Worldwide, *S. pneumoniae* is the leading cause of PNA. In the United States, however, rates of streptococcal PNA have declined following implementation of the pneumococcal vaccine in both adults and children. "Typical" organisms that cause PNA in the

United States include *Haemophilus influenzae* (although less common following development of the *H. influenzae* vaccine in 1987), *S. aureus*, group A streptococcus, *Moraxella catarrhalis*, anaerobes, and aerobic gram-negative bacteria. “Atypical” organisms include *Mycoplasma pneumoniae*, *Legionella* spp., *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

Existing pulmonary infection with influenza, respiratory syncytial virus, human metapneumovirus, adenovirus, and rhinovirus increase the risk of developing a secondary bacterial PNA. Patients admitted to the ICU requiring invasive diagnostic testing frequently become infected with *S. pneumoniae*, but have disproportionate incidence of *Legionella*, *S. aureus*, *H. influenzae*, and enteric gram-negative bacilli (*Klebsiella pneumoniae*, *P. aeruginosa*, *Acinetobacter* spp., *M. catarrhalis*). Identification of the organism responsible for CAP is only established in approximately 40% of cases.

Specific patient risk factors, including failure of outpatient therapy, should be considered to identify involved pathogens in CAP. Consider local trends and outbreaks for diagnosis of *Legionella*, *M. pneumoniae*, and *C. pneumoniae*. Alcoholism is frequently linked to anaerobic bacterial PNA, *K. pneumoniae*, *Mycobacterium tuberculosis*, and *S. pneumoniae*. Patients with high risk of aspiration also have higher rates of anaerobic oral flora underlying PNA. Patients with COPD frequently have PNA caused by *C. pneumoniae*, *H. influenzae*, *Legionella* species, *M. catarrhalis*, *P. aeruginosa*, and *S. pneumoniae*. Exposure to animals such as bats, birds, or farm animals increases risk of *Histoplasma capsulatum* and *Coxiella burnetii* infections. HIV is a risk factor for *H. influenzae*, *M. tuberculosis*, and *S. pneumoniae* in the early stages and a risk factor for *Pneumocystis jirovecii* in late stages with decreased CD4 count. Travel increases risk for *Blastomyces dermatitidis* and *Coccidioides* species. Severe infections that do not respond to initial therapy should raise concern for possible MRSA infection. When clinical management would be altered by confirmed diagnosis of microbial infection or aforementioned risk factors for particular causative organisms exist, effort should be made for more extensive diagnostic testing.

### Hospital-Acquired Pneumonia

Acutely ill, hospitalized patients have a higher risk of aspirating, which accounts for many of the differences in involved pathogens in HAP as compared to CAP. Oropharyngeal colonization with microorganisms that are commonly found in hospitals may occur within 48 hours of admission. Aerobic gram-negative bacilli such as *Escherichia coli*, *K. pneumoniae*, *Enterobacter* spp., and *P. aeruginosa* are more commonly identified in patients with HAP, but gram-positive cocci are also identified. HAP, distinct from CAP, places patients at higher risk for MDR pathogens. Prior intravenous (IV) antibiotic use is a strong risk factor for MDR HAP. MRSA is also more common in patients with HAP, primarily due to prior IV antibiotic use as well. MDR *P. aeruginosa* is identified most frequently in patients who have received IV antibiotics, previously on mechanical ventilation, and with a history of COPD, cystic fibrosis, and bronchiectasis.

### Diagnosis

Symptoms of PNA most often include fever, cough, shortness of breath, purulent sputum, and chest pain. Physical exam may demonstrate bronchial breath sounds and crackles, although breath sounds may also be entirely normal, especially in the elderly. Oxygen saturation is often reduced, and chest radiography may demonstrate lobar consolidation, pleural effusion, and/or cavitary lesions. Depending on the severity of illness, patients may be treated in the outpatient or inpatient acute care settings, or may require intensive care for ventilatory or vasopressor support.

### Community-Acquired Pneumonia

Diagnosis of CAP requires the presence of symptoms (fever, cough, purulent sputum, pleuritis, and/or shortness of breath) plus chest radiographic findings consistent with PNA such as lobar consolidation, pleural effusion, and/or cavitary lesions. Blood oxygen saturation is frequently low and white blood cell counts may be elevated,

**TABLE 1** 2007 Infectious Diseases Society of America/American Thoracic Society Criteria for Defining Severe Community-Acquired Pneumonia

#### Minor Criteria

Respiratory rate  $\geq 30$  breaths/min

$\text{PaO}_2/\text{FiO}_2$  ratio  $\leq 250$

Multilobar infiltrates

Confusion/disorientation

Uremia (BUN  $\geq 20$  mg/dL)

Leukopenia only due to infection (white blood cell [WBC] count  $< 4000$  cells/ $\mu\text{L}$ )

Thrombocytopenia (platelet count  $< 100,000/\mu\text{L}$ )

Hypothermia (core temperature  $< 36^\circ\text{C}$ )

Hypotension requiring aggressive fluid resuscitation

#### Major Criteria

Septic shock with need for vasopressors

Respiratory failure requiring mechanical ventilation

BUN, Blood urea nitrogen.

often with a neutrophilic predominance. Presentation in the elderly may be more subtle, with atypical or absent symptoms, blunted febrile response, and lack of leukocytosis. A patient meets the criteria for severe CAP, as defined by Infectious Diseases Society of America/American Thoracic Society CAP severity criteria, when meeting either one major criterion or three or more minor criteria (Table 1).

Patients diagnosed with bacterial PNA treated in the outpatient setting do not require specific microbial identification; neither non-invasive nor invasive testing is recommended for this population (including blood cultures, endotracheal aspirates, and urine antigen testing).

Expectorated sputum samples for gram stain and culture are not routinely recommended for outpatients. Sputum samples for gram stain and culture should be collected, ideally before initiation of treatment, from those who are hospitalized and who meet one of the following: (1) classified as having severe CAP, (2) being empirically treated for MRSA or *P. aeruginosa*, (3) having prior infection with MRSA or *P. aeruginosa*, or (4) having been hospitalized and have received parenteral antibiotics in the past 90 days. Early gram stain can direct initial empiric therapy, especially with findings of less common pathogens. Sputum samples become lower yield as the time between treatment initiation and collection of the sample increases. Inadequate samples ( $< 10$  inflammatory cells per epithelial cell) should not be sent for gram stain or culture. Nebulized hypertonic saline may be used to induce sputum sample when necessary.

Obtaining blood cultures are recommended for the same population of patients for whom sputum culture collection is indicated. In the general population of patients hospitalized with PNA, false positive blood cultures are common and can increase the duration of hospital stay and potentially misinform treatment decisions. Additionally, false positive blood cultures frequently lead to use of broad-spectrum antibiotics, increasing microbial resistance patterns.

Pneumococcal urinary antigen testing should only be obtained for those with severe CAP. *Legionella* urinary antigen testing routinely should be performed for those with severe CAP or when indicated by epidemiologic factors.

During times of community circulation of influenza, those with CAP should be tested for influenza virus, preferably via nucleic acid amplification. Although biomarkers such as procalcitonin (PCT) can be used to monitor response to therapy, PCT, soluble triggering receptor expressed by myeloid cells 1 (sTREM-1), and C-reactive protein should not be used to guide the diagnosis of bacterial PNA.

### Hospital-Acquired Pneumonia

The diagnosis of HAP can be made in hospitalized patients who develop pulmonary infection  $\geq 48$  hours after hospital admission. Criteria for HAP require new or progressive findings on chest radiography, fever, leukopenia or leukocytosis, or altered mental status (for patients aged  $\geq 70$  years), and new or worsening clinical symptoms or signs consistent with bacterial PNA in the absence of mechanical ventilation.

Similar to the management of CAP, sputum and blood cultures should be obtained only when clinically indicated and biomarkers for diagnostic purposes are not routinely recommended. Low dose computed tomography for diagnosis of HAP may assist in diagnosis.

### Treatment Setting

Determination of appropriate treatment setting is important for both patient outcomes and healthcare costs. Inpatient care of PNA can be 25 times as costly as outpatient management and also increases risk of thromboembolic events and superinfection with drug-resistant or virulent organisms. However, inappropriate outpatient management of patients at higher risk of death can lead to potentially avoidable morbidity and mortality.

Several scoring systems have been developed to help predict short-term mortality and need for hospital or ICU admission in patients with bacterial PNA. The following clinical decision aids are the most commonly used:

- **Pneumonia Severity Index (PSI):** Commonly used, well-validated scoring system that evaluates 20 items with emphasis on the age of the patient. Higher PSI scores indicate higher risk of requiring ICU level care or short-term mortality. See [Table 2](#) for details of PSI scoring. Patients classified as risk classes I and II should be managed as outpatients; those with risk class III should be treated in an observation unit or with short-stay hospitalization; risk classes IV and V should be admitted to the hospital.
- **CURB-65:** Severity-of-illness score which incorporates confusion, uremia, respiratory rate, low blood pressure, and age  $\geq 65$  years into a prognostic model to determine a patient's candidacy for outpatient therapy. A CURB-65 score of  $\geq 2$  is indicative of likely need for hospitalization, with consideration for ICU care for those with scores 3 or greater. This shorter scoring system may be less cumbersome in a busy setting, but the effect on hospital admission rates and patient outcomes have been studied less extensively than the PSI score.
- **SMART-COP:** Assists the physician in determining whether the patient requires ICU level care. The algorithm takes into account systolic blood pressure, multilobar chest x-ray findings of infiltrate, albumin, respiratory rate, tachycardia, confusion, oxygenation, and pH and stratifies patients into risk groups that estimate risk of requiring intensive respiratory or vasopressor support.

In addition to clinical judgment, PSI is preferred over CURB-65 in helping guide determination of the need for inpatient management of adults with CAP.

Patients with septic shock requiring vasopressor therapy in the setting of CAP should be admitted to the ICU. If there is clinical concern for impending airway compromise, the patient should be intubated and admitted to the ICU. In several clinical studies, patients who were critically ill and were not initially admitted to the ICU had higher rates of morbidity and mortality.

### Treatment

General recommendations for empiric treatment of both CAP and HAP are detailed in [Table 4](#). Antibiotics and supportive care (oxygen, IV fluids, and ventilatory or vasopressor support when necessary) is the mainstay of treatment for both community and hospital-acquired bacterial PNA. Antibiotic selection is guided by several factors:

- Age
- Severity of illness
- Risk of infection by MDR pathogen ([Table 3](#) for risk factors)
- Setting (both timing and location) of PNA onset

Initiation of initial treatment should also be guided by geographic antibiograms, which should be available through local hospitals. The CDC Antibiotic Resistance Patient Safety Atlas

**TABLE 2** Pneumonia Severity Index

RISK FACTORS	POINTS
<b>Demographics</b>	
Age, men	Age in years
Age, women	Age in years–10
Nursing home resident	+10
<b>Comorbid Conditions</b>	
Active Neoplasm	+30
Liver disease	+20
History of CVA	+10
Chronic heart failure	+10
Chronic renal failure	+10
<b>Physical Exam</b>	
Altered mental status	+20
Respiratory rate elevated $>30$	+20
Hypotension, SBP $<90$ mm Hg	+20
Temperature $<95^{\circ}\text{C}$ or $>40^{\circ}\text{C}$	+15
Tachycardia, pulse $>125$ bpm	+10
<b>Laboratory and Imaging Findings</b>	
Acidosis, arterial pH $<7.35$	+30
Hyponatremia, Na $<130$ mmol/L	+20
BUN $\geq 30$ mg/dL	+20
Glucose $\geq 250$ mg/dL	+10
Hematocrit $<30\%$	+10
PaO <sub>2</sub> $<60$ mm Hg	+10
Pleural effusion	+10
Total points	

Total points less than 51 indicates low incidence of death from CAP. Patients with increased total points have higher risk of death; the greatest risk for those greater than 130 total points with rate of death for adults diagnosed with CAP of 24.9%. BUN, Blood urea nitrogen; CAP, community-acquired pneumonia; CVA, cerebrovascular disease, SBP, systolic blood pressure; Na, sodium; PaO<sub>2</sub>, partial pressure of arterial oxygen.

**TABLE 3** Risk Factors for Multi-drug Resistant Pathogens in Hospital-Acquired Pneumonia

#### Risk Factors for MDR Pathogens in Ventilator-Associated Pneumonia (VAP)

Prior intravenous antibiotic use within 90 days

Septic shock at time of VAP

ARDS preceding VAP

Hospitalization greater than or equal to 5 days prior to VAP

Acute renal replacement therapy prior to VAP

#### Risk Factors for MDR Pathogens in HAP, MRSA in VAP/HAP, and Pseudomonas in VAP/HAP

Prior Intravenous antibiotic use within 90 days

ARDS, Acute respiratory distress syndrome; MDR, Multi-drug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*.

provides similar information for the aggregate of hospital-acquired infections. Antibiotic therapy should be narrowed as soon as possible based on culture and subsequent sensitivity results, if culture was obtained.

**TABLE 4** Empiric Antibiotic Therapy for Pneumonia for Adults

TYPE OF PNEUMONIA	SETTING	ANTIMICROBIAL THERAPY
Community-Acquired Pneumonia	Outpatient, patient without co-morbidities and without risk-factors for MRSA or <i>Pseudomonas aeruginosa</i> <sup>1</sup>	Amoxicillin 1 g 3 times daily OR Doxycycline 100 mg 2 times daily OR Macrolide (only if local pneumococcal resistance is <25%), such as azithromycin (Zithromax) 500 mg on day 1 followed by 250 mg daily or clarithromycin (Biaxin) 500 mg 2 times daily
	Outpatient, patient with co-morbidities <sup>2</sup>	Respiratory fluoroquinolone <sup>3</sup> OR β-lactam <sup>4</sup> PLUS macrolide or doxycycline
	Inpatient, non-severe	Respiratory fluoroquinolone <sup>3</sup> (levofloxacin or moxifloxacin) OR Select β-lactam (ampicillin+sulbactam [Unasyn],* cefotaxime [Claforan], ceftriaxone [Rocephin], or ceftaroline [Teflaro]) PLUS macrolide (azithromycin or clarithromycin)
	Inpatient, severe	Select β-lactam (ampicillin+sulbactam,* cefotaxime, ceftriaxone, ceftaroline) PLUS macrolide OR Select β-lactam PLUS respiratory fluoroquinolone <sup>3</sup> (levofloxacin or moxifloxacin)
	Prior respiratory isolation of <i>P. aeruginosa</i>	ADD piperacillin-tazobactam (Zosyn), cefepime (Maxipime), ceftazidime (Fortaz), imipenem (Primaxin), meropenem (Merrem),* or aztreonam (Azactam) to inpatient regimen
	Prior respiratory isolation of MRSA	ADD vancomycin or linezolid (Zyvox) to inpatient regimen
Aspiration Pneumonia	Outpatient	Amoxicillin/clavulanate (Augmentin) OR clindamycin OR levofloxacin OR moxifloxacin
	Inpatient	β-lactam/β-lactamase inhibitor (ampicillin/sulbactam,* piperacillin/tazobactam) OR carbapenem OR respiratory fluoroquinolone <sup>3</sup> OR 3rd or 4th generation cephalosporin (ceftriaxone, cefepime)
	Inpatient, risk of predominantly anaerobic infection <sup>5</sup>	ADD clindamycin to regimen
	Prior respiratory isolation of MRSA	ADD vancomycin or linezolid to inpatient regimen
Hospital-Acquired Pneumonia	Not at high risk of mortality <sup>6</sup> AND no risk factors for MRSA	Piperacillin/tazobactam OR cefepime OR levofloxacin OR carbapenem (imipenem, meropenem*) OR ceftolozane/tazobactam
	Not at high risk of mortality AND risk factors for MRSA	Select β-lactam (cefepime, ceftazidime, imipenem, meropenem, or piperacillin/tazobactam) OR fluoroquinolone (levofloxacin, ciprofloxacin) OR aztreonam PLUS vancomycin or linezolid
	High risk of mortality, administration of intravenous antibiotics in past 90 days, VAP	Two of select β-lactam (cefepime, ceftazidime, imipenem, meropenem,* or piperacillin/tazobactam) OR fluoroquinolone (levofloxacin, ciprofloxacin) OR aminoglycoside (amikacin, gentamicin, tobramycin) OR aztreonam PLUS vancomycin or linezolid

<sup>1</sup>Risk-factors include prior respiratory isolation of MRSA or *P. aeruginosa* OR recent hospitalization and administration of intravenous antibiotics in the last 90 days.

<sup>2</sup>Presence of comorbid conditions (chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancies, asplenia, immunosuppression [iatrogenic or pathologic]), Use of antimicrobials within the past 3 months, High-rate (>25%) of macrolide-resistant *S. pneumoniae*.

<sup>3</sup>Respiratory fluoroquinolones include levofloxacin (Levaquin) 750 mg daily, moxifloxacin (Avelox) 400 mg daily, or gemifloxacin (Factive) 320 mg daily.

<sup>4</sup>Amoxicillin/clavulanate (Augmentin) 500 mg/125 mg 3 times daily, amoxicillin/clavulanate 875 mg/125 mg 2 times daily, cefuroxime (Ceftin) 500 mg 2 times daily, cefpodoxime (Vantin) 200 mg 2 times daily.

<sup>5</sup>Risk factors for predominantly anaerobic infection include patients with severe periodontal disease and necrotizing pneumonia or lung abscess.

<sup>6</sup>Risk factors for mortality include need for ventilatory support and septic shock.

\*Not FDA approved for this indication.

MRSA, Methicillin-resistant *Staphylococcus aureus*; VAP, ventilator associated pneumonia.

PCT may be used as an indicator of response to therapy after diagnosis of CAP and HAP based on recent trial data. If PCT measurements decrease to less than 0.1 µg/L, a provider may consider discontinuation of antibiotics.

In addition to antimicrobial therapy for those who require hospitalization, care should be taken to maintain appropriate oral hygiene and to maintain head of bed at 30 to 45 degrees in efforts to minimize risk of aspiration. Serum glucose goal should be less than 180 mg/dL. A few additional considerations exist for patients with severe PNA during hospitalization. These individuals should all receive dual antibiotic therapy, as noted in Table 4. For those who remain hypotensive despite adequate fluid resuscitation, consider screening for occult adrenal insufficiency within 24 hours of admission. Those with hypoxemia or respiratory distress may receive a closely monitored trial of non-invasive ventilation followed by intubation as indicated.

Low-tidal volume ventilation (6 mL/kg of ideal body weight) should be utilized.

#### Community-Acquired Pneumonia

Patients with suspected CAP should first be risk stratified using one of the PNA severity scoring indices discussed above and in Table 2. If being admitted to the hospital, the first dose of empiric antibiotic (see Table 4) should be administered in the ED as soon as the diagnosis of PNA is made. In addition to the established antibiotics noted in Table 4, the two antibiotics omadacycline (Nuzyra) and lefamulin (Xenleta) were approved in 2018 and 2019, respectively, for the treatment of CAP. Both are available in IV and oral formulations and were shown to be non-inferior to treatment with moxifloxacin (Avelox) in the management of CAP. Patients may be transitioned from IV to oral antibiotics when they are hemodynamically stable, able to

**TABLE 5** Recommended Vaccinations for the Prevention of Pneumonia

VACCINE	POPULATION	RECOMMENDATIONS
Influenza	All persons older than 6 months	Annually If first lifetime dose of influenza vaccine (infants $\geq 6$ months and children $\leq 9$ years), 2nd dose should be given 4 weeks after 1st dose
Pneumococcal	All adults	Should receive 1 dose of pneumococcal polysaccharide vaccine (PPSV23 [Pneumovax 23]) at age 65 years or older, at least 5 years after previous dose of PPSV23 (if administered prior to age 65). 1 dose of 23-valent pneumococcal polysaccharide vaccine (PPSV23)
	Adults 19–64 years who smoke tobacco or who have chronic heart disease (excluding hypertension), chronic lung disease, chronic liver disease, alcoholism, or diabetes mellitus	
	All immunocompetent adults 65 years and older	Engage in shared clinical decision-making to see if 1 dose of pneumococcal conjugate vaccine PCV 15 (Vaxneuvance) or PCV 20 (Pevnar 20) would be appropriate. Eligible adults may receive either PCV 15 in series with PPSV23 or PCV 20 alone. If PCV 15 is used, it should be administered first, followed by PPSV23 at least 1 year later. If they received dose of PPSV23 prior to age 65, dose of PCV 15 should be given at least 1 year after 1st dose of PPSV23 and dose of PPSV23 should be given at least 5 years after 1st dose of PPSV23.
	Adults 19 and older with immunocompromising conditions*	Eligible adults may receive either PCV 15 in series with PPSV23 or PCV 20 alone. If PCV 15 is used, administer 1 dose of PCV 15 first and then dose of PPSV23 at least 8 weeks after dose of PCV 15 and a second dose of PPSV23 5 years after 1st dose of PPSV23. At age 65 and older, administer one final dose of PPSV23 at least 5 years after previous dose of PPSV23 and at least 8 weeks after dose of PCV 15. Only 1 dose of PPSV23 is recommended after age 65 years.
	Adults 19 and older with cerebrospinal fluid leak or cochlear implant	Eligible adults may receive either PCV 15 in series with PPSV23 or PCV 20 alone. If PCV 15 is used, administer 1 dose of PCV 15 first and then dose of PPSV23 at least 8 weeks after the dose of PCV 15. At age 65 and older, administer one final dose of PPSV23 at least 5 years after previous dose of PPSV23. Only 1 dose of PPSV23 is recommended after age 65 years.
<i>Haemophilus influenzae</i> type B (HiB)	All children younger than 5 years old, unvaccinated older children and adults with certain medical conditions,* people who receive bone marrow transplant	Administer 1 dose of HiB at age 2, 4, 6 (per product) and 12–15 months with minimum of age 6 weeks. Children with one dose at age $>15$ months need no further doses. For high-risk conditions, children age 12–59 months who previously received 1 or no doses should receive two additional doses of HiB, 8 weeks apart. For children who received two doses before 12 months of age should receive one additional dose. Hib may be given to high-risk adults.

\*B- or T- lymphocyte deficiency, complement deficiencies, phagocytic disorders (excluding chronic granulomatous disease), HIV infection, chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, multiple myeloma, solid organ transplant, iatrogenic immunosuppression, anatomical or functional asplenia.

tolerate oral medications, and are able to absorb these medications enterally. When possible, an oral antibiotic should be chosen from the same or similar antibiotic class as the IV antibiotic used. Observation of inpatients after transition to oral antibiotics is not necessary as long as the patient is clinically stable and has a safe disposition plan. The recommended duration of antibiotic therapy is at least 3 days for beta lactams and 5 days for other antibiotics, with discontinuation only after the patient has been afebrile for at least 48 to 72 hours and remains clinically stable. Concern for a coexisting extrapulmonary infection may affect antibiotic selection and extend duration of therapy.

If a patient has prior respiratory isolation of MRSA or *P. aeruginosa*, then presumptive treatment should be initiated and cultures obtained to help guide, and potentially narrow therapy. If the patient was recently hospitalized, had IV antibiotics in the past 90 days, and locally validated risk factors for MRSA or *P. aeruginosa*, cultures should be obtained. If managing non-severe PNA, only initiate appropriate coverage if cultures return positive or if rapid nasal polymerase chain reaction is positive for MRSA. If PNA is characterized as severe, then initiate empiric coverage, while awaiting culture results to help guide de-escalation of or continuation of therapy. Treatment with probiotics<sup>7</sup> may improve the clinical course of CAP.

<sup>7</sup>Available as dietary supplement.

### Hospital-Acquired Pneumonia

All patients with suspected HAP should be treated with broad spectrum antibiotics (see Table 4). Antibiotic choice should be governed by local antibiograms. The recommendations for further diagnostic testing, including cultures and PCR testing, were described in more detail in the diagnosis section. As described in Table 4, if the patient has risk factors for mortality or for MDR pathogens, then therapy with multiple agents is indicated. However, in selecting antimicrobial coverage, clinicians must weigh the benefit of initiating adequate coverage as soon as possible against the harms of uniform broad-spectrum coverage, such as increased resistance rates, risk of *Clostridium difficile* infection, and adverse drug effects. Whenever MRSA is suspected, treatment with vancomycin or linezolid (Zyvox) should be initiated; daptomycin (Cubicin) should not be used to treat pulmonary MRSA infection.

### Prevention

Immunization against influenza, *S. pneumoniae*, and *H. influenzae* is the best protection against bacterial PNA in adults and children. Recommended vaccine schedules are described in Table 5. In general, everyone should receive an annual influenza vaccine and individuals should receive *H. influenzae* and pneumococcal immunization on a schedule based on age and risk factors. The pneumococcal vaccines have a 44% to 75% efficacy against invasive

disease from *S. pneumoniae* for persons 65 and older and have been shown to be cost effective in populations aged 50 years and older. A systematic review demonstrated that the influenza vaccine effectively reduces PNA, hospital admission, and death. Annual influenza immunization is recommended as neuraminidase and hemagglutinin evolve rapidly, and new formulations targeting predicted strains are needed.

## BLASTOMYCOSIS

Method of

John M. Embil, MD; and Donald C. Vinh, MD

### CURRENT DIAGNOSIS

- Blastomycosis is most commonly caused by the thermally dimorphic fungi *Blastomyces dermatitidis* and *gilchristii*, which together comprise the *B. dermatitidis* complex.
- *Blastomyces* spp. are endemic to the United States (southeastern and south central states bordering Mississippi and Ohio rivers; upper Midwestern states bordering the Great Lakes) and to Canada (Manitoba and Ontario bordering the Great Lakes; Quebec adjacent to St. Lawrence River).
- Blastomycosis should be suspected in the appropriate clinical context in patients who have resided or traveled to an endemic area.
- Blastomycosis has a broad range of manifestations, mimicking other infectious (e.g., bacteria, mycobacteria) and neoplastic processes.
- Blastomycosis may be asymptomatic, or it can manifest with disease involving the lung, skin, bone and joints, genitourinary system, or central nervous system.
- Diagnosis requires microscopic examination and/or culture of clinical specimens. *Blastomyces* antigen detection is also useful. Serology has no diagnostic value.

### CURRENT THERAPY

- Treatment varies with the severity of disease.
- Long-term suppressive therapy may be required for those who are immunosuppressed.

The *Blastomyces dermatitidis* complex are the thermally dimorphic fungi that most commonly cause blastomycosis. Although novel *Blastomyces* species have been identified, they appear to be much less common than the *B. dermatitidis* complex; these new species have distinct mycological features and may produce atypical presentation of disease. *Blastomyces* spp. exist in mycelial form in the environment but grow as yeast forms at body temperature. Although the *B. dermatitidis* complex is endemic to certain specific regions within North America, numerous cases have been reported from areas where it is not considered endemic. It is presumed that those patients acquired infection in the endemic areas and subsequently presented outside of these geographic locations. However, it is also possible that the natural reservoirs of the fungus are evolving. The clinical manifestations of blastomycosis can be diverse, and therefore this infection should be suspected within the appropriate clinical context in persons with a history of residence or travel to such endemic areas.

## Epidemiology

Our knowledge of the exact geographic distribution of *B. dermatitidis* complex is limited by the fact that the fungus cannot be readily recovered from nature; thus, identification of the endemic area has been largely derived from outbreak investigations and small case series. Most epidemiologic studies have depended upon recovery of *B. dermatitidis* in culture from clinical specimens or histologic visualization to establish the diagnosis. In addition, the incidence and prevalence of blastomycosis has been difficult to establish because suitable serologic or skin-prick assays (demonstrating acceptable sensitivity and/or specificity) to confirm infection are lacking. The geographic niche of *Blastomyces* spp. may therefore be greater than is currently believed.

The currently known areas of endemicity for *B. dermatitidis/gilchristii* are the south central and upper midwestern United States, including areas surrounding the Great Lakes. *B. dermatitidis* is also endemic in Wisconsin (1.3 cases per 100,000 population) and Mississippi (1.4 cases per 100,000 population), as well as parts of Missouri, Kentucky, Tennessee, Arkansas, and Alabama. In Canada, the major areas of endemicity include the province of Manitoba (0.62 cases per 100,000 population), the southern region of Québec (0.46–0.79 cases per 100,000 population), and the Kenora region of the province of Ontario (7.11 cases per 100,000 population). Although most cases of blastomycosis are concentrated in these regions, it should be remembered that persons can acquire infection with *Blastomyces* spp. in these areas but present at a later time to health care providers in locations where blastomycosis is not usually observed. Inquiring about residence or travel to these areas is important to help establish the diagnosis.

Risk factors for acquiring blastomycosis have been defined by case reports, case series, and a small number of case-control studies and have not been conclusively established. Exposure while in endemic regions to soil, decaying wood, or to dust clouds generated by soil disruption is important; however, specific outdoor occupations or activities have not been confirmed. The fungus may also be associated with exposure to river waterways.

Race may be a contributing factor to disease. In one study from Mississippi, African-American race and prior history of pneumonia were independent risk factors for blastomycosis; however, neither environmental nor socioeconomic risk factors were detected. These findings were in contrast to previously noted studies where race and gender were not identified as specific risk factors for acquisition of blastomycosis. One study in Canada noted an increased incidence among the Indigenous population of Manitoba. Thus, it remains unclear if certain ethnic groups are at increased risk for disease or simply reflect differences in exposure.

Immunosuppression may also be an important risk factor, particularly for the tendency to develop severe disease. Blastomycosis has been reported in pregnant women, persons with diabetes mellitus, organ transplant recipients, and persons infected with HIV.

Dogs and humans are the species most commonly affected by *B. dermatitidis* complex. Anecdotally, dogs can serve as a sentinel marker for human disease (i.e., dogs present with systemic infection before their owners), leading to early suspicion of human

infections by astute veterinarians. In such cases, it is speculated that humans and their pet dogs have a simultaneous exposure to the same source of fungus and therefore develop synchronous infection. This hypothesis, however, remains to be confirmed, and in a more recent study, canine blastomycosis was not deemed to predict human disease among the human owners. Additional studies are required to establish the relationship between blastomycosis in humans and disease in their pet dogs.

The most common mode of transmission is presumed to be by inhalation of aerosolized conidia from the environment. There are, however, reports of cutaneous blastomycosis occurring after accidental cutaneous inoculation, for example in the laboratory setting during autopsy or after dog bites. The median incubation period, established by reviewing the results of point-source outbreaks, ranges from 30 to 45 days.

### Pathophysiology

Following inhalation of conidia into the lungs, the fungus is phagocytosed by alveolar macrophages. The human body temperature allows the fungus to transform to the yeast phase. It is speculated that a process similar to infection with *Mycobacterium tuberculosis* then occurs. The fungus might spread to other organs via the bloodstream and lymphatics. The primary defense against *B. dermatitidis* is through a suppurative response initially with neutrophils, followed by influx of monocytes with establishment of cell mediated immunity, resulting in noncaseating granuloma. The patient with intact immunologic responses can contain the process without progression to clinical disease. Alternatively, the patient can develop a

symptomatic pneumonia and then mount a suitable immunologic response and recover. Impaired immunity favors the development of progressive pulmonary disease with or without extrapulmonary manifestations. It has also been suggested that reactivation of disease can occur at pulmonary or extrapulmonary sites. The pathophysiology of *B. gilchristii* is thought to be similar to that of *B. dermatitidis*. A vaccine that protects humans against infection with *Blastomyces* spp. is unavailable.

### Clinical Manifestations

After inhalation of the conidia, an initial infection can occur. Most primary infections (at least 50%) are asymptomatic or mild and usually go unrecognized, resolving spontaneously. In others, a symptomatic pneumonia can develop; recovery can occur either spontaneously or with therapy, without further progression. Some persons develop progressive pneumonia or extrapulmonary manifestations. The type of clinical manifestations (localized, extrapulmonary or disseminated disease) can have a seasonal variation: Persons with manifestations occurring early after exposure (1–6 months) developed localized pneumonia, whereas those who presented later after exposure (4–9 months) tended to have isolated extrapulmonary or disseminated disease. Blastomycosis has been termed “the great mimic,” because its clinical manifestations are nonspecific and can be similar to those of many different clinical entities. The most common organ systems involved in blastomycosis, in descending order of frequency, include lung, skin, bone, genitourinary, and central nervous systems (CNS). **Box 1** summarizes the key clinical manifestations of blastomycosis.

## BOX 1 Clinical Manifestations of Blastomycosis

### Lung

#### Acute Pneumonia

Acute pneumonia is clinically indistinguishable from bacterial pneumonia.

Patients may present with fevers, chills, dyspnea, and cough, which initially might not be productive but, with time, may be accompanied by sputum production.

Radiographic findings can also be difficult to discern from those due to a bacterial pneumonia.

The radiographic pattern of pulmonary blastomycosis includes the following:

- Lobar infiltrates that mimic bacterial pneumonias
- Cavitory lung lesions and miliary patterns, which can mimic tuberculosis
- Mass lesions that may be mistaken for neoplasms
- Cystic lesions that resemble abscesses

There is no definitive plain radiograph or computed tomographic scan findings characteristic of pulmonary blastomycosis.

The spectrum of clinical pulmonary disease ranges from spontaneous resolution to pneumonia, with or without the acute respiratory distress syndrome; the latter is accompanied by high (50%–89%) mortality rates.

#### Chronic Pneumonia

A nonresolving pneumonia is one of the hallmarks of pulmonary blastomycosis.

Chronic pneumonia may be associated with fever, chills, weight loss, sputum-producing cough, and hemoptysis.

There is no characteristic radiographic appearance to help establish the diagnosis.

### Skin

Cutaneous lesions are the most common extrapulmonary manifestations of blastomycosis. Lesions usually result from dissemination of a primary pulmonary lesion or rarely from direct inoculation.

Lesions can have a number of different appearances, with verrucae (wartlike lesions) and ulcers being the most common

manifestations. The verrucous lesions have a heaped-up appearance with a raw excoriated center. These lesions can mimic squamous cell carcinomas. Cutaneous abscesses may be associated with these lesions.

Ulcerative lesions initially manifest as pustules that eventually erode, producing a bed of granulation tissue that is friable and bleeds when traumatized. Other skin lesions include subcutaneous nodules and isolated abscesses.

### Bone and Joint

The most common manifestation of extrapulmonary blastomycosis, after cutaneous disease, is involvement of bones and joints.

Any bone may be involved, although the long bones and axial skeleton are the most commonly affected.

The radiographic findings are indistinguishable from bacterial osteomyelitis and arthritis.

### Genitourinary Tract

In the genitourinary tract, the prostate has been reported to be commonly affected by blastomycosis.

Symptoms can mimic prostatitis, and patients can present with obstructive uropathy.

### Central Nervous System

The CNS is infrequently affected by *B. dermatitidis*. Infection may occur in isolation or with concomitant non-CNS infection.

CNS blastomycosis can occur in immunocompromised patients (e.g., HIV, solid organ transplant), as well as in patients with little/no risk factors (e.g., diabetes mellitus alone; persons with no underlying co-morbidities).

Clinical manifestations depend on the area of involvement and range from focal neurologic findings (e.g., due to mass lesions in the brain parenchyma) to symptoms of meningitis due to involvement of the meninges.

Radiographically, the findings may be indistinguishable from bacterial processes. Other sites of involvement have been described but are infrequent compared to those summarized above.

## Blastomycosis in Special Populations

Children account for a small percentage of the cases of blastomycosis, ranging from 2% to 11%. Children demonstrate a similar spectrum of manifestations as in adults (excluding prostatic disease). The most common symptoms include cough, headache, chest pain, weight loss, fever, abdominal pain, and night sweats. It is postulated that children experience disseminated infection more frequently than do adults.

Although there are few published reports of blastomycosis in pregnancy, disease has been observed in pregnant women, with presumed subsequent intrauterine and perinatal transmission.

Blastomycosis has been reported in persons with advanced HIV and among those who have undergone solid organ transplants. In immunocompromised hosts, it appears that a significant percentage developed rapidly progressive pulmonary disease, leading to respiratory failure and death. For those who are immunocompromised, the reported mortality rate range is 30% to 40%, with death occurring within the first few weeks of disease onset.

## Diagnosis

The most reliable technique for confirming the diagnosis of blastomycosis is recovery of the fungus in culture. Alternatively, direct observation of the pathogen by light microscopy or with calcofluor white stain or in histopathologic examination of tissue establishes a presumptive diagnosis. *Blastomyces* spp. are characteristically observed as a thick-walled, broad-based budding yeast. Because colonization does not occur, identification of *B. dermatitidis/gilchristii* should never be considered a contaminant. Serologic assays are extremely variable in their sensitivity and specificity and do not play a role in confirming or excluding the diagnosis, thus limiting their value in therapeutic decision making. A reliable skin test is unavailable, but a urinary antigen detection assay exists that may aid in diagnosis and may be of benefit to follow the efficacy of treatment in established infections. **Box 2** summarizes techniques for establishing the diagnosis of blastomycosis.

## Treatment

The treatment recommendations for blastomycosis from the Infectious Diseases Society of America (IDSA) are summarized in **Table 1**. Amphotericin B deoxycholate (Fungizone) is the agent with which there is the greatest experience, particularly for the treatment of patients with severe blastomycosis or for those who have CNS involvement. Lipid preparations of amphotericin B (Abelect, Amphotec, AmBisome)<sup>1</sup> have been shown to be effective in animal models, although clinical trial data are unavailable for these agents in humans. Clinical experience suggests that the lipid formulations are as effective but less toxic than the deoxycholate preparation.

It is generally accepted that in patients with severe disease or CNS involvement, amphotericin B-based products should be used to initiate therapy until the patient is stable, followed by step-down to an azole, specifically itraconazole (Sporanox), to complete the total duration of therapy. Patients on itraconazole should have serum levels of the antifungal drug measured after at least 2 weeks of therapy, targeting a level >1.0mcg/mL and <10.0mcg/mL. Ketoconazole (Nizoral), although once recommended as the agent of choice, is less effective and more toxic than itraconazole. Experience with fluconazole (Diflucan)<sup>1</sup> for the treatment of blastomycosis is limited, although *in vitro* studies have demonstrated that fluconazole is effective against *B. dermatitidis*. Fluconazole does, however, have excellent penetration into the CNS; therefore, fluconazole may be considered as an alternative treatment of CNS blastomycosis. There are also a number of reports of voriconazole (Vfend)<sup>1</sup> being used for the successful treatment of CNS blastomycosis, as well as in persons

## BOX 2 Establishing the Diagnosis of Blastomycosis

### Direct Examination

A wet preparation of respiratory secretions or a touch preparation of tissues examined under high magnification by light microscopy can reveal the characteristic thick-walled, broad-based budding yeast form. However, this method has a low diagnostic yield: 36% for a single specimen and 46% for multiple specimens.

Calcofluor white stains can help in identifying the pathogen but require fluorescence microscopy.

### Histopathologic Examination

The fungus may be difficult to identify with hematoxylin and eosin stain.

If there is a high index of suspicion, the Gomori methenamine-silver stain should be used to optimize detection of thick-walled, broad-based budding yeast forms compatible with *B. dermatitidis*.

### Culture

Diagnostic yield ranges from approximately 86% from sputum to 92% from specimens obtained by bronchoscopy.

Culture is the gold standard for diagnosis. However, the fungus can take several weeks to be isolated in culture.

Confirmation of identity traditionally requires demonstration of thermal-dimorphism (mycelial-to-yeast conversion), which can further delay diagnosis. Commercially available nucleic acid probe assays can more rapidly provide definitive identification without the need to demonstrate thermal dimorphism.

Isolation of *B. dermatitidis* should not be considered a contaminant.

### Serology

Current serologic assays are neither sensitive nor specific, and they should not be used to establish or refute a diagnosis or in therapeutic decision making.

### Nucleic Acid Detection

This method permits genetic-based identification of *B. dermatitidis* from culture of clinical specimens, rather than relying on thermal-dimorphism to confirm identity of the fungus, thus reducing the time required for its identification.

### Antigen Detection

The only currently available antigen detection assay has its greatest sensitivity in urine, although antigens can be detected in serum and other body fluids.

Cross reaction with antigens from other fungi (e.g., *Histoplasma* spp.) can occur.

The greatest benefit of the antigen detection assay may be to follow efficacy of treatment in patients with established disease (antigen levels decrease with successful treatment or rise with recurrence).

### Skin Testing

A commercially available standardized reagent for skin testing is not available.

Modified from Chapman SW, Bradsher RW, Campbell GD, et al: Practice guidelines for the management of patients with blastomycosis. *Cin Infect Dis* 2000;30:679–683; and Martynowicz MA, Prakash UBS: Pulmonary blastomycosis: An appraisal of diagnostic techniques. *Chest* 2002;121:768–773.

with refractory blastomycosis. A case series of patients with CNS blastomycosis suggested that voriconazole may be the most desirable azole for the management of CNS disease. Similarly, there are reports on the successful use of posaconazole (Noxafil)<sup>1</sup> and isavuconazole (Cresemba)<sup>1</sup> for blastomycosis. The echinocandins

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Treatment Suggestions for Infections Caused by *Blastomyces dermatitidis*

MANIFESTATION	TREATMENT RECOMMENDATIONS		COMMENTS
	PRIMARY RECOMMENDATION	ALTERNATIVE RECOMMENDATION	
<b>Pulmonary Infection</b>			
Mild to moderate	Itraconazole (Sporanox) 200mg PO tid × 3 days, then qd or bid × 6–12mo	Fluconazole (Diflucan) <sup>1</sup> 400–800 <sup>3</sup> mg/day or ketoconazole (Nizoral) 400–800mg/kg × 6–12mo	For Itraconazole, measure serum levels after at least 2 weeks, to ensure adequate drug exposure. Target level: >1.0mcg/mL and <10.0mcg/mL
Moderate to severe	Lipid formulation of amphotericin B (AmBisome, Abelect, Amphotec) <sup>1</sup> 3–5mg/kg/day OR Amphotericin B deoxycholate (Fungizone) 0.7–1mg/kg/d for 1–2wk or until improvement, followed by itraconazole 200mg PO tid × 3 days then 200mg PO bid × 6–12mo		Amphotericin B toxicity can be attenuated by minimizing the duration of therapy and switching to oral therapy when the patient is stable For Itraconazole, measure serum levels after at least 2 weeks, to ensure adequate drug exposure. Target level: >1.0mcg/mL and <10.0mcg/mL
<b>Disseminated Infection Not Involving the Central Nervous System</b>			
Mild to moderate	Itraconazole 200mg PO tid × 3 days then qd or bid × 6–12mo		
Moderate to severe	Lipid formulation of amphotericin B 3–5mg/kg/d OR Amphotericin B deoxycholate 0.7–1mg/kg/d for 1–2wk or until improvement, followed by Itraconazole 200mg PO tid × 3 days then 200mg PO bid to complete at least 12mo		To minimize toxicity, switching to oral therapy once the patient is stable should be considered Bone and joint infections are usually treated for at least 12mo with itraconazole For Itraconazole, measure serum levels after at least 2 weeks, to ensure adequate drug exposure. Target level: >1.0mcg/mL and <10.0mcg/mL
<b>Central Nervous System Involvement (with or without other manifestations)</b>			
	Lipid preparations of amphotericin B <sup>1</sup> 5mg/kg/d × 4–6wk followed by an oral azole for ≥12mo		It has been suggested that liposomal amphotericin B achieves higher CNS levels than other lipid formulations When switching to oral azole, options include fluconazole <sup>1</sup> 800mg PO qd, <sup>3</sup> itraconazole 200mg PO bid or tid, <sup>3</sup> or voriconazole (Vfend) <sup>1</sup> 200–400 <sup>3</sup> mg PO bid Longer durations of therapy may be necessary in the immunocompromised host
<b>Special Populations</b>			
Immunocompromised	Lipid formulation of amphotericin B 3–5mg/kg/d OR Amphotericin B deoxycholate 0.7–1mg/kg/d for 1–2wk or until improvement, followed by Itraconazole 200mg PO tid×3 days then 200mg PO bid to complete at least 12mo		Lifelong suppression with itraconazole 200mg PO qd may be required for those in whom immunosuppression cannot be reversed
Pregnant patients	Lipid formulation of amphotericin B 3–5mg/kg/d		No duration of lipid formulation amphotericin B treatment provided; continue until clinical cure During pregnancy, azoles should be avoided because of potential teratogenicity If the placenta or newborn demonstrates evidence of infection, give amphotericin B deoxycholate 1.0mg/kg/d
Children: mild to moderate	Itraconazole <sup>1</sup> 10mg/kg/d for 6–12mo		Maximum dose of itraconazole should be 400mg/d
Children: moderate to severe	Amphotericin B deoxycholate 0.7–10.0mg/kg/d OR Lipid formulation amphotericin B 3–5mg/kg/d × 1–2wk followed by itraconazole 10mg/kg/d × 12mo

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

(caspofungin [Cancidas],<sup>1</sup> micafungin [Mycamine],<sup>1</sup> and anidulafungin [Eraxis]<sup>1</sup>) have limited activity against *B. dermatitidis* and are not considered appropriate choices.

Table 1 summarizes the therapeutic options for treatment of various types of blastomycosis. Amphotericin B-based therapy is usually the treatment option of choice in persons who have severe disease. Whenever the patient is clinically stable, it is desirable to switch from the potentially toxic amphotericin B to a less-toxic agent (usually an azole). It is important to note that amphotericin B in cumulative doses of 1.5 to 2.5 grams for persons with disseminated blastomycosis, with life-threatening disease, or in those who are immunocompromised or pregnant, can lead to cure without relapses.

In patients with overwhelming pulmonary disease, amphotericin B-based products are the therapeutic agents of choice. Although acute respiratory distress syndrome (ARDS) can complicate the management of these patients, data on the beneficial role of corticosteroids in the management of patients with overwhelming pulmonary disease or ARDS are limited to few case reports. For patients with less-severe pulmonary disease, an alternative to amphotericin B is a 6- to 12-month course of oral itraconazole. A similarly prolonged course of oral itraconazole is also appropriate for persons with bone and joint disease. The precise duration of therapy, however, is unknown and should be individualized. The same is true for cutaneous blastomycosis. For persons with CNS blastomycosis, an initial treatment course of 4 to 6 weeks with intravenous lipid formulation of amphotericin B should be followed with an oral azole to complete at least 12 months of therapy. For those who are immunocompromised, prolonged therapy is also necessary. Patients who are immunosuppressed and in whom the immunosuppression cannot be reversed can require lifelong suppressive itraconazole therapy at 200mg per day. Additional details for the management of the various stages of blastomycosis should be sought from the most current version of the IDSA guidelines.

## CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Method of

Paresh J. Timbadia, MD; J. Barry Fagan, MD

### CURRENT DIAGNOSIS

- Chronic obstructive pulmonary disease (COPD) is a treatable, though not curable, disease.
- Smoking is the most common risk factor for COPD worldwide.
- Sixteen million Americans are diagnosed with COPD. An additional 11 million Americans have COPD but have not been diagnosed.
- Alpha 1 antitrypsin deficiency occurs in 1 in every 1500 to 3000 individuals of European ancestry and is treatable by alpha-1 antitrypsin augmentation.
- Dyspnea, cough, and sputum production are common presenting complaints.
- Examination may reveal use of accessory muscles of ventilation, increased AP diameter, diminished breath sounds, wheezing, rhonchi, or crackles.
- Spirometry is the cornerstone of the diagnosis of COPD. COPD is defined by a reduction in the forced expiratory volume in 1 second/forced vital capacity (FEV<sub>1</sub>/FVC).
- The severity of COPD is defined by the FEV<sub>1</sub> percent of predicted; mild (stage 1) FEV<sub>1</sub> >79%; moderate (stage 2) FEV<sub>1</sub> 50% to 79%; severe (stage 3) FEV<sub>1</sub> 30% to 49%; very severe (stage 4) FEV<sub>1</sub> <30%.

### CURRENT THERAPY

- Smoking cessation is the cornerstone of COPD management. Counseling and pharmacotherapy improve quit rates.
- Patients with COPD should receive pneumococcal, influenza, and COVID vaccines.
- Pulmonary rehabilitation improves activity capacity and quality of life and decreases dyspnea and hospitalization.
- Supplemental oxygen is used for resting, nocturnal, or exertional hypoxemia. Supplemental oxygen use prolongs life in those with resting hypoxemia (SpO<sub>2</sub> <89%).
- Pharmacotherapy can improve symptoms and decrease exacerbation rate.
- Proper inhaler technique is necessary for maximal benefit from inhaled medications.
- Short-acting beta agonists are appropriate for mild, intermittent symptoms.
- A long-acting beta agonist (LABA), long-acting antimuscarinic (LAMA), or both may be added in patients with more frequent or severe dyspnea.
- Inhaled corticosteroids can decrease exacerbation frequency.
- Attention should be paid to management of retained secretions.
- Noninvasive ventilation can decrease hypercapnia and dyspnea in patients with chronic hypercapnic respiratory failure.
- A selected group of patients with severe disease may benefit from endobronchial valve treatment or surgical interventions, such as lung volume reduction surgery or lung transplantation.
- Exacerbations of COPD in outpatients may be managed with increased frequency of short-acting bronchodilators, systemic corticosteroids, and antibiotics.
- Palliative care is appropriate for patients with severe, refractory symptoms.

## Epidemiology

Over 16 million Americans have chronic obstructive pulmonary disease (COPD), but including those undiagnosed, the number may be as high as 24 million. In 2018, overall age-adjusted prevalence of COPD in the United States was 6.6%. The exact prevalence of COPD worldwide is largely unknown, but estimates vary from 7% to 19%. The medical cost of COPD increased to 49 billion in 2020 from 32 billion in 2010. COPD is the fourth leading cause of death in the United States, and third leading cause of death worldwide, causing 3.23 million deaths in 2019. The COPD death rate among men decreased 25% from 57.4 per 100,000 population in 1999 to 42.9 per 100,000 in 2018, while the rate among women has remained relatively stable over this period.

## Risk Factors

Smoking is the leading risk factor for COPD in the United States and around the world. In 2018, 13.7% of American adults over age 18 are smokers (15.6% of men and 12% of women), which is approximately 34.2 million people. Globally, some 8 million people use the burning of biomass fuels or coal as their main source of energy for both cooking and heating. This indoor pollution is a significant risk factor for COPD in nonsmoking women and children in the Middle East, Africa, and Asia, and it is estimated to kill 2 million women and children each year. Occupational dusts and chemicals are additional risk factors. Alpha-1 antitrypsin (A1A) deficiency is an important genetic risk factor for COPD. A1A occurs in 1 in every 1500 to 3000 individuals of European ancestry but is less common in Asian and black populations. The metalloproteinase 12 gene is associated with decline in lung function; the relationship between other genes and reduction in lung function is less well understood. It appears that women are more susceptible to the effects of cigarette smoke than men. Other factors possibly playing a role in COPD development include childhood respiratory infections, asthma, and low socioeconomic status.

## Pathophysiology

COPD is an inflammatory lung disease caused by an imbalance between proinflammatory cytokines, enzymes, and effector cells, and the pulmonary defense mechanisms. An increase is seen in the number of proinflammatory cells, including circulating neutrophils and CD8 T lymphocytes as well as the number of macrophages in bronchial mucosa. CD8<sup>+</sup> cells have the potential to release tumor necrosis factor  $\alpha$ , perforins, and granzymes, though the exact role of T lymphocytes in COPD remains unclear. Neutrophils produce proteases, which have the potential to cause alveolar destruction, elastase destruction, and mucus hypersecretion. Macrophages produce proteases and a variety of inflammatory mediators. Cigarette smoke promotes the release of these proinflammatory mediators and also inactivates several antiproteases, causing an inflammation/antiinflammation imbalance. This imbalance causes a cycle of injury and repair which results in permanent damage to airways, lung parenchyma, and vasculature. The airways become narrowed by increased numbers of goblet cells, increased size of submucosal glands, mucosal thickening, collagen deposition, ciliary dysfunction (promoting retention of secretions within the airway), and destruction of alveolar walls and alveolar support. Loss of pulmonary vascular bed, vascular remodeling, and arterial vasoconstriction lead to hypoxemia from ventilation perfusion mismatch and pulmonary hypertension.

