, and MOG-IgG-associated disease are reviewed elsewhere.

<sup>1</sup>Not FDA approved for this indication.

## PARKINSON DISEASE

Method of

Jessica Tate, MD

### CURRENT DIAGNOSIS

- Clinical diagnosis based on four cardinal features:
  - Bradykinesia
  - Rigidity
  - Resting tremor
  - Postural instability
- Supportive features: asymmetric onset, response to dopaminergic medication, and presence of nonmotor features such as REM behavior disorder and anosmia.
- Single-photon emission tomography or olfactory testing may aid diagnosis in specific circumstances.

### CURRENT THERAPY

- Initial symptomatic treatment with monoamine oxidase-B (MAO-B) inhibitor, dopamine agonist, or carbidopa/levodopa.
- Carbidopa/levodopa (Sinemet) first line for patients >70; should be initiated in younger patients when severity of motor symptoms warrants it, rather than strict levodopa-sparing approach.
- Anticholinergic can be used as first-line treatment in younger patients with predominant tremor.
- MAO-B inhibitor, dopamine agonist, or catechol-O-methyltransferase (COMT) inhibitor can be added to levodopa to reduce on-off fluctuations.
- Amantadine (Symmetrel) can reduce levodopa-induced dyskinesias.
- Deep brain stimulation (DBS) is effective for patients with medication-refractory tremor.
- DBS or carbidopa/levodopa enteral suspension (Duopa) is more effective than oral medication alone for patients with severe motor fluctuations.
- Exercise is crucial at all stages and may have neuroprotective benefits.

### Epidemiology

Parkinson disease (PD) affects roughly 1% of the population over the age of 60 years and is projected to affect approximately 1.2 million people in the United States by 2030. Updated epidemiologic studies are currently under way. PD is more common in men than women and is suggested to be more common in whites than other racial groups, although this may relate to disparities in healthcare. The average age of onset is in the seventh decade of life, but onset is before age 40 in 3% to 5% of cases. Ninety percent of cases are considered sporadic or idiopathic, whereas approximately 10% are inherited.

### Risk Factors

Age is the most significant risk factor. Other proposed risk factors include exposure to pesticides, herbicides, solvents, and well water. Cigarette smoking, coffee consumption, regular exercise, and elevated uric acid levels may be protective. Risk of PD is doubled in first-degree relatives of those affected.

### Pathophysiology

The formation of Lewy bodies, intracellular accumulations of the protein  $\alpha$ -synuclein, is central to the pathogenesis of PD. This leads to degeneration of dopamine-producing neurons in the substantia nigra pars compacta, setting off a chain of altered

signaling in the basal ganglia and ultimately reduced activation of the motor cortex. However, Lewy body deposition and neurodegeneration also occurs in other brain regions, perhaps well before the degeneration of the substantia nigrae. This may explain the myriad nonmotor manifestations of PD, such as early loss of smell and REM behavior disorder, which are under consideration as prodromal symptoms of PD.

Unfortunately, the pathophysiological process that leads to Lewy body formation is not well understood at this time, and several different mechanisms have been proposed. PD is likely caused by a combination of genetic predisposition and environmental factors, which may differ from one individual to another depending on the specific gene or genes responsible. Early disease-modifying interventions, when they become available, are likely to target specific genetic subtypes, and thus genetic testing will likely play a more crucial role in the future diagnosis and treatment of PD.

### Clinical Manifestations

The hallmark signs and symptoms of PD are bradykinesia (slow, small-amplitude movement or lack of movement), muscle rigidity (increased resistance to passive movement of the joints that is not velocity-dependent), and resting tremor. Although tremor is a common presenting symptom in PD, some patients with PD *never* develop tremor. The other hallmark symptoms of gait dysfunction and postural instability (loss of postural reflexes crucial to maintaining balance) are uncommon in the early stages of PD but occur later in the disease course.

Loss of dexterity with fine motor tasks, micrographia (small handwriting), hypophonia (soft speech), masked facies (diminished facial expression and reduced blinking), shortened strides, and decreased arm swing while walking are all potential manifestations of bradykinesia.

Rigidity can lead to complaints of stiffness, aching, or cramping. This symptom can lead a patient to explore musculoskeletal causes, such as seeking out a specialist in sports medicine, before realizing it has a neurologic basis. Many physicians believe “cogwheeling” to be specific to a diagnosis of PD. However, cogwheeling typically will not be evident in PD patients without tremor. In addition, patients with essential tremor can exhibit cogwheeling without underlying rigidity.

Parkinsonian tremor most classically starts in one hand, although it can be seen in the jaw and lower extremity as well. It has a slow frequency (4 to 6 Hz) and is visualized with the affected body part at rest. It is often enhanced by distraction (conversation, having the patient perform calculations or name the months backward) and can be temporarily alleviated by concentration or repositioning. When a patient with PD tremor extends an affected upper extremity, the tremor may reappear after a delay. This is referred to as “reemergent rest tremor” and differs from essential tremor, which is typically present immediately on extending the arms.

Early gait changes can include bent posture and shuffling or dragging of the feet, often initially on one side of the body. Later gait changes can include freezing (hesitancy and difficulty initiating a stride with a sensation of feeling stuck to the floor) and festination (a series of small, rapid steps with a sensation of being propelled forward and unable to stop). Postural instability is assessed with the “pull test,” in which the examiner stands behind the patient and tugs back firmly on his or her shoulders. An abnormal response is defined by taking two or more steps backward or, in severe cases, by complete lack of response, leading to the examiner catching the patient as he or she falls back.

### Diagnosis

The diagnosis of PD is still made clinically in most cases, with a detailed history and neurologic examination. Often, the United Kingdom Parkinson's Disease Society Brain Bank Criteria is used, which requires the presence of bradykinesia along with at least one other cardinal feature as described above. When patients are seen by a movement disorders specialist (a neurologist with additional subspecialty training in PD and related conditions), these clinical features are often objectively scored and tracked over time using a

**TABLE 1** Recognition and Management of Common Nonmotor Symptoms in Parkinson Disease.

SYMPTOMS	MANAGEMENT SUGGESTIONS	CONSIDERATIONS
Mood disorders Depression Anxiety disorders	If periodic, optimize PD treatment to minimize on-off fluctuations If more static, typical individualized treatment options including selective serotonin reuptake inhibitors (SSRIs), serotonin and norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), counseling, psychotherapy, transcranial magnetic stimulation, etc.	Multiple antidepressants shown to be safe in combination with MAO-B inhibitors, but be aware of rare risk of serotonin syndrome
Sleep disturbances REM sleep behavior disorder (REM-BD) Insomnia Restless leg syndrome (RLS)	For REM-BD, melatonin <sup>7</sup> or clonazepam (Klonopin) <sup>1</sup> at bedtime For insomnia, sleep hygiene counseling, screening for sleep apnea with referral for sleep study if warranted, management of nocturia, treatment of nocturnal stiffness or cramping, etc. For RLS, iron supplementation if ferritin <75, dopamine agonists, gabapentin (Neurontin) <sup>1</sup>	Avoidance of sedative hypnotics due to high risk of adverse effects
Psychosis Illusions Hallucinations Delusions	Lower PD medication dosages <i>if</i> possible; discontinuation of other potential offending medications Acetylcholinesterase inhibitors, quetiapine (Seroquel) <sup>1</sup> or clozapine (Clozaril) <sup>1</sup> , pimavanserin (Nuplazid)	If acute, requires full medical/neurologic evaluation for infection and other possible causes
Constipation	Hydration, exercise, removal of offending medications if possible PEG 3350 (Miralax)	
Urinary dysfunction	Mirabegron (Myrbetriq) may be helpful for patients without benign prostatic hypertrophy	Urodynamic testing recommended, since multiple factors may be at play (such as BPH) Caution regarding anticholinergics; possible delirium
Orthostatic hypotension	Abdominal binder or compression stockings Midodrine (Proamatine), fludrocortisone (Florinef) <sup>1</sup> , or droxidopa (norepinephrine precursor) (Northera)	Extra caution in the hour following levodopa doses Must balance with supine hypertension, which may improve by raising head of bed 30 degrees or a nighttime antihypertensive
Fatigue	Exercise, treatment of depression or sleep disorders if present Avoiding under-medication of PD symptoms Selegiline (Eldepryl), amantadine (Symmetrel) Stimulants such as methylphenidate (Ritalin) <sup>1</sup> (rarely, in extreme cases)	
Drooling	Hard candy or gum RimabotulinumtoxinB (Myobloc) or incobotulinumtoxinA (Xeomin) injections in salivary glands Sublingual atropine <sup>1</sup>	
Weight loss	Monitoring, nutritional supplementation, referral to nutritionist	Associated with negative outcomes in PD including dementia and earlier death; unclear if causal

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

MAO-B, Monoamine oxidase type B; PD, Parkinson disease.

validated measure such as the Unified Parkinson's Disease Rating Scale. Additional supportive diagnostic criteria are also required, which can include unilateral onset, persistent asymmetry, progression with time, and response to levodopa. Patients also should be questioned about the presence of specific nonmotor symptoms suggestive of PD. These can include loss of smell or presence of REM sleep behavior disorder, which can precede onset of motor symptoms by years or even decades, and autonomic symptoms such as constipation, urinary frequency and urgency, sexual dysfunction, or drooling. These are discussed further in [Table 1](#).

### Differential Diagnosis

The differential diagnosis for PD varies somewhat depending on age of onset. In young patients, secondary Parkinsonism should be excluded with testing for Wilson disease. Dopa-responsive dystonia (DRD) can also mimic PD in younger patients. Drug-induced Parkinsonism, usually secondary to dopamine-blocking agents such as atypical antipsychotics or antiemetics, can occur at any age. In older patients, vascular Parkinsonism can resemble idiopathic PD but is secondary to accumulation of significant chronic microvascular ischemic changes, often in the periventricular brain regions, or an accumulation of acute cerebral infarcts over time. These findings can be easily visualized on a noncontrast magnetic resonance imaging (MRI) scan of the brain. An MRI

scan can also reveal disproportionate enlargement of the ventricles that may raise suspicion for normal pressure hydrocephalus, a poorly understood and somewhat controversial condition that can lead to a shuffling gait or freezing of gait resembling PD. Atypical Parkinsonism syndromes include progressive supranuclear palsy (PSP), multiple systems atrophy (cerebellar and Parkinsonian types), corticobasal degeneration, and Lewy body dementia. These conditions can be very difficult to differentiate from idiopathic PD early in their course. Red flags include symmetric onset, lack of response (distinguished from intolerance) to an appropriate dose of levodopa, and early onset of symptoms typically seen in advanced stages of PD such as gait freezing, postural instability, severe autonomic dysfunction such as symptomatic orthostatic hypotension, or hallucinations.

In specific situations, particularly those in which DRD, vascular Parkinsonism, or drug-induced Parkinsonism are suspected, a [<sup>123</sup>I]FP-CIT single-photon emission tomography scan—known as a DaTscan—can be used to provide supportive information. This scan is designed to detect reduced presynaptic dopamine activity in the caudate and putamen. Uptake is expected to be normal in essential tremor, DRD, drug-induced Parkinsonism, and most cases of vascular Parkinsonism, whereas it is reduced in neurodegenerative Parkinsonism. A major limitation of the DaTscan is its inability to differentiate between PD and atypical Parkinsonism such as PSP.

**TABLE 2** Medication Choices in Early Parkinson Disease.

DRUG CLASS	MEDICATION NAMES	TYPICAL DOSE RANGE	SIDE EFFECTS TO CONSIDER	COMMENTS
MAO-B Inhibitors	Selegiline (Eldepryl)	5 mg daily to 5 mg BID	Insomnia, confusion, hallucinations	Controversy re: neuroprotective benefits Potential medication interactions (serotonin syndrome)
	Rasagiline (Azilect)	0.5–1 mg daily		
Anticholinergics	Benzotropine (Cogentin)	0.5 mg daily to 1 mg TID	Dry mouth, cognitive impairment, hallucinations, urinary retention, blurred vision	Useful for tremor, high risk in elderly
	Trihexyphenidyl (Artane)	1 mg daily to 3 mg BID		
Dopamine Agonists	Pramipexole (Mirapex)	IR 0.125–1.5 mg TID ER: 0.375–4.5 mg daily	Nausea, leg edema, weight gain, daytime sleepiness, impulse control disorders, hallucinations Patch: skin irritation	Less favorable side effect efficacy profile than levodopa
	Ropinirole (Requip)	IR 0.25–8 mg TID XL: 2–24 mg daily		
	Rotigotine (Neupro)	Transdermal 2–8 mg/24 h		
Oral Levodopa Preparations	Carbidopa/levodopa (Sinemet) C/L controlled release (Sinemet CR)	25/100 mg BID-TID to 50/200 mg BID-TID	Nausea, daytime sleepiness, orthostatic hypotension, hallucinations	Dyskinesias are a long-term complication of therapy

*BID*, Two times daily; *C/L*, carbidopa/levodopa; *ER*, extended release; *MAO-B*, monoamine oxidase type B; *PD*, Parkinson disease; *TID*, three times daily.

## Treatment

Exercise is believed to have neuroprotective benefits and should be strongly encouraged in all stages of PD. Most emphasis has been on cardiovascular forms of exercise, but strength and balance training are likely to be beneficial in this population as well. There are multiple Parkinson's-specific exercise programs appearing nationwide, including stationary cycling, noncombat boxing, and dance.

Symptomatic medication is often initiated either when tremor becomes bothersome, or when motor disability is affecting day-to-day activities. A sizable minority of patients with PD may have medication-refractory tremor, an important point to keep in mind because a patient with isolated tremor and lack of improvement with dopaminergics should not necessarily be considered a non-responder. Dopaminergics may still be useful to those patients in the future for symptoms such as bradykinesia and rigidity.

For early-stage PD, there are three classes of drugs that are frequently used: monoamine oxidase (MAO)-B inhibitors, dopamine agonists, and levodopa. Levodopa may be chosen as initial therapy in a patient 70 years of age or older because of the lower potential for side effects. In younger patients, it is common to start with an MAO-B inhibitor or dopamine agonist and escalate to levodopa if either of those are poorly tolerated or ineffective. Although a levodopa-sparing strategy has been commonly adopted by clinicians, evidence suggests that earlier initiation of levodopa is associated with better long-term outcomes for patients. Regardless of the patient's age, levodopa should be started when the patient is experiencing disabling symptoms that have not responded to other medication choices. Especially for patients on levodopa, it is best practice to treat with the lowest effective dose to help reduce the risk of dyskinesias. This symptom will be discussed in further detail in the next section. Typical dosages and side effects to consider can be found in Table 2.

Patients with moderate to advanced PD have typically reached a degree of symptom severity that necessitates levodopa. Eventually,

they will begin to develop medication fluctuations. These include wearing-off of symptomatic benefits before the next dose, erratic failures of dosages to take effect, and dyskinesias. Dyskinesias are rocking, writhing, or twisting movements that can affect any region of the body. They most commonly occur at the peak of a levodopa dose but, for some patients, can occur at the end of a dose or in a biphasic manner. The pathophysiology behind dyskinesias is not fully understood, but they are believed to be a function of both disease stage and dosage of levodopa. If dyskinesias are not bothersome to the patient, they do not require treatment. If they are bothersome, dosage reduction can be considered but is not always possible due to worsening of motor symptoms. The addition of amantadine (Symmetrel) can be helpful. For early wearing-off, dosing—particularly frequency—of levodopa can be modified, or adjunctive medication can be used such as an MAO-B inhibitor, a dopamine agonist, or a COMT inhibitor. Patients should also be counseled about the potential effect of protein on levodopa absorption and encouraged to space their doses 30 to 60 minutes from meals. For dose failures or abrupt wearing-off, apomorphine can be used to provide rapid onset of symptom relief. Typical dosages and side effects of drugs used for advanced PD are summarized in Table 3. When medication fluctuations are severe, the patient may be considered for an advanced treatment option such as DBS or carbidopa-levodopa enteral suspension (Duopa). The ideal candidate for DBS has idiopathic PD, does not have dementia, and is typically receiving less-than-ideal benefit from medications for one of two reasons. In the first circumstance, levodopa is providing definite symptom reduction, but medication fluctuations have become a significant problem. In the second circumstance, the patient has medication-refractory tremor with or without additional troublesome motor symptoms. The enteral suspension, delivered continuously to the small intestine via a percutaneous endoscopic transgastric jejunostomy (PEG-J) tube and pump, is for patients experiencing significant motor fluctuations with oral medications.

**TABLE 3** Medication Choices in Advanced Parkinson Disease.

DRUG CLASS	MEDICATION NAMES	TYPICAL DOSE RANGE	SIDE EFFECTS TO CONSIDER	COMMENTS
MAO-B Inhibitors	Selegiline (Eldepryl)	5 mg daily to 5 mg BID	Insomnia, confusion, hallucinations	Adjunct to levodopa
	Rasagiline (Azilect)	0.5–1 mg daily		
	Safinamide (Xadago)	50–100 mg daily		
Dopamine Agonists	Pramipexole (Mirapex)	IR 0.125–1.5 mg TID ER: 0.375–4.5 mg daily	Nausea, leg edema, weight gain, daytime sleepiness, impulse control disorders, hallucinations	Adjunct to levodopa
	Ropinirole (Requip)	IR 0.25–8 mg TID XL: 2–24 mg daily		
	Rotigotine (Neupro)	Transdermal 2–8 mg/24 h	Skin irritation	
	Apomorphine (APOKYN)	Subcutaneous 0.2 mL (2 mg) to 0.6 mL (6 mg)	Orthostatic hypotension, nausea	Rapid onset used as rescue medication
	Apomorphine (Kynmobi)	Sublingual 10–30 mg, up to 5 times daily	Orthostatic hypotension, nausea	Rapid onset, used as a rescue medication
	COMT Inhibitor	Entacapone (Comtan)	200 mg with each dose of levodopa, up to 8 times daily	Orange urine, diarrhea
Opicapone (Ongentys)		50 mg at bedtime	Constipation, hypotension, weight loss	Used to prolong levodopa effects Can worsen dyskinesias
Levodopa Preparations	C/L (Sinemet) C/L controlled release (Sinemet CR)	Variable—total of 1200–2500 mg levodopa/d	Nausea, daytime sleepiness, orthostatic hypotension, hallucinations	Escalating dosage and frequency in advanced PD to combat wearing-off, must be balanced with side effects
	C/L ER capsules (Rytary)	23.75 mg/95 mg TID—variable		
	C/L/entacapone (Stalevo)	25/100/200 mg TID to 50/200/200 mg 6 times/d	Orange urine, diarrhea	
	Levodopa inhalation powder (Inbrija)	84 mg 1–5 times daily	Cough, upper respiratory infection, nausea, discolored sputum	Used as rescue medication for off periods Contraindicated in patients with lung disease
	NMDA Antagonist	Amantadine (Symmetrel)	50 mg daily to 100 mg TID	Livedo reticularis, leg edema, insomnia, dry mouth, confusion, hallucinations, myoclonus
Amantadine ER (Gocovri)		137–274 mg nightly		FDA-approved for PD dyskinesia May reduce off time as well
Amantadine ER (Osmolex ER)		129–322 mg		

C/L, Carbidopa/levodopa; COMT, catechol-O-methyltransferase; ER, extended release; MAO-B, monoamine oxidase type B; NMDA, N-methyl-D-aspartate PD, Parkinson disease; TID, three times daily.

### Monitoring

Swallowing function should be monitored periodically, typically with a modified barium swallow, and modifications in diet and swallowing technique may reduce aspiration risk. A cognitive screening tool such as the Montreal Cognitive Assessment should be administered yearly. Supportive treatment strategies should be used on an ongoing basis, including speech/swallow therapy, physical therapy, and occupational therapy. Therapists with specific training in neurologic disorders should be used when possible. PD-specific programs such as the Lee Silverman Voice Therapy Loud (speech therapy) and Big (physical therapy) programs are particularly helpful.

### Complications and Nonmotor Symptoms

Nonmotor symptoms of PD can be more disabling in some cases than the more well-known motor symptoms. These are summarized in Table 1. Depression and anxiety, in particular, affect high numbers of patients with PD. Psychosis is not an inevitable occurrence but affects approximately 50% of patients, usually in more advanced stages of the disease. When PD psychosis is causing fear or agitation, it should be treated with an escalating strategy. Typically, acetylcholinesterase inhibitors will be introduced first, followed by either low-dose quetiapine (Seroquel)<sup>1</sup> or

<sup>1</sup>Not FDA approved for this indication.

pimavanserin (Nuplazid) if symptoms are not stabilized. Pimavanserin is the only drug approved by the Food and Drug Administration for Parkinson's psychosis. Atypical antipsychotics have been associated with an increased risk of death in the elderly, and deaths have also been reported in patients receiving pimavanserin, although causality is not necessarily clear. Risks and benefits must be carefully weighed, but currently these medications may be the only option for a patient experiencing severe psychosis.

The gradual progression of PD is inevitable but highly variable in speed and severity from one individual to another. This is likely dependent on age of onset, other comorbid health conditions, access to expert care, and level of physical activity among other factors. Abrupt worsening of any symptoms of PD should prompt a workup for provoking medical conditions, such as occult urinary tract infection. PD does not directly lead to death, but death can occur in the setting of dysphagia leading to failure to thrive or aspiration pneumonia, or from serious injuries incurred from falls.

## REHABILITATION OF THE STROKE PATIENT

Method of

Marlís González-Fernández, MD, PhD; and Dorianne Feldman, MD, MSPT

### CURRENT THERAPY

- Stroke rehabilitation improves functional outcomes.
- A comprehensive rehabilitation team composed of physicians, nurses, therapists, and community reintegration professionals can achieve the best outcomes.
- Early evaluation of family support and the home environment is critical to prevent unnecessary institutionalization.
- Evaluation and management of modifiable stroke risk factors, such as smoking, hypertension, and diabetes mellitus, are imperative during stroke rehabilitation to prevent stroke recurrence.
- Rehabilitation of the stroke patient can be hindered by conditions such as pneumonia (usually caused by aspiration), deep venous thrombosis, urinary tract infections, shoulder pain, depression, and spasticity. Early identification and treatment of these conditions are necessary to maximize functional outcomes.

According to the U.S. National Center for Health Statistics, 5.6 million Americans live with disability caused by a previous stroke. Stroke is the leading cause of permanent disability in adults. Conservative estimates suggest that about 45% of stroke patients have moderate to severe disabilities requiring rehabilitation.

The goals of stroke rehabilitation are to maintain and optimize medical management, to maximize functional recovery, to minimize disability, and to improve quality of life and participation in society. The rehabilitative approach endeavors to provide patient-centered care that is organized, comprehensive, and specific to the needs of the stroke patient. The concerted efforts of the patient, family, and rehabilitation team are essential to achieve these goals. Recovery after stroke can be a long and challenging process for the patient and the family. Although functional gains occur most rapidly in the first year after a stroke, additional motor recovery is possible beyond 1 year when patients are involved in targeted rehabilitation programs.

The rehabilitation team is composed of rehabilitation physicians (physiatrists), other physicians such as neurologists and neurosurgeons, rehabilitation nurses, occupational therapists, physical therapists, speech and language pathologists, rehabilitation neuropsychologists, social workers, case managers, nutritionists, vocational counselors, and pharmacists. A goal of the acute inpatient rehabilitation team is to discharge the patient to the least restrictive environment, ideally home. To accomplish this goal, it is critical to evaluate family support and the home environment.

Rehabilitation should start as part of the acute stroke inpatient stay. The decision-making process to determine the appropriate rehabilitation setting after discharge is described in [Figure 1](#). Speech-language pathologists, physical therapists, and occupational therapists evaluate deficits in cognition, communication, deglutition, mobility, and activities of daily living. The severity of deficits in these major areas and the ability of the patient to tolerate therapy determine the appropriate rehabilitation setting.

Stroke patients with mild deficits are able to return home with home or outpatient therapy services. Patients with moderate to severe strokes benefit from more intensive therapy in an institutional setting. Comprehensive inpatient rehabilitation is suitable for patients with moderate to severe deficits who can tolerate intensive rehabilitation (3 hours of therapy per day for 5 days each week or 15 hours of therapy over a 7-day period). If the severity of deficits or medical comorbidities limits the ability of the patient to participate in intensive therapy, alternate settings can be considered.

During the inpatient rehabilitation stage, medical management focuses on secondary stroke prevention in terms of diet; exercise; smoking cessation; and reduction of complications, including optimization of blood pressure control while maintaining cerebral perfusion; prevention and treatment of lipid disorders; and management of poststroke pain, depression, and abnormal muscle tone. During this stage, much of the rehabilitation effort is directed toward educating stroke survivors about complications and the importance of adherence to medical recommendations.

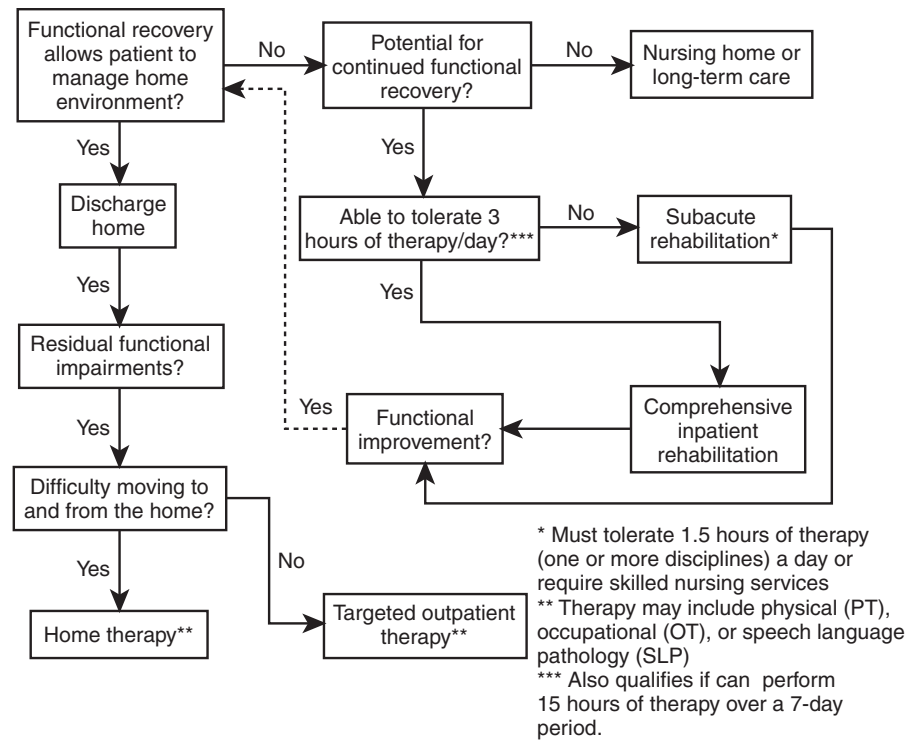

Medical complications, such as deep venous thrombosis and related thromboembolism, pneumonia (usually related to aspiration), skin breakdown, and urinary infections, can hinder a patient's recovery. Early identification of these complications is necessary to maintain progress in the rehabilitation effort. Other complications, such as seizures and cardiac decompensation, are possible and should be monitored.

Stroke often causes significant impairment and activity limitations. Deficits in strength, swallowing, vision, balance, muscle tone, communication, comprehension, cognition, attention, sensory perception, and bladder function are common and can cause difficulty completing activities of daily living, walking, transferring to and from different surfaces, and getting in and out of bed. Post-stroke depression, fatigue, and pain are common and should be addressed to maximize participation in rehabilitative efforts.

Transition to the chronic phase begins after the patient is medically stable and inpatient therapy goals are met. Outpatient therapy services are initiated in conjunction with psychiatric, primary care, and neurologic follow-up.

### Hemiparesis

Hemiparesis, or one-sided weakness, is one of the most frequent complications after stroke. Recovery of motor function varies. Often, it is limited by muscle atrophy, co-contraction of agonists and antagonists, and abnormal tone. Usually, motor recovery is

**Figure 1** Determination of rehabilitation needs of patients being discharged after an acute stroke.

preceded by the development of patterned muscle movements, or synergies. Synergies occur when select muscles contract in a predictable manner. In the paretic upper extremity, a flexion synergy pattern (i.e., humeral adduction, internal rotation, elbow flexion, forearm pronation, and wrist and finger flexion) is common. In the lower extremity, extension synergies (i.e., hip internal rotation, adduction, extension, knee extension, and ankle extension and inversion) predominate. These patterns can be regarded as functional and nonfunctional. For instance, extension synergy patterns of the lower limb can augment rehabilitation because this position fosters early ambulatory therapy. Conversely, flexion synergy patterns in the upper extremity can significantly impair arm function.

Rehabilitation of the patient with hemiparesis should concentrate on maintaining range of motion and improving strength and posturing. Exercise programs should incorporate functional use of the hemiparetic limb and weight bearing to promote limb recognition, better alignment, muscle elongation, and muscle tone reduction. Bilateral movement in conjunction with sensory training has demonstrated benefit in post-stroke rehabilitation by triggering dual neural networks to be active in both hemispheres to increase motor recovery.

Hemiparesis can lead to contracture, particularly when profound weakness is present, and contracture occurs most commonly in the wrist and ankle. Resting hand splints and solid ankle-foot orthoses can be used to maintain the limb in a neutral position. These devices can be used to prevent loss of motion, control muscle tone, and aid in positioning, particularly when a wheelchair is necessary.

Functional electrical stimulation (FES) has gained increasing interest as a means of enhancing functional movement and strength. Muscle contraction is induced with electrical stimulation. Many products on the market incorporate FES technology for the treatment of footdrop and hand weakness.

Preservation of scapulohumeral positioning is a critical component of rehabilitation. With shoulder weakness, the scapula becomes downwardly rotated, which causes the glenoid fossa to move vertically and result in humeral subluxation. Traditionally, shoulder slings have been prescribed for the hemiplegic shoulder, but their effectiveness in preventing subluxation is questionable.

FES has been used to augment motor return in the hemiplegic shoulder and prevent subluxation. Despite advances in the

treatment of the hemiplegic shoulder, it is still unclear which therapeutic interventions should constitute the standard of care.

Constraint-induced therapy (CIT), a therapeutic approach in which the nonparetic limb is restrained, can improve functional movement of the paretic upper extremity in patients with residual hand and wrist movement, even in patients more than 1 year after a stroke. More recently, CIT concepts have been applied to the treatment of aphasia. By limiting the use of nonverbal communication and stimulating verbal output, participants were able to improve language performance and communication.

Weight-supported treadmill training has been proposed to enhance gait training after a stroke. Although a recent clinical trial showed no clear benefit from weight-supported treadmill training on improving gait speed, walking ability, or balance, some advocate for continued research on the effects of this training on overall health, including maintaining bone mass and decreasing insulin resistance.

### Dysphagia

Dysphagia after stroke occurs acutely in approximately 50% of stroke patients. Identifying dysphagia in this population is essential for preventing associated morbidity and mortality. Stroke patients with dysphagia are at risk for dehydration, malnutrition, and aspiration pneumonia. As allowed by their overall clinical status and consciousness level, stroke patients should be evaluated as early as possible during their acute hospital stay. Trained clinicians (most commonly speech-language pathologists) should evaluate the patient to make recommendations regarding further dysphagia evaluation or testing and the need for diet modifications or dysphagia rehabilitation.

### Hemiplegic Shoulder Pain

Stroke survivors with residual hemiparesis or weakness are at risk for pain syndromes (particularly in the upper extremity), which can significantly limit rehabilitation efforts. These pain syndromes are usually multifactorial. During their rehabilitation, prevention of shoulder pain is key, and interventions should focus on proper positioning, handling, and transfer techniques.

In severe cases, shoulder pain can be accompanied by swollen hands, tenderness, skin changes, erythema, hyperhidrosis, and allodynia. When this occurs, it is referred to as *shoulder-hand syndrome*, a subtype of complex regional pain syndrome (CRPS).

**TABLE 1** Neuropharmacologic Agents Commonly Used During Stroke Rehabilitation

DRUG CLASS	DRUG NAME	INDICATION	POTENTIAL PROBLEMS
Benzodiazepines	Diazepam (Valium)	Agitation <sup>1</sup> , spasticity	Sedation, confusion, sundowning
	Lorazepam (Ativan)	Agitation <sup>1</sup> , seizures	Sedation, paradoxical reactions, confusion, sundowning
Tricyclic antidepressants (TCAs)	Nortriptyline (Pamelor) Amitriptyline (Elavil)	Depression, neuropathic pain <sup>1</sup> , central pain <sup>1</sup>	Anticholinergic effects, sedation
Selective serotonin reuptake inhibitors (SSRIs)	Sertraline (Zoloft) Escitalopram (Lexapro) Citalopram (Celexa)	Depression, stimulation <sup>1</sup>	Long titration period, suicidal ideations, serotonin syndrome, syndrome of inappropriate antidiuretic hormone (SIADH), somnolence, seizures
	Fluoxetine (Prozac)	Depression motor recovery <sup>1</sup>	As above for other SSRIs
Stimulants	Modafinil (Provigil) Methylphenidate (Ritalin)	Drowsiness <sup>1</sup> , decreased alertness <sup>1</sup> , impaired concentration <sup>1</sup> , diminished attention <sup>1</sup>	Arrhythmia, seizures, hepatotoxicity, blood pressure changes

<sup>1</sup>Not FDA approved for this indication.

Although the mechanism and cause are unclear, it has been suggested that this process is the result of an overreaction to a neurologic insult and may be inflammatory in nature. In some cases, the pain is severe, resulting in decreased and guarded movements of the limb that limit functional use. Shoulder pathology such as rotator cuff strains or tears, bicipital tendonitis, subacromial and subdeltoid bursitis, and glenohumeral subluxation or dislocation contribute to post-stroke shoulder pain and should be treated.

Nonpharmacologic treatment focuses on desensitization techniques, gentle range-of-motion exercises, and physical modalities (e.g., heat, cold, transcutaneous electrical nerve stimulation [TENS], FES). Pharmacologic management includes medications typically used for neuropathic pain syndromes, such as anticonvulsants, tricyclic antidepressants (TCAs), nonsteroidal antiinflammatory drugs, topical agents (e.g., lidocaine [Xylocaine]<sup>1</sup>, clonidine [Catapres-TTS]<sup>1</sup>, capsaicin [Zostrix]<sup>1</sup>), and injections of steroids or local anesthetics. Antispasmodic medications have been used. When pain relief is not achieved with conservative treatment, sympathetic blocks can be considered. Sympathectomies and spinal cord stimulators can be considered as a last resort.

### Spasticity

Spasticity after stroke can significantly impact rehabilitation. The classic upper extremity flexor synergy pattern (i.e., adducted shoulder with flexed elbow, wrist, and fingers) can markedly interfere with the function of the affected arm. Conversely, the classic lower extremity extensor synergy pattern (i.e., extended hip and knee and ankle plantar flexion) can be advantageous for ambulation if plantar flexion can be controlled by physical or pharmacologic agents. If untreated, these patterns can lead to abnormal positioning and contracture.

Treatment of spasticity after stroke should address positioning and exacerbating factors. Splinting or bracing, appropriate wheelchair sitting position, and physical therapy techniques are important to prevent contracture and promote motor recovery. Painful or noxious stimuli can exacerbate spasticity. Shoulder pain, pressure sores, deep venous thrombosis, bladder distention, and constipation are examples of stimuli that can exacerbate spasticity. Pharmacological treatment should take into account the presence of these triggers because spasticity is likely to improve after the stimuli are resolved or relieved.

Pharmacologic treatment of post-stroke spasticity presents some challenges. Effective antispasticity agents such as baclofen (Lioresal) or tizanidine (Zanaflex) can cause somnolence or weaken unaffected muscles, which can significantly affect rehabilitation.

<sup>1</sup>Not FDA approved for this indication.

Localized treatments such as botulinum toxins (Botox, Dysport, Myobloc, Xeomin)<sup>1</sup> injections or phenol blocks<sup>1</sup> can be useful, because treatment can be directed toward muscles that are affecting functional use of the limbs. Surgical interventions can be used for patients who have severe spasticity that limits their functional positioning or for patients with the potential for functional grip if tendon lengthening or transfer can be considered.

### Cognitive Dysfunction

Stroke patients can experience many cognitive deficits, including visuospatial neglect, cognitive-linguistic deficits, apraxia, memory loss, and attention deficits. Cognitive rehabilitation should concentrate on treatment of the specific deficits of the patient. Visuospatial rehabilitation (including scanning training) is recommended for deficits associated with visual neglect after right stroke. Cognitive-linguistic therapy should be considered for left hemispheric stroke patients with language deficits. Treatment of apraxia should include specific gestural and strategy training.

The use of medications that may impair cognitive function should be limited. Medications that are commonly considered during a stay in a rehabilitative facility that may have a significant impact on cognition and rehabilitation are listed in [Table 1](#).

### Depression and Neuropharmacology

Depression is observed in up to one-half of all stroke patients. Depression has been associated with poor functional outcomes and more severe impairments. Vegetative symptoms can have a significant impact on rehabilitative efforts because patient participation in therapy is critical.

Psychoactive drugs can be beneficial and should be considered. Selective serotonin reuptake inhibitors (SSRIs) are recommended in this population because of a better side effect profile and because of the undesirable anticholinergic side effects of TCAs. In patients who are unresponsive to treatment with SSRIs, nortriptyline (Pamelor) may be helpful. In the rehabilitation setting when rapid short-term improvement in symptoms is necessary to increase participation in therapy, the use of psychostimulants (e.g., methylphenidate [Ritalin]<sup>1</sup>) may be indicated. [Table 1](#) shows the neuropharmacologic agents commonly used during stroke rehabilitation. Psychotherapy has been associated with modest improvement in post-stroke depression and is considered to be part of a multidisciplinary approach. Research has demonstrated the benefit of the

<sup>1</sup>Not FDA approved for this indication.

**Figure 2** Adaptive equipment commonly used during stroke rehabilitation. The tapered front scoop dish (A) has nonskid feet to keep the plate from sliding. The curved edge simplifies scooping food. The dish is especially suited for patients who have limited flexibility, have decreased motor coordination, or feed using one hand, such as individuals who have had a hemiparetic stroke. The reacher (B) is used to retrieve items from the floor. The long-handled dressing aid (C) is used to reach clothes on the floor or to bring clothes up the paretic side. The long-handled shoehorn (D) facilitates slipping feet into shoes. The long-handle sponge (E) is used to reach the involved side while bathing or when the shoulder range of motion does not allow reaching. The leg lifter (F) and the sound upper limb can be used to assist in moving the paretic lower limb. Adapted feeding utensils (G) are used for patients with grip weakness or difficulties with upper limb range of motion; *left to right*: bent-handle spoon, no-grip fork, rocker bottom knife, and thick-handle spoon. No-tie laces (H) are elastic shoelaces that do not require tying. When using the sock-donning aid (I), the sock slides onto the plastic portion of the device, and the strap is used to pull the sock with the device on the foot.

antidepressant fluoxetine (Prozac)<sup>1</sup> on motor recovery; administration of the drug for 3 months as an adjunct to physical therapy improved motor functioning in post-stroke patients.

### Bladder Dysfunction

Bladder dysfunction after stroke depends on the location of the stroke. During the rehabilitation phase, the most common problem is urinary incontinence and urgency associated with uninhibited bladder contraction. Ultrasound bladder scans (usually every 4 hours and after voiding) should be ordered to detect bladder distention and urinary retention. It is standard practice to intervene in cases of bladder volume greater than 500 mL. If volume exceeds this cutoff, intermittent catheterization should be started. Intermittent catheterization is preferable to indwelling catheters because the risk of urinary tract infection is higher with the indwelling catheters. Bladder scans are usually discontinued when postvoiding residual volumes at 3- to 4-hour intervals are low (<150 mL) for a period of 24 to 48 hours.

### Mobility and Use of Adaptive Equipment

Activity limitations vary among stroke survivors and can include difficulties with bed mobility, wheelchair propulsion, transfers, gait, stairs, and the basic activities of daily living. The goal of physical therapy and occupational therapy is to maximize functional independence. Addressing mobility limitations is fundamental in stroke rehabilitation because such limitations are related to long-term care needs and independence.

Transfer training comprises learning how to maneuver from one surface or height to another. Ideally, patients should learn to roll and transfer toward their involved and uninvolved sides; however, early mobility efforts are directed to the uninvolved side to minimize the risk of injury.

Gait deviations are common after stroke and interfere with safety and efficiency of locomotion. If an assistive device is needed, the goal of physical therapy is to progress to the least restrictive device possible. Hemiwalkers and wide-based quad canes provide the most stability. An ankle-foot orthosis may be indicated for patients with decreased ankle control and footdrop. Instruction in ascending or descending stairs depends on assistive device requirements. With

weakness, stairs are ascended by initiating movement with the uninvolved or stronger lower extremity. This process is reversed when descending.

For some stroke survivors, functional ambulation is not a realistic goal. In these cases, the wheelchair becomes the primary means of locomotion. Wheelchair prescription requires considerable skill and training and must take into account posturing, body habitus, cognition, physical fitness level, and the home environment. An appropriate wheelchair prescription is required to maximize mobility and prevent complications such as shoulder pain. Physical and occupational therapists should evaluate the patient before providing wheelchair recommendations to vendors. Hemi wheelchairs (i.e., wheelchairs situated closer to the ground) and one-arm drive wheelchairs allow hemiplegic patients to use the uninvolved side for wheelchair propulsion. Lap boards with arm supports can be added to improve hemiparetic arm posturing and sitting symmetry.

For some stroke survivors, the ability to return to driving is considered one of the most important long-term rehabilitation goals. Formal driving rehabilitation programs are available to evaluate and improve driver safety. Driver rehabilitation specialists perform vision, cognitive, and perceptual examinations. Perception tests assess reaction times to visual and auditory stimuli. Values for vision and reaction times are standardized and state-dependent. Specialists should also perform a behind-the-wheel assessment, beginning in a parking lot and progressing to the negotiation of more complex traffic situations. Many modifications can increase independence and assist with a return to driving, including a spinner knob, which can be attached to the steering wheel to allow one-arm control; hand controls for acceleration and braking; left foot pedals to compensate for right foot impairment; and wheelchair lifts.

Adaptive equipment, including bracing, shoe modification, and other tools, increases independence through completion of activities of daily living (e.g., long-handled sponge, reacher, shoe horn, mirror, sock aids) and is extremely beneficial for those with moderate to severe strokes, particularly if hemiparesis is dense (Figure 2). Silverware, pens, and other utensils can be modified for easier maneuverability. Multi Podus boots can be used to prevent plantar flexion contracture development in the hemiparetic limb.

<sup>1</sup>Not FDA approved for this indication.

## Falls

Falls are common after moderate to severe strokes. In rehabilitation settings, fall prevention usually requires a multimodal approach. Strategies include use of bed-chair alarms, placing those at risk close to the nursing station, wearing skid socks, limiting or refraining from polypharmacy, eliminating slick or irregular floors, and, in some cases, providing a sitter for closer monitoring. Physical and occupational therapists must include general safety and fall recovery as part of the treatment plan.

## Visual Impairment

Depending on the location of the stroke, the visual system may be involved. One of the most debilitating visual impairments is visuospatial neglect, a complication of right hemisphere strokes. Left-sided stimuli are not attended to or recognized, and affected individuals must learn to deal with this deficit. Other complications include gaze weakness or paralysis, diplopia, visual field loss, ptosis, tracking disorders, decreased visual acuity, and cortical blindness.

Screening for primary visual skills, including visual acuity, visual fields, and visual tracking, should be done by physiatrists, neurologists, and occupational therapists. If problems are identified, patients should be referred to neuro-ophthalmologists and low-vision rehabilitation programs. Visual acuity problems often can be addressed by incorporating the use of glasses into the therapy session or by changing the prescription. Eye movement disorders and visual field deficits usually lessen as time elapses and may respond to treatment with prisms, head positioning, and unilateral eye occlusion with tape or a patch technique. Prism therapy has also shown promise in treating hemispatial neglect. Patients with continued visual field impairment should be taught eye movement techniques to expand the visual area.

## Brain-Based Therapies: Noninvasive Brain Stimulation

Repetitive transcranial magnetic stimulation (rTMS) applies a brief magnetic field to the scalp with enough intensity to penetrate the skull and induce neuronal activation. Some promising results have been seen when rTMS is used after stroke. A second modality, transcranial direct current stimulation (tDCS), applies low-voltage electrical current to stimulate or modify neuronal activity in the brain cortex. The stimulation is applied to discrete areas of the head to target affected areas. Noninvasive brain stimulation has been tested in acute, subacute, and chronic stages of stroke. Studies are evaluating the efficacy of such stimulation therapies on motor recovery, vision impairment, aphasia, and swallowing. Although the side-effect profile of these techniques is positive, more research is necessary to determine the best candidates for treatment and optimal treatment protocols.

## Robotics

The aim of robotic technology is to use an adjustable, programmable device to augment mobility in a task-specific manner. Robots can serve in an assistive capacity (perform a desired function) or therapeutic capacity (enhance gait or upper extremity function) and are suitable for this purpose. Robots not only enable more intensive therapy than conventional modes but also incorporate a greater degree of activity repetition. These technologies have shown a small impact on strength gains in the paretic upper extremity. Noninvasive brain stimulation using bilateral tDCS has also been trialed in conjunction with upper extremity robotics in chronic stroke rehabilitation and has demonstrated better results in patients with subcortical strokes as opposed to cortical strokes. The current recommendations are for robotics to be used as an adjunct to traditional rehabilitation interventions.

## Virtual Reality

Virtual reality or a computer-devised three-dimensional image has become an increasingly popular rehabilitation therapy for stroke

patients. The use of gaming systems that employ this technology are immersive, intensive, and deliver an enjoyable and repetitious means to augment task performance and possibly stimulate upper extremity motor recovery. Additionally, virtual reality gaming can be implemented at home, making it cost effective, available, and adoptable. Current research suggests no superiority when compared to traditional therapies but rather potential efficacy as a supplemental intervention.

## Conclusions

Stroke rehabilitation requires the concerted efforts of the patient, family, and medical professionals. A multidisciplinary team with training to address the particular impairments and functional limitations of the stroke patient is critical. The physician's efforts should focus on preventing complications and treating stroke sequelae with the primary goal of improving overall function and participation in society.

## SEIZURES AND EPILEPSY IN ADOLESCENTS AND ADULTS

Method of

Jose A. Padin-Rosado, MD

### CURRENT DIAGNOSIS

- Obtain a thorough clinical history, including a detailed description of the paroxysmal events from the patient and from witness accounts.
- Perform a complete physical and neurologic examination.
- Perform laboratory tests including electrolytes, blood glucose, liver function, and toxicology.
- Obtain a lumbar puncture if signs of infection are present.
- Neuroimaging is strongly recommended. Magnetic resonance imaging (MRI) is the preferred test because of its higher resolution. Head computed tomography (CT) is acceptable in the acute setting to rule out hemorrhage.
- Routine electroencephalography (EEG) with sleep deprivation and activation procedures should be performed as close to the time of occurrence of the paroxysmal event to increase the diagnostic yield.

### CURRENT THERAPY

- Choose the right medication for the type of epilepsy and epilepsy syndrome.
- Consider the side-effect profile, cost, and drug dosing schedule, and adapt to the unique patient characteristics taking into consideration the patient's comorbidities.
- Aim for monotherapy whenever possible.
- Start low and increase slowly when initiating antiseizure drug (ASD) therapy to minimize side effects and increase compliance.
- An adequate ASD trial with titration of the medication until clinical effectiveness or side effects occur is recommended.
- When switching from one drug to another, consider overlapping medications to provide protection until the first drug is discontinued.
- If the patient fails two antiseizure drug trials either in monotherapy or polytherapy, refer the patient to an epilepsy center for evaluation.
- If the patient is seizure free after 2 years of treatment, consider withdrawing ASDs for epilepsies of unknown etiology or epilepsy syndromes known to resolve.

Epilepsy is a disease characterized by an enduring predisposition to generate seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. Epilepsy is commonly defined as having two or more unprovoked seizures greater than 24 hours apart. However, as per the classification proposed by the International League Against Epilepsy (ILAE) in 2014, a single seizure can be classified as epilepsy if risk of seizure recurrence is high (see the “Classification” section later in this chapter).

A seizure is defined as transient signs or symptoms caused by abnormal excessive synchronous activity of brain neurons. Seizures can be classified as either acute symptomatic (provoked) or unprovoked. Acute symptomatic seizures are associated with a transient systemic or brain insult and will usually not require treatment with antiepileptic drugs because of the transient nature of the precipitant and the associated low risk for development of epilepsy. Unprovoked seizures, on the other hand, may represent the beginning of epilepsy.

### Epidemiology

Epilepsy is one of the most common neurologic conditions, affecting more than 50 million people worldwide. The prevalence of epilepsy (number of people with active epilepsy) is approximately 1% in the United States, with 3.4 million people (3 million adults and 470,000 children) suffering from the disease. The incidence of epilepsy (number of new cases) is around 150,000 each year or 55 per 100,000 population. The incidence is higher in patients younger than 2 years of age and in those older than 65 years of age. The risk of developing epilepsy is slightly higher in men than in women. African Americans and disadvantaged populations are affected at a higher rate than Caucasians. The lifetime risk of developing a seizure is around 9% to 10%.

### Classification

#### Definition of Epilepsy

In 2014, the ILAE published a practical definition of epilepsy. This definition classifies epilepsy as a disease of the brain characterized by any of the following criteria: at least two unprovoked or reflex seizures occurring more than 24 hours apart; one unprovoked or reflex seizure and a probability of recurrent seizures similar to the general recurrence risk (60%) after two unprovoked seizures, occurring over the next 10 years; or diagnosis of an epilepsy syndrome.

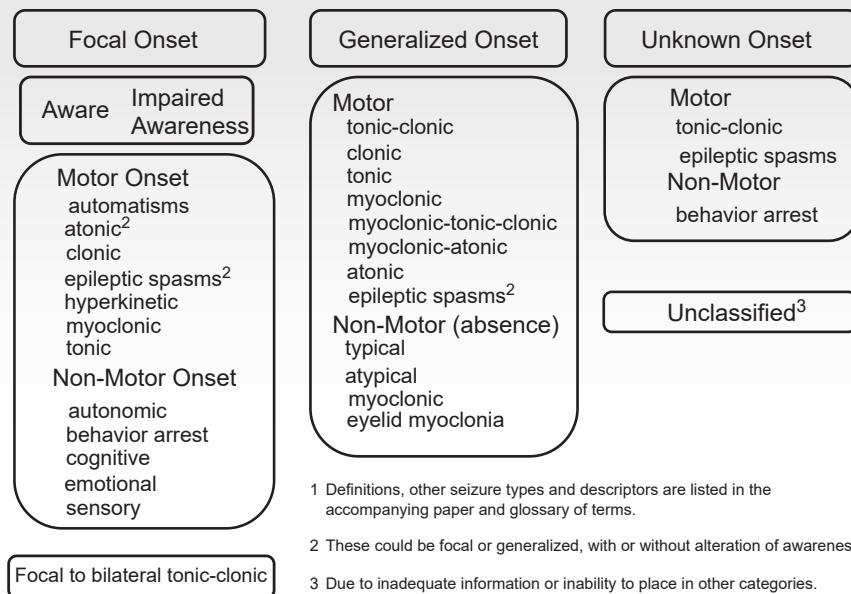

In 2017, the ILAE released a major revision of both the classification of the epilepsies and epilepsy syndromes and the classification of seizure types. The classification of the epilepsies and epilepsy syndromes has three levels: (1) classification of the seizure type, (2) classification of the epilepsy type, and (3) diagnosis of an epilepsy syndrome whenever possible. The cause and associated comorbidities are considered at each diagnostic step because these carry treatment implications.

The first step is to classify the type of seizure (Figure 1 and Box 1). It assumes that the patient has been diagnosed with an epileptic seizure and then organizes the seizures by where they originate in the brain into either a *focal-onset seizure*, formerly known as *partial-onset seizure* (emanating from networks in one lobe or hemisphere), *generalized-onset seizure* (engaging bilateral neural networks), and *unknown-onset seizures*. The term *secondary generalized seizure* is replaced by *focal to bilateral tonic-clonic seizure*, and it is placed in a special category. Then focal-onset seizures can be optionally classified into seizures with preserved awareness as *focal aware seizures* (formerly known as *simple partial seizures*) and seizures with impaired awareness as *focal impaired awareness seizures* (formerly known as *complex partial seizures*). Focal-onset seizures, generalized-onset seizures, and unknown-onset seizures can be optionally and further subdivided into whether they have associated motor symptoms or other nonmotor symptoms. In some settings, classification into seizure type will be the only attainable level possible for diagnosis because there may be no access to EEG, video, and imaging studies or too little information available to make a higher level of diagnosis.

The second step is to classify the type of epilepsy (Figure 2). This step in the classification assumes that the patient fulfills the diagnosis of epilepsy (according to the ILAE 2014 definition of epilepsy discussed earlier) and classifies the epilepsies into *focal* (focal clinical features and EEG with focal epileptiform abnormalities), *generalized* (bilateral clinical features and EEG with generalized epileptiform abnormalities), *combined generalized and focal* (features of both on clinical evaluation and on EEG), and *unknown* type (either no clinical information available and normal or no EEG available).

The third step is the diagnosis of an epilepsy syndrome whenever possible. A *syndrome* refers to a cluster of features such as seizure type, EEG findings, and imaging features that tend to occur together and may provide information regarding treatment implications and prognosis. Within the generalized epilepsies, a well-known subgroup, known as the *idiopathic primary generalized epilepsies*, exists and includes four distinct syndromes: *childhood absence epilepsy*, *juvenile absence epilepsy*, *juvenile myoclonic epilepsy*, and *generalized-tonic-clonic seizures*.

## ILAE 2017 Classification of Seizure Types Expanded Version<sup>1</sup>

**Figure 1** Classification of seizure types. From Fisher RS, Cross JH, French JA, et al.: Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology, *Epilepsia* 58(4):522–530, 2017.

<sup>1</sup> Definitions, other seizure types and descriptors are listed in the accompanying paper and glossary of terms.

<sup>2</sup> These could be focal or generalized, with or without alteration of awareness.

<sup>3</sup> Due to inadequate information or inability to place in other categories.

### BOX 1 Changes in Seizure Type Classification from 1981 to 2017

- Change of “partial” to “focal”
- Certain seizures types can be either of focal, generalized, or unknown onset.
- Seizures of unknown onset may have features that can still be classified.
- Awareness is used as a classifier of focal onset seizures.
- The terms *dyscognitive*, *simple partial*, *complex partial*, *psychic*, and *secondary generalized* were eliminated.
- New focal seizure types include automatisms, autonomic, behavioral arrest, cognitive, emotional, hyperkinetic, sensory, and focal to bilateral-tonic-clonic seizures. Atonic, clonic, epileptic spasms, myoclonic, and tonic seizures can be either focal or generalized.
- New generalized seizure types include absence with eyelid myoclonia, myoclonic absence, myoclonic-tonic-clonic, myoclonic atonic, and epileptic spasms.

From Fisher RS, Cross JH, French JA, et al.: Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology, *Epilepsia* 58(4):522–530, 2017.

From the moment the patient is diagnosed with having an epileptic seizure, a cause should be sought. Etiologies include structural etiology (structural abnormality seen on brain MRI that is strongly associated with the development of seizures), such as temporal lobe seizures from mesiotemporal sclerosis; genetic etiology (epilepsies with a presumed genetic mutation), such as benign familial neonatal epilepsy with mutation in *KNCQ2* or *KNCQ3* (potassium channels); infectious etiology, such as neurocysticercosis; metabolic etiology, such as porphyria and pyridoxine-dependent seizures; immune etiology, such as anti-NMDA receptor encephalitis and anti-LG1 encephalitis; and unknown etiology.

Comorbidities should be considered for every patient with epilepsy at each stage of classification, just like etiology. Comorbidities include learning, psychological, and behavioral problems.

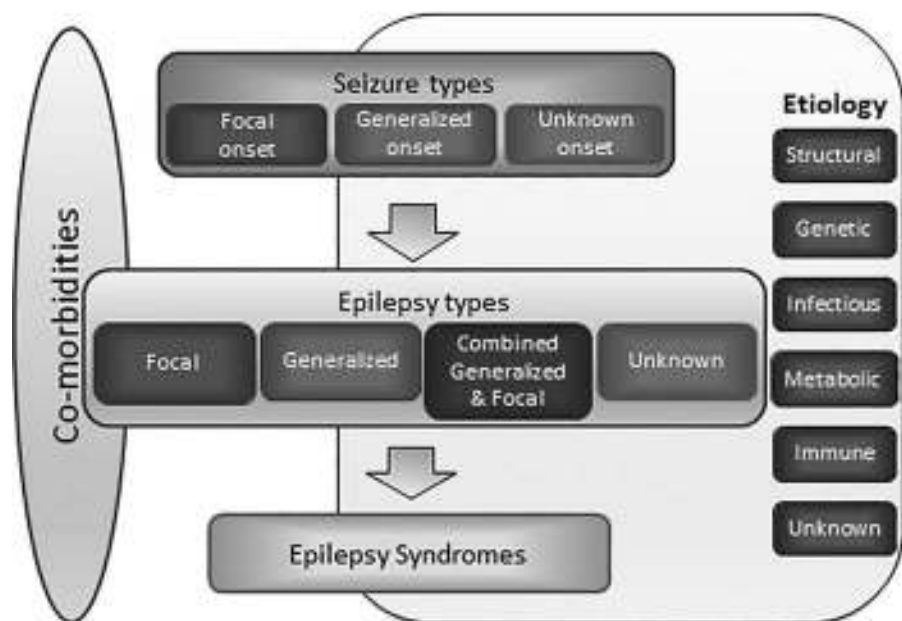

The term *benign* is replaced by *self-limiting* (likely spontaneous resolution of a syndrome) and *pharmacoresponsive* (the epilepsy syndrome will be controlled with appropriate ASD treatment). This classification is aimed at providing tools for improved diagnosis and understanding of etiology and targeted therapies to the patient’s disease.

### Diagnosis

The diagnosis of a seizure and epilepsy is largely a clinical one and is highly dependent on the history and physical examination. The clinical history should be obtained from the patient and from a witness. After the aforementioned is obtained, the information is analyzed to determine whether indeed the paroxysmal event in question represents a true seizure or a seizure mimicker. If the event of concern represents a seizure, then it is further classified into *focal* or *generalized* and into *acute symptomatic*, a transient phenomena with lower seizure recurrence, or *unprovoked*, which confers a higher risk for seizure recurrence and development of epilepsy.

The clinical history is aimed at obtaining a clear description of the prodromal or premonitory state, the pre-ictal state, the ictal state, and the post-ictal state. The prodromal state occurs hours to days before the ictus and is most commonly seen in generalized seizures (but may also occur in focal onset seizures) and consists of behavioral changes, mood swings, fatigue, and changes in sleep patterns. Regarding the pre-ictal period, the patient should be questioned about the presence of warning signs immediately before the seizure onset, also known as *auras*. An aura is a simple partial seizure or a seizure without impaired awareness. An aura points to a focal seizure onset, and we can potentially determine the lobe of onset according to the description of the aura. For example, a rising gastric sensation and a sensation of déjà vu points to seizure onset in the temporal lobe, and visual hallucinations point to the occipital lobe.

The clinician then asks the patient what happened during the event (ictal period). Issues to consider include the level of awareness, the presence of ability to speak, the presence of automatisms (lip-smacking, ipsilateral hand automatisms, and contralateral dystonia points to ipsilateral temporal lobe seizures), other behavior, and the duration of the event (true seizures usually last less than 2 minutes, whereas nonepileptic events are usually of longer duration).

**Figure 2** Classification of the epilepsies. From Scheffer IE, Berkovic S, Capovilla G, et al.: ILAE classification of the epilepsies: Position paper of the ILAE Commission for Classification and Terminology, *Epilepsia* 58(4):512–521, 2017.

The next questions focus on what happened after the event (post-ictal period). These include whether there is any confusion or fatigue, how long it takes the patient to come back to baseline, the presence of tongue bites and muscle aches, and the presence of urinary incontinence (commonly seen with true seizures). The clinician also asks about triggers including sleep deprivation, stress, drug intake, and alcohol withdrawal.

Other information to obtain includes the presence of diurnal variations—for example, frontal lobe seizures usually occur at nighttime and generalized tonic-clonic and myoclonic seizures occur mostly during the morning. If more than one seizure occurs, the clinician then asks the patient about the maximum seizure-free period; seizure frequency to assess for disease severity and response to treatment; number of visits to the hospital or emergency department to assess for seizure severity; and the presence of falls or injuries during seizures to assess for risks and degree of seizure control.

Medical history should include questions regarding the patient's prenatal history and development to assess for remote symptomatic causes of seizures; history of febrile seizures; history of central nervous system (CNS) lesions (tumors, stroke) and infections; history of brain trauma, specifically with associated penetrating injuries with intraparenchymal blood, skull fractures, and prolonged loss of consciousness; and family history of epilepsy.

Social history should include questions about level of education and employment. Patients with a higher level of education usually will have a better understanding of their diagnosis and prognosis. Employment is important because patients at higher risk for development of subsequent seizures after a first seizure have a higher risk of injury if they work in a high-risk job (e.g., in construction handling heavy machinery). Patients with altered awareness during a seizure should not drive. Clinicians should be familiar with the specific state laws regarding driving in patients with seizures and epilepsy. Use of drugs and alcohol are risk factors for the development of a first provoked seizure, and some illegal drugs may exacerbate or cause seizures. Patients should be discouraged from using illegal drugs and from excessive intake of alcohol. Review of current medications or newly started medications should be performed to determine whether any can precipitate seizures (e.g., tramadol, bupropion).

After the medical history is obtained, a thorough physical and neurologic examination should be performed. The clinician should look for skin abnormalities such as neurocutaneous manifestations of diseases (tuberous sclerosis and neurofibromatosis). It is also important to test for muscle strength to rule out subtle

weakness or post-ictal Todd paralysis; look for lateral tongue/cheek bites, which are commonly seen in true epileptic seizures; also look for bruises, scrapes from falls, burns, and muscle and back pain commonly seen in compression fractures caused by convulsive seizures.

The evaluation of a new-onset seizure should be aimed at determining whether the seizure represents an acute symptomatic seizure, usually a transient phenomenon or an unprovoked seizure.

If the history and physical examination points to a probable acute symptomatic seizure, then life-threatening conditions should be ruled out (e.g., hemorrhage, CNS infection, neoplasms) as soon as possible. Basic laboratory tests should be ordered including complete blood count, electrolytes (sodium), blood glucose, liver function tests, and toxicology to rule out drug use. If signs of CNS infection are present (fever, nuchal rigidity), consider performing a lumbar puncture. Emergency neuroimaging (usually head CT in an acute setting) should also be performed. If the patient continues to be altered or confused or to have focal deficits not explained by neuroimaging or is not at baseline 30 to 60 minutes after a seizure, emergency EEG or continuous video EEG monitoring should be performed to look for subclinical seizures. If there is evidence of provoking factors (sleep deprivation, alcohol or drug use), normal neuroimaging, and the patient is back to baseline, then the EEG can be delayed and performed in the outpatient setting. The EEG is important because some patients with symptomatic seizures can also have epileptiform abnormalities that may require ASD treatment, such as an alcohol withdrawal seizure with focal interictal epileptiform discharges (IEDs) originating from an area of encephalomalacia caused by a fall.

Unprovoked seizures are classified into seizures of unknown etiology and seizures with a preexistent brain lesion (remote symptomatic). If the initial workup points to a probable unprovoked seizure, an MRI with epilepsy protocol (3 Tesla MRI with 1- to 3-mm slices and coronal fluid-attenuated inversion recovery sequences) interpreted by a neuroradiologist should be performed to rule out subtle lesions such as cortical dysplasias and mesiotemporal sclerosis, which confer a higher risk for development of epilepsy. Also, the EEG is of paramount importance to stratify patients at risk for recurrent seizures. The EEG should be performed with sleep deprivation and with activating procedures and as close as possible to the seizure (within 24 hours) to increase the yield of detecting interictal epileptiform abnormalities. There is a 51% chance of recording epileptiform abnormalities if the EEG is performed 24 hours after a seizure.

## Differential Diagnosis

The diagnosis of a seizure or epilepsy can be challenging. There are many paroxysmal conditions, both psychiatric and organic, that may mimic seizures. Of all the seizure mimickers, psychogenic nonepileptic attacks (also known as *psychogenic nonepileptic seizures*) are the condition most commonly misdiagnosed as epilepsy. The estimated prevalence of psychogenic nonepileptic attacks is 2 to 33 per 100,000, and most patients are younger females. The clinical history and physical examination usually points to the diagnosis of psychogenic nonepileptic attacks. Red flags include poor control on multiple ASDs with a series of normal EEGs, psychiatric history, unusual triggers such as pain and getting upset, diagnosis of chronic pain syndrome and fibromyalgia, seizures in outpatient clinics or at doctor visits (presence of an audience), and a never-ending list of symptoms on review of systems. Some of these patients also have a history of sexual, emotional, or physical abuse. The physical examination may reveal give-way weakness and histrionic behavior. The “gold standard” for the diagnosis of psychogenic nonepileptic events is continuous video EEG monitoring. The combination of atypical semiology and lack of EEG findings during the paroxysmal event allows for a definitive diagnosis. Common behaviors seen during a nonepileptic paroxysmal event include position of convenience, ictal eye closure, retained awareness with bilateral motor features resembling a convulsive event, opisthotonic posturing (arched back), pelvic thrusting, crying/weeping, ictal stuttering, baby talk, side-to-side head movements, pseudo-sleep, irregular out-of-phase motor activity (like a fish out of water), gradual onset and termination, prolonged attacks, and stop-and-go phenomena.

Syncope is the second most common paroxysmal event misdiagnosed as seizures. Syncope represents a transient lack of blood flow to the brain. Some features are helpful in differentiating syncope from true seizures, and these include prodromal symptoms of general malaise, sweating, dizziness, nausea, palpitations and chest pain, and loss of consciousness with rapid recovery after hitting the ground as a result of rapid brain reperfusion. The challenging part is the fact that many syncopal events show “convulsive-like” behavior such as clonic phenomena, making the diagnosis more challenging. Syncopal events are usually shorter than typical convulsive seizures, and recovery is faster with no post-ictal state and usually no tongue-bites or urinary incontinence, a feature commonly seen in true convulsive seizures. The most common type of syncope is vasovagal and is precipitated by some situations such as pain and sight of blood. The other type is reflex syncope caused by micturition, cough, the Valsalva maneuver, and defecation. The EEG shows a typical progression of generalized slowing followed by suppression without any associated ictal features. Cardiac mechanisms should be explored because some could be life-threatening (e.g., Brugada syndrome or other arrhythmias) and require immediate intervention.

Migraines, especially complicated migraines, and migraine auras cause positive focal symptoms such as visual auras, sensorimotor phenomena, and weakness, which could potentially mimic partial seizures. However, the course of migraines is in the range of minutes, and the course of seizures is in the range of seconds. A complicated migraine may be misdiagnosed as Todd paralysis. Patients with migraines do have a history of headaches and retained awareness during the attack; these two features favor the diagnosis of migraine headaches.

Transient ischemic attacks (TIAs) should not be misdiagnosed as seizures because this entity has marked focal negative phenomena (weakness, numbness, aphasia), whereas seizures present mostly positive phenomena (movement, automatisms, jerking). Positive symptoms rarely occur during TIAs (limb-shaking TIA).

Other conditions that may mimic seizures include hypoglycemia, panic attacks, paroxysmal movement disorders, nonepileptic myoclonus, sleep disorders, parasomnias, cataplexia, and hypnic jerks. It is important therefore to obtain a detailed history, followed by continuous video-EEG monitoring to try to capture

these events for final diagnostic purposes, because it is not uncommon to misdiagnose and mislabel these conditions as epilepsy.

## Treatment

Treatment should be initiated only if the potential benefit from treatment exceeds the potential for harm. In general, if the patient has an acute symptomatic seizure, treatment with an antiseizure drug is usually not necessary because these seizures are caused by a transient and reversible precipitating factor. In these cases, it is best to treat the provoking factor (discontinue the offending drug or treat the electrolyte abnormality) or allow sufficient time for the acute provoking etiology to resolve.

If an acute symptomatic cause cannot be found, then it is possible that the patient’s seizure represents the first unprovoked seizure of an underlying epileptic disorder. About 150,000 adults will have an unprovoked first seizure. Unprovoked seizures are classified into *remote symptomatic seizures* (preexistent brain lesion) or *seizures of unknown etiology*. The rate of seizure recurrence after an unprovoked single seizure ranges from 31% to 56% over 2 to 5 years, and most patients will experience a recurrence in the first year. Seizure recurrence rates are significantly higher if there is a prior brain insult (twofold increase), if the EEG shows epileptiform abnormalities, if there is an abnormality on neuroimaging, and if the seizure occurs out of sleep (nocturnal seizure). If any of the aforementioned factors are present, then ASD treatment may be warranted. If ASD treatment is recommended, then patients should be advised that the risk of side effects will range from 7% to 31%, and they are mild and reversible. Patients should be informed that immediate ASD therapy will reduce the risk of seizure recurrence in the first 2 years after the seizure but will not improve the long-term (>3 years) chance of attaining seizure remission. Also, a single seizure can potentially be treated if the consequences of a recurrent seizure will significantly affect quality of life such as driving, work, or general safety. If two or more unprovoked seizures separated by 24 hours occur or if seizure recurrence risk is equal to 60% or more after a single event, then epilepsy is diagnosed, and treatment with an ASD is strongly recommended.

The goal of therapy is complete seizure freedom with no side effects. Around 50% to 60% of patients become seizure free on a single drug. Unfortunately, this is not possible in 30% to 40% of patients, necessitating referral to epilepsy centers for evaluation to rule out seizure imitators, evaluate for the presence of possible surgically remediable syndromes, and to try other options including diets and/or devices (vagal nerve stimulator, responsive nerve stimulator).

When starting ASD treatment, it is important to choose the medication that is effective for the seizure type or epilepsy syndrome. Of all available ASDs, five have a “broad spectrum” of action (work for both focal and generalized seizures): valproate (Depakote), lamotrigine (Lamictal), levetiracetam (Keppra), topiramate (Topamax), and zonisamide (Zonegran).<sup>1</sup> Consider a broad-spectrum ASD if the type of seizure is unknown. All of the available ASDs are effective against focal seizures except ethosuximide (Zarontin); this medication is only effective for treatment of typical absence epilepsy.

Next, consider the side-effect profile, cost, and drug dosing schedule, and adapt to the unique patient characteristics taking into consideration the patient comorbidities (Tables 1 and 2). For example, drugs with a once-a-day dosing schedule are optimal for patients with a history of prior poor compliance and for older adults; in patients taking multiple drugs for other comorbidities, administration of liver enzyme inducers (phenytoin) should be avoided. If the patient suffers from obesity, topiramate should be considered. In patients with migraine, either valproate or topiramate should be considered because these drugs are also effective for migraine prophylaxis.

<sup>1</sup>Not FDA approved for this indication.

Aim for monotherapy whenever possible to decrease side effects and drug interactions. Begin titration with a low dose, and increase slowly to maximize compliance and decrease side effects. If mild side effects occur, reassure the patient because most are usually transient.

Increase the ASD dose until seizure freedom is achieved or until side effects occur. If side effects occur, decrease the dose to the maximum tolerated dose. When switching from one ASD to another, always overlap the medications. For example, if a new medication is added, consider titrating to the effective dose before decreasing the failed medication. This approach provides some protection against breakthrough seizures during medication transitions.

If polytherapy is needed, consider ASDs with different mechanisms of action (rational polytherapy) such as a sodium channel blocker with a GABA enhancer or synergistic mechanisms (e.g., valproate and lamotrigine). Consider medications with parenteral formulations and a rapid time to therapeutic onset for rapid control of seizures if you are planning to discharge the patient from the emergency department with an adequate therapeutic dose. Drug levels should be obtained when compliance is an issue. Medication drug levels are a guide and not a goal. Always follow the patient's clinical response to ASDs.

In general it is reasonable to consider ASD discontinuation in patients who have been seizure free for 2 years. The reported relapse rate after discontinuing ASDs is around 41% or less. Factors associated with higher relapse include symptomatic epilepsy, age of onset between 10 and 12 years, cognitive delay, abnormal neurologic examination, juvenile myoclonic epilepsy, symptomatic partial epilepsy, abnormal EEG, family history of seizures or epilepsy, poor initial response to a drug, and more than one drug before discontinuation. If epileptiform abnormalities are seen and there is worsening of the EEG (increased EEG abnormalities) during discontinuation, then relapse rates are higher. Therefore consider performing an EEG before and after AED discontinuation.