Airway obstruction results in air trapping, hyperinflation, and flattening of the diaphragms. As the diaphragms flatten, the patient requires the use of accessory muscles of ventilation to move air. Airway narrowing or collapse increases the resistance to airflow, increasing the work of breathing and resulting in dyspnea. Lung compliance is decreased at high lung volumes, so breathing at high lung volumes due to hyperinflation also results in dyspnea. Work of breathing is increased at rest in COPD and increases exponentially with activity. Dyspnea often leads to the vicious cycle of decreased activity, deconditioning, and progressive disability.

## Diagnosis

Most patients with COPD present to their provider with complaints of dyspnea, cough, and sputum production, or decreased activity capacity. This presentation may be relatively late in the disease course. Many smokers accept their cough as a “smoker’s cough.” Nonsmokers have a large ventilatory reserve; we breathe about 5 L/min, but our maximum ventilatory volume is approximately 180 L/min. Because of this, especially if the patient is sedentary, they may not notice dyspnea until there has been considerable loss of pulmonary function.

The diagnosis of COPD should be considered in all patients with dyspnea, cough, sputum production, or exposure to risk factors. A careful history should include questions regarding quantity and duration of smoking and exposure to passive smoking or other occupational or environmental exposures. The patient should be asked about activity capacity; activities resulting in dyspnea, cough, and mucus production; and ease or difficulty clearing secretions. The input from a family member or friend is valuable in that the patient may have become desensitized to dyspnea. On observation, the patient may be found in the “tripod” position, resting arms on a surface elevating the clavicles, which places the accessory muscles of ventilation at better mechanical advantage. (This is why patients will often relate that they can walk farther while using a shopping cart, “tripoding” on the cart’s handles.) Patients may be observed to be pursed lip breathing, exhaling through pursed lips, elevating the pressure in the airways, stenting them open, and allowing a fuller expiration, decreasing air trapping and hyperinflation. Percussion may reveal evidence of hyperinflation. Auscultation may reveal wheezing or prolonged expiration resulting from airway obstruction, as well as rhonchi from retained secretions in the airways. Normal breath sounds originate in the terminal airways, and emphysematous destruction of these airways results in diminished breath sounds. Emphysema results in increased compliance of the lung, which raises the closing volume (the volume of air within the lung at which airways close). The closing volume may rise above functional residual capacity (the normal end-expiratory volume) causing inspiratory crackles.

Spirometry is the cornerstone of diagnosis of COPD. Airway obstruction is defined by a forced expiratory volume in one second (FEV<sub>1</sub>)/forced vital capacity (FVC) of <70%. Patients with airway obstruction may be able to exhale much of their vital capacity (VC), but because of airways narrowing, they cannot do it very quickly, resulting in the low ratio. The degree of obstruction is defined by the FEV<sub>1</sub> percent of predicted value (Table 1). It is recommended that an A1A be obtained in all patients diagnosed with COPD. It is important to note that A1A is an acute-phase reactant and can be elevated during an exacerbation of COPD; it is therefore best to obtain when the patient is clinically stable.

## Differential Diagnosis

COPD may be confused with other obstructive airway diseases, most notably asthma. Asthma will most often present at

**TABLE 1** Chronic Obstructive Pulmonary Disease Staging

SEVERITY	SPIROMETRY
Stage I: mild	FEV <sub>1</sub> /FVC <70%
	FEV <sub>1</sub> >80%
Stage II: moderate	FEV <sub>1</sub> /FVC <70%
	50% ≤ FEV <sub>1</sub> <80%
Stage III: severe	FEV <sub>1</sub> /FVC <70%
	30% ≤ FEV <sub>1</sub> <50%
Stage IV: very severe	FEV <sub>1</sub> /FVC <70%
	FEV <sub>1</sub> <30%

FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity.

a younger age, though it may be diagnosed during any decade of life. Asthmatics generally have more reversibility and less fixed obstruction, but overlap is seen. Both may have hyperinflation and reduction in forced expiratory flows on pulmonary function testing, but a reduction in diffusing capacity would be more characteristic of COPD. Exhaled NO will more often be elevated in asthma. Eosinophils are characteristically elevated in the sputum blood and BAL fluid in asthmatics, whereas neutrophils are more commonly elevated in patients with COPD. Considerable overlap occurs in each of these areas. There are a small percentage of patients where COPD and asthma cannot be differentiated; this is called the “overlap syndrome.”

### Treatment of Stable Chronic Obstructive Pulmonary Disease

The goals of treatment of COPD include improving quality of life, decreasing dyspnea, increasing activity capacity, preventing and treating complications and exacerbations, and prolonging life.

#### Smoking Cessation

Smoking cessation is the cornerstone of management of COPD. Stopping smoking, along with supplemental oxygen in patients with severe chronic hypoxemia, are the only two interventions that prolong life in patients with COPD. During each clinical interaction with a patient who smokes, it is appropriate to *ask* about their smoking status, *advise* all smokers to quit, *assess* the willingness of the patient to quit, *assist* the patient in quitting, and *arrange* a follow-up visit. Brief counseling alone can improve quit rate. In those patients who express a willingness to attempt to quit, adding pharmacotherapy to counseling is appropriate. Considerations for pharmacotherapy include nicotine replacement therapy, bupropion (Zyban), and varenicline (Chantix) (Table 2). E-cigarettes are not currently recommended to assist with smoking cessation.

**TABLE 2** Smoking Cessation Medications

MEDICATION	DOSAGE AND ADMINISTRATION
Nicotine Transdermal (NicoDerm CQ)	21 mg/24 hours, 14 mg/24 hours, 7 mg/24 hours If >10 cigarettes/D, then use 21 mg/D for 6 weeks, then 14 mg/D for 2 weeks, then 7 mg/D for 2 weeks. If ≤10 cigarettes/D, then use 14 mg/D for 6 weeks, then 7 mg/D for 2 weeks
Nicotine lozenges (Nicorette)	4 mg, 2 mg weeks 1–6, 1 lozenge every 1–2 hours, weeks 7–9 1 lozenge every 2–4 hours, weeks 10–12, 1 lozenge every 4–8 hours
Nicotine gum (Nicorette, Thrive)	4 mg, 2 mg weeks 1–6, 1 gum every 1–2 hours, weeks 7–9 1 gum every 2–4 hours, weeks 10–12, 1 gum every 4–8 hours
Nicotine inhaler (Nicotrol)	10 mg/cartridge up to 12 weeks, 6–16 cartridges/day up to 12 weeks (if necessary), gradual reduction
Nicotine nasal spray (Nicotrol NS)	0.5 mg/spray each nostril, beginning 1–2/hour, maximum 10/hour, maximum 80 sprays/day up to 8 weeks, then taper up to 6 weeks
Bupropion hydrochloride SR (Zyban)	150 mg per day, first 3 days, then 150 mg bid
Varenicline (Chantix)	Day 1–3, 0.5 mg q day, day 4–7, 0.5 mg bid, day 8–end of treatment, 1 mg bid. Patients who quit at 12 weeks may be treated an additional 12 weeks.

### Pulmonary Rehabilitation

Pulmonary rehabilitation programs are widely available and can be defined as multidisciplinary programs, which seek to improve the quality of life for patients with COPD or other lung diseases. Programs vary in content but will always include an exercise and an educational component, supervised by a respiratory therapist. They often meet 2 or 3 times weekly and last about 4 to 12 weeks. The educational component includes information on the disease state, medications used to manage COPD, energy-conserving techniques such as pacing activities, breathing techniques such as pursed-lip breathing, and what steps to take during an exacerbation. Programs may include nutritional advice, smoking cessation education, or psychosocial counseling. The exercise component is tailored to the individual patient and often includes treadmill or stationary bicycle exercise, light weights, arm ergometry, and stretching. Programs stress the importance of maintaining exercise following completion of the program and may offer a phase 3 component for continued exercise. Pulmonary rehabilitation has many proven benefits, including decreased dyspnea, improved quality of life, improved activity capacity, and decreased hospitalization. Pulmonary rehabilitation may be offered to any COPD patient with symptoms of or high risk for exacerbation.

#### Vaccinations

Annual influenza vaccines are recommended for all patients with COPD. Polysaccharide pneumococcal vaccine (PPSV23 [Pneumovax 23]) are recommended for all patients who smoke and/or have COPD with a repeat dose given 5 years after the first dose. At age 65, pneumococcal conjugate vaccine (PCV13 [Pneumovax 13]) is given, since it is more important for those that are immunocompromised, which happens with more advanced age. Patients with COPD are at high risk for COVID-19 infection and poor outcomes. COVID-19 vaccination is recommended for all patients with COPD.

#### Medications

Commonly used medications for the treatment of stable COPD are listed in Table 3. The beta-agonists stimulate beta 2 receptors on airway smooth muscle, causing muscle relaxation and bronchodilation. The short-acting beta-agonists have onset of action in 1 to 3 minutes and duration of action 4 to 6 hours. Because of their quick onset and short duration of action, they are used as “rescue” or prn medications. Some long-acting beta-agonists (e.g., *Formoterol*) also have rapid onset of action, but the duration of action is 12 to 24 hours. Potential side effects of beta-agonists include tremor, tachycardia, and, uncommonly, hypokalemia.

The antimuscarinic bronchodilators bind to muscarinic receptors, which are found on smooth muscle and submucosal glands. Two of these receptors, the M1 and M3 receptors, facilitate acetylcholine transmission which results in bronchoconstriction. Potential side effects of the antimuscarinics include dry mouth and urinary hesitancy. The beta-agonists and antimuscarinics have additive effects on bronchial smooth muscle. Inhaled corticosteroids decrease airway inflammation and have been shown to decrease the frequency of exacerbation of COPD. Unlike asthma, inhaled corticosteroids are not used as sole maintenance therapy in COPD. Potential side effects of the inhaled corticosteroids include a small increase in risk of pneumonia and oral candidiasis. There are now many varieties of inhaler devices. Instruction in the use of the devices and observation of proper technique is necessary to ensure maximal benefit.

In the 2021 Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines (Figure 1) (<https://www.guidelines.co.uk/respiratory/gold-copd-2021-strategy/45088.article>), medication recommendations are dictated by a classification system based on symptom score and exacerbation history. Patients are categorized as having either zero or one exacerbation, not requiring hospitalization, or two or more exacerbations, or at least one exacerbation requiring hospitalization. Symptom severity is based on a symptom scoring scale, such as the Modified British Medical Research Council (mMRC)

**TABLE 3** Commonly Used Inhaled Medications for Stable COPD

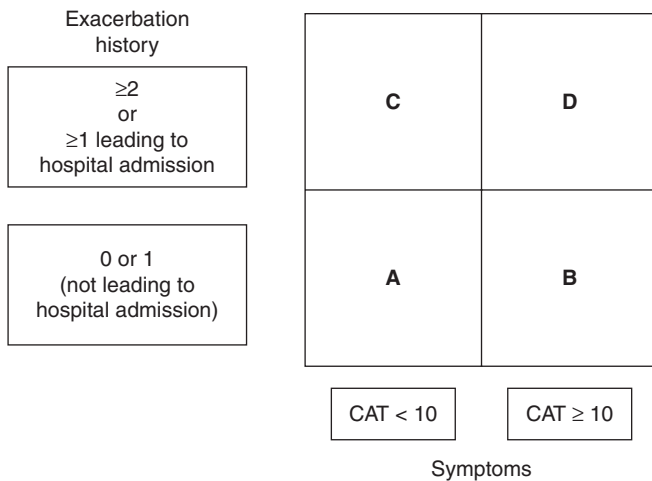

MEDICATION	DOSAGE
<b>Short-acting beta-2 agonist (SABA)</b>	
Albuterol (multiple brands)	2 puffs q 4–6 hours, prn
Levalbuterol (Xopenex)	1–2 puffs q 4–6 hours prn
Ipratropium (Atrovent)	2 inhalations 4 times a day
Albuterol/ipratropium (Combivent Respimat)	1 inhalation 4 times a day
<b>Long-acting beta-2 agonist (LABA):</b>	
Salmeterol (Serevent Diskus)	1 inhalation twice daily
Indacaterol (Arcapta Neohaler)	Inhale contents of one capsule q day
Olodaterol (Striverdi Respimat)	2 puffs once a day, same time of day
Arformoterol (Brovana)	2 mL nebulized twice daily
Formoterol (Perforomist)	2 mL nebulized twice daily
<b>Long-acting antimuscarinic agent (LAMA):</b>	
Tiotropium (Spiriva Handihaler)	2 inhalations of the powder contents of a single Spiriva capsule once daily
Tiotropium (Spiriva Respimat)	2 inhalations once daily
Aclidinium (Tudorza Pressair)	1 inhalation twice daily
Umeclidinium (Incruse Ellipta)	1 inhalation daily
Glycopyrronium Bromide (Seebri Neohaler)	1 capsule inhaled twice daily
Glycopyrrolate (Lonhala Magnair)	1 vial inhaled twice daily
Revefenacin (Yupelri)	1 vial nebulized once daily
<b>Combination medications:</b>	
<b>LABA/LAMA</b>	
Umeclidinium/vilanterol (Anoro Ellipta)	1 inhalation once daily
Olodaterol/tiotropium (Stiolto Respimat)	2 inhalations once daily
Formoterol/glycopyrrolate (Bevespi Aerosphere)	2 inhalations twice daily
Aclidinium/formoterol (Duaklir Pressair)	1 inhalation twice daily
<b>ICS/LABA</b>	
Budesonide/formoterol (Symbicort 160/4.5, 80/4.5)	2 inhalations twice daily
Fluticasone/salmeterol (Advair Diskus 100/50, 250/50, 500/50; Wixela Inhub and AirDuo) (Advair HFA 45/21, 115/21, 230/21)	1 inhalation twice daily 2 inhalations twice daily
Mometasone/formoterol (Dulera 100/5, 200/5) <sup>1</sup>	2 inhalations twice daily
Fluticasone/vilanterol (Breo Ellipta 100/2.5, 200/2.5)	1 inhalation once daily
<b>LABA/LAMA/ICS</b>	
Fluticasone/umeclidinium/vilanterol (Trelegy Ellipta 200/62.5, 25, 100/62.5/2.5)	1 inhalation once daily
Budesonide/glycopyrrolate/formoterol (Breztri Aerosphere 160/9/4.8)	2 inhalations twice daily

<sup>1</sup>Not FDA approved for this indication.

Dyspnea Scale (Table 4) (<https://www.mdcalc.com/mmrc-modified-medical-research-council-dyspnea-scale>) and COPD Assessment Test (CAT) (Table 5) (<https://www.mdcalc.com/copd-assessment-test-cat>). On the CAT, the patient is asked a series of 8 questions, grading severity as 0 to 5. The sum of the scores is used to categorize the patient in the GOLD classification grid.

Patients in group A are given a trial of short- or long-acting bronchodilator. The medication is continued if the patient is determined to have benefited from the intervention. Group B patients should be started on a long-acting bronchodilator, either LABA or LAMA. If the patient has continued dyspnea, LAMA and LABA may be used

together. For patients with severe dyspnea, treatment may begin with both agents. Initial therapy for group C patients is a LAMA. For patients with persisting exacerbations, adding a LABA is the primary choice. Adding an ICS would be a secondary choice. Recommended initial treatment for group D patients is a LABA/LAMA combination. Consideration could be given to initiating treatment with a LABA/ICS combination, in patients with prominent asthmatic symptoms or an eosinophil count  $\geq 300$  cells/microliter. Patients with continuing exacerbations may be switched to a LABA/LAMA/ICS combination. In patients with persisting exacerbations on this treatment, the phosphodiesterase-4 inhibitor roflumilast (Daliresp) 500

**Figure 1** Exacerbation history.

**TABLE 4** Modified MRC Dyspnea Scale

mMRC Grade 0	I only get breathless with strenuous exercise.
mMRC Grade 1	I get short of breath when hurrying on the level or walking up the hill.
mMRC Grade 2	I walk slower than people of the same age on the level because of breathlessness, or I have to stop for breath when walking on my own pace on the level.
mMRC Grade 3	I stop for breath after walking about 100 meters or after a few minutes on the level.
mMRC Grade 4	I am too breathless to leave the house, or I am breathless when dressing or undressing.

**TABLE 5** Chronic Obstructive Pulmonary Disease Assessment Test

I never cough.	0 1 2 3 4 5	I cough all the time.
I have no phlegm (mucus) in my chest at all.	0 1 2 3 4 5	My chest is completely full of phlegm (mucus).
My chest does not feel tight at all.	0 1 2 3 4 5	My chest feels very tight.
When I walk up a hill or one flight of stairs, I am not breathless.	0 1 2 3 4 5	When I walk up a hill or one flight of stairs, I am very breathless.
I am not limited doing any activities at home.	0 1 2 3 4 5	I am very limited doing activities at home.
I am confident leaving my home despite my lung condition.	0 1 2 3 4 5	I am not at all confident leaving my home because of my lung condition.
I sleep soundly.	0 1 2 3 4 5	I don't sleep soundly because of my lung condition.
I have lots of energy.	0 1 2 3 4 5	I have no energy at all.

mcg/day or prophylactic azithromycin (Zithromax)<sup>1</sup> 250 mg/day or 500 mg on Monday, Wednesday, and Friday have been shown to decrease the frequency of exacerbations.

Sustained release theophylline preparations have a mild bronchodilator effect and may be added to an otherwise maximized regimen, or may be used when cost considerations prohibit the use of long-acting bronchodilators.

Retained secretions may increase dyspnea and hypoxemia. Management may include use of guaifenesin<sup>1</sup> 200 to 400 mg orally every 4 hours as needed, not to exceed 2.4 g/day; potassium iodide (SSKI) 0.3 mL (300 mg) or 0.6 mL (600 mg) diluted in one glassful of water, fruit juice, or milk 3 to 4 times daily, and positive expiratory pressure devices, such as the Acapella.

On follow-up visits, medications may be escalated or de-escalated based on symptoms or exacerbations.

### Noninvasive Ventilation

Bilevel ventilation has been used in patients with chronic hypercapnic respiratory failure. Regular use of noninvasive ventilation in this population has shown improvement in walk distance, dyspnea, and hypercapnia by increasing minute ventilation and decreasing work of breathing. Medicare guidelines for prescribing require documented hypercapnia ( $\text{PaCO}_2 > 51$ ) and a nocturnal oximetry showing desaturation to  $\text{SaO}_2 < 89\%$  for at least 5 consecutive minutes during sleep. Initial settings are somewhat empiric, often beginning at IPAP 12 cm  $\text{H}_2\text{O}$  and EPAP 5 cm  $\text{H}_2\text{O}$ . These settings may be adjusted based on comfort and degree of hypercapnia.

### Surgical Remedies

Lung volume reduction surgery is a consideration for patients with severe disease meeting certain criteria. The rationale is that removing the most diseased portions of lung in patients with emphysema will decrease hyperinflation, improve ventilation/perfusion matching, and decrease lung compliance. This elevates the diaphragms, placing them at better mechanical advantage, and stents open the airways. Selection criteria come from the National Emphysema Therapy Trial (NETT) and include patients with emphysema who are <75 years old, smoke-free for 6 months, on no more than 20 mg/day of prednisone with functional limitation good compliance, and severe dyspnea despite maximum medical therapy. Laboratory evaluation must demonstrate upper lobe predominant emphysema on chest CT, hyperinflation, low  $\text{FEV}_1$  ( $\leq 45\%$  predicted;  $\geq 5\%$  predicted if age over 70), and postrehabilitation 6-minute walk >140 m. Exclusionary criteria include morbid obesity, significant comorbidities, previous chest surgery or chest wall deformity that might interfere with the procedure, resting pulmonary hypertension, well-preserved exercise capacity, and significant pleural or interstitial disease.

Lung transplantation may be considered in patients <65 years old (<60 years old for double lung transplant), with  $\text{FEV}_1 < 25\%$  predicted and/or  $\text{PaCO}_2 > 55$  mm Hg and/or pulmonary hypertension, especially in patients with progressive disease requiring supplemental oxygen. Exclusionary criteria include other major organ dysfunction, recent malignancy, HIV-positive status, and hepatitis B or C.

An emerging therapy is endobronchial valve therapy in which one-way valves are placed in some airways endoscopically to produce a nonsurgical lung volume reduction. This treatment has been shown to result in improved pulmonary function, exercise capacity, and quality of life in some patients with emphysema.

### Supplemental Oxygen

The use of supplemental oxygen in patients with COPD is based on the fact that its use in severely hypoxemic patients helps prevent pulmonary hypertension, cor pulmonale, and premature death. Indications for continuous supplemental oxygen are resting  $\text{PaO}_2 \leq 55$  mm Hg or  $\text{PaO}_2$  56 to 59 mm Hg with evidence of complication, such as pulmonary hypertension or polycythemia. Supplemental oxygen may be prescribed during activity for

<sup>1</sup>Not FDA approved for this indication.

SaO<sub>2</sub> <89% during activity and may be prescribed during sleep for patients with SaO<sub>2</sub> <89% for at least 5 minutes during sleep.

### Treatment of Exacerbations of Chronic Obstructive Pulmonary Disease

COPD exacerbations are defined as an acute increase in symptoms requiring an adjustment in medication. They are defined as mild (requiring only bronchodilator adjustment), moderate (requiring antibiotics and/or oral corticosteroids), or severe (requiring hospitalization or emergency department management). Some factors that help determine the need for hospitalization include severity of symptoms, failure to respond to initial management, increasing hypoxemia or hypercapnia, or mental status changes. Underlying comorbidities or lack of support at home may also contribute to the need for hospitalization. Exacerbations may be triggered by viral or bacterial infections or environmental factors.

An increase in frequency of use of as-needed short-acting beta agonists is initial management for exacerbations. Systemic corticosteroids improve pulmonary function measurement and shorten recovery time. Prednisone 40 mg/day for 5 days is effective and has been shown to have similar effect to intravenous steroid administration. The addition of an antibiotic course, 5 to 7 days, has been shown to improve outcomes in outpatients with either increased dyspnea or increased sputum production plus increased sputum purulence. Antibiotics have been shown to decrease mortality and the incidence of nosocomial infection in patients with exacerbation who require invasive or noninvasive mechanical ventilation.

## COCCIDIOIDOMYCOSIS

Method of

Divya Chandramohan, MD; and Gregory M. Anstead, MD, PhD

### CURRENT DIAGNOSIS

- Maintain a high index of suspicion in patients from endemic areas and travelers
- Diagnostic tests include:
  - Serologic detection of immunoglobulin M and immunoglobulin G antibodies by immunodiffusion, complement fixation, and enzyme immunoassay
  - Culture of sputum, exudates, cerebrospinal fluid, and tissue
  - Direct observation of *Coccidioides* spherules in histopathologic and cytologic specimens
  - Urine antigen enzyme immunoassay

### CURRENT THERAPY

#### Pulmonary Infection

- No risk factors for dissemination; not severe disease—observe
- Risk factors; prolonged symptoms—fluconazole (Diflucan)<sup>1</sup> 400 mg/day or itraconazole (Sporanox)<sup>1</sup> 200 mg twice a day for 3 to 6 months
- Diffuse or severe pneumonia—amphotericin B (Fungizone) 1 mg/kg/day or lipid formulation of amphotericin (Abelcet, AmBisome)<sup>1</sup> 5 mg/kg/day; after improvement, switch to azole; treat for 1 year
- Chronic fibrocavitary disease—azole therapy for at least 1 year; resection in selected cases

#### Disseminated Disease

- Nonmeningeal, severe disease—amphotericin B 1 mg/kg/day or lipid formulation of amphotericin<sup>1</sup> 5 mg/kg/day; after improvement, switch to azole for 1 to 2 years; consider posaconazole (Noxafil)<sup>1</sup> suspension 200 mg four times daily or tablets 300 mg daily or voriconazole (Vfend)<sup>1</sup> 400–600 mg daily in refractory cases
- Nonmeningeal, slowly progressive—azole therapy for 1 to 2 years; itraconazole<sup>1</sup> preferred for bony involvement; consider posaconazole<sup>1</sup> or voriconazole<sup>1</sup> (as above) in refractory cases
- Meningeal, central nervous system involvement—fluconazole<sup>1</sup> 800 to 2000 mg daily<sup>2</sup>; intrathecal amphotericin B<sup>1</sup> or voriconazole (Vfend)<sup>1</sup> 200 mg twice daily in refractory cases<sup>1</sup>; shunting for hydrocephalus; consider corticosteroids if vasculitis is present

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Exceeds dosage recommended by the manufacturer.

Coccidioidomycosis is caused by soil fungi of the genus *Coccidioides*, divided genetically into *Coccidioides immitis* (California isolates) and *Coccidioides posadasii* (isolates outside California). There are no distinct clinical differences between the two species. *Coccidioides* occurs only in the Western hemisphere, primarily in the southwestern United States (Arizona and parts of California, New Mexico, Utah, Nevada, and Texas) and in northern Mexico, areas characterized by arid to semiarid climates, hot summers, low altitude, alkaline soil, and sparse vegetation. Hyperendemic areas include the San Joaquin Valley in California and Pinal, Pinal, and Maricopa Counties in Arizona. *Coccidioides* is also found in parts of Latin America (Guatemala, Honduras, Nicaragua, Argentina, Paraguay, Venezuela, and Colombia). Cases may be observed in nonendemic areas because of travel or reactivation of prior infection. In the United States, an estimated 150,000 cases of coccidioidomycosis occur annually, with the clinical presentation ranging from a self-limiting respiratory infection to devastating disseminated disease. The incidence of coccidioidomycosis is increasing in the United States as a result of increasing populations and subsequent construction in endemic areas. Risk factors for increased severity of coccidioidomycosis include receiving immunosuppressive medications such as corticosteroids, transplant drugs, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) antagonists; pregnancy (especially in the third trimester); genetic factors (defects in the IL-12/interferon- $\gamma$  axis and STAT3 pathways, certain ABO blood groups and HLA types); and specific races/ethnicities (African Americans, Asian-Pacific Islanders, and Native Americans). Outbreaks may occur after dust storms, earthquakes, droughts, and activities causing soil disruption, such as construction and archeologic digs. Persons with occupations involving exposure to soil are also at risk for acquiring coccidioidomycosis.

*Coccidioides* is dimorphic; in the soil, the organism exists in its mycelial form, which produces barrel-shaped arthroconidia. The usual means of infection is the inhalation of arthroconidia; uncommon routes include direct cutaneous inoculation

and organ transplantation. Arthroconidia germinate to produce spherules filled with endospores, the characteristic tissue phase. Spherules rupture to release endospores, which form additional spherules. The spherules become surrounded by neutrophils and macrophages, which leads to granuloma formation. Both B and T lymphocytes are essential for host defense against this pathogen.

### Clinical Manifestations

Coccidioidomycosis is asymptomatic in 60% of infected individuals. In the remaining 40%, a self-limiting, flulike illness with dry cough, pleuritic chest pain, myalgias, arthralgia, fever, sweating, anorexia, and weakness develops 1 to 3 weeks after exposure. Primary infection may be accompanied by immune complex-mediated complications, including an erythematous macular rash, erythema multiforme, and erythema nodosum. Acute infection usually resolves without therapy, although symptoms may persist for weeks. In 5% of these patients, asymptomatic pulmonary residua persist, including pulmonary nodules and cavitation. Immunocompromised patients may develop chronic progressive pulmonary infection, with the evolution of thin-walled cavities that may rupture, leading to bronchopleural fistula and empyema formation.

Extrapulmonary disease develops in 1 in 200 patients and can involve the skin, soft tissues, bones, joints, and meninges. The most common cutaneous lesions are verrucous papules, ulcers, or plaques. The spine is the most frequent site of osseous dissemination, although the typical lytic lesions may also occur in the skull, hands, feet, and tibia. Joint involvement is usually monoarticular and most commonly involves the ankle and knee. Fungemia may occur in immunocompromised patients and carries a poor prognosis.

In coccidioid meningitis, the basilar meninges are usually affected. Cerebrospinal fluid findings include lymphocytic pleocytosis (often with eosinophilia), hypoglycorrhachia, and elevated protein levels. The mortality rate is greater than 90% at 1 year without therapy, and chronic infection is the rule. Hydrocephalus or hydrocephalus coexisting with brain infarction is associated with a higher mortality rate. Coccidioidomycosis is a great imitator and has many diverse clinical presentations, including immune thrombocytopenia, ocular involvement, massive cervical lymphadenopathy, laryngeal and retropharyngeal abscesses, endocarditis, pericarditis, peritonitis, hepatitis, and lesions of the male and female genitals and urogenital tracts.

### Diagnosis

Coccidioidomycosis may be diagnosed by direct observation of spherules in tissues or in wet mounts of sputa or exudates. The growth of *Coccidioides* in culture usually occurs in 3 to 5 days, with sporulation after 5 to 10 days. Definitive identification is made by DNA probe or exoantigen testing. Laboratory personnel should exercise extreme caution when handling cultures of *Coccidioides*.

Serologic methods are useful in establishing the diagnosis and for monitoring the course of disease. Immunoglobulin M (IgM) antibodies are present soon after infection or relapse but then wane; quantification does not correlate with disease severity. The IgG antibody appears later and remains positive for months. Increasing titers of IgG are associated with progressive disease, and decreasing titers are associated with resolution. The IgG antibodies can fix complement when combined with coccidioid antigen and can be detected by immunodiffusion complement fixation (IDCF); titers of 1:16 or greater suggest disseminated disease. In the cerebrospinal fluid, a positive IDCF of any titer is considered diagnostic of meningitis and is much more sensitive than culture in making the diagnosis. An enzyme immunoassay (EIA) is also available for the detection of IgM and IgG antibodies, but it is less specific. According to the Infectious Diseases Society of America guidelines, an indeterminate IgM and IgG EIA result should be considered nonreactive. If only the IgM EIA is reactive, this could be a false-positive result, and the IgM/IgG test should be repeated at a later time. A specific urinary antigen test is also available for the diagnosis of coccidioidomycosis; this assay has a sensitivity of 71% in moderate-to-severe disease compared with 84% for culture, 29% for histopathologic examination, and 75% for serologic testing.

### Treatment

In most patients, primary pulmonary infection resolves spontaneously without treatment. However, all patients require observation for at least 2 years to document resolution of infection and to identify any complications as soon as possible. For patients who have risk factors for disseminated disease (listed earlier), treatment is necessary. Other indications for treatment are severe disease (infiltrates involving both lungs or more than half of one lung; significant hilar or mediastinal lymphadenopathy; complement fixation titers >1:16) and highly symptomatic disease (weight loss >10%; night sweats present for >3 weeks; symptoms present for >2 months).

For diffuse or severe pneumonia, therapy with amphotericin B deoxycholate (Fungizone) 0.5 to 1.5 mg/kg/day or a lipid formulation of amphotericin B (Abelcet or AmBisome)<sup>1</sup> 2 to 5 mg/kg/day should be given for several weeks, followed by an oral azole, such as itraconazole (Sporanox)<sup>1</sup> 200 mg twice daily or fluconazole (Diflucan)<sup>1</sup> 400 to 800mg/day. The total duration of therapy should be at least 1 year; for immunosuppressed patients, oral azole therapy should be maintained as secondary prophylaxis. In HIV patients with CD4-positive T-cell counts greater than 250 cells/mm<sup>3</sup> who had focal pneumonias that responded to azoles, antifungals may be discontinued. Azole therapy may be used initially for less severe disease. During pregnancy, amphotericin B is the preferred drug because of the teratogenicity of azoles.

An asymptomatic patient with a solitary nodule or pulmonary cavitation due to *Coccidioides* does not require specific antifungal therapy or resection. However, the development of complications from the cavitation, such as hemoptysis or bacterial or fungal superinfection, necessitates initiation of azole therapy. Resection of the cavities is an alternative to antifungal therapy. Rupture of a cavity into the pleural space requires surgical intervention with closure by lobectomy with decortication, in addition to antifungal therapy. For chronic pneumonia, the initial treatment should be an oral azole for at least 1 year. If the disease persists, one may switch to another oral azole, increase the dose if fluconazole was initially selected, or switch to amphotericin B. Resection should be performed for patients with refractory focal lesions or severe hemoptysis.

The treatment of disseminated infection without central nervous system involvement is based on oral azole therapy, such as itraconazole<sup>1</sup> or fluconazole<sup>1</sup> (400 mg/day, or higher in case of fluconazole). If there is little or no improvement or if there is vertebral involvement, treatment with amphotericin B is recommended (dosage as for diffuse pneumonia). Concomitant surgical débridement or stabilization is also recommended. In patients with refractory coccidioidomycosis that has failed to respond to fluconazole, itraconazole, and amphotericin B and its lipid formulations, treatment with posaconazole (Noxafil)<sup>1</sup> suspension 200 mg four times daily with a fatty meal or voriconazole (Vfend),<sup>1</sup> at doses of 400 to 600 mg/day, has been successful. A posaconazole tablet with improved oral bioavailability and an intravenous preparation are now available, and likely these new forms of posaconazole are more efficacious. The posaconazole tablet has been dosed at 300 mg/day.<sup>2</sup> Clinical experience with voriconazole is limited.

For coccidioid meningitis, lifetime treatment with azoles is indicated. Fluconazole,<sup>1</sup> at doses of 800 mg/day or higher,<sup>2</sup> is recommended. There have been several reports of successful treatment of coccidioid meningitis with voriconazole (Vfend)<sup>1</sup> 200 mg orally twice daily after a loading dose. Itraconazole is not recommended because of its irregular oral absorption. Limited studies exist for the use of isavuconazole (Cresemba)<sup>1</sup> in the treatment of coccidioidomycosis, including coccidioid meningitis. For patients with increased intracranial pressure at the time of meningitis diagnosis, repeated lumbar punctures are recommended. Obstructive hydrocephalus requires shunting. Intrathecal amphotericin B<sup>1</sup> is now strictly reserved for meningitis that is refractory to high-dose azoles or for coccidioid meningitis in the first trimester of pregnancy. In patients with central nervous system vasculitis with cerebrovascular accident caused by

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Exceeds dosage recommended by the manufacturer.

coccidioidomycosis, those who received corticosteroids were less likely to develop additional infarcts compared with those who did not. Reduction of immunosuppression is an important adjunct to antifungal therapy, including initiation of antiretroviral therapy if the patient has HIV infection. In patients with AIDS and non-meningeal coccidioidomycosis, antifungal therapy can be discontinued when the CD4 count exceeds 250 cells/mm<sup>3</sup>.

## CURRENT THERAPY

- A given patient's overall treatment regimen is often based on various factors, including age, clinical presentation, organ systems involved, disease progression/severity, *CFTR* genotype, and comorbidities.
- Primary treatment includes augmented airway clearance with bronchodilators, mucolytics, or mucus hydrators along with mechanical airway vibration.
- For the vast majority of patients, secondary treatment includes use of a *CFTR* modulator.
- Nutritional therapy consists of enzymes and vitamin replacement for those who are pancreatic insufficient.

## Epidemiology

Cystic fibrosis (CF) is an autosomal recessive, inherited multisystem disease caused by mutations of the *CFTR* gene on chromosome 7. There are currently close to 2000 known *CFTR* mutations. Carriage of the gene is highest in individuals of Northern European descent, leading to an incidence of 1 in 3000 non-Hispanic Caucasians in the United States. The incidence is lower in Hispanic Caucasians and those of African descent. There are more than 31,000 individuals with CF in the United States, more than 100,000 individuals worldwide, and approximately 1000 new diagnoses each year. The average life expectancy is increasing with new therapies but still varies among countries. In the United States and Canada, the life expectancy is currently about 50 years.

## Pathophysiology

### Cystic Fibrosis Transmembrane Regulator

#### Genotypes–Genotype/Phenotype

*CFTR* is a protein in the adenosine triphosphate-binding cassette transporter family that has two transmembrane domains, two nucleotide-binding domains, and a regulatory domain. It shares structural elements with other membrane pumps. Mutations in the gene coding the *CFTR* fall broadly into six categories. The first category includes premature truncation mutations, leading to no full-length protein. The second category includes the *Phe508del* (i.e., *F508del*) mutation, which is the most common mutation and accounts for 75% of all mutations in the United States. Class II mutations result in the cell degrading the *CFTR* before full maturation and function. Class III mutations result in a chloride channel at the cell surface that does not function (also called a *gating mutation*). Class IV mutations result in a chloride channel embedded at the cell surface that has decreased and ineffective chloride movement function, and class V mutations are promoter or splicing abnormalities resulting in a reduced number of functional chloride channels at the cell surface. Class VI mutations result in a chloride channel that is not stable on the cell surface and thus, like class V mutations, insufficient quantities of chloride channel at the cell surface.

Understanding the genetics of any given individual with CF is vital in understanding the pathophysiology. Disease manifestation is directly related to the amount of chloride moved at the cell surface. Class I, II, and III mutations result in minimal chloride movement, less than 5% of normal, and “classic” or severe disease phenotype. The presence of one mutation in the class IV, V, or VI category results in greater chloride movement at the surface, typically 10% or more, and a “mild” or “nonclassic” phenotype. Approximately 15% of individuals with CF fall into this latter category and have some preserved chloride channel activity and milder disease phenotype.

#### Mechanism

CF affects all organs with epithelial cells expressing *CFTR*, which typically means the cells lining a ductal system and the fluid outside that system are affected. In the lungs, the respiratory epithelium is lined with cells that express *CFTR*. When *CFTR*

## CYSTIC FIBROSIS

Method of

Hanna Phan, PharmD; and Cori L. Daines, MD

## CURRENT DIAGNOSIS

- Cystic fibrosis (CF) is an autosomal recessive genetic disorder that causes dysfunction of the cystic fibrosis transmembrane conductance regulator (*CFTR*) on the apical surface of epithelial cells leading to the inability to move adequate ions, specifically chloride, out of the cell.
- This defect leads to thick, dehydrated mucus in the respiratory tract that manifests as chronic cough and recurrent infections.
- Diagnosis is made via a sweat chloride test using quantitative pilocarpine iontophoresis.
- Close to 2000 *CFTR* mutations are known, leading to a multitude of clinical phenotypes and disease severity.

does not move appropriate amounts of chloride, the chloride is trapped inside the cell, which leads to the epithelial sodium channel pumping additional sodium into the cell to balance. The resulting salt inside the cell creates an osmotic gradient across the cell surface, and water enters the cell. The water first comes from the periciliary fluid layer, dehydrating the fluid around the cilia, making it difficult for them to beat. Next, the water is removed from the outer mucus layer, also dehydrating it, making it thick and viscous. In the sinopulmonary tract, this inspissation of the mucus limits natural mucociliary clearance and leads to inflammation and an advantageous environment for bacterial colonization. Damage to the airways becomes irreversible and leads to a loss of lung function.

A similar process occurs in other organs with any epithelial cell lining a ductal system. In the pancreas, for instance, epithelial cells line the ducts of the exocrine pancreas. The cells pull water from the normal pancreatic excretion, dehydrating it and clogging the ducts. The enzymes then autodigest the exocrine pancreas, rendering it nonfunctional. The same is true in the biliary ducts of the liver. In the sweat glands, salt and water are trapped in the ducts, making the sweat very salty and leading to the diagnostic result of the sweat chloride test.

## Clinical Manifestations

### Pulmonary

The tracheobronchial tree in CF has poor mucociliary clearance, as noted previously. Patients with CF have excessive cough, make mucus, and might wheeze. They have periodic episodes of exacerbation in which excessive mucus builds up and bacterial infection occurs. The thick mucus becomes a source of persistent infection with bacteria that are unable to be cleared. Often, the infections are caused by bacteria that are not present in the normal undamaged airway, especially *Staphylococcus aureus* and *Pseudomonas aeruginosa*. When the bacteria become active and the patient experiences an exacerbation, the cough and sputum production will worsen. Exacerbations in children are often triggered by viruses and typical childhood illnesses, and in adults, exacerbations may also be triggered by other environmental factors. With exacerbation, there may be shortness of breath, chest pain, wheezing, dyspnea on exertion or at rest, and fatigue. Other symptoms of a pulmonary exacerbation include weight loss, poor appetite, and fever. Over time, there is progressive loss of lung function resulting from infections, mucus, and inflammation. Symptoms become more persistent and bothersome over time, and exacerbations become more common.

### Sinuses

The sinuses in CF have the same mucostasis that occurs in the lungs. The mucus impaction leads to chronic sinus congestion and obstruction, persistent infections, and persistent inflammation. Patients with CF are more likely to develop polyps as well. Symptoms include nasal congestion or drainage, sinus headache, and inability to smell.

### Pancreas

Poor growth occurs as a result of insufficient nutrient breakdown and absorption, resulting in malabsorptive, greasy stools. Fat-soluble vitamins in the diet are also malabsorbed as a result of the malabsorption of fat. Individuals with CF can develop significant deficiencies in vitamins A, D, E, and K. In general, the endocrine pancreas that makes insulin is not initially affected in CF. Over time, individuals with CF often develop CF-related diabetes (CFRD) caused by global inflammation of the pancreas. More than 30% to 40% of adults will develop CFRD.

### Liver

In the liver, there is inspissation of the bile in the bile duct caused by excessive reabsorption of water from the bile. The resulting blockage of the bile ducts leads to hepatic inflammation. In general, this is asymptomatic for the patient with CF and is found by

checking laboratory levels of liver function tests. Occasionally, this bile blockage is severe and leads to chronic inflammation and biliary cirrhosis of the liver. A small percentage of individuals with CF, typically less than 5%, have fulminant liver failure with portal hypertension, esophageal varices, and splenomegaly and would need a liver transplant.

### Intestines

Excessive reabsorption of fluid in the gut can lead to constipation and even small bowel obstruction. This can also occur when stools are malabsorptive. Some people with CF will have rectal prolapse caused by straining, with either malabsorptive or constipated stools. Other manifestations of CF in the intestines can be a result of medication side effects.

### Sweat Glands

Excessive salt is trapped in the sweat, leading to excessive salt loss in the sweat and electrolyte imbalance and dehydration.

### Genitourinary

Men with CF generally all have congenital absence of the vas deferens, rendering them naturally infertile. Men still produce sperm but do not have the other structures. Women with CF may have decreased fertility as a result of poor nutritional status, but they typically can have children.

### Other

CF causes clubbing of the fingers, which is usually more prominent as lung disease progresses. CF-related arthropathies occur in a small percentage of individuals with CF, usually caused by inflammatory markers in circulation that deposit in the joints.

## Diagnosis

Because CF is an insidiously progressive disease, it is important to make an early diagnosis and begin therapies as soon as possible. In the United States, the majority of diagnoses are made via newborn screening. Depending on the state, testing involves immunoreactive trypsinogen (IRT) levels with possible genetic panels of mutations. When the state reports a positive newborn screen, the care provider must order/obtain a sweat chloride test on the infant. Diagnoses are then based on the results of the screens. The Cystic Fibrosis Foundation guidelines state that a positive sweat diagnosis of CF is greater than 30 mmol/L chloride, with 30 to 60 mmol/L chloride being the intermediate zone. Consensus remains that if a child has two mutations, symptoms, and an abnormal sweat chloride (30 to 60 mmol/L), this is consistent with a diagnosis of CF. Children with symptoms and a sweat chloride greater than 60 mmol/L have CF as well. A secondary diagnosis of CF-related metabolic disorder (CRMS) designates those individuals whose diagnoses are unclear. Those with one mutation and an intermediate sweat (30 to 60 mmol/L) or those with two mutations and a negative sweat (<30 mmol/L) are followed prospectively for the development of symptoms and should have periodic sweat tests and periodic evaluations for the evolution of symptoms at a certified cystic fibrosis center, where the testing methodology is certified by the national Cystic Fibrosis Foundation.

As newborn screening has only been widely available for the past 10 to 20 years, children and adults who did not receive newborn screening are still being diagnosed the traditional way, which is the presence of symptoms and a positive sweat test. Here again, a positive sweat means a value of 60 mmol/L, while a value of 30 mmol/L or greater deserves further investigation, such as genetic testing. Sweat tests should be done at a certified cystic fibrosis center. Traditional symptomatology per the Cystic Fibrosis Foundation is represented in the following:

- Very salty-tasting skin
- Persistent coughing, at times with phlegm
- Frequent lung infections, such as pneumonia or bronchitis
- Wheezing or shortness of breath
- Poor growth or poor weight gain in spite of a good appetite
- Frequent greasy, bulky stools or difficulty with bowel movements

- Nasal polyps
- Chronic sinus infections
- Clubbing or enlargement of the fingertips and toes
- Rectal prolapse
- Male infertility

If a diagnosis of CF is suspected because of symptomatology, a sweat test for a definitive diagnosis should be performed regardless of the patient's age or newborn screening status.

## Treatment

### Pulmonary Treatment

#### Nonpharmacologic Therapy

Because of the increased viscosity of airway secretions and the subsequent obstruction and even mucus plugging in CF, there is a fundamental need for airway clearance or chest physiotherapy as part of chronic care. As a core component of therapy in the pulmonary management of CF, airway clearance or chest physiotherapy helps loosen this mucus, and help with expectoration should be done routinely two to three times per day as part of chronic management for patients of all ages; increased frequency may be necessary during periods of pulmonary exacerbation. Manual physiotherapy or percussion and postural drainage is often the first technique introduced into care. Other airway clearance techniques can be used, depending on age and access to devices. These techniques include the use of autogenic drainage, the active cycle of breathing technique, high-frequency chest compression (e.g., vest), oscillatory positive expiratory pressure (OPEP) devices, and exercise.

#### Chronic Pharmacologic Therapy

The selection of medications used in the pulmonary management of chronic CF is currently based on age and clinical need. This is based on current guidelines, U.S. Food and Drug Administration (FDA)-approved indications for newer agents (e.g., CFTR modulators), and current evidence in cases of off-label medication use. Such pharmacotherapy consists of various medication classes, including bronchodilators, mucolytics, inhaled antibiotics, anti-inflammatory agents, and CFTR modulators.

*Inhaled medications* are used in conjunction with chest physiotherapy to facilitate airway clearance, helping loosen mucus and expectoration, and suppress bacterial growth of pathogens in the airways. The use of a short-acting  $\beta$ -agonist, such as albuterol (Proventil, Ventolin),<sup>1</sup> in either meter dose inhaler or aerosolized or nebulizer form, facilitates mucociliary clearance through bronchodilation and decreases occurrence of bronchospasm from subsequent inhaled therapies such as mucolytics (e.g., hypertonic saline (sodium chloride 7% [HyperSal, PulmoSal]), dornase alfa (Pulmozyme), mannitol inhalation powder (Bronchitol)), and antibiotics. Mucolytics are also fundamental in mucociliary clearance. Nebulized hypertonic saline, most commonly sodium chloride 7% and administered twice a day, increases hydration of sputum through osmotic action, thinning sputum for airway clearance. Dornase alfa breaks down extracellular DNA in sputum, thereby decreasing its viscosity. This nebulized mucolytic is most commonly administered daily, usually following the use of nebulized hypertonic saline in sequence. The use of hypertonic saline and dornase alfa is recommended to help improve lung function and reduce exacerbations. Recently approved as a possible add-on maintenance therapy for persons with CF ages 18 years and older, mannitol inhalation powder (Bronchitol) is a dry powder formulation and thus does not require use of a nebulizer for administration and is dosed twice daily. Because of its acute bronchospasm risk, it should only be used in those who have passed the Bronchitol Tolerance Test, which is administered and performed under supervision. Inhaled corticosteroids with or without a long-acting  $\beta$  agonist are not used to treat CF itself but are appropriate in cases of concurrent asthma.

Some patients with CF may require the use of an inhaled antibiotic to help suppress bacterial burden in the airways and

improve patient outcomes such as lung function and exacerbation frequency. Currently, the only FDA-approved inhaled antibiotics are tobramycin inhalation solution (Bethkis, Tobi), tobramycin inhalation powder (Tobi Podhaler), and aztreonam inhalation solution (Cayston) for patients with CF with *P. aeruginosa*. For patients who newly acquire *P. aeruginosa*, it is recommended to treat with an inhaled antibiotic for 28 days, with the preferred agent being tobramycin-inhaled solution, in an attempt to eradicate the pathogen. The use of an inhaled antibiotic to prevent acquisition of *P. aeruginosa* is not recommended. For patients with CF with the persistent presence of *P. aeruginosa* from respiratory cultures, the chronic use of inhaled antibiotics, such as tobramycin or aztreonam, is recommended to improve lung function and reduce exacerbations. For chronic use, cycling (e.g., on 28 days, off 28 days) of an inhaled antibiotic is common. The use of continuous inhaled antibiotic therapy in which two different inhaled antibiotics (e.g., tobramycin and aztreonam) are used rotationally is not routine but has been used by specialists in cases of multidrug-resistant pathogens, advanced or severe lung disease, or frequent acute exacerbations.

*Antiinflammatory agents*—specifically oral azithromycin and/or high-dose ibuprofen—are also noted in the current guidelines. Azithromycin (Zithromax), a macrolide antibiotic, is not used in chronic CF for its anti-infective properties but for its anti-inflammatory and immunomodulatory properties. For patients with CF with the persistent presence of *P. aeruginosa* from respiratory cultures, the use of chronic azithromycin<sup>1</sup> is recommended to improve lung function and reduce exacerbations. Use in patients with CF who lack the persistent presence of *P. aeruginosa* can be considered to help reduce the frequency of exacerbations. Monitoring for the presence of nontuberculosis mycobacterium (NTM) in respiratory cultures and the potential for drug interactions with azithromycin (e.g., medications that may prolong the QT interval) is recommended with the use of chronic azithromycin. A less commonly used anti-inflammatory agent used among certified cystic fibrosis centers is high-dose ibuprofen.<sup>1</sup> The therapeutic benefit of slowing the loss of lung function is greatest in children 6 to 17 years of age. This therapy requires therapeutic drug monitoring (i.e., pharmacokinetic assessment of serum ibuprofen levels) and dose adjustment. Subtherapeutic levels can have negative effects on lung function because of an increase in inflammatory mediators, and suprathreshold levels increase the risk for toxicities (e.g., bleeding, nephrotoxicity). This therapy is less commonly used because of its potential for adverse effects, the need for laboratory monitoring, and the need for pharmacokinetic-based dosing. Routine, chronic use of systemic steroids such as prednisone is not recommended in the chronic management of CF.

CFTR modulators, a newer class of medications, are available for patients with CF with certain CF genotypes. The initial consideration for use and dosing of CFTR modulators is based on age, CF genotype, weight, concurrent therapy, ability to swallow tablets or capsules, and available dosage forms. There are three main types: potentiators, correctors, and amplifiers; however, the latter type is not currently available and is being developed and studied. Ivacaftor (Kalydeco) is a potentiator, increasing chloride movement through the CFTR protein channel. Ivacaftor is intended for patients  $\geq 4$  months of age who have the approved genotypes with gating and conducting mutations. Lumacaftor is a corrector, facilitating correct formation and stabilization of the CFTR protein. Lumacaftor is combined with ivacaftor as Orkambi for the treatment of CF in patients 2 years of age and older whose genotype is homozygous *Phe508del*. Tezacaftor is also a corrector but is longer acting and has some differences compared with lumacaftor with regard to drug interactions and side effects. Like lumacaftor, tezacaftor is combined with ivacaftor as Symdeko for chronic treatment of CF. Symdeko is approved for patients 6 years of age and older whose genotype is homozygous *Phe508del* and a number of residual function mutations. Elexacaftor is also a corrector; however, it binds to a different site on the CFTR protein than tezacaftor. Elexacaftor provides an additive effect in improving cellular processing and trafficking of

<sup>1</sup>Not FDA approved for this indication.