### Characteristics of Specific Antiseizure Drugs

#### Phenytoin

Phenytoin (Dilantin) is one of the most used antiseizure medications. It is effective for treatment of focal seizures and generalized seizures, prophylaxis after neurosurgical procedures,<sup>1</sup> and status epilepticus that does not respond to benzodiazepines. It can exacerbate absence seizures and myoclonus. Phenytoin exerts its antiepileptic effect by blocking sodium channels, thereby preventing post-tetanic potentiation. It is metabolized by the cytochrome P450 enzyme system in the liver and follows zero-order or nonlinear kinetics, therefore very steep elevations in blood levels can occur with minimal drug increases when the blood level is close to 20 µg/mL. Idiosyncratic reactions include blood dyscrasias and hepatitis, but these are rare. Common cumulative side effects include gum hyperplasia, coarsening of facial features, hirsutism, ataxia caused by cerebellar degeneration, nystagmus, drowsiness, lethargy, rash, headaches, nausea, vomiting, bone marrow hypoplasia, vitamin K and folate deficiency, and osteoporosis. Phenytoin is a strong inducer of hepatic enzymes, and it alters the metabolism of other drugs.

Fosphenytoin sodium (Cerebix) is a prodrug, with phenytoin as its active metabolite. This medication is intended for parenteral administration; it is better tolerated than parenteral phenytoin because it is an aqueous solution with a neutral pH and can be administered three times as fast as phenytoin (150 mg/min vs. 50 mg/min). It has fewer cardiovascular side effects, including less hypotension, because, unlike phenytoin, it is not mixed with polyethylene glycol and will not cause vein irritation or purple glove syndrome because of its neutral pH.

#### Carbamazepine

Carbamazepine (Tegretol) is one of the most used ASDs in the world. It has been used in the United States since 1974 for treatment of focal epilepsies and generalized tonic-clonic seizures. It is highly effective and usually well tolerated. Carbamazepine, like phenytoin, blocks sodium channels. This medication is metabolized in the liver, and the major metabolic pathway is epoxidation to CBZ 10-11-epoxide. This epoxide confers most of the toxicity associated with this drug. It undergoes autoinduction and therefore induces its own metabolism in the first 3 to 5 weeks, and it takes longer to reach steady-state blood levels. Usually the extended-release formulations (Carbatrol and Tegretol XR) are better tolerated than the immediate-release formulations. Idiosyncratic side effects are rare and include aplastic anemia, agranulocytosis, hyponatremia, thrombocytopenia, hepatitis, and Stevens-Johnson syndrome. White blood cell counts may decrease mildly and do not require intervention unless the level decreases below 3000/mm<sup>3</sup>. Dose-related side effects include diplopia, dizziness, nausea, and ataxia.

#### Phenobarbital

Phenobarbital (Luminal) was the most commonly used ASD of the 20th century. It is inexpensive and long acting, but it has fallen out of favor for newer ASDs because of its poor side-effect profile. It is used for treatment of focal-onset, generalized seizures and neonatal seizures.<sup>1</sup> It is a barbiturate and acts on the GABA-A barbiturate binding site and therefore prolongs the duration of calcium channel opening, stabilizing neuronal membranes. It has a very long half-life (70 to 120 hours) in adults and therefore is suitable for once-a-day administration. It is a powerful inducer of microsomal liver enzymes. Side effects include cognitive problems, sedation, psychomotor slowing, depression, coarsening of facial features, osteopenia, folic acid deficiency, Dupuytren contractures, megaloblastic anemia, and hepatitis (autoimmune reaction). Withdrawal of this medication should be performed very slowly because of the high risk of withdrawal seizures.

Primidone (Mysoline) is metabolized to phenobarbital (main active metabolite) and phenylethylmalonamide. It is a second-line agent used for treatment of focal seizures and secondary generalized seizures, and the side-effect profile is similar to phenobarbital.

#### Valproic Acid

Valproic acid (Depakene) and its sodium salt divalproex (Depakote) are broad-spectrum medications and the drugs of choice for treatment of primary generalized epilepsies such as juvenile myoclonic epilepsy, absence epilepsy, photosensitive epilepsy, and Lennox-Gastaut syndrome (LGS); they are a second-line choice for epileptic spasms. They are also approved for treatment of focal-onset epilepsies, although higher doses are needed to treat focal epilepsy. A parenteral form (Depacon) is available for treatment of status epilepticus. It works by enhancing GABA function; it may increase GABA by stimulation of glutamate decarboxylase (GAD) and by selective modulation of voltage-gated sodium channels. Divalproex sodium (Depakote) is a powerful inhibitor of both oxidation and glucuronidation. Common side effects include dyspepsia, thinning and curling of hair, weight gain, tremor, rashes, bone marrow suppression, polycystic ovarian syndrome, amenorrhea with anovulatory cycles, thrombocytopenia, hepatitis and pancreatitis that could be life threatening, hyperammonemia, and sedation. Valproic acid should not be given to women of childbearing potential because of the high risk of fetal defects (10%), specifically neural tube defects. Decreased IQ scores have been noted in children whose mothers were treated with valproate during pregnancy.

#### Ethosuximide

The mechanism of action of ethosuximide (Zarontin) is blockade of T-type calcium channels, and it is indicated for treatment of

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Dosage and Side-Effect Profile of Commonly Prescribed Antiseizure Drugs

DRUG	HALF-LIFE	INITIAL DOSAGE	MAINTENANCE DOSAGE	INCREMENT	DOSING SCHEDULE	ADVERSE EFFECTS
Carbamazepine (Tegretol)	12–17 h	200 mg BID	600–1800 <sup>3</sup> mg	200 mg q wk	TID–QID	Hyponatremia, leukopenia, rare aplastic anemia and hepatitis
Gabapentin (Neurontin)	5–7 h	300 mg QD	1200–3600 mg	300 mg q3–7 d	TID	60% removed by hemodialysis, prolonged half-life to 51 h with hemodialysis Dosed 300 mg after hemodialysis
Lacosamide (Vimpat)	13 h	50mg QD	300–600 mg <sup>3</sup>	100 mg q wk	BID	Extra 50% of dose after each hemodialysis Can prolong PR interval at high doses
Lamotrigine (Lamictal)	25 h alone 60 h with VPA	6.25–12.5 mg QD to QOD	400 mg alone 100 mg with VPA	12.5–25 mg	BID q2wk	Life-threatening rash, especially with rapid titration and VPA Titration and maintenance doses vary based on other AEDs
Levetiracetam (Keppra)	7 h	500 mg QD	2000–4000 <sup>3</sup> mg	500 mg q wk	BID	Decrease dose in chronic renal insufficiency, severe hepatic disease
Oxcarbazepine (Trileptal)	9–11 h	300 mg QD	900–2400 mg	300 mg q wk	BID	Hyponatremia Fewer side effects than carbamazepine
Phenobarbital	80–100 h	30–60 mg QD	60–120 mg	30 mg q1–2 wk	QD–BID	Sedation, Dupuytren contractures, rebound seizures with rapid tapering
Phenytoin (Dilantin)	22 h	200 mg QD	200–300 mg	100 mg q wk	QD–BID	Gum hypertrophy, hirsutism, cerebellar ataxia or atrophy, peripheral neuropathy, rare hypersensitivity, hepatitis
Pregabalin (Lyrica)	6 h	50 mg QD	150–600 mg	50 mg q3–7d	BID–TID	Weight gain
Topiramate (Topamax)	21 h	25 mg QD	200–400 mg	25 mg q1–2wk	BID	Cognitive impairment at >400 mg/day, rare kidney stones, glaucoma, oligohidrosis
Valproic acid (Depakene)	9–16 h	250 mg QD	750–3000 mg	250 mg q3–7 d	TID–QID	Tremor, weight gain, alopecia, thrombocytopenia Rare hepatitis and pancreatitis Risk of teratogenesis and neural tube defects
Zonisamide (Zonegran)	63 h	100 mg QD	200–400 mg	100 mg q2wk	BID	Kidney stones, oligohidrosis, rare blood dyscrasias

ASD, Antiseizure drug; *BID*, two times daily; *d*, day; *h*, hour; *q*, every; *QD*, every day; *QID*, four times daily; *QOD*, every other day; *TID*, three times daily; *VPA*, valproic acid; *wk*, week.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

**TABLE 2** Choice of Antiseizure Drug in Special Situations

SPECIAL SITUATION	DRUG OF CHOICE	COMMENTS
Partial seizures	Carbamazepine, lamotrigine, levetiracetam, oxcarbazepine, topiramate, gabapentin	
Refractory partial seizures	Lacosamide, pregabalin, zonisamide	Second-line treatment
Generalized epilepsies	Lamotrigine, topiramate, valproic acid, <sup>1</sup> zonisamide <sup>1</sup>	Avoid valproic acid in women
Absence seizures	Ethosuximide, lamotrigine, <sup>1</sup> valproic acid, topiramate <sup>1</sup>	Ethosuximide is the choice for only pure absence seizures and is insufficient in other associated generalized tonic-clonic or myoclonic seizures
Juvenile myoclonic epilepsy	Valproic acid, <sup>1</sup> topiramate, <sup>1</sup> lamotrigine, <sup>1</sup> zonisamide, <sup>1</sup> levetiracetam	Avoid valproic acid in women
Myoclonic seizures	Clonazepam, valproic acid, <sup>1</sup> levetiracetam	Lamotrigine occasionally exacerbates myoclonic seizures
Women of childbearing potential	Lamotrigine, topiramate, levetiracetam, oxcarbazepine	Avoid enzyme-inducing agents that alter steroid hormones and OCP levels; use OCPs with $\geq 50$ $\mu\text{g}$ of estrogen; OCPs increase the elimination of lamotrigine Significant increased risk of teratogenicity with valproic acid
Older adult patients	Lamotrigine, gabapentin, levetiracetam, topiramate	Avoid polypharmacy and highly protein-bound ASDs and ASDs with high drug-drug interactions
Depression	Lamotrigine, <sup>1</sup> topiramate <sup>1</sup>	
Bipolar disorder	Valproic acid, <sup>1</sup> carbamazepine, lamotrigine, topiramate <sup>1</sup>	
Migraine	Valproic acid, topiramate	Consider the choice according to sex, side-effect profile, and seizure type
Chronic pain	Pregabalin, <sup>1</sup> gabapentin <sup>1</sup>	
Neuropathic pain	Carbamazepine, <sup>1</sup> gabapentin, <sup>1</sup> pregabalin	

ASD, Antiseizure drug; OCP, oral contraceptive pill.

<sup>1</sup>Not FDA approved for this indication.

typical absence epilepsy. This medication will not work to control any other seizure types. Common side effects are minimal and include dyspepsia, nausea, loss of appetite, and tiredness.

### Felbamate

Felbamate (Felbatol) is effective for treatment of multiple seizure types, but it was briefly withdrawn from the U.S. market in 1994 because of the occurrence of aplastic anemia and hepatic failure. It is now available only for patients with intractable seizures in whom other medications have failed and when the benefits outweigh the risks. Its mechanism of action is blockade of NMDA receptors, modulation of sodium channels, and blockade of calcium channels. The risk for hepatic failure is 14 in 110,000 patients and increases with polytherapy.

### Gabapentin

Gabapentin (Neurontin) is similar to the structure of GABA but has no effect on the GABA receptor. It enhances GAD, thereby increasing levels of GABA. This medication has no drug interactions. It is excreted entirely unchanged in the kidneys. Gabapentin is used for treatment of focal seizures with or without secondary generalization. It is ineffective in myoclonus and primary generalized seizures, and it is ineffective at lower doses. The dose should be adjusted in patients with renal disease according to creatinine clearance.

### Pregabalin

Pregabalin (Lyrica) is an analogue of GABA, but like gabapentin (Neurontin), it has no effect on the GABA receptor. It has no

drug interactions, and it is usually well tolerated. It must be dose-adjusted in patients with renal failure, and it is 50% removed after hemodialysis. It is used as an adjunct in adult patients with focal epilepsies. Common side effects include dizziness, drowsiness, weight gain, dry mouth, and edema.

### Lamotrigine

Lamotrigine (Lamictal) works by sodium channel blockade and inhibits release of glutamate. It is broad spectrum, and it is used for adjunctive treatment of focal-onset seizures with or without secondary generalization, for crossover to monotherapy, and in LGS. It is also effective for treatment of atypical absence seizures,<sup>1</sup> tonic/atonic seizures, and myoclonic seizures, although it may cause exacerbations in some patients with juvenile myoclonic epilepsy. It is one of the preferred drugs to treat older adult patients and pregnant women because of its favorable safety and pharmacokinetic profile. Lamotrigine levels should be closely watched and will increase significantly with coadministration of valproate; these two medications cause a synergistic therapeutic effect but could also increase adverse reactions (rash). It could cause a rash (5%) if the drug is titrated too quickly; this rash could progress into a life-threatening condition (Stevens-Johnson syndrome; 0.1%) and is more common in children with concomitant valproate use. If rash occurs, the medication should be discontinued immediately. Other common side effects include tremor, insomnia, headaches, ataxia, and somnolence. Pregnancy increases

<sup>1</sup>Not FDA approved for this indication.

lamotrigine clearance by 50%, necessitating dose adjustments; therefore lamotrigine levels should be monitored before, during, and after pregnancy, and doses should be adjusted accordingly.

### Levetiracetam

Levetiracetam (Keppra) is one of the most widely used ASDs because of its good pharmacokinetics, favorable side-effect profile, and multiple formulations, including parenteral and liquid (ease of administration). It is a broad-spectrum drug. It has a unique mechanism of action (binds to synaptic vesicle protein 2A-SV2A). It does not induce liver enzymes and therefore does not affect the metabolism of other drugs and does not bind to proteins in plasma. This medication must be dose-adjusted in patients with renal disease and after hemodialysis (add an extra 500 mg). It is one of the only ASDs that decreases the interictal epileptic burden (the other one is Depakote). It is approved for adjunctive treatment of primary generalized tonic-clonic seizures in adults and children 6 years of age and older with idiopathic generalized epilepsy, adjunctive treatment of focal onset seizures in adults and children 4 years of age and older, and adjunctive treatment of myoclonic seizures in adults and adolescents 12 years of age and older with juvenile myoclonic epilepsy. It is also used off-label for prophylaxis in patients after traumatic brain injury and in status epilepticus. Common adverse effects include behavioral changes (avoid in patients with psychiatric conditions), somnolence, asthenia, headache, dizziness, and flulike symptoms. It does not have any serious idiosyncratic reactions and is safe for older adults and probably safe to take during pregnancy. Consider obtaining levels during pregnancy because clearance is increased during pregnancy, necessitating dose adjustments.

### Brivaracetam

Brivaracetam (Briviact) is a chemical analogue of levetiracetam with a similar mechanism of action but a higher affinity (20-fold) for the SV2A receptor. Like levetiracetam, it exhibits linear kinetics with a favorable side-effect profile. It is indicated for adjunctive treatment of focal-onset seizures with or without secondary generalization in adults and children 16 years of age and older. It does not have added therapeutic benefit if coadministered with levetiracetam. It may increase serum concentrations of carbamazepine epoxide and phenytoin.

### Oxcarbazepine

Oxcarbazepine (Trileptal) is an analogue of carbamazepine but without the toxic epoxide. Thus it is better tolerated than carbamazepine (Tegretol). It is metabolized to the 10 monohydroxy metabolite, which confers its pharmacologic effect. It is used as monotherapy or adjunctive therapy for focal epilepsies in adults, as monotherapy for focal epilepsies in children 4 years of age and older, and as adjunctive therapy in children 2 years of age and older. It may exacerbate myoclonic seizures and absence seizures. It interacts with oral contraceptives, thereby reducing its efficacy. Hyponatremia is rare in children but may be higher in older adult populations. Other side effects include dizziness, fatigue, and headache, and these are dose dependent. Patients who develop rash with carbamazepine (Tegretol) may develop rash if treated with oxcarbazepine (Trileptal) because of cross-reactivity.

### Tiagabine

Tiagabine (Gabitril) works by reversible inhibition of the GABA-transporter-1, thereby increasing the availability of GABA in the synaptic cleft. It is approved as an adjunctive medication for treatment of refractory focal-onset seizures. It can worsen absence seizures and cause status epilepticus in patients with primary generalized epilepsy. Common side effects include tremor, nervousness, dizziness, abdominal pain, diarrhea, and emotional lability.

### Topiramate

Topiramate (Topamax) is a broad-spectrum ASD with multiple mechanisms of action. It works by inhibiting sodium conductance and weakly inhibiting carbonic anhydrase, blocks the

AMPA glutamate receptor, and enhances GABA. It is approved for adjunctive treatment of focal-onset seizures or primary generalized epilepsy and for treatment of LGS. Enzyme inducers (e.g., phenytoin) decrease topiramate levels by 50%. This medication will need dose adjustments in patients with renal failure. Topiramate (Topamax) reduces the levels of oral contraceptives, thereby decreasing its effectiveness. Common side effects include word-finding difficulties, weight loss (decreased appetite), paresthesias in the fingers and mouth, kidney stones, anhidrosis caused by the drug's carbonic-anhydrase effect, acute myopia in closed-angle glaucoma, ataxia, and tiredness. Usually doses >400 mg are poorly tolerated.

### Zonisamide

Zonisamide (Zonegran) is a broad-spectrum ASD used for treatment of focal epilepsy with or without secondary generalization. It is also effective for treatment of myoclonus (juvenile myoclonic epilepsy)<sup>1</sup> and absence seizures (T-type calcium channel blockade). This ASD has a structure similar to the sulfonamides; therefore it is contraindicated in patients with allergies to these antibiotics. It has a long-half life (>60 hours); therefore it can be taken once a day, which increases compliance. The major mechanism of action is the blockade of sodium channels; it also works on T-type calcium channels and weak inhibition of carbonic anhydrase. Enzyme inducers and valproate (Depakote) decrease half-life. The most common adverse reactions include anorexia with associated weight loss, headache, mental slowing, confusion, ataxia, dizziness, kidney stones (1%), oligohidrosis, and paresthesias (carbonic anhydrase inhibition).

### Vigabatrin

Vigabatrin (Sabril) is a structural analogue of GABA and binds irreversibly to the GABA-T (GABA transaminase), thereby increasing GABA concentrations in the brain. It is indicated for treatment of epileptic spasms in tuberous sclerosis and in refractory focal-onset epilepsies. It may exacerbate absence seizures and myoclonic seizures and, like tiagabine, may cause generalized spike-and-wave status epilepticus in patients with absence seizures or primary generalized epilepsy. This ASD causes visual field defects (nasal constriction and concentric constriction with preserved central vision), and these may be irreversible. Other side effects include fatigue, dizziness, headache, tremor, and double vision.

### Rufinamide

Rufinamide's (Banzel) mechanism of action is probable modulation of sodium channels (prolongation of inactive state of the channel). It is indicated as adjunctive treatment of seizures associated with LGS in both children and adults.

### Lacosamide

Lacosamide (Vimpat) has a novel mechanism of action by enhancing the slow inactivation of voltage-gated sodium channels. It is approved for the adjunctive treatment and conversion to monotherapy and monotherapy treatment of focal onset epilepsies. It is also used off label for treatment of status epilepticus in the intensive care unit because of availability of an IV formulation. This medication does not have significant drug interactions.

### Clobazam

Clobazam (Onfi) is a benzodiazepine with a 1,5 substitution instead of the common 1,4 substitution; therefore it has less anxiolytic and sedative effects. It works by binding to the GABA-A receptor. It is approved for the adjunctive treatment of LGS. It may also be effective for treatment of primary or focal seizures with secondary generalized seizures<sup>1</sup> as well as catamenial epilepsy.<sup>1</sup> It has no significant clinical interactions. Side effects

<sup>1</sup>Not FDA approved for this indication.

include sedation, dizziness, ataxia, and weakness. No idiosyncratic reactions have been identified.

### Perampanel

Perampanel (Fycompa) is a noncompetitive AMPA receptor antagonist and is indicated in the adjunctive treatment of focal-onset seizures with or without secondary generalization and in primary generalized seizures in adults and adolescents 12 years of age and over. The recommended dose is 8 to 12 mg/day for focal seizures and 8 mg/day for primary generalized seizures. This medication has a black box warning because it can cause severe psychiatric and behavioral reactions (aggressiveness, suicidality, homicidal threats and ideation, and irritability). Common adverse effects include somnolence, headache, dizziness, and fatigue.

### Eslicarbazepine

Eslicarbazepine (Aptiom) is a prodrug of S-licarbazepine with a mechanism of action similar to oxcarbazepine (Trileptal) sodium channel blockade. It is approved as monotherapy or adjunct therapy for treatment of focal-onset seizures. Common adverse effects include dizziness, nausea, diplopia, and headache.

### Cannabidiol

Cannabidiol (EPIDIOLEX) is the first prescription pharmaceutical formulation of purified CBD oil approved by the FDA (in June 2018) for the treatment of seizures associated with LGS and Dravet syndrome in patients 1 year of age and older.

The most common side effects of this drug include increase in liver enzymes, especially when used in conjunction with valproate or valproate and clobazam, decreased appetite, diarrhea, rash, tiredness, sleepiness, and infections.

### Fenfluramine

Fenfluramine (Fintepla) is a phenethylamine that is structurally similar to serotonin and exerts its antiepileptic effect by increasing the release of serotonin, which stimulates multiple 5-HT receptor subtypes, and by acting as a positive modulator of sigma receptors. This medication was approved by the FDA in June 2020 for treatment of seizures in Dravet syndrome and LGS in patients 2 years of age and older. The most common side effects include decreased appetite, weight loss, diarrhea, fatigue, lethargy, and pyrexia. It has few relative drug-drug interactions.

### Everolimus

Everolimus (Afinitor) is a rapamycin derivative that inhibits mTOR (mammalian target of rapamycin). mTOR overactivation has been linked to the pathogenesis of tuberous sclerosis complex (TSC), therefore it can target the etiology of the disease. It was approved by the FDA as adjunctive treatment for TSC with partial onset seizures in patients 2 years of age and older. The most common adverse effects are stomatitis, pyrexia, pneumonia, diarrhea, and hypercholesterolemia.

## Special Populations

### Women

Epilepsy is one of the most common conditions occurring in women of reproductive age (1.1 million). Women of reproductive age who are taking ASDs for epilepsy should be counseled on the possibility of teratogenicity from ASD therapy and the potential interaction with contraception. Some ASDs (enzyme inducers) affect oral contraceptives (OCPs), leading to decreased effectiveness and unwanted pregnancies. These ASDs are phenobarbital, phenytoin, carbamazepine, oxcarbazepine, eslicarbazepine, felbamate, topiramate (doses >200 mg/day), lamotrigine (doses >300 mg/day), primidone, rufinamide, and clobazam. OCPs can reduce the levels of lamotrigine, leading to breakthrough seizures. In patients taking these ASDs, a second barrier method versus changing to a non-enzyme-inducing ASD is recommended. Seizures during pregnancy will remain the same or decrease, but around 15% to 30% will have an increase in seizure frequency. Most women (84% to 92%) with epilepsy who were seizure free

9 months before the pregnancy will remain free from seizures during the pregnancy. Blood levels of lamotrigine, phenytoin, carbamazepine (to a lesser extent), and possibly levetiracetam and the active oxcarbazepine metabolite, will decrease during pregnancy because of increased clearance; therefore these ASD levels should be monitored and medication dosages adjusted as needed. The risk to the fetus from seizures (especially convulsive seizures) is higher than the risk to the fetus from ASDs. More than 90% of female patients with epilepsy will deliver a normal baby. The rates of congenital malformations in women with epilepsy taking ASDs is around 4% to 6% (double that of the general population) but remain low. The risk of malformations increases with polytherapy and with higher dose of ASDs. Valproate/valproic acid is the ASD that carries the highest teratogenicity (6% to 10%), mostly associated with neural tube defects. It also produces long-term cognitive problems, with a reduction in children's IQs when mothers take valproate (Depakote) during pregnancy. Therefore valproic acid is contraindicated and should not be used as a first-line treatment in women of childbearing potential. Women of childbearing potential who have epilepsy should be supplemented with folic acid at a dose of 0.4 mg/day to decrease the risk of congenital malformations if they become pregnant. Breast-feeding is an important concern in the postpartum period in women taking ASDs. Even though some ASDs (e.g., primidone and levetiracetam) transfer into breast milk, breast-feeding is encouraged. The infant should be monitored for increased sedation if mothers are on those two ASDs.

### Older Adults

The current world population is aging, and the risk for epilepsy increases dramatically after 65 years of age. The recognition of seizures in this group may be more complicated because the presentation may be atypical. Also, many other conditions may mimic seizures in older adults, making diagnosis a challenging proposition. The most common seizure type in older adults is complex partial seizures, which present with confusion, staring, change in mental status, and unresponsiveness. The most common cause of epilepsy in this group is cerebrovascular disease. Other conditions that may cause epilepsy include neurodegenerative conditions (Alzheimer disease), head trauma, and brain tumors. When treating older adult patients, the pharmacokinetic and pharmacodynamic properties of medications should be considered. Older adults have reductions in protein binding, renal elimination, and hepatic metabolism, thereby conferring a higher risk for idiosyncratic reactions and altered kinetics. Gabapentin, lamotrigine, levetiracetam, pregabalin, and oxcarbazepine are usually well tolerated and recommended as first-line treatment in this patient population. AEDs with hepatic enzyme-inducing mechanisms are not recommended in older adult patients because of the potential for interactions with other drugs. Fortunately, seizures in this population are easy to control, and monotherapy is usually effective.

### Drug-Resistant Epilepsy

Drug-resistant or intractable epilepsy is defined as the failure of adequate trials of two tolerated, appropriately chosen and used ASDs used in monotherapy or polytherapy to achieve sustained seizure freedom. Drug-resistant epilepsy affects one-third of patients living with epilepsy.

These patients should be referred to an epilepsy center for further management, including evaluation by an epileptologist who will perform a detailed clinical and physical examination and order further diagnostic tests including video EEG monitoring to record the patient's events for final diagnostic purposes and to evaluate for possible epilepsy surgery. Surgical resection of the epilepsy focus is the only available treatment to cure epilepsy. Seizure freedom rates after temporal lobectomy are 70% to 90% for mesiotemporal sclerosis and 40% to 70% for neocortical resections. In patients who are not suitable candidates for epilepsy surgery, dietary treatment or neuromodulation is recommended. Dietary options include the ketogenic diet, the modified Atkins diet, and the low glycemic index diet.

These diets can be used as adjunctive therapy in combination with ASDs and devices, such as the vagus nerve stimulator (VNS), responsive neurostimulation system (RNS), and deep brain stimulator (DBS). These diets have similar seizure reduction rates (around 50%) in one-half of patients. The low glycemic index diet is better tolerated and less restrictive than the modified Atkins diet and the classic ketogenic diet.

The VNS, RNS, and DBS are approved for treatment of pharmacoresistant epilepsy in the United States. The VNS works by delivering an intermittent mild current to the left vagus nerve. The mechanism of action is unknown but believed to include alterations in the reticular activating system, the central autonomic network, the limbic system, and the diffuse noradrenergic projection system. With long-term use, this device provides >50% seizure reduction in about 50% to 60% of patients, with around 8% becoming seizure free after 2 years. The new SenTiva generator (LivaNova, London, UK) combines traditional VNS therapy with seizure detection technology via changes in cardiac rhythms.

RNS therapy (Neuropace, Mountain View, CA) was approved by the FDA in 2013 for treatment of refractory focal-onset seizures. This device continuously monitors and detects abnormal electrical activity that can lead to a seizure and then delivers electrical stimulation to the area of seizure generation to try to abort the seizure. It has two leads, and either subdural or depth electrodes or a combination of both can be used and placed close to or over the epileptogenic zone. These leads are connected to the generator that seats on the skull. Treatment with the RNS system is recommended in patients who are not amenable to surgery and have multifocal epilepsy with no more than two discrete seizure onset zones. The median seizure reduction at 5 years was >65%, with 15% of patients achieving seizure freedom.

The FDA approved DBS in 2018 for adjunctive treatment of patients with drug-resistant focal onset epilepsy who are 18 years of age or older. This device is particularly useful if the seizure focus is difficult to localize to one or two brain regions. Leads are placed in the anterior nucleus of the thalamus for delivery of electrical stimulation. According to the Stimulation of the Anterior Nuclei of the Thalamus for Epilepsy (SANTE) trial with 110 patients randomized to receive active stimulation versus sham stimulation, a median reduction in seizures of 69% from baseline was observed at the end of 5 years, and seizure severity and quality of life improved significantly.

## SLEEP DISORDERS

Method of

Meghna P. Mansukhani, MD; Bhanu Prakash Kolla, MD, MRCPsych; and Erik Kent St. Louis, MD, MS

Sleep is a universal biological imperative for all mammals. Sleep deprivation and sleep disorders are frequent and underappreciated determinants of health status. Sleep is essential for survival, and sleep loss and sleep disorders are associated with major health problems, including cardiovascular, metabolic, neuropsychiatric, and neoplastic disorders, as well as neurobehavioral-associated accidents and risks. Healthy sleep must be regarded along with nutrition and exercise as key pillars for good health.

Recent evidence has suggested that a chief purpose of sleep may be to maintain cerebral metabolic homeostasis, clearing waste products that accumulate during wakefulness such as beta-amyloid, a protein known to abnormally accumulate in Alzheimer's disease. Insufficient sleep quantity appears to be associated with a variety of health problems and may contribute to mortality and dementia risk. Total sleep deprivation, as well as selective deprivation of nonrapid eye movement (NREM) or rapid eye movement (REM) sleep, may be lethal in laboratory animals. Adequate sleep quality is similarly necessary to ensure optimal daytime functioning because basic vigilance, attention and cognitive performance, and overall quality of life are each substantially eroded by disordered sleep, and insufficient sleep and sleep-disordered breathing (SDB) pose significant health hazards. Unfortunately, insufficient sleep quantity and quality is a widespread public health crisis in children and adults worldwide in the developed world, and primary sleep disorders are a highly prevalent cause of morbidity, an important contributor to mortality, and a public health hazard that raises risk for motor vehicle collisions and catastrophic occupational injuries and accidents.

The clinical specialty of sleep medicine initially emerged during the 1970s and 1980s, surrounding growing clinical application of diagnostic polysomnography (PSG). While the main diagnostic use remains evaluation and initial treatment for SDB, PSG and related techniques have tremendous utility for the evaluation of selected patients with nocturnal events, periodic limb movement disorder (PLMD), narcolepsy and related primary central nervous system (CNS) hypersomnias.

In this chapter, we review the classification of common sleep disorders, a practical bedside approach toward interviewing and examining patients with sleep problems, advantages and limitations of diagnostic implements within the sleep laboratory, and summarize diagnostic and therapeutic approaches to common sleep disorders.

### The International Classification of Sleep Disorders

The International Classification of Sleep Disorders (ICSD) provides a common nomenclature and taxonomy for disorders of sleep for clinicians and researchers alike. The most current ICSD, ICSD-3, divides sleep disorders into six distinct categories. The ICSD-3 nomenclature is shown in **Box 1**, and the most common sleep complaints and disorders are presented and discussed in detail throughout this chapter.

**Insomnia**

- Chronic insomnia disorder
- Short-term insomnia disorder
- Other insomnia disorder  
Isolated symptoms and normal variants
- Excessive time in bed
- Short sleeper

**Sleep-Related Breathing Disorders**

The continuum of obstructive sleep-disordered breathing: snoring, Upper-airway resistance syndrome, and obstructive sleep apnea (OSA)

**Obstructive sleep apnea (OSA) disorders**

- OSA, adult
- OSA, pediatric

**Central sleep apnea syndromes**

- Central sleep apnea with Cheyne-Stokes breathing
- Central apnea due to medical disorder without Cheyne-Stokes breathing
- Central sleep apnea due to high altitude periodic breathing
- Central sleep apnea due to a medication or substance
- Primary central sleep apnea
- Primary central sleep apnea of infancy
- Primary central sleep apnea of prematurity
- Treatment-emergent central sleep apnea

**Sleep-related hypoventilation disorders**

- Obesity hypoventilation syndrome
- Congenital central alveolar hypoventilation syndrome
- Late-onset central hypoventilation with hypothalamic dysfunction
- Idiopathic central alveolar hypoventilation
- Sleep-related hypoventilation due to a medication or substance
- Sleep-related hypoventilation due to a medical disorder
- Sleep-related hypoxemia disorder  
Isolated symptoms and normal variants
- Snoring
- Catathrenia

**Central Disorders of Hypersomnolence**

- Narcolepsy Type I
- Narcolepsy Type II
- Idiopathic hypersomnia
- Kleine-Levin syndrome
- Hypersomnia due to a medical disorder
- Hypersomnia due to a medication or substance
- Hypersomnia associated with a psychiatric disorder
- Insufficient sleep syndrome  
Isolated symptoms and normal variants
- Long sleeper

**Circadian Rhythm Sleep-Wake Disorders**

- Delayed sleep-wake phase disorder

- Advanced sleep-wake phase disorder
- Irregular sleep-wake rhythm disorder
- Non-24-hour sleep-wake rhythm disorder
- Shift work disorder
- Jet lag disorder
- Circadian rhythm sleep-wake disorder not otherwise specified

**Parasomnias**

**NREM-related parasomnias**

- Disorders of arousal (from NREM sleep)
- Confusional arousals
- Sleepwalking
- Sleep terrors
- Sleep-related eating disorder

**REM-related parasomnias**

- REM sleep behavior disorder
- Recurrent isolated sleep paralysis
- Nightmare disorder

**Other parasomnias**

- Exploding head syndrome
- Sleep-related hallucinations
- Sleep enuresis
- Parasomnia due to a medical disorder
- Parasomnia due to a medication or substance
- Parasomnia, unspecified  
Isolated symptoms and normal variants
- Sleep talking

**Sleep-Related Movement Disorders**

- Restless legs syndrome
- Periodic limb movement disorder
- Sleep-related leg cramps
- Sleep-related bruxism
- Sleep-related rhythmic movement disorder
- Benign sleep myoclonus of infancy
- Propriospinal myoclonus at sleep onset
- Sleep-related movement disorder due to a medical disorder
- Sleep-related movement disorder due to a medication or substance
- Sleep-related movement disorder, unspecified

**Isolated symptoms and normal variants**

- Excessive fragmentary myoclonus
- Hypnagogic foot tremor and alternating leg muscle activation
- Sleep starts (hypnic jerks)

**Other Sleep Disorders**

- Fatal familial insomnia
- Sleep-related epilepsy
- Sleep-related headaches
- Sleep-related laryngospasm
- Sleep-related gastroesophageal reflux
- Sleep-related myocardial ischemia

*Abbreviations:* CNS = central nervous system; NREM = non-rapid eye movement [sleep]; REM = rapid eye movement [sleep].

**Clinical Approach to the Sleep Medicine Patient: The Interview and Examination**

The three most common clinical presenting sleep-related complaints are hypersomnia, insomnia, and unusual behaviors or events at night (parasomnias). Hypersomnia, which is excessive sleepiness during waking hours, is often multifactorial and may be related to insufficient sleep quantity, quality, or timing; SDB; sedating medications; or certain medical, psychiatric, or neurologic conditions. Insomnia may be regarded as a problem in initiating or maintaining sleep under conditions that are normally conducive to sleep. Parasomnias are unusual behaviors that are often dangerous to the patient or bed partner during sleep.

Insomnia is a subjective complaint. To some patients it is not at all bothersome to require 20 to 30 minutes to fall asleep, while to others it seems very wrong. While insomnia is fundamentally a subjective symptom, the manifestations follow common patterns. Sleep latency, the time taken to fall asleep, varies significantly, but initial sleep latency longer than 30 minutes may be considered prolonged, once proper sleep-conducive conditions have been established (lights off, dark and quiet sleep environment without distracting stimuli). There is also significant variation in what degree of subjective sleep disruption reflects sleep-maintenance insomnia, as normal individuals may briefly awaken as often as 10 to 15 times each hour, with most such arousals being below

the threshold of conscious awareness. Multiple nocturnal awakenings that are disturbing to the patient, especially when there is difficulty reinitiating sleep and prolonged wake after sleep-onset time, may be regarded as sleep-maintenance insomnia. Patients admitting to insomnia should be asked to estimate what amount of their problem is ascribable to an active mind or worries, restless legs, or body pain. Disturbing influences in the sleep environment such as the ambient light, temperature, and noise conditions in the bedroom should be sought. A precise diagnosis is not possible without detailed knowledge of sleep and wake behavior over the entire circadian cycle during a more protracted time, such as 1 to 2 weeks. A sleep diary can be very helpful in gaining needed insights for diagnosis. Increasingly, helpful information about timing and duration of sleep may be logged in applications for personal mobile computing devices.

The patient and physician may at times have difficulty differentiating between hypersomnia and complaints of fatigue (a sense of lacking enough energy to carry out usual daily activities, without the tendency toward dozing or nodding off inadvertently). A quick, incisive bedside test that helps distinguish between hypersomnia and fatigue is the Epworth Sleepiness Scale (ESS), a short questionnaire asking the patient his or her likelihood of dozing inadvertently during usual permissive daytime sedentary settings including reading, watching television, or traveling in a car. An online version is available at <http://www.stanford.edu/~dement/epworth.html>. Scores over 10 are considered abnormal and indicative of a possible underlying primary sleep disorder and suggest the need for further evaluation. Complaints of hypersomnia must be placed into the context of the sleep history with particular emphasis on the quantity, timing, and quality of sleep.

Patients may also present with complaints of disturbing or unusual activities during sleep (parasomnias). Key diagnostic points in determining the diagnosis for parasomnias include their onset, duration, frequency, time of night, stereotypy, injuries sustained, and whether there is any further behavioral change following the parasomnia episode.

Collateral history obtained from a bed partner may be particularly instructive. Patients should be asked whether they are reported to snore, whether the snoring is intermittent or constant, and if the snoring volume is related to sleeping in a supine position. Disruptive snoring loud enough to be heard outside a closed bedroom door, or witnessed stop-breathing episodes indicating apneas or self-awareness of arousals related to a snort or gasp, are particularly suggestive symptoms of obstructive sleep apnea (OSA). Symptoms such as morning dry mouth and sore throat, frequent morning headaches, or heartburn may indicate a higher likelihood of significant SDB. Patients should be asked about awareness of restless legs symptoms or movements during sleep, and whether they have been told of peculiar sleep-related behaviors or evidence of acting out their dreams, yelling or thrashing in sleep, or exhibiting sleep walking or other amnesic behaviors during sleep.

In addition to a detailed sleep history, taking a thorough general medical history is important because sleep disorders are frequently tightly linked to other diseases. OSA is closely associated with hypertension, coronary artery disease, cerebrovascular disease, atrial fibrillation, obesity, and the metabolic syndrome. Congestive heart failure, even when well compensated, is frequently associated with central sleep apnea syndrome. Restless legs syndrome and periodic limb movements in sleep (PLMS) are more common in patients with systemic iron deficiency or renal impairment, or in those with spinal cord or peripheral nerve pathologies. Hypoventilation is more prevalent in patients with neuromuscular disease; advanced obstructive lung disease; kyphosis; and in traumatic, vascular, neoplastic, or degenerative disorders that affect the medullary centers of the brain. Various genetic syndromes such as trisomy-21 produce craniofacial abnormalities predisposing to OSA due to anatomic narrowing of the upper airway.

Physical examination in sleep medicine focuses on signs indicating predisposition or associated sequelae of SDB. Careful

inspection of the oropharynx and nares is particularly important because significant oropharyngeal narrowing is the chief anatomic substrate for obstructive SDB, while nasal septal deviation or other nasal obstruction, in addition to a thickened neck and overweight body habitus, may also contribute toward sleep apnea. Careful inspection for signs of neuromuscular disease, such as weakness of cervical flexor or extensor muscles, fasciculations or thoracoabdominal paradox, may help detect the underlying cause for sleep-related hypoventilation. Elevated blood pressure, a cardiac gallop, wet rales, and peripheral edema may be present as signs of systemic hypertension, heart failure, or cor pulmonale associated with untreated SDB.

## Diagnostic Tools in the Sleep Laboratory

### Polysomnography

Laboratory polysomnography (PSG) is the “gold standard” for formal assessment of suspected SDB, hypersomnia, or parasomnias. PSG is a diagnostic test most often performed in a sleep laboratory; attended by trained technicians; and combining evaluation of sleep, breathing, and movement. During PSG, several polygraphic physiologic variables are analyzed, including electroencephalography (EEG) as well as chin electromyography (EMG) to allow determination of sleep staging, limb EMG leads to analyze periodic leg movements that may disrupt sleep, oronasal airflow measured by a thermistor and nasal pressure sensors, electrocardiography, and respiratory effort measured by inductance plethysmography or piezocrystal monitors. Body position is also analyzed to delineate effects of sleeping position on breathing.

Each 30-second epoch of the PSG is subsequently scored by a sleep technologist as either wake, NREM sleep (N1 or N2 light NREM, or N3 slow wave sleep), or REM sleep according to well-defined guidelines. Sleep architecture, or the composition of sleep by different stages, varies greatly by age, but in middle-aged adults is approximately 60% to 75% N1-N2, 10% to 20% N3, and 15% to 25% REM sleep. Children usually have higher, and elderly individuals have lower, percentages of N3 and REM. Arousals from sleep and their mechanisms, whether due to breathing, movement, or spontaneous causes, are determined. Accordingly, a precise determination of the duration of a patient's total sleep time, sleep efficiency (total time spent asleep divided by time in bed), and disrupting influences on sleep, such as abnormal respiration or movement, may be determined. The effects of confounding medications and medical disorders on sleep architecture, such as selective-serotonin reuptake inhibitors (SSRI) that suppress and delay REM sleep, or benzodiazepines that reduce the N3 and REM amounts and increase sleep stage shifting leading to heightened light NREM N1 and N2, must also be considered.

Attended PSG is advantageous because it allows precise measurement of sleep and relevant cardiorespiratory and neurologic behaviors and allows intervention with therapeutic positive airway pressure (PAP) trials if indicated. Disadvantages of PSG include patient inconvenience, a foreign sleep environment, and expenses due to highly trained personnel and technology. For those patients whose disease severity is difficult to predict, or who may have other complicating medical illnesses that would render interpretation of an out-of-center cardiopulmonary sleep test inaccurate (such as those with significant cardiopulmonary or neurologic diseases), or those who may require noncontinuous PAP modalities, or for those with parasomnia symptoms, attended PSG and treatment design is needed. Split-night PSG remains a cost-effective strategy for many patients.

PSG is currently the only way to actually measure sleep; although the sleep state is currently defined by the variables measured in PSG (EEG, EMG, and EOG), the science of sleep medicine may develop other ways of characterizing the sleep state that are more convenient, precise, and correlate even better with health and disease.

### Home Sleep Apnea Testing

PSG is comprehensive, but for patients with characteristic clinical presentations for OSA syndrome, it is often possible to arrive at a diagnosis using a significantly reduced number of recording channels that may be conducted in the home setting. A recent systematic review concluded that many commercially available home monitoring devices do not perform well in sensitivity or specificity. The best out-of-center testing devices use similar measures as PSG but exclude EEG, EMG, or EOG channels needed to score sleep. Thus, these devices typically measure at a minimum airflow using thermistors and nasal pressure transducers, breathing effort using respiratory impedance plethysmography, oxygen saturation using pulse oximetry, and snoring. Using these signals, the frequency of apneas and hypopneas per hour of recording, called the respiratory event index (REI), may be determined. Some testing devices add markers for sleep, such as actigraphy (see below), position sensors, or pattern recognition of pulse or autonomic variability to estimate sleep time (called peripheral arterial tonometry). Home sleep apnea testing (HSAT) devices are thus far only considered for evaluation of OSA syndrome and are not suitable for diagnostic evaluation of other sleep disorders. Because of limited sensitivity, they are best employed when there is a high pretest probability that the patient has at least moderately severe OSA syndrome. Patients appropriate for HSAT would be those who satisfy three criteria: have a high likelihood of having at least moderately severe OSA, will be good candidates for either autotitrating continuous PAP (CPAP) or an oral appliance, and do not have underlying diseases that either will obscure HSAT or who may have other disorders that require PSG for diagnosis. Because of the poor sensitivity of HSAT, a negative result should be cause for PSG: the patient should have had a high pretest probability for having at least moderately severe OSA.

For medically uncomplicated patients fitting the above criteria, using HSAT followed by APAP most often leads to similar results as attended PSG with CPAP therapy based upon in-lab titration of pressure. This strategy is increasingly being used, largely owing to reduced costs. These good results depend, however, upon expert PAP mask fitting and follow-up. It is best to remember that treatment is chronic and requires ongoing follow-up. More is written about this in the section on OSA below.

### Multiple Sleep Latency and Maintenance of Wakefulness Testing

The multiple sleep-latency test (MSLT) provides an objective measure of sleepiness compared with normal individuals lacking primary sleep disorders. The chief clinical indication for MSLT is for evaluation of narcolepsy and related primary CNS hypersomnias such as idiopathic hypersomnia and Kleine-Levin syndrome. A MSLT is carried out during the daytime in a sleep laboratory following nocturnal PSG, with four or five nap opportunities at standard times and intervals, usually at 9:00 and 11:00 AM and 1:00, 3:00, and 5:00 PM. Careful inspection of each nap is subsequently performed to determine the timing of sleep onset relative to commencement of each nap, and whether REM sleep occurs during each nap. A mean sleep latency is then calculated from the average initial sleep latency from each nap. Mean sleep latencies shorter than 8 minutes are considered abnormal and indicative of pathologic excessive daytime sleepiness. Whether or not a sleep-onset REM period (a SOREM, i.e., reaching REM sleep within 15 minutes of sleep onset during a nap) is captured is also considered and tabulated. More than one SOREM is abnormal and is consistent with the diagnosis of narcolepsy.

There are several considerations prior to performing and interpreting a valid MSLT. Patients should be instructed to sleep well for at least 2 weeks preceding the study, to allow at least 6 to 7 hours per night (and when possible, extending time in bed to 8-9 hours), and many sleep specialists document the quantity of sleep before the test with actigraphy monitoring or a sleep diary to ensure adherence to this recommendation and exclude the contaminating influence of insufficient sleep quantity. If it is safe and practically possible to do so, patients should be instructed

to taper or discontinue sedative, stimulant, or REM suppressant medications (i.e., opiate analgesics, antidepressants, or other psychotropic or CNS active drugs) with the oversight and permission of other relevant treating primary care, psychiatry, and pain physicians at least 2 weeks prior to MSLT, and certain psychotropic drugs such as fluoxetine (Prozac) with a long elimination half-life should be discontinued for at least a month prior to MSLT to avoid decrease in MSLT sensitivity for delay of REM latency. Patients should undergo a full-night diagnostic PSG the night before a MSLT study to ensure that there is not another primary sleep disorder, such as SDB or PLMD, that could provide an alternative reason for significant sleepiness and to ensure that sufficient sleep quantity of 6 hours or more is obtained.

While the MSLT is designed to assess sleepiness, the maintenance of wakefulness test (MWT) is used to assess the ability to remain awake. The MWT is most useful when an objective measure of the effectiveness of treatment for disorders causing hypersomnolence is needed. The patient is seated in a dim room in a comfortable, semi-reclined position and asked to remain alert but passive for four 40-minute periods that are 2 hours apart. EEG, EOG, and chin EMG are measured, and the signals are analyzed to detect any epochs of unequivocal sleep during each 40-minute period. Normal patients have a mean time to epochs of unequivocal sleep of 30.4 minutes; however, the data is not normally distributed, and 42% of all patients remain awake for the entire 40 minutes on all four opportunities. Since simulated and actual driving performance is compromised with sleep times of 19 minutes or less on MWT, this is a reasonable threshold for the distinction of clinically significant daytime sleepiness, and driving or other safety sensitive tasks should be curtailed when sleep latencies are 19 minutes or shorter.

### Actigraphy Monitoring

Wrist actigraphy monitoring is utilized to provide a rigorous estimation of sleep quantity and its circadian pattern. The actigraphy monitor may be worn like a wristwatch and contains an accelerometer that detects movements, which are recorded over time periods lasting up to weeks. The magnitude and pattern of movements may be analyzed and modeled to infer the sleep-wake pattern and provides a graphic representation of the patient's sleep schedule. The test is used in the evaluation of suspected circadian rhythm disorders, to assess response to treatment of insomnia, and for investigating patients with hypersomnia prior to PSG and MSLT to more accurately document the adequacy of sleep prior to the assessment for sleepiness. Recent applications utilizing the accelerometer in smartphones and wrist-worn fitness devices show promise, but most have not been validated as diagnostic tools.

### Diagnostic and Therapeutic Approach to Common Sleep Disorders

#### Insomnia

The insomnia disorders all share three basic components: repeated complaints of insomnia, which may involve difficulties falling asleep, staying asleep, poor sleep quality, or waking undesirably early; an adequate time and opportunity for sleep; and a complaint of resultant daytime impairment. Insomnia is the most common of sleep complaints: nearly 45% of people were affected intermittently within the past year in some large studies, and up to 15% suffer chronic insomnia disorders. Risks for insomnia include female sex, older age, and a psychiatric or medical comorbidity. Chronic insomnia should be distinguished from short-term insomnia, which may occur in anyone occasionally (e.g., the night before an important job interview, or during increased stress). Per the ICSD-3, the sleep disturbance and associated daytime symptoms have to occur at least three times a week for at least three months to meet criteria for chronic insomnia disorder (see [Box 1](#)). Insomnia may begin in childhood, continue throughout a patient's lifetime, and appear as a manifestation of neurologic hyperarousal, with demonstrable increases in cerebral metabolism via functional MRI and increases in beta and

theta EEG activity as well as generalized increased metabolism and stress hormone production compared with normals in either wake or sleep states. To a lesser extent, these same markers for hyperarousability are seen in other causes of primary insomnia (see [Box 1](#)).

In the past, insomnia was classified into primary and secondary, with secondary insomnia being far more common. Secondary insomnia was thought to be a result or accompaniment of an underlying illness. This may be incorrect. For example, it has previously been thought that treatment of secondary insomnia ought to focus on treatment of the underlying disorder. Newer evidence indicates that this approach may be suboptimal for the following reasons: secondary insomnia does not reliably improve when the underlying disorder does; secondary insomnia in general responds to treatment directed at insomnia; and in some cases, the underlying disorder, such as depression, responds better to treatment when the insomnia is addressed directly and concurrently. Furthermore, in several illnesses, such as depression, insomnia may predate the depression by months, and insomnia is a risk factor for future development of many psychiatric illnesses. In addition, primary insomnia was further divided into subtypes of idiopathic insomnia, psychophysiological (learned) insomnia and paradoxical insomnia (sleep state misperception). Secondary insomnia was also divided into various subtypes such as inadequate sleep hygiene, insomnia due to medical condition, mental disorder, drug or substance. However, it is rare to encounter patients who fit under one of these subtypes exclusively. Most patients with insomnia, primary and secondary, tend to have some diagnostic criteria listed under many of these subtypes. Thus, in the current ICSD-3 insomnia is no longer classified into primary and secondary insomnia and no distinction is made between various etiologic subtypes of primary and secondary insomnia.

Chronic insomnia may be preceded in predisposed individuals by precipitating factors such as illness or stress and may be propagated by behavioral or maladaptive cognitive factors. Some individuals do not appear to require precipitating or propagating factors to develop chronic insomnia and have underlying predisposition toward insomnia. They are prototypic for an underlying predisposition toward insomnia. These individuals manifest insomnia from infancy and persist despite optimization of sleep hygiene and habit. However, in most cases of insomnia, precipitating and/or propagating influences may be found through careful interview and help establish a secure diagnosis.

In these individuals, identifiable precipitating causes that may be traumatic, stressful periods or struggles, medical illness, drugs, or toxins. However, even when the cause is removed, a conditioned response built upon associated and at times maladaptive sleep-related behaviors ensues. Instead of beginning to relax for sleep under permissive circumstances, the affected patient experiences paradoxical arousal as they approach their sleep conditions. The patient under the influence of the precipitating cause may have spent many hours worrying, uncomfortable, clock-watching, or otherwise raising their anxiety levels. Propagating factors include these same behaviors that help maintain sleeplessness once it has begun and may additionally include irregular sleep schedules and the use of drugs. Abuse of alcohol may contribute or be secondary to the sleep disturbance.

Effective treatment strategies for insomnia focus on removing any residual precipitating influences and mitigating or eliminating propagating influences. The main therapies for insomnia are sleep hygiene, behavioral therapies, cognitive therapies, and pharmacologic therapies. Patients often respond best to combined modalities. There is high-level evidence that combined cognitive/behavior therapies (CBT) are at least as effective as pharmacologic therapy for most patients with insomnia. CBT also appears to have enhanced rates of insomnia remission, so these approaches ought generally to be employed first. The addition of hypnotics to CBT has resulted in more rapid remission in some, but not all, studies. Growing recognition of the adverse effect profile of sedative-hypnotic drugs, particularly zolpidem (Ambien), which has been associated with heightened risks of falls and sleep walking, sleep

eating, and related amnesic behaviors, has also encouraged a shift toward an earlier application of behavioral approaches to coping with insomnia.

In childhood, the most common causes of insomnia are behavioral. Insomnia may occur when parents fail to establish and enforce an appropriate nightly bedtime, so that their child may subsequently stall and refuse to go to bed in a timely fashion. In other cases, insomnia may occur when a child cannot fall asleep until a usual condition is present, such as being held, rocked, or fed. Appropriate advice and treatments include strict limit-setting for bedtime resistance; maintaining regular sleep schedules with avoidance of napping during the daytimes; and curtailing disrupting influences, such as television watching, gaming, and computer use. Suggesting a nightly cell phone or personal device (i.e., iPod, iPad, or Wii U) check-in procedure is especially helpful in teenage children, and caffeinated soda and excessively stimulating activities should be avoided during the evenings. Selected children benefit from incentives such as a patient-parent contract that offers privileges for slightly later bedtimes on weekends after the child adheres regularly to a specified sleep schedule during school nights.

Four considerations for restoring normal sleep hygiene to discuss with all insomnia patients in the office include these three central concepts:

- Maintain a regular sleep schedule. Go to bed and arise at the same time each day. Ideally, the schedule should match the patient's biologic clock, with nocturnal sleep and bedtime/rise time matching their tendency for sleepiness and alertness (sleep education/hygiene).
- Avoid lying sleepless in bed. After 20 to 30 sleepless minutes spent trying to fall asleep, the patient should be instructed to leave the bedroom to pursue a quietly distracting activity, such as reading mundane material or watching a boring television program, and waiting until he or she feels sleepy enough to return to bed. Patients should explicitly avoid reading in bed, listening to the radio in bed, or watching television in bed if they are having difficulty initiating or maintaining sleep. This is a practical form of stimulus control ([Table 1](#)).
- Avoidance of clock-watching behavior. Patients should be instructed to remove clocks from their bedrooms or hide the clock face so as to make the insomnia period timeless and of uncertain duration. Falling asleep should not be a race against time, and repetitive checking of the time only serves to reinforce anxiety and further activate the mind (see stimulus control, [Table 1](#)). For the same reason, when watching television, discourage patients from watching news shows with scrolling tickertape newflashes with clock time shown.
- Schedule thinking time earlier in the evening, well in advance of the sleep period. Patients who worry, plan, or think out their problems in bed should be encouraged to schedule a time earlier in the evening, well in advance of their normal bedtime, to attempt to work out these concerns prior to carrying them into bed. This "constructive worry" or "worry time" represents a practical form of cognitive and stimulus control therapy.

There are numerous other associated issues and behaviors that may be useful for application in selected patients, such as cutting down overall time in bed (sleep restriction), establishing a regular and relaxing bedtime routine (such as by taking a relaxing bath, listening to soothing music, or having a light snack before bed), avoiding daytime naps, avoiding caffeinated beverages after noontime, and establishing a regular morning exercise routine and avoiding evening exercise. It is important for the physician to avoid overloading the patient with too many considerations and tasks at once, however, as the burden of implementing these suggestions then becomes tantamount to too many obtrusive "swing thoughts" during a golf swing. One or two concepts to start with are sufficient, and once mastered and implemented, the patient can gradually phase in other ideas over time. Relaxation training and cognitive behavioral therapy can be very helpful in selected receptive patients who have failed the above typical self-help

**TABLE 1** Therapeutic Tools for Treating Insomnia

Therapy Type	Specific Therapies/Components	Goals
Education/sleep hygiene	Improve knowledge about behaviors that foster or hinder healthy sleep	Improve opportunity and environment for sleep
Behavioral therapies	Stimulus control <ul style="list-style-type: none"> <li>• Unmodified extinction</li> <li>• Graduated extinction</li> <li>• Positive routines/faded bedtime with response cost</li> <li>• Scheduled awakenings</li> </ul> Sleep restriction	Dissociate anxiety or conditioned autonomic response from the process or location of going to sleep  Increase pressure for sleep by decreasing the time allotted for sleep, increasing the probability of successful sleep attempts  Reduce physiologic and/or cognitive arousal that hinders or disrupts sleep
	Relaxation training <ul style="list-style-type: none"> <li>• Progressive muscle relaxation</li> <li>• Passive relaxation</li> <li>• Autogenic training-biofeedback</li> <li>• Imagery training</li> <li>• Meditation</li> <li>• Hypnosis</li> <li>• Paradoxical intention</li> </ul>	Reduce performance anxiety that confounds ability to successfully go to sleep
Cognitive therapies	Cognitive restructuring Decatastrophizing Reappraisal Attention shifting	Decrease unrealistic expectations about sleep, misconceptions, or misattributions regarding causes of insomnia, consequences of insomnia, ability to control sleep; produce a more appropriate and adaptive mind-set
Pharmacologic therapies	Hypnotics Sedating antidepressants Herbal supplements	Enhance sleepiness at appropriate times or to enhance convenience of sleep time and/or duration

measures, and as a last resort, periodic or even scheduled chronic pharmacotherapy can also be implemented.

There are now several highly effective and tolerable hypnotic medications available for short-term, intermittent, and chronic use. The class of nonbenzodiazepine receptor agonists (the so-called “Z” drugs, or zolpidem [Ambien], zaleplon [Sonata], and eszopiclone [Lunesta]) are preferred by most sleep specialists but some of them remain costlier than the older generation choices, including the benzodiazepines—which have adverse effects on sleep architecture—as well as diphenhydramine (Benadryl) and trazodone (Desyrel),<sup>1</sup> which each have less specific sleep-promoting effects and more adverse effects and potential for drug-drug interactions, especially in elderly patients. The clinical pharmacology of the most commonly prescribed and most useful hypnotic medications are summarized in Table 2. A concern with each of these may be the potential for habituation of efficacy; fall risk; and the potential to cause sleepwalking, sleep eating, or other amnesic behaviors during sleep. If these adverse effects result, the hypnotic drug should be promptly discontinued with a shift toward the use of cognitive behavioral therapy strategies. In women, zolpidem should be used with particular caution given the slower metabolism of the drug, thereby promoting vulnerabilities to carryover sedation and unpleasant “hangover” type feelings or driving safety risks during the commute the next morning. Pharmacologic therapy of insomnia may be bolstered by the advent of suvorexant (Belsomra), a novel hypocretin antagonist that has a wake-suppressing rather than sleep-promoting mechanism of action. However, it should be noted that the higher doses that were primarily studied were determined as overly sedating and unsafe by the FDA and only the lower doses were approved. Further clinical experience will likely be necessary to establish the role of this medication as a treatment for insomnia.

### Sleep-Disordered Breathing

Breathing during sleep is carefully regulated to maintain homeostasis of oxygen, carbon dioxide, and blood pH. The mechanisms and homeostatic set points for ventilation vary systematically between wake, non-REM sleep, and REM sleep. In wake, the resulting ventilatory pattern is governed by careful integration of classic feedback systems designed to keep blood pH at approximately 7.40, arterial PaCO<sub>2</sub> at approximately 38 to 45 mm Hg, and PaO<sub>2</sub> greater than approximately 60 mm Hg with cortical influences that govern functions such as speaking, laughing, eating, singing, and other voluntary activities. During non-REM sleep, ventilation is considerably more rhythmic and is governed almost exclusively by the chemoresponsive feedback systems indicated above; during REM sleep, the chemoresponsive feedback system is further influenced by additional input from REM-influenced neurons, resulting in a less rhythmic and less-carefully regulated metabolic milieu.

Significant deviation from these norms is termed “sleep-disordered breathing” (SDB), and is marked by several distinct event types. Apneas are total or near-total cessations of airflow. Hypopneas are significant declines in tidal volume sufficient to result in significant reduction in oxygenation. Excess effort for breathing may result in arousals from and disturbance of sleep, and are termed respiratory effort-related arousals (RERAs). These types of events are often related as a rate, either as the apnea-hypopnea index (AHI; apneas+hypopneas per hour of sleep), the respiratory disturbance index (apneas+hypopneas+RERAs per hour of sleep), or the REI (apneas+hypopneas per hour of recording when sleep is not measured directly). In addition to these types of SDB, the general baseline minute ventilation may fall to the point where sustained hypoventilation takes place during sleep, termed sleep-related alveolar hypoventilation.

### Obstructive SDB: Snoring and OSA

The dynamic upper-airway obstruction, which occurs as a result of sleep in some persons, leads to a continuum of SDB varying from mild snoring to hypopneas to obstructive apneas. The

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Clinical Pharmacology of Hypnotic Medications

	MECHANISM OF ACTION	DOSAGE (MG)	DURATION OF ACTION ( $T_{1/2}$ )	TYPICAL ADVERSE EFFECTS	INTERACTIONS
Diphenhydramine (Benadryl)	H1	25–50	Intermediate (2.4–9.3 h)	Dry mouth, constipation, urinary retention	Nonsignificant
Trazodone (Desyrel) <sup>1</sup>	SRI	50–150	Short (3–6 h)	Dry mouth, dizziness, rash	CYP substrate; several others
Triazolam (Halcion)	BRA	0.125–0.5	Short (1.5–5.5 h)	Tolerance	CYP induction
Temazepam (Restoril)	BRA	7.5–30	Intermediate (8–18 h)	Tolerance	Nonsignificant
Melatonin <sup>2</sup>	MT1–MT2	1–3	Ultra-short (35–50 min)	Hangover type effect	None
Zolpidem (Ambien)	NBRA	5, 10	Short (2–2.6 h)	Amnestic behavior	Numerous
Zaleplon (Sonata)	NBRA	5, 10	Short (1 h)	Headache, amnestic behavior	Several
Eszopiclone (Lunesta)	NBRA	1–3	Intermediate (6 h)	Headache, amnestic behavior, rash possible	Nonsignificant
Ramelteon (Rozerem)	MT1–MT2	8, 16 <sup>3</sup>	Short (1–2.6 h)	Hyperprolactinemia	Ketoconazole (Nizoral), rifampin
Doxepin (Silenor)	H1	3, 6	Intermediate (12–15 h)	Dizziness, tachycardia	Nonsignificant
Suvorexant (Belsomra)	Orexin antagonist	10–20	Intermediate (12 h)	Headache, dizziness, abnormal dreams	CYP3A4 inducer
Lemborexant (Dayvigo)	Orexin antagonist	5–10	Intermediate ( $\leq 7$ h)	Drowsiness, fatigue, headache	CYP3A4 substrate

*Abbreviations:*  $t_{1/2}$ =half-life of drug; h=hours; H1=antihistaminergic H1 receptor blocker; SRI=serotonin reuptake inhibitor; BRA=benzodiazepine receptor agonist; CYP substrate=metabolized by cytochrome metabolism, susceptible to enzyme inhibition and elevated serum levels by multiple drugs; CYP induction=cytochrome enzyme inducer, may cause multiple potential drug-drug interactions via this mechanism; NBRA=nonbenzodiazepine benzodiazepine receptor agonist; MT1/MT2=melatonin type 1 and type 2 receptor agonist.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

likelihood and extent of upper-airway collapse is determined by the neural input into the dilating upper-airway muscles, influence of sleep state, and upper-airway anatomy. Obstructive events are more likely to occur in REM sleep when muscle tone is lowest, during transitions from lighter non-REM sleep to deep non-REM sleep when sleep is unstable, or when muscle tone is decreased by substances such as alcohol or drugs. The single biggest risk factor for snoring or OSA is obesity, wherein fatty deposition reduces upper-airway dimension, humoral factors reduce net dilating forces of the muscles, and the mechanical effects of obesity reduce lung volumes and the stabilizing effect of tracheal traction on the upper airway. Beyond obesity, many but not all patients have a predisposing anatomy of a narrowed oropharynx, such as a low-lying palate or redundant soft palate tissue, a thickened tongue base, or a narrow hypopharynx, although nasal anatomy with septal deviation or chronic congestion may also aggravate the problem.

Snoring without other symptoms, signs, or polysomnographic evidence of upper-airway obstructions such as hypersomnia, frequent associated arousals, or significant airflow limitation is termed primary snoring. While snoring may be a socially objectionable symptom or disruptive to the patient's sleep partner, snoring in isolation is otherwise not considered to be abnormal and such patients may be reassured if their bed partners are not bothered by their snoring. If treatment is desired, options include relieving nasal obstruction if present, commercially available lubricant throat sprays, mandibular positioning devices, and nasal or upper-airway surgical approaches such as nasal septal repair or uvulopalatopharyngoplasty (UPPP, or UP3 procedure). An otorhinolaryngology consultation may be helpful in determining which surgical approaches may be most beneficial for the individual.

OSA is an extremely common public health problem present in at least 2% to 4% of the general population and has been linked to development of hypertension and is a risk factor for incidental development of stroke, coronary artery disease, congestive heart failure, and atrial fibrillation. OSA has been shown to be associated with a wide variety of endothelial and metabolic abnormalities that favor vascular disease, and when patients with moderate to severe OSA are compared to normals or treated OSA patients, they appear to have a higher mortality and cardiovascular event frequency. Thus, the two main reasons to detect and treat OSA are to improve symptoms and to decrease cardiovascular risks. There are good data to show that treatment of OSA improves symptoms and quality of life. Data regarding the reversal of cardiovascular risk are not as firm, but most experts agree that at least moderate and severe OSA ought to be treated, regardless of symptom severity.

OSA severity is rated by the polysomnographic AHI, the hourly rate of apneas and hypopneas averaged over the total sleep time, or, in the case of HSAT, by the REI. An AHI of 4 per hour or less is considered normal. Mild OSA is diagnosed with an AHI of 5 to 14 per hour, moderate OSA with AHI of 15 to 29 per hour, and severe OSA with AHI being 30 per hour or higher. In most laboratories, correlation of the AHI with specific sleep stages and body positions is usually performed to determine whether positional therapy may be offered, as many patients have OSA only during the supine sleep position (position-dependent OSA), and some manifest OSA only during REM sleep in the supine position.

A form of OSA called the upper-airway resistance syndrome is defined by a clinical complaint of hypersomnia, often accompanied by snoring but without an abnormally high frequency of overt apneas or hypopneas resulting in significant decline in oxygen saturation.

**TABLE 3** Treatment of Sleep-Related Breathing Disorders

SLEEP-RELATED BREATHING DISORDER	TREATMENT MODALITY	GOAL	
OSA syndrome	Lifestyle/behavior modification	<ul style="list-style-type: none"> <li>• Weight loss</li> <li>• Alcohol avoidance</li> </ul>	<p>Reduced weight may result in improvement airway patency</p> <p>Alcohol worsens OSA; avoidance of exacerbating factor is encouraged</p>

PSG confirms repetitive arousals related to the increased respiratory effort (respiratory effort-related arousals, or RERAs, during PSG) required to overcome upper-airway obstruction. Because of the similar pathogenesis and treatment response to relieve upper-airway obstruction, this is considered a variant of OSA.

Therapeutic options for snoring and sleep apnea include reducing nasal congestion or obstruction, positional therapy, nasal continuous positive airway pressure, oral appliances, the nasal expiratory positive airway pressure device, oral pressure therapy (OPT), or surgical management (Table 3). Patients with OSA have higher morbidity from vascular events and higher motor vehicle accident rates. Assessment and appropriate counseling for weight

loss, cardiovascular risk factors, and driving while untreated (or extreme caution) should be part of a treatment plan.

**Weight loss.** Weight loss may reduce soft tissue in the neck, making the oropharynx less compressible. The improvement in lung volumes accompanied by weight loss also favor enhancement of longitudinal traction on the upper airway, the so-called “tracheal tug.” About 30% to 40% of patients who are able to achieve substantial weight loss may become cured of their OSA. Careful follow-up is needed because many remissions are not permanent. Alcohol and other substances that reduce upper-airway tone or cause sedation or reduced responsiveness worsen OSA and should be prudently avoided.

**Positional therapy.** Among the lifestyle or behavioral changes, positional therapy involves employing one or more simple strategies to enforce sleep only in nonsupine body positions, usually on the side. One method is the “tennis ball in T-shirt” approach. The patient wears a snug-fitting T-shirt with a pocket sewn onto the back between the shoulder blades with two or three tennis or wiffle balls inserted into it to discourage the patient from turning onto the back during sleep. Other options include similar commercially marketed shirts or vests (the FDA-approved ZZoma sleep apnea pillow, the “snoring backpack,” and similar strategies) and body pillows propped or wedged behind the patient or hugged by the patient. A correctional device for positional sleep apnea is also approved in the European Union. Unfortunately, shoulder or hip pain often limits the application of positional therapy, especially in elderly persons, and long-term adherence or compliance remains poor, with only about one-third of patients able to perpetuate positional therapy strategies in long-term follow-up. Patients with position-dependent OSA should be counseled to be cautious for development of severe OSA problems during any future anticipated prolonged periods of supine sleep, such as postoperative recovery periods following surgery or following a major injury.

**Positive airway pressure.** The mainstay of treatment for OSA for the majority of patients remains positive airway therapy (PAP). The main components of PAP appliances are the blower unit, which delivers calibrated pressures to hold open the airway; tubing to conduct the pressurized air to the patient; an interface such as a nasal or oronasal mask; and a harness to hold the mask firmly to the patient’s face during use. Of the PAP therapies, continuous positive airway pressure (CPAP), which delivers a continuous set pressure between 5 and 20 cm H<sub>2</sub>O, is usually first tried in the setting of PSG; in many sleep centers, the practice of performing split-night PSG (an initial diagnostic phase followed by a treatment phase of CPAP titration toward an optimal pressure for the individual patient) allows diagnosis and treatment prescription to occur in an efficient manner. If an optimal pressure cannot be determined by laboratory titration or data is not available to guide prescription of a specific pressure for a patient, application of an autotitrating PAP device may be considered, offering flexibility for delivering a relatively wide range of self-adjusting treatment pressures as the patient changes sleep position and enters different sleep stages through the night with accordingly varying apnea severity. Autotitrating PAP has been found to be efficacious in most patients diagnosed with OSA by HSAT. However, close clinical follow-up is needed in all patients who have recently started PAP.

PAP is typically delivered through an interface chosen as most comfortable by the patient, either a nasal mask, nasal pillows, or an oronasal. Nasal pillows, a type of cannula that provides a tight seal within the nares, and a newer tube-like frame that sits in front of and not within the nares are most effective at lower treatment pressures; they may be favored by many patients with claustrophobia but may dislodge at higher pressures or with frequent nocturnal movement. Nasal masks of various types are used in many patients, but if mouth breathing and consequent leak are a problem, a chin strap may be added, or an oronasal face mask may be substituted. Many newer PAP machines offer the feature of pressure relief during exhalation, which may enhance patient tolerability at higher level PAP pressures by “giving way” as the patient expires. Bilevel positive airway pressure (BPAP) may also be employed at higher treatment pressures if CPAP is not well tolerated. Setting a pressure delta  $\geq 4$  cm between the inspired and expired pressure may also add a degree of positive pressure ventilation for patients with concurrent sleep-related hypoventilation from an intrinsic pulmonary disease or neuromuscular respiratory muscle weakness.

**Oral appliances.** Oral appliances may be fitted by a dental sleep specialist. They provide a means of advancing the mandible that pull the tongue base forward slightly, opening the oropharyngeal airway to some degree and obviating some

apnea and hypopnea events. The device is most effective for mild to moderate severity and supine position-dependent OSA and generally less predictably effective for most cases of severe OSA. However, the use of oral appliances is increasing due to greater availability of competent dental professionals working with the devices, awareness that for some patients adherence is better with OAs than PAP, and improvements in appliance design that allow enhanced efficacy in some instances. Because oral appliances are less reliably effective in controlling SDB, repeat testing—either with out-of-center sleep testing or PSG after maximal adjustment—is needed to confirm efficacy.

**Nasal valve appliances.** An expiratory nasal resistance valve appliance (Provent) was approved by the FDA for treatment of OSA. The device may be an alternative for some patients with OSA who fail to tolerate CPAP therapy. The device is a small, disposable oval appliance that is affixed over each of the patient’s nares by self-adhesive with an airflow port that offers resistance to expiratory airflow, thereby producing expiratory positive airway pressure and preserving nasal and oropharyngeal airway patency with minimal impedance to inspiratory airflow. The device was proven to significantly reduce polysomnographic AHI and subjective sleepiness on the ESS in a sham-controlled randomized trial. Because they are disposable, a new device must be affixed each night. Appropriate patient characteristics and long-term results are not yet clear, but these may be considered in patients who do not prefer CPAP or oral appliances and are agreeable to follow-up to ensure efficacy.

**Oral pressure therapy.** A newer option for treatment of mild to moderate OSA is OPT (Winx), which combines an oral appliance with negative intraoral pressure to help keep the tongue and soft palate in a more anterior position, enlarging the retrolingual and retropalatal space. There is as yet limited experience with the device; however, this may be an option for some patients who are averse to or intolerant of other therapies.

**Surgery.** Surgical modifications of the upper airway are principally of two basic approaches, palatal approaches, tongue-based procedures (genioglossus advancement, hyoid myotomy and suspension, lingualplasty), or maxillomandibular advancement (MMA). Palatal approaches such as UPPP, or “UP3” performed by otorhinolaryngologists are effective for relief of snoring but mostly ineffective for treatment of OSA, especially if severity is moderate or greater in degree. MMA appears to be quite effective in mild to moderate OSA and can even be applied with good effect even in selected severe OSA cases; however, morbidity from perioperative pain is considerable and long-term outcomes remain unclear. A hypoglossal nerve stimulation implant (Inspire) is a novel surgical treatment for PAP-intolerant patients. A recently published randomized controlled trial demonstrated efficacy and reasonable tolerability; however, this device was only recently FDA approved and there is limited clinical experience with it, thus, its future role and scope of use in OSA management remains to be determined.

### Central Sleep Apnea Syndrome

Central sleep apnea syndrome results from an unstable ventilatory drive during sleep, resulting in periods of insufficient ventilation and compromise of gas exchange despite a patent oropharyngeal airway. Clinically, patients may share similar symptoms with those with OSA, including snoring, except patients with central sleep apnea more frequently complain of insomnia than hypersomnia. Central sleep apnea has a heterogeneous pathophysiology and may be idiopathic or due to high-altitude-induced periodic breathing, due to Cheyne-Stokes breathing, or narcotic-induced. Neurologic causes—such as brainstem infarction or neurodegenerative disorders, including multiple system atrophy—may also cause central apnea. In heart failure, the presence of central sleep apnea syndrome or Cheyne-Stokes breathing imparts a poor prognosis. A high-quality clinical trial showed that on average, CPAP did not reduce mortality. However, central sleep apnea is often at least

partially resistant to treatment with conventional nasal CPAP therapy, and while CPAP may effect improved mean oxygenation, frequent arousals that fragment sleep often continue. However, a recent large multicenter randomized control trial, the SERVE-HF study, showed elevated all-cause and cardiovascular mortality risk in patients with central sleep apnea and symptomatic heart failure with an estimated ejection fraction of  $\leq 45\%$  who were randomized to ASV. Therefore, use of ASV in this patient population is not advised at the current time. Remede, a phrenic nerve stimulator, has recently been approved by the FDA as a treatment option in selected cases with central sleep apnea.

### Treatment-Emergent Central Sleep Apnea Syndrome

Treatment-emergent central sleep apnea syndrome is a subtype of central sleep apnea wherein patients have significant obstructive/anatomical problems with ventilation, but also have unstable ventilatory patterns noted in patients with central sleep apnea syndromes. These patients have a clinical and PSG presentation of OSA, but once the upper airway is opened with CPAP, they experience frequent central apneic events that may or may not later resolve with continued exposure to PAP in the home setting. Some patients clearly continue to manifest frequent central sleep apneic events more than five times per hour, leading to the suboptimal outcomes of persisting clinical complaints of hypersomnia and medical risk. Treatment-emergent central sleep apnea syndrome may occur in as many as 4% to 15% of those with OSA. There is emerging evidence that alternative modes of PAP—particularly ASV—may be superior to conventional CPAP for treatment of treatment-emergent central sleep apnea syndrome. A randomized controlled trial recently showed that ASV more reliably relieves SDB, while CPAP fails to control SDB in up to one-third of cases. However, there is also evidence to suggest that treatment-emergent central sleep apnea resolves over time in a substantial number of patients who continue to remain on CPAP therapy.

### Sleep-Related Hypoventilation

The causes of hypoventilation during sleep include primary pulmonary parenchymal disorders, neuromuscular conditions affecting bellows musculature, or restrictive physiology of the chest wall accompanying kyphoscoliotic disorders or morbid obesity. While each of these disorders may also ultimately cause daytime hypoventilation, sleep recumbency, especially supine sleep positioning, and REM sleep stage (which leads to relative paralysis of the chest wall and sole dependency on diaphragmatic excursion to drive respiratory effort) often lead to exclusive or initial sleep-related hypoventilation with subsequent medical risk consequent to suboptimal nocturnal oxygenation. Failure to treat significant nocturnal hypoventilation may result in the development of sequelae of hypoxemia such as polycythemia, pulmonary hypertension, and right heart failure, or of hypercapnic respiratory failure. Treatment most often involves use of NIPPV (see Table 4). A newer modality of positive pressure ventilation, volume-assured pressure support ventilation (AVAPS™), consists of a short delivery of a provider-set tidal volume, which, when coupled with a set backup respiratory rate, assures delivery of a minimum minute ventilation, even when changes in the patient's muscular strength or ventilatory load change. These therapies are best titrated in the context of a supervised overnight laboratory polysomnogram under the direction of a sleep or pulmonary medicine specialist. One must be careful not to resort to the potentially dangerous solution of added oxygen therapy alone in severe COPD or neuromuscular etiologies of sleep-related hypoventilation, because as ventilation fails and hypercapnea results, the hypoxic drive to breathe may become the chief factor leading to continued ventilatory effort and oxygen in this context may precipitate acute respiratory failure in some individuals. A morning arterial blood gas on room air following PSG is indicated to assess for potential hypercapnia and assess the impact of ventilatory support. In the context of severe hypercapnia (i.e.,  $P_{CO_2}$  of 55 or greater), serial arterial blood gases to monitor the

effects of ventilatory support, oxygenation, and accumulating hypercapnia may help determine whether nocturnal mechanical ventilatory support is indicated.

### Narcolepsy and Central Disorders of Hypersomnolence

Narcolepsy is the prototypical central disorder of hypersomnolence. Narcolepsy is categorized further as Narcolepsy Type I (previously called narcolepsy with cataplexy) and Narcolepsy Type II (previously called narcolepsy without cataplexy). Cataplexy is a distinctive and highly specific symptom characterized by emotionally provoked muscle atonia intruding into wakefulness that is seen in a minority of patients overall and may precede but more often follows onset of the main symptom of hypersomnia. In the absence of cataplexy, a diagnosis of Narcolepsy Type I may also be made if cerebrospinal fluid (CSF) hypocretin-1 concentration, measured by immunoreactivity, is  $<110$  pg/mL or  $<1/3$  of mean values obtained in normal subjects with the same standardized assay. In Narcolepsy Type II, there is no cataplexy, and the CSF hypocretin level does not meet the above criteria or has not been measured. In addition to sleepiness and cataplexy, the full clinical pentad of narcolepsy also includes symptoms of sleep paralysis (the inability to move the body upon awakening), hypnagogic hallucinations (the intrusion of dream imagery and mentation into conscious awareness following awakening), and sleep-maintenance insomnia (with frequent nocturnal arousals and difficulty maintaining sleep). However, narcolepsy is most frequently monosymptomatic, with the sole symptom being pervasive, enduring sleepiness and decreased vigilance with a tendency toward dozing off inadvertently in permissive settings and the overwhelming desire to nap during the daytime, especially in the afternoons. Naps are most often highly refreshing; scheduled naps can be utilized to therapeutic advantage or indeed, in rare patients, as the sole treatment for those bent on avoiding stimulant pharmacotherapy. Narcolepsy is relatively uncommon, affecting approximately 1:2000 of the general population. While the etiology of narcolepsy remains unknown, most experts continue to favor a long hypothesized autoimmune cause. Major advances in the understanding of the neurobiology of narcolepsy over the past two decades have included the clear linkage of the HLA DQB1\*0602 haplotype in up to 90% patients having narcolepsy with cataplexy, discovery of wake-promoting hypocretin/orexin peptides produced by the perifornical posterolateral hypothalamus, and low to unmeasurable CSF hypocretin in nearly 90% of narcolepsy with cataplexy patients. Within the last few years, epidemic narcolepsy-cataplexy following H1N1 vaccination in Europe and Asia also provided further support for the autoimmune hypothesis of narcolepsy. Unfortunately, these tantalizing discoveries have not yet yielded clear insight into pathogenic mechanisms nor more specific therapies for patients, and the mainstay of treatment for the condition remains the use of older stimulant and wake-promoting medications, or prescribed therapeutic napping, as naps are most often highly refreshing and restorative in narcolepsy patients. Supportive laboratory evidence for narcolepsy includes a relatively normal polysomnogram to exclude other causes of hypersomnia such as OSA or PLMD, followed by a confirmatory MSLT, which demonstrates mean sleep latency shorter than 8 minutes and two or more sleep-onset REM periods during four or five nap opportunities.

Idiopathic hypersomnia is a closely related condition often difficult to distinguish from narcolepsy without cataplexy, although a few nuanced clinical features tend to distinguish it from narcolepsy, chiefly a characteristically reported unrefreshing nocturnal sleep and nap quality. Idiopathic hypersomnia has previously been further subclassified as variants with or without prolonged sleep period, although these phenotypes are overlapping and current diagnostic standards have eliminated this distinction. Other similar enigmatic and poorly understood primary CNS hypersomnias include posttraumatic hypersomnia when there is a history of temporally related antecedent substantial head injury, and recurrent hypersomnia,

**TABLE 4** Clinical Pharmacology of Stimulant and Wake-Promoting Medications

	MECHANISM OF ACTION	DOSAGE (MG)	DURATION OF ACTION ( $T_{1/2}$ )	TYPICAL ADVERSE EFFECTS	INTERACTIONS
Modafinil (Provigil)	Unknown	100–600 <sup>3</sup>	Intermediate (15 h)	Tremor, jitteriness, palpitations, hypertension	Oral contraceptives
Armodafinil (Nuvigil)	Unknown	150–450 <sup>3</sup>	Intermediate (15 h)	Tremor, jitteriness, palpitations, hypertension	Oral contraceptives
Pitolisant (Wakix)	Histamine-3 receptor inverse agonist/antagonist	8.9–35.6 mg	Long (8–24 h)	Headache, nausea, insomnia	Antihistamines, oral contraceptives, CYP2D6 inhibitors, CYP3A4 inducers, mirtazapine, TCAs and other QT-prolonging agents
Solriamfetol (Sunosi)	DNRI	75–150 mg	Intermediate (7 h)	Headache, nausea, anxiety, insomnia	Dopamine agonists, CNS stimulants, sympathomimetics, esketamine, MAOIs, SNRIs, bupropion
Methylphenidate (Ritalin)	DNRI	15–100 <sup>3</sup>	Short (2–4 h)	Tremor, jitteriness, palpitations, hypertension	Nonsignificant
Methylphenidate SR (Concerta) <sup>1</sup>	DNRI	18–72	Intermediate (3.5 h)	Tremor, jitteriness, palpitations, hypertension	Nonsignificant
Amphetamine/dextroamphetamine (Adderall)	DNRI	15–100 <sup>3</sup>	Intermediate (10–13 h)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion (Wellbutrin)
Dextroamphetamine (Dexedrine)	DNRI	15–100 <sup>3</sup>	Long (10–28 h)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion
Lisdexamfetamine (Vyvanse) <sup>1</sup>	DNRI	20–100 <sup>3</sup>	Short (<1 h as prodrug) (10–28 h as dextroamphetamine)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion
Methamphetamine (Desoxyn) <sup>1</sup>	DNRI	15–100 <sup>3</sup>	Intermediate (9–15 h)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

Abbreviations:  $t_{1/2}$ =half-life of drug; h=hours; DNRI=dopamine and norepinephrine monoamine reuptake inhibitor; QTc=corrected QT interval; MAOI=monoamine oxidase inhibitor; SSRI=serotonin selective reuptake inhibitor; SNRI=selective norepinephrine reuptake inhibitor; TCA=tricyclic antidepressant (the potential interaction with all these agents is largely theoretical concern for potentiation of serotonin syndrome).

also known as the Kleine-Levin syndrome, which in addition to hypersomnia includes other neuropsychiatric sequelae such as cognitive and behavioral changes like hypersexuality and hyperphagia. Hypersomnia is also commonly associated with as many as 50% of those with myotonic dystrophy type 1.

The mainstay of treatment for each of these conditions is stimulant and wake-promoting agent therapy, with the goal of improved vigilance and psychomotor functioning. Stimulants and wake-promoting agents range in intensity from lower to higher intensity and efficacy/tolerability options, from modafinil (Provigil) and armodafinil (Nuvigil) on the milder end of the spectrum—although selected narcolepsy patients respond quite well to these drugs—to methylphenidate (Ritalin), and to the amphetamine/dextroamphetamine (Adderall). Relevant clinical pharmacology of the stimulant medications commonly used in clinical practice are summarized in Table 4. Patients with uncontrolled

hypersomnias should be cautioned against driving, operating dangerous machinery, or engaging in other similarly dangerous activities or hobbies while they are drowsy, as they may be prone to sudden and unpredictable sleep attacks. Sodium oxybate (gamma hydroxy butyrate) is an FDA approved tightly controlled substance for the treatment of sleepiness and cataplexy in patients with narcolepsy. Sodium oxybate (Xyrem) is usually given in two divided doses, before bedtime and in the middle of the night; it can be dangerous in the setting of uncontrolled OSA or respiratory conditions and central nervous system depressants. Other REM suppressing medications such as tricyclic antidepressants, SSRIs and SNRIs are also used in the treatment of cataplexy.

#### Circadian Rhythm Sleep Wake Disorders

Circadian rhythm sleep disorders result in misalignment of the timing of the sleep period relative to the desired bed and

rise times, resulting in concurrent insomnia and hypersomnia symptoms despite normal total sleep time. The most common circadian rhythm disturbances are actually exogenous influences on the patient and his/her circadian axis, which in these cases is functioning normally but is unable to adjust rapidly enough to the required new temporal milieu. These exogenous disorders include jet lag disorder and shift work disorder, resulting either from imposed transmeridian travel or alternating work shifts, respectively, that disturb the patient's environmental entraining cues and homeostatic drives for sleep and wakefulness, thereby resulting in misalignment of the patient's endogenous biological sleep drive and typical sleep schedule to the clock time and environment to which they must rapidly adapt.

Jet lag disorder results when an individual crosses several transmeridian time zones in a single day. Crossing one or two time zones is usually not too difficult for the traveler to accommodate, but crossing three time zones typically causes symptoms of jet lag. Flying eastward is generally much more difficult than flying westward, as patients more easily accommodate phase delay than phase advancing, or "loss" of time. Treatments for jet lag syndrome usually involve efforts to rapidly reentrain the patient to the new environment, and protocols for advance preparation including setting back (for eastward travel) or setting ahead (for planned westward travel) one's daily routine 2 to 3 weeks prior to the trip so that the traveler is already partially reset in his or her circadian routine before departing. Also critical is attempting to rapidly adapt to the new time zone, such as by seeking regular sunlight exposure during the daytime and avoiding light exposure in the evening. Brief use of a hypnotic medication and regular daily doses of melatonin<sup>7</sup> 0.5 to 5.0 mg at bedtime for the first few nights after arrival can help reset the sleep schedule in the new time zone.

Shift-work sleep disorder results from workers who must constantly and regularly alter or rotate their work schedules between different shifts (so-called "swing shifts") or workers who must accommodate a regularly scheduled second or third shift (i.e., shifts other than a day shift). Shift workers often have difficulty adapting and shifting their sleep-wake schedules and develop symptoms of insomnia or hypersomnia. Shift workers must be educated to prioritize regularly obtaining a sufficient quantity of sleep, regardless of their work circumstances. Swing shift workers should also be counseled to avoid working more than five night shifts in a row, as night shift work frequently leads to a greater degree of sleep deprivation over time. Shift workers should also be counseled to avoid rotating swing shifts whenever possible, to strictly avoid scheduling overtime duty, and to avoid long commutes (and to exercise special caution to avoid drowsy driving). Judicious use of caffeinated beverages, or prescribed stimulant therapy with modafinil may be helpful for enhancing vigilance in some patients, but should be used with caution as they might interfere with sleep initiation.

The two most common endogenous circadian disorders are delayed sleep-wake phase disorder (DSWPD) and advanced sleep-wake phase disorder (ASWPD), disorders that are most prevalent in opposite extremes of life. DSWPD is seen most often in adolescents and young adults who are biological night owls in their circadian preference, preferring a delayed bedtime and rise time (i.e., bedtimes well past midnight and subsequent arising times in the late morning or early afternoon). DSWPD patients have an extreme and enduring form of this tendency, however, resulting in persisting misalignment of the patient to societal norms. Adolescent and young adult patients present with profound intractable initial insomnia due to their inability to fall asleep at a conventional bedtime as required for school or most daytime occupations, and profound daytime hypersomnia due to their inability to arise and function in the morning

hours. Diagnosis is easily recognized by clinical history and sleep diaries, with or without adjunctive actigraphy to objectively verify the pattern of consistent delayed sleep-phase periods. Contrarily, ASWPD is more common in elderly individuals who are biological larks (i.e., preferring an early bedtime and early rise time by nature). However, the ASWPD elderly are unable to stay awake for desired evening activities (often even unable to go out to dinner with friends), and awaken undesirably early in the morning with a consequent inability to fall back asleep in early morning hours. The presentation can mimic depression, whose hallmark biological sign is often noted to be an early morning awakening; care should be taken to carefully distinguish between these two diagnoses. Treatment of each is difficult; options include specifically timed bright light therapy, with or without light restriction, and timed administration of low dose melatonin. The time of administration differs for the two disorders, and is determined by the patient's own endogenous dim light melatonin onset and arise time, and the phase response curve for light and melatonin administration. Bright light therapy is administered at approximately 2500 lx intensity for at least 30 minutes. The timing of bright light administration is first thing in the morning after arising in DSWPD, where a phase-advancing influence is desired; for ASWPD patients, bright light is prescribed in the late afternoon and early evening hours where it will have a phase-delaying effect. Weeks to a few months of regular therapy are necessary to achieve effect. Adherence is difficult and compliance unable to be verified. Specifically timed melatonin usually given at very low doses for this indication (contrary to its use in higher supraphysiologic doses as a hypnotic agent by many patients in other contexts of insomnia, or its high-dose use in REM sleep behavior disorder [RBD]) may also be administered, but its dose and timing are complicated; it must be given in accordance with the circadian phase response curve to have optimal effects and to avoid complicating the problem. For most patients with DSWPD, immediate release melatonin 0.5 mg should be administered at approximately 1 hour before desired bedtime; in ASWPD, melatonin would instead be given prior to the time point of 8 hours following the patient's usual rise time (so as to have a phase-delaying effect). Adjunctive light restriction is recommended in the late afternoon and evenings for DSWPD to avoid precipitating additional phase delays—such as the avoidance of working with luminescent computer screens or viewing video media from close distance in the late evenings—and some experts advocate the use of commercially available blue light restricting glasses as biologically reasonable, as blue light stimuli in evening hours may exacerbate phase delay and confound other recommended treatment effects. However, the efficacy of blue light restriction currently lacks explicit evidence from large clinical trials. As a last resort, the measure of chronotherapy, a progressive delay of bedtime every few days, is prescribed, with the bed and rise times being progressively and successively delayed until the desired bed and rise times are achieved. Attempts to then entrain the patient on this schedule with the aforementioned measures are again attempted with scheduled bright light and prescribed timed melatonin dosing. This is a lengthier process for DSWPD patients and necessitates work restriction during the approximate 2-week time frame necessary to achieve a turnaround of the desired patient's sleep/wake schedule.

#### Parasomnias and Other Nocturnal Events

Parasomnias are nocturnal events that disrupt sleep but usually do not appreciably disturb sleep quality. As such, nocturnal events do not typically present with symptoms of insomnia or hypersomnia unless there are other comorbid primary sleep disorders such as OSA, which is a frequent comorbidity presenting along with the parasomnias, especially in adult patients.

Parasomnias may arise from either NREM or REM sleep. The NREM parasomnias are essentially all variations on the theme

<sup>7</sup>Available as a dietary supplement.

**TABLE 5** Distinguishing Features of Nocturnal Events

	PREMONITORY SYMPTOMS	BEHAVIORAL CHARACTERISTICS	DURATION	FREQUENCY	EEG/PSG FINDINGS
<b>NREM Parasomnias</b>					
Night terrors	None	Inconsolable screaming	Minutes	1 or less nightly	Arousal from N2-N3
Confusional arousals	None	Confused, amnesic	Seconds to minutes	1 or less nightly	Arousal from N3>N2
Sleepwalking	None	Ambulation, amnesia	Minutes	1 or less nightly	Arousal from N3 » N2
<b>REM Parasomnias</b>					
Nightmares	Dream recall	Arousal, frightened, palpitations	Seconds	Generally 1/nightly	Arousal from REM
RBD	Variable dream recall	Thrashing, complex motor behavior	Seconds to minutes	>1/night, second>first half	REM sleep without atonia
<b>Epilepsies</b>					
BECTS	Facial twitching, hypersalivation	Focal motor or GTC, postictal	Seconds to minutes	>1/night	Arousal from NREM, IEDs EEG pattern
ADNFLE	Bizarre stereotyped motor behavior	Focal motor, bizarre motor	Seconds, < 1 min	1 or multiple attacks/night	Arousal from N2
TLE	Aura variable	CPS, postictal	1–2 min	1 or multiple attacks/night	Arousal from N2
Psychogenic spells	Variable	Variable	often>5 min	1 or multiple attacks/night	Normal awake EEG

*Abbreviations:* NREM=nonrapid eye movement sleep; N2=stage 2 NREM sleep; N3=stage 3 NREM sleep; REM=rapid eye movement sleep; IEDs=interictal epileptiform discharges; EEG=electroencephalogram; PSG=polysomnogram; BECTS=benign epilepsy of childhood with centro-temporal spikes; ADNFLE=autosomal dominant nocturnal frontal lobe epilepsy; TLE=temporal lobe epilepsy; RBD=REM sleep behavior disorder.

of disorders of arousal, where the behavioral sleep state lingers into awakening, leaving arousal from sleep incomplete. Consequent clinical manifestations are surprisingly heterogeneous and often age related, with specific syndromes such as sleep terrors (also called night terrors) in children, sleep walking and confusional arousals seen in children and adults, and sleep-related eating behavior seen almost exclusively in adults, especially those receiving zolpidem or other newer prescribed hypnotics. NREM disorders of arousal are especially common in children in the first decade of life and are regarded as a relatively normal variant (and perhaps in some cases simply representing an exaggerated manifestation of the physiological difficulty in arousing from the characteristically deeper N3 NREM sleep inherent in the developing brain). As such, pediatric parasomnias are frequently outgrown; however, in some patients, they do endure throughout life. In adult patients who present with newly evolved nocturnal events proven to be NREM disorders of arousal, one should be highly suspicious of comorbid primary sleep disorders that provoke arousing events, such as SDB or PLMD.

REM parasomnias include nightmares and RBD. Nightmares are undesirable, disturbing dreams that lead to sudden arousal from sleep with heightened autonomic sequelae of sweating, hypervigilance, tachycardia, and tachypnea. Nightmares and vivid dreaming are present in between 10% and 50% of normal young children and in about 50% of adults, but become abnormally disturbing in content or frequency much less frequently, and the true prevalence of nightmare disorder remains unknown. Patients who present with a chief complaint of frequent nightmares should be reassured as to their biological nature and receive a detailed physical and neurologic history and examination to exclude potential provoking comorbid causes such as a recent medication change in type or dosage, mood or anxiety disorder, or primary sleep disorder such as SDB. If no certain readily reversible triggering cause may be identified, referral for consideration of hypnosis, behavior treatment in the form of imagery rehearsal therapy, or pharmacotherapy with

clonazepam (Klonopin)<sup>1</sup> may be helpful in some cases. Nightmares that involve flashbacks of previous traumatic events, most often also with similar daytime flashbacks, suggest the alternative diagnosis of posttraumatic stress disorder (PTSD) and the need for psychiatric evaluation. Recent evidence has suggested that alpha-blocking medications such as prazosin (Minipress)<sup>1</sup> or terazosin (Hytrin)<sup>1</sup> may be helpful in suppressing nightmares associated with PTSD.

RBD is characterized by potentially injurious dream enactment behaviors that mirror frightening dream content (characteristically involving fighting off attackers or defending oneself against assailants). In RBD, bed partners will describe objective witnessed dream enactment manifested by violent limb thrashing movements such as punching or kicking and screaming or shouting vocalization during sleep. While RBD patients rarely leave the bed and sleepwalk, falls or other injurious behavior to self or the bed partner are frequent. Importantly, RBD is strongly associated with future development of neurodegenerative disorders. Elderly patients newly diagnosed with RBD harbor up to an 91.9% risk of developing Parkinsonism within 15–25 years of symptom onset, with a shorter-term risk of 30% to 50%, so that all patients with RBD require serial neurologic examinations and follow-up. RBD in young adults may, however, be caused by antidepressant medications, especially the SSRIs, and removal of the offending drug may lead to resolution of dream enactment in some cases. Diagnosis of RBD is by clinical history as well as confirmatory evidence for increased REM sleep muscle tone evident on polysomnographic electromyogram (EMG) leads in the chin and limbs (known as REM sleep without atonia). Treatment options include melatonin, initially at doses of 3 to 6 mg and gradually titrating toward 12 mg nightly as needed to suppress witnessed injurious behaviors, or clonazepam (Klonopin)<sup>1</sup> 0.5 to 1.0 mg increased to 2 to 3 mg nightly. Great care should be taken to first exclude comorbid

<sup>1</sup>Not FDA approved for this indication.

**TABLE 6** Clinical Pharmacology of Treatments for Restless Leg Syndrome

	MECHANISM OF ACTION	DOSAGE	TYPICAL ADVERSE EFFECTS	INTERACTIONS
Iron Replacement				
Ferrous sulfate <sup>1</sup>	Fe	324 mg, 1 tab every alternate day	Nausea, constipation	None
Ferrous fumarate+vit C <sup>1</sup>	Fe	200/125 mg, 1 tab every alternate day	Nausea, constipation	None
Carbidopa-Levodopa (Sinemet) <sup>1</sup>	DA	25/100 1–2 prn	Nausea, dizziness, ICD	None
Pramipexole (Mirapex)	DA	0.125–1.0 mg <sup>2</sup> qhs	Nausea, dizziness, ICD	None
Ropinirole (Requip)	DA	1–6 mg <sup>2</sup> qhs	Nausea, dizziness, ICD	None
Rotigotine (Neupro Transdermal Patch)	DA	1–3 mg qam	Nausea, dizziness, ICD	None
Gabapentin (Neurontin) <sup>1</sup>	Unknown	300–1200 <sup>2</sup> mg qhs	Nausea, dizziness, pedal edema, weight gain	None
Gabapentin Enacarbil (Horizant)	Unknown	600 mg	Nausea, dizziness, pedal edema, weight gain	None
Pregabalin (Lyrica) <sup>1</sup>	Unknown	100–600 mg qhs	Nausea, dizziness, pedal edema, weight gain	None
Tramadol (Ultram) <sup>1</sup>	MRA	50 mg	Nausea, dizziness	None
Codeine	MRA <sup>1</sup>	400 mg qhs 30–60 mg	Nausea, dizziness	None
Oxycodone <sup>1</sup>	MRA	5–15 mg	Nausea, dizziness	None

<sup>1</sup>Not FDA approved for this indication.

Abbreviations: mg=milligrams; Fe=iron replacement; DA=dopamine agonist; MOR=mu opiate receptor agonist.

OSA prior to use of clonazepam, a potential respiratory and upper-airway suppressant.

Nocturnal epilepsies or psychogenic nonepileptic spells may also arise from sleep or apparent sleep and are additional diagnostic considerations in the differential diagnosis of parasomnias. A high degree of stereotypy (one attack being essentially identical to the next) with multiple attacks within a single night are features suggestive of organic partial extratemporal (frontal lobe) epilepsy, even in the absence of EEG changes between or during an episode. In children, benign rolandic epilepsy may lead to stereotyped episodes of facial twitching and drooling, with or without secondary generalized tonic clonic seizures. Children or adults with autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) may present with bizarre brief motor behavior (typically of 10- to 60-second duration) without post-ictal sleepiness. ADNFLE has recently been mapped in several kindreds as a channelopathy, producing a defect of the neuronal nicotinic acetylcholine receptor. Psychogenic nonepileptic spells are instead characterized by nonstereotypic and often prolonged attacks that arise from a behavior state of apparent sleep that is instead confirmed during video-EEG PSG to represent normal waking EEG background. Distinguishing features for the differential diagnosis of nocturnal events are shown in [Table 5](#).

### Sleep-Related Movement Disorders

Sleep-related movement disorders include restless legs syndrome (RLS), periodic limb movement disorder (PLMD), leg cramps, bruxism, rhythmic movement disorder, and others.

#### RLS and PLMS

Diagnosis of RLS is based completely on a clinical history and typically requires four central elements of the described symptoms: an uncomfortable urge to move the legs, with or without uncomfortable leg sensations; temporary relief by movement; symptoms occurring solely or predominantly at rest; and nocturnal worsening

of symptoms. About 50% of patients with RLS will carry a positive family history of the disorder, but positive family history is not necessary for the diagnosis. The nature of the symptoms as described by the patient may be quite variable with regard to the symptom quality, location or distribution, temporal occurrence, frequency, and severity. RLS symptoms are usually described as uncomfortable, although not really painful, with a sense of a creepy-crawly or prickling discomfort, often below the knees and centered about the shins or calves, but sometimes more proximally in the thighs, or even isolated to the feet and ankles. Symptoms may occur in the arms as well, especially proximally near the shoulders. Augmentation is common, occurring in about 50% of patients treated with dopaminergic drugs and involves a worsening of the symptoms: symptom onset occurs earlier during the day, becomes more intense, and spreads up to the arms. RLS has been linked to deficient iron stores and dopaminergic neurotransmission in the brain and is more common in patients with parkinsonism, multiple sclerosis, epilepsy, and in those with chronic renal insufficiency.

While periodic limb movements of sleep (PLMS) are seen in 80% to 90% of RLS patients, PLMS are not necessary for the diagnosis of RLS. Furthermore, PLMS are also extremely frequent in the general population, seen in 5% to 15% of younger adults and as many as 45% of elderly individuals. PLMD is diagnosed when PLMS is thought to cause daytime hypersomnia in the absence of other sleep disorders.

Nonpharmacologic treatments including warm or cool baths, massage, stretching, or even the application of spontaneous compression devices have been reported to be effective anecdotally and in small case series, but an evidence base for these measures remains poor, and most patients seeking medical care for the symptom have severe enough symptoms to merit pharmacologic treatment.

Iron and pharmacologic treatments for RLS are outlined in [Table 6](#). Iron deficiency, or even low normal body iron stores, may worsen or precipitate symptoms. Measuring a serum ferritin should be considered early in all RLS patients, with iron replacement therapy begun if serum ferritin values are less than

50 mcg/L. Iron therapy can be constipating or cause GI distress, and the formulation of iron with added vitamin C (Ferrex 150 Plus, Vitelle Irospan) is often better tolerated by those who cannot stomach ferrous sulfate.

Carbidopa-levodopa (Sinemet)<sup>1</sup> may be used for patients with only intermittently disturbing symptoms, but chronic nightly use of carbidopa-levodopa, especially above a dosage of 200 mg daily, may raise the risk of augmentation. For nightly use, the newer dopaminergic agonist medications pramipexole (Mirapex) or ropinirole (Requip) remain a mainstay of treatment. Pramipexole may be initiated at 0.125 to 0.25 mg nightly and titrated every few days to the 0.375 to 0.50 mg range or beyond if needed for symptom control. Doses beyond 1.0 mg<sup>3</sup> are typically not additionally effective and appear to raise augmentation risk. Ropinirole may be initiated at 0.5 to 1.0 mg with gradual upward titration to the 4 to 6 mg<sup>3</sup> range as needed and tolerated. Generally, dosing 1 hour prior to bedtime is sufficient, but if earlier evening or late afternoon symptoms emerge, cautious application of divided doses may be utilized, and some experts advise at least a low morning dosage administered daily to achieve a more chronic steady state of dopamine administration since this may be a sensible strategy to minimize augmentation risk. For either initial first-line therapy, or particularly when patients are beginning to experience earlier symptom onset during the day and may have failed the other short-acting dopaminergic drugs pramipexole and ropinirole, a rotigotine (Neupro) patch has been an advent in RLS management and often may be substituted for those other agents to provide more day-long symptom relief and reduce a growing augmentation tendency. Rotigotine offers several other advantages, as its transdermal delivery system provides continuous day-long release of medication that may minimize peak/trough serum concentration variation and minimize the occurrence of other potential adverse effects. Rotigotine also appears to result in augmentation less frequently than other dopaminergic drugs. All patients receiving dopaminergic agents should be counseled upfront about the approximate 15% idiosyncratic risk of impulse control disorder symptoms (such as pathologic gambling, shopping, or hoarding/punding behaviors), and be forewarned that should such problems result, the medication must be withdrawn and another nondopaminergic drug substituted for symptom control. Typical dose-related adverse effects are also described further in [Table 6](#).

Gabapentin (Neurontin)<sup>1</sup> is increasingly becoming an alternative first-line medication for RLS, dosed 300 to 1200<sup>3</sup> mg every night at bedtime as needed and tolerated. Gabapentin may be the agent of choice in patients with comorbid anxiety, pain and insomnia or in patients who are intolerant, resistant to, or have developed augmentation with dopamine agonist medications. On the other hand a dopamine agonist is still generally the first choice for pharmacologic treatment of RLS in severe cases and may be preferred over gabapentin in patients with comorbid depression, obesity, metabolic syndrome, OSA and history of falls. Gabapentin encarbil (Horizant) is a prodrug of gabapentin that is better absorbed and carries an indication for RLS, but generic gabapentin is also frequently effective and well tolerated, and there has been no head-to-head trial showing superiority of the more expensive prodrug gabapentin encarbil over that of gabapentin. Other alternatives include clonazepam<sup>1</sup> and tramadol (Ultram).<sup>1</sup> For patients unresponsive to these measures, opiate treatment with oxycodone (Roxicodone)<sup>1</sup> 5 to 15 mg at bedtime, hydro-morphone (Dilaudid),<sup>1</sup> or methadone (Dolophine)<sup>1</sup> are often effective. A large randomized trial showed that the combination oxycodone-naloxone (Targiniq ER)<sup>1</sup> resulted in substantial improvements in RLS symptoms in patients who had previously shown inadequate response to dopamine agonists. Small case

series suggest other alternatives for refractory RLS such as carbamazepine (Tegretol),<sup>1</sup> oxcarbazepine (Trileptal),<sup>1</sup> and lamotrigine (Lamictal).<sup>1</sup> The impact of comorbid OSA should also be considered, as optimization of treatment for SDB may improve both subjective RLS symptoms as well as PLMD frequency in many patients.

### Sleep-Related Leg Cramps

Sleep-related leg cramps are a common and enigmatic problem affecting 7% to 10% of children and up to 70% of elderly adults. Unfortunately, despite their extremely common occurrence and impact on the quality of life of cramp sufferers, little is known about the pathophysiology or treatment of this condition. Cramps are painful, involuntary sustained muscle contractions, lasting 2 to 10 minutes and affecting the unilateral or bilateral calves, thighs, or feet, with residual tenderness of the affected muscle lasting up to an hour or longer. The clinical approach to sleep-related leg cramps is to first determine whether they are also present during daytime in addition to sleep. If daytime cramping is prominent, exclusion of a precipitating neuromuscular disorder is paramount, including amyotrophic lateral sclerosis, peripheral neuropathy, myositis, or cramp-fasciculation syndrome. In elderly men, peripheral vascular disease and other systemic medical comorbidities are also common. (The reader is referred to the chapter on neuromuscular disorders for further advice on the diagnosis of these conditions.) A neurologic examination should be conducted on all cramp sufferers, and those having sensorimotor findings, fasciculations, or pathologic reflex findings should be referred for EMG, serum creatinine kinase, or additional blood and urine tests for exclusion of symptomatic causes of neuropathy as appropriate. While additional testing for electrolyte abnormalities such as hypomagnesemia, hypocalcemia, hyponatremia, and hypokalemia can be considered, they are of extremely low yield. When examination findings are normal and cramps are isolated to the sleep state, further diagnostic work-up can usually be avoided. Symptomatic treatment measures for sleep-related leg cramps include tonic water with lemon and advising adequate hydration and nightly stretching of the calves and thighs. Prescription quinine (Qualaquin)<sup>1</sup> carries a FDA black box warning for leg cramp treatment and is essentially no longer used for this indication. For refractory frequent cramp sufferers, a sodium-channel blocking anticonvulsant such as carbamazepine<sup>1</sup>, oxcarbazepine<sup>1</sup>, or lamotrigine<sup>1</sup> may also be considered.

### Sleep-Related Bruxism

Sleep-related bruxism, rhythmic grinding of the teeth during sleep, may lead to significant tooth wear and dental or jaw pain. The condition is usually idiopathic, although it may be associated with psychiatric conditions such as mood or anxiety disorders, especially if it is also present during daytime. Treatment usually involves dental referral for consideration of a fitted mouth guard, although in extreme cases pharmacotherapy with clonazepam<sup>1</sup> or consideration of botulinum toxin (Botox)<sup>1</sup> may be necessary.

### Other Sleep-Related Movement Disorders

Sleep-related rhythmic movement disorder usually occurs in patients with psychomotor maldevelopment and involves repetitive head and neck or axial body movements. This behavior is not strictly voluntary and often persists during PSG into deep drowsiness or light NREM sleep, so behavioral treatments alone are often ineffective. Head banging behavior, sometimes into the headboard of the bed, can be injurious at times: a protective helmet or treatment with clonazepam<sup>1</sup> is advisable in some cases. Most other movement disorders, such as organic tremors, myoclonus, or dyskinesias generated by the basal ganglia, are

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>1</sup>Not FDA approved for this indication.

suppressed during sleep but may reemerge during drowsiness or nocturnal awakenings.

Propriospinal myoclonus at sleep onset is characterized by myoclonic jerks having their primary and earliest onset in abdominal and axial muscles prior to spreading to the limbs and may be associated with thoracic spinal cord pathology. Spinal imaging with MRI is advised. Treatment with clonazepam<sup>1</sup> is usual for this uncommon diagnosis, although it is unfortunately often ineffective, and many cases of propriospinal myoclonus are instead found to represent a functional movement disorder.

### Isolated Symptoms and Normal Variants

These conditions are felt largely to represent either normal variants or otherwise largely benign disorders. The definition of long and short sleepers are somewhat arbitrary, but may be considered as greater than 10 hours or shorter than 5 hours of habitual sleep. Short or long sleep time are each assumed to be variants of normal behavior in the absence of hypersomnia or nighttime symptoms of insomnia.

Sleep talking, or somniloquy, in isolation is rarely of concern. History is often lifelong in such patients. When sleep talking is newly evolved in an elderly individual or a younger patient receiving antidepressant therapy, RBD should be considered in the differential diagnosis, and the patient should be questioned about other potential evidence for dream enactment behavior. A careful medication history and neurologic examination alone will usually dictate whether further evaluation with PSG may be indicated, but in most cases isolated sleep talking is not a cause for concern.

Sleep starts, hypnic jerks or physiologic myoclonus are near universal in their occurrence and often associated with recent excessive caffeine intake or emotional or physical stress. A history of occurrence of jerks limited to the arms, legs, or axial musculature causing arousal within the first 5 to 10 minutes of sleep, and lacking later recurrence during the night, is typical. Reassurance and avoidance of precipitating factors is advised; however, if hypnic jerks are excessive or recur later in the night, PSG is occasionally necessary to distinguish this benign diagnosis from PLMD or propriospinal myoclonus. Propriospinal myoclonus at sleep onset is characterized by myoclonic jerks having their primary and earliest onset in abdominal and axial muscles prior to spreading to the limbs and may be associated with thoracic spinal cord pathology. Spinal imaging with MRI is advised. Treatment with clonazepam<sup>1</sup> is usual for this uncommon diagnosis.

### Other Sleep Disorders

Undesirable influences in the patient's sleep environment can serve to regularly distract or disturb him or her from initiating or maintaining sleep. Typical influences include a bed partner who snores loudly or who causes bed motion due to restless or disturbed sleep; pets who sleep in bed with the patient and cause awakening; environmental noise from neighborhood dogs, car alarms, or neighboring freeway or train way; too much outdoor ambient light; or undesirable household ambient temperature. There is considerable overlap in this category of environmental sleep disturbance with inadequate sleep hygiene, as activating stimuli in the environment may lead the patient toward chronic insomnia and adapting undesirable sleep-related behaviors that serve to further disrupt restful sleep.

### Sleep-Related Medical and Neurologic Disorders

Fatal familial insomnia is an exceedingly rare, autosomal dominant variant form of familial Creutzfeldt-Jakob disease, a prion disorder that leads to progressive insomnia and progressive cognitive impairment, with death inevitably occurring within 3 years of onset. Aggregate prion protein accumulates in the thalamus and other brain regions, and relentlessly progressive insomnia,

panic disorder, hallucinosis, and dementia ensue. Unfortunately, no treatments are currently known for this rare disorder.

### Conclusions

Sleep disorders are common and result in significant patient morbidity, daytime dysfunction, and impaired quality of life. Untreated sleep disordered breathing (SDB) may also raise the risk for hypertension, vascular events, and mortality. The most common presenting symptoms of sleep disorders include insomnia, characterized by difficulty initiating and maintaining sleep with poor sleep quality, and hypersomnia, the symptom of excessive daytime sleepiness. Evaluation begins with a detailed history and physical examination, which in select cases may require support and clarification by polysomnography and multiple sleep-latency testing. Fortunately, effective therapies are available for the majority of sleep disorders. Insomnia typically requires behavioral or pharmacologic interventions, while SDB may be effectively treated in most cases with positive airway pressure (PAP) therapy. Primary CNS hypersomnias including narcolepsy require stimulant management in most cases, while most parasomnias benefit from clonazepam.<sup>1</sup> Circadian sleep disorders may require timed light and melatonin therapies. Patients having RLS and PLMD should be evaluated for iron deficiency and may enjoy symptom control through dopaminergic or other alternative symptomatic treatments. The majority of patients with sleep disorders benefit from a careful clinical evaluation and appropriately selected therapies.

## SPORTS-RELATED HEAD INJURIES

Method of

Brandon Hockenberry, MD; Margaret Pusateri, MD; and Christopher McGrew, MD

### CURRENT DIAGNOSIS

- Initial evaluation of any sports-related head injury should follow standard emergency medicine procedures.
- Presence of any “red flag” symptoms is concerning for a more serious head injury (skull fracture and intracranial hemorrhage) and requires emergency evaluation.
- If “red flag” symptoms are present and advanced imaging is indicated, a noncontrast computed tomography (CT) scan of the head is the initial study of choice.
- If no “red flag” symptoms are present, one of several validated neuropsychological tests should be administered to evaluate cognitive function (e.g., Sports Concussion Assessment Tool, version 5 [SCAT 5]; <https://bjsm.bmj.com/content/bjsports/early/2017/04/26/bjsports-2017-097506SCAT5.full.pdf>).
- Ultimately, concussion is still a clinical diagnosis.
- Advanced neuroimaging, fluid biomarkers, genetic testing, helmet sensors, and video surveillance have all been purported as possible prognostic indicators but require further validation.

### CURRENT THERAPY

- Blood pressure control is critical for patients with intracranial hemorrhage.
- Small intracranial hemorrhages without midline shift or significant symptoms may be monitored, but surgical decompression is otherwise required.
- For patients requiring sedation, propofol (Diprivan)<sup>1</sup> is often preferred due to its short half-life, which makes it easier to monitor neurologic status.
- Mannitol can also be used to help lower intracranial pressure.
- For posttraumatic seizures, phenytoin (Dilantin)<sup>1</sup> is the preferred medication.
- If there is any concern for concussion, the athlete should immediately be removed from play.
- An athlete should never be allowed to return to play on the same day as the injury.
- After an initial rest period of 24–48 hours, an athlete should begin progressing through return-to-play and return-to-learn protocols ([https://www.cdc.gov/headsup/providers/return\\_to\\_activities.html](https://www.cdc.gov/headsup/providers/return_to_activities.html)).
- In the first 24 hours after injury, acetaminophen is the treatment of choice for associated headaches; nonsteroidal antiinflammatory drugs (NSAIDs) and aspirin can worsen an undiagnosed intracranial hemorrhage.
- If headaches persist longer than 3–5 days, medications that do not pose a risk for rebound headaches (e.g., tricyclic antidepressants) can be used.
- Good sleep hygiene is important for recovery. If insomnia persists for more than 2–3 days after injury, medications can be considered.
- Typical recovery time is up to 2 weeks in adults and 4 weeks in children.
- Access to a multidisciplinary team including physical therapists, neurologists, and psychiatric providers is beneficial for athletes with complicated or prolonged recoveries.
- If an athlete has a history of a learning disability, depression, anxiety, or chronic headaches, recovery can be complicated by an exacerbation of the underlying disease.

<sup>1</sup>Not FDA approved for this indication.

## Introduction and Epidemiology

Sports-related head injuries include a heterogeneous group of insults to the brain caused by either a direct impact to the head or an impact to the body associated with energy transfer into the head.

In the United States, sports are among the leading causes of head injuries. Specifically between the ages of 15 and 24 years, athletic activities are the second leading cause of head injuries; only motor vehicle accidents have a higher incidence. Athletic and recreational activities vary widely in terms of biomechanics and kinetics, resulting in a wide range of associated risks. Many sports are limited by the speed at which an athlete can run (e.g., rugby or soccer), but others allow athletes to compete at much higher speeds, some nearly equivalent to those of motor vehicles (e.g., cycling or skiing). These sports potentially put athletes at a higher risk for more severe head injuries.

Sports- and recreation-related traumatic brain injuries (SRR-TBIs) are monitored by the National Electronic Injury Surveillance System—All Injury Program (NEISS-AIP). According to this program, there were more than 3.4 million visits to emergency departments (EDs) across the United States for SRR-TBIs between 2001 and 2012, or approximately 340,000 per year.

Concussion is by far the most common head injury associated with athletic activity. It is estimated that 1.7 to 3.0 million concussions per year are related to sports and recreational activities. The overall rate is 2.5 concussions per 10,000 athletic events, and concussions make up 5% to 18% of reported injuries in the National Collegiate Athletic Association. It is estimated that 50% of concussions go unreported or undiagnosed. The most common severe head injury is a subdural hematoma, which accounts for greater than 90% of all sport-related catastrophic head injuries. These are most often seen in American football, cheerleading, and skiing/snowboarding and occur in less than 1 per 100,000 athletic events. Fatalities from sports-related head injuries are very rare; however, subdural hematoma is a serious injury. In one study, it was reported that American football players with subdural hematoma had a fatality rate of 8.5% and a 48% rate of suffering permanent neurologic deficits.

## Risk Factors

Every athlete is potentially at some risk for a head injury during activity. Many factors contribute to relative risk, with the type of activity being the largest contributing factor. In their younger years, males sustain the most head injuries playing football or wrestling, whereas bicycling and basketball take over top spots after the high school and college years. In females, bicycling and horseback riding contribute the most head injuries. It should be noted that some activities have higher incidence rates of head injuries than the aforementioned activities (e.g., men’s/women’s ice hockey) but are not as commonly played and therefore do not contribute to the sheer volume of injuries that other activities do. With respect to concussion specifically, men’s ice hockey and football have the highest incidence rates (5.5 to 6.5 concussions per 10,000 athletic events) in the high school and college populations. On the women’s side, soccer and lacrosse have the highest rates (3 to 3.5 concussions per 10,000 athletic events).

Children and teens are at increased risk for head injuries because they are developmentally immature and more frequently participate in activities that have a higher risk for head trauma. Overall, 70% of all SRR-TBIs are in the age group of 0 to 19 years. In the young athlete, a larger head-to-neck ratio, smaller amount of neck/shoulder musculature, and thinner cranial bones all contribute to an increased chance that a blow to the head will cause a head injury. The active elderly have better balance, fewer falls, and fewer TBIs than their more chronically ill counterparts. Therefore increased age is not an independent risk factor for SRR-TBIs.

At the high school and college levels, males have more concussions than do women in sheer numbers but a lower incidence rate overall. Females may have greater risk because of decreased neck musculature compared with males. Female sex has been associated more commonly with abnormal imaging, surgical

intervention, complication, and death. A history of previous concussion increases risk for future concussions compared with non-concussed athletes, and the greatest risk for repeat concussion is during the 10-day period after the most recent concussion.

### Pathophysiology

The pathophysiology of SRR-TBIs and sports-related concussion (SRC) is multifactorial. Several mechanisms have been identified. Biomechanically, a combination of acceleration, deceleration, and rotational/translational forces directly applied or transmitted to the head affect change at the level of individual cells. Metabolic derangements, neurotransmitter dysfunction, changes in cerebral blood flow, neuroinflammation, microstructural damage, and diffuse axonal injury have all been implicated as potential pathways. Helmet-based measurement studies have attempted to quantify head impacts, providing information on force, frequency, and location. However, results vary widely among athletes diagnosed with concussions. In addition, the accuracy of the data detected by helmet sensors and video surveillance systems has been called into question; it does not necessarily reflect the impact on the brain itself, and there is no evidence to support the use of such systems to attempt to diagnose SRC.

### Assessment and Diagnosis of Sports-Related Head Injury

The initial assessment of any sports-related head injury should follow standard emergency medicine procedures. Assessment of the “ABCs” (airway, breathing, and circulation) and evaluation for concomitant cervical spine injury should be the first steps in management. The presence of any red flag symptoms (Box 1) should raise concerns for a serious head injury, such as an intracranial hemorrhage or skull fracture, and requires immediate evaluation in the ED, likely advanced head or neck imaging, and possible specialist consultation. The appropriate emergency action plan should be initiated and the athlete stabilized and transported to the designated medical facility.

Once in the ED, the decision whether to obtain images needs to be made. Some assessment tools have been developed, such as the Pediatric Emergency Care Applied Research Network (PECARN; <https://www.mdcalc.com/pecarn-pediatric-head-injury-trauma-algorithm>) and Canadian CT Head Injury algorithms. A Glasgow Coma Scale score below 14, palpable skull fracture, or presence of red flag symptoms would all be reasons to image acutely. The initial imaging test of choice after head injury is a noncontrast head CT, which will show fractures, intracranial hemorrhage, midline shifts, and signs of edema. CT with angiography will show decreased blood flow into cerebral vessels because of increased intracranial pressure. However, if increased intracranial pressure due to malignant brain edema or an expanding hematoma is suspected, more invasive intracranial pressure monitoring is a more accurate measure and will be more useful to management (see Box 1).

If no red flag symptoms are present and the athlete does not require emergency medical treatment, he or she should be removed from the field of play if there is any suspicion for

#### BOX 1 Red Flag Symptoms

- Persistent vomiting
- Seizure
- Severe “worst headache of my life”
- Focal neurologic deficit
- Blurred vision
- Slurred speech
- Significant drowsiness/poor awakening
- Poor orientation to person/place/time
- Declining mental status

The presence of any of these symptoms should prompt consideration of emergency department evaluation and head imaging. If no red flags are present, the clinician may be able to send the athlete home safely and follow up in the office the next day.

#### BOX 2 Memory Assessment: Maddocks Questions

- What venue are we at today?
- What half is it now?
- Who scored last in the game?
- What team did you play last week?
- Did your team win the last game?

Note: Can be adapted to specific sports as necessary. These questions help make diagnosis of concussion. No official score cutoff is diagnostic; however, inability to answer them all correctly should raise suspicion for concussion or more severe head injury. Questions can be changed slightly if they are not relevant to a sport, such as swimming.

possible SRC. Several brief neuropsychological tests have been developed to evaluate cognitive function. Examples of practical and validated tests include the SCAT 5 and the Standardized Assessment of Concussion (SAC). The SCAT 5 is broken down into six steps: immediate or on-field assessment, symptom evaluation, cognitive screening, neurologic screening, delayed recall, and decision. In addition to an assessment of the aforementioned red flag symptoms, the immediate or on-field assessment section of the SCAT 5 also includes a review of observable signs (e.g., lying motionless on the playing field, facial injury after head trauma, and blank or vacant look), a memory assessment using the Maddocks Questions (Box 2), a measure of the Glasgow Coma Scale (Table 1), and a cervical spine assessment. It has been found that standard orientation questions (name, location, and year) are not reliable in the immediate assessment of SRC. The Maddocks questions, which focus on sport-specific memory assessment, provide better information to help the examiner determine whether there is a concern for an SRC. Once the initial assessment is complete, if there is any concern for an SRC, the athlete should be removed from the sporting environment and not allowed to return to play on the day of injury.

Diagnosis of SRC remains a clinical diagnosis. Over the past two decades, multiple investigations have focused on the use of advanced neuroimaging (e.g., functional magnetic resonance imaging [f-MRI] and electroencephalogram [EEG]) and body fluid analysis (blood, saliva, and cerebrospinal fluid) as potential tools to aid in the diagnosis of SRCs. (In addition, these modalities have been explored as potential prognostic indicators, attempting to predict clinical recovery or assess the cumulative risk of repetitive trauma.) At this time, advanced neuroimaging, fluid biomarkers, and genetic testing are important research tools but require further validation to determine their ultimate clinical utility in the evaluation and diagnosis of SRC.

### Clinical Manifestations

Clinical manifestations after an SRR-TBI and SRC can be varied. The brain itself is a complex organ. Depending on which area is injured, different symptoms may present. With regard to the more serious diseases, such as intracranial hemorrhages or diffuse axonal injury, the athlete is often critically injured, again demonstrating red flag symptoms and signs of increased intracranial pressure. However, SRC is an evolving injury within the acute phase and can often have an initially subtle presentation. Signs and symptoms rapidly change, especially over the first 24 to 48 hours. Classically, symptoms fall into one of four categories: physical (headache, nausea, and dizziness), cognitive (difficulty concentrating and slowed reaction times), emotional (anxiety and irritability), and sleep disturbances (insomnia and hypersomnia). As part of the SCAT 5 and other concussion assessment tools, an in-depth symptom checklist is used to evaluate SRCs both initially and during follow-up. For example, Table 2 outlines the SCAT 5 symptom checklist. It is important to note that there are no specific scoring guidelines that are diagnostic of concussion. The scores are most commonly used to monitor an athlete’s recovery,

**TABLE 1** Glasgow Coma Scale

BEST EYE RESPONSE (E)	BEST VERBAL RESPONSE (V)	BEST MOTOR RESPONSE (M)
Eye opening spontaneously: 4	Oriented: 5	Obeys commands: 6
Eye opening to voice: 3	Confused: 4	Localizes to pain: 5
Eye opening to pain: 2	Inappropriate words: 3	Flexion/withdrawal from pain: 4
No eye opening: 1	Incomprehensible sounds: 2	Abnormal flexion to pain: 3
	No verbal response: 1	Abnormal extension to pain: 2
		No motor response: 1

Used to rate the severity of head injury. Scores in each category are added for a total of 15 points. Athletes with concussion typically have a Glasgow Coma Scale score of 14 (losing 1 point in the verbal response category) or 15. Scores less than 14 should prompt a visit to the emergency department for head imaging.

**TABLE 2** SCAT 5 Symptoms Checklist

SYMPTOM	SEVERITY
Headache	0 1 2 3 4 5 6
“Pressure in head”	0 1 2 3 4 5 6
Neck pain	0 1 2 3 4 5 6
Nausea and/or vomiting	0 1 2 3 4 5 6
Dizziness	0 1 2 3 4 5 6
Blurred vision	0 1 2 3 4 5 6
Balance problems	0 1 2 3 4 5 6
Sensitivity to light	0 1 2 3 4 5 6
Sensitivity to noise	0 1 2 3 4 5 6
Feeling slowed down	0 1 2 3 4 5 6
Feeling like “in a fog”	0 1 2 3 4 5 6
“Don’t feel right”	0 1 2 3 4 5 6
Difficulty concentrating	0 1 2 3 4 5 6
Difficulty remembering	0 1 2 3 4 5 6
Fatigue or low energy	0 1 2 3 4 5 6
Confusion	0 1 2 3 4 5 6
Drowsiness	0 1 2 3 4 5 6
More emotional	0 1 2 3 4 5 6
Irritability	0 1 2 3 4 5 6
Sadness	0 1 2 3 4 5 6
Nervous or anxious	0 1 2 3 4 5 6
Trouble falling asleep (if applicable)	0 1 2 3 4 5 6
Total number of symptoms	Of 22
Symptom severity score	Of 132

There is no score cutoff that is diagnostic of concussion; it is simply used to monitor a patient’s improvement or decline over time. Higher scores at time of injury are associated with longer recovery times.

SCAT 5, Sports Concussion Assessment Tool version 5.

tracking improvement or decline over time. Of note, higher scores at the time of initial injury are associated with longer recoveries.

### Treatment

Presence of red flag symptoms listed in [Box 1](#) or a Glasgow Coma Scale score of less than 14 should raise suspicion for a more severe SSR-TBI, such as a skull fracture or intracranial hemorrhage, rather than a typical concussion. If an athlete

sustains an SSR-TBI other than concussion, he or she should be evaluated in the ED. In the event of an intracranial hemorrhage of any kind, the largest concern is increasing intracranial pressure. Strict blood pressure control is incredibly important, because an increased blood pressure will increase the pressure in the bleeding vessel and thus the rate and severity of the bleed. Intracranial hemorrhages may be monitored if the bleed is small and not causing a midline shift or significant symptoms. However, definitive treatment with surgical decompression is preferred for subdural and epidural hemorrhages. Most patients will require intubation, sedation, and intracranial pressure monitoring. For sedation, propofol (Diprivan)<sup>1</sup> is the preferred agent at many institutions because it has a short half-life, making it easier to monitor the patient’s neurologic status. In the presence of malignant brain edema, mannitol (Osmirol) can be added to decrease intracranial pressure when strict blood pressure and pain control has failed. For a TBI causing posttraumatic seizure, phenytoin (Dilantin)<sup>1</sup> remains the preferred medication, although many institutions will use older antiepileptic drugs such as valproate (Depakote)<sup>1</sup> or carbamazepine (Tegretol)<sup>1</sup> as treatments of choice.

The current recommendation for the management of SRC is to remove the athlete from play and not allow a return on the same day. The athlete should avoid physical exertion and mental activities that make symptoms worse. After an initial rest period of 24 to 48 hours, the patient should begin progressing to both physical (noncontact) and mental activities. The athlete should return to normal activities of daily living as much as is tolerated without symptom exacerbation. The newest consensus statement on concussion in sport outlines not only a return-to-play protocol but also a return-to-learn protocol. These are outlined in [Tables 3 and 4](#). Children and adolescents should not return to sport until they have fully returned to school. It is important to note that there is no evidence to suggest that any medications or nutritional supplements will improve rate of recovery from concussion. Medications in concussion treatment are primarily used for symptomatic relief.

### Monitoring Concussions

After concussion diagnosis, the clinically stable athlete can be sent home if a responsible adult is available to accompany him or her. Sleep is encouraged, and the athlete need not be awakened for evaluation. The athlete should be followed up in a qualified healthcare provider’s office within 24 to 48 hours for reevaluation. Follow-up examination should include a symptom severity checklist (see [Table 2](#)), history, and neurologic examination at a minimum. Completing a full SCAT 5 evaluation is unnecessary if the athlete had one done at time of injury and still has symptoms. Advanced neuroimaging with MRI is not needed to monitor a concussion and by definition should be normal.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Graduated Return-to-Play Protocol as Outlined by the Consensus Statement on Concussion in Sport

STAGE	AIM	ACTIVITY	GOAL OF EACH STEP
1	Symptom-limited activity	Daily activities that do not provoke symptoms	Gradual reintroduction of work/school activities
2	Light aerobic exercise	Walking or stationary cycling at slow to medium pace; no resistance training	Increase heart rate
3	Sport-specific exercise	Running or skating drills; no head impact activities	Add movement
4	Noncontact training drills	Harder training drills (e.g., passing drills); may start progressive resistance training	Exercise, coordination, and improved thinking
5	Full-contact practice	After medical clearance, participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6	Return to sport	Normal game play	

Start step 1 after initial 24- to 48-hour period of rest. Each step should take a minimum 24 hours to progress through.

**TABLE 4** Example of a Graduated Return-to-Learn Protocol as Outlined by the Consensus Statement on Concussion in Sport

STAGE	AIM	ACTIVITY	GOAL OF EACH STEP
1	Daily activities that do not give the child symptoms	Typical activities of the child during the day as long as he or she does not increase symptoms (e.g., reading, texting, screen time). Start with 5–15 min at a time and build up	Gradual return to typical activities
2	School activities	Homework, reading, or other cognitive activities outside of the classroom	Increase tolerance to cognitive work
3	Return to school part time	Gradual introduction of schoolwork. May need to start with a partial school day or increased breaks during the day	Increase academic activities
4	Return to school full time	Gradually progress school activities until a full day can be tolerated	Return to full academic activities and catch up on missed work

Unlike the return-to-sport protocol, there is no minimum required time for each stage. Some children may be able to tolerate a full school day immediately after injury without difficulty, depending on symptom severity.

As the athlete returns to play, close supervision under a qualified healthcare provider such as a certified athletic trainer or physical therapist is ideal but not always possible. When an athlete has progressed through the return-to-play protocol (see [Table 3](#)), follow-up with an appropriate qualified healthcare provider should be arranged to obtain full medical clearance to return to full contact activity.

### Management of Concussion Complications

Headaches are among the most common symptoms of a concussion and often the symptom that bothers the athlete the most. In the acute period after injury, medications have some potential to mask important symptoms. For the first 1 to 2 hours after the injury, it is important to be able to accurately monitor the patient for a changing clinical picture, which could suggest that the head injury is not a concussion but rather an evolving epidural or subdural hematoma. For the first 24 hours, NSAIDs and aspirin should be avoided because they can thin the blood and potentially make an undiagnosed hematoma become a more significant bleed. Acetaminophen (Tylenol) is the preferred medication for headache in the first 24 hours. After the first day, it is safe to switch to ibuprofen (Motrin), which may have more benefit. If headaches are not improving after 3 to 5 days, it is advisable to switch to another medication that does not pose the risk of creating rebound headaches. Tricyclic antidepressants are a good choice and work very well. Nortriptyline (Pamelor)<sup>1</sup> at a low dose (25 mg/d) is generally well tolerated in children as

well as adults and may be stopped abruptly without withdrawal symptoms once the athlete is feeling well and ready to progress back to activities.

Sleep disturbances in athletes with concussion are also very common. Many will not sleep well the first night after injury and want to nap during the day. Other athletes may sleep much more than usual after initial injury. Although there are no clear studies proving the optimal amount of sleep, current trends are to try to return the athlete to normal sleep cycles and daily living as much as possible. An emphasis on sleep hygiene over the first few days is standard. If insomnia persists after 2 to 3 days, medications may be considered. Melatonin<sup>7</sup> is available over the counter, has very few side effects, and is generally well tolerated. The next step would be amitriptyline (Elavil)<sup>1</sup> at a low dose (10–25 mg/d). This can be especially effective if the athlete has both headaches and poor sleep because it is more sedating than nortriptyline.

A concussion is expected to last no more than 14 days in an adult and less than 4 weeks in the pediatric population. Each individual physician will have a different comfort level treating concussion; however, it is reasonable to consider a referral to a specialty physician once an athlete has passed the normal expected recovery time and is not categorized as a “prolonged concussion.” Each city or region will have a different culture about who takes care of the prolonged concussions. Neurologists, sports medicine physicians, and physical medicine and rehabilitation physicians are all well equipped to take care

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

of these athletes. Physical therapists, particularly those who specialize in vestibular rehabilitation, can be very helpful to patients with continued balance problems, concentration difficulties, and other visual symptoms. Last, neuropsychologists can be extremely helpful in difficult cases. Some athletes have complicated clinical histories prior to the injury. Attention-deficit/hyperactivity disorder, depression, anxiety, and chronic headaches can all make the clinical picture very confusing when the athlete is having symptoms such as concentration difficulties, mood swings, insomnia, or headaches that are not improving as expected. It is important to remember that many athletes would not rate their symptom severity score as all zeros at baseline, so expecting them to achieve this goal after injury is impractical. When this scenario is suspected, referral for neuropsychiatric testing can help to divide out which symptoms may be concussion related and which could be more chronic in nature.

### Prevention

Helmets have been shown to reduce sports-related skull fractures and intracranial hemorrhages but have not been shown to decrease rates of concussion. Mouth guard use decreases the rate of dental injuries and lip lacerations but has not been definitively proven to decrease the rate of concussion or other brain injuries. Sport-specific rule changes have resulted in reduced rates of head injury. The most prominent and well-studied example is that of youth ice hockey. Introduction of the 2013 Canadian national body checking policy change disallowing body checking in Pee Wee hockey players below the age of 13 years resulted in a 50% relative reduction in injury rate and a 64% reduction in concussion rate in 11-year-old and 12-year-old hockey players in Alberta. Reduction of contact practices in certain team sports such as American football reduces exposure to head injury as well. Finally, epidemiologic evidence has demonstrated that the most likely period for repeat SRC is in the first 10 days after the most recent concussion, so disallowing contact activity during this interval has potential to reduce repeat concussions.

## TARGETED TEMPERATURE MANAGEMENT (THERAPEUTIC HYPOTHERMIA)

Scott Leikin, DO; Jennifer Wang, DO; and Adel Bassily-Marcus, MD

### CURRENT THERAPY

- Targeted temperature management (therapeutic hypothermia) should be considered following resuscitation from cardiac arrest to reduce the risk of anoxic brain injury.
- There does not appear to be a benefit to cooling to a temperature of 33°C when compared to cooling to a temperature of 36°C (97°F).
- There is a paradigm shift of therapeutic hypothermia to preventing fever and instituting a targeted temperature.
- Cooling pads are the most commonly used method to induce hypothermia.

### Introduction

Inducing patients to a targeted temperature to reduce anoxic brain injury post cardiac arrest has now become the standard of care at medical institutions around the world. Although the theory has multiple applications for multiple conditions, post cardiac arrest is the most common and studied indication and the focus of this chapter. Although each institution has their own protocol, there are common tenets that are included in each institution's protocols. Current nomenclature is Targeted Temperature Management (TTM) as the theories on ideal temperature for the post cardiac arrest patient have evolved from therapeutic hypothermia. The evolution of TTM is important to understand, as the current theory is fever prevention is where the benefit is and fever is what is associated with poor neurologic outcomes in the post cardiac arrest time period.

The first multicenter, randomized control study on post cardiac arrest care was conducted in Europe and published in the *New England Journal of Medicine (NEJM)* in 2002. A total of 3551 patients were deemed eligible, but only 275 were included. In the study, 137 were assigned to hypothermia (32 to 34°C as measured by bladder temperature for 24 hours) and 138 to normothermia. To qualify in the study, subjects must have had a witnessed cardiac arrest, with an initial rhythm of ventricular fibrillation (VF) with return of spontaneous circulation (ROSC). The results showed a favorable neurologic outcome in 75/136 patients (55%) in the hypothermia group compared to 54/137 patients (39%) in the normothermia group at 6 months as measured by the Pittsburgh cerebral-performance category. The mortality difference at 6 months was 41% in the hypothermia group and 55% in the normothermia group. This validated the utilization of mild therapeutic hypothermia to improve neurologic outcomes and decrease mortality for witnessed VF cardiac arrest.

In 2002, a *NEJM* study described survival with good neurologic outcome to hospital discharge in patients who were unconscious after ROSC in out-of-hospital cardiac arrest. In the study, 77 patients were assigned to normothermia or moderate hypothermia (core body temperature of 33°C within 2 hours of ROSC for 12 total hours). Usually, out-of-hospital cardiac arrests have survival rates of only 5% to 35%. The investigators found 21/43 (49%) patients in the hypothermia group survived and had a favorable neurologic outcome compared to 9/34 (26%) in the normothermia group with ( $P = .046$ ). The authors concluded that moderate hypothermia improved outcomes in patients with coma after ROSC in out-of-hospital cardiac arrest patients.

In 2010, the American Heart Association (AHA) released a class I recommendation for post VF/VT TTM. Pulseless electrical activity/asystole was given a IIb recommendation. TTM is generally defined as a core temperature of 33 to 36°C. Since this recommendation, TTM has been adopted as common practice post cardiac arrest in comatose adult patients.

In May 2011, the Society of Critical Care Medicine published “Targeted temperature management in critical care: A report and recommendations from five professional societies” and determined that TTM with a core body temperature goal of 32 to 34°C be used for post out-of-hospital VF/VT arrest.

In December 2013, the NEJM published a study titled “Targeted Temperature Management at 33°C versus 36°C after Cardiac Arrest.” This international multicenter study aimed to determine the optimal temperature associated with improved neurologic outcomes for out-of-hospital cardiac arrest patients. They found no significant 180-day neurologic outcome or mortality difference between the patients in the 33°C arm and the patients in the 36°C arm. There were no adverse effects or benefits to patients cooled to 33°C. The authors concluded that in patients who were unconscious after ROSC was obtained in out-of-hospital cardiac arrest, a temperature of 33°C did not confer a benefit compared to a temperature of 36°C. This shifted the paradigm of therapeutic hypothermia to preventing fever and instituting a targeted temperature.

The International Liaison Committee on Resuscitation and the AHA Emergency Cardiovascular Care Committee and the Council on Cardiopulmonary, Critical Care and Perioperative and Resuscitation reviewed 5045 studies, of which 6 were RCTs and 5 were observational. They recommended: target core temperatures between 32 and 36°C for at least 24 hours and against using pre-hospital cooling with cooled intravenous fluids.

The theoretical benefits of TTM are that it can reduce brain oxygen usage by 6% for every 1°C reduction while also preventing inflammation and cerebral edema. TTM is currently being studied for encephalopathy, bacterial meningitis, cardiogenic shock, traumatic brain injury, and organ donation.

### Initiation

With few absolute contraindications, TTM should be considered in all patients who achieved ROSC post cardiac arrest regardless of the underlying rhythm during the cardiac arrest. Many post cardiac arrest patients with ROSC will go to the cardiac catheterization lab for an angiogram and this should not delay the initiation of TTM. Determining the etiology for the cardiac arrest is still extremely important and should not have a bearing on the initiation of TTM. The patient populations in whom TTM is considered a relative contraindication include intracranial hemorrhage, exsanguination, hypotension refractory to multiple vasopressors, severe sepsis, and pregnancy. At our tertiary care academic medical center, the only absolute contraindications are cryoglobulinemia, traumatic injury leading to cardiac arrest, and family refusal or advanced directives that preclude the use of TTM.

Eligibility requires a comatose patient; the patient should not be able to follow commands or respond to noxious stimuli. This is equivalent to a Richmond Agitation Sedation Score of -4 or -5 or Glasgow Coma Scale <8. The patient must have a sustained cardiac rhythm that results in adequate brain perfusion.

The most studied rhythms in cardiac arrest which benefited from TTM were VT or VF. It is uncertain whether pulseless electrical activity and a “nonshockable rhythm” would benefit from TTM but we would advocate that any patient regardless of the underlying rhythm have TTM utilized if ROSC is obtained. This is in line with the 2015 AHA guidelines on post cardiac arrest care and emergency cardiovascular care. The

guideline committee came to this conclusion because cohorts who did not receive TTM had such significant neurologic morbidity that the benefits were considered to outweigh the risks. Significant head trauma should be ruled out in patients who present to an emergency department with a noncontrast head computed tomography (CT) scan. Ideally, TTM should be initiated as soon as ROSC is obtained but it is acceptable to initiate it within the first 6 hours, and even up to 12 hours post arrest. We strongly advocate initiating the process as soon as feasible. We would also recommend that pacer pads be applied to the patient’s skin and kept in place. The target core temperature should be maintained at the desired temperature for 24 hours. Based on a review of the literature, initiating a core temperature between 32 and 36°C for these patients with external cooling pads is the target.