CFTR, resulting in improved outcomes, including lung function, symptoms (cough, sputum production), exacerbation rate, and nutritional status. Elexacaftor is combined with tezacaftor and ivacaftor as Trikafta and is approved for patients 6 years of age and older who have at least one *Phe508del* mutation or other approved genotypes. Patients on lumacaftor-ivacaftor (Orkambi) or tezacaftor-lumacaftor (Symdeko) should be considered for transition to elexacaftor-tezacaftor-ivacaftor (Trikafta) when of appropriate age. Currently, tezacaftor-lumacaftor (Symdeko) and elexacaftor-tezacaftor-ivacaftor (Trikafta) are available in tablet blister packs with combination tablets (morning doses) and ivacaftor (evening doses). It is important to make patients/caregivers aware of the different-appearing packaging, prescribed dosing, and administration. All of the mentioned CFTR modulators have similar administration and monitoring considerations. Liver function tests for aspartate aminotransferase (AST), alanine aminotransferase (ALT), and total bilirubin (T bili) should be done before starting therapy, followed by every 3 months for the first year of therapy and annually thereafter. As noncongenital lens opacities or cataracts have been reported in pediatric patients with ivacaftor, a baseline ophthalmologic examination is also recommended in patients who are younger than 18 years of age. Follow-up ophthalmologic examinations are recommended, but the frequency is not well defined. Doses should be taken with a fatty meal and with pancreatic enzymes (for those who require the use of pancreatic enzymes as part of CF management). All of the listed CFTR modulators are substrates and/or inducers of CYP3A4 and other CYP450 isoenzymes (e.g., CYP2C9), so screening for and managing drug interactions are essential. In addition, dosing modifications or discontinuation may be necessary for moderate or severe hepatic dysfunction. FDA-approved age and CF genotype indications for each of the CFTR modulators may be updated with ongoing clinical trials in young ages and other CF genotypes; thus it is recommended to check the latest FDA-approved indications when considering use.

### Acute Pharmacologic Therapy

Many patients with CF, despite the use of chronic therapies, experience pulmonary exacerbations requiring treatment. In addition to increased frequency of airway clearance or chest physiotherapy, acute pulmonary exacerbations may require the use of systemic antimicrobials. Whenever possible, the selection of systemic antimicrobial agents should be guided by a patient-specific history of respiratory cultures and patient clinical response to past regimens.

When a systemic antimicrobial is required for outpatient management, an oral antibiotic is commonly used, with the duration of most agents being 10 to 14 days. For example, if a given patient has a history of *P. aeruginosa*, use of oral ciprofloxacin (Cipro)<sup>1</sup> or levofloxacin (Levaquin)<sup>1</sup> for 14 to 21 days may be appropriate. Patients who have inhaled antibiotics as part of their chronic regimen may continue treatment cycles during outpatient treatment for acute pulmonary exacerbation. Some cystic fibrosis centers may use home infusion services for intravenous antimicrobials; however, this requires additional logistic considerations, including nursing support, infusion equipment, and laboratory monitoring. In addition, factors related to adherence to airway clearance, social support system at home, and appropriateness of home intravenous access should be considered.

For inpatient management, the use of intravenous antibiotics is more common, and the use of oral antibiotic(s) may also be part of the regimen. *P. aeruginosa* is often “double-covered” when possible, specifically when hospitalized and/or requiring intravenous antimicrobials. “Double-coverage” involves the use of two agents active against *P. aeruginosa* from two different antibiotic classes (e.g., beta-lactam and aminoglycoside). The use of both inhaled and systemic (e.g., intravenous) antibiotics of the same class (e.g., aminoglycosides) simultaneously is not common.

Another approach is starting intravenous antimicrobials in the inpatient setting, with transition and completion of the therapy course with home infusion services.

There are special instances in which longer courses of medications such as antibiotics or antifungal therapy may be necessary. For example, in the treatment of nontuberculosis mycobacterium (e.g., *Mycobacterium abscessus*), multiple types of antibiotics (e.g., inhaled and oral) may be used for extended durations (e.g., months). In the treatment of allergic bronchopulmonary aspergillosis, antifungal therapy may be used in addition to systemic corticosteroids (e.g., prednisone) for extensive periods (e.g., weeks or months). These more complex antimicrobial treatment courses are often managed by specialists (e.g., pulmonary and/or infectious disease specialists).

### Nutritional/Gastrointestinal Treatment

#### Nonpharmacologic Therapy

Persons with CF often have greater dietary energy intake needs. Consistent, high-calorie dietary intake can be a challenge because of several physiologic factors, including loss of taste or smell caused by chronic sinusitis and chronic gastroesophageal reflux. Behavioral factors may affect nutritional intake, necessitating behavioral intervention by dietitians and/or psychologists. For patients of all ages with continued suboptimal growth, the use of enteral feeding modes may also be necessary. For patients who have chronic constipation or a history of distal intestinal obstructive syndrome (DIOS), appropriate hydration and increased fiber content in the diet are recommended.

Infant formulas and breast milk do not provide adequate sodium for infants with CF. Because of excessive sodium loss through insensible loss, infants are at risk for developing hyponatremic, hypochloremia dehydration. It is recommended that 1/8 teaspoon of table salt be provided from birth and increased with time to 1/4 teaspoon by 6 months through 1 year of age, divided throughout the day by feedings. Additional supplementation may be necessary for children and adults living in high-temperature climates and/or involved in considerable physical activities (e.g., sports).

#### Chronic Pharmacologic Therapy

For patients with pancreatic insufficiency, the use of pancreatic enzyme replacement therapy (PERT) is needed. There are various brands of PERT that contain various amounts of lipase, protease, and amylase. Pancreatic enzymes should be taken at meal times and snack times and in coordination with enteral feeds (when applicable). The dosing of PERT is based on the lipase component. Typical pancreatic enzyme initial dosing ranges from 500 to 1500 units of lipase per kilogram of body weight per meal, with a maximum of either 10,000 units of lipase per kilogram per day or 2500 units of lipase per kilogram per meal. Enzyme preparations come in a range of concentrations to accommodate all patient needs and minimize the number of capsules required. Given the number of medications a person with CF may require for chronic management, clinicians should be mindful about how many capsules are required per meal or snack when selecting a brand and strength of pancreatic enzyme. When maximal PERT dosing is reached and the patient continues to present with symptoms of malabsorption (e.g., steatorrhea), other etiologies should be investigated. Some clinicians may add an acid suppression agent (e.g., a proton pump inhibitor or H<sub>2</sub> receptor antagonist) to help enhance the activity of pancreatic enzymes through decreasing duodenal acidity; however, the potential risks of long-term acid suppression (e.g., small intestinal bacterial overgrowth [SIBO]) should be considered. A proton pump inhibitor or H<sub>2</sub> receptor antagonist may also be used to treat concurrent gastroesophageal reflux disease.

Supplementation of fat-soluble vitamins (i.e., A, D, E, K) should be provided via specially formulated multivitamins, available in various dosage forms with dosing based on age. Monitoring of vitamin levels is often done at least annually, with adjustments in supplementation of individual vitamins (e.g., vitamin D, cholecalciferol) based on adherence to current treatment, age, and level of deficiency.

For those with chronic constipation or history of DIOS, chronic use of an osmotic laxative such as over-the-counter polyethylene

<sup>1</sup>Not FDA approved for this indication.

glycol 3350 (MiraLAX)<sup>1</sup> may be helpful. Oral *N*-acetylcysteine (Mucomyst)<sup>1</sup> has also been used for the prevention of mucus accumulation in the gastrointestinal tract of some individuals with DIOS.

### Acute Pharmacologic Therapy

Patients presenting with DIOS often require more aggressive treatment than that for chronic constipation related to CF. Treatment of DIOS may include laxatives at higher doses, use of electrolyte intestinal lavage solution (e.g., GoLYTELY),<sup>1</sup> or hyperosmolar enemas. Oral and/or rectal administration<sup>1</sup> of *N*-acetylcysteine solution has also been used for the treatment of mucus accumulation in the GI tract of some individuals with DIOS.

### Monitoring

Monitoring of pulmonary symptoms should be done at each encounter. Spirometry to assess lung function is recommended as part of CF clinic visits to assess changes in forced expiratory volume in one second (FEV<sub>1</sub>) relative to baseline. In addition, routine respiratory cultures including screening for acid-fast bacilli and fungi to monitor for pathogens and susceptibilities are recommended. Nutritional status (e.g., weight, height, weight for length, body mass index) should also be monitored regularly. Annual routine laboratory testing is also done through cystic fibrosis centers and screenings for complications (e.g., CFRD). Recommended monitoring for the various chronic therapies is discussed in the previous section.

### Management of Other Complications

In addition to the general manifestation of CF (e.g., pulmonary, growth, and nutrition), complications may appear with age and disease progression. The following are examples and general management approaches. Referral to other specialists, such as endocrinology, gastroenterology, otorhinolaryngology, or transplant (when appropriate for advanced disease), may be necessary.

#### Sinusitis

Treatment of the acute exacerbations of sinusitis can include systemic (e.g., oral) antibiotics, which are also used in pulmonary exacerbations. The use of intranasal irrigations of antimicrobials (e.g., gentamicin)<sup>1</sup> may also be considered, although guidelines defining and comparing intranasal irrigation agent selection, formulation, dosing, and monitoring are currently lacking.

#### Small Intestinal Bacterial Overgrowth

Treatment of SIBO in persons with CF is similar to treatment of those without CF, including the use of oral antibiotics (e.g., rifaximin [Xifaxan]).<sup>1</sup> Nonpharmacologic treatment may include dietary manipulation, such as reducing carbohydrate consumption, resulting in a high-fat, low-carbohydrate diet.

#### Cystic Fibrosis–Related Diabetes

In addition to dietary modifications, when pharmacologic treatment is needed, insulin therapy includes a regimen consisting of long-acting insulin paired with carbohydrate counting and coverage with rapid-acting insulin. Insulin is the most appropriate therapeutic choice because there is a loss of beta cell function. Acute pulmonary exacerbation or illness may complicate glucose control, especially if systemic corticosteroids are used as part of the management of severe, acute pulmonary exacerbations.

#### Hepatobiliary Disease

In addition to nutritional support, treatment with oral ursodeoxycholic acid or ursodiol (Actigall)<sup>1</sup> is currently recommended.

## HISTOPLASMOSIS

Method of

David van Duin, MD, PhD

### CURRENT DIAGNOSIS

- The most common symptomatic manifestation of histoplasmosis is acute pulmonary histoplasmosis, which is generally characterized by nonspecific symptoms including fevers, chills, malaise, a nonproductive cough, and chest pain.
- Other presentations of histoplasmosis include chronic pulmonary histoplasmosis, disseminated histoplasmosis in immunocompromised hosts, and extrapulmonary disease such as mediastinal histoplasmosis.
- A multimodality approach to diagnosis, which may include serology, histopathology, antigen testing, and culture, should be considered in the appropriate setting.

### CURRENT THERAPY

- Oral itraconazole is the treatment of choice for most forms of histoplasmosis.
- Serum levels of itraconazole are unpredictable and should be monitored during treatment.
- Depending on localization and severity of disease, induction with amphotericin B formulations may be required.
- Careful monitoring of patients during and after treatment is recommended, because relapses are observed in a subset of patients.

<sup>1</sup>Not FDA approved for this indication.

## Mycology and Pathogenesis

*Histoplasma capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii* are the two varieties of *H. capsulatum* that cause human histoplasmosis. *H. capsulatum* var. *duboisii* is the causative agent of African histoplasmosis, which is characterized by skin, bone, lymph node, and subcutaneous tissue involvement. This chapter focuses solely on the manifestations and treatment of *H. capsulatum* var. *capsulatum*, hereafter referred to as *H. capsulatum*.

*H. capsulatum* is a thermally dimorphic fungal pathogen, which grows as a mold in the environment, and converts to a yeast at 37°C during infection. During mold growth, *H. capsulatum* forms macroconidia, which are 8 to 15 µm and have thick walls and protuberances, as well as microconidia, which are 2 to 4 µm and have a smooth surface.

Disruption of soil containing *H. capsulatum*, such as during a construction project, results in the aerosolization of microconidia, which are the infectious particles. Inhaled microconidia are phagocytized but are able to survive and convert to yeast phase inside pulmonary macrophages. The resulting dissemination through the reticuloendothelial system is usually quickly contained in immunocompetent hosts, but it can lead to severe disease in the absence of normal immunity. Microconidia can be carried for several miles by air currents. Therefore, persons who are not in the direct vicinity of the disrupted soil are also at risk for developing histoplasmosis.

In tissues, *H. capsulatum* is recognized as 2- to 4-µm oval yeast forms with narrow-based budding. *H. capsulatum* does not have a capsule; the name is derived from the erroneous interpretation by Samuel Darling of an apparent clearing surrounding these yeasts in tissues as a capsule.

## Epidemiology

Histoplasmosis is most common in North and Central America, but cases occur worldwide, some in microfoci of infection. Areas of high prevalence include the Mississippi and Ohio River valleys in the United States and Rio de Janeiro State in Brazil. *H. capsulatum* thrives in soil that is enriched with bird or bat guano, and it can be found in high quantities near bird roosts, chicken coops, abandoned old buildings, and bat-infested caves. Because *H. capsulatum* can enter a state of latency and reactivate years later, cases have been described in patients who have a remote history of living in or visiting endemic areas. A complete geographic history and a high index of suspicion are required for the correct diagnosis of such cases in nonendemic areas.

## Clinical Manifestations

Most *H. capsulatum* infections are asymptomatic; it is estimated that less than 5% of infections lead to clinical symptoms. The occurrence and severity of a clinical syndrome are thought to be related to the immune status of the host, as well as the size of the infectious inoculum. The most common clinical scenario is acute pulmonary histoplasmosis, but a variety of other symptomatic histoplasmosis syndromes have been described. Also, a substantial number of cases come to clinical attention years after the initial infection during the course of a pulmonary nodule work-up, when malignancy is suspected. Although they are asymptomatic, these cases can lead to anxiety, as well as the morbidity and health care costs associated with radiographic exposures and biopsy procedures.

## Acute Pulmonary Histoplasmosis

Most commonly, acute pulmonary histoplasmosis is a self-limited flulike illness. Symptoms are generally nonspecific and include fevers, chills, malaise, a nonproductive cough, and chest pain. Chest radiographs can show diffuse infiltrates in one or more lobes, often with hilar lymphadenopathy. The differential diagnosis includes more common infections such as bacterial and viral pneumonias. Symptoms usually resolve without treatment in 2 to 3 weeks. However, more-severe cases do occur, even in seemingly immunocompetent hosts. In these cases, severe respiratory distress, prolonged symptoms, and even death can occur in the

absence of adequate treatment. This highlights the importance of timely diagnosis and treatment when indicated.

## Chronic Pulmonary Histoplasmosis

Some patients with acute pulmonary histoplasmosis fail to clear their infection and go on to develop a chronic pulmonary infection. A subset of these patients has chronic cavitary disease.

Chronic pulmonary histoplasmosis may be arbitrarily defined when the duration of symptoms from pulmonary histoplasmosis exceeds 6 weeks. The classic patient is a white middle-aged to elderly man with chronic obstructive pulmonary disease (COPD). Although these are clearly risk factors for the development of chronic disease, case series have illustrated that even never-smokers without preexisting lung disease are at risk for developing this complication.

A combination of systemic and pulmonary signs and symptoms is usually found in chronic pulmonary histoplasmosis. Fevers, night sweats, weight loss, lack of appetite, subjective loss of energy, and malaise are common systemic symptoms, and pulmonary symptoms include cough, sometimes with minimal hemoptysis, dyspnea, and sputum production. In patients with preexisting lung disease it may be difficult to distinguish these symptoms from baseline symptomatology. Radiology studies classically show cavitary disease without hilar lymphadenopathy. However, nodules, infiltrates, and lymphadenopathy are also seen, especially in nonsmoking women.

Untreated, this form of histoplasmosis can lead to death secondary to respiratory failure. With treatment, prognosis depends on coexisting pulmonary disease, and is generally favorable with regard to microbiological cure. However, relapses occur in up to 20% of cases even after prolonged treatment.

## Disseminated Histoplasmosis

Most, if not all, episodes of histoplasmosis have a period of dissemination, during which infected macrophages spread throughout the body via the reticuloendothelial system. In the majority of cases this is a self-limited event, which is quickly contained upon activation of the immune system. However, about 1 in 2000 infections results in progressive disseminated disease. Almost invariably, these cases occur in immunocompromised hosts. Patients at risk for progressive disseminated disease include those with advanced HIV infection, solid organ transplant recipients, patients with hematologic malignancies, and those treated with immunomodulating agents, most notably corticosteroids or tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) inhibitors. Infants are also at risk.

Recognition of disseminated histoplasmosis can be challenging. Symptoms include fevers, malaise, anorexia, respiratory symptoms, and weight loss. Laboratory investigations often reveal elevated acute phase reactants, abnormal liver function tests, and pancytopenia. Hepatosplenomegaly and lymphadenopathy occur in about half of cases. Severe cases can be clinically indistinguishable from bacterial sepsis, and patients present with hypotension and multiorgan failure. A potential diagnostic clue to the diagnosis is the presence of mucosal ulcerations, which are generally painful and can occur anywhere in the oral, pharyngeal, or laryngeal mucosa. Various morphologies may be seen, ranging from superficial to verrucous. Adrenal involvement resulting in adrenal insufficiency can occur. These patients present with enlarged adrenals on imaging and clinical symptoms of Addison disease.

Although survival without antifungal therapy has been described, disseminated histoplasmosis is generally fatal if left untreated.

## Mediastinal Manifestations of Histoplasmosis

Mediastinal disease can manifest itself as mediastinal fibrosis or granulomatous mediastinitis. Mediastinal fibrosis or fibrosing mediastinitis is an uncommon complication of pulmonary disease, in which extensive fibrotic tissue develops in the mediastinum in response to infection. Men between the ages of 20 and 40 years are at the highest risk for this complication. The fibrosis consists of mature collagen, rather than granulomatous tissue, which encases the structures of the mediastinum and can have a progressive course

eventually leading to death. The prognosis depends on the extent of involvement of mediastinal structures. Bilateral disease in which the pulmonary veins are involved is especially associated with poor outcomes. No satisfactory treatment is available.

In contrast, granulomatous mediastinitis, also known as mediastinal granuloma, is characterized by a caseous inflammatory mass of mediastinal lymph nodes. Most patients remain asymptomatic, and cases are often recognized only as an incidental imaging finding. However, a subset of patients develops symptoms related to compromise of mediastinal structures. The prognosis is more benign; usually the process resolves and the involved lymph nodes calcify. The role of treatment in this entity remains unclear.

### Central Nervous System Histoplasmosis

Central nervous system (CNS) involvement during *H. capsulatum* infection occurs infrequently. Like other extrapulmonary disease, CNS disease may be seen as a part of progressive disseminated histoplasmosis in about 5% to 10% of disseminated histoplasmosis cases. Additionally, isolated cases in which no other signs of dissemination are found have been reported. CNS histoplasmosis typically results in chronic lymphocytic meningitis, but parenchymal lesions can also be found. Symptoms are similar to those of other chronic infectious meningitides. The typical presentation is a combination of systemic symptoms including fevers, weight loss, and night sweats and localizing symptoms of headache, focal neurologic deficits, or behavioral changes. Treatment failures and relapses are common. Prognosis in the context of adequate treatment is dependent on the degree and the reversibility of immunosuppression.

### Other Manifestations of Histoplasmosis

Involvement of all organ systems with *H. capsulatum* has been reported, either in the setting of clinical disseminated histoplasmosis or as an isolated extrapulmonary site of infection.

*H. capsulatum* as a cause of endovascular and cardiac infections is well established. In endocarditis cases, native and prosthetic valves may be involved. Pericarditis is found in around 5% of patients with pulmonary histoplasmosis, and it appears to represent an immunologic reaction. Consistent with this, symptoms usually resolve with nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids. Bone, joint, and skin infections can also occur and can present diagnostic difficulty.

Urogenital involvement is often documented in autopsy series, but it infrequently results in clinical symptoms. Few cases of *H. capsulatum* causing symptomatic prostatitis, nephritis, epididymitis, vaginal and penile ulcers, and ovarian involvement have been reported. Similarly, although autopsy series report gastrointestinal involvement in disseminated histoplasmosis in up to 70% to 90% of cases, specific symptoms attributable to the gastrointestinal tract are much less common. Diarrhea, gastrointestinal bleeding, bowel perforation, or bowel obstruction can result from gastrointestinal histoplasmosis.

### Diagnosis

Diagnosing histoplasmosis can be complicated, and the available specific diagnostic tests each have their limitations. If the diagnosis is suspected, using available modalities in combination is generally the right approach. Turn-around time can vary depending on circumstances, and in severe or disseminated cases, empiric therapy may be warranted. Obtaining tissue, when it is feasible to do so, is essential for a pathologic diagnosis.

### Histopathology

One of the most useful modalities in reaching a diagnosis is histopathology. Necrotizing or non-necrotizing granulomas are often seen. An experienced pathologist can recognize the specific pattern of yeast forms, mostly inside but also outside of macrophages. The yeast forms are best visualized by a methamine silver stain, such as the Gomori-Grocott methenamine silver stain (GMS). Alternatively, periodic acid-Schiff (PAS) staining may be used. Confusion with other pathogens or, more commonly, staining artifacts can occur, and expert consultation is required in such

cases. Obtaining tissue for histopathology is usually the real challenge, and a careful evaluation of the risk-to-benefit ratio for each individual patient needs to be made.

### Cultures

Culture confirmation of histoplasmosis is desirable, but often the yield of cultures is limited. In addition, cultures may be subject to a substantial time delay of several weeks. In disseminated histoplasmosis, cultures are often positive from several sites, including blood and bone marrow. In acute pulmonary histoplasmosis, the yield of respiratory cultures is estimated to be between 9% and 40%, depending on the degree of lung involvement. In mild to moderate cases, cultures are rarely positive. In chronic cavitary lung disease, the yield of culture improves, probably as a reflection of the increased fungal burden in these patients, and cultures can grow *H. capsulatum* in as many as 85% of cases. A positive fungal culture, with microscopic characteristics suggesting *H. capsulatum*, should be confirmed by specific testing. This is usually accomplished by DNA probing.

### Serology

Antibody testing can be helpful when used in conjunction with the clinical scenario and other specific testing. The presence of antibodies to *H. capsulatum* may be determined by complement fixation (CF) or immunodiffusion (ID). Immunodiffusion methods evaluate the presence of M and H precipitin bands. Mild acute infections may be characterized by presence of an M band in isolation. Presence of an H band generally indicates more severe or chronic infection and is usually found in combination with an M band. Complement fixation determines the level of antibodies directed against mycelial and yeast antigens separately. For diagnosis, a fourfold rise in either mycelial or yeast CF antibody titer is required.

The incidence of detectable antibodies in persons in endemic areas is much lower than the incidence of positive skin testing, which suggests that detectable antibodies probably wane after exposure to undetectable levels. Therefore, although an isolated antibody titer of 1:32 or greater is not diagnostic, it is very suggestive of histoplasmosis in a patient with a consistent clinical presentation. In addition, any positive titer should lead to additional work-up because a substantial number of patients with confirmed histoplasmosis have antibody titers that are in the low positive range. Antibodies take 2 to 6 weeks to appear, which limits their use in acute cases. Immunosuppressed states clearly diminish the sensitivity of serology, but positive serologies are found in around 50% of disseminated histoplasmosis in immunocompromised patients. Antibody testing may be particularly helpful in CNS histoplasmosis, where cerebrospinal fluid (CSF) cultures are often negative. The finding of detectable anti-*H. capsulatum* antibodies in the CSF is diagnostic in the right clinical setting.

### Antigen Detection

A commercial assay is available to determine the presence of polysaccharide antigens shed by *H. capsulatum* in urine or serum. Previously, urine assays appeared to outperform serum assays, but the most recent generation of antigen assays seems to be equivalent in urine and serum. Measuring antigen shedding in bronchoalveolar lavage (BAL) fluid is a new and promising development. Preliminary data indicate that yields from BAL may be increased in pulmonary disease. In general, antigen detection assays are a valuable adjunct to diagnosis and should be obtained in any case in which histoplasmosis is suspected. Because direct shedding is measured, the yield of this test is not diminished in immunocompromised hosts. In limited disease with a minimal fungal burden, antigens are unlikely to be detected.

### Treatment

In 2007, the Infectious Diseases Society of America (IDSA) published updated management guidelines for the treatment of histoplasmosis (Table 1). The IDSA emphasizes that all of its guidelines

**TABLE 1** 2007 IDSA Guidelines for Treating Histoplasmosis

CLINICAL MANIFESTATION	INDUCTION	DURATION	MAINTENANCE	TOTAL DURATION
<b>Acute Pulmonary</b>				
Mild to moderate <4 weeks	None			
Mild to moderate >4 weeks	None		Itra*	6–12 wk
Moderately severe to severe	AmB <sup>†</sup>	1–2 wk	Itra*	12 wk
<b>Chronic Pulmonary</b>				
	Itra*	3 day	Itra*	1–2 yr
<b>Disseminated</b>				
Mild to moderate	Itra*	3 day	Itra*	1 yr
Moderately severe to severe	AmB <sup>†</sup>	1–2 wk	Itra*	1 yr
Granulomatous mediastinitis	Itra*	3 day	Itra*	6–12 wk
CNS	AmB <sup>†</sup>	4–6 wk	Itra*	1 yr

Abbreviations: AmB = amphotericin B; CNS = central nervous system; IDSA = Infectious Diseases Society of America; Itra = itraconazole.

<sup>†</sup>Not FDA approved for this indication.

\*Itraconazole (Sporanox) dosing for mild to moderate disease is 200 mg qd or bid; for all other indications a loading dose of 200 mg tid × 3 d is recommended followed by 200 mg qd or bid, guided by blood levels.

<sup>†</sup>Amphotericin B, in general liposomal (AmBisome)<sup>1</sup> or lipid formulations (Abelcet)<sup>1</sup> are preferred, but deoxycholate formulation of amphotericin B (Fungizone) may be used as an alternative in the treatment of acute pulmonary histoplasmosis. In CNS histoplasmosis, liposomal amphotericin B<sup>1</sup> is preferred.

“cannot always account for individual variation among patients. They are not intended to supplant physician judgment with respect to particular patients or special clinical situations.” Regarding acute pulmonary histoplasmosis, no evidence from clinical trials is available to guide treatment decisions, and the IDSA guidelines are relatively conservative, reserving treatment only for “moderately severe to severe” cases. No explicit definition of severity is provided. Also, when mild to moderate symptoms persist, treatment is not recommended until the patient has been symptomatic for more than 4 weeks. Here, careful clinical judgment is warranted. Although poor long-term outcomes are uncommon in these patients, symptom resolution upon antifungal treatment is the rule. Therefore, some experts treat even mild to moderate acute pulmonary disease with a symptom duration of less than 4 weeks, in contrast to IDSA guideline recommendations.

Recommended induction treatment for the first 1 to 2 weeks in moderately severe to severe acute pulmonary histoplasmosis is a lipid formulation of amphotericin B (AmBisome, Abelcet)<sup>1</sup> 3 to 5 mg/kg IV daily. During induction therapy, methylprednisolone (Solu-Medrol) may be used as needed for respiratory complications. After that, oral itraconazole (Sporanox) can be used (200 mg three times daily for 3 days and then 200 mg twice daily) for a total duration of treatment of 12 weeks. Oral itraconazole for 6 to 12 weeks is the treatment of choice when the decision is made to treat mild to moderate acute pulmonary histoplasmosis.

When itraconazole is used, careful instructions should be given to ensure optimal oral absorption. Using the solution results generally in higher blood levels, but the unpleasant taste can be an issue for patients. To optimize absorption of the capsules, encourage patients to take them with a cola beverage. Because of substantial interpersonal variability in itraconazole metabolism, blood levels remain unpredictable. As a result, levels should be monitored on all patients whose treatment exceeds 2 weeks. In general, blood levels between 1.0 and 10.0 µg/mL are recommended, even though strong evidence for these cutoffs is lacking.

Chronic pulmonary histoplasmosis requires oral itraconazole therapy for 1 to 2 years. As noted earlier, relapses can occur even with prolonged therapy, and some patients require lifelong suppressive therapy. When an asymptomatic pulmonary nodule is found to be a histoplasma in the course of a malignancy work-up, no treatment is generally indicated.

In disseminated histoplasmosis with moderately severe to severe symptoms, induction treatment with liposomal amphotericin B<sup>1</sup> (3 mg/kg IV daily) is recommended for the first 1 to 2 weeks. This is followed by oral itraconazole for a total of at least 1 year. When symptoms of disseminated histoplasmosis are mild to moderate, the induction phase can be omitted, and treatment with oral itraconazole for 1 year should suffice. The role of treatment in mediastinal complications of histoplasmosis depends on the etiology. If symptomatic and inflammatory findings predominate, as in granulomatous mediastinitis, treatment with oral itraconazole is warranted. In mediastinal fibrosis, antifungal treatment generally does not improve the prognosis. CNS histoplasmosis should be aggressively treated with liposomal amphotericin B (5 mg/kg daily intravenously) for 4 to 6 weeks, followed by oral itraconazole for at least 1 year.

## HYPERSENSITIVITY PNEUMONITIS

Method of

David I. Bernstein, MD; and Haejin Kim, MD

### CURRENT DIAGNOSIS

- History of inhalational exposure to an identifiable environmental antigen associated with development of compatible clinical features.
- Objective evidence of acute pneumonitis or chronic pneumonitis with fibrosis based on physical examination, lung function testing, radiographic features, and lung biopsy findings.
- Clinical improvement in symptoms, lung function, and radiographic abnormalities with avoidance of the causative antigen(s).

### CURRENT THERAPY

- Avoidance of contact with the offending antigen is essential and is often curative if performed early in the course of the disease.
- Although systemic corticosteroids are often required during the acute phase of hypersensitivity pneumonitis, their impact on disease progression and prognosis has not been determined.

Hypersensitivity pneumonitis (HP), also known as extrinsic allergic alveolitis, is an inflammatory disorder of the lungs mediated by immunologic hypersensitivity to a specific antigen, usually organic in nature. Although more than 200 causative antigens have been implicated, only a small number of individuals develop HP in response to exposure. [Table 1](#) lists common causative agents in HP. Comprehensive lists of causative agents are available.

### Pathophysiology

HP is thought to involve primarily delayed type IV (cell-mediated) hypersensitivity and is not mediated by immunoglobulin (Ig)E antibodies. Bronchoalveolar fluid obtained from patients with HP shows a predominant CD8<sup>+</sup> lymphocytosis supporting T cell-mediated disease. Viruses are thought to play a role in the development of HP through upregulation of costimulatory molecules on alveolar macrophages and dendritic cells, leading to increased activation of type 1 helper T cells. Adoptive transfer models in animals have shown that CD4<sup>+</sup> T cells and cytotoxic T cells are the most important effector cells in experimental HP, rather than cytokines, antibodies, or complement alone.

### Clinical Presentation and Diagnosis

The main clinical features for HP are listed in [Table 2](#). HP is diagnosed if the history, physical findings, high-resolution chest CT, and pulmonary function tests indicate infiltrative and restrictive lung disease; exposure is documented to a recognized or new causative agent; and there is significant improvement in symptoms, lung function, and radiographic findings with avoidance of the offending cause. IgG antibody to the offending antigen (serum precipitins) may be demonstrated but is not required for diagnosis. Immediate skin test reactivity is not indicated. These are the most widely accepted criteria, but evidence-based diagnostic guidelines have not been established. The clinician can differentiate acute from chronic HP based on chest CT and lung biopsy findings (see [Table 2](#)). A careful home, environmental, and occupational history is essential to identify one or more causative antigens.

### Treatment

The primary treatment is cessation of exposure to the sources of offending antigens at home or in the workplace. Effective environmental control measures may include modification of work habits, improvement in ventilation, or change in manufacturing procedures. Systemic corticosteroids are often required and aid in recovery during the acute or subacute phases, but there are no long-term studies of their impact on disease progression or survival rates. Referral to a specialist in hypersensitivity lung diseases is recommended for proper diagnosis and identification of the sources of causative antigens. Individuals with advanced lung

## LEGIONELLOSIS (LEGIONNAIRES' DISEASE AND PONTIAC FEVER)

Method of

Julio A. Ramirez, MD

In the summer of 1976, an outbreak of approximately 182 cases of pneumonia occurred in persons attending the American Legion convention in Philadelphia. One year later, Dr. McDade reported the identification of *Legionella pneumophila*, the bacterium responsible for the infection. Today, the family of Legionellaceae

is composed of more than 40 species, with some species having different serogroups. *L pneumophila* causes approximately 85% of all *Legionella* infections. *L pneumophila* serogroup 1 is the single most common member of the family causing clinical infections.

## Epidemiology

*Legionella* is an intracellular organism that lives in natural water. In the aquatic environment, the bacteria live and multiply within freshwater amoebae. The number of *Legionella* organisms in the water can increase significantly with appropriate local conditions such as warm temperature, lack of biocides, stagnant water, and presence of amoebae and other nutrients. These special conditions can be present in artificial water systems such as cooling towers, whirlpools, decorative fountains, and respiratory therapy devices.

The susceptible host acquires the bacteria from water containing the organism. Infection can be acquired by inhaling aerosols containing *Legionella* organisms or by microaspiration of water contaminated with *Legionella*. The hospitalized patient with *Legionella* pneumonia does not require respiratory isolation because legionellosis is not transmitted from person to person.

## Clinical Features

Once *Legionella* organisms reach the respiratory tract, based on the interactions of the organism with the host immune system, the patient can have four possible clinical outcomes: asymptomatic infection, Pontiac fever, Legionnaires' disease, or extrapulmonary disease involving the liver, heart, brain, or other organs. Pontiac fever is a nonpneumonic form of disease characterized by fever, headaches, myalgias, and malaise. The patient has an influenza-like illness, with resolution of disease in a few days without specific antimicrobial therapy. Patients with Legionnaires' disease present with community-acquired pneumonia associated with high fever, gastrointestinal complaints such as diarrhea, and central nervous system complaints such as headaches or mental status changes. Hospital-acquired pneumonia can occur if *Legionella* is present in the hospital water supply.

## Diagnosis

The currently available laboratory tests for diagnosis of *Legionella* infections include the direct fluorescent antibody stain (DFA), culture, antigen detection in the urine, antibody detection in serum

**TABLE 1** Antibiotic Therapy for Legionella Infections

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

by indirect fluorescent antibody testing (IFA), and DNA amplification using the polymerase chain reaction (PCR). The DFA stain can detect all *L pneumophila* serogroups, but a large number of bacteria need to be present in sputum for a positive result. *Legionella* can be cultured from respiratory specimens on selective media composed of buffered charcoal-yeast extract agar. The urinary antigen detection has a specificity greater than 95%; the disadvantage is that the test detects only the antigen of *L pneumophila* serogroup 1. Clinical specimens that have been used to detect *Legionella* by PCR include throat swabs, sputum, tracheal suction, bronchoalveolar lavage fluid, pleural fluid, and lung tissue.

### Treatment

In the pulmonary parenchyma, *Legionella* can infect and multiply inside alveolar macrophages, alveolar epithelial cells, and capillary endothelial cells. The poor clinical outcome with  $\beta$ -lactam antibiotics is due to their lack of penetration into cells. Antibiotics with good intracellular penetration that can be used as monotherapy for *Legionella* infections include macrolides, tetracyclines, and quinolones (Table 1). Rifampin (Rifadin)<sup>1</sup> is not used as monotherapy because resistance can rapidly emerge when it is used alone.

Therapy of the patient with severe disease is initiated with intravenous antibiotics. Once the patient reaches clinical stability, the intravenous therapy can be switched to oral therapy. Doses for the most common antibiotics for intravenous and oral therapy are depicted in Table 1. In the nonimmunocompromised patient, the recommended duration of therapy is 7 to 10 days. In immunocompromised patients, because they are at risk for relapsing infection, the recommended duration of therapy is 14 to 21 days.

Several antibiotics have demonstrated clinical efficacy in Legionnaires' disease. Data with several in vitro and animal studies comparing different anti-*Legionella* antibiotics indicate that

erythromycin (Ery-Tab) is a weak anti-*Legionella* agent. If erythromycin is selected for therapy, it is important to add rifampin to the regimen to increase intracellular killing. From the family of macrolides, azithromycin (Zithromax) is the most active. The best bactericidal activity in the laboratory is achieved with quinolones. Retrospective observational studies indicate that patients treated with levofloxacin (Levaquin) have a shorter time to reach clinical stability and shorter duration of hospital stay. These antibiotics are considered primary anti-*Legionella* agents.

In clinical practice, I treat immunocompromised patients who have severe Legionnaires' disease with a combination of an intravenous quinolone plus an intravenous macrolide (e.g., levofloxacin plus azithromycin). This regimen is based only on the theoretical consideration that synergistic killing may be obtained using a quinolone to alter DNA synthesis and a macrolide to alter protein synthesis.

## LUNG ABSCESS

Method of

Dan Schuller, MD

### CURRENT DIAGNOSIS

- Lung abscess is usually a complication of aspiration in patients with gingivitis or periodontal disease.
- Mixed aerobic-anaerobic copathogens are common, but sputum cultures are not reliable.
- Lung abscesses are rare in edentulous patients and should prompt evaluation for bronchial obstruction.
- CT scan of the chest is very useful in the diagnostic evaluation.

### CURRENT THERAPY

- Prolonged antimicrobial therapy (6–8 weeks) and postural drainage are the cornerstones of therapy.
- Clindamycin (Cleocin) or alternative anaerobic coverage is required even if sputum cultures grow only aerobic bacteria (colonizers or copathogens).
- Percutaneous or bronchoscopic drainage is reserved for selected cases refractory to medical management or at a high risk for complications.
- Surgical resection is seldom needed because of the success of medical therapy.
- Evaluation and management of underlying predisposing conditions should not be neglected.

### Definition and Classification

Lung abscess is defined as a focal area of necrosis of the lung parenchyma resulting from microbial infection and usually measuring more than 2 cm in diameter. Smaller or multiple areas of necrosis in contiguous areas are referred to as *necrotizing pneumonia*. Primary lung abscess (80%) is due to direct infection or aspiration. Secondary lung abscess (20%) is secondary to bronchial obstruction, immunodeficiency, pulmonary infarction, trauma, or complications from surgery. Lung abscesses can also be classified according to pathogen (e.g., mixed anaerobic, *Pseudomonas*, mycobacterial, fungal) or duration of symptoms (e.g., chronic with symptoms for more than a month before presentation). If symptoms are present for more than one month, the lung abscess is considered chronic.

<sup>1</sup>Not FDA approved for this indication.

## Epidemiology and Risk Factors

Most lung abscesses result from aspiration of oral secretions in patients who harbor high bacterial concentrations in the gingival crevices. Periodontal disease, especially gingivitis, is a major predisposing condition, particularly in hosts impaired by altered sensorium due to alcoholism, anesthesia, coma, drug overdose, seizures, or stroke. Because edentulous persons rarely develop lung abscesses, other causes such as malignancy should be carefully sought. Patients with dysphagia, esophageal disease, poor airway protection, or weak cough and respiratory clearance mechanisms are also at risk for developing lung abscess.

Patients whose immune systems are compromised by malignancy, HIV infection, malnutrition, diabetes, chronic use of corticosteroids, or previous organ transplantation are more likely to be infected with aerobic bacteria, mycobacterial or fungal pathogens. These patients are more likely to have multiple abscesses, less response to treatment, and a worse prognosis.

In children, consider secondary causes including foreign body aspiration, congenital cystic adenomatoid malformation, pulmonary sequestration, cystic fibrosis, bronchiectasis, bronchogenic cyst, congenital immunodeficiency, or severe underlying neurologic abnormality.

Lemierre's disease or jugular vein suppurative thrombophlebitis, usually caused by *Fusobacterium necrophorum*, is a rare infection that begins in the pharynx as a tonsillar or peritonsillar abscess and spreads to involve the internal jugular vein, with septic emboli to the lung with secondary cavitations.

## Pathophysiology

The understanding of lower airway microbiota in humans as well as the capacity of a microorganism to cause damage in a host has evolved. The development of a lung abscess usually starts when an insult (e.g., inoculum of highly contaminated oral secretions) overcomes the pulmonary mechanisms of defense and begins a process of pneumonitis in the dependent areas affected by aspiration. Depending on the microbiology and the intensity of the inflammatory response, the acute pneumonitis evolves to tissue necrosis after 7 to 14 days and subsequent cavitation. At first, the enclosing wall is poorly defined, but with time and progressive fibrosis it becomes more discrete. When a communication with the airway exists, the suppurative debris from the abscess can partially drain, leaving an air-containing cavity with a radiographic air-fluid level. Occasionally, abscesses rupture into the pleural cavity yielding an empyema or a bronchopleural fistula (Figure 1). Primary abscesses due to aspiration are much more common on the right side than the left and are most often single. The most common locations include the superior segments of the lower lobes and the posterior segment of the right upper lobe.

**Figure 1** Primary lung abscess in the right lower lobe with rupture into the pleural space causing an empyema.

## Clinical Manifestations

Most patients present with insidious symptoms that evolve over a period of weeks to months. Cough productive of copious amounts of putrid, foul-smelling sputum that occurs in paroxysms after changing position are characteristic. Fevers, chills, night sweats, chest pain, dyspnea, general malaise, and fatigue are common. Hemoptysis can vary from blood-streaked sputum to life-threatening hemorrhage. Physical findings can include fever, tachycardia, periodontal disease, halitosis, signs of lung consolidation or pleural effusion, amphoric breath sounds, and occasionally clubbing of the fingers and toes can appear within a few weeks after the onset of an abscess.

## Diagnosis

Lung abscess is easily diagnosed when there is a classic clinical presentation with indolent symptoms lasting more than 2 weeks in a host with predisposing risk factors and a chest radiograph revealing a cavitory infiltrate or an air-fluid level. However, numerous pathogens are associated with this syndrome, and attempts to establish microbiological diagnosis and exclude other conditions are warranted.

Computed tomography (CT) scans can be useful for better anatomic definition, to evaluate possible associated conditions such as malignancy, and to rule out pleural involvement. Distinguishing between a lung abscess and an empyema with an associated bronchopleural fistula leading to an air-fluid level can sometimes be challenging, but it is crucial because the management of these conditions is very different. Features that suggest empyema include a lenticular shape or a larger diameter of the air-fluid level on the lateral view of the chest film, an obtuse angle of the cavity with the chest wall, and a split pleural sign with contrast enhancement of the pleura.

Most lung abscesses are caused by anaerobic or mixed aerobic and anaerobic infections. Anaerobic bacteria include *Peptostreptococcus*, *Prevotella*, *Bacteroides* spp., and *Fusobacterium* spp. and are difficult to isolate owing to technical issues and contamination by upper airway flora. Other pathogens, including *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas*, *Burkholderia pseudomallei*, *Nocardia*, *Actinomyces*, and mycobacterial or fungal organisms, are more likely to occur in secondary lung abscesses. The bacteriology of lung abscesses may be different in other parts of the world.

Sputum Gram stains and culture should be performed in all patients but interpreted with caution because prior antimicrobial therapy can inhibit growth, and contaminant strains can be misleading. Even when there is abundant growth of a species of aerobic bacteria, treatment should still be directed at covering anaerobes.

In the absence of positive blood or pleural fluid cultures, microbiological confirmation of a lung abscess requires other invasive methods such as a transthoracic needle aspirates (TTNA) or bronchoscopy with bronchoalveolar lavage (BAL) or protected specimen brush (PSB). The best timing for bronchoscopy is controversial because early intervention has the highest diagnostic yield but at the risk of provoking spillage of a relatively contained abscess into additional lobes or the contralateral lung. In patients who are edentulous or in whom there is a high suspicion for malignancy, the indication for bronchoscopic evaluation is almost universal but should be scheduled when the risk for clinical deterioration (e.g., spillage with resultant respiratory failure) has been minimized.

## Differential Diagnosis

In addition to the multiple necrotizing infections or an empyema with a bronchopleural fistula (see earlier), there are many noninfectious diseases that can cause cavitory lung lesions and mimic a lung abscess. The differential diagnosis includes neoplasm (primary or metastatic), bullae or cyst with air-fluid level, bronchiectasis, necrotizing vasculitis, or pulmonary infarction. In patients with multiple cavitory lesions, consider septic emboli.

## Treatment

Lung abscess is best treated with a prolonged course of adequate antimicrobials and postural drainage. Percutaneous or bronchoscopic drainage and surgery are considered only for selected patients whose disease is refractory to standard care.

Initial empiric antibiotic treatment for a typical community-acquired lung abscess should consist of intravenous clindamycin (Cleocin) 600 to 900 mg every 6 to 8 hours, which has been shown to be superior to penicillin. For patients with a nosocomial or health care-associated lung abscess, additional coverage for enteric gram-negative pathogens including *Pseudomonas aeruginosa* and *Staphylococcus aureus* is appropriate.

Alternative antimicrobial options include ampicillin-sulbactam (Unasyn)<sup>1</sup> 1.5 to 3.0 g IV every 6 hours, piperacillin-tazobactam (Zosyn)<sup>1</sup> 3.35 g IV every 6 hours, cefoxitin (Mefoxin) 2 to 3 g every 6 to 8 hours, or a combination of moxifloxacin (Avelox)<sup>1</sup> 400 mg IV daily and metronidazole (Flagyl) 500 mg IV every 6 to 8 hours. The use of metronidazole as single agent has been associated with a high therapeutic failure rate.

After defervescence and radiographic improvement, parenteral antibiotics can be switched to oral bioequivalent therapy for 6 to 8 weeks or longer depending on the course. Shorter antimicrobial courses are associated with a high rate of relapse. Most experts suggest continuing therapy until there is radiographic resolution or a small stable lesion.

Indications for percutaneous or bronchoscopic drainage include persistent sepsis after 5 to 7 days of antimicrobial therapy, abscesses larger than 4 cm that are under tension or enlarging, and need for mechanical ventilator support. Percutaneous drainage should only be considered when there is a reasonable abscess-pleura symphysis and no associated coagulopathy. Lung resection is rarely needed and is reserved for operable cases refractory to medical treatment.

Postural drainage and chest physiotherapy facilitate removal of pus, relieving symptoms and improving gas exchange. Surgical resection is required in less than 10% of patients whose disease is refractory to medical management.

Finally, evaluation and management of the predisposing conditions leading to aspiration should take place after the patient is stabilized. This can include swallowing assessment, dental work, or oral surgery.

## Prognosis

Primary lung abscesses in nonimmunocompromised hosts have cure rates of 90% to 95% with antimicrobial therapy and postural drainage alone. However, in immunocompromised patients and those with bronchial obstruction due to cancer, the mortality has been reported between 20% and 75%.

<sup>1</sup>Not FDA approved for this indication.

## LUNG CANCER

Method of

Erin A. Gillaspie, MD, MPH; Amanda S. Cass, PharmD; Jennifer Lewis, MD, MS, MPH; and Leora Horn, MD, MSc

### CURRENT DIAGNOSIS

- An improvement in lung cancer outcomes is achievable with use of low-dose computed tomography (LDCT) for lung cancer screening.
- All eligible patients should be screened with an annual LDCT scan.
- The accurate staging of lung cancer is crucial to help guide treatment recommendations.
- Many patients have no symptoms at the time of diagnosis.
- Tissue diagnosis can be achieved through image-guided endobronchial and surgical biopsies.

### CURRENT THERAPY

- All smokers should be counseled on smoking cessation.
- Treatment recommendations are based on stage of cancer and patient fitness to tolerate surgery.
- Surgically resectable non-small cell lung cancer (NSCLC) is more commonly approached in a minimally invasive fashion.
- Early-stage NSCLC is most often treated with definitive surgery with or without chemotherapy.
- Locally advanced NSCLC requires a multimodal treatment regimen often using a combination of radiation therapy, surgery, and systemic therapy.
- Recent approvals for immunotherapy and targeted therapy in earlier line setting necessitate earlier molecular and PD-L1 testing for some patients.
- Forty percent of patients will have an advanced stage of disease at diagnosis, and systemic therapy is the mainstay of treatment.
- All patients with stage IV disease should have molecular and programmed death-ligand 1 (PD-L1) testing to help guide therapy.
- Routine disease monitoring is important both after curative-intent treatment and during treatment for incurable disease.
- Small cell lung cancer (SCLC) is aggressive, and the mainstay of treatment is systemic therapy combined with radiation therapy in early-stage disease or immunotherapy in advanced disease.

## Epidemiology

Lung cancer is the leading cause of cancer-related mortality in the United States among both men and women. The overall incidence rate is decreasing, more rapidly among men, largely as a result of the declining use of tobacco. Lung cancer is predominantly a disease of older individuals, 65 to 84 years of age, with average age at diagnosis of 70 years. There is an equal distribution in lung cancer incidence among African Americans and Caucasians as a whole. However, the highest incidence is among African American males and Caucasian females. Incidence and mortality rates among Hispanics, Native Americans, and Asian Americans are approximately 40% to 50% of that of Caucasians. The majority (76%) of cases are diagnosed at locally advanced or advanced stages of disease, which accounts for the relatively poor overall survival. The 5-year overall survival is 22% overall and 26% for non-small cell lung cancer while only 7% for small cell lung cancer.

Epithelial lung cancers are divided into four major cell types: small cell lung cancer (SCLC), adenocarcinoma, squamous cell carcinoma, and large cell carcinoma; the latter three types are collectively known as non-small cell lung cancers (NSCLCs). All

histologic types of lung cancer can develop in current and former smokers, although squamous and small cell carcinomas are most commonly associated with heavy tobacco use. It is essential to distinguish histologically between SCLC and NSCLC because these subtypes have different natural histories and therapeutic approaches. In addition, the molecular subtype of NSCLC has become an important part of treatment planning because some chemotherapeutic agents perform quite differently in squamous cell cancers versus adenocarcinoma. Further, patients with adenocarcinoma are more likely to harbor tumor mutations, making them candidates for targeted therapy.

### Risk Factors

Tobacco use (cigarettes, cigars, and pipes) is by far the greatest risk factor for lung cancer, accounting for approximately 80% of lung cancer deaths. Risk increases as a function of both quantity and duration of tobacco exposure. Environmental tobacco smoke (ETS) or secondhand smoke is also an established cause of lung cancer.

Radon gas is the second most common risk factor. Prolonged exposure to low-level radon in homes might impart a risk of lung cancer equal or greater than that of ETS.

Additional risk factors include asbestos, radiation, agent orange, chromium, cadmium, and arsenic. Individuals with occupations in rubber manufacturing, roofing, paving, and chimney sweeping are also felt to be at an increased risk for developing lung cancer. Finally, family history of lung cancer is a risk factor, but the exact genetic driver remains unclear. Notably, the incidence of lung cancer in never smokers is increasing for reasons that are also unclear.

### Prevention

Smoking cessation is the cornerstone of lung cancer prevention. Stopping tobacco use before middle age avoids more than 90% of the lung cancer risk attributable to tobacco. Moreover, smoking cessation in individuals with an established diagnosis of lung cancer is associated with improved survival and decreased toxicities from therapy.

The combination of smoking cessation counseling with medications leads to a higher likelihood of successful quit attempts. Medications that are approved by the U.S. Food and Drug Administration (FDA) include nicotine replacement therapy (nicotine patches [NicoDerm CQ], lozenges [Nicorette], gum [Nicorelief, Nicorette], spray [Nicotrol NS]), varenicline (Chantix), and bupropion (Zyban). Nicotine patches, which provide longer periods of nicotine replacement, should be used in combination with gum or lozenges to treat short-term cravings. The results of a multicenter, double-blind, randomized controlled trial, the Evaluating Adverse Events in a Global Smoking Cessation Study (EAGLES), compared varenicline, bupropion, nicotine patch, and placebo in more than 8000 smokers and found that the efficacy of each medication was higher than placebo. The results of this trial also demonstrated that there was no increase in neuropsychiatric symptoms in smokers exposed to varenicline, leading the FDA to remove the black box warning.