The most commonly used method to induce hypothermia is with external cooling pads. Once the process is started, the time to target temperature should be within 2 hours. Other less commonly used options include ice bags at the groin, chest, axilla, and neck, and infusing cold saline. Cooled intravenous saline will reduce core temperature by 1°C every 30 minutes. The 2015 AHA guidelines recommend against cooling patients in the prehospital setting with intravenous cooled saline, as survival and neurologic recovery were not shown to be improved in various trials. Urinary catheters with temperature probes are often used to measure core temperature. Other acceptable methods of temperature measurement include esophageal, rectal, central, tympanic, or nasal probes. Axillary and oral temperature measurements are not reliable in measuring core temperature. Potential complications of cooling include electrolyte abnormalities, hyperglycemia, coagulopathy, and arrhythmias.

### Maintenance

In TTM, the targeted core temperature should be maintained within 0.5°C for 24 hours. Shivering should be avoided as it creates heat, thereby increasing oxygen demand. Bedside Shivering Assessment Scale (BSAS) should be utilized to help guide therapy for shivering. For sedation purposes, our recommended first-line treatment is propofol (Diprivan) 15 to 20 µg/kg/min. Midazolam (Versed) 1 to 2 mg/h is an alternative. Fentanyl 25 µg/h infusion can be used if adequate sedation is not achieved.

The BSAS treatment algorithm should be utilized to eliminate shivering. In the BSAS, neuromuscular blockade with an agent such as cisatracurium (Nimbex) 0.15 mg/kg IV bolus followed by an infusion of 1 µg/kg/min can be used, although this protocol may mask seizures. The lowest dose that eliminates shivering using agents with a short half life is recommended because hypothermia slows medication metabolism and elimination.

TTM may worsen or cause hemodynamic derangements and arrhythmias, such as hypotension and bradycardia, that are common post cardiac arrest. Maintenance of a mean arterial pressure (MAP) at or above 65 mm Hg will help ensure adequate brain perfusion.

TTM patients are mechanically ventilated, and some institutions use esophageal probes to track body temperature, although this is less common, as it is invasive. Oxygen saturation should be maintained at 94% to 96% to avoid hypoxia or hyperoxygenation. Hyperglycemia is common with TTM, so serum glucose should be checked at set intervals, with a goal <180 mg/dL. If serum glucose is persistently >200 mg/dL despite treatment, an insulin drip should be considered. Electrolyte abnormalities, especially hypokalemia, are common during TTM. Therefore, the serum potassium level should be checked every 4 to 6 hours and replenished if lower than 3.5 meq/L. Rewarming may increase potassium levels.

It has been reported in the literature that up to 66% of TTM patients will develop an infection. Fever and leukocytosis may be present in the absence of infection and are not reliable indicators of infection. A comprehensive plan needs to be developed for every patient when signs of infection are potentially present. Even if a high percentage of patients develop an infection, this has not been shown to affect mortality.

### Rewarming

Rewarming should occur 24 hours after achieving the targeted temperature. Rewarming should not occur at a rate that is faster than 0.2°C/h until the patient reaches 37°C; this will likely take between 6 to 12 hours. Once at 37°C, this temperature should be maintained for 48 to 72 hours, as rebound hyperthermia is associated with poor neurologic outcomes. Electrolyte abnormalities such as hyperkalemia, hypoglycemia, and hypotension may occur. Blood pressure should be carefully monitored during the rewarming period.

### Post-Therapeutic Hypothermia/Prognosis

The AHA recommends 72 hours before prognosticating neurologic recovery. Presence of at least two of the following: incomplete brain stem reflexes, presence of myoclonus, unreactive electroencephalography (EEG), and absent cortical somatosensory-evoked potentials suggest poor neurologic outcome. A full neurologic examination should be done daily. Involving neurology or neurocritical care is advised to help prognosticate neurologic recovery in post cardiac arrest TTM patients.

## TRIGEMINAL NEURALGIA

Method of

Karlynn Sievers, MD; and Hugh Silk, MD, MPH

### CURRENT DIAGNOSIS

The International Headache Society Diagnostic criteria (classic) are as follows:

- A. Recurrent paroxysms of unilateral facial pain in the distribution(s) of one or more divisions of the trigeminal nerve, with no radiation beyond, and fulfilling criteria B and C
  - B. Pain has the following characteristics:
    - Lasts from a fraction of a second to 2 min
    - Severe intensity
    - Electric shock-like, shooting, stabbing, or sharp in quality
  - C. Precipitated by innocuous stimuli to the affected trigeminal distribution
  - D. Demonstration on MRI or during surgery of neurovascular compression (not simply contact), with morphologic changes in the trigeminal nerve root.
  - E. Not better accounted for by another diagnosis
- International Headache Society Diagnostic criteria (secondary)
- Same as previous except
- F. Secondary trigeminal neuralgia is secondary to another disease process.

### CURRENT THERAPY

- Medications
  - Carbamazepine: start 100 mg twice daily and increase by 200 mg/day to a maximum of 1200 mg/day (number needed to treat = 2)
  - Alternative treatments are available but have not been proven to be as effective (Table 1).
  - For some patients with refractory or severe symptoms, surgical treatment (e.g., microvascular decompression, radiosurgery, alternative invasive procedures) can be helpful.

### Epidemiology

The incidence of trigeminal neuralgia is estimated to be 5.9/100,000 women and 3.4/100,000 men. The peak incidence is in patients aged 60 to 70 years. It has also been called “tic douloureux” because of facial spasms that often accompany the disorder.

### Risk Factors

Increasing age is a risk factor. Trigeminal neuralgia is rarely diagnosed in patients below 40 years of age. Other risk factors include multiple sclerosis (the incidence of trigeminal neuralgia in this population is 2% to 5%), stroke, and hypertension (especially in women). There is no racial predominance.

### Pathophysiology

It is currently hypothesized that trigeminal neuralgia results from demyelination of the fifth cranial nerve, leading to electrical transmission of nerve impulses that are not mediated by neurotransmitters and that generate pain. Demyelination is most commonly caused by aberrant or tortuous blood vessels that cause nerve compression but can also be attributed to sources such as multiple sclerosis or amyloid deposition.

**TABLE 1** Treatment Options for Trigeminal Neuralgia with Evidence of Effectiveness

TREATMENT TYPE	EVIDENCE OF EFFECTIVENESS
<b>Medical therapy</b>	
Carbamazepine (Tegretol)	Likely to be beneficial (gold standard)
Oxcarbazepine (Trileptal) <sup>1</sup>	Likely to be beneficial*
Baclofen (Lioresal) <sup>1</sup>	Likely to be beneficial,* particularly in patients with TN caused by MS
Gabapentin (Neurontin) <sup>1</sup>	Unknown effectiveness
Lamotrigine (Lamictal) <sup>1</sup>	Unknown effectiveness
<b>Surgical therapy</b>	
Microvascular decompression	Trade-off between benefits and harms*
Stereotactic radiosurgery	Trade-off between benefits and harms*
Percutaneous destructive radiosurgical techniques	Trade-off between benefits and harms*

\*Based on observational studies and/or consensus.

<sup>1</sup>Not FDA approved for this indication.

MS, Multiple sclerosis; TN, trigeminal neuralgia.

The most commonly used classification system for trigeminal neuralgia has three categories: classical, secondary, and idiopathic. With classical trigeminal neuralgia, there is no underlying cause for the demyelination other than vascular compression, as described previously. With secondary trigeminal neuralgia, an alternate cause such as multiple sclerosis or tumor is responsible for the demyelination. A third category would include idiopathic trigeminal neuralgia, where there are no radiologic findings that account for the patient's symptoms.

### Prevention

There is no known method for the prevention for trigeminal neuralgia.

### Clinical Manifestations

Trigeminal neuralgia is a clinical diagnosis made on the basis of recurrent attacks of unilateral facial pain. The pain is intense and is usually described as sharp, shock like, or stabbing. Any of the branches of the trigeminal nerve can be affected, but the maxillary branch is the most common and the ophthalmic branch the least common. The pain lasts for seconds, and most patients are asymptomatic between attacks (though some will have a mild, dull, persistent ache in the area of the affected nerve). Attacks can recur infrequently or hundreds of times per day.

Often, patients have trigger zones that will set off paroxysms of pain with minimal stimulation. Activities such as chewing, teeth brushing, or touching a trigger area can set off attacks; sometimes even minimal stimulation such as a light breeze can trigger an episode. Not all patients have trigger zones; however, the presence of these is nearly pathognomonic for trigeminal neuralgia.

### Diagnosis

The diagnosis is clinical, based on the commonly described symptoms listed earlier. Diagnosis of trigeminal neuralgia should be considered in all patients who describe unilateral intense paroxysmal facial pain on three or more occasions.

Careful examination of the head and neck and thorough neurologic examination should be performed in all patients. Exam findings are typically normal in patients with trigeminal neuralgia; therefore exam abnormalities should prompt reconsideration of the diagnosis. Sensory abnormalities (including vision or hearing loss), facial muscle weakness, or loss of the corneal reflex are not associated with trigeminal neuralgia and warrant further workup.

Laboratory studies are typically not helpful in making the diagnosis. Temporal mandibular joint or dental radiographs may be helpful to rule out other pathology for those who present with mid or lower face symptoms. Magnetic resonance imaging (MRI) with and without contrast of the brain can be helpful in distinguishing between classic and symptomatic trigeminal neuralgia and should be considered in all patients with new onset of symptoms. There is some early evidence that structural MRI techniques can help to identify changes associated with trigeminal neuralgia and to predict those patients who will respond well to surgical intervention, but more research is needed in this area.

### Differential Diagnosis

The differential diagnosis includes other types of headaches (migraine, cluster headache, paroxysmal hemicrania), dental sources (cracked teeth, caries, dental abscess), infectious causes (sinusitis, otitis media, postherpetic neuralgia), nervous system pathology (intracranial tumors, multiple sclerosis), temporomandibular joint syndrome, and giant cell arteritis. Many of these other diagnoses will have specific examination findings.

### Treatment

Medical treatment should be initiated for all new cases of trigeminal neuralgia. Carbamazepine (Tegretol) has been shown in multiple randomized controlled trials to reduce pain in trigeminal neuralgia and is considered the gold standard for medical treatment. The number needed to treat is 2. Dosing starts at 100 mg twice daily and increases gradually in increments of 200 mg/day to a maximum of 1200 mg/day. Carbamazepine can have side effects such as drowsiness, dizziness, hepatotoxicity, pancreatitis, blood dyscrasias, and ataxia. Consensus opinion is that it has a greater than 50% failure rate for long-term (5 to 10 years) pain control. Oxcarbazepine (Trileptal)<sup>1</sup> can also be used, though the data are not as robust as for carbamazepine (level B for oxcarbazepine vs level A for carbamazepine). Medication should start at 600 mg/day in two divided doses and then be increased to 300 mg every third day to a maximum of 1800 mg. For both medications, testing for the HLA-B\*15:02 allele should be considered in at-risk patients (e.g., those of Asian ancestry) to avoid Stevens-Johnson syndrome. Pimozide (Orap)<sup>1</sup> has been promoted as equal to carbamazepine; however, the studies are of low quality with no adverse effect comparison, and pimozide has many potentially serious side effects. Tizanidine (Zanaflex)<sup>1</sup> has been shown to be as effective as carbamazepine but also with low-quality studies. Lamotrigine (Lamictal)<sup>1</sup> can be used in patients who do not tolerate carbamazepine or as an adjunct to those without full benefit from carbamazepine, but the dose must be titrated slowly; therefore it is not as effective for acute pain control. Baclofen (Lioresal)<sup>1</sup> and gabapentin (Neurontin)<sup>1</sup> may be useful in patients with multiple sclerosis who also have trigeminal neuralgia, but evidence is lacking regarding their effectiveness in classical trigeminal neuralgia. Topical lidocaine has been used intraorally for those with significant oral pain from trigeminal neuralgia; however, again, there are no well-designed studies of its efficacy. A new sodium channel blocker with affinity for the Na<sub>v</sub> 1.7 sodium channel is

<sup>1</sup>Not FDA approved for this indication.

being investigated with some promising evidence of effectiveness, but it is still in clinical trials and not yet available for prescription.

Recent studies have shown some weak data that botulinum toxin A (Botox)<sup>1</sup> can be an effective treatment in reducing both the intensity of pain and frequency of paroxysms in trigeminal neuralgia; adverse events include facial asymmetry and edema or hematoma at the injection site. Alcohol injections<sup>1</sup> and cryotherapy have also been used to treat the pain of trigeminal neuralgia.

For some patients with refractory or severe symptoms, surgical treatment can be helpful. Microvascular decompression and radiosurgery are both common techniques for the treatment of trigeminal neuralgia, with microvascular decompression generally considered to be first-line surgical intervention. Other surgical techniques can include radiofrequency thermocoagulation, glycerol rhizolysis, stereotactic radiosurgery, balloon compression, peripheral nerve section, partial sensory root section, and gamma-knife radiosurgery. Studies have noted sensory side effects, and most evidence for neurosurgical approaches comes from observational studies.

Neuromodulation is an alternative for patients with symptoms refractory to pharmacotherapy who do not want to pursue surgical treatment. Both central and peripheral neuromodulation have been studied, but evidence of effectiveness is very limited.

Treatment for secondary trigeminal neuralgia typically includes treating the underlying cause.

### Monitoring

Although there is no standard protocol for monitoring patients with trigeminal neuralgia, the condition is extremely painful, and there have been incidents reported of patients accidentally overdosing on medications or taking their own lives. Therefore it is recommended that patients be monitored at regular intervals to make sure that their pain is controlled and to monitor for side effects from treatment.

### Management of Complications

The disease can have relapses and remissions. Medications or alternative treatments should be reinstated as needed. Tests should be run as needed based on side-effect symptoms, and treatments stopped and others considered based on efficacy and patient tolerance.

<sup>1</sup>Not FDA approved for this indication.

## VIRAL MENINGITIS

Method of

RosaMarie Maiorella, MD; and Joanna Thomson, MD, MPH

### CURRENT DIAGNOSIS

- Typical presentation includes fever, headache, and neck stiffness or pain. Constitutional symptoms include mild lethargy, myalgias, nausea, and vomiting.
- Neonates often present with nonspecific signs and symptoms including lethargy, irritability, and poor feeding.
- Cerebrospinal fluid (CSF) profile should be performed. Results show elevated white blood cell count (often but not always with mononuclear cell predominance), normal to slightly elevated protein, normal glucose, normal to slightly elevated opening pressure, and negative bacterial Gram stain and culture.
- Diagnostic polymerase chain reaction (PCR) and serologic studies can identify the etiologic agent.
- Consider neuroimaging before lumbar puncture if there is concern for increased intracranial pressure or if encephalitis is possible.

### CURRENT THERAPY

- Symptomatic and supportive management includes analgesia, antipyretics, antiemetics, and intravenous fluids.
- Hospitalization is recommended for infants (younger than 1 year), elderly patients (older than 65 years), and immunocompromised patients, as well as for patients presenting with altered mental status, seizures, focal neurologic signs, or the absence of classic viral CSF findings.
- Few medications, with the exception of acyclovir (Zovirax) for HSV, effectively treat viral meningitis.

### Epidemiology

The true epidemiology of viral meningitis is unknown because it is not a reportable disease. However, the Centers for Disease Control and Prevention (CDC) estimate 25,000 to 50,000 hospitalizations per year. There is also yearly variation in disease burden. Causes of viral meningitis vary by age group, immune status, season, and geography. There is increased incidence in summer and early fall owing to the high prevalence of enteroviruses and arthropod-borne viruses (arboviruses). Among children, incidence of hospitalization due to viral meningitis peaks immediately after birth and again at age 5. Common etiologic agents include enteroviruses, herpes simplex virus (HSV), arboviruses, lymphocytic choriomeningitis virus (LCMV), cytomegalovirus (CMV), varicella zoster virus (VZV), and Epstein-Barr virus (EBV). Severe acute respiratory syndrome coronavirus-2 (SARS-COV-2) has become an emerging cause of viral meningitis. See [Table 1](#) for features of the common and some less-common viral agents that cause meningitis.

### Pathophysiology

Viral infection begins at the mucosal surface of the respiratory tract or gastrointestinal tract, with viral replication occurring in regional lymph nodes. A secondary viremia then occurs that provides access to the central nervous system (CNS). Symptoms of viral meningitis are due to either an immune response to the virus within the CNS (e.g., enterovirus) or direct viral invasion of neural tissue (e.g., HSV1/2).

### Prevention

To prevent spread of viral agents responsible for meningitis, hand-washing and other infection-control measures are most

important. The infection-control precautions necessary during patient contact depend on mode of transmission of the virus (see Table 1). Vaccines are available for some of the viruses that are known to cause meningitis, including polio (an enterovirus), mumps, measles, varicella, and influenza.

### Clinical Manifestations

Viral meningitis can be difficult to distinguish from bacterial meningitis. Fever, headache, and neck stiffness and pain are the usual presenting complaints. Headache can be localized to the frontal or retro-orbital areas and may be associated with photophobia. Although neck stiffness and pain are usually present, neck rigidity (positive Kerning's sign or positive Brudzinski's sign) is not always present on examination. Constitutional symptoms can include lethargy, myalgias, and nausea or vomiting. There is often a history of concomitant viral respiratory or gastrointestinal illness at the time of presentation. Seizures can occur with viral causes of meningitis, especially HSV, but should prompt consideration of other diagnostic possibilities.

In contrast to children and adults, neonates often present with nonspecific findings such as lethargy, irritability, and poor feeding. See Table 1 for clinical manifestations associated with specific etiologic agents.

Viral meningitis can also manifest with signs of encephalitis, in which case the encompassing diagnosis is meningoencephalitis. Encephalitis or meningoencephalitis are likely if any of the following are present: altered mental status, seizures, focal neurologic deficits (including aphasia, anosmia, ataxia, cranial nerve deficits, motor weakness, or involuntary movements), or behavioral changes.

### Diagnosis

Diagnosis of viral meningitis requires lumbar puncture for CSF studies including cell count, protein, glucose, Gram stain and culture, and specific viral studies. Although a lymphocytic pleocytosis is associated with viral infections, most viral CNS infections initially have a neutrophilic pleocytosis. However, neutrophilic pleocytosis is also associated with bacterial meningitis. In viral meningitis, though CSF protein is normal to slightly elevated, CSF glucose is normal, and no organisms are identified on CSF bacterial Gram stain or culture compared with elevated CSF protein, low CSF glucose, and positive CSF bacterial culture in bacterial meningitis.

Studies to identify a specific virus as the etiologic agent are recommended for patients with severe illness or a complicated course. Viral cultures of CSF are not generally useful given their poor sensitivity, and serologic viral studies require both acute and convalescent titers to demonstrate antibody response to the suspected viral antigen. CSF PCR studies that detect viral DNA or RNA are more sensitive than viral culture and provide more rapid results than serologic viral studies (see Table 1). Multiplex PCR techniques allow for testing of multiple viruses and bacteria with a single CSF sample and a single test. Where available, multiplex PCR may result in considerable savings in time and effort, while improving diagnostic capacity. In some cases, it is useful to perform viral PCR studies on blood (HSV, EBV, CMV, and human herpesvirus [HHV]6), urine (CMV), stool (enterovirus), and skin vesicles (HSV) to further support the diagnosis. However, a positive PCR study from blood, urine, stool, or skin does not provide direct evidence of CNS infection by the same virus. For example, enterovirus isolated from the stool can represent asymptomatic infection or prior infection but may also be isolated from the stool at the same time as concomitant enteroviral meningitis.

Most other testing is not helpful, but further testing (including complete blood count, renal profile, liver function, pancreatic enzymes, and HIV studies) should be guided by the patient's presentation and clinical status.

Neuroimaging (computed tomography [CT] or magnetic resonance imaging [MRI]) should be obtained before lumbar puncture if there is concern for increased intracranial pressure. It is also recommended if symptoms of encephalitis are present (including altered consciousness, seizures, focal neurologic deficits, behavioral changes) to exclude other CNS disease.

### Differential Diagnosis

The major item on the differential diagnosis for viral meningitis is bacterial meningitis. The bacterial meningitis score, validated in children 29 days to 19 years, is a clinical prediction rule that identifies patients as at very low risk (0.1%) for bacterial meningitis if they lack all of the following: positive CSF Gram stain, CSF absolute neutrophil count (ANC) of at least 1000 cells/ $\mu$ L, CSF protein of at least 80 mg/dL, peripheral blood ANC of at least 10,000 cells/ $\mu$ L, and a history of seizure before or at the time of presentation. While C-reactive protein (CRP) is not generally useful because it can be high in viral meningitis and low in the initial stages of bacterial disease, elevated serum procalcitonin levels ( $>0.5$   $\mu$ g/mL in children and  $>0.2$   $\mu$ g/mL in adults) are more sensitive and specific for distinguishing viral from bacterial meningitis.

Other diagnoses to consider include parameningeal infections (i.e., subdural or epidural empyema, brain abscess), meningitis due to fungi, mycobacteria, rickettsia, mycoplasma, parasites, and other CNS infectious or inflammatory processes including malignancy, drug exposure, rheumatologic disease (e.g., systemic lupus erythematosus), or autoimmune (e.g., anti-NMDA receptor encephalitis).

### Treatment

Symptomatic care remains the mainstay of therapy for viral meningitis. Therapy should be directed at pain and fever control (e.g., ibuprofen [Motrin], acetaminophen [Tylenol], ketorolac [Toradol]), management of nausea and vomiting (e.g., ondansetron [Zofran]), and intravenous fluids. Hospitalization is recommended for patients younger than 1 year, the elderly, and the immunocompromised. Patients who present with altered mental status, seizures, focal neurologic signs, or a CSF profile that does not have the classic viral profile should also be hospitalized for clinical management and for antibiotic treatment until bacterial meningitis can be excluded. Advanced care including management of respiratory failure, cardiovascular instability, seizures, disturbed fluid and electrolyte balance, and cerebral edema may be necessary.

Empiric antibiotic coverage may be considered while awaiting CSF culture results in the young, elderly, and immunocompromised, especially if there is suspicion of bacterial meningitis or partially treated bacterial meningitis.

Acyclovir (Zovirax) should be initiated in cases of suspected HSV while waiting PCR confirmation. Dosing of acyclovir is age and weight dependent: 20 mg/kg per dose IV every 8 hours for patients younger than 12 years; 10 mg/kg per dose IV every 8 hours for patients older than 12 years.

In the immunocompromised patient, HHV6 may be treated with foscarnet (Foscavir)<sup>1</sup> or ganciclovir (Cytovene)<sup>1</sup>, and CMV may be treated with ganciclovir, valganciclovir (Valcyte), foscarnet, or cidofovir (Vistide). Case reports suggest benefit of such antiviral therapies in the immunocompromised, but no controlled trials have been performed.

### Complications

The prognosis of viral meningitis depends on cause and severity of illness as well as age. Non-HSV viral meningitis has low mortality rates in adults and children alike. Mortality and morbidity are associated with other organ system involvement, including meningoencephalitis. Although up to 10% of infants hospitalized with non-HSV viral meningitis experience seizures, altered mental status, or increased intracranial pressure during the acute illness, studies have shown no evidence of long-term neurodevelopmental delay. Most adults recover fully within a week without long-term sequelae. Persistent neurologic sequelae (including headaches, incoordination, concentration difficulties, muscle weakness, and focal neurologic deficits) occur more often in patients with meningoencephalitis.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Clinical and Laboratory Characteristics of Viral Meningitis

VIRUS	TRANSMISSION	KEY CLINICAL FEATURES	DIAGNOSIS	COMMENTS
Enterovirus	Fecal-oral	May have rash on exam (e.g., Coxsackie, hand-foot-mouth) Patients with impaired humoral immunity or those <2 wk old can present with a sepsis-like syndrome with multiorgan dysfunction, DIC, cardiovascular collapse	CSF enterovirus PCR	More prevalent in summer and fall
Herpes simplex viruses 1 and 2	Vertical transmission during birth (HSV2), horizontal transmission via contact (HSV1 or HSV2)	10%–30% of adults have symptoms of meningitis with primary HSV2 infection; look for genital vesicular lesions on exam Mollaret's meningitis: >3 episodes of fever and meningismus lasting 2–5 d, with spontaneous resolution; episodes may be months to years apart often due to chronic HSV2 CNS infection	CSF HSV1/HSV2 PCR	Meningitis is uncommon with nonprimary HSV2 infection
Arboviruses	Subcutaneous inoculation via mosquito or tick Prevention: Minimize tick and mosquito exposure with personal protection measures including insect repellents and covering exposed skin	Zika virus associated with Guillan-Barré syndrome and in newborn infants microcephaly; sexual transmission is possible	CSF arboviral PCR Zika RT-PCR (performed at CDC Arbovirus laboratory on CSF or serum within first 5–7 days of symptoms); Zika IgM cross reacts with other flaviviruses (e.g., Dengue)	More prevalent in summer and fall Geographic distribution within the U.S.: Eastern equine encephalitis: Eastern U.S. Western equine encephalitis: Western U.S. St. Louis encephalitis: Across the U.S. (majority of cases in Central and Eastern U.S.) West Nile virus: Across the U.S. California encephalitis (LaCrosse): Midwestern, mid-Atlantic, and Southeastern U.S. Zika virus: Small epidemics occurred in Southeastern U.S. and Gulf Coast states. Currently, there is no local transmission of zika virus in the continental U.S.
Lymphocytic choriomeningitis virus	Virus is present in rodent secretions, feces, and urine Ingestion of contaminated food, exposure of open wounds, or inhalation of aerosolized virus Lab workers, pet owners, and those living in impoverished conditions are highest risk for illness	Accompanied by a flulike illness	Serum LCMV titers (acute and convalescent) CSF findings: May have decreased glucose and WBC count >1000/mL	More prevalent in winter and spring
Cytomegalovirus	Exposure to infected body fluids (e.g., saliva, blood)		CSF CMV PCR	Reactivation of prior infection typically only occurs in the immunosuppressed
Epstein-Barr virus	Exposure to infected body fluids (e.g., saliva, blood)	Alice in Wonderland syndrome: altered body image and distortion of visual perception	CSF EBV PCR	Most common neurologic complication with primary infection

**TABLE 1** Clinical and Laboratory Characteristics of Viral Meningitis—cont'd

VIRUS	TRANSMISSION	KEY CLINICAL FEATURES	DIAGNOSIS	COMMENTS
HIV	Exposure to contaminated blood or other body fluids (e.g., transfusion, sexual contact, percutaneous blood exposure)	During primary infection, a subset have meningitis or meningoencephalitis May expect thrush and cervical lymphadenopathy	HIV studies	Treatment with HAART
Human herpesvirus 6	Respiratory	Roseola: febrile illness followed by viral exanthem	CSF HHV6 PCR	HHV6 has been demonstrated in the CSF of asymptomatic persons Immunosuppressed persons at risk for symptomatic infection and reactivation
Varicella	Respiratory	Typical vesicular skin lesions of chickenpox on exam CSF pleocytosis has also been demonstrated with reactivation; can also occur in the absence of cutaneous findings of herpes zoster (“zoster sine herpette”)	CSF VZV PCR	Rarely diagnosed during acute chickenpox infection; usually a postinfectious complication Other neurologic sequelae of varicella infection are more common than aseptic meningitis; most common is cerebellar ataxia
Mumps	Respiratory	Parotitis on exam is the most prominent sign of infection Aseptic meningitis can precede or follow clinical exam findings CSF profile can demonstrate an unusually high protein with a mild pleocytosis and normal glucose	Serum titers	More common in winter and spring
Measles	Respiratory	CSF pleocytosis in $\leq 30\%$ of patients with measles; patients are usually without clinical meningitis	Serum titers	In the U.S., most cases are imported (e.g., occur in returning travelers), but in recent years there have been outbreaks of measles in the U.S. associated with pockets of unvaccinated people
Influenza	Respiratory	Aseptic meningitis is a less common neurologic complication of influenza infection (encephalopathy is more common)	CSF influenza PCR	More prevalent in winter Increased risk of neurologic complication in young patients and in those with pre-existing medical disease
COVID-19	Respiratory	CSF profile can demonstrate pleocytosis and elevated protein	CSF SARS-CoV-2 RT PCR	Rare complication of COVID-19 infection

Abbreviations: CMV = cytomegalovirus; CNS = central nervous system; CSF = cerebrospinal fluid; DIC = disseminated intravascular coagulopathy; HHV = human herpesvirus; HSV = herpes simplex virus; LCMV = lymphocytic choriomeningitis virus; PCR = polymerase chain reaction; VZV = varicella zoster virus; WBC = white blood cell.

HSV is associated with high rates of morbidity and mortality. Neonatal isolated CNS HSV has a 4% mortality rate even with acyclovir treatment; mortality is 50% without acyclovir treatment. Unfortunately, acute treatment does not affect morbidity, as 70% of infants with neonatal CNS HSV infection will suffer from neurodevelopmental impairments. Improved outcomes have been shown with long-term oral acyclovir suppression therapy. Outside of the neonatal period, CNS HSV infection has a 28% mortality rate with antiviral treatment (70% mortality rate without treatment). Long-term neurologic sequelae occur in two-thirds of survivors who received antiviral therapy, compared with virtually all of those who did not receive treatment.

## ALCOHOL USE DISORDER

Method of

David A. Frenz, MD

### CURRENT DIAGNOSIS

- Unhealthy alcohol use (UAU) represents a continuum of alcohol use associated with negative health consequences, including addiction.
  - *Hazardous use* increases the risk of health consequences.
  - *Harmful use* has caused health consequences but does not meet the threshold for addiction.
  - *Alcohol use disorder* (AUD) represents addiction as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, text revision (*DSM-5-TR*).
- A single-question screener (SQS) is a clinically efficient means to assess for UAU.
  - When negative, UAU has been reliably excluded.
  - When positive, the Alcohol Use Disorders Identification Test (AUDIT) should be administered.
- The AUDIT stratifies patients into four groups.
  - A score <8 points is a negative screen; UAU has been excluded unless there is clear evidence of malingering or deception.
  - A score of 8 to 15 points is consistent with hazardous use.
  - A score of 16 to 19 points is consistent with harmful use.
  - A score >19 points is worrisome for addiction and requires further assessment.
- Checklists based on the *DSM-5-TR* can be used to assess for addiction.

### CURRENT THERAPY

- All patients with UAU should receive counseling.
  - The goal is to reduce alcohol-related risks and harms, not achieve abstinence.
  - Counseling can take the form of simple advice, motivational interviewing (MI), chain analysis, and cognitive-behavioral therapy (CBT).
- Simple advice involves educating patients about drink sizes, daily and weekly drinking limits, pacing and spacing, and avoiding and managing triggers.
  - The National Institute on Alcohol Abuse and Alcoholism (NIAAA) offers a variety of free patient materials to facilitate these discussions and serve as behavioral prescriptions.
- MI helps patients recognize that their current choices and behaviors are ultimately not consistent with their stated goals and values.
  - Patients seemingly discover this “on their own” through skillful conversations involving open questions, reflective listening, and other communication techniques.

- Recognition and felt discrepancy provide the psychic energy or motivation for patients to change.
- Chain analysis helps patients recognize the many intermediate steps between a stimulus to drink alcohol and eventually consuming it.
  - Patients can “break the chain” by developing and following action plans for each link in chain.
- CBT helps patient recognize how their distorted (irrational) beliefs drive alcohol use.
  - Numbing, avoiding, and chemical coping are often the result of rigid demands, awfulizing, frustration intolerance, and depreciation beliefs.
  - Clinicians help patients transform their irrational beliefs into rational, flexible preferences; this tends to reduce alcohol use.
- Addiction pharmacotherapy should be considered for all patients with AUD.
  - Acamprosate (Campral) and naltrexone (ReVia, Vivitrol) reduce drinking and have favorable side-effect profiles.
  - Medication selection is based on patient preference, factors such as medication compliance, and end-organ function.

### Classification

UAU represents a continuum of alcohol use associated with negative health consequences, including addiction. This conceptualization has been adopted by the United States Preventive Services Task Force (USPSTF) and is the basis for screening, brief intervention, and referral to treatment (SBIRT), the contemporary graded approach to management described in this chapter.

UAU consists of three mutually exclusive categories (**Box 1**). *Hazardous use* increases the future risk of negative health consequences; *harmful use* has already caused adverse health consequences but does not meet the criteria for addiction; and *alcohol use disorder* (AUD), or *addiction*, is defined by the *DSM-5-TR*.

Hazardous use is anchored to binge drinking and weekly consumption limits. A binge is alcohol consumption that results in legal intoxication (blood alcohol concentration [BAC]  $\geq 0.08$  gram percent). For healthy adults, this is typically >3 drinks for women and men  $\geq 65$  years of age, and >4 drinks for men <65 years of age, where one U.S. standard drink contains 14 grams of ethanol (**Table 1**). Alcohol intoxication is strongly associated with immediate risks including injuries, suicide, and violence.

Over longer timescales, alcohol is associated with a broad range of conditions including infectious diseases, many cancers, cardiovascular diseases, gastrointestinal diseases, mood disorders, and epilepsy. Consuming >7 drinks per week increases all-cause mortality in a linear manner, regardless of gender. AUD is defined in the *DSM-5-TR* as “a problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two [criteria], occurring within a 12-month period.” The *DSM-5-TR* outlines 11 criteria such as “alcohol is often taken in larger amounts or over a longer

**BOX 1** The Alcohol-Use Continuum**Low Risk Use, Including No Use**

Consumption of alcohol below amounts identified as hazardous; and use in circumstances not defined as hazardous (context)

Example: One glass of wine with dinner several days per week

**Hazardous Use**

Alcohol use that increases the risk for health consequences

**Hazardous Consumption**

Females; males  $\geq 65$  years of age:  $>3$  drinks/day and/or  $>7$  drinks/week

Males  $<65$  years of age:  $>4$  drinks/day and/or  $>7$  drinks/week

**Hazardous Context**

Example: Alcohol use during pregnancy

**Harmful Use**

Alcohol use with health consequences in the absence of addiction

Example: College student who sustains a forehead laceration secondary to falling down while intoxicated

**Alcohol Use Disorder**

Addiction to alcohol per the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5-TR)*

- Mild: 2–3 criteria
- Moderate: 4–5 criteria
- Severe:  $\geq 6$  criteria

The shaded portion represents unhealthy alcohol use (UUA).

**TABLE 1** U.S. Standard Drinks: By Definition, One Standard Drink Contains 14 Grams of Ethanol

BEVERAGE	ALCOHOL BY VOLUME	DRINK SIZE
Beer (regular)	5%	12 fl oz
Wine	12%	5 fl oz
Distilled spirits*	40% <sup>†</sup>	1.5 fl oz

\*Examples include vodka, gin, whiskey, rum, and tequila

<sup>†</sup>80 proof

Data from U.S. Department of Agriculture and U.S. Department of Health and Human Services. Dietary Guidelines for Americans, 2020–2025 (9th ed). Washington, DC: U.S. Department of Agriculture, 2020, p. 49

period than was intended” and “recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.” Consumption (frequency and quantity), the defining features of hazardous use, has never been part of the construct.

Harmful use exists when alcohol-related harm has occurred but the “problematic pattern” and/or criterion threshold for AUD have not been satisfied.

**Epidemiology**

Large, population-based surveys have found that 17.1% to 24.4% of Americans binge drink, with considerable regional variability. This translates into healthcare settings. For example, a cross-sectional study of 2.7 million primary care patients determined that 6.1% exceeded recommended daily consumption limits (male: 8.7%; female: 3.8%).

A similar pattern exists for AUD. The third wave of the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC-III), a cross-sectional survey of American adults, found that 13.9% and 29.1% of the population met criteria for AUD in the preceding year and on a lifetime basis, respectively. Coincidentally, the corresponding prevalence is 13.9% in primary care settings.

**BOX 2** Two-Step Process for Screening for Unhealthy Alcohol Use (UUA) and Associated Management**Step 1: Single-Question Screener (SQS)**

How many times in the past year have you had X or more drinks in a day?

where  $X = 4$  for females and males  $\geq 65$  years of age; and  $X = 5$  for males  $<65$  years of age

**Management**

0 times: None/done (negative screen)

$\geq 1$  times: Proceed to Step 2

**Step 2: Alcohol Use Disorders Identification Test (AUDIT)**

Administer full-scale AUDIT (10 items)

(<https://auditscreen.org/check-your-drinking/>)

**Management**

$<8$  points: None/done (negative screen)

8–15 points: Brief intervention

16–19 points: Brief intervention and continued monitoring

$>19$  points: Assess for Alcohol Use Disorder (AUD), initiate treatment if present

**Diagnosis**

In light of its prevalence and considerable harms, the USPSTF recommends “screening for UUA in primary care settings in adults 18 years or older, including pregnant women, and providing persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce unhealthy alcohol use.”

Various screening instruments exist. The author prefers a two-step process beginning with a single-question screener (SQS)<sup>a</sup> to reduce the testing burden for both patients and clinicians (Box 2). Positive screens are then clarified with the AUDIT (<https://bit.ly/3JjuVSA>). Both instruments are in the public domain and may be used without formal permission or licensing.

Although patients with UUA can engage in malingering and deception, the reported sensitivity of the SQS ranges from 0.73 to 0.88. Its negative predictive value (NPV), which depends on prevalence, is 0.94 to 0.98 when 5% to 15% of those screened have UUA. Said differently, this corresponds to a 2% to 6% false-negative classification (“miss rate”) at typical base rates in primary care.

Patients with significantly elevated AUDIT scores ( $>19$  points) require careful assessment for AUD. This can be accomplished through structured clinical interviews (“checklists” based on DSM-5-TR criteria) or referral to a mental health professional for diagnostic assessment. Suggested checklists include the Structured Clinical Interview for DSM-5 Disorders (SCID-5-CV; Module E) and the Mini International Neuropsychiatric Interview (MINI; Module I).

**Treatment**

Management of UUA depends on patient classification (see Box 1). Most patients, including those with AUD, are appropriate for initial treatment in primary care settings.

**Goals**

Total abstinence from alcohol has traditionally been the treatment goal; however, this disease-oriented outcome is difficult to achieve and maintain in both clinical trials and “real-world” settings. The author prefers pragmatic, patient-oriented treatment goals (“progress not perfection”) that are consistent with the trend toward non-abstinent recovery.<sup>b</sup> This is analogous to

<sup>a</sup>Also known as the NIAAA single-item question or one of the AUDIT-C (consumption) questions.

<sup>b</sup>Sometimes referred to as “harm reduction.” The author considers the term confusing as all of medicine is ultimately harm reduction. Of greater concern, the term is potentially pejorative and can interfere with the therapeutic alliance.

other chronic diseases in which improvement is celebrated (e.g., reduction in hemoglobin A<sub>1c</sub>), even if the ideal state has not been achieved.

For patients who meet *DSM-5-TR* criteria for AUD, a reduction in severity represents clinical progress, for example, when a patient who fulfilled seven criteria (“severe”) at baseline now fulfills three criteria (“mild”). Remission is achieved when no criteria for AUD have been satisfied for at least 3 months, except for the criterion for craving. As noted previously, consumption is not part of the *DSM-5-TR* construct: abstinence is not required for remission.

*Relapse* is a nonclinical term that generally means that drinking has interrupted a period of continuous abstinence. The author suggests using more clinically accurate categories in the UAU spectrum.

### Counseling

The USPSTF recommends behavioral counseling interventions for patients with UAU. This generally begins with simple advice about drink sizes, daily and weekly drinking limits, pacing and spacing, and avoiding and managing triggers. The NIAAA offers a variety of free patient materials to facilitate these discussions and serve as behavioral prescriptions (<https://bit.ly/3Jb6mHh>).

MI is a person-centered style of counseling that is used to address ambivalence about changing one’s behaviors. Systematic reviews have consistently demonstrated its effectiveness for various alcohol-related outcomes, although a recent meta-analysis questioned its efficacy in maintaining abstinence in primary care settings. The method involves open questions, reflective listening, and other communication techniques (Box 3). The goal is to lead patients to recognize that their current choices and behaviors are ultimately inconsistent with their stated goals and values. This discrepancy, when recognized and felt, provides the psychic energy or motivation for the patient to change. Self-help books can provide structure and cadence for office visits and can serve as out-of-session “homework” between visits (<https://amzn.to/3usxUD0>).

Chain analysis helps patients recognize the many intermediate steps between a stimulus to drink alcohol and eventually consuming it. Patients can “break the chain” by developing and following action plans for each link in the chain. Patient worksheets can be used to analyze their behaviors and serve as tools that they can use in the community (<https://bit.ly/38z4rPb>, General Worksheet 2).

CBT helps patients recognize how their distorted (irrational) beliefs cause unhealthy negative emotions and behaviors, including drinking. Irrational beliefs take four general forms:

- Rigid demands: Must, should, ought
- Awfulizing: “It’s awful ... Terrible ... End of the world”
- Frustration intolerance: “I can’t stand it”
- Depreciation beliefs: “I’m no good,” “She’s no good,” “It’s no good”

For example, a patient may experience family conflicts or financial adversities. Frustration intolerance may lead them to use alcohol to numb, avoid, or chemically cope with the situation.

CBT helps patients transform their irrational beliefs into flexible preferences (e.g., “My financial situation is challenging, but I’ve had money problems before and can tolerate it). These new rational beliefs tend to reduce alcohol use. Patient worksheets (<https://bit.ly/3i4QF8A>) and inexpensive self-help books (<https://bit.ly/35Y2zyD>) can support these efforts.

### Medications

Addiction pharmacotherapy, sometimes described as *medication-assisted treatment* (MAT),<sup>c</sup> is generally reserved for patients with AUD (Box 4). Disulfiram (Antabuse), which was approved by the U.S. Food and Drug Administration in 1951, has generally fallen into disuse secondary to lack of efficacy, medication interactions, and potential for various harms.

<sup>c</sup>The author prefers to describe addiction pharmacotherapy as *disease-modifying therapy* (DMT) because medications are often the primary or sole treatment for addiction, especially for other substance use disorders such as opioid addiction.

## BOX 3 Motivational Interviewing

*The patient completed the SQS (positive) and AUDIT (score = 17) as part of a well-adult examination. This exchange demonstrates Open questions, Affirming, Reflecting and Summarizing (OARS), the core motivational interviewing skills.*

**Provider:** Thanks for filling out that paperwork before our visit. [A]

**Patient:** No problem.

**Provider:** Would it be okay to discuss some of your answers?

**Patient:** Sure.

**Provider:** It looks like you’re drinking alcohol on most days. [S]

**Patient:** Yeah, I have a few glasses of wine with dinner.

**Provider:** Seems like that might be a change from last year. [O]

**Patient:** Probably. Work has been stressful.

**Provider:** Say more. [O]

**Patient:** We’re short-staffed, so I’ve been working a ton of hours. And customers have been tough to deal with—they want everything yesterday.

**Provider:** How do you think that’s connected to wine? [O]

**Patient:** I’m pretty wound up after work. I guess wine helps me relax and chill out.

**Provider:** What else? [O]

**Patient:** Well, work is always on my mind. Wine takes that down a few notches. It also helps me sleep.

**Provider:** Work has been stressful, and alcohol helps you with tension and worry. [S]

**Patient:** Yeah; it calms me down.

**Provider:** And getting good sleep is important to you. [R]

**Patient:** Totally—I need energy and have to be mentally sharp for my job.

**Provider:** You’re stuck in a vicious cycle at work, and alcohol helps you cope with that—so it’s helpful from that standpoint. [R]

**Patient:** [Nods in agreement]

*The patient’s AUDIT score suggests alcohol-related problems. The provider might segue to problem items in the following way.*

**Provider:** But it seems like alcohol might have some downsides, too. [S]

**Patient:** Maybe.

Naltrexone (ReVia [oral], Vivitrol [IM]) and acamprostate (Campral) both improve drinking outcomes, although with various nuances depending on trial design and type of data analysis. In placebo-controlled trials, acamprostate but not naltrexone increased abstinence, while naltrexone but not acamprostate reduced heavy drinking. Head-to-head trials found differences between the medications; however, they were ultimately equivalent when these data were subject to meta-analysis. Overall, the author selects one medication over the other based on patient preference and factors such as medication compliance and end-organ function.

The literature continues to evolve on the off-label use of medications including baclofen (Lioresal), gabapentin (Neurontin), and topiramate (Topamax). In the author’s opinion, these should generally be prescribed in consultation with an addiction medicine specialist after patients have tried and failed adequate therapeutic trials of acamprostate and naltrexone despite robust psychosocial treatments.

Historically, medically managed withdrawal (“detoxification”) has occurred in supervised settings. Reliable, carefully selected patients can safely be withdrawn on an ambulatory basis. The author uses the Short Alcohol Withdrawal Scale (SAWS), a patient self-rating scale, to trigger benzodiazepine administration.

**Acamprosate**

Brand name: Campral

Usual maintenance dosing: 666 mg by mouth three times per day

Mechanism of action: Postulated to be a gamma-amino butyric acid (GABA) agonist, glutamate antagonist, or both

Elimination: Excreted unchanged in urine

Adverse effects: Principally gastrointestinal, especially diarrhea

Prescribing pearls:

- Obtain baseline renal function test. Moderate impairment does not preclude therapy but requires monitoring. Do not use if eGFR <30 mL/min
- Initiate therapy at usual maintenance dose. Reduce dose to 666 mg two times per day for patients <60 kg. Reduce dose to 333 mg three times per day for eGFR 30–60 mL/min
- Gastrointestinal symptoms, if they develop, generally occur with initiation of treatment and are dose-related and transient. Consider temporary dose reduction (e.g., 333 mg three times per day for 7 days) for severe symptoms that threaten ongoing therapy
- Can be safely used with benzodiazepines and alcohol. May be started during medically managed withdrawal. Patients who resume drinking should be encouraged to continue taking acamprosate

**Naltrexone**

Brand names: ReVia (oral), Vivitrol (injectable)

Usual maintenance dosing: ReVia 50 mg by mouth daily; Vivitrol 380 mg intramuscularly every 4 weeks

Mechanism of action: Opioid antagonist

Elimination: Extensively metabolized by the liver, primarily excreted in urine

Adverse reactions: Opioid withdrawal syndrome, including precipitated withdrawal if opioid tolerant; hepatotoxicity; injection site reactions

Prescribing pearls:

- Patient must be opioid-free for ≥7 days before initiating therapy. Consider urine toxicology if abstinence cannot be reliably established by history
- Obtain baseline liver function tests. Alcohol-related transaminase elevations are common at baseline and should improve as alcohol consumption decreases. Do not use if transaminases are >5 times normal
- Obtain baseline renal function test. Moderate impairment does not preclude therapy but requires monitoring. Do not use if eGFR <30 mL/min
- Initiate oral therapy at 25 mg per day, titrating to usual maintenance dose over 7–14 days
- Mild opioid withdrawal symptoms, if they develop, generally occur with initiation of treatment, are dose-related and transient (they are likely caused by antagonism of endogenous opioids, e.g., endorphins). Consider temporary oral dose reduction (e.g., 12.5 mg per day for 7 days) for severe symptoms that threaten ongoing therapy
- Repeat liver function tests at 1 month and periodically thereafter
- Can be safely used with benzodiazepines and alcohol. May be started during medically managed withdrawal. Patients who resume drinking should be encouraged to continue taking naltrexone
- Always establish tolerability with the oral formulation before switching to injectable

Data from Center for Substance Abuse Treatment. Incorporating alcohol pharmacotherapies into medical practice. Treatment Improvement Protocol (TIP) Series 49. HHS Publication No. (SMA) 09-4380. Rockville, MD: Substance Abuse and Mental Health Services Administration, 2009.

**Comorbidities**

Other mental disorders frequently co-occur<sup>d</sup> with AUD and often precede its onset. In this context, AUD may represent a maladaptive coping mechanism for affective and anxious symptoms and for psychological trauma. Nascent evidence is mixed on treatment priorities and modalities. In the absence of firm guidance, management is empiric and should likely occur in consultation with local mental health experts.

Similarly, medical conditions such as chronic pain syndromes often co-occur with AUD and portend poorer drinking outcomes. Here, too, the literature is incipient, and management should occur in consultation with local experts (e.g., addiction medicine, pain medicine).

**Uncertainties and Controversies**

Alcoholic Anonymous (AA) formed in the 1930s and continues to play a central role in the recovery community. Its effectiveness has long been debated secondary to defects in trial design such as standardization of interventions, selection bias, blinding, and patient attrition. A recent systematic review focused primarily on manualized Twelve-Step Facilitation (TSF), a standardized, professionally delivered treatment that facilitates involvement in AA. It found that TSF improved complete abstinence compared with MI and CBT, and it was equivalent for six remaining outcomes such as drinking intensity and alcohol-related consequences. The certainty of evidence was variable and ranged from very low to high, depending on the outcome. None of the studies included a true control condition (e.g., wait list control) or compared TSF to addiction

pharmacotherapy. The author takes a “might help, can’t hurt” posture but does not consider community-based (peer-led) AA a substitute for treatments for which there is stronger evidence.

The American Society of Addiction Medicine (ASAM) maintains a comprehensive guideline (*The ASAM Criteria*) for assessing patients and matching them to the most appropriate level of care (e.g., outpatient vs. residential treatment) based on their clinical characteristics (<https://bit.ly/3joihWN>). It first appeared in 1991 and is widely used by treatment providers and funders (health plans, government agencies). The framework represents expert opinion for which outcome data are sparse. Some have more bluntly noted that matching patients to treatment options based on expert opinion is little better than assigning patients by chance. The author considers *The ASAM Criteria* helpful for risk stratification but gives considerable weight to patient preferences in terms of treatment setting. A carefully supervised trial of office-based addiction treatment is reasonable if a patient is unwilling or unable to pursue a higher level of care, provided imminent danger<sup>e</sup> is absent.

<sup>e</sup>ASAM’s doctrine of imminent danger consists of three components: (1) a strong probability that certain behaviors will occur; (2) the likelihood that such behaviors will present a significant risk of serious adverse consequences to the individual and/or others; and (3) the likelihood that such adverse events will occur in the very near future, within hours and days, rather than weeks or months.

<sup>d</sup>There is an old, ungrammatical saw in addiction medicine: “Which came first and which came worse?” Did generalized anxiety disorder (GAD), for example, develop first and then chemical coping and AUD followed? Or, did AUD develop first and anxious symptoms instead represent a substance-induced anxiety disorder? This is often difficult to establish by history and only becomes evident on a post hoc basis.

## AUTISM

Method of

Rachel Brown, MBBS

### CURRENT DIAGNOSIS

- Autism spectrum disorder (ASD) is characterized by the presence of persistent deficits in social communication and social interaction as well as by restricted, repetitive patterns of behavior, interests, or activities
- Symptoms must be present in the early developmental period, cause clinically significant impairment in important areas of functioning, and not be better explained by intellectual disability or global developmental delay.
- ASD may co-occur with intellectual disability, language impairment, with another medical, genetic, environmental, neurodevelopmental, mental or behavioral disorder, or with catatonia.
- Patients with ASD require different levels of support.

### CURRENT TREATMENT

- Early identification and intensive intervention is associated with improved outcomes.
- Intervention should start in early childhood and may need to be lifelong. It should focus on improving functional independence through structured education, supported employment and daily living, therapy focused on social skills and communication, and behavioral therapy, especially applied behavioral analysis (ABA).
- Ongoing surveillance and the management of co-occurring medical (sleep, constipation, etc.) and psychiatric (ADHD, anxiety, etc.) conditions is important.
- No biomedical agent reliably improves the core symptoms.
- Stimulants, guanfacine (Intuniv), and atomoxetine (Strattera) have shown benefit for co-occurring ADHD. Treatment of anxiety and depression should follow practice guidelines for those conditions. Antipsychotic agents, such as risperidone (Risperdal) and aripiprazole (Abilify), reduce symptomatic challenging behaviors. However, potential adverse effects include weight gain, sedation, and extrapyramidal symptoms.

## Epidemiology

Older epidemiologic studies suggested that autism spectrum disorder (ASD) was a rare disorder, with a prevalence of only 4 in every 10,000 population. With time, estimates of prevalence have steadily increased, and current estimates are 0.6% to 0.7%, with some as high as 1% to 2%. The reasons for the increase are not completely known. Improved awareness of the disorder, especially in those less severely affected, and broader diagnostic criteria have played a significant role. However, a real increase in prevalence remains a possibility. Approximately 45% of individuals with ASD also have intellectual disability.

Studies have consistently shown that males with ASD outnumber females by a factor of at least 2–3 to 1. Older studies placed the male predominance even higher, and there is a suggestion that females have been historically under-recognized. Girls are diagnosed somewhat later in life, and studies suggest that more concurrent behavioral or cognitive problems need to be present in girls for the disorder to be recognized. Around a third of individuals with ASD have a pattern of regression (loss of previously acquired skill) occurring in the second year of life.

## Risk Factors, Etiology, and Pathophysiology

The theory that ASD is the consequence of maternal mistreatment has been disproven, and there is no evidence that ASD is caused by vaccination. Both genetic and environmental factors probably play a role. Studies have consistently shown a familial pattern for ASD. Twin studies demonstrate a much higher concordance for monozygotic twins (between 80% and 90%), compared to dizygotic and other siblings, where the risk ranges from around 7% to as high as 20%. The data is somewhat complicated because of the recognition of a so-called “broader autism phenotype” that includes milder but qualitatively similar features to the defining features of autism. Some conditions with known genetic etiology are associated with high rates of ASD. Those include fragile X, Rett, tuberose sclerosis, Down, Angelman, and a variety of others. For the majority of patients with ASD, however, specific syndromes are not present, and the search for a single “autism gene” has been fruitless. Instead, a wide variety of genes are probably associated with ASD susceptibility. Many of the genes are related to transcriptional control, chromatin remodeling, protein synthesis and cellular metabolism, and synapse development and function. Although the estimated heritability of ASD is relatively high, environmental factors also play a part. Recognized risk factors include older maternal and paternal age, gestational hypertension and diabetes, prematurity, and maternal immune activation. Studies of the neurobiology of autism suggest that autism is associated with atypical neural connectivity, and is a problem of neural networks, rather than a structurally discrete abnormality. One commonly reported feature is generalized brain overgrowth in the first 2 years of life, manifested by a larger than average head circumference in a portion of patients with ASD. Studies have also shown some consistent neurologic abnormalities of both white and grey matter in a variety of brain regions, as well as evidence of cortical dysgenesis. Alterations in serotonin and  $\gamma$ -aminobutyric-acid (GABA) systems, as well as oxytocin, vasopressin, and androgens/estrogens are under active investigation. Information about the genetics and neurobiology of this condition are rapidly evolving. It is likely that, in time, ASD may be sub-classified into a number of related conditions, each of which may be diagnosed and treated differently, according to the underlying etiology.

## Clinical Manifestations

For the diagnosis of ASD to be made, patients must have both persistent deficits in social communication and interaction as well as repetitive, restrictive behaviors emerging in early childhood (Table 1). Human beings, including children and young babies, are inherently social and interaction seeking. However, in patients with ASD, social approach and interaction is either absent or qualitatively abnormal. In some patients, the onset of abnormality is present from the beginning, while in others there is a period of normal development followed by loss of skills, most commonly in the second year of life. There is a failure of normal back-and-forth

**TABLE 1** Examples of Typical Symptoms in Autism Spectrum Disorder

Social impairment	Lack of or abnormalities in eye contact Lack of interest in peers Lack of empathy for others Diminished facial expression Diminished/absent pointing to share enjoyment Abnormal requesting of items, e.g., use of another's hand as a tool Failure to respond to name Poorly developed/absent friendships Difficulties modulating social interactions
Communication	Complete lack of language Absence of babbling Use of stereotyped phrases Idiosyncratic use of language Pronoun reversal Echolalia "Scripting" (e.g. repeating of movie scripts, etc.) Failure to use language for social interaction; unusual prosody Inability to have a back and forth conversation
Repetitive, restricted behaviors	Hand flapping, toe walking, spinning, etc., also known as "stimming" Excessive attachment to inanimate objects Abnormal response to pain, noise, textures, etc. Difficulty with transitions between activities Difficulty with changes in routine

conversation and a reduction or absence of normal sharing of interests, affect, and emotion. Normal nonverbal communicative behavior is also abnormal and/or poorly integrated with verbal communication. That means that facial expression may be flat, eye contact disconnected from gestures, such as pointing for shared enjoyment, and from language, including the requesting of preferred objects. Typical gestures, such as waving bye-bye, playing pat-a-cake, and head shaking may be absent or delayed. Children with ASD have difficulties adjusting to social situations and are either disinterested in peers or experience significant difficulty in making friends and sharing interests, including shared imaginative play. Repetitive, restrictive behaviors typically described include motor abnormalities, sometimes known as "stimming," such as spinning and hand flapping, interests focused on a limited number of play items that are not used for imaginative play, resistance to change and transition, and sensory sensitivity, such as overreaction to loud noises, food textures, and pain. Onset of symptoms must be in "early childhood." Delay in diagnosis may be seen, especially in those with higher intellectual ability, more verbal facility, and in girls. Patients who are not diagnosed in early childhood nonetheless present with deficits in communication and interaction, including social isolation, difficulties in making friends, and focused interests/activities.

### Diagnosis

The diagnosis is based on clinical symptoms consistent with the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). Symptoms must be present in the early developmental period and cause clinically significant impairment in social, occupational, or other important areas of functioning. ASD may occur with or without accompanying intellectual impairment and language impairment. ASD may be associated with a known genetic or medical condition, with another neurodevelopmental or behavior disorder, and with catatonia. Full evaluation should include a detailed history of presenting symptoms and early development, and observation of the child in a setting where social interaction is required. Although there is no psychological "test" for ASD, validated, structured observation tools may be employed

as a component of a detailed diagnostic evaluation. Of these, the most commonly seen is the Autism Development Observation Scale (ADOS), available in multiple versions appropriate for different age groups, and including a version for diagnosis in adults. It is important for practitioners to be aware of local regulations. In some states, access to resources (e.g. early childhood intervention, respite care, applied behavioral analysis, etc.) may only be triggered after specific evaluation requirements are met; those may include assessment by certain kinds of professionals, evaluation in approved settings, or the use of specific tools.

There is a difference between a clinical diagnosis of ASD and a determination that a child is eligible for autism-related educational services. Children with a clinical diagnosis may not necessarily be eligible for special educational services. The latter are determined by assessment for educational need and may be delivered through an Individualized Education Plan (IEP). Families may benefit from advocacy in accessing educational services for social and behavioral difficulties, even when their child is doing well academically. On the other hand, not every child deemed eligible for educational services for autism will have received a formal clinical diagnosis. The latter is important when a child transfers to adult services, when a clinical diagnosis may be necessary to determine eligibility for disability, guardianship, vocational education, or sheltered workshops and group homes.

### Differential Diagnosis

DSM-V states that disturbances in development and behavior must not be better explained by intellectual disability or global developmental delay. The latter are the most common differentials. Many individuals with ASD also have intellectual disability. However, to make comorbid diagnoses of ASD and intellectual disability, social communication should be below the general developmental level, and significant repetitive, restrictive activities must be present. Additional differential diagnoses include communication disorders, of which social (pragmatic) communication disorder is the most difficult to distinguish. Language delay is no longer required for the diagnosis of ASD but is very common. Social (pragmatic) language disorder is diagnosed in patients who have deficits in communication but do not have the characteristic repetitive behaviors seen in patients with ASD. Specific sensory deficits in hearing and vision must be excluded. Finally, studies of individuals who have suffered extraordinary and extreme early childhood neglect show that some of these children later demonstrate a pattern of "pseudo-autism."

### Screening, Clinical Assessment, Intervention, and Monitoring

Because of the increasing evidence that early intervention for children with ASD may be critical to long term outcomes, routine early screening for ASD is essential. Primary care physicians should follow recommendations for the developmental screening of babies and young children, which include specific screening for ASD at 18 and 24 months. A positive screen should result in a referral for a comprehensive evaluation from a qualified specialist, such as a behavioral pediatrician, child and adolescent psychiatrist, or pediatric neurologist. The comprehensive evaluation will likely be multidisciplinary, and may include evaluations by psychology, speech and language therapy, and occupational therapy. Critical elements include a detailed birth, developmental and medical history, and family medical and psychiatric history, and may include structured interviews of the parent(s). Careful observation of the child is essential and is often supplemented by structured clinical observation. Assessments of adaptive skills should be included, along with intellectual ability and academic and work-related performance where appropriate. Primary care physicians may contribute by completing a full medical examination, including measurement of head circumference, screening for vision and hearing anomalies, careful review for dysmorphology, and assessment for seizure disorder, which is present in 20% of patients with ASD. Children with

suspected genetic syndromes should be referred for expert evaluation and follow-up, as should those with suspected specific sensory impairments and seizure disorders. Recommended blood work for children with ASD includes comprehensive blood count, lead level and chromosomal microarray with Fragile X.

There may be a significant delay before the results of a full evaluation become available. However, a child with a significant delay in development should be referred promptly to early intervention, whether or not the diagnosis of ASD has been confirmed. Every state has an early intervention program for children from birth to 3 years, and older preschool-age school children may be eligible for early childhood special education. Additional referrals for occupational, physical, and speech therapy may also be made, as well as for other enrichment programs, such as Headstart.

As in the management of any other complex medical condition in a child, support for parents and families, and coordination of services is a critical role for primary care. Parent-parent resources may be helpful, both local and internet-based. Although there will be geographic variation in the availability of specific programming, the cornerstone of intervention throughout life should be an individualized program designed to optimize a particular patient's strengths and address deficits, with interventions targeted at maximizing function and quality of life.

Behavioral approaches supplemented by other therapies and interventions supporting social engagement are recommended for children with ASD diagnoses. Programs focus on the development of language and social skills, and reductions in disability and comorbidity, particularly the impairments associated with behavioral disinhibition and aggression. Early intensive behavioral intervention should include applied behavioral analysis, which focuses on the building of discrete skills as well as on diminishing problematic behavioral patterns. Interventions may be delivered through comprehensive programs such as the Early Start Denver Model or TEACCH (Treatment and Education of Autistic and related Communication Handicapped Children), or via a combination of behavioral and educational services and therapy interventions. Programming typically involves parents in the delivery of interventions designed to enhance emotional engagement and communication. Communication is facilitated where necessary through visual scheduling (Picture Enhanced Communication Systems [PECS]), technology enhanced communication, and the use of sign language. Many children with ASD benefit from ongoing special educational interventions, which should target behavioral and social skills training as well as academic interventions. Vocational intervention is recommended for older children, adolescents, and adults. The transition to adult services may be challenging both for patient and family. Planning should start in early adolescence and, besides the transition of medical services if needed, should include careful consideration and planning for appropriate independence and support, including safe driving, options for further education and employment, and the need for possible ongoing guardianship by parents or other relatives. Unemployment is, sadly, very common in adults with ASD, who may become very isolated. Supports should be designed to facilitate their fullest possible engagement with their community, while protecting them, where necessary, from exploitation and abuse.

Patients with ASD may respond in unusual ways to common medical conditions, especially those that are painful and uncomfortable such as dental pain, headache, sinus pain, menstrual cramps, etc. This may be because of unusual response to physical symptoms, because of difficulty in communication, or both. Routine preventive medical and dental visits should be encouraged from early childhood onward. New onset and exacerbations of agitation, irritability, or self-injury in a patient with limited ability to communicate should always prompt a search for a physical cause, including a thorough physical examination.

Certain medical conditions (sleep disturbance; gastrointestinal problems, especially constipation; and seizure disorders) are particularly common in individuals with ASD and are associated with increased likelihood of irritability and behavioral disturbance. Routine surveillance should include attention to these conditions as well as appropriate management and referral. Seizure onset may be in later childhood or adolescence, and poorly controlled seizures are associated with both educational and behavioral deterioration. Some individuals with ASD have very limited dietary intake. Careful enquiry may be followed by blood work if indicated, including blood count, ferritin, vitamin D, and zinc. Referral may be made to a dietician, to behavioral therapy for mealtime related behaviors and/or to occupational therapy if the eating problems are related to problems with texture or swallowing. Many children with ASD have constipation and other gastrointestinal issues such as reflux, diarrhea, and inflammatory bowel disease. These conditions should be monitored and managed aggressively. Finally, sleep difficulties may be prominent, especially in many young children with ASD. Nonpharmacologic approaches (psychoeducation and cognitive-behavioral therapy [CBT]) should be implemented first; these typically include education about the nature and function of sleep and the implementation of good sleep hygiene and bedtime routines. There is some evidence that the use of melatonin as a supplement to sleep-focused CBT may be helpful.

Co-occurring psychiatric disorders are not uncommon in individuals with ASD. Historically, the diagnosis of attention deficit hyperactivity disorder (ADHD) was not possible in patients with ASD, but this changed with the DSM-5. There is suggestive evidence that stimulants,  $\alpha$ -2 agonists and atomoxetine (Strattera) are helpful for ADHD, though potentially in a lower percentage of patients and with a higher frequency of side effects compared to the non-ASD population. Anxiety, particularly social anxiety, and generalized anxiety disorders, may present in older children, adolescents, and adults, along with depression and other mood symptoms. CBT is an established treatment in ASD patients without intellectual disability who present with anxiety. There are less data to support the use of CBT in ASD patients who have an intellectual disability and in those who experience mood symptoms rather than anxiety.

### Pharmacotherapy

There are currently no pharmacologic interventions available that address the underlying core deficits of autism, though studies targeting the cholinergic, glutamergic, and oxytocin systems are under way. Psychotropic medication interventions may be used for co-occurring psychiatric conditions, where those are present. Stimulant medications, guanfacine (Intuniv), and atomoxetine may be used for ADHD in patients with ASD. Some supporting data shows efficacy, but in a smaller percentage of ASD than non-ASD patients and with a higher side effect burden. Psychopharmacologic intervention for anxiety and depression should follow clinical guidelines for patients without ASD, including the use of selective serotonin reuptake inhibitors (SSRIs), with awareness that side effects, especially irritability, may be more common (Table 2). Antipsychotic medications have been shown to be effective for symptomatic relief of aggressive, agitated behaviors in adolescents with ASD; however, studies are relatively short term, and the side effects of this group of medications limit their utility. Practice guidelines include specific monitoring for weight gain and associated metabolic abnormalities.

Patients with ASD have been the target of many complementary and alternative interventions (e.g., high dose vitamin regimes, dietary modification such as gluten-casein free diets, omega-3 fatty acids, secretin, chelation, hyperbaric oxygen, antifungal regimes, etc.), none of which have proven efficacy and some of which are frankly dangerous. Patients and their families may need support and guidance in resisting inaccurate, nonscientific claims made by organizations marketing unproven interventions (Table 3).

**TABLE 2** Psychopharmacology in Patients With Autism Spectrum Disorder

MEDICATION	TARGET	EVIDENCE FOR EFFECTIVENESS	RELATED CONSIDERATIONS
Atypical antipsychotics—risperidone (Risperdal) and aripiprazole (Abilify)	Agitation, aggression, irritability in patients with ASD	Moderate to high, however, side effects may limit utility	Practice guidelines for monitoring; weight gain (for which metformin may be helpful), sedation, extrapyramidal symptoms, and elevated prolactin
SSRIs—citalopram (Celexa) <sup>1</sup> , escitalopram (Lexapro), fluoxetine (Prozac) <sup>1</sup> , sertraline (Zoloft) <sup>1</sup> and others	Anxiety and mood disorders	Little data for patients with ASD and co-occurring anxiety/depression. Not effective for core ASD symptoms	Common side effects include gastro-intestinal symptoms and increased irritability
Stimulants (methylphenidate [Ritalin], dextroamphetamine [Dexedrine])	ADHD	Well established for ADHD in patients without ASD; moderate evidence for ADHD in patients with ASD	Probably effective in a lower percentage of ASD patients than in uncomplicated ADHD. Side effects include irritability, decreased appetite, insomnia, weight loss, and headache
Melatonin <sup>7</sup>	Sleep disturbance	Some support	Use as an adjunct to CBT for sleep

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

ADHD, Attention deficit hyperactivity disorder; ASD, autism spectrum disorder.

## DELIRIUM

Method of

Tessa E. Rohrberg, MD

### CURRENT DIAGNOSIS

- Delirium is a syndrome characterized by the acute onset of cerebral dysfunction with a change or fluctuation in baseline mental status, inattention, and either disorganized thinking or an altered level of consciousness.
- The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, offers diagnostic criteria for delirium.
- Hyperactive delirium is the most easily recognized subtype and includes symptoms of irritability, restlessness, agitation, or uncooperativeness.
- Hypoactive delirium has been associated with a higher mortality and includes behaviors such as reduced motor activity, apathy, lack of awareness, or lethargy.
- Delirium usually lasts 1–2 weeks, but complications may persist beyond hospitalization.

### CURRENT THERAPY

- Prevention is the most effective approach to treatment.
- Antipsychotic medication should not be used prophylactically to prevent delirium.
- Nonpharmacologic therapies are key in management.
- Pharmacologic therapies should be used when nonpharmacologic strategies are not effective or when patients present with a potential for harm to themselves or others.
- Caregivers should be included in a multidisciplinary treatment plan.

## Epidemiology

Delirium can be seen in persons of all ages across many clinical settings. Prevalence is affected by patient age, underlying medical diseases, severity of acute insult, and baseline mental status. Although up to 29% of adults may experience delirium during non-intensive

care unit (ICU) hospitalization, prevalence is as high as 80% in patients in the ICU with mechanical ventilation and 60% in patients following orthopedic surgery. In addition, up to 80% of patients may experience delirium at the end of life. Delirium may be missed in more than half of the cases. Patients with delirium may have increased length of hospital stay, long-term cognitive impairment, and higher mortality. The costs of delirium and associated complications have been reported up to \$150 billion worldwide annually.

### Pathophysiology

Although the exact etiology of delirium is unclear, it is often multifactorial and complex. Delirium is a syndrome that results from an acute insult causing cerebral dysfunction. Mechanisms contributing to delirium may include neurotransmitter imbalances and anatomic deficits. Neurotransmitter alterations—including serotonin imbalance, acetylcholine deficiency, dopamine excess, and/or melatonin deficiency—are thought to contribute. These alterations may lead to increased cytokine levels and an inflammatory response that changes the blood-brain barrier and cerebral oxidative metabolism. Higher cortical areas of the brain, such as the prefrontal and nondominant posterior parietal regions, have been implicated by brain imaging in patients with delirium. Other regions thought to be involved include the anterior thalamus, basal ganglia, and temporo-occipital cortex. More research is needed to fully elucidate the stress response and effect of risk factors.

### Risk Factors

Many risk factors for developing delirium have been identified; they can be divided into predisposing and precipitating factors. See [Table 1](#) for differentiation of these risk factors. A patient with many predisposing risk factors may experience delirium with only a minor precipitating event, whereas a patient with few predisposing risk factors may require multiple precipitating factors to develop delirium. Medications present a great risk for developing delirium. Those posing a higher risk comprise anticholinergics (including antihistamines, muscle relaxants, and urinary incontinence agents like oxybutynin [Ditropan]), benzodiazepines, dopamine agonists, and meperidine (Demerol); those that pose a moderate-to-low risk include antibiotics, anticonvulsants, antiemetics (metoclopramide [Reglan]), anti-dizziness

agents, antihypertensives, antivirals, corticosteroids, opiates, nonsteroidal antiinflammatory drugs, sedatives, and tricyclic antidepressants.

### Clinical Manifestations

The three subtypes of delirium are hyperactive, hypoactive, and mixed. Hyperactive delirium is more commonly recognized in the clinical setting. It typically includes irritability, agitation, restlessness, and uncooperative behaviors. Patients may also have fast or loud speech, combativeness, fast motor responses, nightmares, tangentiality, or persistent thoughts. This subtype is seen in patients experiencing withdrawal from substances of abuse, including drugs or alcohol. Hypoactive delirium may be more difficult to distinguish and thus is associated with more severe complications, including a higher mortality. Hypoactive delirium is frequently found in the elderly and includes sluggishness, apathy, lethargy approaching stupor, lack of awareness, slowed movements, sparse or slow speech, and staring. Metabolic dysfunction—such as hepatic encephalopathy or hypercapnic respiratory failure—may make it more difficult to identify hypoactive symptoms. Delirium may also present with a mixed level of activity and may fluctuate rapidly between hyperactivity and hypoactivity or between normal and disturbed psychomotor activity. Mixed delirium may be misdiagnosed as sundown syndrome.