Patients must want to stop smoking and must be willing to work hard to achieve the goal of smoking abstinence to achieve success. Counseling using the 5 As (*ask, advise, assess, assist, arrange*) remains the recommended five major steps in intervention (Table 1). A shortened version, the 3 As, is an alternative for

busy clinicians and involves *asking* and recording smoking status, *advising* the patient of health benefits, and *acting* on the patient's response.

### Early Detection

Clinicians have an important opportunity to improve lung cancer outcomes through early detection. Increasing evidence demonstrates a mortality benefit when screening high-risk patients with low-dose computed tomography (LDCT). The U.S. Preventive Services Task Force (USPSTF) recommends lung cancer screening with LDCT for individuals 50 to 80 years of age, current or former smokers who have quit within the past 15 years, and smokers who have at least a 20 pack-year history of smoking. Medicare covers LDCT screening for a similar group of high-risk individuals, differing only in the upper age limit (50 to 77 years of age). These policy decisions were made following the results of the National Lung Screening Trial (NLST).

The NLST was a large multicenter, randomized controlled trial performed in the United States that compared annual chest x-ray (CXR) with LDCT in 53,454 patients who were considered high risk for development of lung cancer. This trial was terminated early when it met its primary endpoint of achieving a 20% relative reduction in lung cancer mortality favoring the LDCT arm. Nearly twice as many early-stage 1A cancers were detected in the LDCT group compared with the CXR group (40% vs. 21%). The overall rates of lung cancer death were 247 and 309 deaths per 100,000 person-years in the LDCT and CXR groups, respectively. Compared with the CXR group, the rate of death in the LDCT group from *any* cause was reduced by 6.7% (95% CI 1.2 to 13.6,  $P = .02$ ). A common critique of the NLST is the high false-positive rate. However, across three rounds of screening in the LDCT arm, only 24.2% of screening examinations were positive and went on to require additional imaging or biopsy. The interpretation of screening LDCT continues to improve through the use of the American College of Radiology's structured reporting system, Lung-RADs, which has further decreased the false-positive rate.

Similarly, the Danish-Belgium Lung Cancer Screening Trial (NELSON) found a 26% relative reduction in lung cancer mortality when screening high-risk individuals with LDCT compared with no screening, further supporting the role for annual LDCT scans in high-risk individuals as part of health maintenance.

### Clinical Manifestations

The tumor size, location, and manifestation of paraneoplastic syndromes determine the clinical presentation of most patients with lung cancer. Most patients with early-stage disease are asymptomatic, and their cancer is discovered incidentally on CXR or LDCT scans (Table 2).

Peripheral tumors may invade the chest wall and can present with pain. Centrally located tumors may cause symptoms from direct invasion or compression of mediastinal structures. Symptoms may include cough, hemoptysis, wheezing, stridor, or even postobstructive pneumonia. Patients may present with diaphragmatic paralysis caused by phrenic nerve invasion, superior vena cava (SVC) syndrome with facial edema, bluish discoloration of the upper chest, and shortness of breath. They may even have dysphagia from esophageal compression. Mediastinal lymph node involvement can cause disruption of the recurrent laryngeal nerve, leading to hoarseness. Tumors arising in the superior sulcus, so-called *Pancoast tumors*, can result in lower brachial plexopathy and Horner syndrome. Pleural effusion may also be the presenting sign for lung cancer and can cause pain, dyspnea, or cough (see Table 2).

Symptoms from metastatic disease may be the first sign of malignancy. Frequent sites of metastasis include supraclavicular and cervical lymph nodes, bone, brain, liver, and adrenal glands. Brain metastases occur in 10% to 30% of patients. Symptoms

TUMOR LOCAL EFFECT	DISTANT METASTASIS EFFECTS	PARANEOPLASTIC SYNDROME
Cough	Bone pain	Hypercalcemia
Dyspnea	Headache	SIADH
Hemoptysis	Nausea and vomiting	Lambert-Eaton syndrome
Chest pain	Seizure	Cerebellar ataxia
Hoarseness	Weight loss	Encephalitis
SVC syndrome	Fatigue	Cachexia/anorexia
Postobstructive pneumonia	Abdominal pain	Cushing syndrome
Pleural effusion	Spinal cord compression	
Pericardial effusion	Pathologic fracture	

SIADH, Syndrome of inappropriate antidiuretic hormone secretion; SVC, superior vena cava.

include seizures, nausea and vomiting, headache, or focal neurologic dysfunction. Bony metastases present with pain, pathologic fracture, or spinal cord compression. Liver metastases can cause biliary obstruction and jaundice; however, this is not particularly common. Constitutional symptoms may include anorexia, weight loss, weakness, fever, and night sweats.

Lung cancers are notable for ectopic production of hormones leading to several paraneoplastic syndromes. These are most commonly described in SCLC; however, they can occur in rare cases of NSCLC. The most common paraneoplastic syndromes in NSCLC are tumor cachexia and hypercalcemia. The causes of tumor cachexia are not well characterized. Hypercalcemia is mediated by the production of parathyroid hormone–related peptide (PTHrP). The peptide stimulates the release of calcium from bones, resulting in an elevation in calcium in the blood and osteopenia. This syndrome is treated effectively with bisphosphonate therapy. Hypertrophic pulmonary arthropathy can occur with NSCLC or SCLC and is characterized by digital clubbing and periostitis of the long bones that are demonstrable on plain x-rays.

Paraneoplastic syndromes unique to SCLC include Lambert-Eaton myasthenic syndrome (LEMS), syndrome of inappropriate antidiuretic hormone (SIADH), and Cushing syndrome. A patient presenting with LEMS should always be ruled out for malignancy; 50% of patients who present with this syndrome have cancer, and in 95% of those cases, it is SCLC. Another paraneoplastic syndrome related to SCLC is SIADH. SIADH generally resolves within 1 to 4 weeks of initiating chemotherapy. During this period, serum sodium can usually be managed and maintained above 128 mEq/L via fluid restriction. Demeclocycline (Declomycin)<sup>1</sup> can be a useful adjunctive measure when fluid restriction alone is insufficient. Vasopressin receptor antagonists also have been used in the management of SIADH but are costly and have increased unique toxicities such as liver injury.

Cushing syndrome caused by ectopic production of adrenocorticotropic hormone (ACTH) by SCLC and pulmonary carcinoids results in electrolyte disturbances rather than the classic changes in body habitus. Treatment with standard medications such as metyrapone (Metopirone)<sup>1</sup> and ketoconazole (Nizoral)<sup>1</sup> is largely ineffective.

Cerebellar degeneration may be associated with anti-Hu, anti-Yo, or P/Q channel autoantibodies. Cutaneous manifestations such as dermatomyositis are rare. Thrombosis including Trousseau syndrome, marantic endocarditis, and coagulopathies

are also uncommon and are usually associated with a poorer prognosis.

### Diagnostic Techniques

Once lung cancer is suspected, tissue biopsy is required to make a definitive diagnosis. In patients with suspected metastatic disease, a biopsy of a distant site of disease is preferred for tissue confirmation because it provides additional staging information. Several methods can be considered depending on the location of the tumor, and the technique should be tailored to the location of the primary tumor and the presence of mediastinal nodal involvement or metastatic disease.

For peripheral lesions, a CT-guided needle biopsy may be considered. This route of biopsy is associated with a risk of pneumothorax that requires intervention in approximately 5.6% of cases.

The advent of navigational bronchoscopy has allowed interventional pulmonologists to sample nodules both centrally and in the periphery of the lungs with very high yield. This may be coupled with endobronchial ultrasonography (EBUS) to allow for mediastinal staging in the same setting.

Mediastinal nodal involvement or direct extension into the mediastinum may be evaluated by bronchoscopy paired with endoscopic ultrasonography (EUS) or surgically by mediastinoscopy.

Surgical biopsies using a minimally invasive approach (video-assisted thoracoscopic surgery [VATS] or robot-assisted thoracoscopic surgery [RATS]) may be used as both diagnostic and therapeutic options. For patients presenting with a pleural or pericardial effusion, cytologic examination of the fluid may establish the diagnosis.

The tenets of biopsy are the same no matter which method is chosen: there should be adequate tissue for diagnosis, histologic subtyping, and molecular testing. If sufficient tissue is not obtained to further classify the subtype of lung cancer, additional procedures to obtain sufficient tissue are often warranted, particularly in patients with advanced-stage disease.

### Staging

The accurate staging of lung cancer is crucial in guiding treatment recommendations (Tables 3 and 4). Staging makes use of imaging modalities combined with biopsy to help determine the size, location, and histology of a lesion. A complete history and physical examination along with an assessment of performance status is important in evaluating a patient's ability to tolerate therapy (Figure 1).

### Imaging

CT scanning is a standard part of the workup for lung cancer and determining the candidacy for resection. Although excellent in delineating the extent of the primary lesion disease and some sites of metastatic disease, it is the least sensitive and specific modality for the identification of lymph node involvement or distant metastatic disease. CT scan of the chest should always be obtained with extension through the adrenal glands, a common site of metastatic disease.

Positron emission tomography (PET) plays an important role in both nodal and extrathoracic staging. PET attempts to identify sites of malignancy based on glucose metabolism by measuring the uptake of <sup>18</sup>F-fluorodeoxyglucose (FDG). Rapidly dividing cells will preferentially take up <sup>18</sup>F-FDG and appear as a "hot spot." Combined <sup>18</sup>F-FDG PET-CT imaging has been shown to improve the accuracy of staging in NSCLC compared with visual correlation of PET and CT on either study alone. A standardized uptake value (SUV) of >2.5 on PET is considered highly suspicious for malignancy. False negatives can be seen in diabetes, in lesions <8 mm, and in slow-growing tumors (e.g., carcinoid tumors or well-differentiated adenocarcinoma). Confirmation of PET scan abnormalities with tissue diagnosis remains important because this modality of imaging also carries the risk of false-positive upstaging, particularly in regions where histoplasmosis is prevalent.

Mediastinoscopy was once considered the gold standard diagnostic technique for the assessment of mediastinal lymph nodes. Mediastinoscopy can evaluate lymph node stations 2R, 4R, 2L, 4L, and 7, and it can uniquely resect whole lymph nodes to submit for

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** TNM Staging

PRIMARY TUMOR (T)		LYMPH NODES (N)		DISTANT METASTASIS (M)	
T0	No evidence of primary tumor	N0	No regional lymph nodes involved	M0	No distant metastases
Tis	Carcinoma in situ	N1	Ipsilateral lymph node peribronchial and/or ipsilateral hilar or intrapulmonary lymph nodes involved	M1	Distant metastases present
T1	Tumor $\leq 3$ cm, surrounded by lung or visceral pleura without bronchoscopic evidence of invasion more proximal than lobar bronchus	N2	Ipsilateral mediastinal or subcarinal lymph nodes involved	M1a	Separate tumor nodule(s) in contralateral lobe; pleural or pericardial nodule(s) or malignant pleural or pericardial effusion
T1a	Tumor $\leq 1$ cm	N3	Contralateral mediastinal or hilar lymph nodes or ipsilateral or contralateral scalene or supraclavicular lymph nodes involved	M1b	Single extrathoracic metastasis
T1b	Tumor $>1$ cm but $\leq 2$ cm			M1c	Multiple extrathoracic metastases in one or more organs
T1c	Tumor $>2$ cm but $\leq 3$ cm				
T2	Tumor $>3$ cm but $\leq 5$ cm or with any of the following: involves main bronchus but does not involve carina, invades visceral pleura, associated with atelectasis or obstructive pneumonitis				
T2a	Tumor $>3$ cm but $\leq 4$ cm				
T2b	Tumor $>4$ cm but $\leq 5$ cm				
T3	Tumor $>5$ cm but $\leq 7$ cm or with any of the following: separate tumor nodule(s) in same lobe as primary or directly invades				
T4	Tumors $>7$ cm in greatest dimension or any tumor that invades the mediastinum, diaphragm, heart, great vessels, recurrent laryngeal nerve, carina, trachea, esophagus, or spine or a separate tumor in a different lobe of the ipsilateral lung				

analysis. This has been replaced in many centers by EBUS, which is less invasive and offers the ability to ultrasonographically evaluate each lymph node and to sample N1, N2 and N3 nodes. A review of available publications reveals a median sensitivity of 89% for EBUS and a very low risk of complications. In addition, cytologic rapid on-site evaluation (ROSE) confirms the adequacy of samplings at the time of procedure to enhance overall yield.

Brain MRI with contrast is mandatory in all patients with SCLC. An MRI of the brain should also be performed in all NSCLC patients if the tumor is larger than 4 cm, lymph nodes are involved, or the patient has neurologic symptoms.

### Assessing Treatment Candidacy

After establishing the stage of cancer, a meticulous evaluation should be performed before recommending therapy (see [Figure 1](#)). Workup should include history and physical examination, blood work including a complete blood count, renal function and liver function tests, pulmonary function tests, nutritional assessments, and cardiac clearance in patients being selected for surgery. Assessment of a patient's performance status has important prognostic and therapeutic implications and should be noted in all patients.

In patients who are being considered for surgery, smokers should be counseled to stop immediately. In addition to helping reduce the

risk of perioperative pulmonary complications and death, it will also help reduce the long-term consequences related to tobacco use.

### Assessment of Cardiovascular Risk

Major cardiac-related adverse events occur in approximately 2% to 3% of patients after pulmonary resection. The Thoracic Revised Cardiac Risk Index is a validated tool that can be used to help guide which patients should be sent for additional preoperative consultation. Patients who score more than 1.5 on the cardiac risk index or those who describe limited exercise capacity or recent diagnosis of active heart disease all warrant evaluation by a cardiologist.

### Assessment of Pulmonary Function

Patients undergoing pulmonary resection commonly have several coexisting conditions and exposures that can affect pulmonary function. It is therefore essential to ensure adequate pulmonary reserve before proceeding with resection. Surgeons will request a spirometry and measurement of diffusing capacity of the lung for carbon monoxide (DLCO) for all patients undergoing pulmonary resection. These are calculated as a percentage of the predicted value. The forced expiratory volume in 1 second (FEV<sub>1</sub>),

measured during spirometry, determines the mechanical function of the lung, that is, the airflow limitations of medium to large airways. The DLCO value provides a gross estimate of the function at the alveolar-capillary membrane. The DLCO (the actual and predicted postoperative percentage) has been shown in various studies to be the most important predictor of perioperative complications and mortality.

A postoperative predicted FEV<sub>1</sub> or DLCO of less than 60% should prompt additional testing such as a shuttle walk test or stair-climbing exercise. If the postoperative predicted DLCO is less than 30% to 40%, this denotes an increased risk and warrants a formal cardiopulmonary exercise test with measurement of maximal oxygen consumption. This quantitative assessment has established thresholds associated with surgical risk. A ventilation-perfusion scan may also be helpful in patients with heterogeneous underlying lung disease.

**Surgical Approach to Lung Cancer**

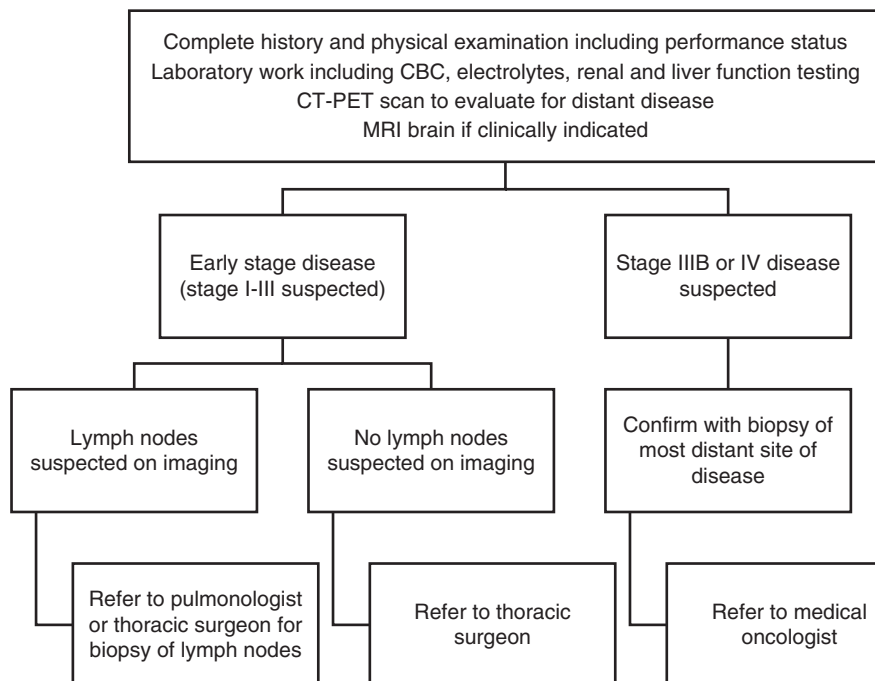

The approach to surgery and extent of pulmonary resection is determined by the size and location of the tumor and the experience of the surgeon.

**Open Lobectomy**

Many pulmonary resections continue to be performed in open fashion via thoracotomy with division of muscle and removal of a small segment of rib to allow for rib spreading.

Surgery is performed with a special endotracheal tube (a double-lumen tube) that allows the operative lung to be collapsed while maintaining ventilation to the contralateral lung. After thoracotomy, the chest is inspected to rule out metastatic disease and confirm that the tumor is resectable.

Surgery begins with the removal of N1 and N2 lymph nodes, which are sent to pathology. A lobectomy is performed by isolating the arteries, vein, and bronchus associated with the lobe and dividing each along with the fissure that connects the upper, middle (right), and lower lobes. Once the lobectomy is completed, the remaining lung is re-inflated to fill the pleural space, and chest

**Figure 1** Approach to diagnosis. CBC, Complete blood count; CT-PET, computed tomography/positron emission tomography; MRI, magnetic resonance imaging.

tubes are positioned to help drain fluid and air while the patient recovers.

Lung resections carry a significant risk of perioperative morbidity, with 37% of patients experiencing some form of postoperative complication. Atrial arrhythmia and prolonged air leak are the most common complications. Other complications include infection, bleeding, hypoxia, and death.

#### Video-Assisted Lobectomy

Technologic advancements including VATS and RATS have allowed most medical centers to transition to a minimally invasive approach for the majority of pulmonary resections.

VATS for lobectomy is conducted in a similar fashion to an open lobectomy but utilizes two to three small ports in the chest, each measuring approximately 1 cm, and a slightly larger utility incision measuring 3 cm through which the specimen is removed. VATS differs from open surgery in both the length of incisions as well as minimal disruption or division of muscle fibers, and there is no rib spreading. A camera and special instruments have been designed to make the surgery possible.

Comparison of outcomes shows that both open surgery and VATS provide equal cancer-specific outcomes. Both VATS and open surgery have similar patterns of postoperative complications, although at a lesser rate for minimally invasive approaches. Additional benefits of VATS include earlier recovery, earlier discharge, less pain, less impact on pulmonary function, better quality of life, and increased delivery of adjuvant therapy.

#### Robot-Assisted Lobectomy

Robot-assisted lobectomies were first performed in 2003, and the use of this technology has continued to increase with time. Much like VATS, a robotic lobectomy is performed through small incisions.

This newer technology has several advantages over traditional thoracoscopic surgery in that it provides a three-dimensional, high-definition visualization compared with only a two-dimensional

view in thoracoscopic surgery. In addition, the instruments have 9 degrees of freedom and include the ability to staple and seal vessels. Robotic surgery also boasts the same patient benefits as VATS.

#### Extent of Resection: Lobar vs. Sublobar Resection

Lobectomy has long been considered the standard of care and the optimal oncologic procedure for management of resectable lung cancer. More limited resections (including segmentectomy or wedge resection) were thought to be associated with a higher risk of recurrence and historically were reserved for patients with limited cardiopulmonary reserve.

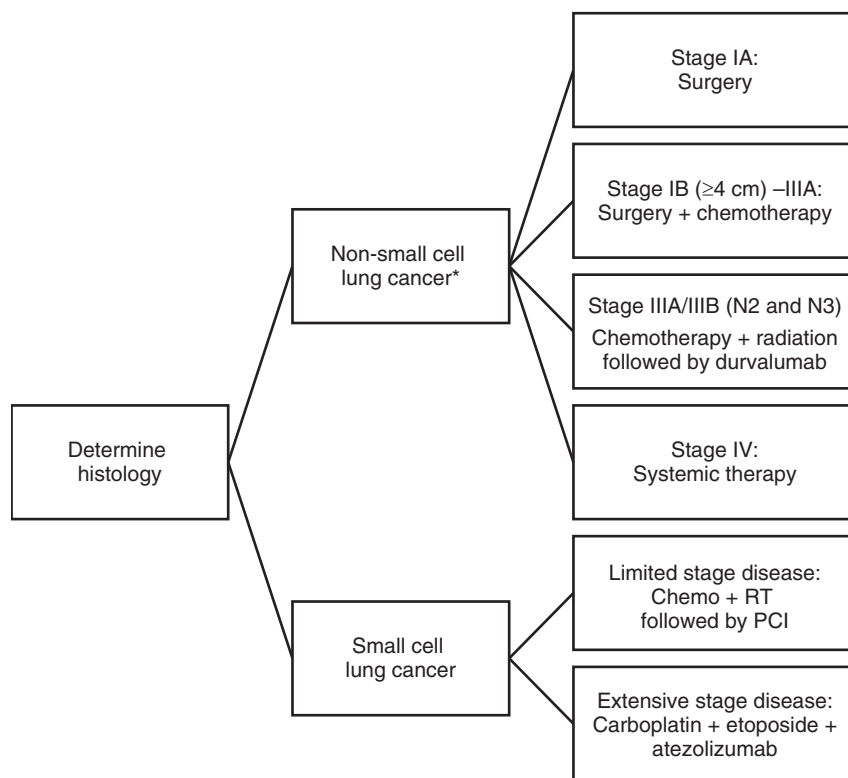

The advent of CT screening for lung cancer and improvements in imaging technology have led to the identification earlier-stage cancers (<2 cm), partially solid lesions, and completely ground-glass lesions. This has prompted a renewed interest in the possibility of more limited resection that preserves more pulmonary function and thereby a patient's ability to undergo subsequent resections if required.

The recommended extent of resection remains highly controversial. Investigators have not been able to definitively explain the ideal tumor size or histology for a sublobar resection. Detractors argue that most evidence supporting sublobar resections comes from single-institution, retrospective analysis with pooled histology and surgical technique (wedge or segmentectomy), resulting in confounded results that may not be broadly disseminated.

#### Treatment: Non–Small Cell Lung Cancer

##### Stage I and II Lung Cancer

Surgery is recommended as part of the treatment regimen for stage I, stage II, and some stage IIIA NSCLCs (Table 3; Figure 2). Stages I and II, based on the American Joint Committee on Cancer eighth edition staging system, includes tumors that are node negative and up to 7 cm in size, tumors that involve the chest wall, and pericardium or satellite nodules in the same lobe. Surgery is also performed for patients who have smaller

\* For patients with stage IV NSCLC knowledge of histologic subtype, PD-L1 and molecular testing are essential for selecting systemic therapy

**Figure 2** General treatment algorithm for lung cancer. NSCLC, Non–small cell lung cancer; PCI, prophylactic cranial irradiation; RT, radiation therapy.

tumors up to 5 cm or tumors involving the main bronchus and ipsilateral, hilar nodes.

Operative mortality rates for patients undergoing pulmonary resection are lower if the resection is performed by a surgeon who practices at a high-volume center (>70 procedures per year) or has had dedicated thoracic surgical training.

Comprehensive pathologic staging is just as important at the time of surgery as it is included in the workup. Lymph nodes should be sampled from N2 stations (on the right side, stations 4R, 7, and 9R; on the left side, stations 5, 6, 7, and 9L) and N1 stations (stations 10 to 14) at the time of surgery. There is notably a 6% to 8% rate of occult N2 disease discovered at the time of final pathology for patients with T1 tumors and negative preoperative assessments.

The Commission on Cancer 2020 Operative Standards were recently updated to reflect the new recommendations for extent of lymphadenectomy at the time of lung cancer resection. Each patient should have at least one separately submitted N1 or hilar lymph node as well as three distinct mediastinal lymph node (N2) stations submitted for pathologic assessment.

Patients with a primary tumor >4 cm or nodal involvement should be considered for neoadjuvant and/or adjuvant therapy. Studies have demonstrated that surgery can be performed safely with equivalent perioperative morbidity and mortality after neoadjuvant therapies.

Recently, the PDL-1 inhibitor nivolumab (OPDIVO) was approved by the FDA in combination with platinum doublet chemotherapy for the neoadjuvant treatment of patients with resectable stage IB to IIIA NSCLC based on the phase III Check-Mate-816 trial. Patients were treated in the neoadjuvant setting with nivolumab (OPDIVO) in addition to chemotherapy or with chemotherapy alone, which resulted in an event-free survival of 31.6 months and 20.8 months, respectively. This resulted in a 37% reduction in the risk of disease recurrence, disease progression, or death by 37% in this patient population.

The role of neoadjuvant chemotherapy in these patients remains unclear; however, adjuvant chemotherapy is recommended for patients with tumors that are determined on final pathology to be >4 cm or in patients with lymph node involvement. The benefit of adjuvant chemotherapy was firmly established in 2008 by a landmark meta-analysis (the Lung Adjuvant Cisplatin Evaluation Study [LACE]) that demonstrated a 5.4% improvement in 5-year survival for patients treated with surgery followed by adjuvant chemotherapy compared with surgery alone.

The benefit was primarily confined to patients with stage II or IIIA disease, with only a modest benefit in patients with tumors <4 cm. In 2011, the NSCLC Collaborative Group compiled a postoperative chemotherapy meta-analysis and reported a similar survival benefit in patients with stage II disease. There is no role for adjuvant chemotherapy in patients with stage IA NSCLC.

The optimal platinum-based chemotherapy regimen remains a topic of debate. Although the aforementioned trials employed different platinum doublets, cisplatin (Platinol)<sup>1</sup> and vinorelbine (Navelbine) was one of the most common regimens adopted. The E1505 trial assessed the addition of bevacizumab (Avastin) to cisplatin-based chemotherapy. Although this trial demonstrated no benefit in overall survival, a post hoc analysis compared the different platinum doublet regimens (pemetrexed [Alimta], gemcitabine [Gemzar], docetaxel [Taxotere], and vinorelbine) and found no difference in either overall survival or disease-free survival, but noted that cisplatin plus pemetrexed was associated with improved tolerance and was preferred among physicians for patients with non-squamous NSCLC.

If a decision is made to proceed with adjuvant chemotherapy, treatment should be started within 6 to 12 weeks after surgery, assuming that the patient has fully recovered, and should be administered for no more than four cycles. Although cisplatin-based chemotherapy is the preferred treatment regimen, carboplatin (Paraplatin)<sup>1</sup> can be substituted for cisplatin in patients who are unlikely to tolerate cisplatin for reasons such as reduced renal function, presence of neuropathy, or hearing impairment.

The use of PDL-1 inhibitors in the adjuvant setting has also been studied recently, and atezolizumab (Tecentriq) has FDA approval for this indication in patients who have resected NSCLC with PDL-1  $\geq 1\%$ . The IMpower010 was a phase III trial that evaluated the addition of atezolizumab (Tecentriq) treatment for 1 year compared with basic supportive care in patients with stage II to IIIA NSCLC following resection and platinum-based chemotherapy. Median disease-free survival was not reached in the atezolizumab (Tecentriq) arm compared with 35.3 months in the basic supportive care arm. However, it is unclear if the addition of immunotherapy in the adjuvant setting is safer or more effective than when used in the neoadjuvant setting.

Targeted therapy is now being used in the adjuvant setting in select patient populations. Patients with stage IB to IIIA NSCLC who have undergone resection and whose tumors harbor an *EGFR* mutation can now receive osimertinib (Tagrisso) in the adjuvant setting. In a phase III trial, patients received adjuvant osimertinib (Tagrisso) for up to 3 years or placebo with the primary outcome of disease-free survival in patients with stage II to IIIA NSCLC post-resection. Of note, in this study, patients could receive adjuvant chemotherapy but were not required to. At 24 months, 90% of patients in the osimertinib (Tagrisso) arm were alive and disease free compared with 44% in the placebo group. Overall survival data are immature and have not been reported.

Postoperative radiation is usually reserved for patients in whom there is a concern for residual disease (e.g., patients with positive margins on final pathology). In patients with stage I and II disease who either refuse or are not suitable candidates for surgery, stereotactic body radiation therapy (SBRT) is a treatment option for patients with tumors that are  $\leq 5$  cm. Treatment is typically administered in three to five fractions delivered over 1 to 2 weeks and is associated with a disease-control rate of approximately 90% and 5-year survival rates of up to 60%. Cryoablation is another technique occasionally used to treat small, isolated tumors (i.e.,  $\leq 3$  cm). However, very little data exist on long-term outcomes with this technique.

### Locally Advanced Lung Cancer

The treatment of locally advanced lung cancer is complex and requires a multidisciplinary approach. More treatment regimens are incorporating immune checkpoint inhibitors and targeted therapies to enhance progression-free and overall survival.

#### T3N1 Tumors

T3N1 is a relatively infrequent stage of lung cancer, but surgery has a well-defined role as the primary treatment for these tumors. T3 lung cancers range in size from 5 to 7 cm or invade structures that can be routinely taken en bloc with the lung: the chest wall, pericardium, or a single phrenic nerve. Often, hilar nodal involvement is discovered at the time of resection. The surgical goal is an en bloc resection with microscopically negative margins.

Surgical resection should be preceded with neoadjuvant therapy or followed by adjuvant systemic therapy as described previously. If a complete resection is not technically feasible then concurrent chemoradiotherapy is recommended as described in the following section.

#### Stage IIIA Tumors

This is a heterogeneous group that comprises patients with (1) small tumors (T1 to T2) with ipsilateral mediastinal lymph node involvement (N2); (2) large tumors (T3 to T4) with ipsilateral lymph node involvement (N1); and (3) large tumors (T4) without lymph node involvement (N0). In the following sections, we will discuss some of the nuances in the subcategories of this complex group of tumors: N2 disease, T4 tumors, and superior sulcus tumors.

#### N2 Disease

The optimal management of N2 disease is perhaps the most challenging and controversial area in thoracic oncology. Tumor characteristics and nodal burden of disease as well as performance

status play an important role in determining who should be considered for surgery. Patients with clinical stage I or II disease who are discovered to have N2-positive nodes at the time of resection should undergo lobectomy with mediastinal lymphadenectomy and then be referred for adjuvant chemotherapy as described previously. In most cases, pathologic involvement of mediastinal lymph nodes is documented preoperatively, and a multimodal approach is recommended because these patients are at high risk for local and distance recurrence.

In patients who are deemed surgically resectable, the optimal combination and order of treatments remains debated. Some centers favor neoadjuvant chemotherapy, and others favor neoadjuvant chemoradiotherapy (6000 cGY).

The Intergroup 0139 study sought to help define the roles of therapy for N2 disease. The trial found no definitive survival benefit with surgery after neoadjuvant chemoradiotherapy compared with definitive chemoradiotherapy alone. The study outcomes were confounded by a very high mortality rate in patients undergoing pneumonectomy, which likely affected this outcome. Subgroup analysis did show a trend toward survival benefit in patients undergoing lobectomy as a part of trimodal treatment.

More contemporary studies (mostly single institution) have demonstrated significantly higher median survival and freedom from recurrence compared with the INT0139 trial for trimodal therapy. Vyfhuis et al. achieved a median survival of 60 months with trimodal therapy compared with a 20-month survival for bimodality (chemotherapy and radiation) in surgically resectable patients.

Concurrent chemoradiotherapy with cisplatin<sup>1</sup> and etoposide (Toposar)<sup>1</sup> is the preferred therapeutic combination, although carboplatin (Paraplatin)<sup>1</sup> and paclitaxel (Taxol) is often substituted for patients who cannot tolerate cisplatin-based chemotherapy for reasons stated previously.

A recent randomized, placebo-controlled, phase III trial demonstrated a significant improvement in progression-free survival and overall survival in patients treated with concurrent chemoradiotherapy followed by 1 year of therapy with the immune checkpoint inhibitor durvalumab (Imfinzi) compared with placebo. This trial has established this as a new standard of care for patients with locally advanced, unresectable disease. There is no role for durvalumab in patients treated with trimodal therapy.

Esophagitis and pneumonitis are the two most common toxicities associated with concurrent chemoradiotherapy.

#### T4 Tumors

T4 tumors are locally aggressive with invasion of critical mediastinal structures such as the pulmonary artery, heart, aorta, superior vena cava (SVC), trachea, esophagus, spine, or diaphragm. Surgery can be considered as part of a multimodal therapy plan in high-volume centers with dedicated thoracic surgeons. Meticulous preoperative planning and in some cases a multidisciplinary surgical approach is necessary to ensure complete resection.

#### Superior Sulcus Tumors

Superior sulcus tumors, also known as *Pancoast tumors*, arise from the apical segment of the right upper or left upper lobe. These tumors may invade any of the structures in the apex of the chest: brachial plexus, subclavian artery, subclavian vein, musculature, ribs, paravertebral sympathetic chain, or spinal nerve roots. Patients may present with shoulder pain, Horner syndrome, or neurologic complications of the upper extremity.

As with other locally advanced tumors, a multidisciplinary approach is the mainstay of management of superior sulcus tumors. Complete staging is important to help determine resectability. MRI is often used in conjunction with other imaging modalities to better assess chest wall invasion and neurologic involvement.

Treatment with neoadjuvant chemoradiotherapy followed by surgery results in superior survival for patients with N0 or N1 disease. Surgery is generally completed 3 to 5 weeks after completion of chemoradiotherapy and involves en bloc resection of the tumor, chest wall, and any other involved structures with subsequent reconstruction.

Patients with unresectable disease (medical inoperability, positive mediastinal nodes) should be offered concurrent chemoradiotherapy followed by durvalumab consolidation as described previously.

#### Stage IIIB

Stage IIIB includes any tumors with contralateral mediastinal nodal involvement or large tumors (>5 cm) with ipsilateral mediastinal nodal involvement. These tumors are considered inoperable because surgery has not been shown to confer any survival benefit. These patients should be treated with concurrent chemoradiotherapy followed by durvalumab.

#### Stage IV

Approximately 40% of patients present with stage IV disease at the time of diagnosis. Moreover, a significant proportion of patients who present with early-stage NSCLC will relapse despite initial curative-intent therapy. Systemic therapy depends on a patient's performance status, histology, and PD-L1 and molecular status. Of note, the early application of palliative care in conjunction with chemotherapy is associated with improved survival and a better quality of life.

#### Chemotherapy

Chemotherapy has been an important therapeutic option for decades in the treatment of patients with stage IV NSCLC. A landmark meta-analysis in 1995 established cisplatin-based regimens as the standard of care and conferred a survival benefit in patients with stage IV disease.

Treatment recommendations have continued to evolve over the years. Histology of the NSCLC has come to be very important in treatment consideration; phase III trials have demonstrated cisplatin<sup>1</sup> and pemetrexed to be superior to cisplatin<sup>1</sup> and gemcitabine (Gemzar) in patients with non-squamous NSCLC, while cisplatin and gemcitabine was superior in patients with squamous cell histology. This survival difference is thought to be related to the differential expression of thymidylate synthase (TS), one of the targets of pemetrexed, among tumor subtypes. Importantly, bevacizumab (Avastin), a monoclonal antibody that targets VEGF, was also established as unsafe to administer in patients with squamous NSCLC and is FDA approved in combination with carboplatin and paclitaxel as a first-line option only in non-squamous NSCLC patients.

#### Immunotherapy

Immune checkpoint inhibitors have increasingly become part of the first-line treatment paradigm in patients with metastatic NSCLC and no driver mutations. Checkpoint inhibitors exert antitumor effects by inhibiting negative T-cell regulators. Regardless of histology, all patients with advanced-stage lung cancer should undergo PD-L1 testing before embarking on therapy. A phase III trial demonstrated a superior response rate and progression-free and overall survival rates when pembrolizumab (Keytruda) was compared with platinum-based chemotherapy in patients with tumors that were PD-L1  $\geq 50\%$  and *EGFR* and *ALK* wild type. Similar results were also seen in a phase III trial comparing nivolumab (OPDIVO) plus ipilimumab (Yervoy) with platinum based chemotherapy. More recently, combination therapy with platinum-pemetrexed (Alimta) and pembrolizumab in non-squamous NSCLC and platinum-taxane (paclitaxel [Taxol] or nab-paclitaxel [Abraxane]) and pembrolizumab in squamous cell lung cancer was found to be superior to chemotherapy alone

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

regardless of the patient's PD-L1 status. Likewise, this was also seen with combination therapy including nivolumab (OPDIVO) plus ipilimumab (Yervoy) plus histology-appropriate platinum-based doublet chemotherapy. However, the additive benefit of chemotherapy to patients with tumors that are PD-L1  $\geq 50\%$  to pembrolizumab alone remains unclear beyond a small subset of analyses from the aforementioned trials. Combination chemotherapy with carboplatin (Paraplatin),<sup>1</sup> paclitaxel, bevacizumab (Avastin), and atezolizumab (Tecentriq) has also been shown to be superior to carboplatin, paclitaxel, and bevacizumab in patients regardless of PD-L1 status and is also FDA approved as a first-line treatment option for non-squamous NSCLC (Figure 3). Numerous other trials are currently ongoing to evaluate the use of immunotherapy in NSCLC, both alone and in combination with other immunologic agents, chemotherapy, targeted therapy, and radiotherapy.

### Targeted Therapy

Driver mutations have been detected in 50% of non-squamous NSCLCs including *KRAS*, *EGFR*, *ALK*, *BRAF*, *HER2*, *ROS1*, *RET*, *PIK3CA*, *MET*, *NRAS*, *MEK1*, *AKT1*, *FGFR1*, *DDR2*, and *NTRK*. Targeted therapy has FDA approval for patients with *EGFR* mutations, *ALK* rearrangements, *ROS1* rearrangements, *NTRK1* rearrangements, *BRAF* mutations, *KRAS* mutations, *RET* rearrangements, and *MET* exon 14 skipping mutations. In patients who harbor a mutation and are also strongly PD-L1 positive, the presence of the mutation should drive selection of therapy (Figure 4).

*EGFR* mutations have been reported in approximately 15% of North American patients with metastatic non-squamous NSCLC, of which 90% are exon 19 deletions or exon 21 L858R point mutations. First- and second-generation *EGFR* tyrosine kinase inhibitors (TKIs) erlotinib (Tarceva), gefitinib (Iressa), and afatinib (Gilotrif) are approved as first-line therapy based on clinical trials demonstrating superior response rates, progression-free survival, and overall survival compared with chemotherapy in treatment-naïve patients with *EGFR* mutation-positive NSCLC. Despite the observed survival benefits, a majority of patients eventually develop therapeutic resistance. Furthermore, approximately 50% of patients who develop acquired resistance to *EGFR* TKI therapy acquire a second site mutation occurring within

exon 20 (i.e., T790M). Consequently, osimertinib (Tagrisso), a third-generation mutant-specific *EGFR* inhibitor that irreversibly binds to the kinase domain of *EGFR*, was recently approved for patients with T790M mutations who have acquired resistance to first- and second-generation *EGFR* inhibitors. Osimertinib was also demonstrated in the FLAURA trial to have improved progression-free survival compared with the first-generation inhibitors erlotinib and gefitinib in patients with treatment-naïve *EGFR* mutation-positive NSCLC, establishing osimertinib as the preferred first-line option for this cohort of patients.

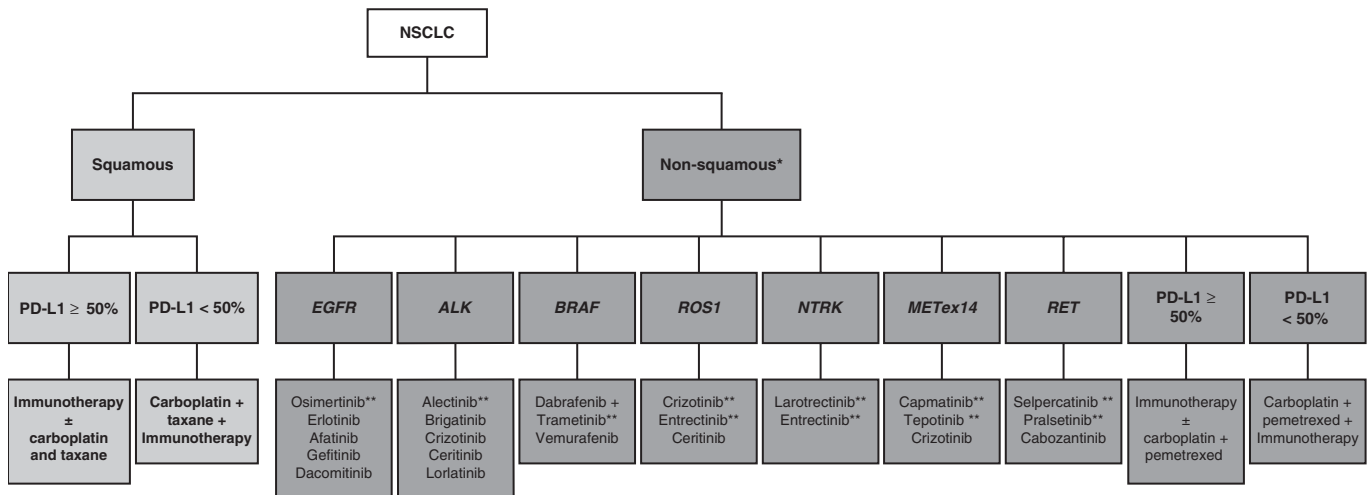

*ALK*-positive NSCLC accounts for approximately 3% to 7% of patients diagnosed with NSCLC. Crizotinib (Xalkori) was the initial *ALK* TKI to gain accelerated approval by the FDA in 2011 after two open-label, randomized phase III trials demonstrated improved progression-free survival with crizotinib compared with chemotherapy in both first- and second-line settings. Ceritinib (Zykadia) is also approved as a first-line therapy option, demonstrating superior progression-free survival compared with chemotherapy in patients with *ALK*-positive NSCLC. More recently, alectinib (Alecensa) and brigatinib (Alunbrig) demonstrated superior progression-free survival and central nervous system control compared with crizotinib (Xalkori) in patients with *ALK*-positive NSCLC, with alectinib (Alecensa) receiving FDA approval and considered the preferred option as first-line therapy for *ALK*-positive NSCLC. Lorlatinib (Lorbrena) is also approved in patients who have progressed on a prior *ALK* inhibitor and is particularly effective in patients who develop a G1202R mutation as a mechanism of resistance to *ALK* inhibitor therapy.

*ROS1* rearrangements occur in approximately 1% to 2% of NSCLC. Crizotinib (Xalkoro) and entrectinib (Rozlytrek) are the preferred first-line therapy for patients with *ROS1*-positive NSCLC. Ceritinib (Zykadia)<sup>1</sup> and lorlatinib (Lorbrena)<sup>1</sup> have also been shown to be active in this cohort of patients.

*BRAF* mutations occur in approximately 2% to 3% of NSCLC patients, and more than 50% of these are *BRAF* V600E mutations. Dabrafenib (Tafinlar) and vemurafenib (Zelboraf)<sup>1</sup> have demonstrated promising results in phase II trials. Dabrafenib in combination with the MEK inhibitor trametinib (Mekinist) had response rates of more than 60% and progression-free survival of 9 months, establishing this combination as the preferred treatment option for patients with *BRAF* V600E-positive NSCLC.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

\*All patients with non-squamous NSCLC should undergo molecular testing. In patients with a driver mutation who are also PD-L1 positive, the driver mutations is more important and first line therapy should be a TKI  
 \*\* NCCN preferred

**Figure 4** Treatment algorithm for metastatic non-small cell lung cancer.

*NTRK* rearrangements have been reported in 1% of patients with NSCLC. Recently larotrectinib (Vitrakvi) received FDA approval for *NTRK*-positive tumors based on a phase II trial that enrolled patients with *NTRK*-positive tumors regardless of tumor type.

Around 4% of patients with NSCLC have tumors that harbor a *MET* exon 14 skipping mutation. Tepotinib (Tepmetko) and capmatinib (Tabrecta) both received FDA approval based on phase II studies showing response rates of over 40% in these patients. Peripheral edema was the most common adverse event for both agents. Crizotinib (Xalkori)<sup>1</sup> has also shown benefit in this patient population; however, it does not have CNS penetration compared with the newer *MET* inhibitors.

Two agents, selpercatinib (Retevmo) and pralsetinib (Gavreto), have received FDA approval for patients with NSCLC with *RET* translocations. *RET* translocations occur in up to 2% of patients with NSCLC. Approval for these agents was based on phase III trials that showed response rates of over 60%. The most common adverse events in both trials were hypertension and myelosuppression. Although, interstitial lung disease can occur with both agents, there is a greater risk with pralsetinib (Gavreto) compared with selpercatinib (Retevmo). Of note, these agents also target VEGF and can cause delayed wound healing, so they should be held in patients undergoing surgical procedures.

### Second-Line Therapy and Beyond

Second-line therapy for advanced NSCLC was almost never recommended until a seminal study in 2000 showed that docetaxel (Taxotere) improved survival compared with supportive care alone. Over a decade later, docetaxel and ramucirumab (Cyramza) received FDA approval after a phase III trial found the combination to impart a modest improvement in response rate, overall survival, and progression-free survival compared with docetaxel alone. More recently, nivolumab (OPDIVO) and atezolizumab (Tecentriq) received FDA approval in patients who progress on platinum-based chemotherapy, while pembrolizumab (Keytruda) is also approved in patients with tumors that are PD-L1  $\geq 1\%$ . It should be noted that patients who progress on a first-line TKI or pembrolizumab should be considered for a platinum-based doublet as their second-line therapy, not single-agent docetaxel or docetaxel plus ramucirumab.

<sup>1</sup>Not FDA approved for this indication.

Traditionally, patients with *EGFR* exon 20 insertion mutations have not had an option for targeted therapy because of the inherent resistance of *EGFR* exon 20 insertion mutations to traditional *EGFR* inhibitors. Amivantamab (Rybrevant) is a bispecific *EGFR*-*MET* antibody that engages both *EGFR* and *MET* pathways. This is approved in patients with *EGFR* exon 20 insertion mutations in the second-line setting based on a phase I trial that showed a response rate of 40%. Amivantamab (Rybrevant) was well tolerated with the most common adverse events being infusion-related reactions and paronychia. Incidence of infusion related reactions was 65% on cycle 1 day 1 but decreased to 3.4% on cycle 1 day 2 and then 0.4% with the week 2 infusion. Mobocertinib (Exkivity) is a TKI and is also approved in these patients after progression on platinum-based therapy. This approval was based on a phase III trial that showed a median duration of response of 17.5 months. Adverse events were mild in nature and most commonly were gastrointestinal or cutaneous in nature. Future studies are needed to see if these agents will have benefit in the first-line setting for patients with NSCLC that harbors an *EGFR* exon 20 insertion mutation.

The *KRAS* mutation, which occurs in 15% to 25% of patients, has long been an undruggable target in NSCLC. However, sotorasib (Lumakras) is a GTPase inhibitor that is now approved in NSCLC patients with *KRAS* G12C mutations who have progressed on platinum-based therapy. Approval was based on a phase II trial showing benefit in these patients. Treatment was well tolerated, and the most common adverse events were nausea, fatigue, and increased liver enzymes. Sotorasib (Lumakras) cannot be used in patients with other *KRAS* mutations. Studies of other *KRAS* inhibitors are ongoing for patients with non-G12C mutations. The role of sotorasib (Lumakras) in patients with NSCLC with *KRAS* G12C mutations in the first-line setting is currently unknown.

### Oligometastatic Disease

The concept of oligometastatic disease (single-site metastatic disease) was first proposed in 1995. Studies at this time described patients with disease in the adrenal gland or brain as actually having a relatively favorable prognosis. For these lesions, the standard of care includes surgical resection of both the primary tumor and the metastasis if they present synchronously (metachronous disease) or resection of the recurrence. Generally, when the primary tumor and metastatic disease are identified at the same time, the metastatic site is treated first. If this cannot be successfully addressed, there is no benefit to resecting the primary tumor.

## Treatment Small Cell Lung Cancer

SCLC, which accounts for 15% to 20% of new lung cancer cases, is an aggressive disease characterized by rapid growth and early widespread metastasis. The primary etiologic agent responsible for SCLC is tobacco smoke. The aggressive nature of SCLC is underscored by its high mutational burden, including loss of expression of the tumor suppressor genes *p53* in 70% to 80% and retinoblastoma in almost 100% of tumors. Although there is a shift in recommendations for the staging of SCLC, most patients are still diagnosed using the traditional staging system of limited-stage disease (LD) and extensive-stage disease (ED). At the time of diagnosis, approximately 30% of patients have *limited-stage disease* (LD-SCLC), defined as tumors confined to the hemithorax that can be encompassed in a tolerable radiation port, while about 70% of patients have *extensive-stage disease* (ED-SCLC), defined as the presence of overt metastatic disease by imaging or physical examination. Regardless of stage at diagnosis, the majority of patients relapse and develop chemotherapy-resistant disease, with a median survival of 12 to 20 months for patients with LD and 7 to 11 months for patients with ED; only 6% to 12% of patients with LD-SCLC and 2% of patients with ED-SCLC live beyond 5 years. For decades, first-line therapy consisted of four to six cycles of platinum-based chemotherapy with either cisplatin<sup>1</sup> or carboplatin<sup>1</sup> plus either etoposide (Toposar) or irinotecan (Camptosar)<sup>1</sup> followed by observation. A recent phase III trial in patients with advanced-stage disease demonstrated superior survival when atezolizumab (Tecentriq) was combined with carboplatin and etoposide for four cycles followed by maintenance atezolizumab compared with carboplatin and etoposide alone, making combination chemotherapy with a checkpoint inhibitor a new treatment option for patients with this disease. Similar results were seen with durvalumab (Imfinzi) in combination with a platinum agent and etoposide and is another option for patients in the first-line setting.

Although up to 80% of patients will respond to first-line chemotherapy, the majority will eventually relapse. Topotecan (Hycamtin) and lurbinectedin (Zepzelca) are the only agents approved for second-line therapy. Additionally, patients who relapse >6 months after first-line therapy can repeat their original platinum-based treatment. Nivolumab (Opdivo)<sup>1</sup> or pembrolizumab (Keytruda)<sup>1</sup> can be used in the third-line setting, but only in patients who have not received an immune checkpoint inhibitor in the first-line setting.

Radiation therapy is also an important component in the therapeutic armamentarium for patients with SCLC. Patients with LD are generally treated with concurrent chemoradiotherapy with four cycles of chemotherapy and radiation added to either cycle one or cycle two of therapy. For patients who are not candidates for concurrent chemoradiotherapy, sequential therapy can also be considered with radiation after chemotherapy. Prophylactic cranial irradiation (PCI) should be considered in patients who have responded well to initial therapy. In patients with ED, thoracic radiation can be considered, although it has not been shown to improve overall survival. Similarly, a large phase III trial in patients without brain metastases following chemotherapy demonstrated no improvement in overall survival for patients treated with PCI compared with observation. Long-term toxicities, including deficits in cognition, have been reported after PCI, and for many patients observation with an MRI every 3 months has been adopted as the standard of care.

Surgery has for many decades played a very limited role in the treatment of SCLC because of its propensity to metastasize. The pendulum is beginning to shift for early-stage, node-negative SCLC. More contemporary studies have demonstrated that surgery may play a beneficial role in a select group of patients.

Invasive mediastinal staging should be performed for patients without evidence of metastatic disease. In node-negative patients with T1 and T2 tumors, a lobectomy followed by adjuvant

chemotherapy should be offered to medically fit patients. The 5-year survival rate in this group of patients is 40% to 50%.

## Monitoring

Routine disease monitoring is important both after curative treatment and during treatment for incurable disease.

## Non-Small Cell Lung Cancer

The National Comprehensive Cancer Network (NCCN) guidelines have clear recommendations for the follow-up of NSCLC and SCLC divided by stage, and these are summarized here.

After completion of curative therapy for stages I and II, a history and physical examination along with a chest CT (+/-) with contrast every 6 months for the first 2 to 3 years should be performed. If after 2 to -3 years there are no findings that would require alternative monitoring, the patient can be transitioned to annual history, physical examination, and noncontrast LDCT scan of the chest.

Patients with stages I and II who were treated with radiation rather than surgery should be followed by a slightly more aggressive regimen. Patients should have a history and physical examination along with a chest CT (+/-) with contrast every 3 to 6 months for the first 3 years, and then every 6 months for the next 2 years. At that time, if there are no findings that would require alternative monitoring, the patient can be transitioned to annual history, physical examination, and a noncontrast LDCT scan of the chest.

Patients with stages III and IV oligometastatic disease should likewise be followed with a history and physical examination along with a chest CT (+/-) with contrast every 3 to 6 months for the first 3 years, and then every 6 months for the next 2 years. If there are no findings that would require alternative monitoring, the patient can be transitioned to annual history, physical examination, and a noncontrast LDCT scan of the chest.

Any residual or new radiographic abnormalities will require consideration of more frequent imaging. Please note that PET-CT and brain MRI are not routinely indicated as part of surveillance; however, they should be tailored to each patient and their primary sites of disease.

Symptoms of shortness of breath, cough, wheezing, new bone pain, headache, or constitutional symptoms should prompt immediate evaluation with imaging to rule out disease recurrence, and the patient's primary oncologist should be contacted.

While patients are being treated with palliative systemic therapy, scans are routinely obtained every 6 to 8 weeks while on chemotherapy or every 8 to 9 weeks while on immunotherapy.

## Small Cell Lung Cancer

SCLC has a distinct follow-up recommendation. Patients who were diagnosed and treated for limited-stage disease should have follow-up with a history and physical examination along with CT scan of the chest/abdomen every 3 months for the first year and every 6 months for the subsequent 2 years. At that time, patients may transition to annual examinations and imaging. MRI scans of the brain are essential as well and are recommended every 3 to 4 months for the first year and every 6 months for the second year.

Patients with extensive-stage disease will require more frequent follow-up examinations. A history and physical examination with CT scans of the chest/abdomen should occur every 2 months for the first year, every 3 to 4 months for the second and third years, every 6 months for the fourth and fifth years, and then annually. Monitoring of the brain is the same as for limited-stage disease, with MRI of the brain recommended every 3 to 4 months for the first year and every 6 months for the second year.

Any patient, regardless of type of cancer, should have a survivorship plan created as part of their follow-up. These plans apply to survivors across the continuum of care. This comprehensive, individualized plan includes the aforementioned cancer-specific follow-up but also highlights important nutritional considerations, physical activity, and immunizations. Patients should be encouraged

<sup>1</sup>Not FDA approved for this indication.

to continue routine screening for other malignancies and routine health maintenance. Ongoing smoking cessation should be encouraged.

## Summary

The treatment of cancers is rapidly changing with the advent of immunotherapy, targeted therapy, localized radiation treatments, and minimally invasive surgical approaches. The intricacies of treatment, now more than ever before, demand a multidisciplinary approach to ensure that patients are provided with the best possible care to optimize both their quantity and quality of life.

## OBSTRUCTIVE SLEEP APNEA

Method of

Omar G. Ahmed, MD; and Masayoshi Takashima, MD

## CURRENT DIAGNOSIS

### Symptoms

- Excessive daytime fatigue and somnolence
- Morning headaches
- Loud snoring and gasping for air
- Witnessed apneic episodes following loud snoring
- Frequent nocturia with no other underlying etiology
- Hypertension

### Clinical Signs and Risk Factors

- Central obesity with body mass index (BMI)  $>30$  kg/m<sup>2</sup>
- Large neck circumference ( $>17$  inches in men;  $>16$  inches in women)
- Being male or a postmenopausal female
- Use of sedatives or alcohol before going to bed
- Family history of sleep apnea
- Craniofacial abnormalities: retrognathia, micrognathia, congenital malformations

## CURRENT THERAPY

- Gold standard for treatment is positive airway pressure
- Weight loss, smoking cessation, avoidance of sedatives
- Improvement of sleep hygiene and sleep schedule
- Minimally invasive procedures (i.e., oral appliances, palatal stents, radiofrequency turbinate reductions) may be beneficial for a select patient population
- Surgical therapy is usually reserved for patients not tolerating or unable to use CPAP or BiPAP
- Implants for muscle stimulation
- Initial procedures are focused on decreasing upper airway resistance to improve compliance with CPAP or BiPAP
- Identification of anatomic sites of obstruction is critical to successful surgical outcomes

BiPAP, Bilevel positive airway pressure; CPAP, continuous positive airway pressure.

Sleep-disordered breathing encompasses the spectrum from upper airway resistance syndrome to obstructive sleep apnea (OSA). OSA is characterized by episodes of partial or complete upper airway collapse leading to cessation or reduction of airflow. Such events lead to oxygen desaturation and sleep fragmentation, causing excessive daytime sleepiness, morning headaches, depression, memory loss, impaired alertness, decreased libido, and reduced cognitive function. Nighttime symptoms are often more telling, and obtaining a sleep history from a bed partner is exceptionally helpful. The most common symptoms include loud snoring, restless sleep, choking or gasping episodes, and frequent awakening from sleep. Nocturnal perspiration, nocturia, and symptoms of nocturnal gastroesophageal reflux are also commonly associated with severe OSA.

As the severity of OSA typically increases with age, nightly hypoventilation and activation of the sympathetic nervous system lead to pathophysiologic derangements, such as hypertension, ischemic heart disease, myocardial infarction, stroke, arrhythmia, and premature death. An apnea-hypopnea index (AHI) of greater than 5 has been shown to be associated with increased risk of cerebrovascular accident. An AHI greater than 20 is associated with increased mortality. Patients with oxygen desaturation below 90% have an elevated incidence of cardiac arrhythmia. These potentially severe consequences, along with a patient's decreased quality of life, substantiate the need for early recognition and treatment.

Definitions of terms related to sleep apnea are listed in Box 1.

## Epidemiology

On the basis of available population-based studies, the prevalence of OSA among adults between 30 and 60 years of age is estimated to be 6% for women and 13% for men. This represents relative increases over the last two decades of 14% to 55% among subgroups divided by age, gender, and body mass index (BMI). OSA remains undiagnosed in 70% to 80% of patients because their symptoms are often vague, and OSA must be diagnosed with polysomnography.

## Risk Factors

When controlling for gender and BMI, patients over age 50 have an increased prevalence of OSA secondary to decreased muscle tone.

Obesity (BMI  $>30$  kg/m<sup>2</sup>) is a risk factor for OSA. A 10% increase in weight is associated with a sixfold increase in risk for development of OSA, and a 10% weight loss is associated with a 26% decrease in AHI. Patients undergoing bariatric surgery on average have postsurgical reductions in AHI of 29 events per hour. There is evidence of a potential link between OSA and insulin resistance.

## BOX 1 Definitions of Sleep Medicine Terms

- Apnea-hypopnea index (AHI): Sum of apneas and hypopneas per hour of sleep.
- Obstructive apnea: Cessation of airflow for  $\geq 10$  s associated with ongoing ventilatory effort.
- Obstructive hypopnea: (1) Decreased airflow by  $\geq 30\%$  which is  $\geq 10$  s and a  $\geq 3\%$  oxygen desaturation and/or associated with an arousal. (2) Decreased airflow  $\geq 30\%$  which is  $\geq 10$  s which is associated with a  $\geq 4\%$  oxygen desaturation
- Obstructive sleep apnea (OSA): AHI  $> 5$  events per hour of sleep, often associated with oxygen desaturation  $< 90\%$ . Mild OSA is defined by an AHI of 5–15. Moderate OSA is an AHI 15–30, and severe OSA is an AHI  $> 30$ .
- Obstructive sleep apnea syndrome: OSA in association with daytime symptoms of excessive sleepiness or other neurobehavioral symptoms.
- Primary snoring: Snoring with an AHI  $< 5$  and no complaints of excessive daytime sleepiness.
- Respiratory effort–related arousals: Sleep fragmentation that is caused by arousals from increasing respiratory effort but that does not meet criteria for an apnea or hypopnea. The event lasts longer than 10 s.
- Respiratory disturbance index: Sum of apneas, hypopneas, and respiratory effort–related arousals per hour of sleep.
- Upper airway resistance syndrome (UARS): Snoring in association with AHI  $< 5$ , frequent arousals, and abnormally negative midsophageal pressure ( $< -10$  cm H<sub>2</sub>O) or increased diaphragmatic electromyogram activity.

Approximately 30% of hypertensive persons have OSA and up to 50% of OSA patients have hypertension. Resistant hypertension, which is defined as blood pressure greater than 140/90 mmHg despite therapy with at least three different anti-hypertensive classes, is especially prevalent in the OSA population. It is estimated that 90% of male patients and 77% of female patients with resistant hypertension have OSA. A dose-effect relationship between OSA severity and severity of hypertension has been established. Mechanisms for hypertension center around hypoxemia and hypercapnia leading to increased oxidative stress, decreased nitric oxide secretion, and increased catecholamine, angiotensin II, aldosterone, renin, and endothelin-1 secretion.

Male patients are nearly twice as likely to have OSA as female patients. Estrogen and progesterone might play a protective role because population-based studies have demonstrated that postmenopausal women have a two- to threefold increased risk of OSA compared to premenopausal women.

African Americans and Asians are at greater risk for OSA than Caucasians. Being African American is an independent risk factor for severe sleep-disordered breathing, with an odds ratio of 2.55 compared with Caucasians. Asians have a narrower cranial base, a higher Mallampati score, smaller thyromental distance, and steeper thyromental plane than Caucasians, which might account for their increased risk.

### Pathophysiology

Airway obstruction leading to OSA can occur anywhere along the pathway from the nostrils, soft palate, base of tongue, hypopharynx, and the epiglottis. The airway lacks skeletal structure and is vulnerable to influences, such as muscle tone, fat deposition, and tissue redundancy.

### Prevention

Lifestyle modification can prevent OSA. Patients should adopt a healthy and athletic lifestyle to develop good muscle tone and

weight loss, avoid sedatives and alcohol at bedtime, establish regular sleeping patterns, avoid the supine sleeping position, and elevate the head when sleeping.

### Diagnosis

Definitive diagnosis of OSA is made by polysomnography. Mild OSA is defined as an AHI of 5 to 15 per hour; moderate OSA is an AHI of 15 to 30 per hour; and severe OSA is an AHI greater than 30 per hour. There are several types of polysomnograms patients can obtain, ranging from Level 1 to 3. Level 1 sleep studies are performed in a sleep laboratory with a technician in attendance. It assesses at least seven channels of data (but usually 16+), including respiratory, cardiovascular, and neurological parameters. Level 1 sleep studies have long been the gold standard of diagnoses of sleep-disordered breathing and other sleep disorders. Patients spend the night in a sleep laboratory during which multiple physiologic variables are continuously monitored. These include electroencephalogram (EEG), electrooculogram (EOG), electromyogram (EMG), oronasal airflow, chest wall effort, body position, snore volume, electrocardiogram (ECG), and oxyhemoglobin saturation. Laboratory testing also includes a complete accounting of sleep variables, monitoring of cardiac rhythm, and assessment of possible restless legs syndrome (RLS) or periodic limb movements (PLMs) during sleep. This information enables the clinician to determine the severity of the condition and identifies potentially relevant comorbidities.

Level 2 sleep studies use the same equipment as Level 1 but do not have a technician in attendance. These are rarely offered or ordered. In recent years, Level 3 sleep studies have grown in popularity. These tests use portable monitors that allow sleep studies to be performed in a patient's home. Level 3 studies only measure three channels of data: oximetry, airflow, and respiratory effort. A thorough diagnostic study requires at least 6 hours of sleep, allowing assessment of variability related to sleep stages.

If there are sufficient apneas or hypopneas during the first half of the study (ideally 4 hours of diagnostic testing, with a minimum of 2 hours if an AHI  $> 40$  is confirmed), a split-night study may be performed, in which the second half of the night (minimum of 3 hours of sleep) is devoted to titration of continuous positive airway pressure (CPAP) therapy. If the criteria for a split-night sleep study are not achieved during the night, a second night for titration study is ordered. The split-night protocol is a cost-effective use of laboratory resources that is particularly well suited for patients with severe OSA.

A meta-analysis comparing Level 1 and 3 studies showed that Level 3 portable sleep studies displayed good diagnostic performance compared to Level 1 in-lab sleep studies in adult patients with high pre-test probability of moderate or severe OSA, and no unstable comorbidities. For patients suspected to have other types of sleep disorders, a Level 1 sleep study remains the gold standard.

According to the Institute for Clinical Systems Improvement (ICSI), polysomnography should be performed in patients with symptoms of OSA and one or more of the following: cardiovascular disease, hypertension, coronary artery disease, obesity, sleep complaints, type 2 diabetes mellitus, recurrent atrial fibrillation, and large neck circumference.

### Treatment

Initially, patients should be counseled to avoid practices that can potentially worsen the severity of OSA. CNS depressants taken before sleep (alcohol, sleep medications, pain medications) can worsen upper airway collapse during sleep and should be discouraged. Weight loss and maintenance should always play a role in the treatment of these patients. Myofunctional therapy, which is a series of isometric and isotonic exercises of the oral cavity and pharyngeal muscles, is designed to increase upper airway tone. Oral pressure therapy uses a mouthpiece to generate negative pressure to gently pull the palate forward, opening the retropalatal airway. End positive airway pressure (EPAP) therapy

uses nasal appliances to increase expiratory resistance and prevent pharyngeal collapse.

In patients with positional OSA, defined as greater than a two-fold difference in AHI between supine and nonsupine positions, avoiding the supine position during sleep may suffice to normalize ventilation during sleep. There are several commercial devices worn around the neck or back that gently vibrate when a patient is supine. Nightly compliance rates are 75% to 96%.

### Continuous Positive Airway Pressure Therapy

CPAP remains the therapeutic mainstay for primary treatment of OSA. It serves as a pneumatic stent for the upper airway and is effective in reducing the physiologic abnormalities measured on polysomnography. Additionally, CPAP is thought to augment lung volumes and elicit a reflex that increases tone in the upper airway musculature. Overall, it has been shown to reduce AHI, improve quality of life, and reduce cardiovascular risk.

There are many manufacturers of CPAP devices and many interfaces that help maximize comfort with treatment. Expiratory pressure release (EPR) is available through several CPAP manufacturers. EPR does not seem to compromise the effectiveness of CPAP therapy and improves the patient's sense of comfort with therapy, but it does not seem to systematically improve the level of adherence. Automatically adjusting positive airway pressure (APAP) is similar to CPAP, but instead of delivering a constant pressure, APAP adjusts delivered pressure breath to breath.

Bilevel respiratory-assist devices deliver alternating levels of positive airway pressure and may be considered an alternative therapeutic option when standard CPAP is not tolerated or when oxygen saturation is not raised sufficiently with standard CPAP. In some cases of severe OSA (in particular among patients with underlying pulmonary conditions), supplemental oxygen can be used in conjunction with CPAP therapy.

The main disadvantage with positive airway pressure treatment is poor compliance. CPAP adherence rates—defined as at least 4 hours per night—70% of nights are between only 39% and 50% overall CPAP compliance. Treatment is effective as long as the patient uses the device for the entire night, every night. APAP, CPAP desensitization, and the use of integrated heated humidifiers help improve adherence to therapy.

### Oral Appliances

Oral appliances worn in the mouth during sleep can help maintain a patent airway, especially in patients with significant positional sleep apnea who sleep supine and experience airway collapse secondary to the tongue falling posteriorly. In general, there are two types of appliances, mandibular-advancement appliances and tongue-retaining devices. The mandibular-advancement appliances are currently used more often and have been more widely studied. They require viable dentition for retention and they are fitted to the maxillary and mandibular dentition to enable the protrusion of the mandible, therefore increasing oropharyngeal patency. The most common side effect is drooling. Temporomandibular joint pain might limit the viability of this therapy, and chronic use of the appliance can result in a change of the dental occlusion. A dentist with expertise in sleep medicine should ideally implement and monitor this type of treatment.

### Surgical Procedures

If patients are not tolerating CPAP and a significant upper airway anatomic obstruction is identified, surgery should be considered. A variety of procedures help stabilize the retropalatal region, and others are intended to stabilize the retro-lingual airway (Box 2). Sleep surgery has been shown to be most effective when addressing multiple levels of obstruction. Procedures are often combined for maximum effectiveness, such as septoplasty, turbinate reduction, tonsillectomy,

## BOX 2 Treatments for Obstructive Sleep Apnea

### Nasal Obstruction

- Septoplasty
- Rhinoplasty or nasal valve surgery
- Turbinate reduction
- Adenoidectomy

### Retropalatal Obstruction

- Tonsillectomy
- Uvulopalatopharyngoplasty
- Z-palatoplasty
- Lateral pharyngoplasty
- Palatal stents
- Radiofrequency soft palate surgery

### Retro-lingual Obstruction

- Transoral robotic-assisted base of tongue reduction
- Lingual tonsillectomy
- Genioglossus advancement
- Hyoid suspension
- Tongue base suspension
- Upper airway stimulation device (hypoglossal nerve stimulator)
- Maxillomandibular advancement

uvulopalatopharyngoplasty, and genial tubercle advancement. With the advent of transoral robotic surgery (TORS), surgeons are now able to access the posterior oropharynx, base of tongue, and hypopharynx more easily, and procedures to address these areas are more common.

It is challenging to predict which patients are likely to have a successful surgical outcome. Much of this difficulty is associated with accurately identifying the site(s) of obstruction. The current gold standard is drug-induced sleep endoscopy (DISE), a procedure that examines the upper airway while the patient is in a drug-induced (propofol [Diprivan]<sup>1</sup> or dexmedetomidine [Precedex]), sleep-resembling state. As the patient snores and obstructs, a flexible fiberoptic scope is passed through the nose to evaluate the upper airway for the site of obstruction. The advantage of a DISE in comparison to assessing the airway while awake is it can more naturally evaluate sites of obstruction during sleep. DISE has shown to alter surgical treatment plans in 50% of OSA patients. The VOTE system is the most commonly used scoring system that evaluates the four major anatomical areas for potential obstruction, including the velum (palate), oropharyngeal walls (lateral), tongue, and epiglottis. Both the extent and configuration of collapse are noted. Although there is no clear consensus that DISE improves surgical outcomes for sleep surgery, there are retrospective studies that have shown benefit. Patients with anterior-posterior palatal collapse on DISE compared to concentric collapse had better outcomes following UPPP. Another study found DISE helped identify patients with significant oropharyngeal lateral wall collapse and complete base of tongue obstruction. These features were inversely correlated with surgical success.

In recent years, the development of new implantable devices that allow for upper airway stimulation has offered a new solution for patients with specific anterior-posterior collapse of the upper airway. The upper airway stimulation device monitors respiratory patterns and stimulates primarily tongue muscles to protrude during inspiration, relieving OSA.

A substantially more invasive procedure, the maxillomandibular advancement, has been shown to be very effective in a number of case series. However, the only definitive surgical cure is tracheostomy, which completely bypasses the upper airway but is not without its comorbidities.

## Monitoring

The patient's response to therapy needs to be monitored. In the case of CPAP therapy, monitoring of CPAP adherence is critical, because subjective reports are inaccurate. Resolution of excessive sleepiness is the desired outcome for patients who are symptomatic at baseline. If excessive sleepiness remains problematic despite documentation of desirable CPAP adherence, treatment with modafinil (Provigil) 100 to 400 mg in the morning might be considered. Other potential conditions affecting sleep need to be monitored and, if necessary, treated. Often, other conditions, such as poor sleep hygiene, RLS, PLMs, or psychophysiological insomnia, interfere with adequate response to therapy.

For patients who undergo surgery, retesting is indicated. The interval at which retesting should be done depends on the type of surgery that was performed. Retesting 3 months following the surgical intervention is adequate in most cases.

## PLEURAL EFFUSION AND EMPYEMA

Method of

Timothy M. Millington, MD; and David J. Finley, MD

### CURRENT DIAGNOSIS

- At least 200 mL of pleural fluid must be present to be seen on chest x-ray.
- Decubitus x-ray or CT may be needed to assess for loculations or atelectatic lung.
- Pleural fluid evaluation by laboratory studies (pH, glucose, LDH, protein), cytology, and microbiology can usually determine the etiology of an effusion.
- Repeat chest CT after drainage or directed inspection of the pleural space may be needed in cases where malignancy is suspected.

### CURRENT THERAPY

- Most transudative effusions will resolve with treatment of the underlying medical process.
- Exudative effusions may be managed by serial thoracentesis, per-cutaneous drainage, or pleurodesis, depending on the etiology
- Pleural space infection is treated with a combination of instilled fibrinolytics and surgical drainage.
- Malignant pleural effusions frequently recur after drainage, and the most durable treatment strategy is surgically-directed talc pleurodesis or indwelling pleural catheter.

Pleural effusions have multiple etiologies, which makes diagnosis and management a common clinical issue. Although the amount of fluid produced varies significantly, an average 0.1 to 0.2 mL/kg is maintained within the pleural space. Production of fluid is matched with removal during normal physiologic states, but aberrations of this homeostasis with local or systemic diseases lead to the formation of an effusion. Symptoms are related to the volume of fluid and the etiology of the fluid accumulation, including both benign and malignant processes. Secondary infection of a pleural effusion, known as an empyema, is a significant complication that necessitates aggressive treatment of both the underlying cause and the empyema itself.

Symptoms are variable and include dyspnea, orthopnea, cough, and chest discomfort, although patients can be asymptomatic, even with very large effusions. Dullness to percussion and decreased breath sounds are often hallmarks of effusions, but these signs are also seen with lung masses and consolidative pneumonias. A clinical history, physical examination, and imaging studies are often needed in combination to diagnose an effusion.

### Etiology

Many local and systemic illnesses are associated with the formation of a pleural effusion. Clinical history can indicate the most common cause of the effusion, but diagnostic procedures are often necessary to delineate the etiology. Determination of an exudative or transudative effusion can point out possible disease that may be the cause (Box 1).

Fluid that is low in total protein is a transudative effusion, which is most commonly caused by decreased oncotic pressure or increased capillary hydrostatic pressure. Transudative effusions can also be caused by fluid traversing the diaphragm, as seen in patients with ascites.

Exudative effusions are high in total protein (pleural fluid-to-serum ratio >0.5) and often have an elevated cell count. Increased capillary permeability and decreased lymphatic clearance, usually due to a local or systemic inflammatory illness, produce exudative

**BOX 1** Etiologies of Transudative and Exudative Effusions**Transudative**

Congestive heart failure  
 Cirrhosis  
 Pulmonary emboli  
 Peritoneal dialysis  
 Renal disorders  
 Myxedema  
 Sarcoidosis

**Exudative**

Malignancy  
 Infection  
 Drugs (e.g., nitrofurantoin [Marcodantin, Macrobid],  
 methotrexate [Trexall])  
 Chylothorax  
 Pulmonary emboli  
 Gastrointestinal diseases (e.g., pancreatitis)  
 Collagen vascular disease (e.g., rheumatoid arthritis)  
 Asbestos exposure  
 Trauma (e.g., hemothorax, chest surgery)  
 Postpericardiectomy or postmyocardial infarction syndrome  
 Pleuropericarditis

effusions. The causes are varied, but the most common causes are malignancy, infection, and pulmonary emboli.

**Diagnosis****Imaging**

Approximately 200 to 500 mL of pleural fluid is necessary before it can be visualized on a posteroanterior upright chest x-ray, usually as blunting of the costophrenic angle. A lateral decubitus chest x-ray is more sensitive, often discerning fluid with as little as 100 mL present; layering of the fluid confirms that it is free flowing. Loculations can be seen on x-ray but may be mistaken for lung or pleural masses. Large effusion can completely opacify the hemithorax where the effusion is located. Distinguishing pleural fluid from atelectatic lung due to airway occlusion can be challenging and, in such cases, drainage should not be attempted until ambiguity is resolved by additional imaging studies.

Ultrasound is useful in defining the location and extent of an effusion and can also identify loculated effusions, pleural thickening, and masses. When used to help guide thoracentesis, it can increase diagnostic accuracy and yield and decrease complications.

Chest computed tomography (CT) has distinct advantages over x-ray and ultrasound, although without intravenous contrast it may still be difficult to differentiate pleural fluid from consolidated lung. The utility of chest CT to detect masses is significantly decreased when there is a large effusion associated with compressive atelectasis. Imaging with CT after initial drainage of a large effusion is recommended to obtain the most information regarding the possible etiologies of the effusion and aid in operative planning for treatment of an empyema. It also delineates pleural masses and helps differentiate pleural disease from lung pathology (e.g., loculated effusion vs. lung abscess).

**Thoracentesis**

It is often difficult to discern the cause of an effusion solely based on the patient's clinical presentation and image studies. Also, when concerned about a malignant process or an infected effusion, these studies do not give enough information to make a definitive diagnosis. Thoracentesis is the diagnostic procedure of choice, allowing drainage of the fluid to relieve symptoms for the patient and provide a specimen for evaluation. Ultrasound should be employed to help guide thoracentesis, especially if the effusion is small or loculated. Care must be taken when draining

a large amount of fluid in one setting due to the risk of reexpansion pulmonary edema. If a patient becomes symptomatic during the procedure (persistent cough, significant pleuritic pain, or shortness of breath), no more fluid should be removed at that time. Coagulopathy is a contraindication to thoracentesis due to the risk of intrathoracic bleeding. If the fluid appears cloudy, bloody, or milky then leaving a drainage catheter in place following thoracentesis should be strongly considered. Imaging should be obtained after all drainage procedures to document resolution and ensure that no pneumothorax is present. Pneumothorax after thoracentesis may be iatrogenic but may also reflect inability of a trapped lung to fully expand (ex vacuo pneumothorax) and warrants additional work-up.

**Pleural Fluid**

The initial evaluation of pleural fluid is done at the bedside by inspecting the fluid for color, viscosity, and odor. These simple steps can point the clinician toward the correct diagnosis. In addition to bedside evaluation, the fluid should be sent for the following laboratory studies: pH, glucose, lactate dehydrogenase (LDH), protein, cytology, Gram stain, and culture (including fungal and viral). Serum pH, protein, LDH and glucose should be sent at the same time.

Light's criteria are helpful in differentiating between an exudative and transudative effusion (Box 2). The sensitivity and specificity of Light's criteria is 82% to 90%.

Transudative effusions rarely need any further intervention, and the goal of treatment is directed at the underlying condition (see Box 1). For exudative effusions, the cause of the effusion dictates the treatment. Incorporating the clinical picture and radiographs with the pleural fluid chemistry studies, cytology, and cultures, the diagnosis is often obtained. Malignant effusions can have positive cytology, but they are more likely to have a pleural fluid glucose level less than 60 mg/dL and to be bloody. An elevated amylase level is seen in esophageal perforation, pancreatitis, and malignant effusions. Chylothorax can be definitively diagnosed if the triglyceride level is more than 110 mg/dL within the pleural fluid. Finally, pH, glucose, and cultures are useful in the treatment of patients with a presumed infected pleural effusion (empyema).

Up to 25% of patients will not have a definitive diagnosis based on the clinical scenario and pleural fluid evaluation. These patients can require further diagnostic testing, including repeat thoracentesis or evaluation of the chest cavity via video-assisted thoracoscopic surgery (VATS) with pleural biopsies.

**Treatment**

After initial evacuation of pleural fluid effusion, treatment is directed at preventing reaccumulation. In the case of hepatic hydrothorax, cardiogenic effusion or effusion related to renal insufficiency, the effusion should resolve with appropriate medical treatment of the underlying disease. Esophageal perforation and chylothorax generally require addressing the primary process with endoscopic, interventional, or surgical approaches. Special cases in which surgical management may be indicated include malignant and infectious effusions.

**Malignant Pleural Effusion**

Palliation of malignant pleural effusions is accomplished either by pleurodesis or palliative indwelling catheter. Both strategies are more likely to be successful in patients being treated with appropriate chemotherapy.

The most effective strategy for chemical pleurodesis is thoracoscopically directed spray talc pleurodesis, which will achieve resolution in about 85% of cases. A VATS approach has the added advantage that directed pleural biopsies may be obtained, with a significantly higher sensitivity for diagnosing pleural metastatic disease than fluid cytology alone. Bedside pleurodesis via tube thoracostomy can be attempted but is less likely to be successful.

**BOX 2** Light's Criteria for an Exudative Effusion

Pleural fluid-to-serum ratio of protein >0.5  
 Pleural fluid-to-serum ratio of LDH >0.6  
 Absolute pleural fluid LDH >2/3 of upper limit of normal serum levels

LDH, Lactate dehydrogenase.

For very high output malignant effusions or if incompletely lung expansion occurs, a tunneled indwelling long-term silicone-elastic catheter (PleurX) may be placed either operatively or percutaneously. This tube may be drained with a closed suction canister either on a regular schedule or as needed for symptoms. Regular drainage of malignant effusion achieves spontaneous pleurodesis in the majority of cases in about 6 weeks.

**Infected Pleural Space and Empyema**

A parapneumonic effusion (exudative effusion in the setting of pulmonary infection) is seen in 20% to 40% of patients admitted for pneumonia, of whom 10% to 20% will develop a complicated parapneumonic effusion or empyema (pus in the pleural space). Progression to empyema is most often due to delay in treatment and leads to longer hospital stays and increased morbidity and mortality. Other causes of infected effusions are trauma, thoracic surgical procedures, perforated esophagus, systemic infection, and transdiaphragmatic spread.

Parapneumonic effusions can be separated into three stages: exudative (stage I), fibropurulent (stage II), and organizational (stage III). Stage I effusions are free flowing, sterile reactive exudates and often do not reaccumulate after initial drainage. Although small, minimally symptomatic stage I effusions may resolve with appropriate antibiotics, it is difficult to determine the stage of an effusion clinically and at a minimum thoracentesis is indicated in most cases. Careful consideration should always be given to leaving a drainage tube in case a more advanced parapneumonic effusion is diagnosed.

Stage II effusions, or complicated parapneumonic effusions, are more viscous with lower glucose level and pH. Multiple pockets of loculated fluid with proteinaceous septations may be present. Complete drainage of all loculations is required to prevent progression to empyema or organized effusion and a chest drain (image-guided percutaneous catheter or thoracostomy tube) should be left behind in all cases. Early surgical intervention with thoracoscopic adhesiolysis may be considered if loculations are present. Alternatively, combination therapy with intrapleural tissue plasminogen activator (t-PA) and deoxyribonuclease (DNase) improves fluid drainage and reduces the need for surgical intervention. Complete drainage of all loculated pockets is of paramount importance and surgery may still be necessary after treatment with fibrinolytics.

Complicated parapneumonic effusions may go unrecognized and be treated late, particularly in patients with other medical or social comorbidities such as diabetes mellitus, dementia, developmental delay, and intravenous drug use. The result is progression to frank intrapleural pus, or empyema. Complete evacuation of the effusion is now required, and initial tube thoracostomy is indicated although often insufficient. If the patient does not improve promptly or the space is not completely drained, then surgery is recommended. The initial attempt at drainage should be thoracoscopic although conversion to thoracotomy may be required. Multiple large-bore chest tubes should be left in place until drainage has resolved. In the presence of frank pus, fibrinolytic therapy is less likely to be of benefit, although it may be considered in patients who are medically unable to tolerate surgery.

If infected fluid is evacuated but a residual cavity remains, then chronic infection is likely. This risk is greatly increased by the presence of a bronchopleural fistula, either arising from a lung

abscess or due to surgical complication. In these situations, long-term drainage with an open thoracostomy or Eloesser flap, may be required to eradicate the infection. Ultimate obliteration of the space may require a rotational muscle flap.

If the pleural space is incompletely drained but adequately sterilized with antibiotics, the effusion may progress to the organizational stage. This is characterized by heavy fibrin deposit with the formation of a thick peel throughout the pleura with loculations and trapping of the lung, preventing re-expansion. Patients may report significant dyspnea and pulmonary function tests will show a restrictive pattern. Classic CT findings include thickened pleura with multiple loculations. Decortication, either via VATS or thoracotomy, is required to completely remove the peel off the parietal and visceral pleura. A robotic-assisted approach increases the likelihood of successful minimally invasive decortication.

**PNEUMOCONIOSIS: ASBESTOSIS AND SILICOSIS**

Method of

David N. Weissman, MD

**CURRENT DIAGNOSIS**

- History of inhalation of mineral or metal dust
- Respiratory symptoms such as cough and dyspnea
- Spirometry and lung volumes show restriction or mixed obstruction/restriction in advanced disease
- Interstitial lung disease can usually be demonstrated by chest imaging. Biopsy is usually unnecessary in the setting of good exposure history and typical findings on chest imaging.
- No other likely cause of interstitial lung disease is present

**CURRENT THERAPY**

- Treatment is symptomatic and similar to that for other patients with chronic lung disease
- Give pneumococcal and influenza vaccinations.
- Provide empiric treatment with short- and long-acting inhaled bronchodilators and inhaled corticosteroids when they are found to provide symptomatic relief.
- Give supplemental oxygen therapy if pulmonary hypertension is present or to prevent pulmonary hypertension if O<sub>2</sub> saturation is less than 88% at rest, with exercise, or with sleep.
- Consider lung transplantation in the setting of end-stage lung disease.

**TABLE 1** Representative Pneumoconioses

SOURCE	MAIN CLINICAL FEATURES	OCCUPATION	DUST
Crystalline silica	Silicosis, COPD, increased susceptibility to TB, lung cancer, autoimmune diseases	Mining, stone cutting, pottery, foundry work, artificial stone countertop work	Free crystalline silica (SiO <sub>2</sub> )
Asbestiform fibers	Asbestosis, bronchogenic carcinoma, mesothelioma, various forms of benign pleural disease	Insulation, shipbuilding, construction, some mining (e.g., vermiculite mining in Libby, MT)	Various asbestiform fibers
Coal	Coal workers' pneumoconiosis, COPD	Coal mining	Coal mine dust
Hard metal	Hard metal lung disease (cobalt lung), asthma	Machinists, metal workers	Hard metal, composed primarily of tungsten carbide and cobalt

COPD, chronic obstructive pulmonary disease; TB, tuberculosis.

The pneumoconioses are a group of interstitial fibrotic lung diseases predominantly associated with occupational exposures. They are caused by inhalation of mineral or metallic dust particles small enough to penetrate into the deep lung (respirable size range) (Table 1). These agents interact with pulmonary target cells, including alveolar macrophages and alveolar epithelial cells, to activate a cascade of inflammatory mediators including growth factors. Although exposure to these dusts can induce other types of respiratory disease as well, the final common pathway leading to pneumoconiosis is alveolar epithelial cell damage and interstitial fibrosis. This chapter focuses on silicosis and asbestosis, two common forms of pneumoconiosis.

### Asbestosis

Asbestos is composed of strong, heat-resistant fibers of hydrated magnesium silicate classified morphologically as serpentine (chrysotile) or amphibole (crocidolite [riebeckite asbestos], amosite [cummingtonite-grunerite asbestos], anthophyllite asbestos, actinolite asbestos, and tremolite asbestos). In addition, certain asbestiform fibers (winchite, richterite, erionite) can cause adverse health effects identical to those of asbestos. Fiber dimensions and persistence in tissues are key determinants of toxicity. There is a dose-response effect between the quantity of asbestos inhaled and the severity of fibrotic lung disease. Asbestos is also a carcinogen, and increasing exposure is associated with increased risk for lung cancer, mesothelioma, ovarian cancer, and laryngeal cancer.

Although asbestos is no longer mined in the United States, importation of asbestos-containing products continues. Exposures also continue to occur, especially in construction and renovation (due to reservoirs of asbestos that are still present in many older buildings), the heating trades (where asbestos is often encountered), and with exposure to older or imported asbestos-containing automotive friction products such as brake linings and clutch facings. Workers exposed to asbestos can carry it home on their clothing, resulting in exposure of family members. Living near geological formations prone to asbestos formation in California has been implicated as a risk factor for mesothelioma.

The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for asbestos is 0.1 fiber per cc air. This limit was based in part on the limits of the analytical methodology used in exposure assessment. Exposure to the PEL every day over a 45-year working lifetime has been estimated to be associated with an increased risk of cancer (lung, mesothelioma, and gastrointestinal) of 336 cases per 100,000 exposed persons and an increased risk of asbestosis of 250 cases per 100,000 exposed persons.

Asbestosis causes symptoms of dyspnea and cough. Latency between initial exposure and disease onset is related to exposure intensity. In the United States, this period is generally about two or more decades. The disease can lead to chronic respiratory failure. Effects of smoking add to the severity of the disease and can

cause obstructive findings in addition to the expected decreased lung volume and diffusion capacity associated with fibrotic lung diseases. Bibasilar inspiratory crackles on auscultation, finger clubbing, and bibasilar small, irregular parenchymal opacities on chest x-ray with extension to mid- and upper-zones with advancing disease are characteristic.

The International Labour Organization (ILO) has established a system for classification (grading) of radiographs for the presence of radiographic abnormalities in lung parenchyma and pleura that are associated with pneumoconiosis, as well as their severity. The ILO classification system is widely used in epidemiology, surveillance, administrative, and legal settings. The small opacity profusion grades of 0/1 and 1/0 are often considered as defining the boundary between normal and abnormal lung parenchyma.

High-resolution computed tomography (CT) is the most sensitive imaging method for suspected asbestosis. Findings associated with asbestos exposure include lower lobe or diffuse irregular opacities, bronchial wall thickening, rounded atelectasis, and pleural abnormalities such as pleural plaques and diffuse pleural thickening. The presence of pleural plaques on radiography (particularly bilateral calcified pleural plaques); or uncoated asbestos fibers or fibers coated with an iron-rich proteinaceous material (asbestos bodies) in sputum, bronchoalveolar lavage, or lung biopsy help differentiate asbestosis from idiopathic pulmonary fibrosis.

### Criteria for Diagnosis

Diagnosis is supported by radiographic chest imaging or lung biopsy findings of interstitial lung disease compatible with asbestosis; documentation of exposure to asbestos by history, the presence of pleural plaques (bilateral pleural plaques are essentially pathognomonic for asbestos exposure), or the presence of asbestos bodies or an excessive burden of uncoated asbestos fibers in lung biopsy tissue or possibly via bronchoalveolar lavage or sputum; and no other likely explanation for the diffuse fibrotic lung disease.

### Asbestos-Related Benign Pleural Disease

Pleural plaques are characteristic forms of localized parietal pleural thickening that are usually bilateral and asymmetrical, involve the lower lung fields or the diaphragm, and spare the costophrenic angles and apices. Pleural plaques are a marker for exposure to asbestos and are often associated with other asbestos-related conditions. Pleural plaques generally result in minimal reductions in forced vital capacity and do not degenerate into malignant lesions.

In contrast, diffuse visceral pleural thickening can result in adhesions between the visceral and parietal pleura with major decreases in forced vital capacity and respiratory insufficiency sufficient for consideration of decortication.

Benign pleural effusions can occur in the first decade after asbestos exposure and contain erythrocytes and a mixed inflammatory cell infiltrate of lymphocytes, neutrophils, and eosinophils. The thickened visceral pleura and adjacent atelectatic lung tissue can result in a pleural-based area of rounded atelectasis, simulating a lung mass on chest radiography. CT can reveal the comet sign, a pleural band connecting the apparent mass to an area of thickened pleura.

### Lung Cancer and Malignant Mesothelioma

Exposure to all forms of asbestos increases the risk of lung cancer. The peak risk occurs at about 30 to 35 years after the onset of exposure. Tobacco smoking increases this risk in a supra-additive fashion, increasing risk to a level greater than for asbestos or smoking alone. In contrast, smoking does not further increase the asbestos-associated risk for malignant mesothelioma. Asbestos-associated malignant mesothelioma can also affect the peritoneum (and sometimes the pericardium), but when it affects the pleura, this disease manifests with dyspnea, chest pain, and bloody pleural effusion (most often unilateral). A latency period of 30 years or longer after initial exposure is common. Biopsy and specialized immunohistochemical stains are typically required to distinguish malignant mesothelioma from benign mesothelial proliferations and various carcinomas such as adenocarcinomas. It is currently unclear when to screen asbestos-exposed individuals at increased risk for lung cancer with low-dose chest computed tomography.

### Treatment

Treatment of asbestosis is primarily symptomatic and similar to that for other patients with chronic lung disease (Box 1). The U.S. Food and Drug Administration (FDA) recently approved the anti-fibrotic drug nintedanib (Ofev) to slow the rate of decline of pulmonary function in chronic fibrosing interstitial lung diseases with a progressive phenotype. However, the safety and effectiveness of treating progressive asbestosis with nintedanib<sup>1</sup> has not yet been documented in the literature and hence, remains unknown. Lung transplantation should be considered in the setting of end-stage lung disease. Treatment of benign pleural disease is also symptomatic; as already noted, decortication is an option for managing severe cases of diffuse visceral pleural thickening. Depending on extent of disease, mesothelioma may be treated with surgery, radiation, chemotherapy, or some combination of these. In general, prognosis is poor. Mesothelioma-associated malignant pleural effusion can require palliation through procedures such as pleurodesis, pleurectomy, and decortication. Asbestos-associated lung cancer is managed in the same fashion as lung cancer occurring without a history of exposure to asbestos.

### Silicosis

Silicosis is a fibrosing interstitial lung disease resulting from the inhalation of crystalline silicon dioxide (silica) in dust of respirable size. The commonest form of crystalline silica is quartz, which is the main component of sand and is present in most rocks. Noncrystalline (amorphous) silica, like that in diatomaceous earth or glass, does not cause silicosis. However, heating amorphous silica, as occurs in foundries when molten metal is poured into clay castings, can convert amorphous silica into cristobalite, a hazardous form of crystalline silica. Mining, stone cutting, sandblasting, and foundry work are all examples of trades associated with exposure to respirable dust containing crystalline silica. The International Agency for Research on Cancer (IARC) has designated crystalline silica as a Group 1 human lung carcinogen.

In 2016, OSHA established a new PEL for respirable crystalline silica of 0.05 mg/m<sup>3</sup>. It also established requirements for engineering and administrative controls, personal protective equipment, and medical surveillance including periodic chest radiography and spirometry obtained at least every 3 years. Reporting of silicosis cases to public health authorities is required in some states.

## BOX 1 Recommendations for Managing Patients With Silicosis or Asbestos-Related Lung Disease

### Patients

- Stop further exposure to silica or asbestos.
- Stop smoking, avoid exposure to tobacco products.

### Physicians

- Provide early treatment of respiratory infections with antibiotics.
- Give pneumococcal and influenza vaccinations.
- Maintain a high index of suspicion and provide early evaluation of symptoms for lung, laryngeal, and ovarian cancers and mesothelioma in asbestos-exposed patients.
- Maintain a high index of suspicion for pulmonary infection with *Mycobacterium tuberculosis*, nontuberculous mycobacteria, and fungi in silica-exposed patients.
- Screen silica-exposed patients for latent tuberculosis infection. Treat latent infections with one of the currently-approved drug protocols.
- Provide empiric treatment with short- and long-acting inhaled bronchodilators and inhaled corticosteroids when they are found to provide symptomatic relief.
- Give supplemental oxygen therapy if pulmonary hypertension is present or to prevent pulmonary hypertension if O<sub>2</sub> saturation is less than 88% at rest, with exercise, or with sleep.
- Consider lung transplantation in the setting of end-stage lung disease.

### Radiographic Patterns of Silicosis

Three main radiographic patterns of silicosis have been described. Two are nodular interstitial patterns and one is an alveolar-filling pattern. The *simple* pattern is associated with nodules that are smaller than 10 mm and that are predominantly rounded and in the upper lung zones. *Progressive massive fibrosis* (PMF) is found in more advanced interstitial disease. It is associated with multiple coalescent larger nodules, upper lobe fibrosis, upward retraction of the hila, and compensatory hyperinflation of the lower lobes. The large upper-zone opacities can cavitate, sometimes in the setting of superimposed mycobacterial infection. Hilar adenopathy can occur in association with either pattern, sometimes with an egg-shell pattern of hilar node calcification. A third radiographic pattern is an alveolar-filling process. Overwhelming silica exposure over a short period can cause a pathologic response called *silicoproteinosis*, in which alveoli become flooded with proteinaceous fluid. The condition resembles idiopathic pulmonary alveolar proteinosis. The radiographic alveolar filling pattern favors the lower lung zones and is not necessarily associated with the changes of simple silicosis or PMF.

### Silicosis Syndromes

Three syndromes of silicosis can be defined based on clinical course and radiographic pattern. Chronic silicosis develops slowly, usually 10 to 30 years after first exposure. It most often has the simple radiographic pattern, but it can be associated with PMF.

Accelerated silicosis develops more rapidly, within 10 years after first exposure. It is associated with higher intensity exposures and can be associated with either the simple or PMF radiographic patterns. Accelerated silicosis is differentiated from chronic silicosis by its more rapid course. Patients with accelerated courses are at greater risk for developing PMF. The clinical presentations of chronic and accelerated silicosis are variable but include cough, dyspnea, and a variety of chest findings ranging from a normal chest examination to crackles, rhonchi, or wheezing. PMF is associated with more severe symptoms and respiratory impairment. Findings compatible with both restrictive and obstructive lung disease (decreased forced vital capacity [FVC], forced expiratory volume at 1 sec [FEV<sub>1</sub>], FEV<sub>1</sub>/FVC,

<sup>1</sup>Not FDA approved for this indication.

diffusion capacity) can occur, potentially leading to cor pulmonale and respiratory failure.

*Acute silicosis* is associated with very intense exposures to silica, leading to symptoms within a few weeks to a few years after exposure. Intense exposure results in lung injury caused by flooding of alveoli with proteinaceous material, or silicoproteinosis. As already noted, the radiographic appearance is that of an alveolar-filling pattern favoring the lower lung zones. Patients present weeks to a few years after exposure with cough, weight loss, fatigue, and occasional pleuritic chest pain, crackles on auscultation, and progression to respiratory failure often complicated by mycobacterial infection.

### Criteria for Diagnosis

The diagnosis of silicosis is predicated on a history of exposure to respirable crystalline silica, typical chest x-ray findings, and the lack of a more likely diagnosis. High-resolution CT detects changes of silicosis with greater sensitivity than chest radiography. Lung biopsy is seldom required for diagnosis in the setting of a good exposure history and typical findings on chest imaging.

### Treatment

Treatment is primarily symptomatic and similar to that for other patients with chronic lung disease (see [Box 1](#)). Experimental therapies such as oral corticosteroid therapy and whole-lung lavage have been reported, but clinical benefit is unclear. Similarly, as noted for asbestosis, the clinical benefit of treating progressive silicosis with the antifibrotic drug nintedanib is also currently unclear. Lung transplantation should be considered for patients with end-stage lung disease.

All forms of silicosis, as well as substantial exposure to crystalline silica in the absence of silicosis, are associated with an increased risk of pulmonary tuberculosis and fungal infections. Patients should be evaluated for latent tuberculosis infection by tuberculin skin testing or with an interferon gamma release assay. A positive tuberculin skin test in a patient with a history of substantial silica exposure of at least 10 mm of induration should be considered evidence of tuberculosis infection, regardless of previous immunization with bacille Calmette-Guérin. If testing for latent tuberculosis infection is positive, an evaluation for active tuberculosis should be performed and active disease treated. If active tuberculosis is not present, treat for latent infection. As in other settings, treatment for active or latent infection should be provided using one of the drug treatment protocols recommended by the Centers for Disease Control and Prevention. Vaccination for influenza should be provided annually. In addition, adults with silicosis should be vaccinated with 15-valent pneumococcal conjugate vaccine (PCV 15, Vaxneuvance) and 23-valent pneumococcal polysaccharide vaccine (PPSV23, Pneumovax 23) or with PCV 20 (Pneumovax 20) alone, according to current Centers for Disease Control and Prevention recommendations.

## PULMONARY HYPERTENSION

Method of

Dan Schuller, MD; and Anthony Peter Catinella, MD, MPH

### CURRENT DIAGNOSIS

- Pulmonary arterial hypertension (PAH) is a type of pulmonary hypertension (PH) based on restricted flow because of vascular wall remodeling and increased pulmonary vascular resistance. PH does not equal PAH.
- The clinical presentation of PH is subtle and nonspecific with dyspnea, fatigue, and exercise limitation. A high index of suspicion is required.
- Echocardiography is the recommended initial screening test.
- Right heart catheterization, preferably at an expert center, should be obtained before initiation of specific PAH treatments.
- PAH is a diagnosis of exclusion.
- Multimodality risk stratification with combination of functional class assessment, echocardiography, exercise testing (6-minute walk test), B-type natriuretic peptide, and hemodynamic parameters are required at the time of initial diagnosis and for longitudinal monitoring.

### CURRENT THERAPY

- Early referral to a PH expert center is recommended
- General measures and supportive care include avoiding pregnancy and high altitude travel, influenza, COVID-19, and pneumococcal immunizations, supplemental oxygen for hypoxemia, diuretics and electrolyte replacement when needed, correction of anemia and optimal evaluation, and management of associated comorbidities.
- There are now 12 Food and Drug Administration (FDA)–approved drugs for the treatment of PAH.
- With a few exceptions, PAH patients at low or intermediate risk should be treated with upfront combination therapy with endothelin receptor antagonists (ERAs) and phosphodiesterase-5 inhibitors (PDE5i).
- In high-risk PAH patients, combination therapy including intravenous prostanoid and referral for lung transplantation is recommended.
- PAH requires a multidimensional approach to care that includes rehabilitation, psychosocial, spiritual support, and palliative care.