### Diagnosis

The diagnosis of delirium may be missed due to its multifactorial etiology, atypical symptoms of hypoactive delirium, and resemblance to other comorbidities. Diagnosis is dependent on early recognition through routine monitoring. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, includes diagnostic criteria for delirium that can be described by the following:

1. A disruption in cognition with inattention, including inability to maintain concentration and awareness of the environment.
2. The disruption from baseline occurs acutely, usually within hours to days, and fluctuates over time.
3. An additional alteration in cognitive processes of memory, orientation, language, or visual perception.
4. The disruption in criteria 1 and 3 cannot be related to another chronic or developing neurocognitive syndrome and cannot happen in a state of unconsciousness or coma.
5. The history, examination, and clinical data indicate that the cognitive disruption results from another medical condition, substance abuse or withdrawal, adverse medication reaction, or exposure to toxins.

The diagnosis of delirium can be further specified as acute (lasting a few hours or days) or persistent (lasting weeks to months), and a hyperactive, hypoactive, or mixed level of activity. Evaluation for the diagnosis of delirium should be done for underlying causes and can be individualized for each patient. Laboratory and radiologic testing usually consists of a complete blood count, comprehensive metabolic panel, urinalysis with microscopy, blood cultures, electrocardiography, and chest radiography. Additional testing might include an arterial blood gas, urine drug screen, serum ammonia, blood alcohol level, computed tomographic (CT) imaging of the head, and cardiac biomarkers. It is important to screen for drug or alcohol withdrawal, as this can present with delirium.

### Differential Diagnosis

Many other diseases may closely resemble delirium. Cognitive impairment and mood disorders may be confused with delirium, including dementia or depression. See [Table 2](#) for a comparison of characteristics of these diseases. In the elderly and those with postoperative side effects, it is important to consider urinary and fecal retention. The Critical Illness, Brain Dysfunction and Survivorship (CIBS) Center website (<http://www.icudelirium.org>) has many mnemonics that can be useful when one is considering other circumstances that mimic delirium. One such mnemonic is “I WATCH DEATH.”

**TABLE 1** Risk Factors for Delirium

PREDISPOSING FACTORS	PRECIPITATING FACTORS
Male sex	Dehydration
Age >65 years	Fractures
Previous diagnosis of delirium	Hypoxia
Chronic pain	Infection
Medical comorbidities	Ischemia
Alcohol abuse	Shock
Terminal illness	Recent surgery
Dementia	Urinary or stool retention
Depression	Uncontrolled pain
Elder abuse	ICU environment
Recurrent falls	Sleep deprivation
Malnutrition	Physical restraints or immobility
Polypharmacy	Mechanical ventilation
Sensory impairment	Foley catheter
Pressure ulcers	Coma
Urinary or fecal incontinence	Medications

ICU, Intensive care unit.

Infection	Sepsis, urinary tract infection, pneumonia, HIV
Withdrawal	Alcohol, barbiturates, sedative-hypnotics, opiates
Acute metabolic	Acidosis, alkalosis, electrolyte disturbance, renal or hepatic failure
Trauma	Head injury, heat stroke, postoperative, burns
Central nervous system pathology	Abscess, hemorrhage, subdural hematoma, seizures, encephalitis, meningitis, stroke, tumors, hydrocephalus, syphilis
Hypoxia	Anemia, hypotension, respiratory failure, congestive heart failure, carbon monoxide poisoning
Deficiencies	Vitamin B12, folate, thiamine, niacin
Endocrinopathies	Hypo/hyperthyroid, hypo/hyperglycemia, hyperparathyroidism, adrenal disease
Acute vascular	Hypertensive emergency, pulmonary embolism, arrhythmia, myocardial infarction
Toxins/drugs	Anticholinergics, benzodiazepines, alcohol, illicit drugs, pesticides, solvents
Heavy metals	Lead, mercury, manganese

**Monitoring**

Although many assessment tools exist, the Confusion Assessment Method (CAM) is the most effective screening tool, with a sensitivity of 94% to 100% and a specificity of 90% to 95%. Screening should be performed by a trained health professional and done at least once per shift in patients at moderate to high risk. One should routinely monitor for precipitating factors, including changes in medications, laboratory values, clinical symptoms, and physical examination findings.

**Prevention**

Prevention is the key to decreasing delirium incidence, hospital costs, and complications. Delirium may be preventable up to 40% of the time. Efforts should involve a multidisciplinary and multi-component approach. This includes early mobilization, cognitive reorientation activities using calendars and clocks, promotion of normal sleep-wake cycles using protocols that control light and noise stimuli, clustering of patient activities, and improving access to sensory equipment like glasses or hearing aids. Other key interventions include nutrition and fluid replacement, adequate pain management, and the prevention of constipation. Although

antipsychotic medications should not be used for the prevention of delirium, home psychiatric medications should be restarted when possible so as to lower the risk for delirium.

**Treatment**

Treatment of delirium includes the identification and management of the underlying etiologies, assessment of risk factors, and review of the medication list. Delays to initiation of treatment may result in the prolongation of symptoms, the possibility of long-term cognitive impairment, and higher mortality. Treatment is primarily aimed at prevention utilizing the nonpharmacologic measures described earlier. The Hospital Elder Life Program (HELP) is a widely used evidence-based model that uses this approach and involves physicians, nurses, caregivers, family members, and patients. Research has shown that support of family and caregiver involvement can further increase the effectiveness of this model and can contribute to shorter length of hospitalization, reduced healthcare costs, and a decreased incidence of delirium. Pharmacologic therapies are used when nonpharmacologic strategies are not effective. There are currently no antipsychotic medications that are approved by the US Food and Drug Administration for the treatment of delirium. Antipsychotics should be reserved for patients in whom behavioral interventions have failed or are not possible or in those who have a potential for harm to themselves or others. Antipsychotic medications should be used at the lowest effective dose for the shortest possible duration. Haloperidol (Haldol)<sup>1</sup> is the antipsychotic medication used most often for delirium management; however, atypical antipsychotic medications have been shown to be as effective. Haloperidol, risperidone (Risperdal)<sup>1</sup>, and quetiapine (Seroquel)<sup>1</sup> are considered the safest when used for delirium. Benzodiazepines should not be used for delirium unrelated to alcohol or benzodiazepine withdrawal. Nonopiate medications should be used initially to treat pain in patients diagnosed with delirium. If sedation is required in ICU patients with delirium, studies suggest the use of dexmedetomidine (Precedex) rather than benzodiazepines. See Table 3 for delirium prevention and treatment strategies.

**Complications**

Delirium is associated with significant long-term complications. Although cognitive impairment following a diagnosis of delirium may improve with time, lasting effects are possible. A longer duration of delirium in critically ill patients has been associated with worse long-term executive function and global cognition. The

**TABLE 2** Differential Diagnosis of Delirium

	<b>DELIRIUM</b>	<b>DEMENTIA</b>	<b>DEPRESSION</b>
Features	Confusion and inattention	Memory loss	Sadness, anhedonia
Onset	Acute	Insidious	Slow
Course	Fluctuating, worse at night	Chronic, progressive, stable over course of a day	Single episode or recurrent
Duration	Hours to months	Months to years	—
Consciousness	Altered	Normal	Normal
Attention	Impaired	Normal, except in late stages	May be impaired
Orientation	Fluctuates	Poor	Normal
Speech	Incoherent	Mild errors	Normal or slow
Thought	Disorganized	Impoverished	Normal
Illusions	Common (visual hallucinations)	Rare, except in late stages	Not usually
Psychomotor changes	Yes	No	Yes
Reversible	Usually	Rarely	Possibly

**TABLE 3** Prevention and Treatment of Delirium

NONPHARMACOLOGIC	PHARMACOLOGIC
Identify underlying etiology	<b>Typical Antipsychotics</b>
Medication review	Haloperidol (Haldol) <sup>1</sup> 0.5–2.0 mg PO q4h or IM q30–60min prn; maximum dose 20 mg q24h
Early mobilization	<b>Atypical Antipsychotics</b>
Cognitive reorientation	Risperidone (Risperdal) <sup>1</sup> 0.25–2 mg PO qd–bid
Sensory enhancement	Quetiapine (Seroquel) <sup>1</sup> 25–200 mg PO bid
Pain management	Olanzapine (Zyprexa) <sup>1</sup> 2.5–10 mg PO qd
Cluster activities	Ziprasidone (Geodon) <sup>1</sup> 20–80 mg PO bid
Sleep-wake cycle enhancement	Aripiprazole (Abilify) <sup>1</sup> 10–30 mg PO qd
Family and caregiver support	<b>Benzodiazepines</b>
Nutritional and fluid replacement	Lorazepam (Ativan) <sup>1</sup> 0.5–1 mg orally q4h prn
Prevention of constipation	
Restart home psychiatric medications	
Routine use of the Confusion Assessment Method	

<sup>1</sup>Not FDA approved for this indication.

severity of lasting cognitive impairment has been compared to mild Alzheimer disease or moderate traumatic brain injury. Other complications include the development of mood disorders, loss of function in activities of daily living (ADLs), hospital readmission, longer duration of mechanical ventilation, and increased lengths of stay in the ICU and in hospital. Family members and caregivers may also experience stress in caring for their loved ones with cognitive impairment. Adverse effects of medications used in the treatment of delirium are also impactful and can include extrapyramidal symptoms, QT interval prolongation, insulin resistance, sedation, increased risk of falls, and hypotension. Mortality in patients suffering from delirium is as high as 37% during hospitalization, with a 10% increased risk of death per hospital day. Patients diagnosed with delirium are also up to three times more likely to die at 6 months after discharge. Mortality is greater in those with hypoactive delirium.

### Special Considerations

Data regarding incidence and impact of delirium in patients with COVID-19 are limited thus far. The risk of acute delirium and long-term complications appears high due to direct central nervous system involvement of SARS-CoV-2 and the inflammatory cascade, subsequent organ failure, prolonged mechanical ventilation and use of sedative medications, immobilization, social isolation, and advanced age. Management and prevention of delirium in patients with COVID-19 may prove challenging, but a multidisciplinary and multicomponent approach remains significant in addition to caregiver support.

## DEPRESSIVE, BIPOLAR, AND RELATED MOOD DISORDERS

Method of

Alice M. Ing, MD, MA; and Andrei Novac, MD

### CURRENT DIAGNOSIS

- Clinical evaluation of mood disorders starts with a thorough psychosocial and medical history.
- Identify symptoms and patterns of the appearance of mood changes.
- Differentiate between unipolar and bipolar symptom patterns.
- Use collateral history, if possible.
- For recent-onset disorder, rule out new medical disorders. Always check thyroid function.

### CURRENT THERAPY

- Any underlying medical conditions must be treated simultaneously.
- The mainstay of treatment for all mood disorders remains the combination of pharmacology and psychotherapy.
- Monitor frequently for suicidality.
- Allow at least 2 to 4 weeks for response before a medication switch.
- Switch medication early in cases of intense side effects.
- Monitor for hypomanic switch on medications in undiagnosed bipolarity.

### Introduction

Unipolar and bipolar mood disorders are part of a large group of psychiatric conditions referred to as *mood disorders* or *affective disorders*. They are among the medical conditions that are most commonly encountered in everyday clinical practice. Although current psychiatric texts classify mood disorders in two broad categories (unipolar and bipolar), the clinician must keep in mind that many mood disorders are mixed and manifest in many comorbid and atypical forms. Thus, mood disorders and related mood dysregulation encompass a broad range of human experiences: (1) psychiatric disorders, which are well defined and described in medical texts; (2) a variety of mood syndromes, often comorbid and less well classified and often undiagnosed, which coexist with medical and other psychiatric disorders alike; and (3) mood dysregulation, an aggregate of dispositional traits, at times

transient in nature, that are outside clear-cut psychiatric diagnosis but are often related to disturbances of personality. They all deserve particular attention because they can gravely impact the level of functioning, compliance, treatment outcome, and quality of life.

### Mood Disorders

Both the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, (*DSM-V*) and the *International Classification of Diseases*, tenth revision, Clinical Modification (*ICD-10-CM*) classify mood disorders into similar types. These include major depressive disorders (MDDs; unipolar, single episodes, and recurrent); persistent depressive disorder ([PDD] dysthymia); bipolar I disorder; bipolar II disorder; cyclothymic disorder; mood disorder due to medical conditions; substance-induced mood disorders; and the “unspecified” unipolar and bipolar disorders. In addition, the *DSM-V* has included new clinical entries, such as disruptive mood dysregulation disorder (DMDD), PDD (dysthymia) with intermittent MDDs, and premenstrual dysphoric disorder. The previously entitled *not otherwise specified* syndromes are now called *unspecified mood disorders*. New to the *DSM-V* are the following *specifiers* that apply to *both* bipolar and unipolar disorders: (1) with anxious distress (a mixture of mood disorder and anxiety disorder), (2) with mixed features, (3) with melancholic features, (4) with atypical features, (5) with psychotic features, (6) with catatonia, (7) with peripartum onset, and (8) with a seasonal pattern.

### Epidemiology for Unipolar and Bipolar Disorders

Most recent data regarding prevalence come from the National Comorbidity Survey, which has exposed in detail the rates of subtypes of mood disorders: unipolar, bipolar, and the subthreshold disorders. The lifetime prevalence of any mood disorder was found to be 21.4% (female 24.9%, male 17.5%), with MDD occurring at a lifetime prevalence of 16.9% (female 20.2%, male 13.2%) and 12-month prevalence of 6.8%. PDD (dysthymia) occurs at a lifetime prevalence of 2.5% (female 3.1%, male 1.8%) and a 12-month prevalence of 1.5%. The *DSM-V* specifies the prevalence for dysthymia as being approximately 0.5% and for the chronic form of MDD as 1.5%. Bipolar disorders present with a lifetime prevalence of 4.4% (female 4.5%, male 4.3%). If broken down, bipolar I disorder occurs at a lifetime prevalence of 1.0%, and 0.6% of new cases over 12 months. Bipolar II disorder occurs at a prevalence of 1.1% and 0.8%, respectively. Subthreshold bipolar disorder is twice as common at 2.4% lifetime and 1.4% new cases over 12 months.

### Risk Factors Common to Unipolar and Bipolar Disorders

For unipolar MDDs, risk factors include gender (women at greater risk), age (18 to 44 years of age at greater risk), marital status (separated and divorced at greater risk), family history (relatives with depression), early parental death, life events (negative stressful events, chronic exposure to stress), low confidence, and urban environments. For bipolar disorder, risk factors are similar. In addition, for bipolar disorder, higher rather than lower socioeconomic status and suburban environments have been cited as risk factors.

Individuals with anxiety disorder, chronic exposure to stress and trauma, substance abuse, psychotic disorders, and chronic medical conditions are all known to be at risk for mood disorders.

Additionally, results from the World Health Organization (WHO) World Mental Health Surveys revealed that 22.9% of adult mood disorders and 31% of anxiety disorders are attributed to childhood adversity. Certain types of adversity, such as frequent childhood bullying, result in a high risk of poor social, health, and economic outcomes with an increase of suicidality, depression, anxiety disorders, and alcohol dependency, nearly four decades after exposure. In addition, psychiatric symptoms that are present in childhood constitute a risk factor for adult psychopathology, including mood disorders. Anxiety/depression, labile affect, and manic symptoms are all predictors for

future onset of bipolar spectrum disorder. Acute and transient psychotic disorder resulted in a 28% onset of affective disorder, but only 15% schizophrenia at 1-year follow-up. Finally, a more recently identified risk factor for mood disorders constitutes a gene-environment interaction that results in methyltetrahydrofolate reductase (MTHFR) deficiency and inadequate homocysteine metabolism, a risk factor for depressive disorders. MTHFR activity can be evidenced by readily available genetic testing (i.e., GeneSight; Myriad Genetics, Salt Lake City, UT). More recently, studies have pointed to the relationship between severity of depression and abnormalities in immune response. Depression has been associated with high levels of C-reactive protein and low levels of fractional exhaled nitric oxide.

### Unipolar Depressive Disorder

The *DSM-V* reclassifies unipolar depression into the following categories: DMDD; major depression; persistent depressive disorder (dysthymia); premenstrual dysphoric disorder; substance/medication-induced depression; depressive disorders due to another medical condition; other specified depressive disorders; and unspecified depressive disorders.

In this chapter, we will first present major depression as the prototype of most of depression encountered in clinical practice.

### Major Depressive Disorder

The mainstay of MDD is a major depressive episode. The *DSM-V* provides criteria according to a threshold of symptoms, yet all mood disorders must be understood as lying on a continuum. Therefore even individuals who do not meet all criteria must be carefully followed, and in many cases preventive treatment is warranted.

At least five or more of the following symptoms during the same 2-week period are required: (1) depressed mood most of the day, nearly every day (sadness, feelings of emptiness, and tearfulness); (2) marked diminished interest or pleasure in almost all activities; (3) significant weight loss or weight gain or fluctuations in appetite; (4) insomnia or hypersomnia; (5) psychomotor retardation or agitation nearly every day; (6) fatigue or loss of energy; (7) feelings of worthlessness and/or inappropriate guilt; (8) inability to concentrate, think, and make decisions; and (9) recurrent thoughts of death and/or suicidal ideation. These symptoms (1) cause significant distress or impairment in social, occupational, and/or personal functions and (2) are not caused by a general medical condition. In the *DSM-V*, contrary to previous classifications, bereavement and depression are not mutually exclusive. In fact, bereaved individuals can also develop MDD, which would warrant additional medical treatment (Table 1). The following are some forms of manifestations:

- MDD, single episode: Episodes may occur only one time in life or may occur again years later, usually triggered by major stressful events.
- MDD, recurrent type: Episodes recur at shorter intervals. Often the distance between episodes shortens with advancement in age. The first few episodes are more likely to be triggered by stressful life events, while in time the condition becomes self-maintained and self-triggered.
- Depressive disorder with catatonic features (motoric immobility, catalepsy, stupor, extreme opposition, posturing, and echolalia).
- MDD occurring after giving birth may predict further depressive episodes years later. Postpartum depression has also been associated with bipolar disorder.

Depressive disorder can also take a chronic course. Some patients present with *melancholic features* (profound loss of pleasure, depression worse in the morning, early morning awakening, severe psychomotor retardation, severe anorexia, and weight loss). Melancholia may be a predictor of a relatively favorable response to medications. *Atypical depression* features are characterized by inverted functional shift (weight gain and increased appetite, craving for sweets, hypersomnia, leaden paralysis, and long-standing interpersonal rejection sensitivity).

**TABLE 1** Guidelines to the Differential Diagnoses

DIAGNOSIS	SIMILARITIES	DIFFERENTIATING DETAILS	CLINICAL CLUES	TREATMENT RESPONSE
MDD versus PDD (dysthymia)	Depressed mood; depressive cognition (pessimism); and vegetative symptoms (physical)	MDD: Acute or subacute onset; possible recent life stressors; and often more numerous symptoms PDD: May overlap with MDD; chronic, fluctuating course	MDD: Usually a marked drop in functionality PDD: Significant chronic impairment; often symptoms are ego-syntonic; and “personality disorder” flavor	MDD: Antidepressants and/or initial antianxiety medications; consider psychotherapy PDD: Cognitive-behavioral psychotherapy; antidepressants (often long term); sometimes enhancement pharmacology
Mixed mania versus agitated depression	Psychomotor agitation; dysphoria; and mood swings	Mixed mania: Labile affect; often rapid switch with brief euphoric states  Agitated depression: No euphoric states; severe anxiety, including sympathetic symptoms	Mixed mania: Personal and family history  Agitated depression: Anxiety symptoms, often subtle, precede depressive symptoms	Mixed mania: Mood stabilizers; caution regarding antidepressants: can cause worsening  Agitated depression: Antidepressants and sedating mood stabilizers; avoid long-term tranquilizers
Mania versus cyclothymia	Intermittent states of high energy and euphoria with or without recurrent depression	Mania: Distinct states of high energy; depression is sometimes unnoticed  Cyclothymia: Distinct cycling from depression to hypomania	Mania: More often severe insomnia without fatigue; severity of mania and insomnia directly related  Cyclothymia: May take unpredictable forms; fluctuation of mood and sleep	Mania: Mood stabilizers; caution about antidepressants; and atypical antipsychotics if needed  Cyclothymia: Same as above, according to clinical judgment
Substance abuse disorder versus cyclothymia	Intermittent use of stimulant abuse may mimic cycling mood disorder; may coexist	Substance abuse: Substance abuse tends to escalate  Cyclothymia: Cyclothymia may remain constant for years (even lifelong)	Substance abuse: Look for specific syndromes; drug screen  Cyclothymia: Negative drug screens; no withdrawals; and no drug culture history	Substance abuse: Rehabilitation; treat underlying psychiatric symptoms  Cyclothymia: Mood stabilizers and/or antidepressants and/or atypical antipsychotics
Personality disorder versus mood disorder	More often overlap; requires concomitant treatment	Personality disorder: Long-term pervasive history since adolescence  Mood disorder: More often episodic	Personality disorder: Borderline personality disorder includes mood lability/depressive episodes; often narcissistic personality includes grandiose/hypomanic states  Mood disorder: More often symptoms are egodystonic	Personality disorder: Acute decompensation; long-term psychotherapy; mood stabilizers; and atypical antipsychotics  Mood disorder: See treatment of mood disorders
Bereavement versus MDD	May overlap; attention to recent major loss; sometimes similar picture; bereavement and MDD may co-occur	Bereavement: Tends to improve over time  MDD: Tends to worsen over time	Bereavement: Preoccupation with loss persists  MDD: Duration of average major depressive episode is 9 months	Bereavement: Social support; grief counseling; psychotherapy; and if MDD present, treat as MDD  MDD: See treatment of MDD
TIRM changes versus MDD	May overlap; attention to symptom patterns	MDD has a more favorable response to medications  TIRM dominated by sadness and grief	Fear of and preoccupation with death often progress with progression of medical condition	Both warrant trial with antidepressants, recommended before any end-of-life decisions  Experimental only: Treatment with entheogen-enhanced psychotherapy such as psilocybin, lysergic acid diethylamide (LSD), methylenedioxymethamphetamine (MDMA)*

*Continued*

**TABLE 1** Guidelines to the Differential Diagnoses—cont'd

DIAGNOSIS	SIMILARITIES	DIFFERENTIATING DETAILS	CLINICAL CLUES	TREATMENT RESPONSE
Primary mood disorder versus mood disorder arising from a medical condition	Clinical picture may be identical	Primary mood disorder: May be triggered by external stressful events	Neurologic, endocrine, infectious, systemic, and blood disorders <sup>†</sup>	Treat both primary medical condition and mood disorder; treatment same as for primary mood disorder
		Medical condition: Often onset is insidious; sometimes precedes medical condition		

\*Not yet approved for use in the United States.

<sup>†</sup>Medical conditions complicated by mood disorders: Addison disease, acquired immunodeficiency syndrome, anemia, brain tumors, chronic pain, complex partial seizures, Cushing disease, cerebrovascular accident, dementia, diabetes mellitus, encephalitis, head trauma, hepatitis, hyperparathyroidism, hyperthyroidism, hypopituitarism, hypothyroidism, infectious mononucleosis, influenza, lupus erythematosus disseminatus, meningitis, multiple sclerosis, pneumonia, porphyria, rheumatoid arthritis, scleroderma, sleep apnea, toxoplasmosis, and others.

MDD, Major depressive disorder; PDD, persistent depressive disorder; TIRM, terminal illness–related mood.

**TABLE 2** Subtypes of Mood Disorders (Specifiers) Common to Both Unipolar and Bipolar Mood Disorders

SUBTYPE WITH	PRESENTATION	FEATURES
Anxious distress (with elements of mood disorder and anxiety disorder) 74.6% of MDD	During the majority of days of depressive, manic, or hypomanic episode	Feeling keyed up or tense, feeling restless, unable to concentrate, fear that something awful may happen, and so forth
Mixed features 15.5% of MDD	Meets criteria for either mania, hypomania, or depression	With mixed symptoms (if manic, there is associated dysphoria and depression), observable by others
Melancholic features	During the most severe period	Severe anhedonia, worse in the morning, early-morning awakening, psychomotor retardation or agitation, and weight loss or gain
Typical features	During majority of days of a major depressive episode	Inverted functional shift (hypersomnia, hyperphasia, and weight gain), leaden paralysis, and long-standing pattern of interpersonal rejection sensitivity
Psychotic features	The presence of delusions and/or hallucinations	Mood-congruent psychosis (delusions/hallucinations include themes consistent with the type of mood [manic or depressed]) Mood-incongruent psychosis
Catatonia	The presence of catatonia	Catatonic features are present during most of depressive or manic episodes
Peripartum onset	Mania, hypomania, MDD in bipolar I or II disorders	During pregnancy or in the 4 weeks following delivery
Seasonal pattern	At least one type of episode (mania, hypomania, or depression) within a seasonal pattern	Temporal relationship between an episode and a particular time of the year (fall or winter, in bipolar I or II)

MDD, Major depressive disorder.

Table 2 presents the subtypes (specifiers) of mood disorders according to the *DSM-V*. These subtypes are encountered both in unipolar and in bipolar mood disorders. Under these new *DSM-V* classifications, conditions such as catatonia, seasonal affective disorder (SAD), and atypical depression may occur both in individuals with unipolar disorder and in individuals with bipolar disorder.

MDD with psychosis is more often encountered in inpatient settings. However, early prodromal symptoms, which start with suspicion, paranoid features, or transient perceptive abnormalities, are relatively common. Most of the time, patients with prodromal psychotic features do not volunteer such symptoms; therefore clinicians must specifically ask about the presence of suspicions (“unusual perceptions”), which carry a significant, severe prognosis. Such clinical features of psychosis may complicate the treatment regimen. Antidepressive medications alone may sometimes be insufficient or exacerbate some of the psychotic features. In such cases, the addition of antipsychotic medications, frequent

monitoring, and psychiatric consultation is necessary. SAD is a recurrent type of depression, often combined with bipolar features. Most patients develop MDD of different degrees between October and February-March in the northern hemisphere. Clinicians must specifically inquire about this pattern of occurrence. Curiously, many patients with this subtype of depression have limited awareness of their seasonal pattern. Specific modalities that have emerged in recent years for SAD include light therapy and social rhythm therapy.

#### **Persistent Depressive Disorder (Dysthymia)**

Persistent depressive disorder (PDD), the new designation for dysthymic disorder, is a chronic form of depression in which the depressed mood has persisted for at least 2 years (in children for at least 1 year), as manifested by at least two of the following symptoms: (1) poor appetite or overeating, (2) insomnia or hypersomnia, (3) low energy or fatigue, (4) low self-esteem, (5) poor concentration or difficulty making decisions, and (6) feelings of

hopelessness. These manifestations are distinct from any major depressive episode, there have been no manic symptoms, and there is significant distress or impairment in social, occupational, or personal functioning. Dysthymia can occur in any age and can co-occur with MDD.

The following clinical forms have been identified: (1) with pure dysthymic syndrome: no full criteria of MDD have been met in the past 2 years; (2) with persistent major depressive episode: full criteria of a major depressive episode have been present in the past 2 years; (3) with intermittent major depressive episodes, with current episode: full criteria for major depressive episodes are currently met, but there have been periods of at least 8 weeks in the past 2 years when MDD criteria have not been met; and (4) with intermittent major depressive episodes, without current episode: no current MDD is identified (only symptoms of dysthymia), but there has been one or more major depressive episode(s) in the past 2 years. PDD may also qualify for any of the specifiers described in Table 2. (Note: Table 2 specifiers can apply to any of the unipolar and bipolar forms of mood disorders.) The term *minor depression* to distinguish from *major depression* has also been used in earlier contributions. *Minor depression* refers to two to four symptoms of depression lasting for more than 2 weeks but less than 2 years. This clinical variant falls within the spectrum of PDD (dysthymia). MDD and PDD (dysthymia) can coexist. More often, an individual suffering from dysthymia develops MDD as a complication. Earlier literature refers to these complications as *double depression*. Such patients necessitate long-term maintenance treatment beyond the acute major depressive episode.

#### Disruptive Mood Dysregulation Disorder

This condition occurs in childhood or adolescence between 6 and 18 years of age. It is characterized by (1) severe recurrent temper outbursts manifested verbally (verbal rages) and/or behaviorally (physical aggression toward people or property) that are grossly out of proportion in intensity or duration to the situation or provocation; (2) temper outbursts that are inconsistent with developmental level; (3) temper outbursts that occur on average three or more times per week; (4) a mood between temper outbursts that is persistently irritable or angry most of the day, nearly every day, and is observable by others; (5) the previous criteria, which have been present for 12 or more months (with no lapse in symptoms for a duration of 3 or more months); and (6) an age of onset that is before 10 years. Diagnosis should not be made before 6 years of age or after 18 years of age.

DMDD was introduced into the *DSM-V* for a subgroup of children with mood dysregulation and as an alternative to the diagnosis of childhood bipolar disorder. Some of these patients do move on to develop bipolar disorder. There is a significant overlap between DMDD and the onset of bipolar disorder. In one study of children in psychiatric hospitals, 30.5% met criteria for DMDD by parent report and 15.9% by inpatient unit observation. In clinical practice, young children may present with symptoms of attention-deficit/hyperactivity disorder and comorbid DMDD. Such patients often require careful assessment, complex pharmacologic treatment, and monitoring for possible worsening of bipolar symptoms.

#### Premenstrual Dysphoric Disorder

- The condition is characterized by the majority of menstrual cycles that include five symptoms. The following symptoms occur in the final week before the onset of menses and begin to improve within a few days after the onset of menses.
- One or more of the following symptoms must be present: (1) marked affective lability (mood swings, feeling suddenly sad or tearful, increased sensitivity to rejection); (2) marked irritability or anger or increased interpersonal conflict; (3) marked depressed mood, feelings of hopelessness, or self-deprecating thoughts; (4) marked anxiety, tension, and/or feelings of being keyed up or on edge.

**TABLE 3** Examples of Medications Known to Trigger Depression as a Side Effect

CLASS	EXAMPLES
Antihypertensive medications	Clonidine, reserpine, $\beta$ blockers
Cardiovascular medications	Digitalis
Steroids	Prednisone and dexamethasone (Decadron)
Antiarthritic medications	Indomethacin (Indocin)
Hormonal substitutes	Estrogen, progesterone, testosterone, anabolic steroids, and birth-control pills
Cancer medications	Most chemotherapy combinations, that is, cycloserine (Seromycin), tamoxifen (Nolvadex), vinblastine (Velban), and vincristine (Vincasar)
Tranquilizers and hypnotics	Diazepam (Valium), triazolam (Halcion), and zolpidem (Ambien)
Analgesics	Codeine, propoxyphene, <sup>2</sup> and potentially all opiates
Anti-Parkinson medications	Levodopa (L-DOPA) and bromocriptine (Parlodel)
Other medications	Anti-HIV; Medications used in the treatment of hepatitis C

<sup>2</sup>Not available in the United States.

One or more of the following symptoms must be present to reach a total of five symptoms: decreased interest in usual activities; subjective difficulty in concentration; lethargy; easily fatigued; marked changes in appetite, overeating, or specific food cravings; hypersomnia or insomnia; a sense of being overwhelmed or out of control; physical symptoms such as breast tenderness or swelling, joint or muscle pain, or bloating or weight gain.

#### Substance/Medication-Induced Depressive Disorder

This diagnosis is used when persistent disturbance in mood predominates the clinical picture and is characterized by depression and diminished interest or pleasure in activities. These symptoms occur during or soon after substance intoxication or withdrawal or after exposure to a medication. The substance in question must be known to cause symptoms of depression. Many substances that are abused (illicit and prescription) can cause depression. A 2018 study by Qato et al., which included 26,000 patients, found that more than one-third of American adults could be experiencing depression as a result of their prescription medication. Table 3 lists principal groups of medications to be considered when assessing patients with depression.

#### Depressive Disorder Due to Another Medical Condition

This diagnosis is used when a depressive disorder is triggered by a medical condition (diagnosed by physical examination and laboratory findings) known to cause symptoms of depression. These may include disorders of the central nervous system (CNS), systemic disorders (lupus and cancer), and so forth. Additionally, depression can aggravate many medical conditions, including chronic pain, multiple sclerosis, and cardiovascular disease.

#### Other Specified Depressive Disorders

These are depressive disorders that do not fully meet the criteria of the previously described conditions. However, they may appear in one of the following forms:

- Recurrent brief depression (symptoms lasting 2 to 13 days at least once per month) not associated with menstrual cycles

- Short-duration depressive episode (symptoms lasting 4 to 13 days) with at least four symptoms of major depressive episode associated with clinical distress and impaired functioning that persist but never meet criteria of MDD
  - Depressive episode with insufficient symptoms (at least one of the symptoms of MDD associated with distress and impairment persisting for at least 2 weeks with no prior history of MDD)
- These “other specified depressive disorders” are helpful to clinicians in refining the description of a clinical pattern exhibited by a particular patient.

### Unspecified Depressive Disorder

Finally, the previously used designation of *not otherwise specified* now reads *unspecified depressive disorder* (when none of the criteria are fully met, yet the patient is suffering from a mood disorder).

## Bipolar Mood Disorders

### Manic Episode

A manic episode is characterized by a period of at least 1 week with abnormal and persistently elevated, expansive, or irritable mood. At least three of the following should also be present: (1) inflated self-esteem or grandiosity, (2) decreased need for sleep (yet still feeling rested), (3) more talkative than usual or inability to stop talking, (4) flight of ideas or racing thoughts, (5) distractibility, (6) increase in goal-oriented activities (socially, sexually) or psychomotor agitation, and (7) excessive involvement in pleasurable activities with little regard for consequences (e.g., sexual indiscretions and unwise investments). These symptoms (1) result in marked impairment in most areas of life and (2) are not caused by substance abuse or general medical conditions.

### Hypomania

A hypomanic episode is similar to, but less intense than, a manic episode. At least three symptoms from the same symptom cluster (inflated self-esteem, decreased need for sleep, excessive talking, racing thoughts, hyperactivity, and increased involvement in pleasurable activities) are required, but the condition is not severe enough to cause marked impairment in social, occupational, and personal functioning, and it does not necessitate hospitalization. However, functional impairment is noticeable over time.

*Bipolar I disorder* requires only one full manic episode for the diagnosis. Usually, individuals with bipolar I disorder also have both manic and depressive episodes, but the depressions can range from severe and disabling to very brief and unnoticed. Therefore, a history of a depressive episode is not required for the diagnosis.

*Bipolar II disorder* is characterized by long periods of hypomania, with occasional major depressive episodes. Such individuals are usually not hospitalized for their hypomania and tend to function relatively well between depressive episodes. Hypomanic states are episodic and exhibit an unequivocal change in functioning that is uncharacteristic for the individual when not symptomatic. These changes are observable by others. Depressions tend to be severe and disabling. Bipolar II disorders do not include full manic episodes.

### Mixed States and Rapid Cycling

The particular specifiers for bipolar disorder are mixed states and rapid cycling. *Mixed states* refer to manic or hypomanic episodes with at least three of the following depressive symptoms: prominent dysphoria or depressed mood, diminished interest in activities, psychomotor retardation, fatigue or loss of energy, feelings of worthlessness, and recurrent thoughts of death. Often there is a rapid alternation between mania and depression (rapid cycling). Contingent upon severity, mixed states are usually accompanied by severe impairment. *Rapid cycling* refers to bipolar disorder that includes at least four episodes of illness per year. In addition, bipolar disorders may include any of the specifiers described in [Table 2](#).

### Cyclothymic Disorder

Cyclothymic disorder is a cycling mood disorder lasting for 2 years or more and is characterized by numerous periods with hypomanic symptoms and depressive symptoms that do not meet the criteria for bipolar disorder or MDD. During a 2-year period (1 year in children and adolescents), hypomanic and depressive periods have been present for at least half the time, and the individual has not been without symptoms for more than 2 months at a time. Criteria for MDD, mania, or hypomanic episodes have never been met. However, in the long run, some patients may develop symptoms of bipolar affective disorder. These symptoms should not be attributable to the effect of a substance (drug abuse and medication) or another medical condition (e.g., hyperthyroidism, Cushing disease). The condition is significantly impairing and includes psychological distress. Cyclothymia has the specifier (subtype) *cyclothymia with anxious distress*. This condition consists of cyclothymia and features of anxious distress as outlined in [Table 2](#). A variety of subclinical forms of *subthreshold cyclothymia* may be encountered in clinical practice. Such patients tend to develop overt symptoms of cyclothymia or even bipolar disorder when exposed to a variety of psychosocial stressors, substance abuse, and/or a variety of medications. Finally, [Table 4](#) presents subtypes of bipolar disorder currently listed in the *DSM-V*

**TABLE 4** Other Specified and Unspecified Bipolar Disorders

SUBTYPE	PRESENTATION	FEATURE
Substance/medication-induced bipolar and related disorder	Persistent disturbance of mood characterized by mania, hypomania, with or without depressed mood, which occurs soon after substance intoxication or withdrawal or after administration of a medication	<ul style="list-style-type: none"> <li>• Substance involved is capable of producing described mood symptoms</li> <li>• Does not occur in the course of delirium</li> <li>• There is significant stress or impairment</li> </ul>
Bipolar and related disorder due to another medical condition	<ul style="list-style-type: none"> <li>• Persistent period of abnormally elevated expansive or irritable mood</li> <li>• Evidence from history, physical examination, and laboratory findings that disturbance is a direct pathophysiologic consequence of another medical condition</li> </ul>	<ul style="list-style-type: none"> <li>• With manic features</li> <li>• With manic or hypomanic-like episode</li> <li>• With mixed features (depression is also present)</li> </ul>
Other specified bipolar and related disorder	Symptoms of bipolar disorder, but do not meet full criteria	<ul style="list-style-type: none"> <li>• Short-duration hypomanic episodes (2–3 days) and major depressive episodes</li> <li>• Hypomanic episodes with insufficient symptoms and major depressive episodes</li> <li>• Hypomanic episode without prior major depressive episode</li> <li>• Short-duration cyclothymia (&lt;24 months)</li> </ul>
Unspecified bipolar and related disorders	Patients with bipolar symptoms and clinical distress and impairment; however, the clinician chooses not to specify the reason that the criteria are not met	

as other specified bipolar and related disorders and unspecified bipolar and related disorder.

### Specifiers for Bipolar and Related Disorders

Please refer to Table 2 for specifiers of depressive disorders that apply to bipolar disorders as well.

**Diagnosis.** When faced with symptoms of mood disorder, a clinician must decide whether these are transient manifestations related to life circumstances or symptoms of treatable psychopathology. The clinical evaluation of patients with mood disorders starts with a thorough history of the present illness. A thorough medical history is paramount given the numerous medical disorders that present with depression or mania. Mood disorders are, in general, recurrent conditions. Past history will provide not only a suspicion toward a diagnosis but also clues toward clinical manifestations, which, in the cases of depression and mania, are often similar to previous episodes. An early history of childhood behavioral problems can constitute a precursor of mood disorders. The Mental Status Examination provides further clues to the diagnosis. For depressive states, patients often exhibit psychomotor retardation; slow speech; constricted affect; and slow, observable mental activity. For mania and hypomania, the opposite can be observed. Patients show increased psychomotor activity, pressured speech, full or labile affect, and elevated mood. Often, they will appear unrealistically optimistic. In general, the diagnosis of mood disorder is aided significantly by obtaining a collateral history from friends or family members. The value of the Mental Status Examination is enhanced if the clinician knows the patient from before the mood disorder episode. A variety of psychological tests and depression rating scales exist, including the Beck Depression Inventory, the Hamilton Depression Rating Scale, and the Profile of Mood States (POMS) Depression Scale. Although extremely useful in quantifying symptoms of depression, psychological testing is time-consuming and not necessary for the initial diagnosis of a mood disorder.

A thorough account of all symptoms present in a patient can point to treatment choice and outcome. Depression symptoms can be classified into at least three major groups:

- Emotional symptoms: sadness, dysphoria, emotional numbness
- Physical symptoms: low energy, sluggishness with difficulty initiating activities, difficulty concentrating, and sleep and appetite problems
- Cognitive (mental) symptoms: pessimism, loss of enthusiasm, hopelessness, and thoughts of death

Not all three groups of symptoms are present from the beginning. In many individuals, the presence of cognitive symptoms may be a sign of chronicity. At other times, it may have been a premorbid feature or a constant presence between episodes. Cognitive symptoms tend to respond both to medication and to psychotherapy (cognitive-behavioral therapy [CBT]), and their monitoring is paramount to suicide prevention. If a mood disorder is secondary to a medical condition, the diagnosis will be made both by monitoring for mood symptoms and by pathognomonic medical findings.

### Differential Diagnosis

Given the multitude of clinical manifestations, a differential diagnosis both between subtypes of mood disorders and between mood and other psychiatric disorders is necessary. Table 1 presents comparisons and differences between subtypes of mood disorders and guidelines to the differential diagnoses.

Given the frequent overlap of anxiety and mood disorders, it is useful to inquire about the presence of an anxiety disorder in a systematic manner. Anxiety disorder symptoms can also be classified into at least three major groups:

- Emotional symptoms: anxiety and/or fear, either fluctuating or in the form of attacks
- Physical symptoms: palpitations, tachycardia, diaphoresis, sweaty palms, sensation of a knot in the throat, muscle ten-

sion, shortness of breath, gastrointestinal symptoms, insomnia, and so forth

- Cognitive symptoms: intrusive thoughts (such as “What if...,” “I should have...,” other specific exaggerated worries), racing thoughts, ruminative thoughts, and so forth

Because of the long-term, chronic, egosyntonic nature of these symptoms, they are often not readily volunteered by the patient unless specifically asked about. Between mood disorders and anxiety disorders, there is a comorbidity of more than 50%, with generalized anxiety disorder, panic disorders, and posttraumatic stress disorders constituting both a risk factor for and a possible complication of mood disorders. Please note that the DSM-V allows for a specifier “with anxious distress” that can be applied to both unipolar and bipolar mood disorders. Depending on the primary diagnosis, the clinician may choose between adding this specifier or the comorbid separate diagnosis of “anxiety disorder” in addition to mood disorder.

### Treatment

Currently, psychopharmacology and psychotherapy are the mainstay of care for mood disorders. As we will see later, a variety of novel treatments (transcranial magnetic stimulation [TMS], ketamine, entheogens) have recently emerged. An accurate initial diagnosis directs the first choice of treatment. Close monitoring of treatment with frequent visits usually predicts a more favorable outcome. In general, response is considered to be a 50% reduction of symptoms, while remission usually refers to the absence of symptoms or only minimal symptoms for 6 months or longer. By Tohen and colleagues’ opinion, relapse is considered a return of symptoms within 6 months, while recurrence is a return of symptoms after 6 months of remission.

Among risk factors for severity, treatment resistance has been a major clinical challenge. Four predictors have been recently identified. They include symptom severity (3.3-fold increase in likelihood for treatment resistance); suicidal risk (a 1.74-fold increase in treatment resistance); comorbid disorder (1.68-fold increase in risk); and lifetime number of major depressive episodes (15% increase in treatment resistance per prior episode).

### Treatment of Unipolar Depression (Major Depressive Disorder and Dysthymia)

Given the fact that many depressive disorders occur along a spectrum, the treatment of MDD and dysthymia will be covered together.\* In addition, a more recent study confirms the fact that comorbidity features, with anxiety, are significant: the anxious/distressed specifier occurs in 74.6% of cases, and the mixed-features specifier occurs in 15.5% of patients with MDD.

### Psychopharmacology

First, a thorough medical workup should be performed in any new case of mood disorder. The National Institutes of Health (NIH)-sponsored Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) study recommends the initial choice of a selective serotonin reuptake inhibitor (SSRI) (citalopram [Celexa]). In the study, nonresponders were then switched to sertraline (Zoloft) and/or venlafaxine XR (Effexor XR). In clinical practice, other factors must be weighed when choosing the first antidepressant. *Prior response history* to a specific antidepressant or to an overall treatment modality should take precedence in the first choice of treatment. If such a history is unavailable, any family history of response to a specific treatment should be considered. Response to treatment seems to be similar among blood relatives. Table 5 includes a list of the more common medications used in clinical practice for the treatment of unipolar and bipolar disorder. Given the possibility of manic switch with antidepressants, it is recommended that mood stabilizers be started concomitantly with antidepressants for patients with bipolar depression.

Although myriad side effects are known to exist for each medication, all SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs) are generally well tolerated. Any trial of medications should be continued for 4 to 6 weeks before failure is

**TABLE 5** Medications Used for the Treatment of Unipolar and Bipolar Depression

MEDICATION GROUP	MEDICATION	USUAL DAILY DOSE	CAUTIONS
SSRI	Fluoxetine (Prozac)	10–80 mg	All can cause sedation, agitation, insomnia, GI side effects, and sexual dysfunction
	Sertraline (Zoloft)	25–200 mg	
	Paroxetine (Paxil)	5–60 mg	
	Citalopram (Celexa)	10–40 mg	
	Escitalopram (Lexapro)	5–20 mg	
	Fluvoxamine (Luvox) <sup>1</sup>	50–300 mg	
SSRIs with combined action	Vilazodone (Viibryd)	10–40 mg	Same as above
	Functions of SSRI and a 5-HT <sub>1A</sub> receptor agonist Vortioxetine (Trintellix)	5–20 mg	
	Functions of SSRI and multiple serotonin receptor agonists and antagonists		
SNRI	Venlafaxine XR (Effexor XR)	37.5–225 mg	Insomnia, sedation, possible HTN, mydriasis, and urinary hesitation
	Desvenlafaxine (Pristiq)	50–100 mg	
	Levomilnacipran ER (Fetzima)	40–120 mg	
Dopamine/norepinephrine agonist	Bupropion SR, XL (Wellbutrin SR, XL)	100–450 mg	Agitation, GI side effects, and possible HTN
Stimulants (usually used to enhance effects of other antidepressants)	Methylphenidate (Ritalin) <sup>1</sup>	10–60 mg	Agitation, insomnia, psychosis, HTN, and seizures
	Dextroamphetamine (Dexedrine) <sup>1</sup>	5–60 mg	
	Amphetamine/dextroamphetamine mixed (Adderall) <sup>1</sup>	5–60 mg	
Second-generation neuroleptics	Olanzapine (Zyprexa) <sup>1</sup>	2.5–20 mg (in unipolar depression, olanzapine 5 mg, plus fluoxetine 20 mg [Symbyax])	Metabolic syndrome, sedation Oversedation, metabolic syndrome, and cardiovascular complications in older adults Oversedation, metabolic syndrome, and hyperprolactinemia Somnolence or agitation from akathisia and extrapyramidal symptoms
	Quetiapine (Seroquel)	50–300 mg (up to 800 mg in bipolar disorder)	
	Aripiprazole (Abilify)	2–30 mg	
	Risperidone (Risperdal) <sup>1</sup>	0.5–6 mg	
	Lurasidone (Latuda) mainly for bipolar disorder	20–120 mg	
	Cariprazine (Vraylar) <sup>1</sup>	1.5–6 mg	
Tricyclic antidepressants	Amitriptyline (Elavil)	50–300 mg	All can cause anticholinergic effects and sedation; occasional agitation and weight gain
	Imipramine (Tofranil)	50–300 mg	
	Doxepin (Sinequan)	50–300 mg	
	Desipramine (Norpramin)	50–300 mg	
	Nortriptyline (Pamelor)	20–200 mg <sup>3</sup>	
	Maprotiline (Ludiomil)	100–225 mg	
	Protriptyline (Vivactil)	20–60 mg	
Mixed-action (presynaptic and postsynaptic, multiple neurotransmitter action)	Mirtazapine (Remeron)	15–30 mg	Sedation, weight gain
	Trazodone (Desyrel)	150–600 mg	
	Clomipramine (Anafranil) <sup>1</sup>	50–300 mg <sup>3</sup>	
MAOI (dietary restrictions are obligatory)	Phenelzine (Nardil)	15–90 mg	Hypertensive crisis, occasional sedation/activation
	Tranlycypromine (Parnate)	30–60 mg	
Mood stabilizers	Lithium carbonate/citrate/ER <sup>1</sup>	600–1800 mg (attaining blood level from 0.6 to 1.2 mEq/L)	Signs of toxicity: tremor, nausea, vomiting, and staggering gait; monitor kidney and thyroid function Oversedation, GI side effects, may affect blood levels of other medications, and weight gain A variety of severe skin rashes, Stevens-Johnson syndrome Monitor blood count for aplastic anemia/agranulocytosis, possible Stevens-Johnson syndrome, and sedation
	Valproate (valproic acid, Depakote ER) <sup>1</sup>	250–1500 mg (attaining blood level from 50 to 100 mcg/mL)	
	Lamotrigine (Lamictal)/XR <sup>1</sup>	50–400 mg	
	Carbamazepine (Tegretol)* <sup>1</sup>	200–1000 mg (attaining blood level from 5 to 12 mg/mL)	

<sup>1</sup>Not FDA approved for this indication.<sup>3</sup>Exceeds dosage recommended by the manufacturer.

ER, Extended release; GI, gastrointestinal; HTN, hypertension; MAOI, monoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

declared. However, clinical judgment in assessing each circumstance, especially regarding suicide risk, is crucial. Often in the initial phase of response, the physical symptom of low energy remits first while cognitive symptoms of depression (persistent

thoughts of death) persist. The coexistence of higher energy and thoughts of death may constitute a temporary suicide risk in the initial phase of antidepressant treatment. Currently, biological markers for the prediction of treatment response and side effects

**TABLE 6** Biological Treatments for Medication-Resistant Mood Disorders

TYPE OF INTERVENTION	REPORTED RESPONSE	CURRENT AVAILABILITY
Electroconvulsive therapy (ECT)	50.9%–53.2% remission rate	Common
Transcranial magnetic stimulation (TMS)	41.5%–56.4% response rate, 26.5%–28.7% remission rate	Accepted by several insurance plans
Vagal nerve stimulation (VNS)	53% response rate, 33% remission rate after 1 year	Rare (neurosurgical)
Deep brain stimulation (DBS)	29% response rate after 1 year	Rare (neurosurgical)
Ketamine (Ketalar) infusion <sup>1</sup>	79% response rate	Very rare (only in selective institutions)
Anterior cingulotomy	33.3% response rate after 30 months	Very rare (only in selective institutions, neurosurgical)

<sup>1</sup>Not FDA approved for this indication.

are being considered. The Psychiatric EEG Evaluation Registry (PEER) uses quantitative EEG technology to compare variations of normal awake EEG readings with a large database of medication responders. Results are available for antidepressants, mood stabilizers, stimulants, second-generation antipsychotics, and so forth. The validity of PEER has been supported by a wealth of published literature; however, more recently the usefulness of PEER has been disputed. The AmpliChip CYP450 test (Roche Molecular Diagnostics, Alameda, CA) is a method that predicts side effects by measuring the activity of genes that control the cytochrome P450 hepatic enzyme system and, implicitly, the ability to metabolize a specific drug. Both methods are promising, but high cost and questions about large individual response variability have so far prevented general use.

Given the risk of suicide, close monitoring during the treatment of MDD is required. The choice of medication and adjustment must be tailored according to the most dominant initial presentation. For patients with severe insomnia, an SSRI is indicated. If the initial choice (e.g., citalopram [Celexa], escitalopram [Lexapro], or sertraline [Zoloft]) shows little impact in improving sleep, the temporary addition of a sleep aid is a reasonable choice. Alternatively, some clinicians prefer to avoid hypnotics, which may allow close monitoring of the natural improvement in sleep during the first 2 weeks of SSRI treatment. This in turn may predict a favorable response. In geriatric patients, long-term SSRI treatment has been found to delay progression from mild cognitive impairment to dementia. For many years, in patients with hypersomnia and hyperphagia—a variant known as *atypical depression*—the first choice was a monoamine oxidase inhibitor (MAOI). Currently, for atypical depression, clinicians prefer as a first choice a norepinephrine/serotonin reuptake inhibitor (venlafaxine [Effexor], desvenlafaxine [Pristiq]), or a norepinephrine/dopamine-active medication (bupropion [Wellbutrin]). Response to medications is often difficult to predict. Again, early in treatment, a thorough medical workup, which should always include a thyroid panel, should be the norm. Sometimes, switches to other classes of antidepressants (dopamine enhancers, tricyclics) are necessary before a result is obtained. Pharmacologic augmentation with mood stabilizers, neuroleptics, and thyroid hormone has been used in cases of treatment-resistant depression. In cases in which severe anxiety, insomnia, and poor appetite dominate the picture, the early addition of a second-generation neuroleptic (olanzapine [Zyprexa]<sup>1</sup>, quetiapine [Seroquel XR], risperidone [Risperdal]<sup>1</sup>, aripiprazole [Abilify], and, more recently, cariprazine [Vraylar]<sup>1</sup>) is recommended (see Table 5). Medication resistance (after several failed trials) dictates the reassessment of diagnosis to further rule out psychiatric and medical comorbidity. Table 6 presents a list of further biological treatments for medication-resistant mood disorders. Some of these treatments are promising but have yet to be included as routine choices in some of the most difficult-to-treat patients.

<sup>1</sup>Not FDA approved for this indication.

## Psychotherapy

For mood disorders, CBT, interpersonal therapy, and more recently, mindfulness-focused psychotherapy have been considered therapies of choice. CBT and mindfulness therapy directly address the negative, pessimistic bias of the depressive thinking, which is a maintenance factor of depressed mood. The latter addresses social and interpersonal functioning by enhancing coping abilities. Their popularity has been increasing; however, they require special training and supervision. In clinical practice, though, the most readily available therapies remain supportive and insight-oriented psychotherapy. They too complement the effect of pharmacology. Brain-imaging studies have revealed that the activity of the subgenual anterior cingulate cortex (Brodmann area 25) predicts the outcome of response to CBT in depression. As a general rule, therapies should have specific goals that must be discussed with patients at the onset of treatment. This must be part of an overall “informed consent” approach to treatment. Given the availability of a variety of clinicians with different levels of expertise that provide psychotherapy, it is important to monitor results and coordinate care. If “split” treatment (pharmacology and psychotherapy provided by different clinicians) is chosen, communication between parties of the treatment team remains a crucial requirement for rapid response and recovery. Other therapeutic measures, such as an increase in physical activity, normalization of sleep, and improvement of social support, are particularly important in promoting recovery.

## Neurostimulation

TMS was approved by the U.S. Food and Drug Administration (FDA) in 2008. Over the past 2 years, the majority of insurance plans and Medicare have approved TMS treatment for MDD. It is the treatment modality approved by the FDA that has made the greatest strides in providing neuromodulation treatment for patients with MDD in over 1000 centers nationwide. Table 6 includes other neuromodulation treatments that must be considered when TMS remains ineffective.

## Treatment of Bipolar Disorders (Bipolar Type I, Type II, Mixed Type, and Cyclothymia)

The treatment of bipolar disorder has been well refined over the years by a large body of literature. For acute mania, treatment with mood stabilizers and/or antipsychotics has remained the main approach for the past several decades. Severe forms of mania and psychosis usually require hospitalization. Table 7 indicates intervention options for different phases of bipolar disorder.

As indicated in the Table 7, some of the medication choices overlap between different clinical presentations. For chronic forms of bipolarity, such as mixed bipolar and cyclothymic disorder, a variety of new approaches has been developed, including social rhythm therapy. The latter includes monitoring and optimization of social interactions, sleep, and circadian rhythms that seem to benefit bipolar patients. Chronic bipolarity, with its significant impairment and suicide risk, remains a major problem,

often requiring multidisciplinary consultations and referral to a tertiary institution. In treatment-resistant cases, employment of electroconvulsive therapy and other novel biological approaches can be lifesaving. Even with partial treatment response, maintenance is paramount. Lifelong maintenance treatment is likely to prevent suicide and further functional deterioration. More recently, suicide prevention both in chronic mood disorders and in personality disorders has been reported with maintenance treatment of lithium carbonate and clozapine (Clozaril).<sup>1</sup> Among bipolar patients, chronic depression is one of the most treatment-resistant conditions in psychiatry. In any patient with treatment-resistant, undiagnosed bipolar depression, the addition of mood stabilizers may result in the conversion of a treatment nonresponder to a responder. In addition, the value of treatment with lithium carbonate has been recently reiterated in a Finnish study. Lithium carbonate, besides an effective antimanic treatment, can prevent rehospitalization for bipolar disorder. One 2018 study revealed a significant response when 7000-lux bright white light was administered daily for 4 to 6 weeks in conjunction with mood stabilizers. The response rate was 68.2% compared with 22.2% in the placebo group. Among the treatment cases, no mood polarity switches occurred. This improvement occurs even in patients who are not diagnosed with SAD. Further replication of these findings may reveal bright light to be a new modality of

treatment for bipolar depression, which is readily available and free from significant side effects.

### Mood Dysregulation

Mood dysregulation is a broad phenomenon encountered both in clinical and nonclinical settings. For clinicians, a variety of difficult-to-classify syndromes remain relevant (referred to here as *mood syndrome variants*). These mood syndrome variants present anecdotal but clinically pertinent manifestations collected from the medical literature of the past century. Psychiatric and medical disorders often coexist with different degrees of mood dysregulation. Table 8 provides examples of mood syndrome variants with different degrees of mood dysregulation as encountered in the literature over the past century. A more detailed description of each clinical entity in Table 8 is beyond the scope of this chapter. As shown in Table 8, different forms of mood dysregulation can occur both within and outside the DSM-V diagnoses. For instance, atypical depression has been included in the DSM-V, whereas other syndromes, such as neurasthenia, remain unclassified. When encountered, any of the listed syndromes should raise suspicion of an underlying mood disorder. A diagnosis of *unspecified depressive disorder* (F32.9) can be made, and the entire mood disorder treatment armamentarium should be considered.

### Clinical Course and Prognosis of Mood Disorders

Given the heterogeneity of mood disorders, there is great variation in clinical outcome. Clinical course and outcome depend on whether treatment is available, whether an individual is sensitive or resistant to the treatment, and the degree of compliance. Many individuals with mild and subsyndromal disorders remain undiagnosed, whereas others with severe forms of mood disorders refuse treatment. As a general rule, most untreated mood disorders tend to become chronic. Episodic disorders, such as bipolar I and II and depression, recurrent type, may show more frequent recurrences with advancement in age. Other patients with hyposymptomatic presentations and infrequent episodes may show long-term remissions. Such remissions are favored by stable, low-stress lifestyles. Dyslipidemia, hypertension, type 2 diabetes, coronary vascular disease, and stroke are among the numerous medical complications of chronic mood disorders. Some of these complications are direct side effects of long-term use of psychotropic medications, in particular second-generation antipsychotics. They all contribute to shortened life expectancy of individuals with mood disorders. Table 9 demonstrates the severe impact on life expectancy of bipolar disorder. Mortality comes from suicide, cardiovascular disease, and respiratory disorders. However, treatment can at least partially reverse these trends.

**TABLE 7** Intervention Options for Phases of Bipolar Disorder

PHASE OF DISORDER	INTERVENTIONS
Acute	Hospitalization if necessary Antipsychotics, tranquilization, and start mood stabilizers
Subacute	Antipsychotics/neuroleptics, mood stabilizers If already medicated, adjust dose
Rapid cycling/mixed	As in acute phase; check thyroid; and medical workup Rule out substance abuse May require treatment indefinitely
Cyclothymia	Mood stabilizers, long term, with or without antidepressants based on history Close initial monitoring May need treatment indefinitely

**TABLE 8** Examples of Mood Syndrome Variants with Different Degrees of Mood Dysregulation as Encountered in the Literature Over the Past Century

I MSV WITH MANIFESTATIONS OF OTHER PSYCHIATRIC DISORDERS	II MSV WITH UNUSUAL SYMPTOMS (MASKED DEPRESSION)	III MSV AS PART OF OTHER CONDITIONS
Atypical depression	Mood dysregulation and thrill-seeking behavior (gambling, racing, substance abuse, hypersexuality)	Postpartum depression
Subaffective dysthymia	Reactive overeating	Depression secondary to chronic pain
Hysteroid dysphoria	Isolated sleep disturbance and mood dysregulation	Substance- and medication-induced mood dysregulation*
Pseudodementia	Atypical facial pain	“Organic” mood disorders (due to central nervous system disorders)
Pseudoborderline	Dysphagia	Vicarious traumatization†
Somatic depression	Monosymptomatic hypochondriasis	
Underground depression	Monosymptomatic delusions	
Neurasthenia		
Mood syndrome as part of personality disorders		
Mood syndromes and depression in schizophrenia		

\*Medications more often associated with depression are, among others, reserpine,  $\alpha$ -methyl dopa (Aldomet), some  $\alpha$ - and  $\beta$ -blockers, sedative hypnotics, cimetidine (Tagamet), indomethacin (Indocin), anticancer medications, oral contraceptives, and corticosteroids.

†It has been described as a form of secondary trauma in mental health professionals who treat victims of trauma.

MSV, Mood syndrome variant.

## Prevention

Primary prevention of mood disorders requires a concerted effort to educate the public and policymakers for funding of prevention. Depression Awareness Week and other community efforts enhance awareness and decrease stigma. Primary prevention may also include promoting general health and healthy work environments and addressing major social problems, including avoiding early trauma and family problems and preventing excessive stress and trauma in adults. These are all known to be associated with mental illness. Populations at risk must be identified in primary care settings. Secondary prevention requires the availability of mental health services, including early detection, education about the need for adequate treatment, and continuity of care to prevent impairment. Tertiary prevention would include the continuation of treatment to prevent comorbidity of other psychiatric disorders and catastrophic complications, including suicide. Finally, in the case of mood disorders, quaternary prevention would include long-term follow-up, monitoring of recurrences, and medical comorbidity (accidents; cardiovascular, respiratory, and other medical conditions) to avoid overburdening the healthcare system.

The high medical comorbidity rate recently found among patients with mood disorders varies by medical diagnosis and socioeconomic background. Chronic pain, neurologic conditions, gastrointestinal disorders, cardiovascular disorders, and metabolic syndrome are the most common medical conditions associated with mood disorders. Except for thyroid disorders, the seriousness of the comorbid condition seems to be even higher among patients of lower socioeconomic background. This poses a significant medical and socioeconomic burden of untreated mood disorders.

## DRUG USE DISORDERS

Method of

William M. Greene, MD; and Mark S. Gold, MD

### CURRENT DIAGNOSIS

- Screen for substance use in all primary care and emergency settings.
- The clinical interview remains the mainstay of diagnosis.
- Clinicians should have a low threshold for ordering a urine drug test.
- Collateral information should be obtained from family or other sources.
- DSM-5 offers current diagnostic criteria for substance use disorders (Box 1).

- Effective pharmacologic and psychosocial treatments exist.
- Formal detoxification is indicated for dangerous withdrawal states or in patients with serious medical comorbidity.
- Pharmacologic relapse prevention options are substance specific, and particularly useful options exist for nicotine and opioids.
- Psychosocial treatments remain the mainstay of substance treatment, and these range along a continuum of intensity from outpatient counseling to long-term residential treatment.
- Patients should be referred to self-help groups (e.g., Narcotics Anonymous) to complement other therapies.
- Indefinite remission is an attainable goal for many—a relapse does not constitute total failure but provides an opportunity to reevaluate the treatment approach.

### Epidemiology

Widespread pathologic use of intoxicating substances, both legal and illegal, remains one of the greatest public health concerns facing our nation. According to the 2018 National Survey on Drug Use and Health, 53.2 million Americans (19.4% of the population) aged 12 years and older used an illicit drug within the preceding year. By order of frequency, these drugs included marijuana, prescription pain relievers, prescription sedatives, hallucinogens, cocaine, prescription stimulants, methamphetamine, and heroin. In addition, 58.8 million Americans (21.5%) aged 12 years and older used tobacco within the previous month, mostly in the form of cigarettes. Each year in the United States, approximately 480,000 people die of an illness attributable to cigarette smoking, making this the foremost cause of preventable death. Overdose deaths have remained a matter of pressing national concern in the United States; opioids were involved in 67.8% of the estimated 70,237 overdose deaths in 2017. Synthetic opioids such as fentanyl accounted for approximately 3000 deaths in 2013; in 2018, they accounted for over 30,000. US life expectancy increases ended in 2010 and started falling in 2014, with fatal overdoses playing a key role in this shift. They rose by almost 387% between 1999 and 2017. Overall, the estimated annual economic cost of tobacco, alcohol, and illicit drugs in the United States is a staggering \$740 billion, including costs related to crime, lost work productivity, and health care.

From 1997 to 2019, the rate of past-month cigarette use among 12- to 17-year-olds has steadily dropped from 28.3% to 3.7%. The 2019 Monitoring the Future survey data confirm that cigarette smoking has continued to fall to the lowest rate in the survey's history (i.e., past month use among 12th graders is now at only 5.7%, compared with 36.5% in 1997). Encouraging though these trends may be, they are counterbalanced by the explosive growth of vaping. Among 12- to 17-year-olds, past-month vaping of nicotine has increased from 7.5% in 2017 to 18.1% in 2019. Similarly, past-month vaping of marijuana among 12- to 17-year-olds has increased from 3.6% in 2017 to 10.1% in 2019. Between 2011 and 2019, the number of 12th graders who reported having used any illicit drug at some point in their lives has been holding steady between 47% and 50%. Despite advances in our understanding and treatment of substance use disorders, drug use remains an epidemic, especially in the areas of drugged driving and drug use (including tobacco) in pregnancy.

### Diagnosis

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), published in 2013, eliminated the diagnostic categories of substance abuse and substance dependence. In the interest of consistency and clarity and based on large-population data, they were replaced by a new diagnostic entity: “substance use disorder” (Box 1). It is no longer necessary for the clinician to decide between two different diagnoses. Those familiar with

### BOX 1 DSM-5 Diagnostic Criteria for “Substance Use Disorder”

A problematic pattern of use leading to clinically significant impairment or distress as manifested by two or more of the following in a 12-month period:

- Often taken in larger amounts or longer period than intended
- Persistent desire or unsuccessful efforts to cut down or control use
- Great deal of time spent in activities necessary to obtain, use, or recover from effects
- Craving, or strong desire or urge to use
- Recurrent use resulting in failure to fulfill major role obligations at work, school, or home
- Continued use despite having persistent/recurrent social or interpersonal problems caused or exacerbated by the substance
- Important social, occupational, or recreational activities are given up or reduced because of use
- Recurrent use in situations in which use is physically hazardous
- Continued use despite knowledge of having a persistent/recurrent physical or psychological problem likely to have been caused or exacerbated by the substance
- Tolerance (needing increased amounts for desired effect, or diminished effect with same amount)
- Withdrawal (manifested by characteristic syndrome or taking more to relieve/avoid withdrawal)

Specify current severity:

- Mild: Two to three criteria are met
- Moderate: Four to five criteria are met
- Severe: Six or more criteria are met

the terminology of DSM-IV will find the new criteria quite familiar, as they essentially represent a combination of the old abuse and dependence criteria with two notable exceptions: one, the legal problem has been eliminated; and two, a craving criterion has been added. When one is diagnosing a substance use disorder, the specific substance for which criteria are met must be listed. In addition, it is also important to document the severity of the disorder based on the number of symptoms present. Examples of specific diagnoses using the new nomenclature would be “alcohol use disorder, moderate” or “alprazolam use disorder, severe.” This simpler evidence-based diagnostic schema should eliminate some of the confusion previously surrounding the term “dependence,” which was often mistaken to be synonymous with “physiological dependence.” It has long been understood, in the context of certain prescribed drugs, that the presence of tolerance and withdrawal is not pathologic in nature; rather, these represent an expected state of neuroadaptation. This fact is reflected in the new criteria for use disorders involving opioids, stimulants, and sedatives. For these three categories, the tolerance and withdrawal criteria are not considered to be met if present when the substance is taken solely under appropriate medical supervision. It should be noted this exception does not apply to cannabis, even if it is “prescribed.”

Despite the importance and usefulness of the DSM-5, many patients (and clinicians) may still be left wondering if the problem at hand would appropriately be characterized as “addiction.” In a 2011 public policy statement, the American Society of Addiction Medicine offered the following short definition of addiction, which has been well received:

*Addiction is a primary, chronic disease of brain reward, motivation, memory and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief*

**TABLE 1** Pharmacotherapy for Nicotine Dependence

DRUG	MECHANISM OF ACTION	DOSAGE	INSTRUCTIONS	COMMENTS
Nicotine patch (Nicoderm CQ)	NRT	7 mg, 14 mg, 21 mg	1 patch daily	Tapering of doses recommended to discontinue
Nicotine gum (Nicorette)	NRT	2 mg, 4 mg	Chew slightly then “park” on oral mucosa	Tapering of doses recommended to discontinue
Nicotine lozenge (Commit)	NRT	2 mg, 4 mg	Absorbed through oral mucosa; minimize swallowing	Tapering of doses recommended to discontinue
Nicotine inhaler (Nicotrol Inhaler)	NRT	4 mg/cartridge	6–16 cartridges/day	By prescription only; tedious administration
Nicotine nasal spray (Nicotrol NS)	NRT	0.5-mg/spray	1–2 sprays in each nostril q1h; max 80 sprays/day	By prescription only
Bupropion HCl (Wellbutrin <sup>1</sup> , Zyban)	Inhibits reuptake of NE and DA	150-mg SR tab, 300-mg XL tab	300 mg PO (divided qd [XL tab]-bid [SR tab]) daily for 7–12 weeks	Helps with comorbid depression; can help prevent weight gain
Varenicline (Chantix)	Partial agonist at $\alpha_4\beta_2$ nicotinic acetylcholine receptor	0.5 mg, 1 mg	0.5 mg PO qd for 3 days, then 0.5 mg PO bid for 4 days, then 1 mg PO bid for 11 weeks	May smoke during first week; may continue for an additional 12 weeks
Nicotine vaccine (NicVAX) <sup>5</sup>	Antibody sequestration of nicotine	N/A	N/A	In clinical trials

DA, Dopamine; *max*, maximum; N/A, not applicable; NE, norepinephrine; NRT, nicotine replacement therapy; SR, sustained release; XL, extended release.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

*by substance use and other behaviors. Addiction is characterized by inability to consistently abstain, impairment in behavioral control, craving, diminished recognition of significant problems with one’s behaviors and interpersonal relationships, and a dysfunctional emotional response. Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death.*

### Tobacco and Nicotine

Nicotine is the main addictive component in tobacco. It is administered via smoking (e.g., cigarettes, cigars, pipes, bidis, hookah) or in smokeless formulations (e.g., dip, snuff, snus, chew) and now also via vaporization (e.g. electronic cigarettes, vaping devices). Adverse health effects are not equivalent among the different routes of administration; cigarette smoking causes nicotine, affects brain monoamine oxidase (MAO), and other effects in the smoker, some resulting from the smoke and some from the nicotine.

Following administration, nicotine rapidly binds to nicotinic acetylcholine receptors in the central nervous system (CNS), where it acts as a mild psychostimulant and mood modulator in a nonimpairing yet profoundly addictive manner. When the user is tired, smoking has a stimulating effect. When the user is anxious or stressed, smoking exerts a calming effect. Smoking is like an injection without a needle and, given its short half-life, repeated self-administration serves to effectively relieve unpleasant withdrawal symptoms from the nicotine itself. Repeated use quickly leads to both physiologic and psychological dependence.

As with other drugs of abuse, cue-induced cravings play an important role in maintaining the addiction. For example, the smell of the smoke, the sound of a lighter, and the feel of a cigarette on the lips all contribute to an overall process addiction beyond just addiction to the nicotine itself. Tobacco use is also strongly associated with alcohol use, with which it has synergistic toxic effects.

Toxicities from tobacco use are well described and include severe pulmonary disease, cardiovascular disease, and carcinomas

of the upper aerodigestive tract and of the bladder. Even second-hand smoke, previously considered harmless, is now correctly regarded as a serious health risk to the nonsmoker and a “drug” itself. Cigarette smoke contains more than nicotine (up to 4700 components, all of which affect the smoker). Additionally, second-hand tobacco exposure in utero can cause serious adverse health effects in the fetus.

Although quitting remains difficult for even the most motivated tobacco users, effective treatments for tobacco use disorder now exist. Clinical trials indicate that a combination of counseling and medications offers the best chance for success and should be offered to patients who are willing to make an attempt to quit. A wide range of nicotine replacement therapies that have been approved by the US Food and Drug Administration (FDA) are readily available and have similar rates of efficacy (Table 1). Patches (Nicoderm CQ), gums (Nicorette), and lozenges (Commit) are available over the counter, but the nasal spray (Nicotrol NS) and inhaler (Nicotrol Inhaler) are available by prescription only. Recently “electronic cigarettes” have gained in popularity, but unlike other nicotine products, they are not yet regulated as drugs by the FDA.