### Definition and Classification

In 2018, a revised hemodynamic definition of pulmonary hypertension (PH) became a mean pulmonary arterial pressure (mPAP) greater than 20 mm Hg rather than the prior level of 25 mm Hg. This is a hemodynamic definition based on measurements taken during right heart catheterization at rest, as the criterion standard. Based on Ohm's law, resistance is directly proportional to a pressure gradient and inversely proportional to flow. Thus the pulmonary vascular resistance (PVR) is calculated by dividing the pressure gradient (mPAP minus venous pressure as measured by the pulmonary capillary wedge pressure or PCWP) by the cardiac flow rate using the cardiac output or CO:

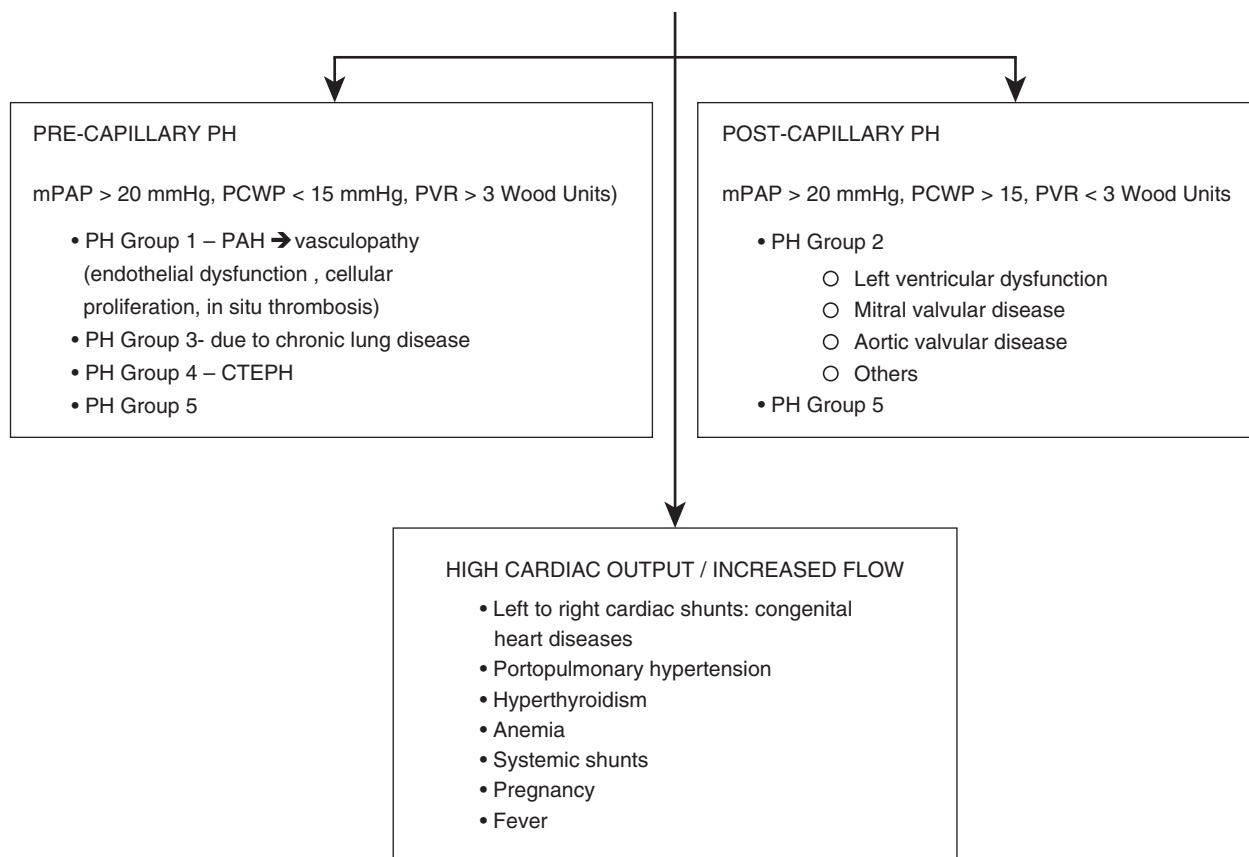

$$PVR = (mPAP - PCWP) / \text{cardiac output (CO)}$$

Rearranging the equation to calculate the mPAP yields  $mPAP = (PVR \times CO) + PCWP$ . From this simple equation, different hemodynamic profiles leading to PH can be distinguished ([Figure 1](#)). PH can occur because there is an increase in PVR (or precapillary PH), an increase in PCWP (or postcapillary PH), an increase in

## HEMODYNAMIC PROFILES IN PULMONARY HYPERTENSION

$$\text{Pulmonary Arterial Pressure} = (\text{Pulmonary Vascular Resistance}) / (\text{Cardiac Output}) + \text{Wedge Pressure}$$

**Figure 1** Hemodynamic profiles in pulmonary hypertension.

flow (high cardiac output state), or any combination of these. Isolated precapillary PH occurs when the mPAP is greater than 20 mm Hg to define the PH state, and the PVR is elevated ( $\geq 3$  Woods unit) while the PCWP is normal ( $\leq 15$  mm Hg). Likewise, isolated postcapillary PH occurs when the mPAP is greater than 20 mm Hg and the PCWP is greater than 15 mm Hg while the PVR is normal at less than 3 Woods unit. Commonly, one finds combined pre- and postcapillary PH with all values abnormally elevated.

Understanding these equations permits appropriate classification, which has therapeutic implications, and for insight into sudden clinical worsening with progression of the natural history of the underlying conditions. For instance, a patient with idiopathic PH can have an increase in pulmonary pressures caused by progression of the disease (precapillary) or from interval development of a high output state such as fever, anemia or pregnancy, or from interval development of fluid overload or left ventricular dysfunction (postcapillary).

PH is classified into five groups (Box 1) based on common underlying mechanisms or pathophysiology. Only PH Group 1 is designated as pulmonary arterial hypertension (PAH) with restricted flow caused by vascular wall remodeling and increased PVR. PH Group 2 is caused by left heart disease, a common condition that elevates pulmonary venous pressures; this group represents the highest proportion of PH patients in the United States. PH Group 3 is caused by chronic intrinsic lung diseases with chronic hypoxia and/or hypercapnia as a common mechanism; in patients with mild to moderate chronic obstructive pulmonary disease (COPD), the prevalence of PH is about 20% and increases to 50% in more advanced cases of the disease. PH Group 4 is predominantly caused by chronic thromboembolic disease, which

causes obliteration of the pulmonary vascular bed by chronic organized thrombus leading to increased PVR. PH Group 5 consists of heterogeneous conditions with multifactorial mechanisms that affect PH.

PAH is a rare, progressive, incurable disease of the small pulmonary arteries characterized by precapillary PH, vascular cell proliferation, aberrant remodeling, and thrombosis in situ (Figure 2). This group is amenable to specific PAH therapies. PAH is further subdivided into categories because of various etiologies and risk factors linked to a common pathogenesis but with significant variability in presentation, natural history, and response to treatment.

In the United States, almost half of the cases of PAH are idiopathic, whereas approximately 25% are associated with connective tissue disease (predominantly scleroderma), nearly 10% with congenital heart disease, 5% with liver disease (porto-pulmonary hypertension), and 5% with drugs or toxins (e.g., methamphetamine [Desoxyn], dasatinib [Sprycel], or appetite suppressants). Schistosomiasis is a rare parasitic infection in the United States, but it is endemic in 74 countries. Worldwide, 85% of persons infected with schistosomiasis are in sub-Saharan Africa and the disease represents the most common cause of PAH worldwide.

Heritable PAH has been associated with a number of genetic mutations (predominantly the bone morphogenetic protein receptor type 2 [BMPR2] gene, activin receptor-like kinase type 1 [ALK1], and endoglin) and accounts for almost 3% of cases in the United States. It is transmitted as an autosomal-dominant trait, with incomplete penetrance estimated to be approximately 10% to 20%. Genetic anticipation, distinguished by decreasing age of disease onset, has been reported in families affected with heritable PAH.

**Group 1: Pulmonary arterial hypertension (PAH)**

- Idiopathic PAH (IPAH)
- Heritable PAH
- Drug- and toxin-induced PAH
- PAH associated with:
  - Connective tissue disease
  - HIV infection
  - Portal hypertension
  - Congenital heart disease
  - Schistosomiasis

- PAH long-term responders to calcium channel blockers
- PAH with overt features of venous/capillaries pulmonary veno-occlusive disease (PVOD)/ pulmonary capillary hemangiomatosis (PCH) involvement
- Persistent pulmonary hypertension (PH) of the newborn syndrome

**Group 2: Pulmonary hypertension caused by left heart disease**

- PH caused by heart failure with preserved left ventricular ejection fraction (LVEF)
- Valvular heart disease
- Congenital/acquired cardiovascular conditions leading to postcapillary PH

**Group 3: Pulmonary hypertension caused by lung diseases and /or hypoxia**

- Obstructive lung disease
- Restrictive lung disease
- Other lung disease with mixed restrictive/obstructive pattern
- Hypoxia without lung disease
- Development lung disorders

**Group 4: Pulmonary hypertension caused by pulmonary artery obstructions**

- Chronic thromboembolic PH
- Other pulmonary artery obstruction

**Group 5: Pulmonary hypertension with unclear and/or multifactorial mechanism**

- Hematologic disorders
- Systemic and metabolic disorders
- Other

**Clinical Manifestations**

The initial symptoms of PAH are often subtle and nonspecific; mean time between symptom onset and PAH diagnosis is approximately 2 years. Patients often report progressive or exertional breathlessness, fatigue, and exercise limitation. With progression, patients may present with near syncope or syncope, palpitations, or anginal chest pain. Early detection requires a high index of suspicion because attribution to conditions such as asthma or “being out of shape” is a common error that can contribute to delay in diagnosis. Failure to respond to typical treatments for heart failure or asthma may be an important clue. Dysphonia or hoarseness caused by compression of the recurrent laryngeal nerve (Ortner’s syndrome), which is caused by an enlarged pulmonary artery, occurs in less than 1% of patients. Early physical findings of PH may be nonspecific and include an accentuated pulmonary component of the second heart sound (P2) and a midsystolic ejection murmur. Physical findings in more advanced cases that involve right ventricular failure include a right parasternal lift, right ventricular gallop, diastolic murmur of pulmonary regurgitation, jugular venous distention, lower extremity edema, ascites, and signs of low cardiac output, including cool extremities. A murmur of tricuspid regurgitation may be audible, and this murmur intensifies with inspiration, unlike that of mitral regurgitation. Patients with suspected PH may also exhibit signs of associated conditions, such as telangiectasias, Raynaud’s phenomenon, sclerodactyly, calcinosis, or malar erythema in connective tissue diseases; evidence of liver cirrhosis or portal hypertension; venous insufficiency or varicosities suggestive of possible thromboembolic disease; and obvious signs of underlying cardiac or respiratory diseases, including obstructive sleep apnea. Suggestive electrocardiographic findings include right axis deviation greater than 110°, which has a positive predictive value between 72% and 93% and a negative predictive value between 26% and 65%. Other associated findings include right atrial enlargement and right ventricular hypertrophy.

**Diagnosis**

The diagnostic evaluation is aimed at screening high-risk individuals, excluding secondary causes of PH, and evaluating possible associated conditions. In addition, various elements of the comprehensive examination are useful for subsequent risk stratification, which is required to select the best therapeutic option and assess prognosis. PAH is always a diagnosis of exclusion.

After reviewing pertinent previous medical records and performing a complete history and physical examination, the pivotal test in the diagnostic algorithm by the primary care provider or non-PH expert center is a transthoracic echocardiogram (TTE) to assess the probability of PH. An echocardiogram has an intermediate or high risk for PH based on a peak tricuspid regurgitation velocity 2.9 m/s or greater or right ventricular systolic pressure  $\geq 35$  mm Hg. In one series, TTE had a sensitivity of 87% (95% confidence interval [CI] 84.8%, 90.0%) and specificity of 66% (95% CI 60.7%, 71.6%). After a positive screen, a decision has to be made as to whether to fast track the referral of the patient to a PH expert center or to advance locally the diagnostic evaluation with additional testing aimed at diagnosing common causes of PH and ruling out chronic thromboembolic pulmonary hypertension (CTEPH). A comprehensive evaluation may include chest film, electrocardiogram, TTE, ventilation-perfusion lung scan, pulmonary function testing, 6-minute walk test, serologic evaluation (HIV, antinuclear antibodies [ANA], BNP, and others), and right-side cardiac catheterization for hemodynamic assessment and vasoreactivity testing. Depending on the results, additional, contingent tests may include a transesophageal echocardiogram, stress echocardiogram, “bubble” echocardiogram, computed tomography (CT) scan of the chest with or without pulmonary angiogram, coagulopathy profile, blood gases, overnight oximetry, polysomnography, or a cardiac magnetic resonance imaging (MRI). During cardiac catheterization, additional interventions, such as exercise or fluid challenges, pharmacologic interventions with vasoactive agents, and/or a left-side cardiac catheterization,

**Figure 2** Typical advanced pulmonary arteriopathy in idiopathic pulmonary arterial hypertension. Note the proliferative changes in all three vessel layers, including intimal hyperplasia, medial hypertrophy, and adventitial fibrosis. From Broaddus VC, Mason RJ, Ernst JD, et al: *Murray & Nadel’s Textbook of Respiratory Medicine*, 6 ed, Elsevier, 2016.

may be useful to secure a definitive diagnosis, assess potential mixed etiologies, and determine the hemodynamic profile for risk stratification.

Vasoreactivity testing in patients with PAH can be accomplished with the use of inhaled nitric oxide,<sup>1</sup> intravenous epoprostenol sodium (Flolan),<sup>1</sup> or intravenous adenosine (Adenocard).<sup>1</sup> A positive vasodilator response is defined as greater than 10% decrease in mPAP to an absolute value of less than 40 mm Hg with no decrease in cardiac output. Patients who show acute vasoreactivity should be considered for a high-dose calcium channel blocker titration challenge under hemodynamic monitoring in an intensive care setting. For the minority of patients that demonstrate a favorable response to either oral diltiazem (Cardizem)<sup>1</sup> or nifedipine (Procardia),<sup>1</sup> the selection of drug and dosing will depend on the cumulative dose of the acute challenge, their heart rate, and hemodynamic tolerance.

Novel diagnostic tools that are being investigated for PAH but are not universally available yet include V/Q single photon emission CT (SPECT) and dual-energy CT (DECT), three-dimensional dynamic contrast enhanced MRI, parametric MRI mapping, intravascular ultrasound, and optical coherence tomography.

### Risk Stratification

In addition to the etiologic classification of PAH, the World Health Organization (WHO) also uses a functional classification for patients with PH, modeled after the New York Heart Association classification for heart failure. PAH patients are classified by severity of dyspnea and limitation of physical activity: Class I includes patients with no limitation on physical activity.

Routine physical activities do not cause increased dyspnea, chest pain, fatigue, or presyncope.

Class II includes patients with mild limitation of physical activities. These patients are comfortable at rest, but routine physical activities result in increased dyspnea, chest pain, fatigue, or syncope.

Class III includes patients with marked limitation of physical activities. They are comfortable at rest, but activities that are less than ordinary result in dyspnea, chest pain, fatigue, or palpitations.

Class IV includes patients unable to perform any physical activity without symptoms. Dyspnea or fatigue may be present at rest, and discomfort increases with any activity.

Low-risk criteria associated with a good prognosis include WHO functional class I–II, 6 MWT distance greater than 440 m, right atrial pressure (RAP) less than 8 mm Hg, Cardiac Index  $\geq 2.5$  L/min/m<sup>2</sup>.

Adverse PAH prognostic factors include PAH associated with connective tissue disease, human immunodeficiency virus (HIV), heritable or porto-pulmonary hypertension; men greater than 60 years; renal insufficiency with eGFR less than 60 mL/min/1.73 m<sup>2</sup>; WHO functional class III or IV; systolic blood pressure less than 110 mm Hg; heart rate greater than 96 BPM; all-cause hospitalization within 6 months; 6 MWT distance less than 165 m; brain natriuretic peptide (BNP) test greater than 800 pg/mL or NT pro BNP  $\geq 1100$  pg/mL; pericardial effusion; diffusion capacity (DLCO) less than 40% of predicted; and RAP  $> 20$  mm Hg.

### Treatment

General supportive measures for patients with PH are listed in **Box 2**. The overall goals of therapy are to prevent clinical worsening, decrease hospital admissions, improve quality of life (decreased symptoms), WHO functional class (increased activity level), improve hemodynamics, 6-minute walk results, and optimize survival. For PH diagnostic groups 2 to 3, early and correct identification of the underlying conditions is paramount to prevent misclassification and provide optimal treatment, such as effective diuresis of heart failure, correction of hypoxemia for

## BOX 2 General Measures and Supportive Therapies for Pulmonary Hypertension

### General Measures

- Avoid pregnancy
- Influenza and pneumococcal immunization
- Avoid travel to high altitude
- Supervised exercise training
- Psychological counseling
- Chronic disease management education
- Patient support groups and networks
- Regional anesthesia preferred over general anesthesia
- Emergency preparedness

### Supportive Therapies

- Supplemental oxygen when indicated
- Diuretics
- Electrolyte replacement
- Consideration for anticoagulation (for IPAH, not in associated PAH)
- Consideration for digoxin
- Correction of anemia
- Treatment of arrhythmia
- Cautious use of beta-blockers
- Access to palliative medicine resources

*IPAH, Idiopathic pulmonary arterial hypertension; PAH, pulmonary arterial hypertension.*

COPD, use of CPAP for OSA, and so forth. Cases consistent with mixed PH where the PVR is increased and believed to be out of proportion for the underlying PH Group 2 or 3 disorder usually require referral to a PH expert center. PAH specific therapies are not FDA approved for these patients and may lead to the development of pulmonary edema in PH Group 2 or worsening gas exchange in PH Group 3 patients.

Patients with CTEPH–PH Group 4 require therapeutic anticoagulation and consideration for pulmonary thromboendarterectomy at a center of expertise. Riociguat (Adempas), an activator of nitric oxide causing vasodilation is indicated and FDA approved for patients with inoperable or persistent/recurrent CTEPH.

Specific PAH therapy is usually started for symptomatic patients in WHO functional class II, III, or IV if they showed no acute vasoreactivity or if they did not maintain an acceptable sustained response to calcium channel blockers. Nonresponders to acute vasoreactivity testing who are at low or intermediate risk should be treated with initial oral combination therapy with an endothelin receptor antagonist (ERA) and a phosphodiesterase-5 inhibitor (PDE5i).

Currently available therapeutic choices include ERAs such as ambrisentan (Letairis), bosentan (Tracleer), or macitentan (Opsumit); PDE-5i's such as sildenafil (Revatio) or tadalafil (Adcirca); soluble guanylate cyclase stimulator, riociguat (Adempas); prostacycline analog agents (PCAs) such as intravenous epoprostenol (Flolan, Veletri), intravenous or subcutaneous treprostinil (Remodulin), inhaled treprostinil (Tyvaso), oral treprostinil (Orenitram); oral selective prostacycline receptor agonist, selexipag (Uptravi), or inhaled iloprost (Ventavis). Use of these medications should be done under the auspices of or at an expert referral center.

Based on the global experience over the last three decades and more than 40 randomized controlled trials performed on nearly 10,000 patients we have learned the following: (a) In treatment-naïve PAH patients, any monotherapy is better than placebo and associated with an improvement in exercise capacity and outcome; (b) in treatment-naïve and newly diagnosed (incident) PAH patients, initial combination therapy improves symptoms, exercise capacity, and outcomes compared with monotherapy; and (c) in already treated (prevalent) PAH patients, sequential combination therapy improves exercise capacity, hemodynamics

<sup>1</sup>Not FDA approved for this indication.

and outcomes compared with patients who continue on background therapy.

In therapy-naïve (incident) PAH patients, initial combination therapy with ambrisentan and tadalafil was associated with a significant lower risk of clinical-failure events that was defined as the first occurrence of a composite of death, hospitalization for worsening PAH, disease progression, or unsatisfactory long-term clinical response. On the other hand, bosentan added to sildenafil therapy in patients with PAH was not superior to sildenafil monotherapy in delaying the time to the first morbidity/mortality event. This discrepancy observed between two different drug combinations within the same categories of drugs may be explained by the known drug-drug interaction where bosentan significantly decreases the plasma concentration of sildenafil, but sildenafil increases the plasma concentrations of bosentan.

In a long-term event-driven trial of predominantly prevalent patients with symptomatic PAH, macitentan monotherapy or added to background therapy significantly reduced morbidity and mortality.

In a randomized, double-blind trial, riociguat significantly improved exercise capacity and secondary efficacy endpoints including PVR, NT-pro BNP, WHO functional class, time to clinical worsening, and dyspnea scores.

Among PAH patients who remained symptomatic on monotherapy with bosentan or sildenafil, inhaled treprostinil improved exercise capacity and quality of life and was usually well tolerated.

In a large, event-driven trial of predominantly prevalent patients with PAH on background therapy, the oral selective prostacyclin receptor (IP) agonist selexipag reduced the risk of death or complications from PAH. In nonvasoactive and treatment-naïve patients at high risk, initial combination therapy including IV PCA is recommended. Intravenous epoprostenol receives the strongest recommendation for high-risk patients because it has reduced the 3-month rate of mortality, even as monotherapy. Referral for lung transplantation should also be considered.

The decision regarding initial therapy must be individualized and incorporates many factors and determinants of risk, including WHO functional class, progression of symptoms, hemodynamic assessment, 6-minute walk test, biomarkers of severity, comorbidities, access to emergent care, and psychosocial support.

Surgical options for advanced cases of PAH including balloon graded atrial septostomy and lung transplantation are beyond the scope of this chapter but remain important treatment options for patients with refractory disease.

## Monitoring

Goal-directed therapy has been described, calling for periodic assessment every 3 to 6 months and possible escalation of therapy. This approach has been associated with improved survival, with specific goals that include clinical stability, WHO functional class II, a 6-minute walk distance of greater than 400 m, and near-normal RAP and cardiac output.

Health coaching, goal setting, and periodic evaluation of advanced directives should always be incorporated in the longitudinal monitoring of PAH patients.

The optimal management of the PH patients requires a holistic, multidimensional approach that incorporates shared decision making integrating medical care, rehabilitation, psychosocial support, spiritual support, palliative care, education, and participation in support groups.

## Special Situations

### Pregnancy

The effect of pulmonary hypertension on pregnancy, although substantial, has been altered by recent treatments. Current guidelines recommend counseling of pregnant women and their partners on the outcomes associated with pulmonary hypertension with discussion of possible termination of the pregnancy, and the need for vigilant avoidance of pregnancy using contraceptive practices. However, some recent studies suggest current treatment

modalities are having some impact on better outcomes. The ROPAC study by Silwa et al. demonstrated maternal and neonatal mortality was substantially lower than previously reported (4.6% and 2.7%, respectively). No maternal deaths occurred during gestation and most occurred at least 1 week after delivery. Most of the maternal deaths occurred in those with more severe pulmonary arterial hypertension. In a more recent meta-analysis of 19 studies, Jha et al. published in 2020 a maternal mortality rate of 11.5 per 100 pregnancies, with 81.6% occurring in the early postpartum period.

Physicians caring for pregnant patients with pulmonary hypertension should consult an obstetrician, maternal fetal medicine specialist, pulmonologist, and geneticist if first-trimester termination is not an option.

## COVID-19

The COVID-19 pandemic has altered the standard of care for patients with PAH with most healthcare systems adapting to new recommendations from healthcare agencies to minimize exposure risks to patients and healthcare providers. The evaluation and initiation of treatments for new PAH patients has been more challenging as a result of difficulties accessing some testing such as pulmonary function, nuclear medicine ventilation scans or elective invasive hemodynamic evaluations.

The initiation of specific PAH therapies and the up-titration of riociguat (Adempas), selexipag (Uptravi), and prostacyclins that traditionally relied on specialized nurse educator visits were less available because of travel and socially distancing restrictions and have adapted to increasingly use telehealth platforms.

COVID-19 vaccination is strongly recommended for patients with pulmonary hypertension because they represent a high-risk population group.

## SARCOIDOSIS

Method of

W. Ennis James, MD; Marc A. Judson, MD; and Megan Veglia, MD

### CURRENT DIAGNOSIS

- The diagnosis of sarcoidosis is one of exclusion.
- Tissue biopsy, confirming noncaseating granulomatous inflammation, is required in most cases.
- Initial evaluation should include screening for dangerous organ involvement.

### CURRENT THERAPY

- Many cases of sarcoidosis do not require treatment.
- Treatment is typically indicated when sarcoidosis results in impaired quality of life or involves potentially dangerous organs.
- Corticosteroids are the most commonly used initial therapy but are associated with significant side effects.

Sarcoidosis is a multisystem granulomatous disease of unknown cause. The lung is most commonly affected, but any organ may be involved. The natural course of sarcoidosis is variable, ranging from an asymptomatic state to a progressive disease causing significant organ dysfunction that may be life threatening. This variability in organ involvement and disease presentation often makes the diagnosis of sarcoidosis problematic.

### Epidemiology

Sarcoidosis occurs worldwide and affects all races and ages. Although the disease has been thought to be most common between ages 20 and 40, analyses from large databases have revealed that the incidence and prevalence of the disease is greatest between ages 45 and 65. There is an earlier onset of disease in Blacks and males. A large analysis from an American national healthcare database found an incidence of 17.8 per 100,000 in African Americans and 8.1 per 100,000 in American Whites, and

a prevalence of 141 per 100,000 in African Americans and 50 per 100,000 in American Whites. Incidence and prevalence rates were lower in Hispanic Americans than Whites and lower still in Asian Americans. The highest prevalence of sarcoidosis is found in whites in Scandinavia and in persons of African descent in the United States. The relative risk for having sarcoidosis increases significantly if a family member has it as well. In the United States, nearly 20% of African Americans with sarcoidosis have an affected first-degree relative, compared with 5% in whites.

The clinical presentation and severity of sarcoidosis vary among racial and ethnic groups. The disease tends to be more severe in African Americans, whereas Whites are more likely to be asymptomatic at presentation. Extrathoracic manifestations are more common in certain populations, such as ocular and cardiac sarcoidosis in Japanese populations, chronic uveitis and lupus pernio in African Americans, and erythema nodosum in Europeans. There is increasing evidence that genetic polymorphisms affect the risks and manifestations of the disease. This is consistent with the current theory that sarcoidosis does not have a single cause but is the result of an abnormal host (granulomatous) response to one of many potential antigens in a genetically susceptible person.

### Immunopathogenesis

The exact immunopathogenesis of sarcoidosis is unknown, but it is thought to be similar to that of other granulomatous diseases. That is, antigen-presenting cells (APCs), usually either macrophages or dendritic cells, process and present an antigen via a human leukocyte antigen (HLA) class II molecule to T lymphocytes and their receptors. These T lymphocytes are usually of the CD4 T-helper 1 (T<sub>H</sub>1) class. The antigen involved in this reaction is unknown, and there may be many antigens that are each associated with a specific HLA class II molecule and T-cell receptor. This could explain the inability to determine one specific cause of sarcoidosis and the varied phenotypic expressions of the disease.

The interaction of APCs and T lymphocytes activates the APCs to produce tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) and other cytokines. A proliferation of CD4 T<sub>H</sub>1 lymphocytes also ensues, which results in the secretion of interferon- $\gamma$  (IFN- $\gamma$ ), interleukin (IL)-2, IL-12, and other cytokines. These cytokines activate and recruit monocytes and macrophages and transform them into giant cells, which are important building blocks of the granuloma. Recent evidence suggests that an additional factor leading to this series of immunologic events is persistence of antigen, possibly related to production of soluble AA amyloid fibrils, that prevents antigen degradation.

The typical sarcoidosis lesion is a noncaseating (non-necrotic) granuloma. The sarcoid granuloma consists of a compact core of macrophage-derived epithelioid and multinucleated giant cells surrounded by a perimeter of monocytes, lymphocytes, and fibroblasts. Granulomas can resolve spontaneously or with therapy; however, they can also persist and lead to persistent hyalinization and fibrosis. The development of such fibrosis can cause permanent organ damage and in large part determines the prognosis.

### Clinical Features and Clinical Course

#### Pulmonary Sarcoidosis

Between 30% and 60% of patients with pulmonary sarcoidosis are asymptomatic, and the disease is detected incidentally on chest x-ray. Some patients present with nonspecific pulmonary symptoms, such as dyspnea, cough, wheezing, and chest pain. Respiratory failure from sarcoidosis is extremely rare at presentation. Unlike in many other interstitial lung diseases, crackles are rarely heard on chest auscultation. Abnormalities on the chest radiograph occur in more than 90% of patients with pulmonary sarcoidosis. Bilateral hilar adenopathy occurs in 50% to 85% at disease presentation, and 25% to 50% have parenchymal infiltrates. Sarcoid granulomas have a predilection for the bronchovascular bundles, subpleural locations, intralobular septa, and the airways.

A radiographic staging system was developed several decades ago (Table 1). Groups of patients with higher radiographic stages have more-severe pulmonary dysfunction, lower remission rates, and greater mortality. However, there is significant overlap

**TABLE 1** Chest Radiograph Stages of Sarcoidosis

RADIOGRAPHIC STAGE	BILATERAL HILAR LYMPH NODE ENLARGEMENT	PARENCHYMAL DISEASE
I	Yes	No
II	Yes	Nonfibrotic
III	No	Nonfibrotic
IV	No or yes	Fibrotic

Adapted from Judson MA, Baughman RP: Sarcoidosis. In Baughman RP, du Bois RM, Lynch JP, Wells AU, (eds): *Diffuse Lung Disease: A Practical Approach*. London, Arnold, 2004, p 10929.

among these groups, and stages are highly inaccurate predictors of outcomes for individual patients.

Advanced pulmonary stage IV (fibrocystic) sarcoidosis displays destruction of the lung architecture, with upward traction of the hila, lung distortion, upper-lobe volume loss, fibrocystic disease, honeycombed cysts, and decreased lung volumes. Aspergillomas can develop in these large cystic lesions and may be associated with life-threatening hemoptysis. Bronchiectasis from airway distortion also can occur and is an additional potential cause of hemoptysis.

The majority of patients with pulmonary sarcoidosis have a vital capacity of greater than 70% of predicted at diagnosis. Pulmonary function and the chest radiographic findings are often discordant and often do not correlate with symptom severity. In pulmonary sarcoidosis patients with a normal lung parenchyma (stage I), the vital capacity, diffusing capacity, partial pressure of arterial oxygen (PaO<sub>2</sub>) at rest, PaO<sub>2</sub> with exercise, and lung compliance are abnormal in 20% to 40% of cases. Patients with abnormal lung parenchyma have abnormal pulmonary function tests 50% to 70% of the time. Patients with stage IV fibrocystic sarcoidosis tend to have the most severe pulmonary dysfunction.

Sarcoidosis is an interstitial lung disease with a restrictive ventilatory defect often found on spirometry. It is underappreciated, however, that endobronchial involvement is common in sarcoidosis, and therefore airflow obstruction may be the major abnormality found on pulmonary function testing. Wheezing may be the prominent presenting symptom of sarcoidosis, and many cases of sarcoidosis are misdiagnosed as asthma. Airflow obstruction is also common in chronic pulmonary sarcoidosis, where it is caused by airway distortion from fibrosis. The cause of dyspnea in pulmonary sarcoidosis is multifactorial. It may be the result of abnormalities of gas exchange, lung mechanics, weakness of the respiratory muscles, obesity from corticosteroid therapy, pulmonary hypertension, sarcoidosis involvement of the heart.

Only 3% to 5% of patients die of sarcoidosis. In the United States, 75% of these deaths are the result of complications of advanced pulmonary fibrosis including pulmonary hypertension, infection, and life-threatening hemoptysis, which may result from the development of aspergillomas. Despite these potential complications, the overall prognosis is favorable in patients stage IV sarcoidosis with a 10-year survival of over 80% (Nardi). Staging systems, including one that incorporates the lung function, pulmonary artery to ascending aorta diameter ratio > 1, and the presence of > 20% fibrosis on imaging, can be useful predictive of mortality (Walsh). Other organs that result in fatalities from sarcoidosis are the heart and the central nervous system. In Japan, death from sarcoidosis is more commonly caused by cardiac than pulmonary involvement.

Patients who present with Löfgren's syndrome or with asymptomatic bilateral hilar adenopathy on chest radiograph have a good prognosis. African Americans tend to have a worse prognosis than Whites, with lower forced vital capacity and are more likely to develop new organ involvement within 2 years of diagnosis. **Box 1** lists risk factors associated with a poor prognosis.

### Extrapulmonary Sarcoidosis

The extrapulmonary manifestations of sarcoidosis can predominate in many patients. Extrapulmonary disease can affect the prognosis and treatment options for sarcoidosis.

**BOX 1** Factors Associated with a Poor Prognosis in Sarcoidosis

- Symptomatic at presentation
- African American race
- Extrathoracic disease
- Stage II to III versus stage I on chest x-ray
- Age >40 years
- Splenic involvement
- Lupus pernio
- Disease duration >2 years
- Forced vital capacity <1.5 L
- Stage IV chest x-ray or aspergilloma
- Pulmonary hypertension

Data from Judson MA, Baughman RP: Sarcoidosis. In Baughman RP, du Bois RM, Lynch JP, Wells AU, (eds): *Diffuse Lung Disease: A Practical Approach*. London, Arnold, 2004, p 109–29.

The eyes and skin are the most common extrapulmonary organs involved with sarcoidosis. Ocular manifestations occur in 25% to 50% of patients; anterior uveitis is the most common manifestation. Symptoms of anterior uveitis include red eyes, painful eyes, and photophobia. However, one-third of patients with anterior uveitis from sarcoidosis have no ocular symptoms. In addition, an intermediate or posterior uveitis can cause vision problems or can be asymptomatic. For these reasons, all patients with sarcoidosis should undergo an eye examination by an ophthalmologist. Other ocular manifestations of sarcoidosis include conjunctivitis, keratoconjunctivitis sicca (dry eyes), scleritis, and optic neuritis.

Skin lesions in sarcoidosis can be classified into two categories: specific lesions that demonstrate noncaseating granulomas on biopsy and nonspecific lesions that do not (**Figure 1**). The specific skin lesions are often papular and have a predilection for areas of previous scars and tattoos. Lupus pernio is a type of specific skin lesion causing disfiguring lesions on the face, often with erythema and significant induration. These lesions have a predilection for the nose, cheeks, medial and lateral sides of the eyes, and lateral sides of the mouth. Lupus pernio lesions are relatively recalcitrant to therapy and often respond only partially to corticosteroids. The most common nonspecific skin lesion is erythema nodosum, which is often seen with an acute sarcoidosis presentation of fever, arthritis (especially in the ankles), pulmonary symptoms, and bilateral hilar adenopathy on chest radiograph. This syndrome is known as *Löfgren's syndrome* and tends to have a good long-term prognosis.

Cardiac and neurologic sarcoidosis can be life threatening and are therefore important to recognize. Cardiac involvement is detected clinically in 5% of sarcoidosis patients during life but in 25% at autopsy. Cardiac sarcoidosis can cause left ventricular dysfunction, cardiac arrhythmias, and sudden cardiac death. All patients with sarcoidosis should be screened for cardiac sarcoidosis. Such screenings should include an electrocardiogram (ECG), as well as eliciting symptoms of left ventricular dysfunction (e.g., orthopnea, peripheral edema) and cardiac arrhythmia (e.g., palpitations, sensation of skipped heartbeats, syncope). Transthoracic echocardiography (TTE) and Holter monitoring have been recommended by some as appropriate additional screening tests. Patients with either significant symptoms, abnormal ECG, or TTE should undergo more definitive testing for the diagnosis of cardiac sarcoidosis. A cardiac magnetic resonance imaging (MRI) provides both diagnostic and prognostic data and is recommended over cardiac positron emission tomography as the initial test of choice; however, this may vary depending on local expertise and availability. The diagnosis of cardiac sarcoidosis is typically made noninvasively, based on a combination of a typical clinical presentation coupled with the detection of characteristic findings on advanced imaging after other possible etiologies have been excluded. Because myocardial involvement is patchy, endomyocardial biopsy is diagnostic in less than 25% and is not commonly performed to make the diagnosis of cardiac sarcoidosis.

**Figure 1** Skin lesions of sarcoidosis. (A) Sarcoid lesions may occur at any site, and they may take nodular, papular, or plaque forms. Biopsy is often necessary for diagnosis. (B) *Lupus pernio* is the term used to describe a dusky-purple infiltration of the skin of the nose, cheeks, or ears in chronic sarcoidosis. (From Forbes CD, Jackson WF: *Color Atlas and Text of Clinical Medicine*, 3rd ed. London, Mosby, 2003, with permission).

Clinically apparent neurosarcoidosis occurs in less than 10% of sarcoidosis patients. Palsy of the seventh cranial nerve is the most common manifestation of neurosarcoidosis, and it often predates the diagnosis of the disease. Sarcoidosis can affect any part of the peripheral nervous system and central nervous system (CNS) and can cause a cranial nerve palsy, mononeuropathy or polyneuropathy, aseptic meningitis, seizures, mass lesions in the brain and spinal cord, hydrocephalus, and encephalopathy. Brain and spinal cord MRI with contrast is the imaging test of choice to evaluate potential CNS sarcoidosis in patients with a compatible clinical presentation.

Sarcoidosis causes clinically apparent peripheral lymphadenopathy in more than 10% of patients. The spleen may be involved in up to 50% of patients, but it is usually asymptomatic and rarely causes hypersplenism.

Bone involvement is occasional, usually occurring as small cysts or cortical defects found in the small bones of the hands and feet. An acute sarcoid arthritis often is present at disease onset and has a good prognosis. This is commonly found in the ankles of patients who present with Löfgren's syndrome. Chronic sarcoid arthritis is rare. It is usually a nondestructive arthropathy of the shoulders, wrists, knees, ankles, and small joints of the hands and feet.

Sarcoidosis of the sinuses is underappreciated. It can occur in the nasopharynx, hypopharynx, larynx, or any of the sinuses and is known as *sarcoidosis of the upper respiratory tract*. Sarcoidosis of the upper respiratory tract is often relatively recalcitrant to therapy.

Histologic evidence of hepatic sarcoidosis is present in 50% to 80% of sarcoidosis patients, although most of these patients are asymptomatic and have normal liver function tests. Hepatomegaly, abdominal pain, and pruritus are the most common symptoms associated with hepatic sarcoidosis but are present only in 15% to 25% of patients with hepatic involvement. Elevation of the serum alkaline phosphatase is the most common liver function test abnormality.

Hypercalcemia or hypercalciuria leading to nephrolithiasis, resulting in renal dysfunction, can occur with sarcoidosis. These phenomena are the result of the enzyme 1 $\alpha$ -hydroxylase in activated macrophages that convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the active form of the vitamin. This results in increased gut absorption and increased renal excretion of calcium that can cause nephrolithiasis. Patients with sarcoidosis-associated hypercalcemia typically have low 25-hydroxyvitamin D levels with 1,25-dihydroxyvitamin D levels that are elevated or at the upper limits of normal in combination with a low or low-normal parathyroid hormone.

Sarcoidosis rarely involves the thyroid, kidney, breast, GU tract and GI tract.

Patients can have constitutional symptoms such as fever, night sweats, weight loss, malaise, and fatigue at presentation. These symptoms occasionally are associated with hepatic sarcoid

involvement but may be a sign of the systemic nature of the disease, presumably from cytokine release, rather than specific organ involvement. A small fiber neuropathy may occur with sarcoidosis and cause pain or autonomic dysfunction.

### Diagnosis and Initial Workup

The diagnosis of sarcoidosis requires a compatible clinical picture, histologic demonstration of noncaseating granulomas, and exclusion of other diseases capable of producing a similar histologic and clinical picture. It is prudent to bear a healthy degree of skepticism in the diagnosis and evaluate the patient closely for additional clues supporting an alternative diagnosis. Mycobacterial and fungal diseases must always be considered as alternative causes of granulomatous inflammation. Therefore stains and cultures of tissue specimens for mycobacteria and fungi always should be obtained when the diagnosis of sarcoidosis is considered. Hypersensitivity pneumonitis, a granulomatous lung disease from inhalation of bioaerosols, is another disease that may mimic sarcoidosis. Bioaerosols from hot tubs and birds are the most common causes of hypersensitivity pneumonitis, and clinicians should specifically inquire about these two exposures in individuals who are being evaluated for sarcoidosis. Sarcoidosis is a systemic disease, so signs or symptoms of extrathoracic disease such as uveitis, skin lesions, or an elevated serum alkaline phosphatase concentration should be sought. All patients should be evaluated for "dangerous" extrapulmonary manifestations, including cardiac, CNS, renal and ocular involvement, as well as treatment-refractory sarcoidosis associated hypercalcemia.

It is prudent to select a biopsy site associated with less morbidity, such as the skin if a lesion is present. Transthoracic needle aspiration under ultrasound guidance (EBUS-TBNA) of mediastinal lymph nodes via bronchoscopy has a high yield for the diagnosis of pulmonary sarcoidosis and has supplanted mediastinoscopy at many centers. Transbronchial lung biopsy has a diagnostic yield of 40% to more than 90% in pulmonary sarcoidosis. Endobronchial biopsy has a 40% to 60% sensitivity and adds to the yield of transbronchial biopsy.

Bronchoalveolar lavage (BAL) with examination of lymphocyte populations has been used in the evaluation of possible pulmonary sarcoidosis. In sarcoidosis, there is an increased number of BAL lymphocytes, and these are predominantly CD4<sup>+</sup>. It has been proposed that an increase in BAL lymphocytes and a BAL CD4/CD8 ratio greater than 3.5 makes the diagnosis of sarcoidosis highly likely.

Although serum angiotensin-converting enzyme (ACE) often is elevated in active sarcoidosis, the specificity and sensitivity of this test are inadequate for it to be used diagnostically. Serum ACE may be used as supportive evidence for the diagnosis, and it also may be used in some instances to follow disease activity.

Gallium-67 (<sup>67</sup>Ga) scanning is cumbersome because it takes several days to complete and is infrequently used as a diagnostic test. However, bilateral hilar uptake and right paratracheal uptake (lambda sign) coupled with lacrimal and parotid uptake (panda sign) with <sup>67</sup>Ga strongly suggest a diagnosis of sarcoidosis. Fluorodeoxyglucose PET scanning (outside the CNS) and MRI studies using contrast (CNS and cardiac) have essentially replaced <sup>67</sup>Ga scanning for detecting sarcoidosis activity.

Ideally, the diagnosis of sarcoidosis requires a demonstration of noncaseating granulomas in at least one organ. However, according to recently published guidelines, certain clinical presentations are so specific for the diagnosis of sarcoidosis that biopsy may not be necessary. Extreme caution must be used in these situations to ensure that there is no clinical information that would suggest an alternative diagnosis that should prompt a tissue biopsy. Clinical or laboratory findings that strongly support the diagnosis of sarcoidosis without a tissue biopsy are listed in [Box 2](#).

In addition to screening for neurologic (symptoms) and cardiac (symptoms, ECG) involvement, all patients should undergo evaluation by an ophthalmologist (even in the absence of ocular symptoms). Laboratory testing to evaluate for other organ involvement at the time of diagnosis should include serum calcium, creatinine, alkaline phosphatase, and a CBC with differential.

**BOX 2** Clinical or Laboratory Findings That Strongly Support a Diagnosis of Sarcoidosis Without a Tissue Biopsy

- Löfgren syndrome
- Heerfordt syndrome (uveoparotid fever)
- Asymptomatic bilateral hilar adenopathy on chest x-ray
- <sup>67</sup>Ga scan showing a lambda sign and a panda sign

## Treatment

Therapy is often not mandatory for sarcoidosis because the disease can remit spontaneously. Systemic ant sarcoidosis therapy is indicated for potentially dangerous disease and for disease causing significant quality-of-life impairment. Potentially dangerous disease includes neurosarcoidosis, cardiac sarcoidosis, renal sarcoidosis, hypercalcemia that does not respond to dietary measures, and ocular sarcoidosis that does not respond to topical (eyedrop) therapy. Therapy should also be considered when the disease is progressive and at risk of resulting in long-term morbidity. In general, treatment is discouraged for asymptomatic stage I pulmonary sarcoidosis, elevations of serum liver function tests, or specific levels of ACE.

The decision to treat sarcoidosis can be problematic, because the disease has a variable prognosis that must be weighed against the potential side effects of therapy. It is often most prudent to monitor patients without therapy if they are asymptomatic or have only mild organ dysfunction. For pulmonary sarcoidosis, asymptomatic patients and those with mild disease that might spontaneously remit usually are not treated. For patients with clinical findings that predict spontaneous remission (e.g., erythema nodosum), the benefits of treatment often are offset by the toxicity of therapy. Often these patients can be managed with supportive therapy such as NSAIDs for arthralgias and fever and bronchodilators and inhaled corticosteroids for wheezing and cough.

It is recommended that patients with mild to moderate pulmonary sarcoidosis be observed for 2 to 6 months, if possible. Patients who improve will have avoided the toxicity of corticosteroids, and patients who deteriorate over this period should be considered for treatment. Patients with pulmonary dysfunction who neither improve nor deteriorate during the observation period may be given a corticosteroid trial, or they may be observed further. Patients with severe pulmonary dysfunction or pulmonary symptoms causing significant impairment should be treated.

Corticosteroids often are used to treat sarcoidosis, but the dose, duration of therapy, and methods by which one can assess effectiveness have not been standardized. Topical corticosteroid therapy should be used whenever possible in an attempt to minimize systemic complications. This includes corticosteroid eye drops for anterior sarcoid uveitis and corticosteroid creams and injections for localized skin lesions. Prolonged use of topical steroids for ocular and cutaneous sarcoidosis is associated with an increased risk of side effects (glaucoma, cataracts; skin discoloration and thinning). Recent guidelines published by the European Respiratory Society (ERS) provides some guidance to the dosing of oral steroid regimens. Pulmonary sarcoidosis usually is treated initially with 20 mg/day of prednisone or its equivalent. Higher doses may be required for neurosarcoidosis and cardiac sarcoidosis. Some advocate for doses as high as 1 mg/kg/day for cardiac and neurologic involvement, although this should not be considered standard practice for all presentations since studies have not consistently shown a clear benefit. Regardless of the starting dose, the patient should be evaluated within 2 to 12 weeks for a response with the goal of tapering corticosteroids down to the lowest effective dose (ideally <10 mg/day) as quickly as possible. This dose is usually continued for at least 6 months. Patients failing to respond to therapy within 3 months are unlikely to respond to a more protracted course of therapy or a higher dose.

The relapse rate after corticosteroid therapy is withdrawn may be as high as 70%, and therefore patients need to be followed closely as the corticosteroid dose is tapered and discontinued. In some patients, there may be recurrent relapses requiring long-term low-dose therapy. On occasion, the chronic prednisone

dose needed to prevent relapse is less than 5 mg/day. Patients who relapse after corticosteroids have been withdrawn can be retreated with corticosteroids. However, corticosteroid-sparing agents should be considered in patients who are unable to taper the corticosteroids to less than 10 mg/day to control the disease.

Methotrexate (Rheumatrex)<sup>1</sup> and hydroxychloroquine (Plaque-nil)<sup>1</sup> are the most-studied alternative sarcoidosis medications. They are usually used as corticosteroid-sparing agents but at times can be used as replacement therapy. Methotrexate is most useful for pulmonary, skin, joint, and eye sarcoidosis. The goal weekly dose is 15 to 20 mg. Hydroxychloroquine given once or twice daily is often used for sarcoidosis of the skin, joints, and nerves and for hypercalcemia from sarcoidosis. Due to risk of retinal toxicity, most patients should not receive a daily dose >5 mg/kg/day or >400 mg, whichever is lower. Azathioprine (Imuran)<sup>1</sup> is also useful as a second line therapy for sarcoidosis. The initial dose is typically 25 to 50 mg once a day, which can be increased by 50 mg every 2 to 4 weeks as tolerated to a goal maintenance dose of 2 mg/kg once daily. Leflunomide (Arava)<sup>1</sup> has also been shown to be useful in the treatment of pulmonary and extrapulmonary sarcoidosis. Monoclonal antibodies against TNF- $\alpha$ , such as infliximab (Remicade)<sup>1</sup> and adalimumab (Humira)<sup>1</sup>, are useful agents in sarcoidosis patients with severe disease and/or who fail to respond to the aforementioned treatments. Minocycline (Minocin)<sup>1</sup> and doxycycline (Vibramycin)<sup>1</sup> (100 mg twice daily) may be useful for skin sarcoidosis. Cyclosporine is ineffective for pulmonary sarcoidosis; cyclophosphamide (Cytoxan)<sup>1</sup> may have a potential role in refractory neurosarcoidosis.

Therapy should also be considered for the non-granulomatous aspects of the disease. Sarcoidosis-associated small fiber neuropathy may respond to medications for neuropathic pain, monoclonal antibodies against TNF- $\alpha$ , or intravenous immunoglobulin<sup>1</sup>. Sarcoidosis-associated fatigue may benefit from a physical training program, neurostimulants, or monoclonal antibodies against TNF- $\alpha$ .

<sup>1</sup>Not FDA approved for this indication.

Laura Elyse Shevy, MD; and Parisa Mortaji, MD

### CURRENT DIAGNOSIS

- Latent tuberculosis (TB) infection is diagnosed in an asymptomatic person previously exposed to TB who has a positive tuberculin skin test or interferon- $\gamma$  release assay.
- A positive tuberculin skin test (TST) or interferon- $\gamma$  release assay (IGRA) does not distinguish latent tuberculosis infection (LTBI) from TB disease.
- The gold standard for diagnosing active pulmonary TB disease is acid fast bacilli (AFB) culture on respiratory specimens; AFB smear and nucleic acid amplification testing are also useful in diagnosis.
- All patients with LTBI or TB disease should undergo HIV testing.

### CURRENT THERAPY

- LTBI: rifamycin-based regimen for 3 to 4 months.
- Treatment of TB disease should be done in conjunction with the local public health department.
- Drug-susceptible pulmonary TB disease: isoniazid (INH) + rifampin (RIF) + pyrazinamide (PZA) + ethambutol (EMB) for 2 months, followed by 4 months of INH + RIF.
- Drug-susceptible extrapulmonary TB disease is typically treated as per pulmonary TB disease but treatment and duration vary based on anatomic site(s) involved.
- Treatment of drug-resistant TB disease should be done in consultation with a TB expert.

### Overview

Mycobacterial diseases occur worldwide and cause significant morbidity and mortality. These organisms comprise *Mycobacterium tuberculosis* complex, the causative pathogen in tuberculosis disease and latent tuberculosis infection; *Mycobacterium leprae* complex, the etiologic agent of Hansen's disease (leprosy); and around 80 pathogenic species of nontuberculous mycobacteria. This chapter mainly focuses on the diagnosis and management of tuberculosis, with a brief overview of Hansen's disease, and some infections caused by nontuberculous mycobacteria.

### Tuberculosis

*Mycobacterium tuberculosis*, the bacteria responsible for tuberculosis (TB) disease and latent tuberculosis infection (LTBI), affects people in every country. It is the leading cause of infectious diseases mortality by a single pathogen worldwide, and it is the ninth leading cause of death overall. An estimated 2 billion people, or 25% of the global population, are thought to be infected with *M. tuberculosis*. The majority of individuals who become infected remain asymptomatic and develop LTBI. Risk factors for TB infection include overcrowding, congregate healthcare and incarceration facilities, poverty, human immunodeficiency virus (HIV) and AIDS, malnutrition, excessive alcohol use, tobacco use, drug use, silicosis, end-stage renal disease, diabetes mellitus, malignancy, and other immunosuppressive disorders and medications. TB disproportionately affects racial and ethnic minorities and people experiencing homelessness.

### Pathophysiology

*M. tuberculosis* is an aerobic, non-spore forming, acid-fast staining, slow-growing bacillus. There are at least nine species in the

genus *Mycobacterium* that comprise *M. tuberculosis* complex, although not all are pathogenic to humans. The majority of TB infections worldwide are caused by *M. tuberculosis sensu stricto*; in West Africa, up to 50% of cases are caused by *M. africanum*. Humans are the only known reservoir of *M. tuberculosis*. Transmission occurs from person to person via aerosolized droplets, which can remain suspended in the air for several hours. For this reason, the proximity, frequency, and duration of exposure are some of the most important factors in infection transmission. Other general factors include immune status of the exposed individual, infectiousness of the person with TB disease, and environmental factors.

Primary infection occurs after inhalation of the tubercle bacilli, which establish in the midlung zone terminal air spaces and are engulfed by alveolar macrophages. When the tubercle bacilli destroy the macrophages, pneumonitis develops. The bacilli are released and travel via lymphatics to regional lymph nodes and can then spread hematogenously throughout the body. The most commonly affected sites that uptake infected cells and allow for bacilli multiplication include the apical posterior lung, lymph nodes, kidneys, long bones, vertebrae, and brain/eyes/meninges. These sites may become nidi of infection either during the acute infection or after a latent period.

The majority of infections are contained through the host's cell-mediated immune response 3 to 9 weeks after transmission. The initial immunologic cascade encapsulates the bacilli and creates granulomas—protective shells that keep the tubercle bacilli in check. This leads to infection latency. Such people with latent TB infection are not symptomatic of TB disease and are not contagious to others.

A minority of people may develop significant infection in the area of initial pulmonary transmission (the Ghon complex) and necrosis and radiographically visible calcification of draining regional lymph nodes (the Ranke complex). This may progress to pneumonia, also known as “progressive primary disease,” and occurs most often in children, older adults, and patients living with HIV.

Progression from LTBI to TB disease occurs in about 5% to 10% of immune competent patients, usually within the first 2 years after infection or under certain medical conditions. Tubercle bacilli multiply rapidly and when no longer contained by the immune response cause TB disease. Pulmonary TB disease is most commonly seen in the lung apices (Figure 1). Reactivation of infection can occur throughout the body, with common extrapulmonary infections including pleural empyema, lymphadenitis, genitourinary infection, vertebral osteomyelitis, meningitis, uveitis, and pericarditis.

### Prevention

Prevention of TB disease transmission is mainly through rapid identification and airborne isolation of patients with suspected or confirmed disease and prompt initiation of treatment. In countries with a high prevalence of TB, the bacille Calmette-Guerin (BCG) vaccine is often administered. This live, attenuated vaccine is derived from *Mycobacterium bovis* and has shown to be effective at preventing severe infection, mainly in children.

### Clinical Manifestations

TB can cause two conditions: latent TB infection and active TB disease. By definition, a person with LTBI has no symptoms of TB disease. TB disease may be pulmonary or extrapulmonary. Clinical features of pulmonary TB disease may include fever, drenching night sweats, weight loss, anorexia, malaise, pleuritic chest pain, productive cough, and hemoptysis, typically with several weeks of symptoms. Clinical manifestations of extrapulmonary TB disease are myriad and are manifestations of the involved organ systems as outlined above.

### Principles of Diagnosis

Of utmost importance, latent TB must be distinguished from active TB disease. Treatment for latent TB infection and TB

**Figure 1** Posteroanterior (A) and left lateral (B) chest x-rays showing typical reactivation (postprimary) tuberculosis in the adult. Bilateral upper lobe fibrocavitary disease affects predominantly the apical and posterior segments of the right upper lobe. From Weller PF, Guarrant RL, Walker DH: *Tropical Infectious Diseases: Principles, Pathogens and Practice*, 3rd ed., Elsevier; 2011.

disease differ greatly. Treating for LTBI when active TB disease is present can induce drug resistance, lead to increased morbidity and mortality, and potentially increase risk of transmission. Typically a test for previous TB exposure is performed—the tuberculin skin test (TST) and/or an interferon- $\gamma$ -release assay (IGRAs). The following must be performed: a full history and physical to evaluate current symptoms and signs of disease; past medical and social history to evaluate for risk factors for infection and progression from infection to TB disease if infection is present; medications for possible drug–drug interactions if treatment is warranted; and so on. A chest radiograph should be performed to evaluate for active pulmonary involvement (i.e., airspace opacities, pleural effusions, parenchymal cavitary lesions). Sputum for other respiratory specimens, and/or sampling of other infected sites, is performed for diagnostic testing as outlined in the following.

## Diagnosis

### Latent Tuberculosis Infection

There are two methods to diagnose LTBI: the TST (Tubersol) and IGRAs. TST is an intradermally injected protein precipitate of heat-inactivated tubercle bacilli—purified protein derivative (PPD)—or tuberculin. In people with previous TB infection and cell-mediated immunity, intradermal PPD induces a delayed-type hypersensitivity reaction characterized by induration. The test is interpreted via transverse diameter measurement of the induration (not erythema) after 48 to 72 hours. The TST therefore requires two clinical visits for TST placement and subsequent interpretation. Table 1 outlines interpretation of the TST based on risk group. False positive results can occur in people who have received BCG vaccination or who have infections with nontuberculous mycobacteria (NTM).

IGRAs are blood tests and measure T-cell release of interferon- $\gamma$  in response to stimulation with highly TB-specific antigens. False positive results do not occur from previous BCG vaccination and are much less likely to occur in setting of NTM infections, which make them more specific than TST. Two commercially available IGRAs include the QuantiFERON-TB Gold Plus (QFT-Plus) and the T-SPOT®TB test (T-Spot). If available and feasible, the IGRA should be used over TST, especially if the patient has a history of receiving the BCG vaccine, is unlikely to return to have the TST interpreted, or has a high likelihood of TB infection.

Due to limited data on IGRA testing reliability in children, TST is the recommended method of testing for children under 5 years old. The American Academy of Pediatrics (AAP) recommends that either a TST or an IGRA be used in children 2 years of age and older. For children previously vaccinated with BCG—regardless

of age—IGRA is preferred to avoid a false-positive TST result caused by the previous BCG vaccination.

Of extreme importance to recognize is that neither TST nor IGRA can distinguish TB disease from LTBI. A true positive TST or IGRA only indicates the person has, at some point, been exposed to and developed some cell-mediated immunity against *M. tuberculosis*. TST and IGRAs cannot be used alone to diagnose active TB disease.

### Active Tuberculosis Disease

Active pulmonary TB disease is diagnosed in the presence of symptoms and/or signs of TB disease and by obtaining three sputum specimens 8 to 24 hours apart for acid-fast bacilli (AFB) smears, cultures, and nucleic acid amplification testing when available. Rapid molecular rifampin (Rifadin, Rimactane)/INH susceptibility testing should be performed, when available, for specific patient populations. *M. tuberculosis* typically takes about 3 to 8 weeks for visible growth on solid media and 10 to 20 days for liquid broth culture growth. Nucleic acid amplification testing (NAAT) uses real-time polymerase chain reaction (PCR) amplification to aid in detection of *M. tuberculosis* genetic material. However, culture remains the gold standard for diagnosis, and susceptibility testing should be performed on the initial positive culture. If a person cannot produce sputum, hypertonic saline can be used to induce sputum production. As a last resort, flexible bronchoscopy can be pursued to obtain respiratory specimens. If a respiratory specimen is positive by AFB smear but negative by NAAT, it is unlikely that the positive smear result represents active TB disease. In a patient in whom suspicion for TB disease is intermediate-high, if a respiratory specimen AFB smear is negative but NAAT is positive, a presumptive diagnosis of TB disease can be given. However, a negative NAAT is not sufficient to exclude pulmonary TB disease.

Active extrapulmonary disease requires sampling of potentially affected fluid or tissues. Cell counts and chemistries should be measured on amenable fluid specimens including pleural, cerebrospinal (CSF), ascitic, and synovial fluids. Adenosine deaminase can be measured on pleural, CSF, ascitic, and pericardial fluids. AFB smear microscopy, culture, NAAT, and histopathology should be performed on available specimens. False negative AFB smears and NAAT are not uncommon and should not be used to exclude diagnosis of active TB disease.

### Principles of Treatment

Treatment of both LTBI and TB disease should be patient-centered, with care tailored to the patient's social situation,

**TABLE 1** Interpreting Tuberculin Skin Testing (TST) Results

RISK OF INFECTION	DEGREE OF INDURATION	POSITIVITY BY RISK GROUP
	≥5 mm	<ul style="list-style-type: none"> <li>• People living with HIV</li> <li>• Recent contacts of people with infectious TB disease</li> <li>• People who have fibrotic changes on chest radiograph</li> <li>• Recipients of solid organ transplants</li> <li>• Other immunosuppressed patients (e.g., patients on prolonged therapy with corticosteroids &gt;15 mg per day of prednisone, patients on TNF-α antagonists)</li> </ul>

medical comorbidities, and clinical condition. Directly observed therapy (DOT), the practice of observing the patient physically ingest antituberculous medications, is a widely implemented standard of practice in TB programs in the United States and has been shown to significantly improve treatment success compared with self-administered therapy. Thus DOT is recommended for routine treatment of patients with all forms of TB as feasible.

The purpose of treating LTBI is to prevent progression to TB disease in those individuals at high risk for infection and progression to disease.

The objectives of treating TB disease are to cure the individual patient, decrease risk of morbidity and mortality from disease, reduce transmission of *M. tuberculosis* to other people, and prevent development of drug resistance during antituberculous therapy.

The treatment of multidrug resistant (MDR) TB disease (defined as resistance to INH and rifampin [Rifadin, Rimactane]) and extensively drug resistant (XDR) TB disease (resistance to INH, rifampin [Rifadin, Rimactane], levofloxacin [Levaquin<sup>1</sup>], and at least one second-line injectable agent) is complicated, and therapy should be pursued in consultation with a TB expert.

## Treatment

### Latent Tuberculosis Infection

The decision to initiate prophylactic therapy for latent TB infection is a risk-benefit decision based on the patient's likelihood of infection and likelihood of progression from LTBI to TB disease. The risk of progression from LTBI to TB disease in an immunocompetent host is 5% to 10% over a lifetime. People with diabetes have a 30% lifetime risk. People living with HIV have a 7% to 10% risk per year of progressing from LTBI to TB disease. Studies have demonstrated benefit in decreasing incidence of TB disease by treating LTBI in people who are under 5 years old, living with HIV, otherwise immunosuppressed (e.g., corticosteroid use >15 mg/prednisone or equivalent/day, use of immunosuppressive drugs such as tumor necrosis factor (TNF)-α inhibitors), household contacts of or have had recent exposure to a person with active TB disease, residents of high-risk congregate health facilities, persons with abnormal chest radiographs consistent with previous TB, and people with silicosis, among other conditions. Treatment regimens are outlined below. It is advisable to consult

a TB expert if the patient is a contact of an individual with known drug-resistant TB disease.

In 2020, the National Tuberculosis Controllers Association (NTCA) and Centers for Disease Control and Prevention (CDC) updated guidelines for treatment of LTBI for persons living in the United States. There are now three preferred regimens, all rifamycin-based, of 3 to 4 months' duration. These regimens are preferred due to their effectiveness, safety profile, and high treatment success rate. Some potential downsides of these regimens include increased cost over alternatives, adverse drug effects and potential for significant drug-drug interactions (including warfarin, oral contraceptives, antifungals, HIV antiretroviral therapy, among others). If drug-drug interactions preclude use of a preferred regimen, alternative regimens of daily isoniazid (Nydravid) (INH) monotherapy for 6 or 9 months' duration can be used. Daily INH regimens are effective, but caution should be used due to the increased risk of hepatotoxicity, and the potential to induce drug resistance from the longer treatment duration. From 25 to 50 mg of pyridoxine (vitamin B6)<sup>1</sup> should be added for those people at risk of developing peripheral neuropathy such as pregnant women or people with diabetes mellitus, chronic kidney disease, malnutrition, HIV, alcohol use disorder, or other conditions; 100 mg dose is recommended for people who already have peripheral neuropathy. If daily INH cannot be used, rifabutin (Mycobutin)<sup>1</sup> may substitute for rifampin (Rifadin, Rimactane) in one of the three preferred regimens, as the former has fewer drug interactions (Table 2).

### Drug-Susceptible Pulmonary Tuberculosis Disease

The preferred treatment regimen for drug-susceptible pulmonary TB disease includes an intensive treatment phase with 2 months of isoniazid (Nydravid) (INH), rifampin (Rifadin, Rimactane) (RIF), pyrazinamide (Zinamide) (PZA), and ethambutol (Myambutol) (EMB), followed by a continuation phase of 4 months of INH and RIF. If drug susceptibilities are available prior to starting treatment, EMB can be omitted; as soon as susceptibility to INH and RIF are confirmed, ethambutol (Myambutol) can be discontinued. The CDC recommends continuous daily dosing of the above agents rather than intermittent dosing for both the intensive and continuation phase of treatment. Pyridoxine,<sup>1</sup> or

**TABLE 2** Preferred Treatment Regimens for Latent Tuberculosis Infection

PREFERRED REGIMENS	DURATION OF THERAPY	DOSAGES	FREQUENCY OF ADMINISTRATION
INH* + RPT	3 months	Adults and children aged >12 years: INH: 15 mg/kg; 900 mg maximum dose RPT: 10–14 kg: 300 mg 14–25 kg: 450 mg 25–32 kg: 600 mg 32–49.9 kg: 750 mg ≥50 kg: 900 mg maximum dose Children ages 2–11 years: INH: 2.5 mg/kg; maximum dose 900 mg RPT: as above	Once weekly
RIF	4 months	Adults: 10 mg/kg, maximum dose 600 mg Children: 15–20 mg/kg, maximum dose 600 mg	Daily
INH + RIF	3 months	Adults: INH: 5 mg/kg, maximum dose 300 mg RIF: 10 mg/kg, maximum dose 600 mg Children: INH: 10–20 mg/kg, maximum dose 300 mg RIF: 15–20 mg/kg, maximum dose 600 mg	Daily

INH, Isoniazid (Nydrazid); RIF, rifampin (Rifadin, Rimactane); RPT, rifapentine (Priftin)

\*Vitamin B6 (pyridoxine)<sup>1</sup> is given in conjunction with INH for those at risk for developing—or already suffering from—peripheral neuropathy per text above.

<sup>1</sup>Not FDA approved for this indication.

Adapted from Sterling TR, Njie G, Zenner D, et al: Guidelines for the treatment of latent tuberculosis infection: Recommendations from the National Tuberculosis Controllers Association and CDC, 2020. *MMWR Recomm Rep* 69(No. RR-1):1–11, 2020.

vitamin B6, should be given throughout the duration of INH administration as discussed above. It is highly advised these regimens are given by DOT. If this frequency of DOT is difficult to achieve, alternative regimens can be used as outlined in the Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Clinical Practice Guidelines: Treatment of Drug-Susceptible Tuberculosis.

#### Drug-Susceptible Extrapulmonary Tuberculosis Disease

The treatment regimens for drug-susceptible extrapulmonary TB disease largely follow that of pulmonary TB disease with 2 months of intensive phase INH, RIF, PZA, EMB, followed by a continuation phase with INH and RIF. The duration of the continuation phase, however, depends on anatomic site involved. Disease that is treated with a standard 6-month regimen, as for pulmonary TB disease above, include tuberculous pericarditis, lymphadenitis, pleural, genitourinary, peritoneal, military, and other disseminated disease.

There has been some controversy in the literature about adjunctive corticosteroid use for TB pericarditis to prevent development of constrictive pericarditis: current ATS/CDC/IDSA guidelines do not recommend routine use of steroids in TB pericarditis, but consideration to steroid use can be given to patients with large pericardial effusion, high levels of inflammatory cells/markers in the pericardial fluid, or those with early signs of constriction.

TB meningitis is treated for 2 months with the standard four-drug regimen (INH, RIF, PZA, EMB) in adults, followed by 7 to 10 months of INH and RIF for drug-susceptible disease. In pediatric patients, the American Academy of Pediatrics recommends initial 2 months of treatment with INH, RIF, PZA, and either ethionamide (Trecator), if possible, or an aminoglycoside, followed by INH and RIF for the 7 to 10 month consolidation phase. Optimal treatment duration of TB meningitis is not well known. Serial lumbar punctures may be of utility to help define total duration. Adjunctive steroids are recommended in the acute illness as they have been demonstrated to provide mortality benefit in clinical trials; steroids should be tapered over 6 to 8 weeks.

Bone and joint infection is typically treated with 9 months total duration, up to 12 months in setting of extensive hardware. Spinal TB disease with TB meningitis is treated as for meningitis above.

#### Multidrug-Resistant TB

Resistance in *M. tuberculosis* develops through spontaneous point mutations. MDR TB is defined as that which is resistant to both INH and RIF. XDR TB is a subset of MDR TB with additional resistance to a fluoroquinolone and a second-line injectable agent. MDR and XDR TB can be acquired as the primary infection, or resistance can develop while on therapy for a previously susceptible TB isolate. Acquisition of primary drug-resistant TB is influenced by geographic area where infection was acquired. Risk factors for development drug resistance while on therapy include incomplete medication adherence, inadequate drug absorption or dosing, and single-drug treatment. Consultation with a TB expert is advised if MDR or XDR TB is suspected or confirmed.

#### Tuberculosis Disease in Special Circumstances

##### Sputum/Culture-Negative Tuberculosis

Sputum/culture-negative pulmonary TB is defined as failure to isolate organisms in the setting of high clinical suspicion of disease. Potential etiologies for negative cultures include low bacillary populations, inadequate sputum specimens, or overgrowth of cultures with other microorganisms. If clinical suspicion is high, treatment should be initiated with reevaluation every 2 to 3 months.

##### Tumor Necrosis Factor- $\alpha$ Inhibitors

Patients being treated with TNF- $\alpha$  inhibitors are at increased risk for reactivation of latent TB and death from disseminated TB disease. Patients who are being considered for initiation of these drugs should have clinical evaluation for TB exposure/disease, IGRA testing (or TST if IGRA is not available), and radiographic chest imaging prior to initiation of anti-TNF- $\alpha$  therapy. All patients should receive treatment for LTBI if identified, and if no absolute contraindications exist, TNF- $\alpha$  inhibitor initiation delayed at least a month into the start of LTBI treatment if feasible.

##### Patients Living With HIV

Patients living with HIV are at high risk for developing TB infection; with a 20- to 40-fold increased risk compared with the general population. TB infection can occur at any CD4 T

lymphocyte cell count, and a direct correlation between degree of immunodeficiency and TB infection risk exists. There are many potential complications of treating TB in patients living with HIV, and it is highly advised that treatment be done in conjunction with a specialist in treating HIV and TB. There are numerous drug–drug interactions between rifamycins and many classes of HIV antiretroviral therapy (ART). Patients with HIV-related TB disease are at risk for immune reconstitution inflammatory syndrome (IRIS), a paradoxical worsening of signs and symptoms of infection after initiation of ART. Finally, even with treatment, these patients are at increased risk for reinfection with TB compared with the general population.

The timing of ART initiation for HIV in setting of TB infection is complicated and beyond the scope of this text, and management by an HIV/TB treatment expert is highly advised. At all CD4 counts, people with HIV without active TB disease have significantly improved outcomes with early initiation of ART. However, there are some opportunistic infections for which early initiation of ART is potentially injurious, including patients with both HIV and TB meningitis.

When TB occurs in patients already on ART, treatment for TB should be started immediately and ART modified to prevent any drug interactions while still working toward virologic suppression.

In patients who have already been on ART, the standard 6-month TB treatment regimen should be used for drug-susceptible TB (Table 3). If ART has not yet been initiated, the continuation phase of TB therapy should be extended by 3 months, for a total of 7 months. ART should be initiated in the first 2 weeks if the CD4 count is <50 cells/uL and by 8 to 12 weeks if the CD4 count is 50 or greater, the exception being in the setting of TB meningitis as above, in which case ART should be held until 8 weeks of TB treatment have been completed.

The most up-to-date TB treatment recommendations for persons living with HIV infection can be found in the AIDSinfo guidelines “Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV.” Consultation with, and evaluation and management by, an expert in HIV and TB treatment is highly advised for patients with these complicated clinical presentations.

### Monitoring and Complications

All patients diagnosed with LTBI or TB disease should have baseline HIV testing. If the patient has risk factors for hepatitis B and/or C, baseline serologies should be checked as well.

All patients should be advised of the potential minor and serious adverse effects of their medication regimens (Table 4). Patients taking rifampin (Rifadin, Rimactane) should be warned about the innocuous orange/rust-colored staining of body fluids (urine, sweat, tears). The most common adverse effects of the first-line agents are outlined below.

Rash is a major adverse effect of all four of the first-line agents and can be due to various mechanisms and of various severities. A pruritic rash without associated symptoms can be managed symptomatically with antihistamines. A petechial rash may indicate thrombocytopenia from rifamycin hypersensitivity and warrants permanent discontinuation of the rifamycin. Rash associated with fever, mucus membrane involvement, or generalized erythema is more likely to suggest Steven-Johnson syndrome or toxic epidermal necrolysis and warrants prompt discontinuation of all medications and consultation with a dermatologist.

The most serious adverse drug event associated with isoniazid (Nydrazid), pyrazinamide (Zinamide), and rifampin (Rifadin, Rimactane) is drug-induced liver injury (DILI). DILI should be suspected if the ALT level is at least three times the upper limit of normal in the presence of hepatitis symptoms or at least five times the upper limit of normal in the absence of symptoms. An asymptomatic increase in ALT concentration occurs in nearly 20% of patients, and in this case therapy should be continued.

**TABLE 3** Preferred Regimens for Drug-Susceptible Pulmonary TB Disease

INTENSIVE PHASE	DURATION	ADULT DOSAGE FOR DAILY ADMINISTRATION
INH* RIF PZA EMB	7 days per week for 8 weeks OR 5 days per week for 8 weeks	INH: 5 mg/kg (typically 300 mg) RIF: 10 mg/kg (typically 600 mg) PZA: 30–40 mg/kg EMB: 15–25 mg/kg
CONTINUATION PHASE	DURATION	ADULT DOSAGE FOR DAILY ADMINISTRATION
INH RIF	7 days per week for 18 weeks OR 5 days a week for 18 weeks	INH: 5 mg/kg (typically 300 mg) RIF: 10 mg/kg (typically 600 mg)

DOT, Directly observed therapy; EMB, ethambutol (Myambutol); HIV, human immunodeficiency virus; INH, isoniazid (Nydrazid); PZA, pyrazinamide (Zinamide); RIF, rifampin (Rifadin, Rimactane).

\*Vitamin B6 (pyridoxine)<sup>1</sup> is given in conjunction with INH for those at risk for developing—or already suffering from—peripheral neuropathy per text above.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** Major Adverse Effects of First-Line Medications for the Treatment of Tuberculosis Disease

FIRST-LINE MEDICATIONS	MOST COMMON ADVERSE SIDE EFFECTS
INH	Hepatotoxicity Rash Drug-induced lupus Peripheral neuropathy
Rifamycins (RIF, RPT, RFB)	Hepatotoxicity Rash GI upset Thrombocytopenia Hypersensitivity reactions
PZA	Hepatotoxicity Rash GI upset Gout
EMB	Optic neuritis Rash

EMB, Ethambutol (Myambutol); INH, isoniazid (Nydrazid); PZA, pyrazinamide (Zinamide); RFB, rifabutin (Mycobutin); RIF, rifampin (Rifadin, Rimactane); RPT, rifapentine (Priftin).

### Latent Tuberculosis Infection

For routine LTBI treatment in an otherwise healthy patient, apart from HIV and viral hepatitis serologies as above, no other baseline or serial laboratory monitoring is necessary. Patients who have/are at risk to have chronic liver disease, use alcohol regularly, are pregnant, are within 3 months postpartum, or have HIV should have baseline alanine aminotransferase (ALT), aspartate aminotransferase (AST), bilirubin, and alkaline phosphatase checked. Liver tests as above should be considered for patients of advanced age, those with chronic medical conditions, and those taking multiple chronic medications. Active viral hepatitis and end-stage liver disease are relative contraindications to the use of INH, RIF, or RPT in LTBI treatment.

While on LTBI treatment, the patient should have a minimum of once monthly medical assessments. During visits, the patient should be evaluated for development of symptoms/signs of TB disease, adherence to LTBI treatment regimen, and symptoms/signs of adverse effects. Serial liver tests, as above, should be monitored in those who have baseline abnormal LFTs, are at

risk for hepatitis, or who develop symptoms/signs of hepatitis while on therapy. Treatment should be discontinued if any of the liver enzymes are greater than three times the upper limit of normal in presence of hepatitis symptoms or five times the upper limit of normal in an asymptomatic individual. For liver enzyme elevations less than three times the upper limit of normal in a symptomatic patient, treatment continuation can be considered provided there is close clinical and laboratory monitoring.

At completion of therapy, patients should be provided documentation of their initial TST or IGRA, treatment regimen and duration, and date of treatment completion. They should be advised to present such documentation if TB testing is required in the future, as IGRAs and TSTs are likely to remain positive despite successful LTBI treatment. Patients should be reminded that treatment for LTBI greatly decreases the risk of progression to TB disease but does not eliminate it 100%, and counseling on the symptoms/signs of TB disease and when/how to seek further care should be provided.

### Active Tuberculosis Disease

Within a week of diagnosis, a treatment and monitoring plan specific to the patient should be developed in collaboration with the local department of health. As previously mentioned, all patients should have baseline HIV testing and viral hepatitis testing as indicated. All patients should have a baseline assessment of platelets, creatinine, ALT, AST, bilirubin, alkaline phosphatase, and a diabetes screen as recommended by the American Diabetes Association. Those patients for whom ethambutol (Myambutol) is included in treatment regimen should have a baseline Snellen test for visual acuity as well as color discrimination tests.

While on therapy, patients should be seen monthly and evaluated for treatment response and any adverse medication effects. Repeat laboratory testing should be done periodically if laboratory abnormalities were present at baseline, or if the patient develops symptoms/signs of adverse drug effects. Patients taking ethambutol (Myambutol) should be asked at each visit about vision changes and undergo monthly color discrimination tests.

During treatment of pulmonary TB disease, sputum, or other specimens for AFB/culture should be obtained at least monthly until cultures convert from positive to negative. If treatment has been continued for at least 2 months and the patient remains culture-positive, repeat drug susceptibility testing should be performed. Repeat chest radiographs can be pursued if there is clinical worsening or failure of symptoms to improve.

Treatment failure can occur for a number of reasons including medication nonadherence, unrecognized drug resistance, malabsorption, drug–drug interactions, or laboratory error (erroneously positive culture in a patient who is otherwise clinically well). The standard of care should be to add two to three new drugs. A single new agent should never be added to a failing regimen as it can lead to amplification of drug resistance as well as acquired resistance to the newly added drug.

The treatment of TB disease can be complicated, especially in patients who have HIV, are pregnant, have chronic liver disease and other comorbid conditions, have or develop drug-resistant TB, or develop serious adverse reactions to therapy. Clinicians who do not have experience with such complicated circumstances should consult a TB expert.

### Nontuberculous Mycobacteria

NTM are a diverse group of environmental bacteria found worldwide. NTM are species other than *M. tuberculosis* and *M. leprae* complex. Not all NTM species are pathogenic to humans. *Mycobacterium avium* complex (MAC) is the most prevalent NTM causing human infection, and pulmonary disease is its most common presentation. NTM infections most often present as pulmonary infections in hosts with altered local or systemic immune function. Extrapulmonary infections can occur in both immune competent and immune suppressed hosts and include infections of lymph nodes, skin/soft tissue, bone, and prosthetic devices and catheters; disseminated infections occur almost exclusively

in patients with advanced immunosuppression (e.g., patients with stage III HIV). Diagnosis of NTM infections requires a clinical syndrome supported by imaging and microbiologic data. Treatment varies by species and susceptibility patterns and typically requires a multidrug regimen to prevent development of drug resistance. Management of these complicated infections should be undertaken in conjunction with an expert in nontuberculous infection diagnosis and treatment.

### Pathophysiology

As above, nontuberculous mycobacterial infections are typically acquired through contact with contaminated soil, water, dust, vegetable matter, or less commonly through zoonotic spread. NTM are not part of normal human flora. Pulmonary infections have been associated with inhalation or microaspiration from contaminated recirculating water systems, as have some skin and soft tissue infections been directly correlated to such aqueous sources. However, the ubiquitous presence of these organisms in nature makes it difficult to determine where a specific person's infection was acquired. Human-to-human transmission does not occur with the rare exception of pulmonary infections transmitted between persons with cystic fibrosis.

Host risk factors for infections include immunosuppression, especially corticosteroid use, uncontrolled HIV, TNF- $\alpha$  antagonist use, certain inherited disorders of immune suppression, and other systemic immunosuppressive states and medications; gastroesophageal reflux disease (GERD); and chronic pulmonary disease such as cystic fibrosis, bronchiectasis, and chronic obstructive pulmonary disease. Some activities that have been associated with NTM infections include use of hot tubs, saunas, steam rooms, and prolonged showers; cleaning swimming pools and fish tanks; waxing hair removal and pedicures at nail salons; and tattooing and other cosmetic procedures.

### Prevention

When possible, reversing/treating causes of immunosuppression can help prevent nontuberculous mycobacterial infections. Prompt initiation of effective ART for patients with HIV and CD4 T lymphocytes  $<50/\text{mm}^3$ , for example, can help prevent MAC and other NTM infections, without need for prophylaxis with macrolides. Previous practice guidelines for people with HIV and CD4 T lymphocytes  $<50/\text{mm}^3$  included initiation of azithromycin (Zithromax) for MAC prophylaxis. Due to the rapid viral suppression observed with current HIV ART, such patients who are starting effective ART no longer require MAC prophylaxis. For patients with chronic lung disease, it is reasonable to avoid exposure to potentially aerosolized NTM such as with recirculating water systems (hot tubs, steam rooms, prolonged showers, swimming pools) and aerosolized soil exposure. For patients with chronic lung disease and known NTM pulmonary colonization or disease, it is advisable to limit systemic and inhaled steroids as much as feasible. Like with *M. tuberculosis*, TNF- $\alpha$  inhibitors increase risk for NTM infection, and more aggressive disease progression and should be avoided when possible for susceptible patients. Avoiding nonsterile and nonregulated tattooing, cosmetic procedures, etc., can also help prevent some NTM infections.

### Clinical Manifestations

Infections have a wide variety of presentations and largely depend on anatomic site of infection, host immune response, and infecting NTM species. Pulmonary infections comprise 80% of NTM infections. Pulmonary infections typically occur in people with underlying lung disease or immunosuppression and in some with chest wall deformities. Presentation is usually subacute or chronic and includes cough; other symptoms may include cough, shortness of breath, low-grade fevers, night sweats, weight loss, anorexia, and fatigue.

Cervicofacial lymphadenitis (“scrofula”) is the most common extrapulmonary manifestation of MAC and is typically seen in children. This presents with typically painless, unilateral, firm

lymph node swelling in the mandibular or jugular regions. Systemic symptoms are uncommon in the immune-competent host. Notably when seen in adults, cervicofacial lymphadenitis is more likely to be due to *M. tuberculosis* than NTM.

Various NTM different species cause skin and soft tissue infections, usually due to direct inoculation after traumatic wound, injections, and cosmetic procedures; rarely cutaneous manifestations of systemic disease can be seen. Lesions can appear as ulcers, papules, nodules, eschars, sporotrichoid lesions, or plaques with local swelling. Tenderness, erythema, swelling may be present and systemic symptoms are often absent.

Multiple species of NTM have been found to cause bone and joint infection. Injuries and implanted prosthetic devices (e.g., prosthetic joints) are risk factors for such infections. Patients may present with pain, swelling, erythema, purulent drainage, and pathologic fractures, with or without systemic symptoms.

Disseminated NTM infections occur in immunocompromised hosts and may present with fevers, chills, sweats, weight loss, and fatigue. Pancytopenia due to bone marrow and splenic involvement can lead to shortness of breath and pallor, easy bleeding/bruising, and superimposed infections due to neutropenia. Gastrointestinal involvement may cause diarrhea, abdominal pain, and hepatosplenomegaly.

Healthcare-associated infections also occur, especially in the setting of implanted prosthetic devices/material and intravascular catheters and after cosmetic procedures including mammoplasty and tattooing.

### Diagnosis

The diagnosis of pulmonary NTM disease requires pulmonary symptoms, radiographic evidence of disease, exclusion of other diagnoses, and microbiologic criteria: Positive culture results from at least two sputum specimens or positive culture from at least one bronchial wash or lavage or lung tissue with granulomatous inflammation and >1 positive sputum or bronchial wash culture. AFB smears are notoriously insensitive. Colonization of the airways can occur with NTM, so a single positive sputum culture is not diagnostic of disease. Patients who don't meet all of the criteria should be followed closely over time, as NTM pulmonary disease may still develop.

Diagnosis of extrapulmonary NTM infections is typically through AFB culture(s) performed on the involved tissue or body fluid in the setting of a compatible clinical syndrome. NTM can colonize nonsterile areas in the body, so the presence of a positive AFB culture without an associated clinical syndrome must be interpreted cautiously. NTM lymphadenitis is best diagnosed by excisional lymph node biopsy for AFB culture and histopathology, as aspiration of NTM infected lymph nodes can lead to fistula formation. Explanted prosthetic devices can be sonicated and AFB culture performed on fluid. Tissue biopsies of affected areas may demonstrate noncaseating granulomatous changes on histopathology, with or without AFB seen on smear, and AFB culture is still necessary for diagnosis and treatment.

Disseminated MAC is diagnosed by isolation of the organism in AFB blood culture or other sterile site such as bone marrow, liver, or spleen. When available, direct detection of MAC in blood by PCR may be as sensitive and specific as culture, with results available in hours as opposed to weeks.

Drug susceptibility testing done on the mycobacterial species isolated is necessary to help guide treatment decisions.

### Treatment

Treatment of NTM infections is, with few exceptions, complicated and requires input or management by specialists in NTM infections. NTM have intrinsic resistance to many antibiotics and can develop resistance on therapy. Treatment therefore typically requires two or three antimicrobial agents for a prolonged period of time, often 6 months to a year. If underlying immune suppression can be mitigated (e.g., holding or decreasing doses of immunosuppressive agents), such modifications should be made. Specific treatments vary for the different anatomic sites affected,

species of NTM involved, antibiotic susceptibility patterns, host immune status, and the patient's tolerance for specific antimicrobials, prolonged duration, and the potential adverse effects. For pulmonary NTM disease, not all patients who meet diagnostic criteria need to be treated: Some people will have spontaneous resolution without antimicrobial therapy; when treated, duration is quite prolonged; treatment requires multiple drugs with various side effect profiles; treatment may require months of intravenous antibiotics; and pulmonary infection has a significant rate of relapse/recurrence.

### *Mycobacterium leprae* Complex

Hansen's disease, also known as leprosy, is an indolent mycobacterial infection largely affecting skin and nerves caused by *Mycobacterium leprae* complex (*Mycobacterium leprae* and *lepromatosis*). It is an underdiagnosed disease due to its insidious onset of symptoms, the stigma associated with diagnosis and the healthcare system, and misrecognition of symptoms especially in areas of low prevalence. According to the World Health Organization (WHO), in 2019 there were 202,256 new cases diagnosed globally, with prevalence of 22.9 per million people. The majority of cases are reported from India, Brazil, and Indonesia. Untreated, Hansen's disease leads to significant morbidity and very impaired quality of life. The psychosocial stigma associated with the disease, however, is often felt by patients to be worse than the physical symptoms and must be addressed from time of initial evaluation through and beyond treatment.

### Pathophysiology

Hansen's disease is a granulomatous infection caused by *Mycobacterium leprae* and *lepromatosis*, which comprise *M. leprae* complex. These organisms are gram-positive AFB that cannot be grown in culture. They replicate slowly, and average disease incubation period is 5 years. Though incompletely understood, transmission is felt to be person-to-person through nasal and respiratory secretions. Nine-banded armadillos in the southeastern United States, red squirrels in Scotland and England, chimpanzees, and macaques have all been found to carry *M. leprae* or *M. lepromatosis*, so zoonotic transmission is also implicated, though less frequently.

More than 95% of people worldwide are felt to have immunity to *M. leprae* complex, so in actuality, Hansen's disease is not very transmissible. Clinical and histopathologic disease occurs on a continuum, classified into five types by the Ridley-Jopling schema, depending on degree of host cell-mediated immune response to *M. leprae* complex. Disease types range from polar tuberculoid form (TT) with a strong immune response including well-formed granulomas, few bacilli, and more classic clinical manifestations, to the polar lepromatous type (LL) with minimal cell-mediated immune response, foamy macrophages without granulomas, and many bacilli seen on histopathology. LL clinical manifestations are less commonly recognized and are described below. Borderline tuberculoid (BT), midborderline (BB), and borderline lepromatous (BL) types have various degrees of both cell-mediated and humoral response.

### Prevention

As with TB, the mainstay of prevention of Hansen's disease is early diagnosis and treatment of infected patients. There is currently no FDA approved vaccine to prevent infection with *M. leprae* complex. BCG vaccine<sup>1</sup>—that given in endemic regions to prevent severe TB disease in children—when given to household contacts of people with Hansen's disease may decrease risk of transmission of *M. leprae* complex. Additionally, in household contacts of infected patients, BCG vaccination decreases likelihood of developing multibacillary disease.

Patients with Hansen's disease who have hypoesthetic lesions are at risk to develop injuries, such as burns and ulcers, in the

<sup>1</sup>Not FDA approved for this indication.

insensate areas. Daily checks for foot wounds, avoiding walking barefoot, use of protective silicone gloves when cooking, and so on are important in the prevention and early detection and management of injury.

### Clinical Manifestations

As *M. leprae* complex cannot be grown in culture, a high degree of clinical suspicion is necessary to pursue diagnosis. *M. leprae* complex requires cooler temperatures for growth and therefore has a predilection for cooler areas of the body including skin, cutaneous nerves, ears, and nose, including septum, eyes, larynx, and testes. Presentations vary according to degree of immune response to the bacilli. Cutaneous manifestations can include macules, patches, papules, or nodules. Lesions can be hypopigmented or reddish. The skin may be thick, scaly, or dry appearing. The hypopigmented areas are often hypoesthetic. Injuries to hypoesthetic areas are common and cause painless ulcers, burn wounds, lacerations, etc. Wounds may become infected. There may be madarosis: loss of the eyebrows and/or eyelashes. Thickening and nodularity of skin on the face can lead to a “leonine facies” appearance. Involvement of the nasal bridge can cause a “saddle nose” deformity. Perforation of the nasal septum can occur. Laryngeal involvement can lead to hoarseness. Eye involvement can include episcleritis and iridocyclitis. Lagophthalmos can occur leading to keratitis, corneal opacities, ectropion, entropion, and trichiasis. Neural involvement can lead to not only anesthetic areas but also thickened peripheral nerves, peripheral neuropathy, claw hand, foot drop, or paralysis of an extremity.

A particular area of concern that significantly affects patients living with Hansen’s disease is the associated stigma and negative beliefs surrounding Hansen’s disease, due to historic, religious, and social implications. Thus one must consider psychological burden associated with this infection when relaying diagnosis and throughout the patient’s care.

### Diagnosis

There are two main schema used for diagnosis: a binary clinical classification schema devised by the WHO for use where histopathology is not readily available and the histopathologic and clinical spectrum of the Ridley-Jopling classification. The WHO schema divides disease into multibacillary and paucibacillary, depending on number of skin lesions visible. The Ridley-Jopling schema classifies disease on a spectrum as outlined above and is based on skin biopsy for histopathology and Fite stain. Additional methods of identification of *M. leprae* complex include identification of the bacilli DNA in tissue biopsies by nucleic acid amplification techniques such as PCR.

### Treatment

Using multidrug regimens, Hansen’s disease is curable. Early recognition and treatment are key to preventing disability. The most active antimicrobial agents used to treat Hansen’s disease include dapsone, rifampin (Rifadin, Rimactane),<sup>1</sup> and clofazimine (Lamprene). Other agents with efficacy include some fluoroquinolones, minocycline (Cleeravue-M, Dynacin, Minocin, Myrac, Solodyn, Ximino),<sup>1</sup> and clarithromycin (Biaxin).<sup>1</sup> As in other mycobacterial infections, multidrug regimens are imperative to prevent emergence of drug resistance and increase cure rates. Glucose-6-phosphate dehydrogenase (G6PD) deficiency testing should be performed prior to starting dapsone and the drug avoided if deficiency is present. Clofazimine (Lamprene) can only be obtained in the United States through the National Hansen’s Disease Program (NHDP) in Louisiana. The NHDP is the sole facility in the United States dedicated to Hansen’s disease diagnosis, treatment, and research. Consultation with their expert physicians and pharmacists is highly recommended. There are many resources available to patients and healthcare providers alike through the NHDP, including review of histopathology specimens, consultation regarding molecular diagnosis

of *M. leprae* complex, antimicrobial therapy free of costs for patients, and educational materials for physicians and patients to improve understanding of the disease and help prevent injury and disability. Finally, resources are available through NHDP for surgical care and rehabilitation of patients referred for digit or limb threatening wounds. Contact information can be found at <https://www.hrsa.gov/hansens-disease/index.html>.

### Monitoring

G6PD deficiency testing should be performed prior to starting dapsone, and the drug avoided if deficiency is present. Patients should be monitored frequently while on therapy for potential adverse effects of various medications including anemia, QTc prolongation (clofazimine [Lamprene] and clarithromycin [Biaxin]), and skin discoloration (minocycline). Treatment efficacy is indicated by resolution of skin lesions and lack of new skin or nerve lesions. Patients should be monitored closely and educated about the signs and symptoms of reversal reactions, which can occur before, during, and even after therapy. At every visit, examination of all extremities should be performed to evaluate new and existing wounds.

### Complications

Complications of Hansen’s disease itself stem from injuries to hypoesthetic areas as above (largely hands and feet) and complications of peripheral neuropathy such as claw hand and foot drop. Evaluation and management by occupational and physical therapists and appropriate surgical referrals are often indicated.

As mentioned above, G6PD levels should be checked prior to initiation of dapsone and the drug avoided if patient is deficient in the enzyme, otherwise hemolytic anemia may develop. CBC with differential and ECG for QTc should be evaluated at baseline and periodically while on clofazimine (Lamprene) therapy.

Before, during, or even after therapy, pathologic immune reactions including reversal reactions and erythema nodosum leprosum can occur. Rarely, specific reversal reactions can be life threatening. Reversal reactions are inflammatory states, and measurement of biomarkers of inflammation can be helpful for evaluation and monitoring. Reversal reactions are treated with various immunosuppressing agents and consultation with the experts at NHDP is recommended.

## VENOUS THROMBOEMBOLISM

Method of

Moniba Nazeef, MD; and John P. Sheehan, MD

### CURRENT DIAGNOSIS

- A comprehensive history is the most important diagnostic tool to assess risk factors including recent surgery, bedridden state, trauma, orthopedic procedure, or active cancer.
- Moderately high-sensitivity D-Dimer assays (>85% sensitivity) can be used to exclude venous thromboembolism (VTE) if there is low clinical probability but should be combined with imaging in all other cases.
- Venous compression ultrasonography (CUS) is a noninvasive, affordable, and widely available test for the diagnosis of deep vein thrombosis (DVT). Computed tomography pulmonary angiography (CTPA) is the current gold standard for the diagnosis of pulmonary embolism (PE).

### CURRENT THERAPY

- The choice of initial therapy is frequently guided by the clinical scenario. Initial therapy includes unfractionated heparin (UFH), low-molecular-weight heparin (LWMH), fondaparinux (Arixtra), or the direct oral anticoagulants (DOACs) rivaroxaban (Xarelto) or apixaban (Eliquis)
- The traditional heparin-warfarin regimen has been increasingly supplanted by the use of direct oral anticoagulants (DOAC).
- Standard treatment for a new episode of DVT or pulmonary embolism (PE) is 3 to 6 months of therapeutic anticoagulation. The recommended duration of anticoagulation for VTE requires individualized analysis of the clinical presentation and patient specific factors that weigh both recurrence and bleeding risk.

Venous thromboembolism (VTE) is a significant health problem, with surveillance data suggesting that 60,000 to 100,000 people die of VTE each year in the United States. Approximately 50% to 60% of this disease burden is associated with a recent hospitalization, underscoring the importance of VTE prophylaxis. VTE is comprised of superficial vein thrombosis (SVT), deep vein thrombosis (DVT), and pulmonary embolism (PE). DVT typically starts in the deep veins of the lower extremities and progresses proximally. If untreated, a clot can break off and travel to the

lungs where it is trapped in the pulmonary circulation, resulting in PE. DVT confined to the deep veins of the calf is termed *isolated distal DVT*, whereas involvement of the popliteal or more proximal veins is termed *proximal DVT*. SVT represents thrombosis in the superficial veins of the legs or arms and rarely progresses to DVT. The focus of this chapter is to understand the risk factors, diagnosis, treatment, and prevention of DVT and PE.

### Pathophysiology/Risk Factors

Venous blood flow is maintained by a delicate homeostatic balance of prothrombotic and antithrombotic factors. Virchow's triad describes the major factors leading to VTE from a pathophysiologic standpoint: (1) intrinsic hypercoagulability, (2) endothelial damage, and (3) venous stasis. Most often, a combination of these factors leads to the development of VTE. Based on the presence or absence of typical clinical risk factors, VTE occurrences can be considered either provoked (e.g., post-surgical) or unprovoked (spontaneous). Furthermore, provoking risk factors may be transient/reversible (e.g., estrogen use) versus nontransient/irreversible (e.g., lower extremity paresis), which has implications for decisions regarding duration of anticoagulant therapy [Table 1](#).

### Acquired Risk Factors

Certain clinical conditions shift the balance between procoagulant and anticoagulant factors to promote thrombosis. These conditions include surgery, pregnancy and puerperium, inflammation, active cancer, major trauma, specific medications, and a variety of conditions that lead to immobility. A more comprehensive list is provided in [Table 1](#). Many of these clinical conditions cause multiple changes relevant to VTE risk. For example, surgical interventions may induce endothelial damage, immobilization leading to venous stasis, platelet activation, and trigger inflammatory responses that increase fibrinogen, factor VIII, and von Willebrand factor levels. Orthopedic procedures involving the lower limbs and abdominopelvic surgeries in cancer patients are especially high risk from a VTE standpoint. Active cancer is associated with 20% of all VTE and involves a variety of mechanisms leading to hypercoagulability, including increased tissue factor

**TABLE 1** Risk Factors for Venous Thromboembolism

#### Transient/Reversible

Surgery (esp. lower limb orthopedic surgery)  
 General anesthesia >30 min  
 Immobility due to surgical or medical condition  
 Oral contraceptives/hormone replacement therapy  
 Pregnancy, puerperium  
 Major trauma  
 Acute inflammation  
 Indwelling venous catheters  
 Heparin induced thrombocytopenia  
 May-Thurner syndrome  
 Travel-associated thrombosis  
 Medications including tamoxifen, L-asparaginase, immunomodulatory agents (lenalidomide), EPO

#### Permanent/Non-Reversible

Active cancer  
 Antiphospholipid syndrome  
 Myeloproliferative neoplasms  
 Paroxysmal nocturnal hemoglobinuria (PNH)  
 Lower extremity paresis from neurologic disease  
 Sickle cell disease  
 Nephrotic syndrome  
 Active autoimmune conditions (SLE, IBD, ITP, TTP)  
 Chronic infection/inflammation  
 Morbid obesity (BMI > 40)

EPO, Erythropoietin; SLE, systemic lupus erythematosus; IBD, inflammatory bowel disease; ITP, immune thrombocytopenic purpura; TTP, thrombotic thrombocytopenic purpura.

expression, venous obstruction, indwelling catheters, reduced mobility, and chemotherapy.

Pregnancy and the puerperium, oral contraceptives (OC), and hormone replacement therapy (HRT) are important VTE risk factors in women. OC and HRT are associated with a number of changes in hemostatic protein levels and platelet function that appear globally prothrombotic. Higher estrogen content is associated with increased thrombotic risk and is modulated by a combination with specific progestins. Additionally, there is a higher risk of VTE in OCP users with a positive family history, suggesting an underlying genetic predisposition.

A variety of conditions that involve prolonged immobilization enhance VTE risk. Cast immobilization of the lower extremity, paresis after neurologic events, multiple trauma, orthopedic surgeries, travel-associated immobility (>4–6 hours) or a bedridden state due to a variety of medical or surgical conditions result in stasis that promotes venous thrombosis. Many of these clinical situations are also associated with an inflammatory state that concomitantly increases intrinsic hypercoagulability of the blood. Venous wall injury may occur via a variety of mechanisms, including surgical interventions, indwelling intravenous catheters, trauma, and vasculitis.

### Genetics of Venous Thromboembolism

Although acquired clinical risk factors are critical to assessing risk, the genetic contribution to VTE is also substantial, with heritability of VTE estimated at 40% to 47%. Like many complex phenotypes, VTE has a multigenic basis in which most individual alleles make relatively small contributions to overall risk. Factor V Leiden and the prothrombin G20210A polymorphism are examples of such alleles (2- to 4-fold relative risk). At least 17 genes have been identified that harbor VTE-associated variants. Importantly, family history remains an independent risk factor even after excluding known gene variants associated with thrombophilia, suggesting that unidentified genes also contribute to VTE risk. Deficiencies of the coagulation inhibitors antithrombin, protein C, and protein S are rare conditions with a more substantial effect on the relative risk of VTE (10- to 20-fold increase) but tend to be diagnosed erroneously in the setting of acute thrombosis. The multigenic basis of VTE has implications for thrombophilia testing that include: (1) identification of minor alleles (e.g., FV Leiden) is not helpful for prediction of VTE recurrence risk; (2) a careful family history is generally more valuable than a thrombophilia evaluation; and (3) the *absolute* risk for carriers of thrombophilic alleles is generally quite small and does not justify indefinite anticoagulation. A robust estimate of individual genetic risk requires systematic screening of all known VTE risk genes or whole genome/exome sequencing approaches that are not routinely available. Thus current thrombophilia testing rarely contributes to clinical decision making in patients with VTE. Testing should never be pursued for provoked events and is best limited to selected situations such as presentations at a young age (<30 years) or known thrombophilic traits occurring in the context of a family history of VTE. A thorough personal and family history is generally sufficient to determine the likelihood of an underlying inherited hypercoagulable state.

### Epidemiology and Natural History

The exact incidence of VTE is unknown, but it is estimated that about 300,000 to 600,000 Americans are affected by VTE each year. VTE incidence appears ~30% higher in African Americans and ~70% lower in Asian and Native American populations relative to Caucasians. Importantly, the incidence of VTE increases with age, particularly after age 50. Whereas overall VTE is slightly more common in men, women have an increased incidence before age 40 based on the impact of pregnancy and contraceptives. In older age groups, the frequency of PE is increased relative to DVT. Finally, the incidence of VTE has been increasing steadily since the mid-1980s, which may, in large part, represent the increased use and enhanced sensitivity of computed tomography (CT) scans and magnetic resonance imaging (MRI).

The natural history of VTE is impacted by the underlying clinical risk factors, provoked versus unprovoked nature of the event, reversibility of risk factors, and location/nature of the thrombotic event. In general, untreated thrombi tend to extend proximally, break off, and embolize to the pulmonary circulation, where they may result in infarction and pulmonary hypertension. The risk of PE is increased for proximal versus distal involvement with DVT. More than 75% of VTE starts in the calf veins, and 20% to 30% of these cases progress to involve proximal veins in the leg or pelvis. Approximately 50% of patients with untreated symptomatic proximal DVT develop symptomatic PE, whereas the incidence of asymptomatic PE is even higher. Importantly, 10% of symptomatic PE is rapidly fatal, and 30% of patients with untreated symptomatic nonfatal PE will have a fatal recurrence. Thus recognition of PE is of the utmost clinical importance. Anticoagulant therapy inhibits thrombus growth and largely prevents interval recurrence, whereas endogenous thrombolysis may result in partial or complete resolution of the thrombus. Uncommonly, progressive thrombosis in the presence of anticoagulation may occur in high-risk situations such as metastatic malignancy or the antiphospholipid syndrome.

The risk of VTE recurrence after stopping anticoagulation varies significantly based on clinical presentation. About 20% to 40% of VTE episodes are unprovoked in nature, which is associated with a substantially higher recurrence rate. For unprovoked clots, recurrence rate is estimated to be ~10% in one year, ~30% in 5 years, and approaches ~40% in 10 years. In contrast, the recurrence risk of VTE associated with surgery (a transient risk factor) is less than 3% per year. Recurrences tend to occur in a similar site to the initial event, which is particularly important in the case of PE, as 25% of pulmonary embolism presents as sudden death. In contrast, the risk of recurrent VTE is much smaller in isolated distal (calf) DVT compared with proximal DVT and PE.

### Long-Term Complications of VTE

#### *Postthrombotic Syndrome (PTS)*

About 20% to 50% patients with DVT develop some degree of PTS within the subsequent 1–2 years. Chronic venous obstruction, inflammation, endofibrosis, and valvular dysfunction contribute to the chronic venous insufficiency of PTS. Risk factors for PTS include persistent DVT symptoms after one month, extensive or recurrent DVT, inadequate anticoagulation, and advanced age. Manifestations include chronic leg edema, pain, heaviness, erythema, and venous ulcers that may result in significant disability. PTS is largely non-reversible, emphasizing the importance of DVT prevention. Graduated compression stockings provide symptomatic relief by preventing pooling of blood in the lower extremities, but do not prevent PTS. In the 5% to 10% of patients with severe PTS, active supportive care and consultation with vascular surgery, dermatology, or vein specialists should be sought early to avoid development of debilitating venous ulcers.