Nonnicotine prescription medications with proven efficacy are available. Bupropion HCl (Wellbutrin) is an antidepressant that was serendipitously noted to dramatically reduce nicotine cravings in some patients; it is now widely used for this purpose (as Zyban). Varenicline (Chantix) was specifically developed to treat tobacco use disorder and represents a considerable advancement, with improved smoking cessation rates. It acts as a partial agonist at the nicotine receptor and effectively serves to satisfy cravings while simultaneously blocking the effects of exogenously administered nicotine. Although probably the most effective agent, varenicline carries a significant risk of psychiatric side effects. The “nicotine vaccine” (NicVAX)<sup>5</sup>, a novel approach, failed phase III clinical trials in 2011 and currently does not appear to hold much promise.

<sup>5</sup>Investigational drug in the United States.

Nicotine replacement, bupropion, and varenicline are all considered first-line pharmacotherapy. Bupropion but not varenicline may also be used in combination with nicotine replacement therapies. All pharmacotherapy options are enhanced with the coadministration of counseling or behavioral therapies. Helpful resources for patients interested in quitting include [www.smokefree.gov](http://www.smokefree.gov) (a government website dedicated to helping people quit smoking), 1-800-QUIT-NOW (a free phone-based services with coaches and educational materials), and a variety of resources available through the American Cancer Society and American Heart Association.

### Cannabis

Cannabis (marijuana, pot, weed, grass, ganja, hash) remains the most used illicit drug in the world. As of 2018, 43.5 million Americans aged 12 or older have reported using marijuana during the preceding year (15.9% of the US population). Cannabis is readily harvested from *Cannabis sativa*; typically it is smoked, although it may also be ingested or vaporized. Despite a recent trend whereby states have legalized the use of marijuana for medicinal and recreational purposes, it is still listed as a Schedule I drug by the Drug Enforcement Agency (DEA), which implies a high potential for abuse and no currently accepted medical use. Delta-9-tetrahydrocannabinol (THC) is the active ingredient, which exerts its desired psychoactive effects at CB<sub>1</sub> receptors diffusely throughout the CNS. Marijuana's THC concentration has been steadily increasing as a result of the selective breeding of plants. Annual analysis of the DEA's record of seizures indicates that the average concentration of TCH increased from approximately 1% in 1975 to approximately 10% in 2008. To what extent this makes the drug more dangerous or more addictive remains unclear.

Acute psychoactive effects of cannabis include euphoria, relaxation, heightened sensations, increased appetite, distorted sense of time, slowed reaction time, illusions and hallucinations, paranoia, and anxiety. Acute somatic effects include conjunctival injection, xerostomia, increased heart rate and blood pressure, muscle relaxation, and reduced intraocular pressure. There is no known risk of dangerous overdose, and withdrawal symptoms are generally mild; however, they include irritability, cravings, diminished appetite, and insomnia. Cannabis is now recognized as unequivocally addictive. Users of this drug commonly develop tolerance and demonstrate loss of control and continued use despite negative consequences—the hallmarks of addiction. It is estimated that 1 million Americans sought treatment for cannabis as their primary drug of choice in 2010.

Not surprisingly, with more than 400 chemicals identified in its smoke, cannabis is dangerous with respect to long-term health. Chronic cannabis use is associated with lung cancer, chronic obstructive pulmonary disease, cardiovascular disease, impaired immunity, persistent disruption of memory and attention, and various psychiatric disorders, most commonly anxiety disorders and depressive disorders. There is a growing body of evidence that cannabis abuse can lead to lasting psychosis (i.e., schizophrenia) in predisposed persons.

Currently, treatment of cannabis use disorder remains entirely psychosocial. Various existing drugs (including fluoxetine [Prozac]<sup>1</sup>, lithium, and buspirone [Buspar]<sup>1</sup>) have been investigated. However, well-controlled clinical trials to support their use are lacking. Preliminary data suggest that dronabinol (Marinol)<sup>1</sup> may be of some utility in relieving cravings and withdrawal symptoms without causing intoxication. Rimonabant (Acomplia)<sup>2</sup>, a CB<sub>1</sub> antagonist previously prescribed for weight loss in Europe, showed promise but has failed to achieve FDA approval because of psychiatric side effects.

### Cocaine, Methamphetamine, and Other Stimulants

As a class, cocaine and other stimulants work primarily by enhancing dopamine transmission in a dose-dependent fashion,

either directly (amphetamines) or by blocking reuptake (cocaine). Cocaine and a variety of amphetamines (e.g., amphetamine/dextroamphetamine [Adderall], dextroamphetamine [Dexedrine], methamphetamine [Desoxyn], methylphenidate [Methylin, Ritalin]) are available for legitimate medical use as Schedule II drugs. Cocaine (in solution) is still used as a topical anesthetic, and amphetamine derivatives are used to treat attention-deficit/hyperactivity disorder (ADHD), narcolepsy, obesity, and binge-eating disorder<sup>1</sup>. Any of these agents may be misused and all carry significant potential for addiction. Even newer “safer” agents such as modafinil (Provigil) and armodafinil (Nuvigil) are associated with use disorders, albeit less commonly than the traditional stimulants.

Prescription stimulant misuse can involve the ingestion of excessive doses to achieve a euphoric high or nonmedical use or diversion of prescriptions (e.g., students sharing medication to facilitate studying). When taken at prescribed doses for an appropriate condition, even methamphetamine is generally safe and effective. In contrast, when it is synthesized in clandestine laboratories and smoked or injected in extremely large quantities, methamphetamine (crystal meth, ice, crank, speed) is alarmingly dangerous. No other commonly abused drug is so strongly associated with permanent brain damage, resembling that seen in victims of traumatic brain injury. As ADHD becomes more recognized and treated, physicians must be aware of the potential for misuse of their well-intentioned prescriptions. To this end, several recent pharmacologic developments have introduced improved options for treatment. Extended-release formulations of methylphenidate (e.g., Concerta) and amphetamine/dextroamphetamine (Adderall XR) are considered to have less abuse potential than the short-acting formulations. Better still, the formulation of lisdexamfetamine (Vyvanse) includes the amino acid lysine coupled with the amphetamine molecule, consequently acting as a pro-drug with the least abuse potential of all ADHD stimulants.

Cocaine and other stimulants induce sympathomimetic effects including tachycardia, hypertension, mydriasis, and diaphoresis. These drugs are commonly associated with seizures, myocardial infarction, hemorrhagic stroke, dyskinesias and dystonias, and psychosis when taken at the doses typically used to achieve euphoria. Withdrawal is generally experienced as a crash and includes fatigue, depressed mood, increased appetite, and cravings. Considered nonaddictive until about 1980, cocaine is now widely recognized as one of the most addictive drugs, particularly in the base form (crack or freebase). MDMA (methylenedioxymethamphetamine), or ecstasy, shares the pharmacodynamic properties of the stimulants combined with serotonergic effects of the hallucinogens.

Currently no medication has demonstrated efficacy in treating cocaine or stimulant use disorders. Pharmacologic treatment remains symptomatic during the acute withdrawal phase. Stimulant-induced psychosis and mania respond well to traditional psychotropics when warranted; however, to date, no medications have reliably demonstrated efficacy in preventing relapse. A “cocaine vaccine,”<sup>5</sup> which enlists the immune system to develop antibodies rendering cocaine useless, has been studied in humans in a phase III trial that unfortunately has not been successful. In the meantime, traditional psychosocial treatments remain the mainstay of clinical care.

### Opioids

Opioids are categorized as endogenous (endorphins, enkephalins, dynorphins), opium alkaloids (morphine, codeine), semisynthetic (heroin, oxycodone [Roxicodone, OxyContin]), or synthetic (methadone [Dolophine], fentanyl [Sublimaze, Duragesic]). The last three categories have a wide range of clinical uses including analgesia, anesthesia, antidiarrhea, cough suppression, detoxification, and maintenance therapy.

Opioids exert their clinical effect at mu, delta, and kappa opioid receptors. The effect on mu receptors is considered the most important, with its activation directly linked to both analgesic

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>5</sup>Investigational drug in the United States.

**TABLE 2** Useful Medications in Treating Opioid Use Disorders

DRUG	UTILITY	FORMS	ADMINISTRATION	NOTES
Naloxone (Narcan)	Overdose; additive to prevent abuse <sup>1</sup>	SC, IM, IV	0.4–2 mg q2–3 min prn	$T_{1/2} = 1$ h; wears off quickly
Naltrexone (ReVia, Vivitrol)	Prevention of relapse	PO, IM	ReVia: 50–100 mg PO daily; Vivitrol: 380 mg IM q4wk	Potential for hepatotoxicity; precipitates withdrawal; useful for ETOH as well
Clonidine (Catapres, Catapres-TTS patch) <sup>1</sup>	Withdrawal	PO, transdermal	0.1–0.2 mg PO tid prn; 0.1–0.3 mg q24h transdermal via weekly patch	Monitor for hypotension
Methadone (Dolophine)	Withdrawal; maintenance	PO	Start 20–30 mg PO qd Target 80–120 mg PO qd	Restricted to methadone clinics
Buprenorphine (Subutex, Suboxone [with naloxone], Buprenex injection) <sup>1</sup>	Withdrawal; maintenance	SL, IM, IV	Start 2–4 mg SL qd-bid Target 4–32 mg SL daily divided qd-tid	Requires special DEA certification

DEA, Drug Enforcement Administration; ETOH, ethanol.

<sup>1</sup>Not FDA approved for this indication.

and euphoric effects. Most humans subjectively experience opioids with a neutral to aversive response. However, when used in sufficient quantities by genetically vulnerable persons, some users experience energy, relief of emotional pain, and a euphoria many describe as a “total body orgasm.” Intoxication manifests with miosis, impaired consciousness, slurred speech, bradycardia, and depressed respiration. Overdose is potentially fatal via respiratory depression, but it is quite amenable to treatment with repeated doses of naloxone (Narcan). The withdrawal syndrome is characterized by a constellation of miserable but not life-threatening symptoms including mydriasis, piloerection, muscle cramps, diaphoresis, vomiting, lacrimation, rhinorrhea, chills, insomnia, cravings, and autonomic hyperactivity.

Since pain was recognized as “the fifth vital sign” in the 1990s, concurrent with heavy marketing campaigns from pharmaceutical companies, the United States experienced a veritable explosion of widespread opioid prescribing for nonmalignant pain. An industry of pain management developed, with the unfortunate side effect of having a sizable proportion of its output being used nonmedically. It is important for prescribers to recognize that the abuse potential of prescription opioids matches—or in some cases even exceeds—that of heroin. Today, oxycodone has a street value of approximately \$1.00 per milligram.

The most common method of misuse involves simply taking more than prescribed, usually by the appropriate route of administration. Alternatively, individuals with opioid use disorders commonly take their medications via nasal insufflation or inject them intravenously. The extended-release property of certain medications, such as oxycodone (OxyContin), can easily be circumvented by crushing the pills, which greatly enhances the euphoric effect. Even transdermal fentanyl patches (Duragesic) can be misused by any number of methods, such as applying heat to a worn patch, employing complex extraction techniques described online, or simply sucking on the patch itself. If the prescription is used up before its renewal date, the user must either supplement the supply or face the unpleasant effects of withdrawal.

There is no shortage of methods to obtain opioids illicitly. These include seeing multiple prescribers (doctor shopping), purchasing online at foreign “pharmacies,” and general trade or purchase on the black market. Also alarming is the growing problem of diversion from hospitals and pharmacies by health care professionals, who are not immune to the disease of addiction. Almost all states have now implemented controlled substance databases (i.e., prescription drug monitoring programs [PDMPs]) aimed at curbing the problem of use disorders involving opioids and other prescription drugs.

Acute detoxification from opioids is achieved by one of two basic strategies: symptomatic treatment with unrelated medications or substitution with a cross-tolerant (opioid) drug with less

potential for abuse (Table 2). The first strategy may employ the use of clonidine (Catapres)<sup>1</sup>, an  $\alpha_2$ -adrenergic agonist, to help with the autonomic component of withdrawal. This is commonly done in combination with other symptomatic treatments on an as-needed basis, using agents such as diazepam (Valium) for anxiety, loperamide (Imodium) for diarrhea, and promethazine (Phenergan)<sup>1</sup> or ondansetron (Zofran)<sup>1</sup> for nausea.

The second strategy typically involves either methadone or buprenorphine (Subutex, with naloxone [Suboxone]). Methadone, a pure mu agonist with a half-life of about 36 hours, is usually started in the 20- to 30-mg range and titrated cautiously by 10 mg every 4 to 7 days. Maintenance therapy with methadone occurs only in the setting of a highly regulated methadone clinic. Buprenorphine, a partial agonist (and kappa antagonist) at the mu receptor, is administered sublingually and has a half-life similar to that of methadone. It was approved in 2002 for office-based treatment of opioid addiction, making pharmacotherapy much more widely available. Caution should be used to avoid administering buprenorphine too soon (before the onset of withdrawal syndrome); otherwise acute withdrawal can actually be precipitated. Buprenorphine is available either alone or in combination with naloxone (Suboxone, Zubsolv, Bunavail). Here, the role of naloxone is primarily to deter intravenous use, because naloxone has negligible bioavailability when taken sublingually as prescribed. The FDA has recently approved longer-acting formulations of buprenorphine, including a monthly subcutaneous injection (Sublocade) and a 6-month subdermal implant (Probu-pine). These hold promise and give patients more options.

Buprenorphine and methadone are useful in managing acute withdrawal as well as in long-term (months to years) maintenance therapy for preventing relapse to heroin or the opioid of choice. As maintenance therapy, these agents serve to block euphoria, satisfy cravings, and reduce illicit use, with consequent verifiable harm reduction. Buprenorphine, with a built-in ceiling effect because of its unique pharmacology, is much safer than methadone, which is often fatal in overdose. Recent evidence supports the benefit of continuing long-term maintenance therapy indefinitely, as discontinuation is often associated with relapse and other adverse outcomes. Buprenorphine is increasingly being initiated in emergency department settings, and this trend is associated with improved patient outcomes. Increasingly, buprenorphine is being used as an analgesic as well (Butrans Transdermal Patch), and it may be the ideal choice in patients with comorbid pain and addiction who have demonstrated an inability to use other opioids safely.

Also approved for the prevention of opioid relapse is naltrexone, an opioid antagonist, which is available in oral (ReVia) and intramuscular depot formulations (Vivitrol).

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Common Sedative-Hypnotics, Equivalent Dose Conversions

GENERIC NAME	TRADE NAME	DOSE (mg)
<b>Benzodiazepines</b>		
Diazepam	Valium	10
Alprazolam	Xanax, Niravam	0.5–1
Lorazepam	Ativan	2
Clonazepam	Klonopin	1–2
Chlordiazepoxide	Librium	25
Clorazepate	Tranxene	7.5
Oxazepam	Serax	10–15
Temazepam	Restoril	15
Triazolam	Halcion	0.25
Flurazepam	Dalmane	15
<b>Barbiturates</b>		
Phenobarbital	N/A	30
Pentobarbital	Nembutal	100
Secobarbital	Seconal	100
Butalbital (with caffeine and aspirin or acetaminophen)	Fiorinal, Fioricet	100
Amobarbital	Amytal	100
<b>Related compounds</b>		
Carisoprodol	Soma	700
Meprobamate	Miltown, Equanil	1200
Chloral hydrate	Noctec	500
Methaqualone <sup>2</sup>	Quaalude	300
Ethchlorvynol <sup>2</sup>	Placidyl	500
Zolpidem	Ambien	20
Zaleplon	Sonata	20
Eszopiclone	Lunesta	3

N/A, Not applicable.

### Sedative-Hypnotics

This class of drugs includes a wide array of compounds (benzodiazepines, barbiturates, and various related compounds) (Table 3), most of which have at least some potential for abuse. Overall, these medications do much more good than harm and are useful in treating anxiety disorders, insomnia, seizures, and muscle spasms. They are also important in managing withdrawal states and as a component of surgical anesthesia. These drugs act as CNS depressants, and their primary mechanism of action is to enhance inhibitory GABA neurotransmission. The risk of toxicity is by respiratory depression, which is magnified by concomitant use of opioids or other CNS depressants, such as alcohol.

Sedative-hypnotic intoxication and withdrawal states closely resemble those of alcohol except for the more protracted time course of withdrawal. Anxiety, restlessness, insomnia, tremor, nystagmus, tachycardia, and hypertension usually appear 2 to 12 hours after the last dose, and symptoms gradually resolve over 1 to 2 weeks. Withdrawal seizures, psychosis, and delirium are fairly common. Detoxification is best accomplished on an inpatient basis and typically involves tapering doses of a long-acting benzodiazepine (e.g., clonazepam [Klonopin], diazepam, clorazepate [Tranxene]) at a rate of about 10% of the initial daily requirement per day. Acute sedative overdose is managed primarily with supportive care and airway management. Flumazenil

(Romazicon) 0.2 to 0.5 mg/min IV may be used for acute benzodiazepine overdose, but only with caution because it can precipitate severe acute withdrawal symptoms.

Since their introduction in the 1960s, benzodiazepines, given their enhanced safety profile, have largely replaced barbiturates. However, barbiturates still in common use include phenobarbital and butalbital. Phenobarbital, used mainly for treating seizures, is considered to have a low potential for abuse. Butalbital, compounded with caffeine plus acetaminophen or aspirin (Fioricet, Fiorinal), has moderate abuse potential, typically in combination with other drugs. Carisoprodol (Soma), though not a barbiturate, is metabolized into meprobamate, a barbiturate-like drug. Commonly taken in combination with opioids and other sedatives, carisoprodol is highly abused.

Alprazolam (Xanax) stands out among its peers as the single most abused, most addictive, and yet currently most prescribed sedative-hypnotic. Its rapid onset ( $T_{max}$  1 to 2 hours) and relatively short half-life (6 to 14 hours) contribute to its abuse liability and propensity for withdrawal seizures. Diazepam, historically the most prescribed sedative, also has a relatively rapid onset and significant addictive potential, but its long half-life makes it an ideal agent for use in treating withdrawal from other sedatives. Flunitrazepam (Rohypnol, “roofies”) is a benzodiazepine that causes anterograde amnesia. It is now illegal in the United States because of its use in drug-facilitated sexual assaults.

$\gamma$ -Hydroxybutyric acid (GHB) and baclofen (Lioresal) also act as GABAergic CNS depressants, with intoxication and withdrawal states consistent with the class. Oddly, GHB is considered a Schedule I drug with high abuse potential and no accepted medical use, but when marketed as sodium oxybate (Xyrem), GHB is available as a Schedule III drug (with special restrictions) for use in treating narcolepsy. Baclofen, on the other hand, appears to have rather low addictive potential and may actually play a role in the treatment of alcoholism.<sup>1</sup>

Relatively new drugs—such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta)—are benzodiazepine-like drugs with CNS depressant activity; they are approved for the short-term treatment of insomnia and have at least some potential for abuse and dependence. Clonazepam (Klonopin) is generally considered to have the lowest potential for euphoria and addiction and is thus the agent of choice if a benzodiazepine must be given to patients with a relative contraindication, such as a history of any drug use disorder.

### Conclusion

Despite intensive supply-reduction strategies, improved primary prevention efforts, and the many recent pharmacotherapy advances, drug use disorders remain largely unchanged in their overall scale with the notable exceptions of the increased use of dangerous opioids and increased vaping of nicotine and cannabis. Another notable exception is the significant reduction in tobacco use since the turn of the century. It is estimated that 25% of patients seen in office settings and 50% of those seen in emergency departments have active problems related to substance use. All patients in primary care settings must be screened for tobacco, alcohol, and illicit drug use. Patients should be asked directly about substance use at the initial point of contact (e.g., emergency departments, primary care offices), and clinicians should maintain a healthy degree of skepticism toward patients' responses, remembering that many patients minimize substance use. When any suspicion exists, urine drug screens should be readily utilized without hesitation or fear of communicating mistrust. A variety of affordable quick screen kits are available, which can be sent out for laboratory confirmation of positive results if necessary.

Physicians and other health care professionals are in a unique position to intervene with drug use disorders at the individual level because these disorders are commonly encountered in clinical practice. The problem must first be identified and, depending on the skill set of the primary provider, patients should be treated

<sup>1</sup>Not FDA approved for this indication.

or referred appropriately. There is an initiative to incorporate formal SBIRT (screening, brief intervention, and referral to treatment) into routine clinical practice. Current procedural terminology (CPT) codes and a reimbursement schedule for screening and brief intervention may be located online at <https://www.samhsa.gov/sbirt/coding-reimbursement>. Screening may involve the written or verbal assessment of substance use to determine whether the patient exhibits a problematic level of use. The brief intervention aspect of SBIRT targets those with milder substance use disorders and provides effective strategies for intervention before the need for more extensive or specialized treatment arises. Referral to specialized treatment is recommended for patients with moderate-to-severe substance use disorders. Data suggest that this approach can be successful in modifying problematic substance use behavior. In addition to formal treatment, physician referral to local 12-step recovery programs (Alcoholics Anonymous, Narcotics Anonymous) has proved beneficial. Ample scientific evidence supports the effectiveness of these programs. Local chapters readily provide physicians with the names and telephone numbers of members willing to welcome newcomers ([www.aa.org](http://www.aa.org); [na.org](http://na.org)).

Physicians are usually well equipped to treat the sequelae of drug use disorders, but they often forget that addiction itself is a treatable disease entity. Treatment ranges in intensity along a continuum that includes medically managed inpatient detoxification, partial hospitalization, intensive outpatient treatment, and outpatient care. The American Society of Addiction Medicine provides patient placement criteria that dictate the appropriate level of treatment based on a multidimensional assessment. Health care professionals should be familiar with the treatment centers in their area; these can place the patient in the appropriate level of care.

It is important to remember that relapse is a characteristic of addiction and does not equate to treatment failure but rather indicates a need for an adjustment in the level of treatment or that of monitoring. Other chronic diseases, such as diabetes and hypertension, necessitate ongoing monitoring and adjustment of treatment interventions as needed, and the same is true of addiction. Recently published data on the treatment and monitoring of recovering physicians (a subgroup of addicts that boasts a 5-year success rate >78%) teach us the lesson that adequate initial treatment coupled with ongoing monitoring is critical. Sustained recovery from a substance use disorder is readily attainable and is characterized by voluntary sobriety, improved personal health, and improved citizenship.

## EATING DISORDERS

Method of

Nandini Datta, PhD; and James Lock, MD, PhD

### Bulimia Nervosa

#### CURRENT DIAGNOSIS

- Binge-eating episodes occur at least once per week for 3 months (eating objectively large quantities of food in a discrete period of time accompanied by a loss of control while eating).
- Compensatory purging episodes occur at least once per week for a period of 3 months (e.g., self-induced vomiting, laxatives, diuretics, excessive and compulsive exercise, enemas) to prevent weight gain.
- Shape and weight are overvalued and impact self-worth and self-esteem.
- Weight is at or above expected range given age, height, and historical growth curves.

#### CURRENT TREATMENT

- Cognitive behavioral therapy (CBT) is the most evidence-based treatment for bulimia nervosa (BN).
- Interpersonal psychotherapy (IPT) is an appropriate alternative.
- Family-based treatment (FBT) is useful for adolescents with BN.
- Antidepressant treatment (selective serotonin reuptake inhibitors [SSRIs]) may be useful in augmenting psychotherapy or as an alternative in the event that psychotherapy is not effective, refused, or unavailable. It is not as effective as CBT and thus not a front-line approach.

### Diagnosis

To diagnose bulimia nervosa (BN), an individual must engage in recurrent binge episodes with compensatory behaviors (e.g., self-induced vomiting, diuretic or laxative use, excessive and compulsive exercise). A binge is a discrete episode of eating a quantity of food that is more than the average person would eat in the same setting, accompanied by a loss of control or feeling as though one cannot stop eating. Nonpurging forms of bulimia occur when an individual uses extreme dietary restriction/fasting and/or exercise as a means of compensating for binge episodes. A disproportionate emphasis on weight and shape in one's self-evaluation is also required in diagnosing BN. DSM-5 criteria require that these episodes occur at a minimum of once weekly for 3 months. Unlike individuals with anorexia nervosa (AN), who may binge and purge, individuals with BN are within range of or above the median body mass index (BMI).

Significant health consequences may accompany BN. Laboratory studies often reveal electrolyte abnormalities, which can lead to cardiac arrhythmias and cardiac arrest in severe cases. Physical examination may detect enamel decay and parotid gland enlargement as a consequence of recurrent vomiting. When ipecac<sup>1</sup> is used to induce vomiting, severe cardiac and skeletal myopathies may develop. Laxative abuse is associated with metabolic acidosis and elevated serum amylase levels. BN has an elevated risk for mortality (crude mortality of 3.9%–6% in an inpatient sample), with many dying by suicide. Most common comorbid psychiatric

<sup>1</sup>Not FDA approved for this indication.

diagnoses are mood, anxiety, personality disorders (specifically borderline personality disorder), and substance use disorders.

### Epidemiology

BN behaviors typically first occur in middle adolescence (ages 14–16), with onset of full syndrome BN in later adolescence and early adulthood (ages 17–24). The lifetime prevalence estimate of DSM-5 BN ranges from 4% to 6.7%, and while less is known about males, at minimum they are estimated to account for between 10% to 25% of all cases. Symptoms may persist for a number of years, with intermittent periods of remission. A review of existing treatment studies suggests that approximately 45% of patients fully recover, with 27% improving considerably and the remaining 23% exhibiting a chronic course.

### Etiology

BN can be explained by a confluence of biologic, sociocultural, psychological, and familial factors. From a biologic standpoint, BN aggregates in families; in twin studies, about half of the variance in heritability can be explained by genetic factors. Serotonin levels may be reduced, and imaging studies show abnormal serotonergic circuitry in the orbital-frontal cortex. Internalization of cultural ideals of beauty may present as a focus on thinness for women, where for males there is often pressure to be muscular with low body fat. Participation in sports where weight and appearance are tied to performance (e.g., gymnastics, wrestling) may increase risk. Early puberty and childhood obesity are common precipitants, as are experiences with peer weight-related teasing. Personality characteristics of individuals with BN may include perfectionism, impulsivity, and instability in interpersonal relationships. Childhood sexual and physical abuse increases the risk for BN.

### Treatment

Given the significant physical, social, and emotional consequences associated with BN, effective treatment requires addressing wide-ranging difficulties. Over 70 randomized controlled treatment trials (RCTs) exist for adults with BN, yet only four focus on adolescents. Most studies have examined behavioral therapies, medications, or a combination thereof. CBT is established as the treatment of choice for adults with BN and has been subjected to a large number of RCTs. The underlying assumption of CBT is that bulimic behaviors are maintained by dysfunctional attitudes about shape, weight, and physical appearance, which thereby lead to an overemphasis of these aspects in self-evaluation. Excessive dieting typically ensues, resulting in physiologic and psychological deprivation that increases vulnerability to binge eating. Feelings of guilt and fear about weight gain are mitigated through engaging in purging behaviors. CBT targets this cycle through the use of self-monitoring to increase an awareness of patterns in behaviors, thoughts, and emotions that maintain BN symptoms.

CBT is found to be more effective than no treatment, pill placebo, nondirective supportive psychotherapy, nutritional counseling, stress management, and antidepressant medication therapy. Response to CBT is good, with approximately 50% recovered and 20% with significant reductions in symptoms at the end of treatment. CBT is acceptable and feasible with adolescents; however, a more recent RCT had a 20% rate of abstinence, compared with previous rates of 56% in a case series and 36% in a guided self-help (GSH) version at the end of treatment. Compared with an alternative intervention, interpersonal psychotherapy (IPT), CBT demonstrates a greater probability of remission and reduction in symptoms at the end of treatment. However, these initial differences appear to diminish at a 1-year follow-up, suggesting that, while less efficient, IPT is a viable alternative. IPT was adapted for BN to target interpersonal factors thought to contribute to the development and maintenance of the disorder. IPT has yet to be studied with adolescents.

More recently, CBT has been expanded to address other maintaining features of eating disorders broadly (e.g., interpersonal difficulties, clinical perfectionism, low self-esteem, and mood

intolerance). Enhanced CBT (CBT-E) addresses these features and is delivered in a focused or broad (addressing aforementioned maintaining features) format. For individuals with more complex psychopathology, the broad version may be more effective. Further, a novel treatment, integrative cognitive affective therapy for BN (ICAT-BN), may be preferable to CBT-E for individuals with greater affective lability and stimulus seeking behaviors.

Other interventions show promise in the treatment of BN and require further examination. For adolescents, FBT may be helpful, demonstrating higher rates of binge/purge abstinence (40%) than supportive psychotherapy in one study, and higher than CBT (FBT: 39% vs. CBT: 20%) in another. Derived from FBT for AN, parents are supported to directly change dysfunctional eating behaviors. For adults, dialectical behavior therapy (DBT) has been shown to significantly decrease binge/purge episodes when delivered in an individual format. Similar effects were found when an appetite-awareness component was added to standard DBT.

Antidepressants (SSRIs) are the most studied medication treatment for BN. Fluoxetine (Prozac) demonstrates greater reductions in binge eating, purging, and eating-related cognitions than placebo when prescribed at higher doses (60 mg/day). A small pilot study of fluoxetine with adolescents suggests it is acceptable and may decrease BN symptoms. Antidepressants alone are not as effective as when combined with CBT, or as CBT alone.

## Binge-Eating Disorder

### CURRENT DIAGNOSIS

- Recurrent episodes of binge eating, defined as eating an objectively large amount of food in a discrete period of time with a sense of lack of control during the episode.
- Binge eating is associated with at least three of the following: eating more rapidly than normal; eating until uncomfortably full; eating outside of physical hunger; eating alone because of embarrassment; and subsequent feelings of self-disgust, depression, or guilt.
- There is marked distress associated during a binge eating episode.
- These episodes occur at least once per week over 3 months.
- There is no associated compensatory behavior (e.g., purging), and bingeing does not occur in the context of another eating disorder diagnosis (anorexia or BN).

### CURRENT TREATMENT

- CBT and IPT have good evidence of efficacy among adults.
- GSH CBT may be effective for those with less psychopathology.
- DBT requires further study to determine whether good outcomes are sustained over time.
- There is no evidence-based treatment for young patients with binge eating disorder (BED).
- Pharmacologic treatments should be considered as an adjunct to psychotherapy.

### Diagnosis

Binge episodes are typically characterized by eating quantities that are larger than others would eat in a similar setting and are accompanied by a feeling of being out of control. Individuals with BED do not engage in compensatory behaviors (e.g., self-induced vomiting, excessive exercise) as in BN. The ICD-11 also recognizes subjective binge episodes, when smaller amounts of food are consumed with loss of control. DSM-5 criteria require that the

episodes occur at a minimum frequency of once per week over a 3-month period. Binge eating (BE) is commonly associated with feelings of guilt and embarrassment and may result in attempts to hide eating. Furthermore, during binge episodes, eating is often rapid and results in feeling uncomfortably full. Most individuals with BED have at least one comorbid psychiatric diagnosis (79% of respondents in one study).

### Epidemiology

Lifetime prevalence of BE among adult females was 3% and 3.6% in two separate studies, and 2.1% in males. It occurs at equal rates across ethnic and racial groups. BE most typically onsets in later adolescence or early adulthood, although it does occur in children and is often associated with overweight and obesity, as well as psychological symptoms. Among adolescents with obesity, an estimated 1% meet the criteria for BED, and up to 26% experience BE/loss of control eating. In BED, obesity often pre-dates dieting and subsequent BE, with women having an earlier onset of both dieting and BE. Remission rates in BED are higher than in other eating disorders, although duration and severity is similar to BN.

### Etiology

The etiology of BED is unknown. Restrictive dieting, body image dissatisfaction, pressure to be thin, low self-esteem, depressive symptoms, and limited social support increase the risk for the onset of adolescent BE. Increased rates of BE in families suggests there may be a genetic link. Heritability estimates range between .39 and .45. Potential medical causes for BE include CNS tumors, Kleine-Levin syndrome, Kluver-Bucy syndrome, Prader-Willi syndrome, and gastrointestinal pathology, and these causes should be ruled out during assessment. Comorbid psychiatric disorders are common among adults with BED, including mood disorders, anxiety disorders, and, at lesser frequency, substance use disorders and personality disorders. There are high rates of obesity among individuals with BED; however, psychiatric symptoms are linked to the severity of BE rather than obese status.

### Treatment

Treatment for adults with BED has received considerable attention in RCTs compared with other eating disorder diagnoses. Most treatments target reduction in BE, psychological symptoms, and weight loss for those who are overweight, as determined by BMI categories. CBT has been applied in multiple formats (group, GSH, CD-ROM delivered, and in combination with medication) and appears to have the highest rates of abstinence. Individual CBT outperformed group CBT in one trial, and a GSH version was more effective in reducing BE than behavioral weight-loss (BWL). CBT targets underlying dysfunctional attitudes and behaviors that maintain BE. An alternative treatment, interpersonal psychotherapy (IPT), is a time-limited psychodynamic therapy targeting interpersonal difficulties that underlie the disorder. IPT is helpful in reducing the frequency of BE. IPT, CBT, and motivational interviewing (MI) all lead to improvements in cognitive restraint, disinhibition, and shape and weight concerns thought to maintain BE.

DBT is another treatment adapted for BED with the aim of targeting affected regulation difficulties formulated to be a maintaining mechanism of BE. Women in a small trial comparing group DBT to a waitlisted group had significantly greater decreases in BE and related eating disorder thoughts and behaviors, with over half abstinent from BE at follow-up. However, compared with supportive psychotherapy, the rate of abstinence, while achieved more quickly in the DBT group, did not differ between the groups at follow-up. Pilot data suggest comprehensive DBT (individual, group, and skills coaching) may be effective.

Pharmacologic treatments targeting BE and weight loss have been tested alone and in combination with psychotherapy. There may be improvement in weight loss with addition of pharmacotherapy. The combination of CBT with topiramate (Topamax)<sup>1</sup>

resulted in greater weight loss and better psychosocial outcomes than CBT with fluoxetine.<sup>1</sup> A high dose of the SSRI escitalopram (Lexapro)<sup>1</sup>, anticonvulsants topiramate and zonisamide (Zonegran)<sup>1</sup>, lisdexamfetamine (Vyvanse) at a dose of 50 mg or 70 mg, and the selective norepinephrine reuptake inhibitor atomoxetine (Strattera)<sup>1</sup> were each associated with significantly decreased binge eating and weight in separate placebo-controlled trials.

## Anorexia Nervosa

### CURRENT DIAGNOSIS

- Persistent restriction of energy (caloric) intake relative to requirements, leading to significantly low weight (e.g., accounting for age, sex, developmental trajectory, and physical health).
- Ongoing behavior interfering with weight gain driven by a fear of becoming fat.
- Disturbance in the perception of shape, weight, overvaluation of weight, and shape in self-evaluation, or lack of acknowledgment of seriousness of low weight.
- Either meets criteria for restricting type, with absence of binge or purge behaviors, or binge eating/purging type.

### CURRENT TREATMENT

- FBT for adolescents with AN has the most evidence supporting its efficacy to date.
- AFT may be a helpful alternative.
- There are no first-line treatments for adults with AN.
- CBT may prevent relapse in weight-restored individuals.

### Diagnosis

AN is characterized by dietary restriction that is severe enough to lead to seriously low weight, fear of weight gain, and difficulty or inability to accurately perceive shape or weight. Secondary amenorrhea is no longer required for a diagnosis of AN in the DSM-5. Individuals may be classified as AN-restricting subtype or AN-binge/purge subtype. The definition of low weight is less than “minimally normal” among adults or “minimally expected” among children and adolescents. Growth charts normed by age and gender are necessary to calculate expected BMI for individuals under 18 and growth curves may help detect deviations from an individual’s growth trajectory. A BMI at or below the 10th percentile is a benchmark reflecting malnourishment associated with AN, and BMI below 18.5 kg/m<sup>2</sup> may be used as guidelines. When an individual meets all criteria for AN, but despite significant weight loss weighs within or above the median BMI range, atypical AN (AAN) may be diagnosed. Otherwise, AAN is associated with the same psychological and physical features of AN.

A wide variety of medical and psychiatric symptoms accompany AN. Potentially life-threatening medical conditions may develop as a result of semistarvation. Vital sign abnormalities (e.g., bradycardia, orthostasis, hypothermia) and amenorrhea are common consequences of malnutrition. Bone loss resulting in osteopenia and, in more severe cases, osteoporosis may occur. Abnormal laboratory findings may occur in some patients with AN who use laxatives, diuretics, and diet pills and who engage in self-induced vomiting.

The lifetime rate of comorbid psychiatric diagnoses among adolescents with AN is approximately 55%. Most commonly, these comorbidities include anxiety disorders (social anxiety, separation anxiety, generalized anxiety and obsessive compulsive disorder [OCD]), depression, and substance abuse. There is significant overlap in OCD symptoms and AN, thus careful consideration

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

must be given to the content of obsessions and compulsions in diagnosis. In AN, obsessional preoccupations are related to eating, food, weight, and shape, and compulsions may appear as calorie counting, excessive exercise routines, and mealtime rituals. Depressive symptoms such as dysphoric thought, low energy, difficulty concentrating, and low self-esteem also manifest in AN and may not indicate a separate depressive disorder.

### Epidemiology

Peak age of onset for AN is between 14 and 18 years. Lifetime prevalence of females with a DSM-5 diagnosis of AN in the United States is estimated to be between .8% and 3.6%, based on method of data collection. The incidence of AN among males is less studied, but recent estimates suggest that 1 out of every 4 cases are male. Little is known about the prevalence of AN across racial and ethnic groups. A recent study did not reflect significantly higher rates of AN among non-Hispanic white adolescents compared with Hispanic and non-Hispanic black peers; however, other evidence suggests that it is less common among persons of African origin.

AN has the highest mortality rate of any psychiatric illness, with reports as high as 5% per decade. Rates of chronicity obtained from long-term adult follow-up studies (AN diagnosis persisting greater than 5 years) are estimated between 7% and 15%. Death occurs most commonly secondary to medical complications of starvation or suicide. Prognosis for adolescents with short duration of illness (less than 3 years) is better than adults.

### Etiology

The causal mechanisms of AN are multiply determined through the interface of biologic/genetic, psychological, and sociocultural factors. Heritability estimates from twin studies range from 48% to 74%, and family aggregation studies report that AN occurs at about five times the expected rate in affected families. The interactional effect between genes and developmental processes is reflected in studies demonstrating greater heritability among 17-year-old twins compared with 11-year-old twins. Hormonal changes during adolescence could mediate gene expression during puberty, explaining this difference.

Perfectionistic and avoidant personality features are associated with AN and are likely heritable. Neurocognitive features including cognitive rigidity and an overly detailed style of information processing are common and may represent an endophenotype as those who are recovered, as well as unaffected siblings who demonstrate similar cognitive styles. Common developmental challenges associated with adolescence may also precipitate or emerge as a consequence of AN. These include navigating issues of autonomy, self-efficacy, and intimacy. Sociocultural factors including exposure to a Westernized “thin ideal” of beauty for females and an overly muscular ideal for males may be internalized, thereby triggering extreme dieting or exercise. Furthermore, activities where weight or appearance is intertwined with performance may also elevate risk (e.g., gymnastics, ballet, wrestling, figure skating).

### Treatment

Given the severity of psychological, social, and health consequences of AN, both close medical monitoring and psychotherapy are the standard of care. In severe cases, inpatient medical monitoring may be required, and standard criteria for hospitalization are available for physicians to treat common consequences of starvation like bradycardia, hypotension, and orthostatic vital sign abnormalities. Findings from RCTs among adults are inconclusive because of dropout rates as high as 50%. Medication trials of antidepressants (serotonin reuptake inhibitors and tricyclics) have high dropout rates and show little to no improvement of weight or eating disorder behaviors. Therefore these should not be used independent of psychotherapy. A recent trial demonstrated an average of 1 lb per month greater weight gain for those taking olanzapine (Zyprexa)<sup>1</sup> than not; however, potential risks, including tardive dyskinesia and metabolic side

effects, need be considered. CBT may help prevent relapse for individuals who are already weight-restored. For underweight individuals, findings are mixed, and nonspecific therapies such as nonspecific supportive clinical management (NSCM) showed better outcomes compared with IPT and CBT at end of treatment. However, improvements in NSCM appear to decline over time, and IPT may catch up to CBT.

Recent treatment studies have focused on improving retention. For example, an enhanced version of outpatient CBT (CBT-E), which employs motivational enhancement strategies, retained 64% of the original sample, improving on previous trends in attrition. Individuals completing treatment had clinically significant improvements in weight and eating disorder psychopathology. When CBT-E was compared with focal psychodynamic therapy and treatment as usual (TAU) in the community, weight gain and improvements in eating disorder symptoms were more rapid. However, focal psychodynamic treatment had the highest rates of recovery at follow-up (35%), though these were only significantly higher than the TAU group.

FBT, otherwise known as *Maudsley family therapy*, has been studied in seven RCTs with superior outcome to other individual therapies. This outpatient treatment empowers parents to disrupt self-starvation and other behaviors that maintain AN. In the initial phase of treatment, parents take full control over managing eating-related behaviors. FBT demonstrates rates of remission ranging from 49% (full remission in weight and eating disorder thoughts and behaviors) to 89% for partial remission. Rates of relapse are about 10% and there is minimal dropout, suggesting it is acceptable to families. FBT delivered in a parent-focused format may be just as effective and preferable to conjoint FBT for families with high levels of expressed criticism.

AFT may be an alternative approach for individuals whose family members are unable to participate. The focus in AFT is on helping an adolescent move toward healthy individuation and increased self-efficacy. AN is conceptualized as an ineffective strategy that the adolescent has adopted in managing common developmental challenges. In AFT, adolescents learn new skills to support eating and weight gain and parents are involved in separated collateral sessions. CBT has also been studied in adolescents; compared with TAU and hospitalization, it appeared to be the most cost-effective approach.

## Avoidant-Restrictive Food Intake Disorder

### CURRENT DIAGNOSIS

- Disturbance in eating/feeding resulting in persistent failure to meet nutritional and/or energy (caloric) needs.
- The disorder must result in one of the following consequences: significant weight loss or faltering growth; significant nutritional deficiency; dependence on nutritional supplements or enteral feeding; and interference with psychosocial functioning.
- The eating/feeding disturbance is not better explained by another medical or psychiatric condition or by cultural or religious practices.

### CURRENT TREATMENT

- There are no established treatments for this new diagnosis, though clinical trials are currently underway.
- CBT or family interventions that employ behavioral strategies are being explored as potential treatment options.

<sup>1</sup>Not FDA approved for this indication.

## Diagnosis

Avoidant-restrictive food intake disorder (ARFID) is a new diagnosis included in the DSM-5, which reflects the recognition of “food neophobia” or extreme picky eating as challenges. Individuals with ARFID can be of any age and exhibit clinically significant feeding/eating difficulties, which result in failure to meet energy (caloric) or nutritional needs. In response, individuals have low weight or failure to meet expectations for growth, significant nutritional deficiency, a need for enteral feeding or oral nutritional supplementation, and/or impairment in psychosocial functioning. Although there may be failure to thrive or to make expected weight gain/weight loss, ARFID is distinguished from AN by the absence of body image disturbance driving restrictive eating symptoms. Low weight can be determined through clinical judgment and examination of developmental trajectory using growth charts. Nutritional deficiency may be assessed through dietary history, as well as physical examination. Related medical consequences may follow those seen in malnourished individuals with AN (e.g., bradycardia, anemia, hypothermia) and can be life threatening. Individuals with ARFID treated in an inpatient setting are more likely to require nasogastric feeding than those with AN. If limited food intake is better explained by cultural or religious practice, an eating disorder in which there is disturbance in experience of shape/weight, or current physiologic or psychiatric conditions that explain the symptoms, ARFID is not diagnosed. Further, in the event of a coexisting medical diagnosis, food refusal is serious enough to warrant separate clinical attention. Thorough assessment should include examination of feeding, and eating history, psychiatric symptoms, development, and underlying medical causes must be ruled out before making a diagnosis.

Individuals with ARFID often exhibit selective eating, food neophobia, and hypersensitivity to sensory features of food (texture, taste, temperature, appearance). Similar clinical presentations may have varying etiology, requiring individualized treatment plans. In some, development of food avoidance can be traced to a specific aversive event, trauma, or related gastrointestinal problem, or may arise out of a choking, swallowing, or vomiting phobia. Individuals may also have a lack of drive or interest in eating or heightened textural sensitivity, which is also common in autism spectrum disorders.

## Epidemiology

No data exist on prevalence, course, and outcome of this disorder. Surveillance studies are underway in the United Kingdom and Canada for related “food avoidance emotional disorder,” with overlap in clinical features. In a school-age sample (ages 8–13), prevalence of ARFID was 3.2%. In pediatric inpatient ED programs, rates of ARFID are reported to be between 5% and 14% comprised of a higher proportion of males than other ED diagnoses and tend to be younger. ARFID appears to arise most commonly in infancy and early childhood but can occur at any age and last into adulthood. Preliminary data suggest ARFID occurs at equal rates in males and females. There is no evidence to guide for whom clinical intervention is warranted versus those whose symptoms resolve over time.

In one study, 53% of individuals ages 9 to 22 had at least one co-occurring lifetime psychiatric diagnosis, the most common being an anxiety disorder. Severity of symptoms among those with a sensory sensitivity profile of ARFID was related to increased risk for current and lifetime conduct, neurodevelopmental and disruptive disorders. Increased severity in the fear of aversive consequences profile was associated with increased risk for current and lifetime anxiety, obsessive-compulsive, and trauma-related disorders.

## Treatment

There are no systematically studied treatments to date for ARFID; however, behavioral interventions with contingency management have been successfully used among children who have food neophobia in the context of a developmental disability. Given limited data, individualized treatment plans are best derived through

assessment of medical history, temperament, psychiatric symptoms, and development. Food avoidance may be treated through use of behavioral strategies (e.g., shaping, chaining, contingency management, extinction) that systematically desensitize individuals to a wider range of foods. Related anxiety management techniques (relaxation training, visualization for mastery) and cognitive strategies derived from CBT may address maintaining psychiatric features. CBT was successfully applied in a case study of young adults with food neophobia, and a transdiagnostic CBT model with family involvement proved useful in a case study of a pediatric patient. Mirtazapine has been used with pediatric patients in two case studies with demonstrated increases in rate of weight gain, improvements in anxiety and eating. In most severe cases of malnutrition, hospitalization for medical stabilization purposes may be needed before outpatient therapy.

## GENERALIZED ANXIETY DISORDER

Method of

Natalie C. Dattilo, PhD; and Andrew W. Goddard, MD

### CURRENT DIAGNOSIS

- Generalized anxiety disorder (GAD) is the most common psychiatric disorder seen in the primary care setting.
- GAD is characterized by feelings of dread, negative anticipation, and worry that are difficult to control and may include hypervigilance, excessive reassurance seeking, and behavioral avoidance of anxiety-provoking situations.
- Symptoms of GAD most often include agitation, irritability, restlessness, muscle aches or tension, dizziness, fatigue, racing heart, dry mouth, nausea, decreased sexual desire, sleep or appetite disturbances, and an inability to relax.
- A thorough medical examination and laboratory work may be indicated to rule out underlying physiologic causes, adverse reaction to medication, caffeine or substance use, and drug or alcohol withdrawal.
- Symptoms that are persistent, disruptive, or distressing warrant treatment.
- The Generalized Anxiety Disorder – 7 (GAD-7) is a screening instrument used to assess symptoms of GAD in primary care settings. Scores of 5, 10, and 15 are taken as the cut-off points for mild, moderate, and severe anxiety, respectively. When used as a screening tool, further evaluation is recommended when the score is 10 or greater.

## CURRENT THERAPY

- Effective treatments for GAD include serotonergic antidepressants, certain forms of psychotherapy, or a combination of both.
- Educate the patient and family members about treatment options as well as realistic treatment expectations.
- Depending on the patient's preference, treatment may include a selective serotonin reuptake inhibitor (SSRI) or a serotonin norepinephrine reuptake inhibitor (SNRI), starting at low doses with careful titration so as not to exacerbate anxiety symptoms.
- Treatment may also include a trial of cognitive-behavioral therapy (CBT) monotherapy or in combination with medication management.
- Refer to or consult with a psychiatrist for patients with severe or particularly complex cases or for patients with a less-than-expected response to treatment.
- Refer to a CBT specialist for patients with a preference for behavioral, skills-based, or nonmedication therapy or for whom pharmacotherapy may be contraindicated.

### Epidemiology

Anxiety disorders are among the most prevalent psychiatric disorders in the world. In the United States, it is estimated that an anxiety disorder is diagnosed in approximately 16 million adults each year and approximately 30 million meet criteria for an anxiety disorder over the course of their lifetimes. Second to depression, anxiety disorders are the most common mental health problem seen by physicians in the general medical setting. In fact, patients with anxiety are more likely to present initially to a generalist physician office than to a mental health care provider.

Anxiety disorders tend to be chronic and disabling and impose a high individual and societal burden. It has been estimated that the United States spends approximately \$40 billion to \$60 billion per year for costs associated with anxiety disorders. These include not only direct costs associated with treatment but also indirect costs associated with lost productivity. Thus early detection and treatment is critically important.

### Risk Factors

Risk factors associated with anxiety disorders include personal or family history of anxiety; recent increase in stressful life events; lack or perceived lack of social support; ineffective emotional coping strategies; being female; experiencing childhood adversity, including trauma or witnessing a traumatic event; having a chronic health condition or serious illness; having an acute or chronic pain condition; and substance abuse. Having a genetic predisposition to developing an anxiety disorder is likely, although environmental stressors clearly play a role. Research has also shown that patients suffering from anxiety are generally more sensitive to physiologic changes than nonanxious patients. This heightened sensitivity leads to diminished autonomic flexibility, which may be the result of faulty central information processing in anxiety-prone persons.

### Pathophysiology

Current evidence suggests that anxiety symptoms are likely caused by dysregulation in the central nervous system fear circuit. Physical and emotional manifestations of this dysregulation can result in a state of hyperarousal. Several neurotransmitter systems have been implicated in the development of this state.

The most commonly considered are the serotonergic and noradrenergic neurotransmitter systems. Very simply, it is believed that an underactivation of the serotonergic system and an overactivation of the noradrenergic system are involved, resulting in dysregulation of physiologic arousal and the emotional experience of this arousal. Disruption of the  $\gamma$ -aminobutyric acid (GABA) system has also been implicated because of the response of many of the anxiety-spectrum disorders to treatment with benzodiazepines.

There has also been some interest in the role of corticosteroid regulation and its relation to symptoms of fear and anxiety. Corticosteroids might increase or decrease the activity of certain neural pathways, affecting not only behavior under stress but also the brain's processing of fear-inducing stimuli. The stress response is hardwired into the brain and is most often triggered when survival of the organism is threatened. The stress response, however, can be triggered not only by a physical challenge or threat but also by the mere anticipation (or fear) of threat. As a result, when humans chronically and erroneously believe that a threatening event is about to occur, they begin to experience the physical and psychological symptoms of anxiety and panic.

Finally, a subcortical neural structure, the amygdala, serves an important role in coordinating the cognitive, affective, neuroendocrine, cardiovascular, respiratory, and musculoskeletal components of fear and anxiety responses (fear expression). It is central to registering the emotional significance of stressful stimuli and creating emotional memories. The amygdala receives input from neurons in the sensory cortex. When activated, the amygdala stimulates regions of the midbrain and brainstem, causing autonomic hyperactivity, which can be correlated with the physical symptoms of anxiety.

### Prevention

No biological markers are specific enough yet to detect anxiety early, and there is no available evidence to suggest that current medications prove efficacious in preventing these disorders. Therefore, it is important to screen for specific risk factors, such as family history and substance abuse. If a person is anxiety prone, he or she should first be encouraged to adopt healthy lifestyle habits. Exercise has been shown to relieve tension, anxiety, and stress. Patients should avoid stimulants such as caffeine and nicotine, which can exacerbate symptoms. Reducing alcohol intake should be encouraged as well. Educating patients on healthy sleep habits can prevent conditioned (or secondary) insomnia issues. It is also recommended that anxiety-prone persons reduce subjective levels of stress by practicing effective methods of relaxation and other stress management activities, like meditation, yoga, social connection, gratitude journaling, and pleasant event scheduling.

### Clinical Manifestations

GAD is characterized by subjective feelings of worry, dread, or anticipation of negative events and can include hypervigilance and avoidance of anxiety-producing situations. Physical symptoms can include jitteriness or shakiness, trembling, muscle aches and tension, sweating, cold or clammy hands, dizziness, or vertigo; fatigue; racing or pounding heart; hyperventilation; sensation of a lump in the throat, choking sensation, or dry mouth; numbness and tingling in the hands, feet, or other body parts; upset stomach, nausea, vomiting, or diarrhea; decreased sexual desire; and sleep and appetite disturbances.

Psychological symptoms include, most predominantly, unrealistic or excessive worry and apprehension, hypervigilance or an inability to relax, distractibility, indecisiveness, and insecurity. Patients often express feelings of impatience, agitation, irritability, and fear. They may ask multiple questions repeatedly in an attempt to quell the anxiety through excessive information or reassurance seeking. In GAD, the worries a patient may express tend to be nonspecific and all-encompassing. They tend to be "worst-case scenario" and "what if?" thinkers. Some patients also exhibit specific phobias such as fear of being far from home or fear of social contact. Patients with GAD may report difficulty falling asleep because they "can't turn their mind off" at night. If a patient reports these symptoms or displays one of several behavioral manifestations of GAD leading to significant distress and/or impairment of function, the condition is unlikely to remit on its own and treatment is warranted.

### Diagnosis

A diagnosis of GAD is made when a patient meets the specific diagnostic criteria outlined in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5). Persons

**BOX 1** Medical Conditions Often Associated With Anxiety Symptoms**Cardiopulmonary**

Angina  
 Mitral valve prolapse  
 Pulmonary embolism  
 Chronic obstructive pulmonary disease (COPD)  
 Asthma

**Endocrine**

 Gastritis

**Neurologic**

Dementia  
 Substance intoxication or withdrawal  
 Seizure disorder  
 Migraine

with GAD experience uncontrollable, excessive anxiety and worry involving several areas of functioning on most days for at least 6 months. The anxiety must be associated with at least three of the following symptoms: restlessness, fatigue, impaired concentration, irritability, muscle tension, or sleep problems. Patients tend to express chronic excessive nervousness, exaggerated worry, tension, and irritability that appear to have no cause or are more intense than the situation warrants. Physical signs such as headaches, trembling, twitching, or sweating often develop, which lead to further worries. GAD symptoms tend to wax and wane over time, with short-term exacerbations of acute anxiety in response to stress. Symptoms show substantial overlap with those of other medical and psychological disorders, particularly major depressive disorder, substance abuse disorders, and other anxiety disorders, which tends to complicate diagnosis.

**Differential Diagnosis**

It is important to perform a thorough medical workup when initially assessing the patient with anxiety symptoms. The differential diagnosis can include several organic causes, such as endocrine dysfunction, intoxication or withdrawal, hypoxia, metabolic abnormalities, and neurologic disorders. It is also important to rule out other comorbid psychiatric disorders. Severe depression, bipolar disorder, prodromal schizophrenia, delusional disorder, and adjustment disorder can often be accompanied by severe anxiety. Many organic causes can be ruled out by a thorough history and basic laboratory work, including thyroid-stimulating hormone, urine toxicology, electrocardiogram, complete blood count, and metabolic panel. The most common medical conditions associated with anxiety are presented in [Box 1](#).

The list of drugs suspected of causing anxiety is extensive. Drugs commonly associated with anxiety include stimulants such as amphetamine, cocaine, methamphetamine, and caffeine. Drugs such as lysergic acid diethylamide (LSD) and 3,4-methylenedioxymethamphetamine (MDMA, or “ecstasy”) can also cause acute and chronic anxiety. Prescription medications to consider include sympathomimetics, antihypertensives, and nonsteroidal antiinflammatory drugs (NSAIDs).

**Treatment and Monitoring**

Current practice guidelines indicate that the treatment of an anxiety disorder begins with education. Many people are confused, scared,

**TABLE 1** Pharmacotherapy for the Treatment of Generalized Anxiety Disorder

DRUG	STARTING DOSE	TARGET DOSE
<b>Selective Serotonin Reuptake Inhibitors</b>

<sup>†</sup>Exceeds dosage recommended by the manufacturer.

or frustrated by the symptoms and behavior and are reassured to know they are not alone and that there are effective interventions. The patient should receive an appropriate medical workup, such as a physical examination, and studies (e.g., electrocardiogram, thyroid-stimulating hormone) when indicated. After ruling out a medical condition, developing a good working alliance with the patient provides a basis for ongoing disease management and prevents unnecessary utilization or overutilization of the medical system, as well as potential exacerbation of symptoms.

A combination of psychotherapy and medication management is recommended as first-line treatment for GAD. CBT has the strongest empirical support to date for the treatment of anxiety. Mindfulness-based stress reduction (MBSR) has an emerging evidence base as an effective alternative or complementary behavioral treatment program for anxiety. Both offer a skills-based approach to treatment. In CBT, the therapist and patient work collaboratively and in an active and problem-solving manner. It is structured and generally short term with an emphasis on reducing symptoms and preventing “flare-ups” by monitoring and changing unhelpful or inaccurate thinking patterns that result in feelings of anxiety and worry. Another critical component of CBT for GAD is learning and applying behavioral relaxation techniques (e.g., diaphragmatic breathing, guided imagery, progressive muscle relaxation) and distress tolerance skills (e.g., mindfulness, acceptance). Volumes of evidence support the efficacy of CBT interventions for GAD, but success requires commitment to treatment on the part of the patient. Its efficacy is also contingent upon the ability of the therapist and the length of time in treatment. Studies show that when compared with patients undergoing monotherapy, patients treated with a combination of CBT and medication experience nearly twice the remission rate.

SSRIs have been shown to be the best-tolerated class of medication, and response rates are significantly higher than placebo for GAD. SSRI medications includes fluoxetine (Prozac),<sup>1</sup> fluvoxamine (Luvox),<sup>1</sup> citalopram (Celexa),<sup>1</sup> escitalopram (Lexapro), paroxetine (Paxil), and sertraline (Zoloft).<sup>1</sup> Some improvement in symptoms should be noted within 3 or 4 weeks, and the dose should be increased if no improvement is seen. In treating any anxiety disorder, SSRIs should be started at low doses and gradually titrated up to therapeutic levels to avoid an initial exacerbation of anxiety. Pharmacotherapy options for the treatment of GAD are presented in [Table 1](#).

<sup>1</sup>Not US Food and Drug Administration (FDA) approved for this indication.

Benzodiazepines, which have been commonly used in the past to treat anxiety disorders, are not recommended except in cases of extreme impairment of function and only for very short-term use. The tolerability and lack of addiction potential make the SSRIs more desirable for long-term management, but the delay in response makes short-term symptom relief with a benzodiazepine desirable for those with the greatest impairment. Because of the risk for rebound anxiety when withdrawing from benzodiazepines with short half-lives, such as alprazolam (Xanax), many prefer the longer-acting benzodiazepines, such as clonazepam (Klonopin).<sup>1</sup> However, the addiction potential and the potential for abuse with either drug make this the treatment option of last resort.

If the patient does not respond to the combination of CBT and medication, a reevaluation of symptoms might reveal a comorbid disorder missed on the first examination. Comorbid psychiatric disorders significantly lower the likelihood of recovery from anxiety and increase recurrence rates. Some clinicians try switching to a different SSRI before considering the next step in treatment; however, a referral to a psychiatrist or integrated care consultant for further evaluation and management may be necessary. Treatment-refractory anxiety can be extremely frustrating for the patient, the patient's family, and the treating physician. If benzodiazepine treatment was initiated, this frustration can and does often lead to an increased dependence on the medication and a requirement of increasingly higher doses to achieve the same effect. For long-term gains, therapy in addition to medication treatment should be recommended.

Education is critical to reassure the patient that effective treatment is available, but that patience may be necessary until the right combination of modalities is found. Although all anxiety disorders display a significant amount of chronicity, most patients have an improved outcome with appropriate treatment. Response rates improve when comorbidity is low. Patients with an earlier onset of symptoms (childhood or adolescence) can generally expect a more chronic course and their anxiety symptoms may be more difficult to treat. Patients rarely have a spontaneous remission of symptoms, but most can continue to function despite the symptoms. Nevertheless, time to resolution of symptoms is shortened and overall functioning typically improves with treatment.

Pharmacotherapy often helps to prevent relapse, and rates are improved when effective treatment is continued for 12 months. When considering termination of pharmacologic treatment, the risk for relapse in GAD should be discussed with the patient. When discontinuing the SSRIs, a slow taper is recommended, with close monitoring for withdrawal symptoms (e.g., headache, gastrointestinal upset, restlessness, and other flulike symptoms). Also monitor for rebound anxiety symptoms. If relapse occurs, reinstating treatment is indicated, and many patients opt for indefinite treatment to maintain remission of symptoms. Lifelong management with pharmacotherapy or psychotherapy, or both, is not unusual for many patients. For many, a maximum reduction of symptoms, rather than a full remission, is an acceptable outcome.

### Complications

Untreated anxiety disorders can lead to, or worsen, other mental and physical health conditions, including bruxism (teeth grinding), cognitive impairment, depression, gastrointestinal disorders, headache, insomnia, heart disease, substance abuse, and significantly impaired quality of life.

<sup>1</sup>Not FDA approved for this indication.

### Conclusion

Anxiety disorders are highly prevalent in the United States. GAD is one of the most common psychiatric conditions seen in primary care, second only to major depression. This condition can be disabling and costly to the patient and to the health care system. Despite the prevalence of anxiety disorders, patients often remain undiagnosed and untreated, and patients with unrecognized anxiety disorders tend to be higher utilizers of general medical care. Patients with anxiety disorders can present with multiple somatic complaints and comorbid disorders, causing great effort and expense in identifying the cause of unexplained symptoms. Once an anxiety disorder is identified, patients may be treated using well-tested and efficacious pharmacologic and psychotherapeutic treatments. Helpful resources for patients and families are listed in Table 2.

## OBSESSIVE-COMPULSIVE DISORDER

Method of

Rachna Kalia, MD

### CURRENT DIAGNOSIS

- Obsessive-compulsive disorder (OCD) is characterized by obsessions (recurrent, persistent, and intrusive unwelcome thoughts, urges, or images) and compulsions (repetitive behaviors or activities that the patient feels forced to perform in response to an obsession).
- Obsessions and compulsions are unwelcome and time-consuming, impair functioning, and usually cause significant anxiety or distress.
- The obsessions or compulsions are not attributable to any toxin, medication, or another medical condition.
- Patients may be unwilling to reveal symptoms of OCD or may lack insight into abnormal thoughts or behaviors.
- Patients with OCD may present with symptoms of depression, another comorbid psychiatric condition, or physical sequelae such as skin damage, fatigue, or insomnia.

### CURRENT TREATMENT

- Selective serotonin reuptake inhibitors (SSRIs) and exposure and response prevention (ERP) behavioral therapy are first-line treatments for OCD with good evidence of effectiveness.
- SSRIs, clomipramine (Anafranil), serotonin-norepinephrine reuptake inhibitors (SNRIs), and monoamine oxidase inhibitors (MAOIs) have demonstrated efficacy in the treatment of OCD.
- Effective SSRI therapy often requires high dosages and 8 to 12 weeks of treatment. Long-term adherence is essential. If a patient fails an adequate trial of SSRI monotherapy, a trial of another SSRI is recommended.
- Evidence-based augmentation strategies for treatment-resistant cases include low-dose antipsychotics.
- Comorbid conditions, including depression with suicidal ideation, must be identified and addressed.

### Epidemiology

Clinically significant OCD has an estimated lifetime prevalence in US adults of 1.9% to 3.0%. About 2.0% of adults report symptoms that meet criteria for the diagnosis within the prior year. Many more individuals suffer from OCD symptoms that do not reach diagnostic thresholds. Approximately 90% of patients with OCD suffer from at least one additional psychiatric condition, mainly anxiety (75.8%), mood disorders (63.3%), impulse control (55.9%), and substance use disorders (38.6%). Patients report that OCD persists for a mean of 8.9 years. The duration, high morbidity, and significant role impairment place heavy demands on patients and families. The World Health Organization (WHO) ranks OCD as one of the 10 most disabling medical conditions worldwide.

The mean age of onset of OCD is 19.5 years, and new cases are rarely diagnosed after age 35. The majority of childhood and adolescent cases are in males. Nearly a quarter of males report onset before 10 years of age. The onset in females tends to be in adolescence and early adulthood. In adults, the prevalence is approximately equal in men and women. No strong evidence supports racial or ethnic difference in the prevalence of OCD.

### Risk Factors, Etiology, and Pathophysiology

Several studies confirm a familial pattern for OCD, especially in childhood-onset forms. Twin studies implicate both genetic and environmental factors. Multiple genes have been implicated,

notably areas on chromosomes 9 and 15. Current theory focuses on dysregulation in a network of genes influencing the glutamatergic, serotonergic, and dopaminergic systems, and possibly other parts of the brain, as underlying the development of OCD. The heritability of OCD is estimated to be approximately 40% with the remaining variation attributed to adverse environmental factors. Suggested environmental triggers for OCD include perinatal events, psychosocial stress, trauma, and inflammatory processes, especially streptococcal infection. Neuroimaging and neuropsychiatric studies indicate OCD-related changes in the cortico-striato-thalamo-cortical (CSTC) circuit, known to be critical in evaluating and taking steps to neutralize perceived threats.

Obsessive-compulsive disorder has several subtypes. Some of the childhood-onset forms are comorbid with Tourette's and other chronic tic syndromes. In adults, the common associations with schizophrenia or schizoaffective disorder, bipolar disorder, and eating disorders could indicate that the conditions have overlapping etiologies or that one condition is a risk factor for the other. Clinicians should have an increased awareness of the possibility of OCD in adolescent and young adult patients presenting with a range of psychiatric conditions.

### Clinical Manifestations

The core features of OCD are obsessions and compulsions (Table 1). Most patients have both. Obsessions are recurrent, persistent, and intrusive thoughts, urges, or images that are unwelcome and usually cause significant anxiety or distress. Patients attempt to ignore obsessions or to suppress or neutralize them by imposing other thoughts or performing specific activities. Compulsions are repetitive behaviors (e.g., handwashing, organizing, or checking) or activities (e.g., praying, counting, or repeating words silently) that the patient feels forced to perform in response to an obsession. Compulsions are characterized by rigid rules and inflexible behaviors but are not connected in a realistic way with what they are designed to neutralize or prevent and are clearly excessive responses to the intrusive thoughts, urges, or images.

Children may be unable to articulate symptoms and adults may be unwilling to disclose experiences that they recognize as abnormal. Individuals with OCD tend to be secretive about their symptoms, because most of them retain insight into the abnormal nature of their fears or behaviors. The estimated 14% to 30% of patients who have poor insight often have more severe and intractable symptoms. By the time patients present to medical attention, OCD is usually impacting function in society and/or eliciting concern from others about the patient's symptoms. The reported average time from onset of symptoms to diagnosis is 11 years. Other psychiatric conditions are commonly comorbid with OCD, and many patients present or are misdiagnosed as suffering primarily from depression or anxiety. Physical symptoms such as skin damage ("intractable dermatitis") from recurrent handwashing or scratching may be the presenting feature of OCD.

Without intervention, OCD is usually a chronic relapsing condition with adult rates of spontaneous remission estimated at about 20%. Remission in treated patients is associated with shorter duration of symptoms, emphasizing the need for prompt recognition and effective therapy. The risk of suicide is high in patients with OCD, particularly those with depression, posttraumatic stress disorder, or impulse control disorders. One large study reported that 20% made suicidal plans and 11% attempted suicide.

### Diagnosis

The diagnosis is based on clinical symptoms consistent with *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) criteria for obsessions and compulsions (see Table 1). The obsessions and compulsions must be time-consuming, often regarded as requiring more than 1 hour per day, or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Simple screening questions have been suggested (Table 2). Several more-detailed inventories are available to document symptoms and their impact, but these are of limited use in diagnosis in a primary care setting.

**TABLE 1** Examples of Common Obsessions and Compulsions

OBSSESSIONS	COMPULSIONS
Contamination or infection (“germophobia”)	Avoidance of people or situations perceived as dirty, infectious, or corrupting; excessive cleaning or use of protective materials (surgical gloves, masks, sanitizer)
Control: Fear of losing control of speech or actions in public; making inappropriate comments; doing shameful or hurtful activities in public; inviting ridicule or negative reactions from others	Avoidance of others and public places; guarded behavior and curtailed speech to minimize contact with others
Religious, especially unworthiness, sinfulness, guilt	Praying, ritualizing acts of penance, seeking forgiveness (expression depends on religious belief/tradition of patient)
Sexual: concerns about acting inappropriately or being deviant	Avoidance of sexual situations, materials
Symmetry, correctness, precision	Arranging, ordering, scheduling, checking; “correcting” work of others
Violence; fear of harming others or becoming dangerous	Vigilance, attention to violent incidents, requiring reassurance

**TABLE 2** Examples of Screening Questions for Obsessive-Compulsive Disorder

- Do you check things repeatedly or wash your hands over and over?
- Do you have unpleasant or unusual thoughts that you can’t seem to get rid of?
- Do you need things symmetrically arranged or always in a certain order?
- Do you have trouble discarding things, so that your house is quite cluttered?

A diagnosis of OCD also requires eliminating other potential causes of symptoms, as described next.

**Differential Diagnosis**

Identifying underlying OCD may be challenging in patients presenting with depression, anxiety, or another comorbidity. Some key features help in distinguishing OCD from these conditions (Table 3).

Insight distinguishes OCD from delusions and other features of schizophrenia. An important distinction is between OCD and obsessive-compulsive personality disorder (OCPD). In OCPD, behavior is ego-syntonic, that is, driven by desire or pleasure seeking rather than fear. Clinical OCD also needs to be distinguished from normal individuals who are meticulous and have rigid, inflexible thought processes or from individuals who describe compulsive behaviors such as eating or gambling that are or were pleasurable.

Obsessive-compulsive symptoms can occur in several neurologic conditions such as brain trauma, stroke, encephalitis, temporal lobe epilepsy, Prader-Willi syndrome, Huntington disease, Parkinson disease, carbon monoxide poisoning, or manganese poisoning, but these can usually be identified by the predominant other symptoms.

**Treatment and Monitoring**

Obsessive-compulsive disorder is a chronic condition with low frequency of spontaneous improvement but high probability of

**TABLE 3** Key Features That Help with Differential Diagnosis

ALTERNATIVE DIAGNOSIS	SYMPTOMS TYPICAL OF OBSESSIVE-COMPULSIVE DISORDER (OCD)	SYMPTOMS TYPICAL OF ALTERNATIVE DIAGNOSIS
Depressive disorders	Focus and content of obsessions is usually broader	Content of depressive ruminations is self-criticism, failures, guilt, regret, or pessimism
Generalized anxiety disorder	Obsessions may not be reality based Rituals may be present	Worries focus on real-life problems, generally more vague Usually no rituals
Posttraumatic stress disorder	Intrusive thoughts are anticipation of future events	Intrusive thoughts are replay of actual events
Schizophrenia, mania	Content is related to OCD Insight usually present	Content is related to persecution, grandiosity, ideas of reference Insight usually absent
Hypochondriasis	Insight usually present Origin is external based	Insight usually absent Origin is misinterpretation of physical signs and symptoms

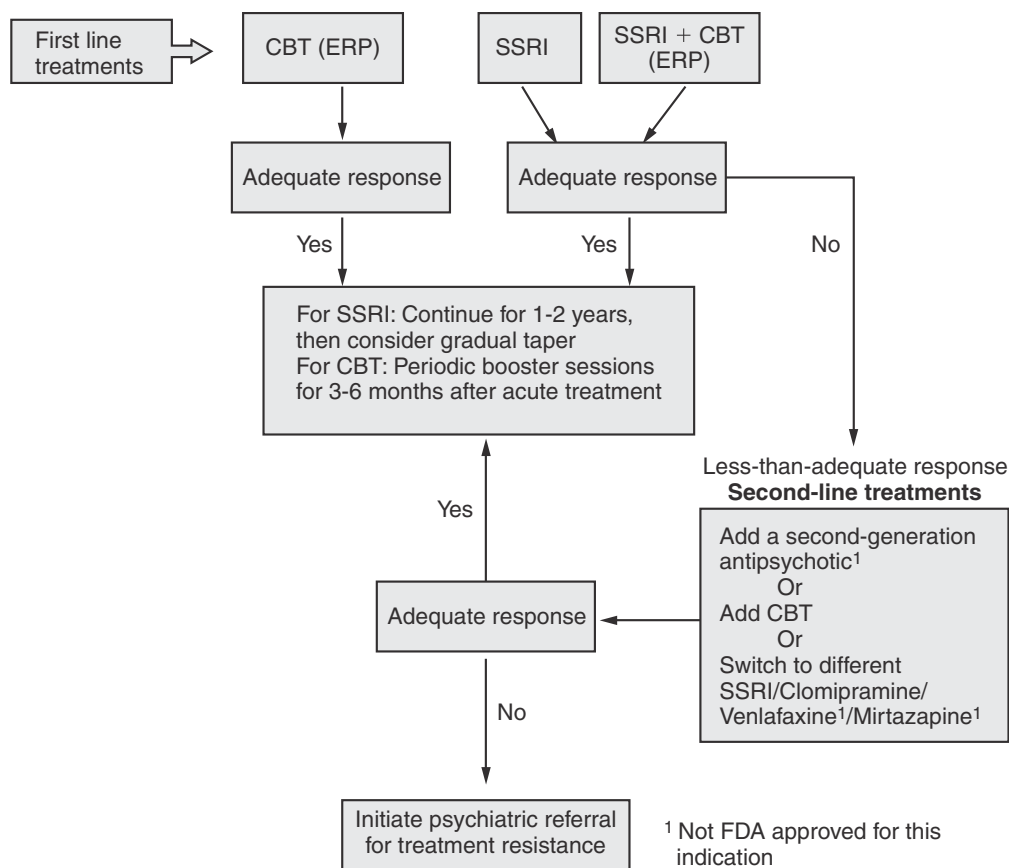

response to therapy if adherence and social support are maintained and comorbidities addressed. Short-term and long-term treatment goals should be established with each patient and those in his or her support system. Goals should focus on management of symptoms to optimize function and quality of life rather than complete resolution of symptoms. Adherence is critical to prognosis. Close follow-up must be secured, especially early in treatment. Given the secretive nature of the illness, the initial presentation may be the only chance to engage these patients in treatment, and must not be missed. Providing patients and families with educational information and access to community resources can help with adherence and social stabilization. Education for patients and others regarding what to expect from pharmacotherapy, including potential adverse effects and the lag period before benefit, can help ease anxiety and improve adherence and prognosis.

Once the diagnosis of OCD has been confirmed, the appropriate setting and strategy for treatment must be decided. The spectrum of treatment settings includes outpatient, adult partial-day programs, residential facilities, and inpatient psychiatric hospitalization. Factors such as suicide assessment, severity of illness, treatment cost, insurance coverage, and social support availability need to be explored to determine the optimal treatment environment.

Both pharmacotherapy and psychotherapy are recommended first-line treatment either alone or in combination (Figure 1). Combined therapy may be more effective than pharmacotherapy alone but has not been shown to be superior to behavioral therapy. Combination therapy may be most useful in patients with a coexisting psychiatric condition for which SSRIs are effective, those with poor response to initial monotherapy, or those who wish to discontinue medication as soon as possible. Practice guidelines recommend use of an approved symptom rating scale to monitor response to therapy, such as the 10-item Yale-Brown Obsessive Compulsive Scale (Y-BOCS).

**Pharmacotherapy**

SSRIs are first-line treatment agents for OCD (Table 4). Fluoxetine (Prozac), clomipramine (Anafranil), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft) are approved by the U.S. Food

**Figure 1** Treatment algorithm for obsessive-compulsive disorder.

**TABLE 4** Dosing of Selective Serotonin Reuptake Inhibitors (SSRIs) to Treat Obsessive-Compulsive Disorder

SSRI	DOSAGE (MG/DAY)		USUAL MAXIMAL
	STARTING	TARGET	
Citalopram (Celexa)*	20	40	40
Escitalopram (Lexapro)*	10	20	40 <sup>†</sup>
Fluoxetine (Prozac)	20	40–60	80
Fluvoxamine (Luvox)	50	200	300
Paroxetine (Paxil)	20	40–60	60
Sertraline (Zoloft)	50	200	200

\*Not U.S. Food and Drug Administration approved for this indication.

<sup>†</sup>Exceeds dosage recommended by the manufacturer.

and Drug Administration (FDA) and appear to be equally effective. Medication selection depends on factors including adverse effect profile, cost, concomitant medications, comorbid medical conditions, previous experience with the medication, and patient preference. The selected medication should be initiated at low dose and slowly titrated to effective levels. The optimal response may require a dose exceeding the manufacturer's recommended maximum dose. The "start low, go slow" strategy minimizes adverse effects, especially in older patients, and improves adherence. Common adverse effects include gastrointestinal upset, agitation, insomnia, fatigue, and sexual side effects. Many adverse effects are transitory. Serotonin syndrome is a serious potential risk at high doses. Patients with OCD are at risk of suicide and self-harm, but studies do not indicate increased risk in those treated with SSRIs, including adolescents.

Most patients will not experience substantial improvement for 4 to 6 weeks, and many require 10 to 12 weeks of treatment at optimal

dosage. Although full remission of symptoms is reported in only about 10% of patients treated with SSRIs, 40% to 65% improve. The mean improvement in symptoms is 20% to 40%. Effective therapy should be maintained for at least a year and possibly indefinitely. If medication is discontinued, gradual tapering is recommended. Relapse rates in patients who discontinue medication after 2 years of treatment are 25% to 40% and up to 80% after shorter periods of treatment.

If response continues to be inadequate and adherence is confirmed, options include changing the primary agent to clomipramine, venlafaxine (Effexor),<sup>1</sup> or mirtazapine (Remeron),<sup>1</sup> or augmentation with a second-generation antipsychotic agent. Referral to a psychiatric provider with expertise in OCD therapy may be the best option for treatment-resistant cases.

A patient may respond well to a different SSRI, but a full trial of several weeks at adequate dose is necessary before changing medication. Clomipramine is as effective as SSRIs but carries safety concerns. It is strongly serotonergic and anticholinergic and may increase risk of seizure or cardiac arrhythmia. Addition of risperidone (Risperdal)<sup>1</sup> and possibly aripiprazole (Abilify)<sup>1</sup> may benefit some treatment-resistant patients. The efficacy of quetiapine (Seroquel)<sup>1</sup> and olanzapine (Zyprexa)<sup>1</sup> is unclear. All antipsychotic agents require careful monitoring for adverse effects. Medications sometimes used for OCD but with only limited evidence of efficacy include topiramate (Topamax),<sup>1</sup> ondansetron (Zofran),<sup>1</sup> pindolol,<sup>1</sup> buspirone,<sup>1</sup> memantine (Namenda),<sup>1</sup> pregabalin (Lyrica),<sup>1</sup> N-acetylcysteine (Acetadote),<sup>1</sup> naltrexone (Vivitrol),<sup>1</sup> and riluzole (Rilutek).<sup>1</sup>

#### Psychological Therapy

The strongest evidence for effective behavioral treatment of OCD supports exposure and response prevention (ERP), a form of cognitive-behavioral therapy (CBT) in which patients learn alternative responses to anxiety-provoking stimuli or situations. Weekly or twice-weekly sessions for a total of 20 to 30 hours are recommended followed by monthly "booster" sessions for 3 to 6 months.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 5** List of Educational Resources for Patients and Their Families

2. Obsessive-Compulsive Information Center: <http://www.miminc.org/aboutocic.html>.
3. Baer L. *Getting Control: Overcoming Your Obsessions and Compulsions*. New York: Plume Books; 2000.
4. Gravitz HL. *Obsessive Compulsive Disorder: New Help for the Family*. Santa Barbara, CA: Healing Visions Press; 1998.
5. Steketee GS. *Overcoming Obsessive-Compulsive Disorder: Client Manual*. Oakland, CA: New Harbinger Publications; 1999.
6. Van Noppen B, Pato M, Rasmussen S. *Learning to Live with OCD*. New Haven, CT: Obsessive Compulsive Foundation; 2003.

Studies report considerable reduction in symptoms in up to 80% of patients with improvement maintained for up to 5 years. Remote-delivery formats of ERP using the telephone, a computer, or the Internet may provide effective and more accessible alternatives to traditional therapist consultation. ERP therapy not only is first-line treatment for OCD but also has strong evidence of effectiveness as an augmentation strategy to pharmacotherapy.

Cognitive therapy focusing on recognizing and changing interpretation of unrealistic thoughts is also associated with improvement in 60% to 80% of patients with OCD and is a good alternative for those unwilling to undertake ERP.

### Other Treatment Options

Deep brain stimulation at the ventral capsule/striatum was approved by the FDA in 2009 for refractory OCD. Good results are reported in about half of patients treated in small trials compared with sham stimulation. Neurosurgical procedures may be recommended for selected patients with intractable OCD. Robust trials of ERP, two or more treatments with different SSRIs, a course of clomipramine, and at least three trials of augmentation therapy are recommended before considering neurosurgical approaches. These include ablative surgeries such as anterior cingulotomy, anterior capsulotomy, subcaudate tractotomy, and limbic leucotomy. These last-resort invasive procedures have had mixed success and carry risk of serious adverse effects. The American Psychiatric Association (APA) warns that they should be performed only at specialist centers.

Table 5 provides a list of educational resources for patients and their families.

## PANIC DISORDER

Method of

Cheryl Wehler, MD

### CURRENT DIAGNOSIS

- Panic disorder (PD) is characterized by the presence of multiple untriggered panic attacks.
- These unexpected panic attacks are associated with significant anticipatory anxiety and/or changes in behavior to minimize the consequences or avoid another panic attack.
  - Patients worry about being negatively judged due to visible panic symptoms.
  - Patients worry about dying or “going crazy.”
- The panic attacks are not attributable to another medical condition or to the effects of a substance (medication or drug of abuse).
- The panic attacks are not better explained by another mental disorder.
- Patients frequently present with concern about somatic symptoms (e.g., fear of heart attack because of shortness of breath and chest discomfort).
- Assess patients for suicidality, as suicide risk increases with panic attacks or recent diagnosis of panic disorder.

### CURRENT THERAPY

- Pharmacology and psychotherapy are effective treatments for PD.
- Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and benzodiazepines have demonstrated efficacy for the treatment of PD.
- The favorable safety profile of SSRIs and SNRIs make them first-line monotherapy agents.
- Although TCAs are effective, their side effects and greater toxicity in overdose limit their clinical utility.
- Monoamine oxidase inhibitors (MAOIs) also appear effective but are reserved for patients who are nonresponders to multiple first-line treatments because of their safety profile limitations.
- Benzodiazepines are not first-line monotherapy but are useful adjuncts to antidepressants if residual anxiety requires additional treatment.
- Although the more rapid response of benzodiazepines (compared with SSRIs/SNRIs) make them attractive, the inevitable physiological dependence make them less so.
- Patients with PD can be sensitive to medication side effects; therefore the adage “start low and go slow” is applicable to dosing.
- Cognitive behavioral therapy (CBT) or CBT with medications are first-line treatments for children and adults with PD.

### Epidemiology

The 12-month prevalence estimate for panic disorder (PD) in the general population of the United States and Europe is approximately 2% to 3% in adults and adolescents. Non-Latino Caucasians and Native Americans have significantly higher rates than Latinos, African Americans, and Asian Americans. Adolescent and adult females are approximately twice as likely as males to be affected (although the clinical features of PD do not differ between males and females). The prevalence is highest in adult females. Prevalence rates decline in older individuals. The overall prevalence of PD is low in children (<14 years). PD is associated with the highest number of medical visits among all anxiety disorders.

## Risk Factors

Risks factors for PD include a disposition to negativity, experience of childhood physical and sexual abuse, and family history, indicating genetic vulnerability. Respiratory disorders such as asthma are associated with panic disorder. Smoking is a risk factor for panic attacks and PD. PD is associated with social and occupational/physical disability and high economic cost. PD may be comorbid with a variety of other psychiatric diagnoses, such as depression, bipolar affective disorder, and other anxiety disorders.

## Diagnosis

PD is defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V) as recurrent unexpected panic attacks followed by at least 1 month of anticipatory anxiety about having another attack, and a significant change in behavior to avoid another panic attack. A panic attack, the core feature of panic disorder, is an abrupt surge of intense fear/anxiety with concurrent physical and cognitive symptoms (Box 1). To be diagnosed as having PD, a patient must have more than one

### BOX 1 DSM-5 Criteria for Panic Disorder

- Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:  
Note: The abrupt surge can occur from a calm state or an anxious state.
  - Palpitations, pounding heart, or accelerated heart rate
  - Sweating
  - Trembling or shaking
  - Sensations of shortness of breath or smothering
  - Feelings of choking
  - Chest pain or discomfort
  - Nausea or abdominal distress
  - Feeling dizzy, light-headed, faint, or unsteady
  - Chills or heat sensations
  - Paresthesia (numbness or tingling sensations)
  - Depersonalization (being detached from oneself) or derealization (feelings of unreality)
  - Fear of “going crazy” or losing control
  - Fear of dying
 Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms [to diagnose PD].
- At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
  - Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”)
  - A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations)
- The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders)
- The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder)

panic attack that is not the result of an obvious trigger or cue. The best example might be a nocturnal panic attack in which the individual is waking from sleep, with no external cues, in a state of intense fear (panic) and experiencing physical and cognitive symptoms. Expected panic attacks, that is, those for which there is an obvious cue or trigger, also occur in patients with PD. In the United States and Europe, approximately half of individuals with PD experience expected panic attacks as well as unexpected panic attacks. The presence of expected panic attacks does not rule out the diagnosis but is insufficient to make the diagnosis of this disorder.

A thorough diagnostic evaluation, including a complete history and thorough physical examination, is necessary to rule out medical or substance-induced panic attacks and establish the diagnosis of PD. Atypical symptoms or features of a panic attack may be suggestive of a medical illness or pharmacologic substance as the precipitant. A workup that includes laboratory tests such as complete blood cell count, complete chemistry panel (including calcium level), thyroid-stimulating hormone (TSH) level, and urine drug screen may be helpful in determining a medical or substance-related cause. These tests may be followed by a chest radiograph, an electrocardiogram, and cardiac enzymes, as warranted. If the clinical examination or history is suggestive, a Holter monitor, EEG, CT scan, or urine catecholamine assay may be performed.

## Clinical Manifestations

In the United States, the median age of onset for PD is 20 to 24 years. PD is rare in childhood but occurs in adolescents; their symptoms are similar to those in adults. Onset after age 45 is unusual. If untreated, the usual course is chronic, and attacks may wax and wane. Some individuals have a chronic course complicated by frequent attacks whereas others have rare episodic symptoms. A minority of individuals have full remission. Caffeine and several other substances can provoke a panic attack.

The severity and frequency of panic attacks vary widely. Individuals who have infrequent panic attacks resemble individuals with more frequent panic attacks with regard to symptoms, demographics, and family history. To be diagnosed with PD, an individual must have more than one full-symptom attack with more than four of the symptoms listed in Box 1. Individuals may, however, have limited-symptom attacks with fewer than four symptoms.

There are three symptomatic facets of PD: acute panic, anticipatory anxiety, and phobic avoidance. Phobic avoidance often includes restricting daily activities to minimize or avoid panic attacks. Panic disorder is associated with other psychopathology, such as other anxiety disorders, particularly agoraphobia.

Although medical illness can precipitate a panic attack, individuals with anxiety, particularly PD, may be hypervigilant and misinterpret mild physical symptoms as harbingers of a catastrophic or fatal illness. Individuals with PD often report feelings of anxiety that are associated with health or mental health concerns.

Panic attacks often contribute to the presentation of other psychiatric illnesses, such as other anxiety disorders and major depression. A thorough history that documents the onset of symptoms, possible triggers, and context of symptoms is critical to establishing the diagnosis of PD. In addition to the history of the present illness and current symptoms, a psychiatric review of symptoms, past psychiatric history, general medical history and current medications, substance use history, family history, and mental status exam are valuable in constructing a psychiatric differential diagnosis and then a final working diagnosis. For instance, an individual with a history of a past trauma presenting with flashbacks, nightmares, and triggered panic attacks may have posttraumatic stress disorder (versus panic disorder).

Suicidal behavior in individuals with anxiety disorders has long been attributed to co-occurring risk factors, such as depression. New research suggests that an anxiety disorder is associated with suicidal ideation and suicide attempts beyond the effects of co-occurring mental disorders. Panic attacks and a recent diagnosis of PD are associated with a higher rate of suicide attempts and suicidal ideation.

### Differential Diagnosis

The differential diagnosis of PD is wide ranging (Table 1). PD is not diagnosed if panic attacks are the direct physiological consequence of another medical condition or substance. Medical conditions that can cause panic attacks include cardiopulmonary conditions such as arrhythmias and asthma or chronic obstructive pulmonary disease (COPD). Endocrine and neurologic disorders such as hyperthyroidism, pheochromocytoma, vestibular dysfunction, and seizures may also cause panic attacks. In addition, central nervous system (CNS) stimulants and withdrawal from CNS depressants may precipitate a panic attack. On the other hand, a panic attack may mimic a wide variety of medical disorders.

### Treatment

PD is a common mental disorder. It is associated with social and occupational/physical disability and high economic cost. When symptoms cause significant distress or interfere with functioning, treatment is warranted. Regardless of the modality chosen, the goal of treatment is a reduction in the frequency and severity of panic attacks as well as the resultant anticipatory anxiety and avoidance behaviors.

Research has confirmed the efficacy of multiple psychosocial and pharmacologic interventions in treating PD. Choice of treatment depends on multiple factors, including patient preference; risks and benefits for an individual patient; cost; past treatment history; and co-occurring medical, psychiatric, or substance abuse issues.

Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and benzodiazepines have demonstrated efficacy for the treatment of PD. The favorable safety profile of SSRIs and SNRIs makes them first-line monotherapy agents. Although TCAs are effective, their side effects and toxicity in overdose limit their clinical utility. Monoamine oxidase inhibitors (MAOIs) also appear effective but are reserved for patients who are nonresponders to multiple first-line treatments because of their safety profile. Benzodiazepines are not first-line monotherapy but are useful adjuncts to antidepressants if residual anxiety requires additional treatment (Table 2).

An important consideration when using psychopharmacologic treatments in PD is the side-effect profile of a particular agent. Because patients with PD can be acutely sensitive to medication side effects, it is prudent to start medications at low doses and gradually increase them to therapeutic doses as tolerated. An effective dose is patient dependent—the goal is to prevent (versus respond to) panic attacks. If a decision is made to discontinue a SSRI, SNRI, or TCA, the medication should be gradually tapered when feasible.

**TABLE 1** Differential Diagnosis of Panic Attacks

SYSTEM	POSSIBLE DIAGNOSES
Psychiatric	Mood disorder (panic attacks associated with depression or bipolar disorder) Anxiety disorders (panic attacks associated with social anxiety, specific phobia, posttraumatic stress disorder, generalized anxiety disorder, obsessive compulsive disorder) Agoraphobia Psychotic disorder (panic attacks associated with psychosis) Somatoform disorder Factitious disorder
Cardiac	Myocardial infarction Angina SVT or other arrhythmia Mitral valve prolapse Labile hypertension
Respiratory	Asthma COPD Pulmonary embolus
Neurologic	Seizure disorder Vestibular dysfunction
Endocrine	Thyroid disorder Hypoglycemia Adrenal dysfunction Hyperparathyroidism Pheochromocytoma
Substance Use	Excess caffeine Psychostimulants
Substance	Caffeine
Withdrawal	Nicotine Alcohol or sedative Opioid

**TABLE 2** Pharmacologic Treatments of Panic Disorder

MEDICATION (TRADE NAME)	INITIAL DOSE (MG/DAY)	DOSE RANGE (MG/DAY)
<b>SSRIs</b>		
Citalopram (Celexa) <sup>1</sup>	10–20	20–40
Escitalopram (Lexapro) <sup>1</sup>	5–10	10–20
Fluoxetine (Prozac)	10–20	20–80

Fluvoxamine CR (Luvox CR) <sup>1</sup>	100	100–300
Paroxetine (Paxil)	10–20	20–60
Paroxetine CR (Paxil CR)	12.5–25	25–75
Sertraline (Zoloft)	25	50–200
<b>SNRIs</b>		
Duloxetine (Cymbalta) <sup>1</sup>	30	60–120
Venlafaxine (Effexor) <sup>1</sup>	25–50	150–225
Venlafaxine ER (Effexor ER)	37.5	75–225
<b>TCAs</b>		
Desipramine (Norpramin)	25–50	100–200
Clomipramine (Anafranil) <sup>1</sup>	25	50–150
Imipramine (Tofranil) <sup>1</sup>	25	50–150
Nortriptyline (Pamelor) <sup>1</sup>	10–25	75–150
<b>MAOIs</b>		
Phenelzine* (Nardil) <sup>1</sup>	45 <sup>†</sup>	45–75 <sup>§</sup>
<b>Benzodiazepines</b>		
Alprazolam (Xanax)	0.25–0.5 tid	5–6
Alprazolam XR (Xanax XR)	0.5–1	3–6
Lorazepam (Ativan) <sup>1</sup>	0.25 tid	2–8 <sup>‡</sup>
Clonazepam (Klonopin)	0.25 bid	0.5–2 <sup>†</sup>

<sup>1</sup>Not FDA approved for this indication.

\*Dietary restrictions required (low-tyramine diet); 2-week washout required before initiation and after termination of monoamine oxidase inhibitor (MAOI) trial.

<sup>†</sup>Divided doses may be given.

<sup>‡</sup>Total daily dosage divided across 2–4 doses/day.

<sup>§</sup>Usually administered tid.

Cognitive behavioral therapy (CBT) and CBT with medications are first-line treatments for children and adults with PD. CBT presents the most evidence of efficacy from random control trials. CBT for panic disorder generally includes psychoeducation, episode monitoring and response, self-awareness of anxious automatic thoughts and beliefs, controlled exposure to fear cues, modification of anxiety-reducing behaviors, and prevention of relapse. Psychosocial interventions, such as CBT, may enhance long-term outcomes by reducing the likelihood of relapse.

## POSTTRAUMATIC STRESS DISORDER

Method of

Natalie C. Dattilo, PhD

### CURRENT DIAGNOSIS

- Posttraumatic stress disorder (PTSD) is quickly becoming one of the most common psychiatric disorders seen in the primary care setting.
- PTSD is diagnosed after a person experiences symptoms for at least 1 month following a traumatic event. However, symptoms may not appear until several months or even years later and can persist as a chronic condition.
- The disorder is characterized by three main types of symptoms: (1) reexperiencing the trauma through distressing recollections, (2) emotional numbness and behavioral avoidance, and (3) increased arousal such as feeling jumpy and easily angered.
- A thorough medical examination and laboratory workup may be indicated to rule out contributing physiologic factors and comorbidities, substance use or misuse, and drug or alcohol withdrawal.
- Symptoms that are persistent, disruptive, or distressing warrant treatment.
- The PTSD Checklist-5 (PCL-5) is a 20-item self-report measure that assesses the 20 *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) symptoms of PTSD. The gold standard for diagnosing PTSD is a structured clinical interview such as the Clinician-Administered PTSD Scale (CAPS-5). When necessary, the PCL-5 can be scored to provide a provisional PTSD diagnosis.

### CURRENT THERAPY

- Effective treatments for PTSD include serotonergic antidepressants, certain forms of trauma-based psychotherapy, or a combination of both.
- Educating the patient and family members about treatment options and setting realistic treatment expectations are critical.
- Depending on the patient's preference, treatment may include a selective serotonin reuptake inhibitor (SSRI) starting at low doses with careful titration so as not to exacerbate anxiety or agitation.
- Treatment may also include a trial of cognitive-behavioral therapy, cognitive processing therapy, or prolonged exposure therapy to boost response rates and prevent relapse.
- Refer to or consult with a psychiatrist for patients with severe or particularly complex cases or for patients with a less-than-expected response to treatment.
- Refer to a cognitive-behavioral therapy specialist for patients with a preference for behavioral, skills-based, or nonmedication therapy or for whom pharmacotherapy may be contraindicated.

### Epidemiology

In the United States, it is estimated that PTSD is diagnosed in approximately 10.5 million adults (3.5%) each year, and approximately 20.4 million (6.8%) will meet criteria over the course of their lifetimes. The lifetime prevalence of PTSD among men is 3.6% and among women is 9.7%. The 12-month prevalence is 1.8% among men and 5.2% among women. As with depression and anxiety disorders, patients with PTSD are more likely to present initially to a general practitioner's office than to a mental health care provider.

Owing, in part, to increased public awareness, PTSD is quickly becoming one of the most frequently seen clinical problems in primary care. Symptoms frequently overlap with other complaints, such as insomnia, irritability, or pain. Most behavioral symptoms of PTSD are a result of anxiety and hypervigilance, and the clinical presentation shares many phenotypic similarities with other anxiety disorders, such as panic disorder (PD) and generalized anxiety disorder (GAD).

### Risk Factors

Risk factors associated with PTSD include exposure to trauma, being female, having lower levels of education and income, being divorced or widowed, having a history of behavioral or psychological problems, family history of behavioral or psychological problems including substance abuse, recent increase in stressful life events, lack or perceived lack of social support, ineffective emotional coping strategies, experiencing childhood adversity or trauma, having a chronic health condition or serious illness, having an acute or chronic pain condition, and substance abuse. Although a genetic predisposition to developing PTSD is likely, environmental stress and early trauma clearly play a role.

### Pathophysiology

Our current understanding of PTSD is incomplete; however, several neurobiologic systems have been implicated in the pathophysiology and vulnerability toward developing PTSD after trauma exposure. As in other anxiety disorders, PTSD symptoms are believed to be due to dysregulation of neuronal activity within the central nervous system (CNS), in particular the fear circuit. This dysregulation causes a state of hyperarousal, which gives rise to the physical and emotional manifestations of the condition. Several neurotransmitter systems have been implicated in the genesis of this hyperaroused state. Overstimulation of the CNS and

the autonomic sympathetic activity it generates affect the prefrontal cortex and the limbic system (e.g., amygdala, hypothalamus), both of which play an important role in our ability to discern stimuli as aversive or threatening and regulate our stress response.

The two most commonly implicated neurotransmitter systems to date include the serotonergic and noradrenergic neurotransmitter systems. Very simply, it is believed that an underactivation of the serotonergic system and an overactivation of the noradrenergic system are involved. These systems interact with other neuronal circuits in various regions of the brain, including the locus ceruleus (LC) and the limbic structures, resulting in a dysregulation of physiologic arousal and the emotional interpretation of this arousal, respectively. Disruption of the  $\gamma$ -aminobutyric acid (GABA) system has also been implicated because of the response of many of the anxiety-spectrum disorders to treatment with benzodiazepines.

There has also been some interest in the role of corticosteroid regulation and its relation to symptoms of fear and anxiety. Corticosteroids might increase or decrease the activity of certain neural pathways, affecting not only an individual's behavior under stress but also how the brain perceives and processes threatening stimuli. The stress response is hardwired into the brain and is most often triggered when survival of the organism is threatened. The stress response, however, can be triggered not only by a physical challenge or threat but also by the mere anticipation (or fear) of threat. As a result, when humans chronically and erroneously believe that a threatening event is about to occur, they begin to experience the physical and psychological symptoms of anxiety and panic.

The hypothalamic–pituitary–adrenal (HPA) axis is another neurocircuit implicated in the initiation of a stress response. The HPA axis assists with the adaptation to stress and the maintenance of homeostasis after challenge. It connects the CNS and the endocrine system, and a dysfunctional HPA axis is associated with numerous psychosomatic and psychiatric disorders. Corticotropin-releasing factor (CRF) is a molecule produced by cells in the hypothalamus in response to physical or psychological stress. Increased levels of CRF in the hypothalamus in response to stress results in the activation of the HPA axis and increased release of cortisol. It is believed that high CRF levels at the time of trauma may facilitate encoding of traumatic memory and enduring anxiety effects. Patients with PTSD exhibit increased cerebrospinal fluid levels of CRF and other abnormalities in the HPA axis system.

Finally, a subcortical neural structure, the amygdala, serves an important role in coordinating the cognitive, affective, neuroendocrine, cardiovascular, respiratory, and musculoskeletal components of fear and anxiety responses. It is central to registering the emotional significance of stressful stimuli and creating emotional memories. The amygdala receives input from neurons in the sensory cortex. When activated, the amygdala stimulates regions of the midbrain and brainstem, causing autonomic hyperactivity, which can be correlated with the physical symptoms of anxiety.

### Prevention

No biological markers are specific enough yet to detect which individuals are more likely to develop PTSD after experiencing a trauma, and there is no available evidence to suggest that current medications prove efficacious in preventing this disorder. Therefore it is important to screen for specific risk factors, such as exposure to trauma (either recent or remote), family history of mental health issues, recent increase in stressful life events, or substance abuse. If a person is found to be at risk, but not symptomatic, he or she should first be encouraged to adopt healthy lifestyle habits. Aerobic exercise and other forms of physical activity have been shown to relieve stress and anxiety and improve mood relatively quickly. These patients should also be encouraged to avoid stimulants such as caffeine and nicotine, which can exacerbate symptoms and contribute to insomnia. It is also highly recommended

that anxiety-prone persons manage stress by learning effective methods of behavioral relaxation, applied meditation, and other healthy stress reduction techniques.

### Clinical Manifestations

PTSD can manifest in many ways. Behavioral signs may include increased alcohol consumption, change in communication, change in sexual functioning, emotional outbursts, inability to rest or relax, change in appetite, pacing, suspiciousness, self-destructive behavior, or social isolation. Cognitive signs may include changes in alertness, confusion, hypervigilance, memory problems, poor attention and concentration, poor decision making or problem solving, and suicidal ideation. Emotional signs may include agitation, anxiety, apprehension, depression, fear, feeling overwhelmed, grief, guilt, irritability, and loss of emotional control. Sleep is also affected for individuals suffering from PTSD, and they will often report insomnia or nightmares. Other common features include a sense of emotional detachment from others and unwanted or intrusive thoughts; however, these can be difficult for clinicians to identify and patients rarely self-report. Physical symptoms can include chills, difficulty breathing, dizziness, elevated blood pressure, fainting, fatigue, grinding teeth, headaches, muscle tremors, nausea, pain, profuse sweating, rapid heart rate, twitches, and weakness. These symptoms cause significant distress and impairment of function.

### Diagnosis

A diagnosis of PTSD is made when the patient meets specific diagnostic criteria as outlined in the DSM-5. In previous versions of the DSM, PTSD was categorized as an anxiety disorder. The diagnosis of PTSD now falls under its own category of mental disorders, called “Trauma and Stressor-Related Disorders,” owing to the myriad ways it can present clinically.

PTSD may develop after a person experiences, witnesses, or confronts a physically or psychologically traumatic event. The event may involve actual or threatened death, serious or life-threatening injury or threat of severe injury, or sexual violence or threat of sexual violence. An individual may directly experience the traumatic event; witness, in person, the traumatic event; or learn that the traumatic event occurred to a close family member or close friend. An individual may also develop PTSD after experiencing repeated or extreme exposure to aversive details of the traumatic events. Examples may be first responders collecting human remains or police officers repeatedly exposed to details of child abuse. Note: This does not apply to exposure through electronic media, television, movies, or pictures, unless exposure is work related.

The disorder is characterized by three main types of symptoms: (1) reexperiencing the trauma through distressing recollections, (2) emotional numbness and behavioral avoidance, and (3) increased arousal such as feeling jumpy and easily angered.

A diagnosis of PTSD can be made in adults, adolescents, and children over the age of 6 when one or more of the following reexperiencing symptoms are present:

- Spontaneous or cued recurrent, involuntary, and intrusive distressing memories of the traumatic events (Note: In children repetitive play may occur in which themes or aspects of the traumatic events are expressed.)
- Recurrent distressing dreams in which the content or affect (i.e., feeling) of the dream is related to the events (Note: In children there may be frightening dreams without recognizable content.)
- Flashbacks or other dissociative reactions in which the individual feels or acts as if the traumatic event is recurring (Note: In children trauma-specific reenactment may occur in play.)
- Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic events
- Physiologic reactions to reminders of the traumatic events

A diagnosis of PTSD can be made in adults, adolescents, and children over the age of 6 when two or more of the following emotional numbness or behavioral avoidance symptoms are also present:

- Inability to remember an important aspect of the traumatic events (not due to head injury, alcohol, or drugs)
- Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., “I am bad,” “No one can be trusted,” “The world is completely dangerous”)
- Persistent, distorted blame of self or others about the cause or consequences of the traumatic events
- Persistent fear, horror, anger, guilt, or shame
- Markedly diminished interest or participation in significant activities
- Feelings of detachment or estrangement from others
- Persistent inability to experience positive emotions

In addition to reexperiencing and avoidance, a diagnosis of PTSD can be made in adults, adolescents, and children over the age of 6 when two or more of the following marked changes in arousal and reactivity are also present:

- Irritable or aggressive behavior
- Reckless or self-destructive behavior
- Hypervigilance
- Exaggerated startle response
- Problems with concentration
- Difficulty falling or staying asleep or restless sleep

Finally, the diagnosis is made if the symptoms have been present for at least 1 month and cause clinically significant distress or impairment in functioning.

### Differential Diagnosis

It is important to perform a thorough medical workup when initially assessing the patient with PTSD symptoms. Differential diagnoses can include several organic causes, such as endocrine dysfunction, intoxication or withdrawal, hypoxia, metabolic abnormalities, and neurologic disorders. It is also important to consider and rule out any cooccurring psychiatric disorders. Major depression with or without suicidality, bipolar disorder, panic disorder, delusional disorder, polysubstance dependence, and adjustment disorder can often accompany PTSD, in addition to relationship problems and difficulty at work or in social situations.

It is not uncommon for patients with PTSD to report chronic pain or present with “ill defined” or “medically unexplained” somatic symptoms such as headaches, dizziness, tinnitus, and blurry vision or medical issues including diabetes, obesity, and cardiovascular, respiratory, musculoskeletal, neurologic, or gastrointestinal problems. Frequently reported medical comorbidities with PTSD across various studies include cardiovascular disease, especially hypertension, and immune-mediated disorders. Because PTSD is associated with limbic dysfunction and alterations in the HPA axis, neuroendocrine and immune function can be significantly disrupted, and because of its impact on the CNS, pseudo-neurologic symptoms and disorders of sleep–wake regulation are also common.

It is also not uncommon for patients with PTSD to “self-medicate” or cope with their symptoms by drinking alcohol, smoking cigarettes, or using drugs, including cannabis and prescription pain medications or anxiolytics. Studies show that people with PTSD have more issues with drugs and alcohol both before and after being diagnosed with PTSD. In addition, having PTSD increases the risk that one will develop a drinking or drug problem, even in the absence of any prior drug or alcohol use.

### Treatment and Monitoring

Current practice guidelines for the treatment of PTSD begin with education. Many people are confused, scared, or frustrated by the symptoms and behavior and are reassured to know they are not alone and that there are effective interventions. The patient should receive an appropriate medical workup, including a physical examination and studies (e.g., electrocardiogram,

thyroid-stimulating hormone) when indicated. In addition to treating any cooccurring or underlying medical conditions, developing a good working alliance with the patient and family provides a basis for ongoing disease management and prevents unnecessary utilization or overutilization of the medical system, as well as potential exacerbation of symptoms.

A combination of psychotherapy and medication management is recommended as first-line treatment for PTSD. Psychological treatments with the most robust empirical support include trauma-focused psychotherapies utilizing exposure techniques, cognitive restructuring, relaxation/stress modulation training, and psychoeducation.

Cognitive-behavioral therapy (CBT) is the most effective non-medication treatment for PTSD. The two types of CBT recommended for PTSD are cognitive processing therapy (CPT) and prolonged exposure (PE). In CPT one examines what he or she is thinking and telling him- or herself about the trauma and decides whether those thoughts are accurate or inaccurate. It can be done individually or in a group. PE works through repeated exposure to thoughts, feelings, and situations the person has been avoiding and helps him or her learn that reminders of the trauma do not have to be avoided. PE is done individually with a therapist. Both CPT and PE offer a skills-based approach to treatment. The therapist and patient work collaboratively and in an active and problem-solving manner. The work structured and generally short term with an emphasis on reducing symptoms. Volumes of evidence support the efficacy of CBT interventions for PTSD, but success requires commitment to treatment on the part of the patient. Its efficacy is also contingent upon the ability of the therapist and the length of time in treatment. Studies show that when compared with patients undergoing monotherapy, patients treated with a combination of CBT and medication experience nearly twice the remission rate.

If combination therapy is initiated owing to symptom severity or patient preference, the SSRIs have been shown to be the best-tolerated class of medications, and response rates are significantly higher than placebo. This class of medication includes fluoxetine (Prozac),<sup>1</sup> fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), paroxetine (Paxil), and sertraline (Zoloft). Some improvement should be noted within 3 or 4 weeks, and the dose should be increased if no improvement is seen. In all cases, SSRIs should be started at low doses and gradually titrated up to therapeutic levels to avoid an initial exacerbation of anxiety or agitation. Pharmacotherapy and psychotherapy options for the treatment of PTSD are presented in [Tables 1A and 1B](#).

Benzodiazepines, which have been commonly used in the past to treat anxiety symptoms, are not recommended except in cases of extreme impairment of function, for short-term use only, and only after a thorough substance abuse history has been obtained. The tolerability and lack of addiction potential make the SSRIs more desirable for long-term management, but the delay in response makes short-term symptom relief with a benzodiazepine desirable for those with the greatest impairment. Because of the risk for rebound anxiety when withdrawing from benzodiazepines with short half-lives, such as alprazolam (Xanax), many prefer the longer-acting benzodiazepines, such as clonazepam (Klonopin).<sup>1</sup> However, the addiction potential and the potential for abuse with either drug make this the treatment option of last resort.

If the patient does not respond to the combination of CBT and medication, a reevaluation of symptoms might reveal a comorbid disorder missed on first examination. Comorbid psychiatric disorders significantly lower the likelihood of recovery from PTSD and increase recurrence rates. Many clinicians try switching between SSRIs before considering the next step in treatment, but a referral to a psychiatrist for further evaluation and management may be necessary if this strategy does not work. Treatment-refractory anxiety can be extremely frustrating for both the patient and

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1A** Pharmacotherapy for the Treatment of Posttraumatic Stress Disorder

DRUG	STARTING DOSE	TARGET DOSE
<b>Selective Serotonin Reuptake Inhibitors</b>		
Paroxetine (Paxil)	10 mg qd	10–60 mg qd
Escitalopram (Lexapro)*	5–10 mg qd	10–20 mg qd
Sertraline (Zoloft)	12.5–25 mg qd	50–200 mg qd
Fluoxetine (Prozac)*	10 mg qd	20–40 mg qd

\*Not US Food and Drug Administration approved for this indication.

**TABLE 1B** Evidence-Based Psychotherapy for the Treatment of Posttraumatic Stress Disorder

PSYCHOTHERAPY	DESCRIPTION	FORMAT
<b>Trauma-Focused Cognitive-Behavioral Therapy (TF-CBT)</b>		
Cognitive processing therapy (CPT)	Teaches you to reframe negative thoughts about trauma	Weekly individual or group meetings
Prolonged exposure (PE)	Teaches you to gain control by facing your fears	Weekly individual meetings

clinician. This can lead to increased dependence on benzodiazepines and an escalation of doses required for the same effect.

When approaching the start of therapy, the clinician should reassure the patient that effective treatment is available but that patience may be necessary until the right combination of modalities is found. Although PTSD, like all anxiety disorders, displays a significant amount of chronicity, most patients have an improved outcome with appropriate treatment. Response rates improve when comorbidity is low. Patients with an earlier onset of symptoms (childhood or adolescence) can generally expect a more chronic course and may be more difficult to treat. Occasionally, patients can have a spontaneous remission of symptoms and many can continue to function despite their symptoms. However, time to resolution of symptoms is shortened and overall functioning can improve with treatment.

Pharmacotherapy often helps to prevent relapse, and rates are improved when effective treatment is continued for 12 months. When considering termination of pharmacologic treatment, the risk for relapse in all the disorders should be discussed with the patient. When discontinuing the SSRIs, a slow taper is recommended, with close monitoring for withdrawal symptoms (e.g., headache, gastrointestinal upset, restlessness, and other flu-like symptoms). Also monitor for rebound anxiety symptoms. If relapse occurs, reinstating treatment is indicated, and many patients opt for indefinite treatment to maintain remission of symptoms. Lifelong management with pharmacotherapy or psychotherapy, or both, is not unusual for many patients. For many, a maximum reduction of symptoms, rather than a full remission, is an acceptable outcome.

### Complications

Untreated anxiety disorders can lead to, or worsen, other mental and physical health conditions, including bruxism (teeth

grinding), cognitive impairment, depression, gastrointestinal disorders, headache, insomnia, heart disease, substance abuse, and significantly impaired quality of life.

### Conclusion

PTSD is a highly prevalent psychiatric condition that can be disabling and costly to the patient and to the health care system. Despite the prevalence of PTSD and other mental health disorders, a high percentage of patients often remain undiagnosed and untreated. These untreated patients also tend to be higher utilizers of general medical care. Patients with PTSD often present with multiple somatic complaints and comorbid disorders, causing great effort and expense in identifying the cause of unexplained symptoms. Once PTSD is identified, patients may be treated using well-tested and efficacious pharmacologic and psychotherapeutic treatments. Helpful resources for patients and families are listed in Table 2.

## CURRENT DIAGNOSIS

- There are three primary symptom domains in schizophrenia:
  - Positive symptoms (i.e., hallucinations, delusions, disorganized thought, and abnormal psychomotor behavior)
  - Negative symptoms (i.e., restricted affect or avolition/asociality)
  - Cognitive symptoms (i.e., attention, language, memory, and processing speed)
- Symptoms last  $\geq 1$  month and there are continuous signs of illness for  $\geq 6$  months.
- There is significant impairment one or more major areas of functioning (work, interpersonal relations, or self-care).
- Rule out that psychosis is not due to a primary mood disorder, schizoaffective disorder, substance intoxication or withdrawal, or a general medical condition.

## CURRENT THERAPY

- Antipsychotic medication, with monitoring for medication adherence and side effects.
- Adjunctive medications as needed, including antidepressants, mood stabilizers, benzodiazepines, beta-blockers, and anticholinergics.
- Aggressive monitoring for and management of medical comorbidities, substance use disorders, and suicidality, including collaboration with primary care physician.
- Psychosocial interventions.
- Involvement of family/support system in care.
- Long-term treatment, including outpatient medication management and therapy, with inpatient care for acute crisis intervention/illness exacerbation.

Schizophrenia is a complex, chronic, and often severe psychiatric disorder that is a leading cause of disability worldwide. Although the literal translation of the word schizophrenia is “split mind,” patients with this disorder do not have a “split personality” or “multiple personality disorder” (known as dissociative identity disorder). Rather, schizophrenia is a psychotic disorder that interferes with a person’s thinking, mood, behavior, and/or interpersonal relations. Schizophrenia often has devastating, lifelong consequences for affected individuals and their families and is associated with an increased risk of premature mortality, including deaths from suicide and cardiovascular disease. In this chapter, the epidemiology and diagnosis of schizophrenia are reviewed. We then discuss pharmacologic and psychosocial treatments for schizophrenia in the context of a chronic disease model. The risks of medical and substance use comorbidity and suicidality are also highlighted.

### Epidemiology and Risk Factors

The etiology of schizophrenia is not known, but it is thought to involve interactions between genetic (or epigenetic) and environmental factors, including developmental problems that occur during gestation. The lifetime prevalence of schizophrenia is approximately 1% and is equal in men and women. The usual age of onset is in the late teens or early 20s to late 30s, although schizophrenia can have onset before age 10 (early onset) or after age 45 (late onset). The age of onset is usually younger for men than women.

Several lines of evidence support a genetic contribution to the risk of schizophrenia. There is a 40% lifetime risk of schizophrenia

in a child of two parents with schizophrenia. Twin-twin concordance is 50% in monozygotic twins, and 12% in dizygotic twins. A recent genome-wide association study and meta-analysis found that schizophrenia is significantly associated with single nucleotide polymorphisms in the major histocompatibility complex region on chromosome 6p22.1 (which includes several immunity-related genes, particularly complement C4), although numerous other genes have been implicated. There are likely multiple candidate genes that increase the risk of schizophrenia, each with small effect size.

Replicated environmental risk factors for schizophrenia include season of birth (winter), advanced paternal age, prenatal stress throughout gestation (famine and acute maternal stress in the first trimester, prenatal infections with a myriad of different agents, loss of the father in the second or third trimester), obstetric complications (including gestational diabetes, low birth weight, asphyxia), severe childhood abuse, and cannabis use. It remains unclear whether some of these risk factors are causal to schizophrenia or represent early manifestations of disease.

### Diagnosis

There are three primary symptom domains in schizophrenia: positive, negative, and cognitive symptoms. Positive symptoms are abnormalities of thought content, including hallucinations (abnormal sensory perceptions in the absence of external stimuli) and delusions (fixed, false beliefs), formal thought disorder (also called disorganized thinking), and abnormal psychomotor behavior (such as catatonia). Hallucinations are most commonly auditory but can occur in any sensory modality. Negative symptoms include impairments in emotional expression (blunted affect), motivation (avolition), social behavior (asociality), speech (alogia), and the ability to experience pleasure (anhedonia). Cognitive symptoms include impairments in attention, language, memory, processing speed, and executive function.

The most commonly used diagnostic criteria for schizophrenia are derived from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5). These criteria include the presence of two or more characteristic symptoms—delusions, hallucinations, disorganized speech, grossly abnormal psychomotor behavior (such as catatonia), or negative symptoms (i.e., restricted affect or avolition/asociality)—for a significant portion of time during a 1-month period (or less if successfully treated), with continuous signs of the disturbance persisting for at least 6 months. At least one of these two characteristic symptoms should include delusions, hallucinations, or disorganized speech. During this period, there is significant impairment in one or more major areas of functioning, including work, interpersonal relations, or self-care. It must also be established that the disorder is not better accounted for by a primary mood disorder, schizoaffective disorder, substance intoxication or withdrawal, or other general medical condition. From these criteria, it is important to note that delusions and hallucinations, although common, are not required for the diagnosis. Furthermore, although cognitive symptoms are also not required for the diagnosis, they are a tremendous cause of illness-related disability. A diagnosis of schizophrenia is most definitively made by interviewing the patient, obtaining collateral history from family and/or friends, and completing a medical workup (physical examination, routine blood and urine tests). According to DSM-5 (released May 2013), the diagnostic criteria no longer identify subtypes of schizophrenia, primarily because of a lack of utility for clinicians. Also of note, the Psychoses Workgroup for DSM-5 considered the addition of “attenuated psychosis syndrome” (i.e., prodromal or high-risk psychosis) as a diagnostic category. Ultimately, attenuated psychosis syndrome is listed in DSM-5 among conditions that require further research before consideration as a formal disorder. Nevertheless, the early identification of individuals with prodromal or high-risk psychosis, investigation of risk factors and biomarkers that might predict conversion to fulminant psychotic disorder, and early interventions for individuals with prodromal or high-risk psychosis are areas receiving significant attention and effort in the field.

## Treatment

At present there is no cure for schizophrenia. Although there is significant clinical heterogeneity within the disorder, schizophrenia is usually a chronic condition that requires long-term treatment. Comprehensive treatment involves outpatient medication management and psychotherapy, psychosocial interventions, involvement of the family/support system, inpatient care for acute crisis intervention/illness exacerbation, and collaboration with primary care physicians. Currently, there is a vigorous research effort for diagnostic, prognostic and theranostic biomarkers in schizophrenia, toward a more “personalized medicine” approach for patients.

Antipsychotic medications play an important role in the pharmacologic management of schizophrenia. So-called first-generation antipsychotics (FGAs) have been in clinical use since the introduction of chlorpromazine (Thorazine) in the 1950s. These agents block the dopamine D2 receptor, and common side effects include extrapyramidal side effects (EPS) (e.g., Parkinsonism, dystonia). The newer or “second-generation antipsychotics” (SGAs), in addition to D2 receptor blockade, are also serotonin 5-HT<sub>2</sub> receptor antagonists. While the risk of EPS is lower for SGAs than FGAs, SGAs are associated with a heightened risk of weight gain and the metabolic syndrome. [Table 1](#) provides a more detailed description of antipsychotic medications. The Texas Medication Algorithm Project (TMAP) currently recommends a trial of a single (non-clozapine) SGA for newly diagnosed patients with schizophrenia, or patients never before treated with an SGA. However, neither the TMAP nor the American Psychiatric Association (APA) guidelines for the treatment of schizophrenia preferentially endorse a particular antipsychotic. Clozapine (Clozaril) is primarily used for “treatment-refractory” schizophrenia, usually defined as a lack of/partial response to an adequate trial of monotherapy with two or three different antipsychotics.

Adjunctive medications may also play an important role in the pharmacologic treatment of some patients with schizophrenia. These include antidepressants for depression and anxiety, mood stabilizers for depression or mood elevation, benzodiazepines for anxiety or agitation, beta-blockers for akathisia, and anticholinergics for EPS.

Medication nonadherence is a major treatment issue in patients with schizophrenia at all phases of the illness. Reasons for nonadherence are complex and multifaceted but may include medication side effects, impaired insight into illness, psychopathology in all three symptom domains, lack of efficacy, and comorbid substance use. Over 70% of patients in the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) Schizophrenia Trial discontinued medication within the first 18 months of treatment. Medication nonadherence leads to dramatically increased risk of illness relapse, hospitalization, and suicidal behavior and should be routinely assessed in clinical visits. The use of rapid-dissolving oral or long-acting injectable medications may improve adherence in some patients.

Psychosocial interventions are also a cornerstone of the comprehensive treatment of patients with schizophrenia, and when utilized in combination with medication, are more effective than antipsychotics alone. Psychotherapy, including cognitive-behavioral therapy, supportive therapy, and group therapy, promotes improved illness management and medication adherence. Involvement of the patient’s family/support system in care, including family-based therapies and psychoeducation, has been shown to increase medication adherence and decrease illness relapse rates. Psychosocial rehabilitation, which may include assertive community treatment, social skills training, vocational rehabilitation, and cognitive remediation, can help maximize patients’ psychosocial functioning. There is growing evidence that cognitive remediation therapy in combination with other psychosocial interventions, particularly vocational rehabilitation, can improve real-world functioning for patients with schizophrenia in a relatively short time period.

Although there is no “typical” patient with schizophrenia, the clinical course is often characterized by acute relapses of the

illness with the inter-episode absence or attenuation of symptoms. Multiple factors increase a patient’s risk of illness relapse, including medication nonadherence, psychosocial stressors, substance use, medical illnesses such as infections, and the natural history of the disorder itself. Hospitalization may be required for acute exacerbations of psychotic symptoms, including hallucinations, delusions, and impaired self-care. Hospitalization may also be required if a patient represents an acute danger to self or others.

The concept of the recovery model and recovery-oriented care is a movement that is currently transforming the delivery of mental health services. Integral to the recovery model are certified peer specialists (CPS). A CPS is a licensed professional who has progressed in their own recovery from mental illness and works to assist patients with schizophrenia and other mental illness in regaining control over their own lives and over their own recovery process. CPSs provide peer support services, serve as consumer advocates, are resources for psychoeducation, and offer the unique perspectives based on their individual experiences.

## Comorbidity

Schizophrenia is associated with an increased risk of premature mortality, and cardiovascular disease is a leading cause of death in this patient population. Multiple factors contribute to this risk, including a high prevalence of smoking, poor health habits, poor health care, medication side effects, and (perhaps) the pathophysiology of the disorder itself. SGAs as a class are associated with weight gain and an increased risk of metabolic syndrome. Over 40% of the 1460 patients in the CATIE Schizophrenia Trial met the criteria for metabolic syndrome at baseline. Recommendations for monitoring of patients on SGAs, based on a consensus statement from the American Diabetes Association and the APA, are described in [Table 2](#). Primary care physicians play an important collaborative role with psychiatrists in the detection and management of metabolic disturbances in patients with schizophrenia, in order to minimize the cardiovascular risks associated with these comorbidities.

Patients with schizophrenia are also at an increased risk of suicide, which is also a leading cause of premature mortality. The prevalence of completed suicide in patients with schizophrenia is about 10%, and suicide attempts occur with even greater frequency. Clinicians should routinely assess patients for suicidal ideation and, if present, explore risk factors for completed suicide, which include a suicidal plan and intent, previous suicide attempts, a family history of suicide, age, sex, access to lethal means, social isolation, and comorbid substance use. Medications, psychotherapy, and/or hospitalization may be required.

Comorbid substance use disorders predominate in patients with schizophrenia, with an estimated prevalence of 40% to 50%. Common substances of abuse include alcohol, marijuana, and cocaine. Patients with schizophrenia and comorbid substance use are at increased risk of medication nonadherence, illness relapse, hospitalization, suicidal and violent behavior, and an overall poor response to treatment. Furthermore, up to 70% to 90% of patients with schizophrenia are tobacco users, which contribute to the increased risk of medical comorbidity. Clinicians are encouraged to routinely screen for and address substance use in their treatment plans.

## Conclusions

Schizophrenia is a complex, heterogeneous, and chronic psychiatric disorder. Comprehensive treatment usually involves long-term medication management and therapy, education for patients and their families, and psychosocial interventions. Primary care physicians play an important collaborative role in the detection and management of medical comorbidities, substance use disorders, and suicidality. Physicians, patients, and families are encouraged to become involved in the National Alliance on Mental Illness (NAMI; [www.nami.org](http://www.nami.org)), which is a tremendous resource for help, support, education, and advocacy for patients with schizophrenia and other mental illness.

**TABLE 1** Antipsychotic Medications

AGENT	MECHANISM OF ACTION*	TYPICAL DOSING	SIDE EFFECTS†	SIDE EFFECTS†	NOTES
<b>First Generation</b>					
Haloperidol (Haldol)	D <sub>2</sub> -antagonist	1.5–15 mg/day	EPS/TD Akathisia	NMS Hyperprolactinemia	PO, IM, IV, and long-acting injection formulations
Loxapine (Adasuve)	D <sub>2</sub> -antagonist	10 mg/day	Dysgeusia Sedation	Throat irritation	INH formulation; for treatment of acute agitation
<b>Second Generation</b>					
Aripiprazole (Abilify)	Partial D <sub>2</sub> -agonist and 5-HT <sub>2A</sub> antagonist	10–30 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Headache EPS/TD Akathisia	PO, rapid-dissolving PO, IM, transdermal patch, and long-acting injection formulations
Asenapine (Saphris)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	10–20 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Sedation EPS/TD Akathisia	Rapid-dissolving PO formulation
Clozapine (Clozaril)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	300–900 mg/day	Weight gain (+++) Dyslipidemia (+++) Glucose dysregulation (++) Agranulocytosis Sedation	Orthostatic hypotension Seizures Myocarditis EPS/TD	PO and rapid-dissolving PO formulations
Iloperidone (Fanapt)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	12–24 mg/day	Weight gain (++) Dyslipidemia (+) Glucose dysregulation (+)	Dizziness Tachycardia Sedation EPS/TD	PO formulation
Lurasidone (Latuda)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	40–80 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Sedation Akathisia Nausea EPS/TD	PO formulation
Olanzapine (Zyprexa)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	5–30 mg/day	Weight gain (+++) Dyslipidemia (+++) Glucose dysregulation (++)	Sedation Dizziness Hyperprolactinemia EPS/TD	PO, rapid-dissolving PO, IM, and long-acting injection formulations
Paliperidone (Invega)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	6–12 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Tachycardia Headache EPS/TD	PO and long-acting injection formulations Active metabolite of Risperidone (Risperdal)
Quetiapine (Seroquel)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	200–800 mg/day	Weight gain (++) Dyslipidemia (+) Glucose dysregulation (+)	Sedation Headache Orthostatic hypotension EPS/TD	PO and extended-release PO formulations
Risperidone (Risperdal)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	2–6 mg/day	Weight gain (++) Dyslipidemia (+) Glucose dysregulation (+)	Sedation Hyperprolactinemia EPS/TD	PO, PO liquid, rapid-dissolving PO, and long-acting injection formulations
Ziprasidone (Geodon)	D <sub>2</sub> -antagonist/5-HT <sub>2</sub> antagonist	80–160 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Sedation QTc prolongation EPS/TD	PO and IM formulations
Aripiprazole lauroxil (Aristada)	Partial D <sub>2</sub> agonist and 5-HT <sub>2A</sub> antagonist	441 mg/month or 882 mg/4–6 weeks	Weight gain (+)	Headache	Long-acting injection formulation
Brexipiprazole (Rexulti)	Partial D <sub>2</sub> and 5-HT <sub>1A</sub> agonist and 5-HT <sub>2</sub> antagonist	1–4 mg/day	Dyslipidemia (+) Glucose dysregulation (+)	EPS/TD Akathisia	
Brexipiprazole (Rexulti)	Partial D <sub>2</sub> and 5-HT <sub>1A</sub> agonist and 5-HT <sub>2</sub> antagonist	1–4 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Increased triglycerides EPS/TD Akathisia	PO formulation

## ACUTE BRONCHITIS AND OTHER VIRAL RESPIRATORY INFECTIONS

Method of

Tomoko Sairenji, MD, MS

### CURRENT DIAGNOSIS

- Most cases of acute bronchitis are caused by viruses and diagnosed clinically.
- Predominant symptom is acute cough, with or without sputum.
- Other diseases such as asthma, pneumonia, chronic obstructive pulmonary disease exacerbation, and heart failure should be ruled out.

### CURRENT THERAPY

- Antibiotics are not recommended for most cases of acute bronchitis.
- Dextromethorphan, guaifenesin, and honey may be considered to relieve cough symptoms.
- Patient education: Cough can last 3 weeks or more.

### Epidemiology

Acute cough is the most common reason for ambulatory care visits. Acute bronchitis, which is characterized by an acute cough, is most commonly caused by viruses such as rhinovirus, enterovirus, influenza A and B, parainfluenza, coronavirus, coxsackie, and respiratory syncytial virus. Bacterial causes such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Bordetella pertussis* are much less common.

### Pathophysiology

Acute bronchitis is caused by an acute inflammatory process in the mucosa of the trachea and bronchi with resultant injury to epithelium of the mucosa.

### Clinical Manifestations

Cough is the primary symptom of acute bronchitis, but it can cause other symptoms such as nasal congestion, wheezing, dyspnea, fever, and nonspecific constitutional symptoms.

### Diagnosis

Acute bronchitis is diagnosed clinically, characterized by an acute cough with or without sputum production. It is often a diagnosis of exclusion, in which other diseases such as asthma, pneumonia, chronic obstructive pulmonary disease exacerbation, and heart failure are ruled out. Initially, manifestations of acute bronchitis can be identical to the common cold and difficult to distinguish. Patients may have a mildly ill appearance, but fever is less

common in bronchitis after the first few days. On auscultation, there may be wheezing or rhonchi that improve with coughing. A patient with a high temperature, otherwise abnormal vital signs, and a more toxic appearance should raise concern for pneumonia or influenza.

Laboratory testing is usually not necessary for the typical patient in the outpatient setting, but it can be done for influenza and pertussis when there is greater suspicion for these diseases.

Imaging such as chest x-rays are not necessary in most cases for patients who have normal vital signs, no bloody sputum, and a normal lung examination. However, it is recommended in those older than 75 years of age, because pneumonia does not always mount a fever or cause tachycardia in the elderly.

### Differential Diagnosis

#### Common Cold/Upper Respiratory Infections (URI)

The common cold can be difficult to differentiate from acute bronchitis. On average, adults have 2 to 4, and young children as many as 6 to 10 episodes annually. It is most commonly caused by rhinoviruses but can also be caused by other respiratory viruses such as coronavirus, influenza, and respiratory syncytial virus and parainfluenza viruses. The symptomatic trajectory of the common cold is sore throat, malaise, and low-grade fever for 1 to 2 days, followed by nasal congestion, rhinorrhea, and cough. Cough can occur in 30% to 40% of cases, and fluid can accumulate in middle ear or sinus cavities. Common cold/URI symptoms are generally the worst on day 3 to 4 and start to improve by day 7. Symptoms that would warrant consideration for more serious disease are respiratory distress, difficulty swallowing, altered mental status, signs suggesting dehydration, stiff neck, rash, or sore throat for more than 5 days. Influenza (high fever with general myalgias), acute bacterial sinusitis (symptoms for more than 10 days without improvement, severe symptoms including fever  $\geq 39^{\circ}\text{C}$ , and purulent nasal discharge lasting more than 3 consecutive days), streptococcal pharyngitis (absence of cough with tender lymphadenopathy and tonsillar exudates), asthma exacerbations triggered by URI, and infectious mononucleosis (fatigue, fever, sore throat, and adenopathy more severe than typical URI) are other conditions on the differential. Testing is not warranted for the diagnosis of a common cold unless one of these diseases is suspected and needs to be ruled out.

Similar to acute bronchitis, antibiotics are strongly discouraged for the common cold because they provide no benefit in terms of reducing symptom severity or duration. If symptoms are severe, treatment focuses mostly on symptomatic management, of which most can be done using over-the-counter therapies. Rest as well as adequate hydration and nutrition are encouraged but not studied in trials. Acetaminophen and nonsteroidal antiinflammatory drugs can help with fever and discomfort. The combination of antihistamines and decongestants may be more beneficial than either component alone for nasal symptoms. When needed, dextromethorphan may provide symptom relief with cough suppression. Intranasal or inhaled cromolyn sodium<sup>1</sup> may help with rhinorrhea, throat pain, or cough. Various formulations of intranasal cromolyn sodium (NasalCrom) are available over the counter, and oral inhaled cromolyn sodium (Intal) is available by a

<sup>1</sup>Not FDA approved for this indication.

prescription. Regular use of vitamin C supplements<sup>1,7</sup> (at least 200 mg/d) may decrease duration of cold symptoms, but they are not effective if started after cold symptoms start. Oral zinc sulfate<sup>1,7</sup> may decrease URI symptom duration and severity, but it is not routinely recommended because of adverse effects (bad taste and nausea).

### Croup

Croup affects children with a peak incidence between 6 and 36 months of age, annually affecting 3% of those in this age range. Parainfluenza virus types 1 to 3 constitute 75% of all cases, but infection with many different viruses can produce this illness. Although some cases of croup can be caused by bacteria, it does not change how it is managed.

Croup is diagnosed clinically. Initially, patients experience cold-like symptoms: low-grade fevers and coryza. Inspiratory stridor, hoarseness, and a barking cough are typical findings that follow, peaking between 24 to 48 hours after onset. These symptoms are caused by mucosal inflammatory swelling of the larynx, trachea, and bronchi. Symptoms are often worse at night and can be exacerbated by emotional distress. Most (85%) cases are considered mild, but nasal flaring and retractions, increased respiratory rate, hypoxia, and tachycardia are indicators of more severe croup. Routine radiologic imaging is not encouraged, because the steeple sign that is often associated with croup is actually nonspecific and can be seen in other causes of glottic and subglottic narrowing such as epiglottitis and bacterial tracheitis.

Management of croup is dependent on the severity of the disease. Administration of corticosteroids (single dose of dexamethasone [Decadron]<sup>1</sup> 0.6 mg/kg) are recommended for croup of any severity because it reduces return visits and hospitalization rates. Oxygen should be given to children with hypoxia or respiratory distress. Nebulized epinephrine<sup>1</sup> (0.05 mL/kg of racemic epinephrine 2.25% [max dose = 0.5 mL] or 0.5 mL per kg of L-epinephrine 1:1,000 via nebulizer [max dose = 5 mL]) is recommended for moderate or severe croup. It takes effect by vasoconstriction of the upper airway mucosa, leading to decreased edema. It has a quick onset of action, but efficacy wanes after 1 to 2 hours, so monitoring patients beyond 2 hours is recommended.

Humidified air has been commonly used for croup, but it has not been shown to be effective in decreasing croup symptoms or hospital admissions in moderate croup.

### Pertussis

Pertussis should be suspected when patients have more than 2 weeks of a characteristic paroxysmal, whooping cough and post-tussive emesis, or recent pertussis exposure. Most pertussis is caused by the bacteria *B pertussis*. The number of outbreaks and pertussis incidence has increased in recent years. In the early catarrhal stage (1–2 weeks), it is difficult to discern from a common cold. The cough becomes more frequent, and severe bouts characterize the following paroxysmal stage (1–6 weeks, maximum of 10 weeks). Paroxysms of cough can be debilitating and cause post-tussive emesis, weight loss, and other conditions related to severe cough, but there are few symptoms otherwise. After this stage, the cough gradually improves over the course of a few weeks.

Atypical presentations are not uncommon, because those who have acquired immunity can present with a lesser degree of paroxysm. Thus pertussis should be suspected if cough symptoms last more than 3 weeks. Infants may also have atypical presentation of cough without paroxysmal whooping.

Diagnosis can be confirmed with either culture, polymerase chain reaction (both better for early stages), or serology (accurate in later stage). Efficacy of antibiotics is questionable because treatment does not improve symptoms. However, antibiotics

(Azithromycin [Zithromax]<sup>1</sup> is first line—Children: 10 mg/kg/d for 3 days, or 10 mg/kg on day 1, then 5 mg/kg/d on days 2–5; Adults: 500 mg/d for 3 days, or 500 mg on day 1, then 250 mg/d on days 2–5) are still recommended because they eradicate *B pertussis* from the nasopharynx and may decrease transmission. Immunization is critical to prevent further outbreaks of pertussis.

### Bronchiolitis

Bronchiolitis is the most common cause for infant hospitalization of infants. Respiratory syncytial virus is the most common cause of bronchiolitis. Bronchioles become plugged with detached epithelium and inflammatory cells. Onset of upper respiratory symptoms is often soon followed by rapid development of wheezing and labored breathing. Infants with bronchiolitis typically do not have a marked response to asthma treatment with bronchodilators and corticosteroids, despite similar presenting symptoms. Treatment primarily consists of supplemental oxygen and intravenous fluids as needed to prevent dehydration. Palivizumab (Synagis) is used to prevent hospitalization rate for high-risk infants, such as those with premature birth, chronic lung disease, and hemodynamically significant congenital heart disease.

### Therapy (or Treatment)

#### Decreasing Antibiotic Use

Antibiotic use in the treatment of bronchitis is strongly discouraged in all major guidelines, but they are often prescribed regardless of the recommendations. The strongest predictor of whether a patient will receive antibiotics is whether the clinician perceives the patient desires them. Patient education such as setting the expectation that cough from acute bronchitis can last 3 weeks, that antibiotics would not effectively aid in shortening the duration of symptoms, and explaining the undesired consequences of inappropriate antibiotic use such as antibiotic resistance and adverse effects is important. One in five patients treated with antibiotics will experience side effects such as headache, nausea, skin rash, diarrhea, and vaginitis. Patients are more likely to respond to this sort of education if they feel their concerns have been heard and addressed. In some cases, using a delayed prescription strategy wherein patients would need to call for a prescription or agree to pick up antibiotics after a certain number of days may be effective in decreasing antibiotic use. Providing methods for symptomatic management is also important for patients who desire treatment.

#### Recommended Cough Treatment

Dextromethorphan, guaifenesin, and honey may be considered to relieve cough symptoms. Dextromethorphan (30 mg orally every 6 to 8 hours) is a central-acting antitussive that reduces the cough reflex. In placebo-controlled studies, it was shown to decrease coughs by 19% to 36% (8 to 10 fewer coughs per 30 minutes) compared with placebo. Guaifenesin ([immediate-release] 200 to 400 mg orally every 4 hours) is an expectorant that increases respiratory tract secretions, hence decreasing mucus thickness. Study results vary, but it has been shown to decrease cough frequency and severity compared with placebo. Honey (2.5–10 mL [0.5–2 teaspoons]) has been compared with dextromethorphan, diphenhydramine, and no treatment in children. It was found to be better than no treatment in its effectiveness in decreasing cough severity and frequency and improving sleep quality. Honey would be an option for children older than 1 year, because antitussive use is not recommended in small children.

#### Cough Treatments that are not Recommended

There is no evidence that centrally acting antitussive codeine<sup>1</sup> has any effect to decrease cough symptoms, and benzonatate (Tessalon Perles), a peripherally acting antitussive has only been shown to be effective in conjunction with guaifenesin. Unfortunately, many over-the-counter therapies do not significantly

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

impact acute bronchitis symptoms. Clinical trials have shown that ibuprofen (Motrin)<sup>1</sup> and antihistamines are not effective in reducing symptoms of cough. The FDA warns against using cough medications that have antihistamines and antitussives in children younger than 4 years of age because of the high risk for potential harm. Use of beta-agonists is also not recommended, unless the patient presents with wheezing at the time of presentation.

<sup>1</sup>Not FDA approved for this indication.

## ACUTE RESPIRATORY FAILURE

Method of

Anthony J. Faugno III, MD; and Scott K. Epstein, MD

### CURRENT DIAGNOSIS

- History and physical examination can give insight into the etiology of hypoxic and hypercapneic respiratory failure but may be insufficient to make a definitive diagnosis and guide therapy.
- An arterial blood gas is mandatory to define severity and whether hypoxic or hypercapneic (or both) respiratory failure is present.
- Additional diagnostic modalities, including chest radiograph, electrocardiogram, cardiac laboratory tests (troponin, brain natriuretic peptide), echocardiography, and selected use of a pulmonary artery catheter, can help identify a specific etiology.

### CURRENT THERAPY

- Treatment of acute respiratory failure often begins with non-specific approaches such as oxygen and mechanical ventilation (noninvasive or invasive).
- The goal of mechanical ventilation is to improve gas exchange and rest the respiratory muscles while waiting for the beneficial effects of specific therapy aimed at the underlying cause (e.g., bronchodilators, antibiotics, and corticosteroids in acute exacerbations of chronic obstructive pulmonary disease [COPD]).
- Noninvasive ventilation avoids many complications associated with invasive ventilation and improves outcomes for patients with acute cardiogenic pulmonary edema and acute exacerbations of COPD.

- High-flow nasal cannula is emerging as the preferred therapy for hypoxic respiratory failure in patients with non-cardiogenic pulmonary edema who do not require urgent intubation.
- Invasive mechanical ventilation can be lifesaving but can cause clinical deterioration if not properly administered.
- Using low tidal volumes (6 mL/kg ideal body weight) can help avoid dangerous dynamic hyperinflation in acute exacerbations of COPD and further lung injury in acute lung injury (e.g., volutrauma, barotrauma).
- Once signs of improvement are evident, focus rapidly shifts to liberating the patient from the ventilator using spontaneous breathing trials to assess the need for ventilatory support followed by airway assessment to determine readiness for extubation.

The respiratory system serves many complex physiologic functions, the most important of which is gas exchange. Using the interface between the alveolar space and capillaries, O<sub>2</sub> is taken up and CO<sub>2</sub> is eliminated. Acute respiratory failure, a life-threatening entity, is present when this system fails, over the course of minutes to hours, resulting in hypoxemia (type I) or hypercapnia (type II), or both. Most patients with acute respiratory failure present with dyspnea, although the correlation with disease severity is poor. Indeed, dyspnea might seem mild in those with baseline chronic respiratory failure, and it might be absent in those with an underlying neurologic process (e.g., drug overdose). Other symptoms and signs such as cough, chest pain, orthopnea, fever, tachypnea, rales, and wheezing are insensitive and nonspecific.

This chapter outlines the general pathophysiology and therapeutic approach to acute respiratory failure by using the examples of three common entities: acute respiratory distress syndrome (ARDS), cardiogenic pulmonary edema (congestive heart failure [CHF]), and acute exacerbation of chronic obstructive pulmonary disease (AECOPD).

## Definitions and Pathophysiology

### Acute Hypoxic Respiratory Failure

Hypoxic respiratory failure is conventionally defined as an arterial oxygen tension (PaO<sub>2</sub>) of less than 60 mm Hg. Because this definition ignores the inspired fraction of oxygen (FiO<sub>2</sub>), some favor a PaO<sub>2</sub>/FiO<sub>2</sub> ratio of less than 300. To account for the arterial CO<sub>2</sub> tension (PaCO<sub>2</sub>), others favor an alveolar-arterial (A-a) O<sub>2</sub> gradient greater than 250 mm Hg, using the equation

$$\begin{aligned} A-a \text{ O}_2 \text{ gradient} &= PAO_2 - PaO_2 \\ &= (713 \times FiO_2) - (PaO_2 + PaCO_2/0.8) \end{aligned}$$

where 713 is the barometric pressure (760) minus the water vapor pressure. A normal A-a O<sub>2</sub> is less than 10 mm Hg, but this threshold value increases with age. The determination of PaO<sub>2</sub> requires an invasive test, an arterial blood gas. Oxygenation can be continuously monitored noninvasively by pulse oximetry, which provides an estimate of arterial oxygen saturation (SaO<sub>2</sub>). In general, an SaO<sub>2</sub> of 0.90 corresponds to a PaO<sub>2</sub> of 60 mm Hg, but the relation depends on temperature, pH, PaCO<sub>2</sub>, and 2,3-diphosphoglycerate (2,3-DPG). Accuracy is adversely affected by low perfusion states, dark skin pigmentation, nail polish, dyshemoglobins (e.g., carboxyhemoglobin, methemoglobin), intravascular dyes, motion, and ambient light.

Clinicians tend to focus on PaO<sub>2</sub> and SaO<sub>2</sub>, but the real parameter of interest is O<sub>2</sub> delivery (DO<sub>2</sub>) to organs and tissues. DO<sub>2</sub> depends on cardiac output and O<sub>2</sub> carrying capacity of arterialized blood (CaO<sub>2</sub>):

$$DO_2 = CO \times CaO_2$$

where

$$CaO_2 = k (\text{Hb} \times SaO_2) + 0.003 \text{ PaO}_2$$

where  $k$  is a constant.  $\text{DO}_2$  decreases when cardiac output or hemoglobin is reduced despite a normal  $\text{PaO}_2$  and  $\text{SaO}_2$ . The peripheral response to reduced  $\text{DO}_2$  is an increased  $\text{O}_2$  extraction ratio ( $\text{O}_2\text{ER}$ ), allowing oxygen uptake  $\dot{V}\text{CO}_2$ , an indicator of metabolic demand, to remain constant. Cellular and organ dysfunction occurs when  $\text{DO}_2$  and  $\text{O}_2\text{ER}$  are outstripped by metabolic demand. The balance between  $\text{DO}_2$  and demand can be estimated by examining the mixed venous  $\text{O}_2$  saturation ( $\text{MvO}_2$ ) using the rearranged Fick equation:

$$\text{MvO}_2 = \text{SaO}_2 - \left( \dot{V}\text{O}_2 / \text{CO} \times \text{Hb} \right)$$

When  $\text{MvO}_2$  falls below 65% to 75%, imbalance is present. When cellular injury is present, extraction capabilities are limited and cellular hypoxia occurs despite “adequate”  $\text{DO}_2$ . Under these circumstances, the  $\text{MvO}_2$  can be paradoxically normal. These parameters can be determined using a pulmonary artery catheter. The data obtained may be useful in individual patients, but randomized, controlled trials show no benefit when the pulmonary artery catheter is used routinely to guide therapy.

The pathophysiologic mechanisms of type I respiratory failure are listed in Table 1. The most common mechanism is ventilation-perfusion  $\dot{V}/\dot{Q}$  mismatch, characterized by a widened A-a  $\text{O}_2$  gradient, a dramatic increase in  $\text{PaO}_2$  in response to supplemental  $\text{O}_2$ , and a variable  $\text{PaCO}_2$ . When areas of low  $\dot{V}/\dot{Q}$  predominate (e.g., reduced ventilation with normal perfusion), the  $\text{PaCO}_2$  may be low as the patient hyperventilates in an effort (only partially effective) to increase the  $\text{PaO}_2$ . When areas of high  $\dot{V}/\dot{Q}$  predominate, much ventilation is wasted, and hypercapnia is also present. Areas of lung that are perfused but not ventilated characterize shunt. The resulting fall in  $\text{PaO}_2$  depends on the percentage of cardiac output circulating through the shunt and the  $\text{O}_2$  content of that blood. Supplemental  $\text{O}_2$  has minimal or small effect on  $\text{PaO}_2$  because the shunted blood is not exposed to the increased  $\text{FiO}_2$ . Therefore, treatment is aimed at decreasing shunt by improving ventilation to the affected area or reducing perfusion to that area. When shunt results from a unilateral process (e.g., pneumonia, atelectasis), placing the good lung in the dependent position decreases shunt perfusion, and oxygenation improves.

### Acute Hypercapneic Respiratory Failure

Hypercapneic respiratory failure is defined as a  $\text{PaCO}_2$  greater than 45 mm Hg. The equation used to determine  $\text{PaCO}_2$  provides insight into the three basic mechanisms underlying hypercapnia:

$$\text{PaCO}_2 = k \left( \dot{V}\text{CO}_2 \right) / V_E \left( 1 - V_D/V_T \right)$$

where  $k$  is a constant,  $V_E$  is total minute ventilation (respiratory rate times tidal volume), and  $V_D/V_T$  is the dead space. Therefore, hypercapnia can result from increased  $\text{CO}_2$  production  $\dot{V}\text{CO}_2$ ,

increased physiologic dead space ( $V_D/V_T$ ), and decreased minute ventilation (Box 1). Increased  $\dot{V}\text{CO}_2$  alone is usually insufficient to cause hypercapnia because the respiratory system responds by increasing minute ventilation to keep  $\text{PaCO}_2$  normal (37 to 43 mm Hg). Conversely, with abnormalities of respiratory muscle function or respiratory drive, or with increased dead space (and diminished reserve), the respiratory response to increased  $\dot{V}\text{CO}_2$  may be insufficient, and hypercapnia results.

### Treatment

Treatment of acute hypoxemic and hypercapneic respiratory failure combines nonspecific (e.g., supplemental  $\text{O}_2$ , mechanical ventilation) and specific therapy (Boxes 2 and 3).

### Oxygen Therapy

In the hospital, 100%  $\text{O}_2$  is supplied from a wall source with a regulator determining flow rate in liters per minute. The final delivered oxygen concentration ( $\text{FiO}_2$ ) depends on this flow rate and the amount of room air breathed by the patient. The  $\text{O}_2$  flow rate is almost never sufficient to meet all of the patient's ventilatory demands, so varying amounts of room air are entrained to meet these needs. The final inspired oxygen concentration depends on the relative fraction of each gas, total minute ventilation, and the pattern of breathing (including the inspiratory-to-expiratory ratio).  $\text{O}_2$  may be administered using nasal prongs, a facial mask, or high-flow devices designed to deliver higher  $\text{FiO}_2$  (Table 2). High-flow nasal cannula (HFNC) devices are more capable of meeting the inspiratory flow demands during respiratory distress (in excess of

40 L/min) and more reliably deliver the set  $\text{FiO}_2$  because they can overcome the entrainment phenomenon. Other reported benefits of HFNC include reduction in respiratory rate and work of breathing and increased end expiratory lung volume. A modest amount of positive end expiratory pressure, approximately 0 to 5 cm  $\text{H}_2\text{O}$ , is supplied by HFNC when breathing with a closed mouth.

Regardless of oxygenation strategy it is important to titrate oxygen support to physiologic endpoints, generally a  $\text{SaO}_2 > 92\%$ . Recent clinical data suggest evidence of potential harm for supraphysiologic blood oxygen tensions, and that an upper limit of supplemental oxygenation should be observed in all patients. The goal here is likely a  $\text{PaO}_2$  between 70 and 120 mm Hg with an upper threshold of 98%  $\text{SaO}_2$ , though this requires further prospective evaluation. In hypercapnic patients (e.g., with AECOPD), high-flow  $\text{O}_2$  can lead to worsening hypercapnia and acute respiratory acidosis. The mechanisms are multifactorial: worsening  $\dot{V}/\dot{Q}$  matching (increased dead space), decreased intracellular binding of  $\text{CO}_2$ , and minute ventilation inadequate for the amount of  $\text{CO}_2$  produced. Therefore, the goal in these patients is to achieve a  $\text{PaO}_2$  of 55 to 60 mm Hg ( $\text{SaO}_2$  88% to 90%) with low-flow oxygen (~24% to 28%  $\text{O}_2$ ). If this (often delicate) balance between maintaining tissue oxygenation and avoiding significant respiratory acidosis cannot be achieved, short-term mechanical ventilation may be required.

**Mechanical Ventilation**

Mechanical ventilation can be delivered noninvasively through a tight-fitting face mask or invasively via an endotracheal tube. The goals of mechanical ventilation are to correct severe arterial blood gas abnormalities, provide respiratory support while specific therapy is used, and unload and rest the respiratory muscles. The ventilator should be set to optimize patient-ventilator interaction and avoid dynamic hyperinflation and intrinsic positive

end-expiratory pressure (PEEPi). PEEPi can worsen gas exchange, predispose to barotrauma, and cause hypotension.

**Noninvasive Ventilation**

Noninvasive ventilation is most commonly applied as continuous positive airway pressure (CPAP), when airway pressure is kept constant throughout the respiratory cycle, or by bilevel positive airway pressure (BiPAP), when inspiratory pressure support actively assists each inspiration. Noninvasive ventilation offers numerous advantages over invasive ventilation, including increased comfort; maintenance of normal swallowing, speech, and cough; less need for sedation; and avoiding the trauma of intubation.

The effective application of noninvasive ventilation starts with carefully explaining the procedure to the patient, followed by selection of a proper-fitting face mask. The mask is placed close to the face to acclimate the patient to high inspiratory flow. The mask is then secured using straps (but not too tightly), and ventilator settings are adjusted to minimize leaks and ensure comfort. The patient is reassessed frequently. Failure to improve within 2 to 4 hours (e.g., reduction in dyspnea, respiratory rate, accessory muscle use, and hypercapnia) signals noninvasive ventilation failure and need for intubation.

Noninvasive ventilation improves outcome (avoids intubation, decreases length of stay, improves survival) in a number of conditions (Table 3). Although randomized, controlled trials show dramatic benefit in AECOPD, other studies show no or uncertain benefit in community-acquired pneumonia, ARDS, pulmonary fibrosis, and routinely after planned extubation. One mechanism for improved outcome is the reduction in infection (pneumonia, sepsis) seen with noninvasive ventilation compared with intubated patients. Noninvasive ventilation should not be used in the presence of respiratory arrest, shock, excessive secretions, inability to protect the airway, an agitated or uncooperative patient, and facial abnormalities that preclude proper application of the mask. Comparison of noninvasive ventilation to high-flow nasal cannula in ARDS suggests evidence of harm in patients with more severe hypoxemia. This phenomenon is hypothesized to be related to ventilator-induced lung injury where tidal volumes are less strictly regulated in noninvasive as compared to invasive ventilation.

**TABLE 2** Short-Term Oxygen Delivery Systems

DELIVERY SYSTEM	O <sub>2</sub> FLOW RATE (L/MIN)	FIO <sub>2</sub> RANGE	COMMENTS
<b>Basic Systems</b>			
Nasal cannula (prongs)	1–6	0.22–0.40	Comfortable Facilitates communication and oral intake Humidification required at high flow rates
Simple masks	5–6	0.30–0.50	Mask acts as reservoir to increase FiO <sub>2</sub> High flow combats CO <sub>2</sub> rebreathing Less comfortable Must be removed to facilitate communication and oral intake Easily displaced with movement
<b>Reservoir Masks</b>			
Nonbreathing	4–10	0.60–1.00	One-way valve between the mask and the reservoir bag Inspired O <sub>2</sub> from wall source and reservoir bag
Partial rebreathing	5–10	0.35–0.90	Lacks one-way valve
Venturi masks	4–10	0.24–0.40	Uses Bernoulli principle (fixed amount of entrained room air added to O <sub>2</sub> ) Maximum delivered FiO <sub>2</sub> can be controlled Often used in COPD to avoid excessive FiO <sub>2</sub> and risk for hypercapnia
High-flow nasal cannula	10–60	0.21–1	Can overcome room air entrainment, set FiO <sub>2</sub> more accurate Generates modest amount of positive end expiratory pressure Reduces CO <sub>2</sub> rebreathing by anatomic dead space washout Reduction in work of breathing in select patients

COPD, Chronic obstructive pulmonary disease; FiO<sub>2</sub>, fraction of inspired oxygen.

### Invasive Ventilation

Invasive mechanical ventilation is delivered via an endotracheal tube. The set parameters include FiO<sub>2</sub> and positive end-expiratory pressure (PEEP). For volume-assist control, the clinician chooses respiratory rate and tidal volume. For pressure support, the clinician chooses the inspiratory pressure level above PEEP, and the patient determines respiratory rate. The resulting tidal volume depends on inspiratory pressure level and patient factors including respiratory muscle strength and respiratory system mechanics. Initially the ventilator is set to meet most of the patient's minute ventilation, allowing respiratory muscle rest. Such full support should not be prolonged because diaphragmatic dysfunction can result. Most patients require sedation, but excessive sedation levels are associated with worse outcomes. Therefore, strategies to minimize continuous intravenous sedation using a sedation protocol or once-daily interruption of sedation are recommended.

Invasive mechanical ventilation, especially when prolonged, is associated with numerous complications including ventilator-associated pneumonia, sinusitis, airway injury, thromboembolism, and gastrointestinal bleeding. Therefore, once significant clinical improvement occurs, efforts should focus on rapidly removing the patient from the ventilator. This is achieved by daily screening for readiness (Box 4) followed by a 30- to 120-minute spontaneous breathing trial on minimal or no ventilator support. Patients tolerating the spontaneous breathing trial are extubated if they have a good cough, manageable respiratory secretions, and an adequate mental status to protect the airway. Approximately 25% of patients do not tolerate the spontaneous breathing trial; they should be returned to full ventilator support for 24 hours and undergo careful evaluation for reversible causes. The clinician should consider a more gradual approach to weaning these patients.

### Specific Causes of Acute Respiratory Failure

#### Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Patients with COPD can experience two or three exacerbations per year, especially if they are actively smoking. The best predictor of future exacerbations is a history of previous exacerbations. Other risk factors for exacerbation include serum eosinophilia, pulmonary hypertension and gastric reflux. Hospital mortality ranges from 2% to 11%, rising to 25% for those requiring critical care.

AECOPD is defined by increased sputum volume, purulence, and dyspnea. Physical examination is notable for tachypnea, use of accessory respiratory muscles, diminished breath sounds, prolonged expiratory phase with wheezing, thoraco-abdominal paradox (inward inspiratory abdominal motion), and Hoover sign (inward inspiratory motion of the lower rib cage). The latter two physical signs indicate the presence of dynamic hyperinflation and diaphragmatic dysfunction. AECOPD is further characterized by hypoxemia (resulting from  $\dot{V}/\dot{Q}$  mismatch) and hypercapnia. Patients with more severe underlying disease might demonstrate evidence of acute and chronic respiratory acidosis.

#### Etiology and Diagnosis

Approximately 50% of AECOPDs result from bacterial infection (e.g., *Pneumococcus* species, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Pseudomonas* species). The remainder result from viral infection and air pollution. In many cases a cause cannot be identified, although there is increasing appreciation that acute myocardial infarction and pulmonary embolism may be present in up to 25%. Pulmonary embolism may be suggested by a PaCO<sub>2</sub> lower than baseline and the need for a higher than expected FiO<sub>2</sub> to maintain the SaO<sub>2</sub> at greater than 90%. Computed tomographic pulmonary arteriogram is recommended to

**TABLE 3** Efficacy of Noninvasive Ventilation in Various Conditions

CONDITION	QUALITY OF EVIDENCE	COMMENT
AECOPD	Strong	↓ Need for intubation ↓ Nosocomial pneumonia ↑ Survival
Acute cardiogenic pulmonary edema	Strong	↓ Need for intubation ↑ Survival
Facilitating weaning in select patients	Strong	↓ Duration of intubation Most effective in AECOPD
High risk for extubation failure	Strong	↓ Need for reintubation
Extubation failure in heterogeneous patient population	Moderate	Not effective, two RCTs
Routinely after extubation	Moderate	Not effective, single RCT
Extubation failure in AECOPD	Moderate	Single case-control study
Type I RF, diffuse infiltrates, not ICH	Moderate	↓ Need for intubation May ↓ survival, requires close monitoring
Hypoxemic respiratory in ICH with diffuse pulmonary infiltrates	Moderate	↓ Need for intubation ↑ Survival
Postoperative respiratory failure	Moderate	↓ Need for intubation ↓ Nosocomial pneumonia ↑ Survival
Asthma	Weak	Uncertain effect on mortality Uncertain effect on intubation Benefit may be in ACOS
Obesity hypoventilation	No RCTs	Probably effective in ↓ need for intubation
Do not intubate patients	Observational studies	Most effective with CHF, COPD
Pulmonary fibrosis	Observational studies	Not effective

ACOS, Asthma COPD Overlap Syndrome; AECOPD, acute exacerbation of chronic obstructive pulmonary disease; CHF, cardiogenic pulmonary edema; COPD, chronic obstructive pulmonary disease;  $FiO_2$ , fraction of inspired oxygen; ICH, immunocompromised host; RCT, randomized, controlled trial; RF, respiratory failure.

#### BOX 4 Screening Criteria to Assess Readiness to Undergo a Trial of Spontaneous Breathing

##### Required Criteria

$PaO_2/FiO_2 \geq 150$  or  $SaO_2 \geq 90\%$  or  $FiO_2 \leq 40\%$  and PEEP  $\leq 5$  cm  $H_2O$

Absence of hypotension

##### Additional Criteria (optional criteria)

Weaning parameters\*

- Negative inspiratory force  $< -20$  to  $-25$  cm  $H_2O$
- Respiratory rate (f)  $\leq 35$  breaths/min
- Spontaneous tidal volume ( $V_T$ )  $> 5$  mL/kg
- $f/V_T < 105$  breaths/L per min.

Absence of significant anemia (e.g., Hb  $\geq 8$ – $10$  mg/dL)

Absence of fever (e.g., core temperature  $\leq 38.5^\circ C$ )

Adequate mental status: patient awake and alert or easily aroused.

\* Recent studies indicate that these parameters are often unnecessary in deciding whether to initiate trials of spontaneous breathing.

Hb, Hemoglobin; PEEP, positive end-expiratory pressure.

make the diagnosis, because  $\dot{V}/\dot{Q}$  scanning is nondiagnostic in nearly half of COPD patients, and false-positive high-probability scans occur.

##### Treatment

Treatment for AECOPD is based on high-quality evidence consisting of numerous randomized, controlled trials and well-performed meta-analyses. Bronchodilator therapy is essential. Nebulized combination therapy (albuterol and ipratropium [DuoNeb]) is effective, but it is not demonstrably superior to single-agent therapy delivered via a metered-dose inhaler. Theophylline should generally be avoided because toxicity outweighs benefits. Antibiotics improve outcome, especially in the presence of fever and increased sputum purulence and volume. Older agents, such as amoxicillin and tetracycline, appear to be less effective than newer macrolides and fluoroquinolones though local resistance patterns should drive antibiotic selection.

Corticosteroids enhance  $\beta$ -agonist activity and counteract the inflammatory state seen in AECOPD. Oral prednisone at a dose of 30 to 40 mg is recommended with a duration of 5 days being noninferior to longer courses. Intravenous therapy (methylprednisolone [Solu-Medrol] 125 mg every 6 hours for 72 hours

followed by oral prednisone) should be used in the critically ill patient or when response to oral therapy is suboptimal. There is no role for mucolytic agents or chest physiotherapy during acute exacerbation. Continuation of beta blockers, previously thought to contribute to bronchoconstriction, may in fact be associated with decreased mortality and exacerbations because of impact on COPD comorbidities such as coronary artery disease.

Admission to the intensive care unit (ICU) is indicated for patients with hemodynamic instability, confusion, lethargy and coma, severe dyspnea unresponsive to emergency management, or severely abnormal gas exchange despite initial therapy ( $\text{PaO}_2 < 40$  mm Hg,  $\text{PaCO}_2 > 60$  mm Hg,  $\text{pH} < 7.25$ ). Randomized, controlled trials demonstrate that noninvasive ventilation decreases the risk for intubation and improves survival in AECOPD when there is severe dyspnea, hypoxemia, tachypnea, and significant respiratory acidosis ( $\text{PaCO}_2 > 45$  mm Hg and  $\text{pH} < 7.35$ ). Patients who fail noninvasive ventilation or who are not candidates require intubation and mechanical ventilation.

A major risk is the development of dynamic hyperinflation (PEEPi), which occurs when expiratory time is not sufficient to reach functional residual capacity. The resulting air trapping within the thorax can worsen gas exchange, predispose to barotrauma (e.g., pneumothorax), and cause hypotension. PEEPi is minimized by keeping delivered minute ventilation at 5 L/min or less; achieved by lowering tidal volume (e.g., 6 mL/kg ideal body weight) or respiratory rate (8 to 10 breaths/min), or by increasing inspiratory flow rate, allowing more time for expiration. PEEPi is suggested by an elevated plateau pressure or persistent expiratory flow at the time of the next ventilator breath. PEEPi can also increase work of breathing by increasing the patient's inspiratory effort to trigger the ventilator. When extrinsic PEEP is at or just below the PEEPi level, the patient triggers more easily and work of breathing is reduced. The approach to weaning and extubation in AECOPD is similar to that for other conditions, although the risk of failing a spontaneous breathing trial is increased.

### Acute Respiratory Distress Syndrome

#### *Etiology and Diagnosis*

ARDS is the result of an acute process and is characterized by hypoxemia ( $\text{PaO}_2/\text{FiO}_2 < 300$ ) with bilateral diffuse alveolar infiltrates, and no evidence of cardiac etiology. Lung injury in this syndrome can result from both pulmonary and extrapulmonary etiologies. Pulmonary causes include pneumonia, gastric aspiration, near drowning, toxic gas inhalation, medication side effects, and lung contusion. Extrapulmonary causes include sepsis, pancreatitis, fat embolism, drug overdose, nonthoracic trauma, and massive transfusion. Conditions that can mimic the clinical findings of ARDS include CHF, diffuse alveolar hemorrhage (DAH), acute cryptogenic organizing pneumonia (COP), and acute eosinophilic pneumonia (AEP). These latter three entities can be diagnosed by bronchoscopy (DAH, AEP) or by open lung biopsy (COP), all of which are treated with high doses of corticosteroids.

Differentiating cardiogenic pulmonary edema from ARDS can be challenging, especially because these conditions can coexist. Physical findings of jugular venous distention and a positive third heart sound, abnormal electrocardiogram (ECG), elevated brain natriuretic peptide (BNP), and positive cardiac enzymes (troponin) point to a cardiac etiology. A chest radiograph showing cardiomegaly, vascular redistribution, widened vascular pedicle, perihilar alveolar infiltrates, and pleural effusions also suggests a cardiac cause. Bedside echocardiography can demonstrate reduced left ventricular function. A pulmonary artery catheter provides definitive evidence of an elevated pulmonary capillary wedge pressure and reduced cardiac output. That said, recent randomized, controlled trials demonstrate no improvement in survival with routine use of the pulmonary artery catheter in ARDS.

#### *Treatment*

The first principle of ARDS management is to prevent further lung injury by employing a lung protective ventilation strategy

limiting the transpulmonary pressure, using the plateau pressure as a surrogate. In general this is accomplished by titrating the set tidal volume to 6 to 8 mL/kg of ideal body weight. Once this is achieved the tidal volume is titrated down to achieve a plateau pressure of 30 cm H<sub>2</sub>O or less, with lower pressures being more protective. This plateau pressure is measured on the ventilator with an inspiratory hold, and approximates the alveolar pressure. Failing to accomplish this places the lungs at risk for further injury by creating significant shear stress with repeated opening of atelectatic areas (atelectrauma) and overdistending less affected areas (volutrauma, barotrauma). Using small tidal volumes often results in significant hypercapnia, which can have an independent protective effect (permissive hypercapnia). The application of PEEP recruits and opens atelectatic lung, thereby reducing harmful shear forces. The optimal level of PEEP remains uncertain; individual studies have tended to show no mortality benefit of a high PEEP versus a low PEEP ventilatory strategy, however trends in mortality reduction and decreased salvage therapy are seen with a higher PEEP strategy in meta-analysis.

The severity of ARDS is generally subdivided by  $\text{PaO}_2/\text{FiO}_2$  ratios indicating mild (300 to 200), moderate (200 to 100), and severe (<100) disease; these thresholds correspond to rising risk of mortality. A  $\text{PaO}_2/\text{FiO}_2$  ratio of less than 150 suggests a higher mortality ARDS phenotype where therapy in addition to lung protective ventilation may provide benefit. Placing the patient in the prone position appears to reduce mortality. The routine use of neuromuscular blockade is controversial with the most recent trial indicating no mortality benefit. Inhaled pulmonary vasodilators, used to optimize V/Q matching, do improve oxygenation but have no impact on mortality. The benefit of extracorporeal membrane oxygenation is yet unclear and is reserved for very severe, high-mortality disease to be used in expert centers. The use of corticosteroids lacked an evidence basis for many years; recent data is suggestive of benefit in a mixed population of ARDS with early use. The clearest benefit of steroids has been seen with treatment of ARDS related to SARs-CoV2 infection, where multiple randomized trials have confirmed a significant mortality benefit.

#### *Cardiogenic Pulmonary Edema*

Cardiogenic pulmonary edema occurs in patients with cardiomyopathy or acutely when ischemia is present. Diagnosis is suggested by jugular venous distention, a third heart sound, diffuse rales, abnormal ECG, and a chest radiograph showing cardiomegaly, diffuse alveolar infiltrates, and bilateral pleural effusion. A markedly elevated BNP or pro-BNP further suggests a cardiac etiology.

Therapy consists of oxygen, nitrates, diuretics, afterload reduction, and anti-ischemic therapy if the history or ECG is suggestive. Mechanical ventilation produces positive intrathoracic pressure, which improves cardiac function by decreasing both left ventricular preload and afterload, reversing hypoxemia, and decreasing work of breathing. In hemodynamically stable patients without active ischemia, CPAP at levels of 8 to 12 cm H<sub>2</sub>O should be used. A meta-analysis of 15 randomized, controlled trials showed that noninvasive ventilation decreased the need for intubation and improved survival. CPAP and BiPAP appear to be equivalent, although many prefer BiPAP when hypercapnia is present.

Because cardiogenic pulmonary edema is rapidly reversible, intubated patients can often be extubated within 24 hours. That said, the transition from positive pressure ventilation to negative ventilation (e.g., T-piece or extubation) can precipitate pulmonary edema. These patients may benefit from lower peri-extubation respiratory support to anticipate postextubation pulmonary edema.

## ASTHMA IN ADOLESCENTS AND ADULTS

Method of

Matthew A. Rank, MD; and Michael Schatz, MD, MS

### CURRENT DIAGNOSIS

- Confirm the diagnosis by demonstrating an increase in forced expiratory volume in 1 second (FEV<sub>1</sub>) by 12% or more after asthma therapy.
- Assess past severity by a history of exacerbations requiring oral corticosteroids, emergency department visits, hospitalization, or intubation.
- Identify environmental exposures, allergic sensitization, and comorbidities that may be aggravating asthma.
- Assess asthma based on symptom frequency, nocturnal awakenings, rescue therapy use, activity limitation, spirometry, and recent exacerbation history.

### CURRENT THERAPY

- Nonpharmacologic therapy includes asthma education (especially regarding inhaler technique, self-monitoring, self-management, and importance of adherence to medication), reduction in environmental triggers, addressing any relevant psychosocial issues, and allergen immunotherapy for select patients.
- Preferred step therapy for long-term asthma management is low-dose inhaled corticosteroids, either scheduled or as needed, for mild asthma; low- or medium-dose inhaled corticosteroids combined with formoterol<sup>1</sup> scheduled and as needed for moderate asthma; and medium- or high-dose inhaled corticosteroids plus long-acting  $\beta$  agonists plus a long-acting muscarinic antagonist for severe asthma, plus additional consideration for other add-on therapies (macrolide antibiotics, biologics, and oral prednisone).
- Asthma exacerbations should be treated with high-dose inhaled  $\beta$  agonists and early use of systemic corticosteroids.

<sup>1</sup>Not FDA approved for this indication.

Asthma is an extremely common chronic medical condition that causes substantial morbidity among its sufferers. In addition to discomfort, asthma can cause sleep disruption, missed school and work, limitations of recreational activities, and acute episodes requiring emergency hospital care. Although the past 40 years have seen the introduction of increasingly effective and convenient medications, recent surveys continue to suggest that asthma remains suboptimally controlled in a substantial proportion of patients. The purpose of this chapter is to describe an approach to assessment and therapy that leads to optimal asthma control. It is based on the Global Strategy for Asthma Management and Prevention (Global Initiative for Asthma [GINA] 2021) update and the 2020 Focused Updates to the Asthma Management Guidelines from the National Heart, Lung, and Blood Institute, but it includes recommendations from multiple sources.

### Diagnosis

The first step in evaluating a patient with asthma is to confirm the diagnosis. This is particularly important in patients with atypical symptoms or a poor response to asthma therapy. Asthma is confirmed by demonstration of reversible airways obstruction, which most commonly is an increase in FEV<sub>1</sub> by 12% or greater and at least 200 mL after administration of an inhaled bronchodilator for adults, and an increase greater than 12% for adolescents. For some patients, 2 to 4 weeks of chronic inhaled asthma therapy or 2 weeks of oral corticosteroid therapy are necessary to demonstrate reversibility. The latter is particularly important in adults with a history of smoking in whom chronic obstructive pulmonary disease (COPD) is a diagnostic consideration. In patients with normal pulmonary function, asthma can also be confirmed by means of methacholine (Provocholine) or exercise challenge, which are two forms of a provocation challenge, along with before and after pulmonary function tests. In addition, an elevated fractional exhaled nitric oxide (FENO >50 ppb) can be suggestive of a diagnosis of asthma.

Particularly important masqueraders of asthma include vocal cord dysfunction, panic attacks, hyperventilation, deconditioning, and cough caused by postnasal drip, reflux, or angiotensin-converting enzyme (ACE) inhibitor therapy. All of these can also coexist with asthma, so their presence does not exclude asthma. Even when these conditions coexist with asthma, their diagnosis and appropriate therapy usually reduce the patient's respiratory symptoms. Other diagnostic considerations include syndromes of which asthma represents one part: allergic bronchopulmonary aspergillosis, eosinophilic granulomatosis with polyangiitis, and aspirin-exacerbated respiratory disease.

### Assessment

Assessment of patients with asthma involves gathering details of past severity, identifying aggravating factors, and defining current asthma control status.

#### Current Status

Assessment of the current therapy the patient is actually taking is necessary for understanding the asthma's severity and to appropriately initiate or change therapy. It is particularly important to determine whether the patient is taking long-term control medications, such as inhaled corticosteroids, long-acting  $\beta$  agonists, leukotriene modifiers, long-acting muscarinic antagonists, oral corticosteroids, or biologics. Both asthma control and risk factors for future exacerbations should be considered. Patients with at least three of the following symptoms in the past 4 weeks are defined as *uncontrolled* in the GINA 2021 guidelines: daytime asthma symptoms more than twice a week, night waking caused by asthma, rescue treatments more than twice a week other than use as pretreatment for exercise, and any activity limitation caused by asthma. Other tools to assess asthma control, such as the Asthma Control Test or the Asthma Control Questionnaire, can also be used to determine asthma control (Table 1).

Asthma can be a mild, infrequent illness or a severe daily one. Certain severity markers identify patients who are more likely to experience severe exacerbations or to have symptoms that are more

**TABLE 1** Determining Asthma Control in Patients 12 Years of Age and Older\*

IN THE PAST 4 WEEKS, HAS THE PATIENT HAD	WELL CONTROLLED	PARTLY CONTROLLED	UNCONTROLLED
Daytime asthma symptoms more than two times per week?	None of these	1 to 2 of these	3 to 4 of these
Any night waking caused by asthma?			
Rescue needed more than two times per week other than for pretreatment for exercise?			
Any activity limitation caused by asthma?			

\*Modified from Global Initiative for Asthma (GINA) 2020 guideline. Can consider using the Asthma Control Test or Asthma Control Questionnaire as other ways to assess asthma symptom control.

**TABLE 2** Risk Factors for Future Asthma Exacerbations in Patients 12 Years of Age and Older\*

Ever intubated or in the intensive care unit for asthma
Had one or more severe exacerbations in the past year
Frequent use of rescue inhaler (more than 200 puffs of rescue inhaler per month)
Not adherent to ICS with good technique
Comorbid conditions: obesity, chronic rhinosinusitis, GERD, pregnancy
Psychological or socioeconomic challenges
Low lung function: FEV <sub>1</sub> % predicted <60%, high bronchodilator reversibility

\*Any of these risk factors increases the risk for exacerbations, even if the patient has few day-to-day asthma symptoms.

FEV<sub>1</sub>, Forced expiratory volume in 1 second; GERD, gastroesophageal reflux disease; ICS, inhaled corticosteroid.

Modified from Global Initiative for Asthma (GINA) 2021 guideline.

difficult to control and who thus require more careful surveillance. These include a history of asthma hospitalization, especially requiring intensive care or intubation, past requirement for oral corticosteroids, and specific comorbid conditions (Table 2). In patients with prior severe exacerbations, the rapidity of the onset of the exacerbation should be ascertained. Some patients may have minimal day-to-day asthma symptoms but still have a high risk for asthma exacerbations.

### Aggravating Factors

Factors that appear to trigger asthma symptoms should be assessed because they may be targets for avoidance therapy. Certain aspects of the patient's environment that can contribute to asthma triggering should be specifically ascertained, including occupational exposures, age of the home, pets, carpeting, visible mold, active or passive smoke, and cockroach exposure. Patients with persistent asthma should have in vitro or skin tests to identify allergic sensitization to pollens, house dust mites, mold spores, animal dander, and cockroaches that can contribute to the maintenance of asthma inflammation or can trigger episodes. The presence of comorbidities that can aggravate asthma, including obesity, rhinitis, sinusitis, gastroesophageal reflux, obstructive sleep apnea, and COPD, should be identified and treated. Finally, psychosocial factors to assess include a history or symptoms of anxiety or depression, attitudes toward asthma and asthma therapy, adherence to therapy, and social support. These may be targets for therapy or may be helpful when creating an effective therapeutic plan and therapeutic alliance.

### Long-Term Management

#### Nonpharmacologic Therapy

The first tenet of nonpharmacologic therapy in the long-term management of asthma is education. Patients must understand the inflammatory pathophysiology of asthma and the relationships among

airway inflammation, bronchospasm, and symptoms. Patients should be informed that the cause of asthma is unknown and that there is no cure, but triggers can be identified and asthma can be controlled. They should receive education regarding self-assessment, either based on symptoms or peak flow monitoring, and regarding the recognition of early signs of an impending exacerbation.

The next step is to discuss and agree on the goals of therapy. Long-term goals of asthma management include the following:

- Achieve good control of symptoms.
- Maintain optimal pulmonary function.
- Maintain normal activity, including work, school, leisure activity, and exercise.
- Prevent recurrent exacerbations, especially those requiring urgent medical visits.
- Provide pharmacotherapy with minimal or no adverse effects.
- Achieve patient and family satisfaction with asthma care.

The healthcare provider should let the patient know that these are the expectations of optimal management and confirm that they are the patient's goals as well.

A very important component of nonpharmacologic therapy is the reduction of relevant environmental triggers. Information should be given regarding environmental control of pollen, mites, mold, animal dander, and cockroach antigens (Box 1) that appear to be relevant based on the history and results of skin or in vitro specific IgE tests. A multifaceted environmental mitigation plan is favored over single interventions. Inhalant allergen immunotherapy should be considered for patients who have persistent asthma when there is clear evidence of a relationship between symptoms and exposure to an allergen to which the patient is sensitive.

Finally, psychosocial issues should be considered and addressed. For many patients, the education and therapeutic alliance described earlier adequately addresses psychosocial concerns. For other patients, poor past adherence requires identifying the barriers to adherence and finding solutions together. Resources for patients with poor social support should be identified. Clinically significant anxiety or depression that can make asthma harder to control should be treated.

#### Pharmacologic Step Therapy

The main principle of asthma pharmacologic step therapy is to add therapy in steps until control is achieved (step up) and decrease therapy in reverse steps (step down) to establish the lowest effective dose necessary to maintain control.

There are two types of asthma medications: quick-relief medications (Table 3) and long-term control medications (Table 4). Systemic corticosteroids can be used either short term to treat an exacerbation (see Table 3) or as long-term maintenance therapy for patients with severe disease (see Table 4). The generally recommended steps of pharmacologic therapy are shown in Table 5. Definitions of low-, medium-, and high-dose inhaled corticosteroids for each of the available preparations are given in Table 6. At each therapeutic step level, the GINA guideline has indicated preferred medications, which generally identify medications with the best balance of efficacy and safety in clinical trials for patients at that level of severity. However, these recommendations are

**Allergens**

An approach that considers multiple relevant triggers is most likely to be successful.

**Animal Dander**

Remove the animal from the house, or, at a minimum, keep the animal out of the patient's bedroom and keep the bedroom door closed.

**Dust Mites****Recommended**

Encase mattress in a special dustproof cover.

Encase pillow in a special dustproof cover, or wash it weekly in hot water.

Wash sheets and blankets on the patient's bed in hot water weekly. Water must be hotter than 130°F to kill the mites. Cooler water used with detergent and bleach can also be effective.

**Desirable**

Reduce indoor humidity to 60% or less.

Remove carpets from the bedroom.

Avoid sleeping or lying on cloth-covered cushions or furniture.

Remove carpets that are laid on concrete.

**Cockroaches**

Keep all food out of the bedroom.

Keep food and garbage in closed containers.

Use poison baits, powders, gels, or paste (e.g., boric acid). Traps can also be used.

If a spray is used to kill cockroaches, stay out of the room until the odor goes away.

**Pollens (from Trees, Grass, or Weeds) and Outdoor Molds**

Try to keep windows closed.

If possible, stay indoors, with windows closed, during periods of peak pollen exposure, which are usually during the midday and afternoon.

**Indoor Mold**

Fix all leaks, and eliminate water sources associated with mold growth.

Clean moldy surfaces.

Dehumidify basements if possible.

**Tobacco Smoke**

Advise patients and others in the home who smoke to stop smoking or to smoke outside the home.

Discuss ways to reduce exposure to other sources of tobacco smoke, such as from daycare providers and the workplace.

**Indoor and Outdoor Pollutants and Irritants**

If possible, do not use a wood-burning stove, kerosene heater, fireplace, unvented gas stove, or heater.

Try to stay away from strong odors and sprays, such as perfume, talcum powder, hair spray, paints, new carpet, or particle board.

based on population data and must be tailored to individual patient needs, circumstances, and responsiveness to therapy.

All patients with asthma should have an action plan that describes their pharmacologic self-management. Aspects of pharmacologic self-management include maintenance of the medication schedule, rescue therapy doses for increased symptoms, when and how to increase controller medication therapy, when and how to use prednisone, how to recognize a severe exacerbation, and when and how to seek urgent or emergency care. Controller medications may be increased with an upper respiratory infection or with symptoms requiring more than two doses of rescue

therapy in 12 hours. Although doubling the dose of inhaled corticosteroids does not appear to generally be sufficient to provide a clinical benefit under these circumstances, quadrupling or quintupling the dose may be helpful. Prednisone is usually needed for patients with incomplete or temporary responses to adequate doses of  $\beta$  agonists (2 to 6 puffs with a spacer, waiting at least 1 minute between puffs), substantial interference with sleep every night, requirement for 12 or more puffs of  $\beta$  agonist in a 24-hour period, or a peak flow less than 60% predicted. Home treatment of exacerbation is further discussed later in this chapter.

Persistent asthma is most effectively controlled with daily long-term control medications, specifically antiinflammatory therapy. For patients receiving long-term control medications, identify their current step of therapy, based on what they are actually taking (see Table 5), and their level of control (see Table 1). Data suggest that the use of antiinflammatory therapy for patients who were previously defined as having mild and intermittent asthma leads to reduced exacerbation risk and can be used as scheduled or intermittent therapy to reduce exacerbations. In general, step up one step for patients whose asthma is not well controlled. For patients with very poorly controlled asthma, consider increasing by two steps, a course of oral corticosteroids, or both. Before increasing pharmacologic therapy, consider adverse environmental exposures, poor adherence, poor inhaler technique, or comorbidities as targets for intervention. For patients with troublesome or debilitating side effects from asthma therapy, explore a change in therapy.

There are six biologic medications approved for severe asthma not controlled by standard therapy (see Table 4). These biologic medications can be considered for patients with frequent and/or severe asthma exacerbations, poor asthma control, or frequent and/or chronic use of systemic corticosteroids in spite of maximal standard therapy.

**Follow-Up**

Patients whose asthma is not controlled should be seen every 2 to 6 weeks (depending on their initial level of severity or control) until control is achieved. Once control is achieved, follow-up contact at 1- to 6-month intervals is recommended. These checkups should ensure continued control, identify other changes in the patient's status, and update the patient's action plan.

When well-controlled asthma has been maintained for at least 3 months, a step down in therapy can be considered to determine the minimum amount of medication required to maintain control or reduce the risk for side effects. Reduction in therapy should be gradual because asthma can deteriorate at a highly variable rate and intensity. Doses of inhaled corticosteroids may be reduced by about 25% to 50% every 3 months to the lowest dose possible to maintain control. Many patients with persistent asthma relapse if inhaled corticosteroids are totally discontinued.

Patients should be encouraged to contact their asthma healthcare provider for signs of loss of asthma control, such as nocturnal symptoms, increasing  $\beta$ -agonist use, or activity limitation. Consultation with an asthma specialist is recommended if the patient has difficulties achieving or maintaining control of asthma, immunotherapy or an asthma biologic is being considered, the patient requires step 4 care or higher, or the patient has had an exacerbation requiring hospitalization.

**Treatment of Exacerbations**

Asthma exacerbations are acute or subacute episodes of progressively worsening shortness of breath, cough, wheezing, or chest tightness associated with decreases in expiratory airflow.

**Home Management**

Patients' action plans should direct their home therapy of asthma exacerbations according to the following recommendations.

Initial therapy can be with inhaled short-acting  $\beta$  agonists (2 to 6 puffs by metered-dose inhaler [MDI] or nebulizer). This may be repeated in 20 minutes. Formoterol, a rapid and long-acting  $\beta$  agonist, in combination with inhaled corticosteroids, can also be used for rescue treatments at home as part of a single maintenance and

**TABLE 3** Usual Dosages for Quick-Relief Medications for Patients 12 Years of Age and Older

MEDICATION	DOSAGE FORM	ADULT DOSE	COMMENTS
<b>Inhaled Short-Acting <math>\beta_2</math> Agonists (SABAs)</b>			
Metered-Dose Inhaler		Applies to All Three SABAs	
Albuterol HFA (Proventil, Ventolin, ProAir)	90 $\mu$ g/puff, 200 puffs/canister	2 puffs 5 min before exercise	An increasing use or lack of expected effect indicates diminished control of asthma.
Albuterol Breath Activated (ProAir RespiClick, ProAir Digihaler with eModule)	90 $\mu$ g/puff, 200 puffs/canister	2 puffs q4–6h prn	Not recommended for long-term daily treatment. Regular use exceeding 2 days/week for symptom control (not prevention of EIB) indicates the need for additional long-term control therapy.
Levalbuterol HFA (Xopenex)	45 $\mu$ g/puff, 200 puffs/canister	2 puffs q4–6h prn	Differences in potencies exist, but all products are essentially comparable on a per-puff basis. May double the usual dose for mild exacerbations. For levalbuterol, the patient should prime the inhaler by releasing 4 actuations before use. For HFA, periodically clean the HFA activator as the drug may block/plug the orifice. Nonselective agents (epinephrine [Primatene Mist], metaproterenol [Alupent]) are not recommended because of their potential for excessive cardiac stimulation, especially in high doses.
<b>Nebulizer Solutions</b>			
Albuterol (AccuNeb, Proventil)	0.63 mg/3 mL 1.25 mg/3 mL 2.5 mg/3 mL 5 mg/mL (0.5%)	1.25–5 mg in 3 mL saline q4–8h prn	May mix with budesonide (Pulmicort) inhalant suspension, cromolyn (Intal), or ipratropium (Atrovent) <sup>1</sup> nebulizer solutions. May double the dose for severe exacerbation.
Levalbuterol (R-albuterol) (Xopenex)	0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/0.5 mL 1.25 mg/3 mL	0.63 mg–1.25 mg q8h prn	Compatible with budesonide (Pulmicort) inhalant suspension. The product is a sterile-filled, preservative-free, unit-dose vial.
<b>Anticholinergics</b>			
<b>Metered-Dose Inhalers</b>			
Ipratropium HFA (Atrovent) <sup>1</sup>	17 $\mu$ g/puff, 200 puffs/canister	2–3 puffs q6h	Multiple doses in the emergency department (not hospital) setting provide additive benefits to short-acting $\beta$ agonists. It is the treatment of choice for bronchospasm caused by a $\beta$ blocker. Does not block EIB. Reverses only cholinergically mediated bronchospasm; does not modify reaction to antigen. May be an alternative for patients who do not tolerate short-acting $\beta$ agonists. Evidence is lacking for ipratropium producing added benefit to $\beta_2$ agonists for long-term control in asthma therapy.
Ipratropium with albuterol (Combivent Respimat) <sup>1</sup>	20 $\mu$ g/puff of ipratropium bromide and 100 $\mu$ g/puff of albuterol, 200 puffs/canister	2–3 puffs q6h	
<b>Nebulizer Solutions</b>			
Ipratropium bromide <sup>1</sup>	0.2 mg/mL (0.02%)	0.5 mg q6h	
Ipratropium bromide with albuterol (DuoNeb) <sup>1</sup>	0.5 mg/3 mL ipratropium bromide and 2.5 mg/3 mL albuterol	3 mL q4–6h	Contains EDTA to prevent discoloration of the solution. This additive does not induce bronchospasm.
<b>Systemic Corticosteroid</b>			
Methylprednisolone (Medrol) Prednisolone (Delta-Cortef, Prelone) Prednisone (Deltasone, Orasone)	2-, 4-, 6-, 8-, 16-, 32-mg tab 5-mg tabs; 5 mg/5 mL, 15 mg/5 mL 1-, 2.5-, 5-, 10-, 20-, 50-mg tabs; 5 mg/mL, 5 mg/5 mL	Short course (burst): 40–60 mg/day as a single dose or two divided doses for 3–10 days	Short courses (bursts) are effective for establishing control when initiating therapy or during a period of gradual deterioration. Action may begin within 1 hour. The burst should be continued until symptoms resolve. This usually requires 3–10 days but can require longer. There is no evidence that tapering the dose following improvement prevents relapse in asthma exacerbations.

**TABLE 3** Usual Dosages for Quick-Relief Medications for Patients 12 Years of Age and Older—cont'd

MEDICATION	DOSAGE FORM	ADULT DOSE	COMMENTS
Dexamethasone (Decadron)	0.5-, 0.75-, 1-, 1.5-, 2-, 4-, and 6-mg tablets and 0.5 mg/5 mL and 1 mg/5 mL	0.6 mg/kg as a single dose	Can be considered as an alternative for children presenting to the emergency department with asthma.
<b>Steroid Injection</b>			
Methylprednisolone acetate (Depo-Medrol)	40 mg/mL 80 mg/mL	240 mg <sup>3*</sup> IM once	May be used in place of a short burst of oral steroids in patients who are vomiting or if adherence is a problem.

\*80 to 120 mg per package insert.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

CFC, Chlorofluorocarbon; EDTA, edetic acid; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; PEF, peak expiratory flow; tab, tablet.

Modified and updated from National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR-3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007, *J Allergy Clin Immunol* 120(5 Suppl):S94–S138, 2007; 2020: Focused Updates to Asthma Management.

**TABLE 4** Usual Dosages for Long-Term Control Medications for Patients 12 Years of Age and Older

MEDICATION	DOSAGE FORM*	ADULT DOSE	COMMENTS
<b>Systemic Corticosteroids</b>			
Methylprednisolone (Medrol)	2-, 4-, 8-, 16-, 32-mg tab	7.5–60 mg qd in a single dose in AM or qod as needed for control	For long-term treatment of severe persistent asthma, administer a single dose in AM either daily or on alternate days. (Alternate-day therapy may produce less adrenal suppression.)
Prednisolone (Delta-Cortef, Prelone)	5-mg tab 5 mg/5 mL, 15 mg/5 mL	Short-course (burst) to achieve control, 40–60 mg/day as a single dose or two divided doses for 3–10 days	Short courses (bursts) are effective for establishing control when initiating therapy or during a period of gradual deterioration. There is no evidence that tapering the dose following improvement in symptom control and pulmonary function prevents relapse.
Prednisone (Deltasone, Orasone)	1-, 2.5-, 5-, 10-, 20-, 50-mg tab 5 mg/mL, 5 mg/5 mL		
Inhaled Long-Acting $\beta_2$ agonists			Should not be used for relief of acute symptoms or exacerbations. Use only with ICS.
Salmeterol (Serevent Diskus)	DPI 50 $\mu$ g/inhalation	1 inhalation q12h	Decreased duration of protection against EIB may occur with regular use.
<b>Inhaled Combined Medications*</b>			
Fluticasone and salmeterol (Advair Diskus, Advair HFA and generic)	DPI: 100 $\mu$ g/50 $\mu$ g, 250 $\mu$ g/50 $\mu$ g, 500 $\mu$ g/50 $\mu$ g HFA: 45 $\mu$ g/21 $\mu$ g, 115 $\mu$ g/21 $\mu$ g, 230 $\mu$ g/21 $\mu$ g	1 inhalation bid <sup>†</sup> 2 puffs bid <sup>†</sup>	100/50 DPI or 45/21 HFA for patients not controlled on low- to medium- dose ICS 250/50 DPI or 115/21 HFA for patients not controlled on medium- to high- dose ICS
Fluticasone and salmeterol (AirDuo RespiClick, AirDuo Digihaler with eModule)	55 $\mu$ g/14 $\mu$ g, 113 $\mu$ g/14 $\mu$ g, 232 $\mu$ g/14 $\mu$ g	1 inhalation bid	
Budesonide and formoterol (Symbicort and generic)	HFA MDI: 80 $\mu$ g/4.5 $\mu$ g, 160 $\mu$ g/4.5 $\mu$ g	2 inhalations bid <sup>†</sup>	80/4.5 for patients not controlled on low- to medium-dose ICS 160/4.5 for patients not controlled on medium- to high-dose ICS
Mometasone and formoterol (Dulera)	50 $\mu$ g/5 $\mu$ g, 100 $\mu$ g/5 $\mu$ g, 200 $\mu$ g/5 $\mu$ g	2 inhalations bid <sup>†</sup>	100/5 for patients not controlled on low- to medium-dose ICS 200/5 for patients not controlled on medium- to high-dose ICS
Fluticasone furoate/vilanterol trifenate (Breo Ellipta)	100 $\mu$ g/25 $\mu$ g 200 $\mu$ g/25 $\mu$ g	1 inhalation daily	200/25 for patients not controlled on 100/25

Continued

**TABLE 4** Usual Dosages for Long-Term Control Medications for Patients 12 Years of Age and Older—cont'd

MEDICATION	DOSAGE FORM*	ADULT DOSE	COMMENTS
Fluticasone furoate/umeclidinium/ vilanterol (Trelegy Ellipta)	100 µg/62.5 µg/25 µg 200 µg/62.5 µg/25 µg	1 inhalation daily	For patients not controlled on ICS/LABA
<b>Inhaled Long-Acting Anticholinergic</b>			
Tiotropium (Spiriva Respimat)	1.25 µg or 2.5 µg/actuation	2 puffs daily	Possibly more side effects compared with LABA as add-on therapy to ICS; more effective than placebo when added to ICS; effective when added to ICS/LABA
<b>Leukotriene Modifiers</b>			
<b>Leukotriene Receptor Antagonists</b>			
Montelukast (Singulair, generic)	4-mg, or 5-mg chewable tab 10-mg tab	10 mg qhs	Montelukast exhibits a flat dose-response curve. Doses >10 mg do not produce a greater response in adults.
Zafirlukast (Accolate, generic)	10- or 20-mg tab	40 mg/day (20-mg tab bid)	For zafirlukast: Administration with meals decreases bioavailability; take at least 1 h before or 2 h after meals. Zafirlukast is a microsomal p450 enzyme inhibitor that can inhibit the metabolism of warfarin. Doses of this drug should be monitored accordingly. Monitor for signs and symptoms of hepatic dysfunction.
<b>5-Lipoxygenase Inhibitor</b>			
Zileuton (Zyflo)	600-mg tab, immediate-release or extended-release tab	2400 mg daily (600 mg qid for immediate release or 1200 mg bid for extended release)	Monitor hepatic enzymes (ALT). Zileuton is a microsomal p450 enzyme inhibitor that can inhibit the metabolism of warfarin and theophylline. Doses of these drugs should be monitored accordingly.
<b>Methylxanthines</b>			
Theophylline (Slo-Phyllin, Theobid, Theo-Dur)	Liquids, sustained-release tab, cap	Starting dose 10 mg/kg/day up to 300 mg max Usual max 800 mg/day	Adjust dosage to achieve serum concentration of 5 to 15 µg/mL at steady-state (≥48 h on same dosage). Because of wide interpatient variability in theophylline metabolic clearance, routine serum theophylline level monitoring is essential. Patients should be told to discontinue if they experience symptoms of toxicity. Various factors (diet, food, febrile illness, age, smoking, and other medications) can affect serum concentration.
<b>Asthma Biologics</b>			
Omalizumab (Xolair)	Subcutaneous (SQ) injection 150 mg/1.2 mL following reconstitution with 1.4 mL sterile water for injection	150–375 mg SQ every 2–4 weeks, depending on body weight and pretreatment serum IgE level	For children 6 years of age and older with moderate to severe allergic asthma not controlled by inhaled corticosteroids. Monitor patient following injections; be prepared and equipped to identify and treat anaphylaxis that may occur. Do not administer more than 150 mg per injection site. Higher doses (up to 600 mg every 2 weeks) can be used for patients with comorbid nasal polyps. The dosing of omalizumab for nasal polyps is based on weight and IgE levels that is different from the dosing for asthma.

**TABLE 4** Usual Dosages for Long-Term Control Medications for Patients 12 Years of Age and Older—cont'd

MEDICATION	DOSAGE FORM*	ADULT DOSE	COMMENTS
Benralizumab (Fasenra)	30 mg/mL single-dose prefilled syringe, 30 mg/mL autoinjector	30 mg SQ every 4 weeks for first 3 doses, then once every 8 weeks	For patients 12 years of age and older with severe eosinophilic asthma
Mepolizumab (Nucala)	100 mg/mL prefilled syringe, 100 mg/mL autoinjector	100 mg SQ every 4 weeks	For patients 12 years of age and older with severe eosinophilic asthma: 100 mg SQ every 4 wks. For patients with comorbid nasal polyps, the dose is the same as for asthma. For patients with eosinophilic granulomatosis with polyangiitis and hypereosinophilic syndrome, the dose of mepolizumab is 300 mg SQ every 4 weeks, with 3 separate 100-mg SQ injections given at least 5 cm apart on the upper arm, thigh, or abdomen. For children 6 to 11 years of age with severe eosinophilic asthma: 40 mg SQ every 4 weeks
Reslizumab (Cinqair)	Intravenous solution 10 mg/1 mL (10 mL)	3 mg/kg IV over 20 to 50 minutes every 4 weeks	For adults with severe eosinophilic asthma
Dupilumab (Dupixent)	Subcutaneous solution in prefilled syringe: 300 mg/2 mL and 200 mg/1.14 mL; Pen-injector: 300 mg/2 mL	400 mg SQ loading followed by 200 mg every other week OR 600 mg SQ loading followed by 300 mg every other week	For patients 12 years of age and older with moderate to severe eosinophilic or corticosteroid-dependent asthma. Consider using the 300-mg maintenance dose for patients with oral corticosteroid-dependent asthma, moderate-to-severe atopic dermatitis, or nasal polyps. For children 5 to 11 years of age, the dosing should be adjusted by weight: For 15 to 30 kg, use 100 mg every 2 weeks or 300 mg every 4 weeks; for >30 kg, use 200 mg every 2 weeks. For children 5 to 11 years of age who also have moderate-to-severe atopic dermatitis, use the atopic dermatitis dosing guidelines.
Tezepelumab-ekko (Tezspire)	Subcutaneous solution 210 mg/1.91 mL	210 mg SQ every 4 weeks	For severe asthma in patients 12 years of age and older

\*See Table 6 for estimated comparative daily dosages for inhaled corticosteroids.

<sup>†</sup>Dose depends on level of severity or control.

ALT, Alanine aminotransferase; amp, ampule; cap, capsule; DPI, dry powder inhaler; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; ICS, inhaled corticosteroid; LABA, long-acting  $\beta_2$  agonist; max, maximum; MDI, metered-dose inhaler; SABA, short-acting  $\beta_2$  agonist; tab, tablet.

reliever treatment strategy, with the total number of puffs permitted varying by age and medication type (see Table 5, steps 1 to 4).<sup>1</sup> With a favorable response (minimal or no symptoms and peak expiratory flow [PEF]  $\geq 80\%$  predicted or personal best), the patient may continue  $\beta$  agonists every 3 to 4 hours for 24 to 48 hours. If repeated  $\beta$  agonists are needed, a short course of oral corticosteroids should be considered.

With an incomplete response to initial therapy (persistent wheezing and dyspnea and PEF 50% to 79% predicted or personal best), oral corticosteroids should be added,  $\beta$  agonists should be repeated, and the patient should contact the clinician that day.

With a poor response (marked wheezing and dyspnea at rest, PEF <50% predicted or personal best), oral corticosteroids should be added, the  $\beta$  agonist should be repeated immediately, and the patient should contact the clinician and usually proceed to the emergency department. For signs of severe distress (e.g., difficulty talking in full sentences, diaphoresis, drowsiness, confusion, or cyanosis), 911 should be called.

#### Emergency Department and Hospital Management

Assessment should rapidly determine the severity of the exacerbation based on the intensity of symptoms, signs (heart rate, respiratory rate, use of accessory muscles, chest auscultation), peak flow (unless the patient is too dyspneic to perform), and pulse oximetry. Treatment should begin immediately following recognition of an exacerbation severe enough to cause dyspnea at rest, peak flow less than 70% predicted or personal best, or pulse oximetry

<sup>1</sup>Not FDA approved for this indication.

**TABLE 5** Stepwise Approach for Managing Asthma in Patients 12 Years of Age and Older\*

STEP	PREFERRED THERAPY	ALTERNATIVE THERAPY
1	As needed SABA or as needed low-dose ICS-formoterol <sup>1</sup>	
2	Low-dose ICS daily plus SABA or low-dose ICS taken whenever short-acting β agonist is taken or as needed low-dose ICS-formoterol <sup>1</sup>	
3	Scheduled and as needed low-dose ICS-formoterol <sup>1</sup>	Medium-dose ICS plus as-needed SABA, low-dose ICS plus LABA or LTRA or tiotropium and as-needed SABA
4	Scheduled and as needed medium-dose ICS-formoterol <sup>1</sup>	Medium-dose ICS plus LABA or LTRA or tiotropium and as-needed SABA
5	Medium- to high-dose ICS plus LABA plus tiotropium plus as-needed SABA	Consider add-on therapy with macrolide antibiotics, and/or biologics (anti-IgE, anti-IL5/5R, anti-IL4R). Oral corticosteroids if necessary.

\*The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

<sup>1</sup>Not FDA approved for this indication.

ICS, Inhaled corticosteroid; LABA, long-acting β agonist; LTRA, leukotriene receptor antagonist; SABA, short-acting β agonist.

Modified from Global Initiative for Asthma (GINA) 2020 guideline; Expert Panel Working Group of the National Heart, Lung, and Blood Institute (NHLBI) administered and coordinated National Asthma Education and Prevention Program Coordinating Committee (NAEPPCC), Cloutier MM, Baptist AP, et al. 2020 Focused Updates to the Asthma Management Guidelines: A Report from the National Asthma Education and Prevention Program Coordinating Committee Expert Panel Working Group, *J Allergy Clin Immunol* 146(6):1217–1270, 2020.

**TABLE 6** Estimated Comparative Daily Dosages for Inhaled Corticosteroids for Patients 12 Years of Age and Older

DRUG	DOSAGE FORM	DAILY DOSE		
		LOW (μg)	MEDIUM (μg)	HIGH (μg)
Beclomethasone (QVAR RediHaler)	40 or 80 μg/puff	80–240	>240–480	>480
Budesonide DPI (Pulmicort Flexhaler)	90 or 180 μg/inhalation	180–360	>360–720	>720
Ciclesonide (Alvesco)	80 or 160 μg/actuation	80–160	>160–320	>320
Fluticasone-HFA (Flovent HFA)	MDI: 44, 110, 220 μg/puff	88–264	>264–440	>440
Fluticasone DPI (Flovent Diskus, ArmonAir RespiClick, Arnuity Ellipta)	DPI: 50, 100, and 250 μg/inhalation (Flovent Diskus); 55, 113, and 232 μg/inhalation (ArmonAir RespiClick); 50, 100, and 200 μg/inhalation (Arnuity Ellipta)	100–250	>250–500	>500
Mometasone DPI (Asmanex)	110 or 220 μg/actuation	110–220	>220–440	>440

DPI, Dry powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler.

Data from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR-3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007, *J Allergy Clin Immunol* 120(5 Suppl):S94–S138, 2007; Kelly HW. Comparison of inhaled corticosteroids: an update, *Ann Pharmacother* 2009;43(3):519–527, 2009; Global Initiative for Asthma (GINA) 2019 guideline.

oxygen saturation less than 95%. While treatment is being given, a brief, focused history and a physical examination pertinent to the exacerbation can be obtained.

In patients with mild to moderate exacerbations (PEF >40% predicted), initial therapy includes oxygen to achieve oxygen saturation greater than 93% and an inhaled short-acting β agonist by nebulizer or MDI (4 to 8 puffs) with a holding chamber, which may be repeated up to three times in the first hour. Oral corticosteroids (prednisone 40 to 80 mg) are recommended if there is no immediate response to therapy or if the patient was recently treated with oral corticosteroids.

In patients with severe exacerbations (PEF <40% predicted), initial therapy includes oxygen as mentioned earlier, an inhaled high-dose short-acting β agonist (e.g., albuterol 5 mg) and ipratropium (Atrovent 0.5 mg)<sup>1</sup> by nebulizer, and oral or intravenous corticosteroids (prednisone or methylprednisolone [Solu-Medrol]

80 mg). The albuterol may be repeated every 20 minutes or used continuously for 1 hour.

Repeated assessments of symptoms, signs, PEF, and oxygen saturation determine the responsiveness of the exacerbation to therapy. Such assessments should be made in patients presenting with severe exacerbations after the initial bronchodilator treatment and in all patients after three doses of bronchodilator therapy (60 to 90 minutes after initial treatment). In patients who are improving, short-acting β agonists may be repeated every hour until a favorable response is achieved (no distress, PEF >70%). When this response is sustained for at least 60 minutes after the last treatment, the patient may usually be discharged on a course of oral corticosteroids (generally prednisone 40 to 60 mg for 5 to 10 days), initiation or continuation of medium-dose inhaled corticosteroids, and arrangement for outpatient follow-up.

In patients who are not improving with the aforementioned therapy, adjunctive therapy, such as with intravenous magnesium sulfate<sup>1</sup> (2 g IV over 15 to 30 minutes) or heliox, may be considered. Noninvasive ventilation or intubation and mechanical ventilation may be required for patients with respiratory failure in spite of treatment.

## Summary

Asthma is a very common problem with the potential to cause substantial interference with quality of life. Although there is no cure for asthma, asthma can be well controlled in the majority of patients with proper management and an effective patient-clinician relationship. We hope that the method described herein for assessing and managing asthma will assist healthcare providers in helping their patients achieve well-controlled asthma.

## ATELECTASIS

Method of

Alykhan S. Nagji, MD; Joshua S. Jolissaint, MD; and Christine L. Lau, MD

### CURRENT DIAGNOSIS

- Hypoxia
- Tachypnea
- Diminished breath sounds
- Wheezing
- Radiologic signs of atelectasis

### CURRENT THERAPY

- Chest percussion or vibration
- Nasotracheal or bronchoscopic suctioning
- Incentive spirometry
- Positive-pressure ventilation
- Ambulation
- Postoperative pain control

Atelectasis refers to the collapse of alveoli that affects segmental or lobar regions of the lung or the entire lung and results in hypoventilation. However, recent studies have suggested that the alveoli are not collapsed but are filled with fluid and foam. These hypotheses are not mutually exclusive; collapsed alveoli and fluid- and foam-filled alveoli may be present concurrently in an atelectatic lung. Although atelectasis is considered a benign condition, early treatment, reversal, and prevention are essential to an overall improved outcome.

## Etiology

### Compression Atelectasis

Compression atelectasis occurs when the transmural pressure distending the alveolus is reduced to a level that allows the

alveolus to collapse. To best illustrate this mechanism, consider the patient who has undergone induction of anesthesia. The diaphragm is relaxed and is displaced cephalad. In the supine position, the pleural pressures increase to the greatest extent in the dependent lung regions and can compress the adjacent lung tissue.

## Surfactant Impairment

Surfactant serves to reduce the alveolar surface tension, thereby stabilizing the alveoli and preventing collapse. Reduction in surfactant occurs with certain types of anesthesia. Studies have shown that hyperinflation by means of increased tidal volume, sequential air inflations to the total lung capacity, or even a single cycle of increased tidal volume can increase the release of surfactant, aiding in recruitment and stabilization of alveoli.

## Gas Resorption

One mechanism by which gas resorption results in atelectasis involves the patent airway. In regions of the lung with increased ventilation compared to perfusion, which produces a ventilation/perfusion (V/Q) mismatch, there is low alveolar oxygen tension. Increasing the fraction of inspired oxygen (FIO<sub>2</sub>) initiates a cascade of events that increases alveolar oxygen tension (PAO<sub>2</sub>) and decreases alveolar nitrogen tension (PAN<sub>2</sub>), which results in loss of alveolar volume secondary to increased absorption of oxygen.

Another mechanism by which gas resorption leads to atelectasis occurs after complete airway occlusion. In such cases, gas is trapped distal to the obstruction. Gas uptake by the proximal blood flow continues without additional gas inflow. This causes the alveoli to collapse.

## Pathophysiology

The trapping of air and hyperinflation of the alveoli are produced from the aforementioned mechanisms. The gases that are trapped are absorbed by the blood perfusing through that region of the lung, which eventually causes collapse of the alveoli. The atelectasis produces alveolar hypoxia and pulmonary vasoconstriction to prevent V/Q mismatching and to minimize arterial hypoxia. This vascular response is effective only if a large part of the lung is not collapsed; otherwise, intrapulmonary shunting occurs.

## Clinical Presentation

The signs and symptoms of atelectasis are often nonspecific. The natural course of atelectasis may lead to fever, cough, tachypnea, wheezing, rhonchi, and chest pain. On physical examination, atelectasis may manifest as an area of localized reduced breath sounds with constant wheeze or reduced chest wall expansion or both.

## Diagnosis

Chest radiographs aid in the diagnosis of atelectasis. They provide both direct and indirect signs that may indicate an atelectatic etiology for the patient's symptoms.

Direct signs include:

- Displaced pulmonary vessels
- Air bronchograms
- Displacement of intralobar fissures (most reliable sign)

Indirect signs include:

- Pulmonary opacification
- Diaphragmatic elevation
- Hyperexpansion of unaffected lung
- Tracheal, heart, and mediastinal shift toward atelectatic side
- Shift of the hilum toward the collapsed lobe
- Segmental ipsilateral rib approximation

## Treatment

Treatment of atelectasis is geared toward the underlying cause. It is important to recognize respiratory distress and to intubate the patient if appropriate.

If the etiology is that of an obstructive atelectasis, chest percussion or vibration and nasotracheal or bronchoscopic

suctioning may help in the clearing of secretions. With regard to lung re-expansion, incentive spirometry, continuous or intermittent positive-pressure ventilation, and early ambulation may be used.

Those patients who have a nonobstructive atelectasis caused by a pneumothorax or pleural effusion benefit from tube thoracostomy or thoracentesis. Additionally, appropriate pain management in the postoperative setting allows for proper ventilation.

## BACTERIAL PNEUMONIA

Method of

Arjun Muthusubramanian, MD, MPH; Alison N. Huffstetler, MD; and Katharine C. DeGeorge, MD, MS

### CURRENT DIAGNOSIS

- The clinical diagnosis of pneumonia is aided by patient symptoms of fever, cough, shortness of breath, purulent sputum, or chest pain, and by chest radiography which may demonstrate lobar consolidation, pleural effusion, or cavitory lesions.
- When determining the appropriate treatment setting, use a validated scoring system such as the pneumonia severity index (PSI) or CURB-65 to predict disease severity and risk of death.
- Hospital-acquired pneumonia may be diagnosed in a hospitalized patient who develops a pulmonary infection greater than 48 hours after admission.

### CURRENT THERAPY

- Treat outpatients with uncomplicated bacterial pneumonia empirically with high-dose amoxicillin or doxycycline. Only use a macrolide as monotherapy if local pneumococcal resistance is less than 25%.
- Use broad-spectrum antibiotics for empiric treatment of patients with hospital-acquired pneumonia and narrow therapy as soon as possible, based on culture results and sensitivities.
- If a patient has prior respiratory isolation of MRSA or *Pseudomonas aeruginosa*, then presumptive treatment should be initiated and cultures obtained to help guide, and potentially narrow therapy.

Pneumonia (PNA) is a leading cause of death in the United States and accounts for more than 400,000 emergency department (ED) visits annually. PNA often presents with shortness of breath, fever, productive cough, with leukocytosis, and radiographic findings of lobar infiltrate. Diagnosis and treatment should be based on underlying characteristics of the patient and their risk factors. The most common cause of community-acquired pneumonia (CAP) is *Streptococcus pneumoniae*, while hospital-acquired pneumonia (HAP) is more frequently caused by gram-negative

bacteria and places patients at a risk for multi-drug resistant (MDR) organisms. Treatment of a non-severe case of PNA in an individual without comorbidities in an outpatient should be empiric and include high-dose amoxicillin or doxycycline; a macrolide should only be used if local pneumococcal resistance is less than 25%. Therapy for inpatients may rely on sputum and blood cultures with targeted antibiotic regimens to reduce cost and complications of therapy. Common treatment regimens for CAP requiring hospitalization include a respiratory fluoroquinolone (such as moxifloxacin [Avelox]) or a beta-lactam (ceftriaxone [Rocephin]) plus a macrolide. Empiric treatment regimens for HAP should be broad and based on local antibiograms, with consideration for coverage for *Pseudomonas aeruginosa* and/or methicillin-resistant *Staphylococcus aureus* (MRSA). Prevention of PNA is essential and pneumococcal vaccines should be routinely provided according to recommended schedules to children and to adults 65 and over.

This chapter discusses diagnosis and treatment of CAP and HAP in adults. While previous guidelines approached healthcare-associated pneumonia (HCAP) and HAP separately, these are now diagnosed and treated as a single disease process (HAP).

## Epidemiology

CAP affects approximately 5 to 6 people per 1000 persons per year, with seasonal variance resulting in higher incidence during winter. The associated morbidity and mortality rates are high; in 2015, 16.1 deaths per 100,000 people in the US population were attributed to PNA. Treating these patients comes at a cost of \$10.6 to \$17 billion in the United States annually. Men are affected more frequently than women, and African Americans more frequently than Caucasians. The very young and elderly (aged  $\geq 65$  years) are affected more often than younger adults. Despite our best efforts, advances in medical therapies have not significantly decreased the mortality rate associated with PNA since the advent of penicillin in 1928.

The incidence of HAP is approximately 1.6 to 3.6 cases per 1000 hospital admissions. HAP is a leading cause of hospital-acquired infections (HAIs) and 22% of HAIs are accounted for by HAP. HAP most frequently occurs in patients outside of the intensive care unit (ICU); however, those in the ICU and on mechanical ventilation are at high risk of ventilator-associated pneumonia (VAP). HAP is associated with complications including respiratory compromise, septic shock, acute renal failure, and empyema.

Aspiration PNA is not a separate entity, but rather a subset that describes the etiology of the particular infection. Microaspiration (aspiration of small amounts of oropharyngeal secretions) is expected in healthy adults during sleep; however, aspiration PNA refers, rather, to large-volume entry of oropharyngeal or upper gastrointestinal contents into the lower respiratory tract (macroaspiration). While 5% to 15% of CAP can be attributed to aspiration PNA, there is no solid data on the contribution of aspiration PNA to HAP.

## Etiology

### Risk Factors

Predisposing factors for development of PNA include several prescription medications (angiotensin converting enzyme [ACE] inhibitors, antipsychotic medications, glucocorticoids, H-2 blockers, proton pump inhibitors, and sedatives), tobacco use, alcohol use, malnutrition, use of dentures at night, bronchial obstruction due to foreign body, altered mental status due to reversible causes, and pulmonary edema. Nonmodifiable risk factors include immobile cilia, cystic fibrosis, chronic obstructive pulmonary disease (COPD), Kartagener's syndrome, human immunodeficiency virus (HIV), lung cancer, and Young's syndrome.

## Community-Acquired Pneumonia Pathogens