#### *Chronic Thromboembolic Pulmonary Hypertension (CTEPH)*

CTEPH is a long-term complication of PE affecting 3% to 4% patients despite adequate anticoagulation. CTEPH is characterized by progressive pulmonary hypertension and right-side heart failure due to remodeling of pulmonary vasculature by thrombotic material. Patients with large central or extensive pulmonary emboli, hemodynamic compromise, and right heart dysfunction at diagnosis are at highest risk. Chronic progressive dyspnea with exertion is the most common symptom, and the clinician must have a high clinical suspicion based on patient's history of PE. An echocardiogram revealing elevated pulmonary arterial hypertension should trigger evaluation with a VQ scan. The presence of chronic mismatched segmental perfusion defects on the VQ scan is diagnostic of CTEPH. If anatomically feasible, treatment of choice is pulmonary endarterectomy, which can reverse the hemodynamic and functional abnormalities. Early recognition and referral to a specialized surgical treatment center are critical to patient outcomes. Lifelong anticoagulation is recommended for all patients with CTEPH.

### Diagnosis of Deep Venous Thrombosis

The diagnosis of DVT proceeds via determination of clinical probability, D-dimer screening, and confirmatory imaging.

#### Clinical Features

Diagnosis begins with evaluation of the clinical scenario for VTE risk factors and suspicious physical exam findings. Suggestive features in the patient's recent history include recent surgery or bedridden state, trauma or orthopedic procedure, active cancer, and other typical risk factors (Table 1). Classic symptoms of DVT include limb swelling, pain, and erythema. On exam, unilateral calf swelling, pitting edema, dilated veins, and tenderness on palpation can be seen. The clinical probability becomes stronger when more of these findings are present. Risk stratification systems such as the Wells model (Table 2) use these clinical features to rapidly classify patients as high (~60% thrombosis), moderate (~25%), or low (~5%) risk for DVT. Differential diagnosis

of DVT includes trauma, cellulitis, osteomyelitis, chronic venous insufficiency, arterial ischemia, ruptured Baker's cyst, hematoma, and superficial thrombophlebitis. Because neither history nor physical examination findings are specific for DVT, D-dimer screening and objective imaging must be pursued if sufficient clinical suspicion exists. A simplified algorithm for diagnosis of DVT is provided (Figure 1).

#### D-Dimer Screening

D-dimer is a specific fibrin degradation product generated by plasmin cleavage of cross-linked fibrin clot, formed by thrombin and Factor XIII activity. D-dimer represents a useful screening tool based on excellent sensitivity and a high negative predictive value for VTE. However, D-dimer lacks specificity, as it is increased in a variety of conditions, including acute inflammation, recent surgery or trauma, pregnancy, DIC, advanced age, or cancer. The level of clinical suspicion also impacts interpretation of D-dimer results. Specific D-dimer assays vary in sensitivity and specificity, although qualitative testing has largely been replaced by enzyme-linked immunosorbent assay-based quantitative assays. More recently, highly sensitive assays (>95% sensitivity) using latex-enhanced immunoturbidimetric immunoassays provide rapid quantitation for use in the diagnosis of VTE. Point-of-care (POC) testing with specified cutoff values are also available. Thus the clinician should be familiar with the type of D-dimer testing available locally. Highly sensitive assays have a good negative predictive value to rule out VTE without further testing. Moderately high-sensitivity assays (>85% sensitivity) can be used to exclude VTE if there is low clinical probability but should be combined with imaging in all other cases. Qualitative or semiquantitative assays are generally not reliable for excluding thrombosis. Finally, if clinical suspicion for DVT or PE is high, a negative D-dimer should not be used to rule out VTE, and appropriate imaging should be pursued to confirm the diagnosis.

#### Imaging

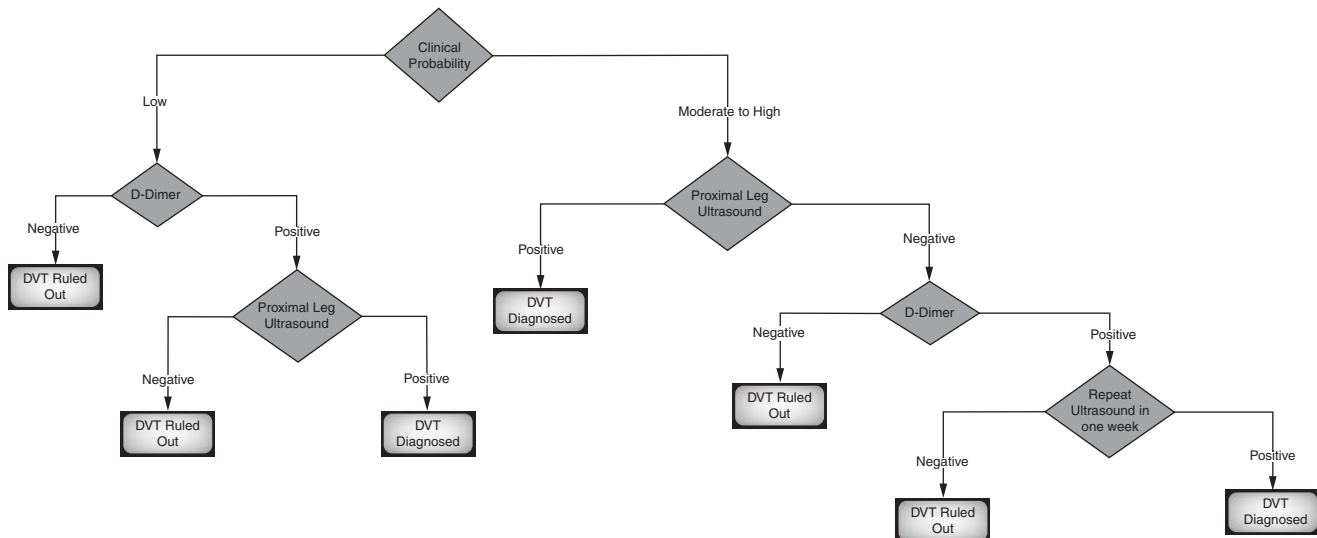

##### Ultrasonography

Venous compression ultrasonography (CUS) is a noninvasive, affordable, and widely available test for the diagnosis of DVT. The deep veins are assessed by use of a compression probe with lack of compressibility in a venous segment indicative of thrombus. Duplex technology or color-coded Doppler scanning visualizes blood flow to allow accurate identification of deep veins. Lack of flow plus non-compressibility increases diagnostic accuracy and also facilitates diagnosis in veins that cannot be compressed (e.g., pelvic and subclavian veins). Venous ultrasonography has an excellent sensitivity and specificity (~94%) for diagnosis of proximal limb DVT. The common femoral, femoral, and trifurcation

**TABLE 2** Wells Model for Predicting Pretest Probability of Deep Vein Thrombosis

CLINICAL VARIABLE	POINTS
Active cancer (treatment ongoing or within previous 6 months or palliative)	1
Recently bedridden >3 days or major surgery within 4 weeks	1
Pitting edema confined to the symptomatic leg	1
Dilated superficial veins (non-varicose)	1
Previous documented DVT	1
Paralysis, paresis, or recent plaster immobilization of the 1 lower extremities	1
Localized tenderness along the distribution of the deep 1 venous system	1
Calf swelling 3 cm greater than asymptomatic side measured 10 cm below tibial tuberosity	1
Alternative diagnosis at least as likely as DVT	-2

Clinical probability by interpretation of total score: >2 points, high; 1 or 2, moderate; <1, low.

**Figure 1** Suggested diagnostic algorithm for diagnosis of deep venous thrombosis (DVT).

of calf veins are readily visualized. In most cases, a negative test is sufficient to rule out proximal VTE. Currently two methods for CUS are used: (1) the two point compression technique, which only evaluates the proximal veins in the groin and popliteal fossa; and (2) whole-leg ultrasound scanning evaluating both proximal and distal veins. The sensitivity and specificity of CUS for calf vein DVT is significantly lower and highly operator dependent. Therefore many centers only perform the proximal vein assessment, which is reliable, reproducible, and efficient. If clinical suspicion remains high after a negative proximal vein ultrasound scan, repeat ultrasound scanning should be performed in about a week to assess for proximal extension in the deep venous system. If negative, no further testing is needed. A negative whole-leg CUS test result essentially rules out DVT and does not need follow-up testing. However, this approach is time consuming, may lead to increased diagnosis of calf vein thromboses, and potential overtreatment. The 3-month incidence of symptomatic proximal venous thrombosis in patients with a normal initial test are comparable at ~1% for both approaches. For upper extremities, compression ultrasonography is about 86% sensitive and specific.

### Contrast Venography

Previously the gold standard for diagnosis of DVT, contrast venography is rarely used because it is invasive and requires contrast exposure. CT and MR venography have a sensitivity and specificity of >90% for DVT in lower extremities. However, these studies are also not widely used for diagnosis because of increased cost, radiation, and contrast exposure. CT and MR venography are useful to define anatomy in patients with multiple recurrent DVT (evaluation by CUS is problematic), an indeterminate abnormality on ultrasound scanning, or a thrombus diagnosed in the setting of very low clinical suspicion.

### Diagnosis of PE

Similar to DVT, the diagnosis of PE requires determination of clinical probability, consideration of D-dimer testing, and confirmatory imaging.

### Clinical Features

A patient presenting with risk factors for VTE and antecedent history of DVT should raise the suspicion for pulmonary embolism. The most common symptoms of PE are shortness of breath and chest pain. Pleuritic chest pain is typical, but PE may also present with substernal pressure or be confused with musculoskeletal pain. Other symptoms may include cough and hemoptysis. Clinical signs include tachypnea, tachycardia, and hypoxia. The findings of DVT in the lower extremities increase the probability of PE. The Well's model for PE provides a useful framework to estimate the pretest probability using these variables (Table 3).

### Chest X-Ray, Electrocardiography, and Troponin

Chest x-ray should be performed in all suspected cases. The classical "Hampton's hump" or peripheral wedge-shaped opacity corresponding to a large pulmonary infarct is seldom appreciated and not very sensitive or specific. However, a chest x-ray is useful in assessing for other conditions such as pneumonia, pneumothorax, and pulmonary edema that can present in similar fashion. Electrocardiography (EKG) should be performed in anyone presenting with chest pain to rule out myocardial infarction. Evidence of right heart strain on EKG has predictive and prognostic value in assessment of pulmonary embolism. Similarly, a troponin level is usually obtained in evaluation for myocardial ischemia. An elevated troponin level in the absence of EKG evidence of ischemia can be suggestive of myocardial injury in the setting of massive or submassive PE.

### Ventilation/Perfusion (V/Q) Scanning

V/Q scans have largely been replaced by computed tomography pulmonary angiography (CTPA). However, V/Q scans remain

**TABLE 3** Wells Model for Predicting Pretest Probability of Pulmonary Embolism

CLINICAL VARIABLE	POINTS
Clinical signs and symptoms of DVT (minimum leg swelling and pain with palpation of the deep veins)	3
An alternative diagnosis is less likely than PE	3
Heart rate >100 beats/min	1.5
Immobilization or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Hemoptysis	1
Active Cancer (treatment ongoing or within previous 6 months or palliative)	1

Clinical probability by interpretation of total score: >6 points, high; 4 to 6, moderate; <4, low.

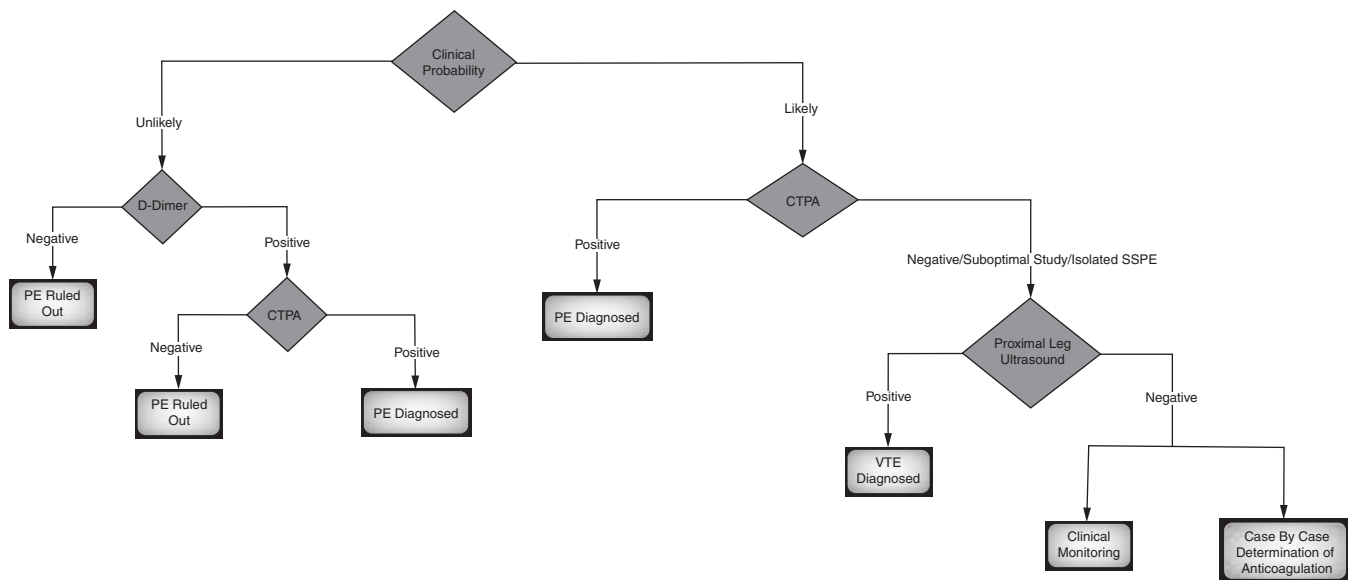

useful in selected patients with significant renal insufficiency (to avoid contrast dye) and young or pregnant females (to avoid radiation exposure). This technique uses inhaled and intravenous radioisotopes to evaluate ventilation and circulation in the pulmonary parenchyma and vasculature, respectively. A normal perfusion scan in the setting of a normal chest x-ray excludes PE. The addition of a ventilation scan increases specificity by accounting for other pulmonary disorders. A normal chest x-ray and ventilation scan in areas with multiple large perfusion defects that involve >75% of a segment (V/Q mismatch) is associated with >80% probability of PE and considered a high-probability V/Q scan. An intermediate-probability scan usually requires further diagnostic evaluation because it is considered nondiagnostic in most situations. Three-dimensional single-photon emission CT (SPECT) is now used by many centers in place of planar VQ scans. SPECT may be more accurate than planar VQ scanning, resulting in fewer nondiagnostic studies.

### Computed Tomography Pulmonary Angiography

Computed tomography pulmonary angiography (CTPA) is the modality of choice for diagnosis of PE. It is a relatively noninvasive procedure that can provide prompt diagnosis of PE. With recent advancements, the availability of thin-slice scans provides a detailed analysis of pulmonary vasculature that increases the sensitivity for detecting thrombi at the subsegmental and peripheral arterial level. In contrast to V/Q scanning, CTPA provides detailed visualization of the lung parenchyma, which can detect peripheral pulmonary infarctions and alternative diagnoses. When required, the CTPA examination can be extended to include the iliac veins, providing a detailed view with a single contrast exposure. CTPA has excellent sensitivity and specificity for diagnosis of lobar and segmental PE. Diagnostic accuracy is lower at the subsegmental level, and results should be interpreted in the context of clinical probability, proximal lower extremity ultrasound results, and D-dimer level. A simplified algorithmic approach to diagnosis of PE is provided (Figure 2). CTPA use is limited by costs, exposure to potentially nephrotoxic contrast dye, and chest radiation. It should be avoided in younger women because of the associated increased risk of breast cancer.

### Pulmonary Angiography

Formerly the gold standard for the diagnosis of PE, pulmonary angiography is an invasive procedure that has been replaced by CTPA and is now very rarely performed.

**Figure 2** Suggested diagnostic algorithm for diagnosis of pulmonary embolism (PE). CTPA, computed tomography pulmonary angiography; SSPE, subsegmental pulmonary embolism.

### Magnetic Resonance Angiography

Pulmonary contrast-enhanced magnetic resonance angiography (CE-MRA) is emerging as a useful alternative to CTPA in select patients such as younger females and those with severe iodinated contrast allergy. Currently, CE-MRA has limited availability and usefulness that is dependent on the expertise and experience of the available radiologists.

### Diagnosis of Recurrent DVT

The diagnosis of recurrent DVT can be challenging, because signs and symptoms of PTS in the affected extremity can obscure the diagnosis. Clinical assessment of the probability for recurrent DVT is less well standardized than initial episodes; however, many predictive factors are expected to be shared. The clinician should assess for the presence of ongoing clinical risk factors, attempt to discern between chronic and acute signs and symptoms, and consider D-dimer testing. A negative D-dimer test can be used to exclude recurrent DVT, although the accuracy of this approach has not been well studied. If D-dimer testing is positive or has not been done, CUS is performed. The finding of non-compressibility of an ipsilateral femoral or popliteal vein segment, which was previously unaffected, can be considered diagnostic. For diagnosing recurrent DVT in a previously affected vein segment, an increase in thrombus diameter of at least 4 mm on serial CUS in combination with a D-dimer measurement can serve as helpful criteria. This diagnosis requires the expertise of an experienced radiologist with the previous ultrasound available for comparison. In practice, comparison with previous CUS is difficult, given the operator-dependent characteristics of the test. If comparison with the previous examination is equivocal or unavailable, CT or MR venography may be considered. An intraluminal filling defect suggests acute rather than remote thrombosis. Alternatively, a patient with initially equivocal CUS findings can undergo serial repeat examinations to detect DVT extension.

### Treatment of Venous Thromboembolism Anticoagulation Therapy for VTE

Patients with newly diagnosed VTE should be promptly initiated on therapeutic anticoagulation. In the absence of a severely symptomatic lower extremity, high thrombus burden pulmonary embolism with right ventricular dysfunction or significant cardiovascular comorbidity, management is predominantly outpatient. In the presence of PE, a simplified pulmonary embolism severity index (sPESI) is often used to assess appropriateness for outpatient therapy. The sPESI score includes the following factors (1

point each): age >80, history of cancer, chronic cardiopulmonary disease, pulse >110 beats/min, systolic blood pressure <100 mm Hg, arterial oxygen saturation <90%. Patients with a sPESI score  $\geq 1$  are considered “high risk” and should be considered for initial inpatient management.

### Choice of Initial Anticoagulant Therapy

The choice of initial therapy is frequently guided by the clinical scenario. Initial therapy includes unfractionated heparin (UFH), low-molecular-weight heparin (LWMH), fondaparinux (Arixtra), or the direct oral anticoagulants rivaroxaban (Xarelto) or apixaban (Eliquis) (Table 4). Therapeutic UFH is administered intravenously (IV) and demonstrates complex pharmacokinetics (both hepatic and renal clearance) that requires laboratory monitoring of drug effect (aPTT or anti-factor Xa activity). Thus UFH therapy requires hospital admission and has largely been replaced by other options. UFH may still be appropriate for patients experiencing inpatient VTE events, especially if a need for invasive procedures is anticipated (half-life, 1–2 hours). The therapeutic target range for UFH is a 1.5- to 2.5-fold increase over the baseline aPTT or 0.3–0.7 U/mL anti-factor Xa activity. In contrast, LMWH is administered subcutaneously and primarily cleared by the kidneys, resulting in predictable pharmacokinetics. Subcutaneous administration facilitates outpatient treatment and predictable pharmacokinetics allow weight-based dosing without laboratory monitoring. Fondaparinux (synthetic pentasaccharide) is exclusively cleared by the kidneys with a long half-life (17–21 hours) that allows for once-daily, weight-adjusted subcutaneous dosing. Fondaparinux similarly does not require routine laboratory monitoring, but caution is warranted in patients with mild renal insufficiency where drug accumulation may increase bleeding risk. Heparin therapy (UFH, LWMH, or fondaparinux) for VTE is administered for a *minimum* of 5 days followed by transition to longer-term oral anticoagulation with an oral vitamin K antagonist (VKA) or a direct oral anticoagulant (DOAC). Alternatively, rivaroxaban or apixaban can be initiated immediately after VTE diagnosis and bypass the need for heparin therapy (see below).

Historically, vitamin K antagonists (VKA) are the primary oral anticoagulants for the long-term treatment of VTE. Warfarin (Coumadin) is the VKA used almost exclusively in the United States. Warfarin and other VKA inhibit vitamin K-dependent  $\gamma$ -carboxylation of the coagulation zymogens (proenzymes). This post-translational modification is required for both efficient protein secretion and function (membrane binding) of

**TABLE 4** Drugs for the Treatment of VTE

DRUG	DOSING	ELIMINATION	HALF-LIFE	MONITORING
UFH	80 units/kg IV bolus, then 18 units/kg/hour initial infusion rate	Complex, hepatic/renal metabolism	1–2 hours	APTT Anti-FXa activity
LMWH	Dalteparin (Fragmin): 200 U/kg SQ QD Enoxaparin (Lovenox): 1 mg/kg SQ BID	Predominantly renal	3–5 hours	None required*
Fondaparinux (Arixtra)	5.0 mg SQ QD (<50 kg) 7.5 mg SQ QD (50–100 kg) 10 mg SQ QD (>100 kg)	Renal	17–21 hours	None required*
Warfarin (VKA) (Coumadin)	Initially 5 mg po QD, broad range (2.5–10 mg)	Extensive hepatic metabolism, Renal excretion for metabolites	Pharmacokinetics: 20–60 hrs, variable †Pharmacodynamics: 42–72 hours	PT/INR (2.0–3.0)
Dabigatran (Pradaxa)	Parenteral anticoagulant × 5–10 days, then dabigatran 150 mg po BID	>80% renal, 20% biliary Pro-drug	12–17 hours 14–17 hours (elderly)	None required
Rivaroxaban (Xarelto)	15 mg po BID × 21 days; then 20 mg po QD	66% renal, 33% biliary CYP450 substrate	5–9 hours 9–12 hours (elderly)	None required
Apixaban (Eliquis)	10 mg po BID × 7 days, then 5 mg po BID	25% renal, 75% biliary CYP450 substrate	8–15 hours	None required
Edoxaban (Savaysa)	Parenteral anticoagulant × 5–10 days, then edoxaban 60 mg po QD (30 mg < 60 kg)	35% renal, 60% biliary	10–14 hours	None required
Betrixaban (Bevyxxa)‡	160 mg first dose, then 80 mg po QD for 35–42 days†	11% renal 85% biliary	19–27 hours	None required

UFH, Unfractionated heparin; LMWH, low-molecular-weight heparin.

\*Anti-FXa activity can be used in selected circumstances such as pregnancy and extremes of body weight (BW) (BW <45 kg or >100 kg).

‡Betrixaban FDA approved for VTE prophylaxis only.

coagulation factors VII, IX, X, and II. Vitamin K is oxidized during  $\gamma$ -carboxylation of these coagulation factors, and warfarin inhibits enzymatic regeneration of the reduced form of vitamin K, creating a functional deficiency. This mechanism of action is the basis for (1) the reversibility of the warfarin by administration of the reduced form of vitamin K, (2) the reduction in warfarin effect by dietary vitamin K, and (3) the enhancement of the warfarin effect by many antibiotics, as bacterial flora are a major source of vitamin K. Warfarin also undergoes extensive metabolism by the liver, which provides multiple opportunities for drug interactions. Thus genetic variation in liver metabolism, variable dietary vitamin K intake, and numerous potential drug interactions generate substantial individual variation in warfarin dose requirements.

Warfarin (2.5- to 10-mg initial dose) is usually started the same day as heparin, overlapped with parenteral heparin therapy for a *minimum* of 5 days and discontinued once a therapeutic warfarin level is obtained on two consecutive days. The warfarin effect is monitored by the international normalized ratio (INR), which represents a prothrombin time (PT) that has been corrected for specific reagent sensitivity. The target INR for VTE treatment is 2.0 to 3.0. The pharmacodynamic effects of warfarin on the INR are primarily determined by the in vivo half-lives of the relevant coagulation factors. Thus the full effect of a warfarin dose change on the INR is usually not seen for 48 to 72 hours, correlating with the half-life of factors IX, X, and prothrombin (factor II). This delayed effect necessitates overlap with heparin therapy for at least 5 days, or longer if further warfarin dose titration is required to reach a therapeutic INR. Initial warfarin dosing should be conservative (2.5 mg daily) if enhanced sensitivity is expected, including patients that are elderly (>65 years old), low

body weight (<45 kg), hypoalbuminemic (<2 g/dL), on antibiotic therapy or have poor oral intake.

The traditional heparin-warfarin regimen has been increasingly supplanted by the use of direct oral anticoagulants (DOAC). DOACs are orally available, low-molecular-weight compounds that directly inhibit the active site of either factor Xa (rivaroxaban [Xarelto], apixaban [Eliquis], edoxaban [Savaysa]), or thrombin (dabigatran [Pradaxa]). In general, these drugs possess predictable pharmacokinetics and relatively short half-lives, allowing fixed once- or twice-daily oral dosing without routine monitoring. Both rivaroxaban and apixaban are approved for initial use after the VTE diagnosis with a more intensive dose regimen that tapers to the standard maintenance dose after 21 days for rivaroxaban or 7 days for apixaban (Table 4). Edoxaban and dabigatran are approved for continued treatment of VTE at their standard maintenance dose after 5 to 10 days of a parenteral anticoagulant (usually LMWH). Differences in clearance mechanisms have implications for clinical usage. For instance, dabigatran is heavily dependent on renal clearance and can accumulate with increased bleeding risk in patients with significant renal insufficiency (CrCl <30 mL/min). In contrast, apixaban dosing is less affected by renal insufficiency but should not be used in patients with significant liver dysfunction or biliary stasis.

#### Comparison of Warfarin Versus DOACs

DOACs demonstrate equivalent efficacy to the traditional combination of LMWH and warfarin in the treatment of VTE. Advantages of the DOACs include rapid onset of action, predictable dose response, no monitoring requirement, elimination of parenteral

**TABLE 5** Reversal Agents

DRUG	REVERSAL AGENT	DOSING	COMMENTS
Heparin	Protamine*	1–1.5 mg/100 U UFH IV	Hypersensitivity reactions, less effective vs. LMWH
Warfarin	4 factor PCC (Kcentra) FFP Vitamin K	25–50 U/kg IV 2–4 liters 1–10 mg oral or IV	Dose depends on INR, PCC favored over FFP Volume overload, Transf rxn Reversal takes 6–24 hours
Dabigatran	Idarucizumab (Praxbind)	2.5 g IV for 2 doses (within 15 min)	Drug specific monoclonal Fab fragment
Rivaroxaban Apixaban Edoxaban <sup>1</sup> Betrixaban <sup>1</sup>	Andexanet alfa (Andexxa) <sup>1</sup> 4 factor PCC <sup>†</sup>	800 mg IV bolus @ 30 mg/min, then 960 mg infusion @ 8 mg/min 50 U/kg IV	Reverses factor Xa active site inhibitors

\*FDA approved for treatment of heparin overdose. Off-label uses: heparin neutralization (adults); intracranial hemorrhage associated with heparin or LMWH; LMWH overdose (adults).

<sup>†</sup>Evidence for reversal of factor Xa inhibitors by PCC is low quality.

<sup>1</sup>Not FDA approved for this indication.

therapy (rivaroxaban and apixaban), no significant diet interactions, limited drug interactions, and an overall safety signal equivalent to or better than warfarin. Meta-analysis of DOAC trials demonstrate that fatal bleeding, intracranial hemorrhage (ICH), and clinically relevant, non-major bleeding are reduced with DOACs compared to warfarin. The rate of GI bleeding was similar. Given the potentially life-changing nature of ICH, the lower rate with DOACs is particularly significant. Disadvantages of DOACs include cost, inability to monitor compliance with routine coagulation testing, the impact of renal function on drug clearance, and lack of widely available reversal agents. The relatively short half-lives of DOACs and recent development of reversal agents (Table 5) partially overcomes the reversibility advantage for warfarin. Largely based on safety profile and ease of use, recent guidelines provide a weak recommendation for DOACs over warfarin in patients without cancer.

#### Cancer-Associated Thrombosis

VTE associated with cancer accounts for ~20% of all cases and clearly is a heterogeneous patient population. Treatment of cancer-associated thrombosis is problematic in that patients are at increased risk for both VTE recurrence and bleeding complications. In addition to the multiple drug interactions that complicate VKA use in cancer patients, LMWH demonstrates significantly lower rates of recurrent VTE relative to VKA therapy. Thus LMWH for the first 6 months after the event has been the standard recommendation. The role of DOACs in cancer-associated thrombosis continues to evolve. Meta-analysis of subgroups from the large DOAC VTE trials demonstrates no difference in VTE recurrence or major bleeding compared with LMWH for primarily low-risk cancer patients. Subsequent comparison of edoxaban and dalteparin (Hokusai Trial) in a broader population of active cancer patients demonstrated a lower rate of VTE recurrence but higher rate of major bleeding. A randomized study comparing rivaroxaban to dalteparin (SELECT-D) demonstrated similar findings with reduced VTE rate and increased non-major bleeding in the DOAC arm. The increased bleeding was primarily observed in patients with upper GI or urothelial cancers in both studies. Ongoing studies will further address the role of DOACs in this setting. Duration of therapy is generally at least 6 months, but may be modified based on disease response, bleeding risk, and prognosis.

#### Special Considerations in the Acute Management of Venous Thromboembolism (VTE)

Although the vast majority of patients diagnosed with venous thromboembolism (VTE) should be promptly initiated on therapeutic anticoagulation, a limited number of acute presentations

may require a modified approach. These presentations include the following:

#### Massive Pulmonary Embolism (PE) With Hemodynamic Instability

Patients presenting with hemodynamically unstable PE (SBP < 90 mmHg for 15 minutes, requiring vasopressors or overt shock) are at high risk for right heart failure and death. The focus for these patients should be resuscitation (IV fluids, pressors, oxygenation, and airway control) and rapid confirmation of diagnosis (perfusion scan or CT pulmonary angiography). If highly unstable, then bedside ECHO may be used for a presumptive diagnosis based on right ventricular findings. Prompt thrombolytic therapy (tPA [Activase] 100 mg IV) or consideration of emergency endovascular therapy should be pursued, with the former being more readily available.

Patients who present with worsening right heart failure, pre-resuscitation cardiopulmonary arrest, free-floating thrombus, or high thrombus burden in the absence of systemic hypotension may also be considered for thrombolytic therapy. Many institutions have a pulmonary embolism response team (PERT) to facilitate decision making and institution of therapy. However, for the majority of patients presenting with evidence of right ventricular dysfunction (by ECHO or CT) without systemic hypotension (i.e., “sub-massive” or intermediate risk PE), the use of thrombolytic therapy remains controversial. This controversy stems from both heterogeneity in patient selection for these trials and the inability to demonstrate long-term benefits over anticoagulation alone.

Broader use of thrombolytic therapy is primarily limited by the increased risk of major bleeding (9.2%) versus anticoagulation (3.4%), which includes a 1.5% incidence of intracranial bleeding. Contraindications include previous intracranial hemorrhage, known intracranial vascular lesion or malignancy, ischemic stroke within 3 months, suspected aortic dissection, active bleeding or bleeding diathesis, and closed head/facial trauma within 3 months. Relative contraindications include poorly controlled hypertension, recent surgery (14 days), and pregnancy. The use of combined modalities (catheter-based fibrinolysis, pharmacomechanical clot dissolution) and lower doses of tissue plasminogen activator (tPA 50 mg IV) may modulate the bleeding risk, but currently broader application of thrombolytic therapy remain controversial.

#### Extensive Proximal Vein Lower Extremity Thrombosis

Proximal iliac vein thrombosis is often highly symptomatic and may result in severe postthrombotic syndrome (PTS). Rarely, compromise of the arterial supply may occur, as described for phlegmasia alba dolens (“milk leg”) and phlegmasia cerulea

dolens. The former describes a swollen, white extremity with early compromise of arterial flow secondary to extensive DVT. The latter is an advanced stage characterized by severe swelling, cyanosis, and blue discoloration of the extremity—a precursor of venous gangrene. These entities are emergencies that require prompt anticoagulation, elevation, and consideration of endovascular intervention. The presence of bilateral proximal iliac vein thrombosis should prompt evaluation for IVC thrombus or agenesis, particularly in younger patients. Catheter-directed thrombolysis and endovascular approaches have been pursued in proximal iliofemoral venous thrombosis in an attempt to reduce the risk of severe PTS. Recent studies have been unable to demonstrate that the desired benefit in PTS reduction outweighs the increased risk of bleeding. Thus the routine use of thrombolytic therapy for proximal iliofemoral venous thrombosis cannot be recommended, and patient selection for this approach remains controversial.

#### *Spontaneous Proximal Upper Extremity Thrombosis*

The majority of upper extremity DVT is related to intravenous catheters, malignancy, or thrombophilia. Spontaneous upper extremity DVT in the absence of provocation is rare. This entity (Paget-Schroetter syndrome) tends to occur in a younger, often adolescent population with a recent history of exercise or strenuous activity usually involving the dominant upper extremity. This presentation in the absence of usual VTE risk factors should prompt an evaluation for venous thoracic outlet syndrome (TOS). Because of the younger age of these patients and significant disability associated with PTS in the upper extremity (particularly the dominant hand), the initial approach has included thrombolysis (within 14 days), anticoagulation, and evaluation for venous TOS. However, no rigorous comparison of these approaches or combinations of approaches has been undertaken. If evidence for venous TOS is demonstrated, first rib resection on the affected side is often recommended. In the absence of a predisposing anatomical abnormality, an underlying thrombophilic state or occult malignancy should be considered.

#### *VTE Presenting With Paradoxical Embolism*

The occurrence of arterial embolism, most commonly cryptogenic stroke, in the presence of DVT and a right-to-left shunt (i.e., patent foramen ovale or PFO) suggests the diagnosis of paradoxical embolus. Standard anticoagulation for VTE is recommended, followed by PFO closure when complete. If indefinite anticoagulation is planned, the additional benefit of PFO closure is unclear.

#### *Acute Venous Thromboembolism With Contraindication to Anticoagulation*

Occasional patients diagnosed with acute VTE will have an absolute contraindication to anticoagulation. Placement of a temporary IVC filter may be considered in these patients to provide short-term protection from PE. However, the vast majority of contraindications to anticoagulation are temporary and definitive anticoagulation therapy should be instituted as soon as feasible. IVC filter use is associated with increased risk of lower extremity DVT. Evaluation for IVC filter removal should be planned within 3 to 6 months, depending on the clinical scenario.

#### *Isolated Subsegmental Pulmonary Embolism and Incidental VTE*

The enhanced sensitivity of current CT scanners and extensive use of CT angiography has led to an increased diagnosis of isolated subsegmental PE. Treatment of isolated subsegmental PE (where proximal DVT has been excluded) is controversial as the natural history and benefit of anticoagulation is unclear. If an isolated subsegmental defect occurs in a clinical context that is high risk for recurrent VTE (e.g., malignancy), therapeutic anticoagulation is preferred. Alternatively, for an isolated subsegmental PE occurring in a patient that is otherwise low risk for VTE recurrence, clinical surveillance is preferred. Based on the frequency of diagnostic and staging CT scans in cancer patients, an incidental

diagnosis of VTE is not an uncommon finding. Although outcome data are limited in this setting, incidental VTE appears to have similar effects on mortality and risk of VTE recurrence. Because the outcomes for incidental and symptomatic VTE in cancer patients appear similar, most cases of incidental VTE should be treated similar to symptomatic VTE.

#### *Special Circumstances for Anticoagulant Monitoring*

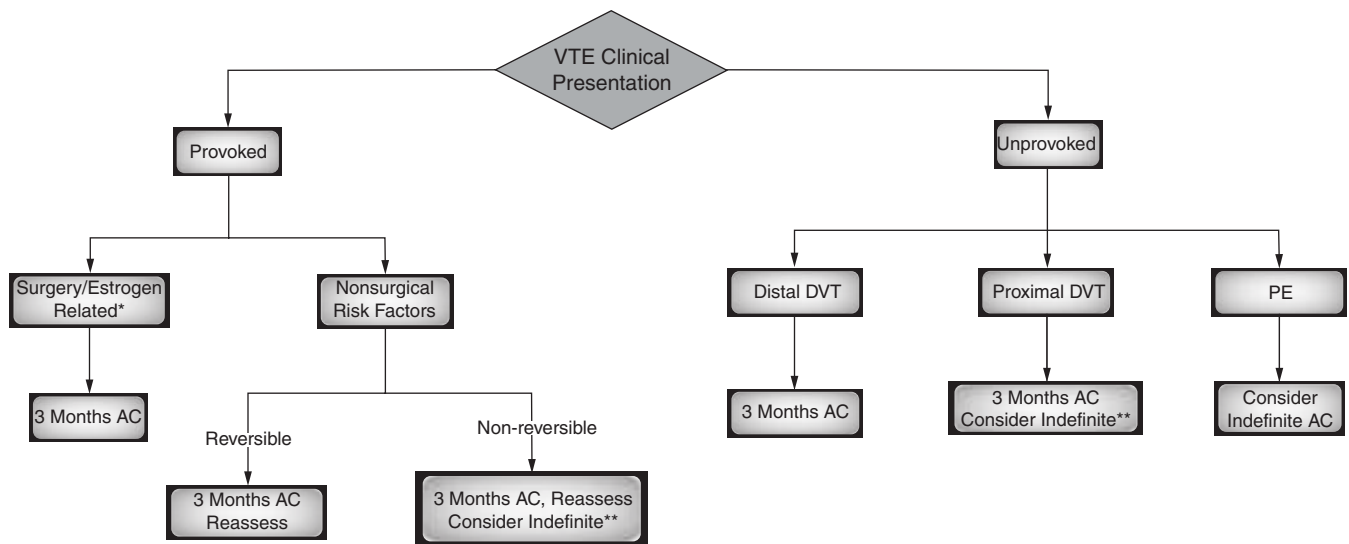

The predictable dose responses for LMWH, fondaparinux and the DOACs allow use without monitoring. However, select circumstances exist where monitoring may be desirable. LMWH is the preferred anticoagulant in pregnancy, but weight-based dosing may not be as accurate during pregnancy. Periodic confirmation of therapeutic target levels (0.5–1.2 U/mL anti-factor Xa activity) 4 hours after subcutaneous injection is often recommended. Likewise, the accuracy of weight-based LMWH dosing with a body weight <45 kg or >100 kg is not extensively validated. Confirmation of therapeutic peak levels in these individuals is recommended. Similarly, a need for DOAC drug levels may arise when assessing compliance, bleeding with potential drug overdose, or for an emergent procedure. DOACs directed against factor Xa (rivaroxaban, apixaban, and edoxaban) are monitored with an anti-factor Xa activity assay using a drug-specific standard curve. Significant dabigatran drug effect is excluded with a normal thrombin time. Alternatively, dabigatran drug effect can be detected by prolongation of the APTT or more specialized coagulation tests. The INR is not sensitive to dabigatran.

#### *Reversal Agents*

Acute reversal of anticoagulation may be required for drug overdose with clinically significant bleeding or emergent procedures. If the situation is non-emergent, holding warfarin (4–5 days depending on INR) or DOACs (2–3 days depending on renal function) is preferable. If urgent reversal is required, specific agents exist for UFH, warfarin, and, more recently, DOACs (Table 5). Although UFH overdose may be reversed with dose-adjusted protamine, the short half-life of UFH and potential toxicity of protamine often mitigate against use. Protamine<sup>1</sup> is most commonly used to reverse high-dose UFH after cardiopulmonary bypass. LMWH overdose may also be treated with protamine, but significantly less effectively. Warfarin is fully reversed by administration of 4 factor prothrombin complex concentrate (PCC) or fresh frozen plasma (FFP). The 4-factor PCC dose is modified based on the INR and favored over FFP, which may be complicated by volume overload and transfusion reactions. Immediate reversal with PCC or FFP should be followed with 5 to 10 vitamin K by the oral or IV route. Vitamin K takes 6 to 24 hours to act but is critical to maintaining anticoagulant reversal because the PCC or FFP effect will wane based on plasma half-life of the coagulation factors. Notably, high doses of vitamin K can result in relative warfarin resistance for the ensuing 1 to 2 weeks. Lower doses of vitamin K (1–2 mg) may be appropriate for less serious bleeding where early reinitiation of warfarin is anticipated. Highly specific agents for the reversal of DOACs are now available. Dabigatran is rapidly reversed by administration of idarucizumab (Praxbind), a humanized monoclonal Fab fragment that neutralizes the parent drug and major metabolites. DOACs targeting factor Xa (rivaroxaban, apixaban, edoxaban, betrixaban [Bevyxxa]) may be rapidly reversed with andexanet alfa (Andexxa), a truncated, inactive form of recombinant factor Xa that acts as a decoy for small molecules targeting the factor Xa active site. Andexanet alfa was approved for life-threatening bleeding in patients treated with rivaroxaban and apixaban based on an open label, single group study (ANNEXA-4). Given the relatively short half-lives of the DOACs, the high cost, and association with increased risk of thromboembolic events for andexanet alfa, it should be reserved for truly emergent procedures or life-threatening anticoagulant-related bleeding.

<sup>1</sup>Not FDA approved for this indication.

**Figure 3** Suggested algorithm for treatment of VTE. AC = anticoagulation. \*Estrogen-related includes oral contraceptives, hormone replacement therapy, pregnancy and puerperium. \*\*Indefinite anticoagulation includes reduced dose DOAC options after initial 3 months therapeutic AC.

### Duration of Anticoagulation

Standard treatment for a new episode of DVT or PE has traditionally been 3 to 6 months of therapeutic anticoagulation. The recommended duration of anticoagulation for VTE requires individualized analysis of the clinical presentation and patient specific factors that weigh both recurrence and bleeding risk (Figure 3).

### Clinical Presentation

Recurrence risk varies widely based on clinical presentation (see Natural History). The key distinction is between events that occur in the absence (unprovoked) versus the presence (provoked) of established VTE risk factors (Table 1). The majority of cases with clinical risk factors present may be categorized as transient/reversible (e.g., surgery, estrogen) or permanent/non-reversible (e.g., dense hemiplegia secondary to stroke). Surgery is a major transient risk factor for VTE with a low recurrence risk (3% at 5 years). Three months of anticoagulation is sufficient for this population, while shorter durations are associated with increased risk of recurrence. Estrogen-related events have a similarly low risk of recurrence if re-exposure is avoided. A second category of VTE events occurs in association with a nonsurgical transient risk factor (leg injury, significant medical illness, travel-associated) and demonstrates an intermediate recurrence risk (15% at 5 years). This subgroup is substantially more heterogeneous than the surgical group, with a variety of triggering factors and broader recurrence risk estimates. VTE events associated with nonreversible clinical risk factors may require extended anticoagulation with periodic reassessment of risks and benefits. Unprovoked VTE demonstrates a high risk of recurrence (30% at 5 years) and, in many respects, behaves as a chronic disease. Finally, patients with an underlying malignancy represent ~20% of VTE cases but are usually excluded from natural history studies. Cancer-associated thrombosis demonstrates a 15% annualized recurrence risk with longer-term risk more difficult to estimate based on competing mortality from the underlying cancer. These patients have concomitant increased bleeding risk, complicating the risk-benefit analysis for anticoagulation.

### Thrombus Site

Thrombus location significantly influences recurrence risk, with more proximal events demonstrating higher rates of recurrence. Patients with isolated distal or calf vein DVT are half as likely to have recurrent events compared to proximal DVT or PE. Patients presenting with proximal DVT have similar recurrence risk to patients with PE. However, patients initially presenting with PE

are substantially more likely to have a PE recurrence relative to patients presenting with DVT only. This finding takes on particular importance when one considers the cause specific mortality rate associated with PE is greater than 10%. Thus patients presenting with unprovoked PE deserve particular attention with regard to consideration of indefinite anticoagulation.

### Standard Versus Indefinite Anticoagulation

Clinical presentation categorizes patients with regard to recurrence risk, which is critical to the decision between standard (3 months) and indefinite anticoagulation (Figure 3). This decision is also influenced by bleeding risk and requires clinical judgment. As above, VTE associated with surgical or estrogen-related provoking factors and distal DVT (provoked or unprovoked) should be treated with therapeutic anticoagulation for 3 months. Conversely, most patients with unprovoked proximal DVT or PE should be considered for indefinite therapy based on their substantial recurrence risk, unless they also have high bleeding risk. There is little rationale for arbitrary extended periods of anticoagulation beyond the standard 3 to 6 months, unless awaiting resolution of a risk factor (e.g., extended immobilization). Prolongation of anticoagulation beyond 6 months in patients with unprovoked VTE delays but clearly does not prevent recurrence. A number of strategies, including postanticoagulation D-dimer testing (3–5 weeks) and risk stratification models, have attempted to identify patients with unprovoked VTE for which anticoagulation may be safely stopped. Post-anticoagulation D-dimer testing is the most established strategy, further stratifying these patients into high (8.8%) and low (3.0%) first-year recurrence rates. Conversely, the presence of persistent or multiple antiphospholipid antibodies increases recurrence risk (1.8- to 4.5-fold) for patients presenting with unprovoked VTE. Alternative approaches to risk reduction in unprovoked VTE include indefinite anticoagulation with reduced intensity DOACs or daily ASA. ASA reduces recurrence risk by ~1/3 in unprovoked VTE but is inferior to reduced dose rivaroxaban and apixaban (EINSTEIN CHOICE, AMPLIFY-EXT).

VTE associated with nonsurgical risk factors is more problematic with regard to definitive assessment of recurrence risk. Patients who suffer VTE with minor provocations may have a recurrence rate that approaches unprovoked VTE. These patients should be treated for at least 3 months and reassessed. Clinical factors that may impact a decision for indefinite anticoagulation include underlying cardiopulmonary disease (decreased ability to tolerate recurrence), ongoing inflammation (inflammatory bowel disease, autoimmune disease, chronic infections), prolonged immobilization (stroke), and male sex. For patients

with a prolonged but ultimately reversible risk factor (i.e., stroke immobilization improving with physical therapy), prolongation of anticoagulation until resolution of the underlying risk factor is reasonable. Similarly, travel-associated thrombosis may be a recurring risk that requires an intermittent prophylaxis plan. Bleeding risk assessment is important to decisions regarding recommended duration of therapy. Major risk factors for bleeding on anticoagulation include: advanced age, previous bleeding history, cancer, renal or liver failure, previous stroke, diabetes mellitus, nonsteroidal inflammatory drugs or antiplatelet therapy, comorbidity and reduced functional capacity, recent surgery, frequent falls, and alcohol (Table 6). Additional risk assessment tools (e.g., HAS-BLED score) exist, primarily validated for warfarin therapy.

### Clinical Decision Making

Particularly for clinical situations with modest evidence, shared decision making between physician and patient is desirable in determining the duration of anticoagulant therapy. Medical comorbidities affecting bleeding or fall risk in the elderly, patient anxiety about recurrent VTE events, and occupational/lifestyle risks for trauma may substantially impact anticoagulation decisions. Family history should be obtained with particular attention to first-degree relatives affected by VTE, including unprovoked events and age of presentation. Questions regarding the underlying cause for a VTE event often drive requests for thrombophilia evaluations. These requests generally fail to acknowledge the complex, multigenic basis for VTE and rarely contribute to clinical decision making (see “Genetics of Venous Thromboembolism”). The clinical presentation and family history are substantially more useful than identification of minor thrombophilia traits, which are poor predictors of VTE recurrence. Finally, when a decision is made to pursue indefinite anticoagulation, periodic reassessment of this decision is important. The risk-to-benefit ratio of anticoagulation may change as the patient’s medical history evolves. The hematology consultant serves an important role in facilitating difficult anticoagulation decisions.

### Prevention of Venous Thromboembolism

About 60% of VTE events are associated with recent hospitalization or surgery, and up to 70% of these cases are preventable. However, less than half of hospitalized patients receive appropriate prophylactic measures. Given the significant morbidity and mortality associated with VTE, primary prophylaxis strategies in high-risk situations are of great medical importance and may provide a cost savings. Risk stratification of patients based on surgery or medical illness, patient characteristics (previous VTE, active cancer, duration of immobility, etc.), and bleeding risk impact recommendations for pharmacologic and mechanical prophylaxis. Pharmacologic agents include LMWH, fondaparinux, low-dose UFH, VKA, and DOACs. The focus in this section is primarily on heparin and DOACs given the available evidence. Mechanical prophylaxis includes graduated compression stockings (GCS) that are >15mm Hg at the ankle or intermittent pneumatic compression devices (IPCs). IPCs enhance lower extremity deep vein blood flow and may increase fibrinolytic activity. These modalities can be used alone or in combination for patients with high bleeding risk who cannot use pharmacologic prophylaxis. IPCs are considered more effective than GCS alone, particularly after orthopedic surgery.

### General Surgery

For general surgery patients, well-established risk assessment tools such as the Caprini or Rogers scores stratify patients by VTE risk to identify those who would benefit from pharmacologic prophylaxis. In general, if the risk of VTE is moderate to high and bleeding risk is low, pharmacologic prophylaxis with

### Categorization of Risk of Bleeding

	ESTIMATED ABSOLUTE RISK OF MAJOR BLEEDING		
	LOW RISK (0 RISK FACTORS)	MODERATE RISK (1 RISK FACTOR)	HIGH RISK (≥2 RISK FACTORS)
Anticoagulation 0–3 mo			
Baseline risk (%)	0.6	1.2	4.8
Increased risk (%)	1.0	2.0	8.0
Total risk (%)	1.6	3.2	12.8
Anticoagulation after first 3 mo			
Baseline risk (%/y)	0.3	0.6	≥2.5
Increased risk (%/y)	0.5	1.0	≥4.0
Total risk (%/y)	0.8	1.6	≥6.5

Data from the 9<sup>th</sup> Edition of the Antithrombotic Guideline (AT9).

LMWH or low-dose UFH should be given. If the bleeding risk is high, intermittent pneumatic compression with or without GCS should be used. Ideally, the minimal duration of prophylaxis is 5 to 10 days but varies widely based on duration of bed rest, inpatient stay, and comorbid conditions. In patients with active cancer undergoing abdominopelvic surgery, prophylaxis should be extended to 4 weeks after surgery.

### Orthopedic Surgery

Orthopedic procedures are associated with high risk of VTE, especially those involving the lower extremities and pelvic region. For patients undergoing total hip or total knee arthroplasty, pharmacologic prophylaxis using LMWH, UFH, DOACs, or adjusted-dose warfarin should be used if no

**TABLE 7** Risk Factor Stratification and Prophylaxis Options

RISK STRATIFICATION	RECOMMENDED PROPHYLAXIS	DURATION
<b>Low Risk</b>		
Same-day surgery Medical illness in a fully mobile patient	Early mobilization	-
<b>Moderate Risk</b>		
Most general surgery procedures	LMWH UFH IPC/GCS with or without pharmacologic prophylaxis as appropriate	5–14 days
Most acute medical illnesses	LMWH UFH Betrixaban <sup>^</sup>	Duration of inpatient stay Extended duration beyond hospitalization may be appropriate for very-high-risk patients in whom bleeding risk is low
<b>High Risk</b>		
Hip or knee replacement surgery	LMWH UFH Fondaparinux Rivaroxaban Apixaban Dabigatran* Adjusted dose Warfarin	At least 10–14 days Extended duration up to 4 weeks preferred ASA may be used subsequently for extended duration of therapy
General surgery with active cancer, previous VTE	LMWH** UFH Adjusted dose Warfarin	Extended duration (4 weeks) for abdominopelvic surgeries in cancer patients
Major Trauma, Spinal cord injury	IPC with or without GCS, use pharmacologic prophylaxis when appropriate	

**Abbreviations:** DVT: deep venous thrombosis; GC: graduated compression; IPC: intermittent pneumatic compression; LMWH: low-molecular-weight heparin; UFH: unfractionated heparin; VTE: venous thromboembolism.

<sup>^</sup>Usually started postoperatively and adjusted to achieve an international normalized ratio of 2.0–3.0

<sup>^</sup>FDA approved for patients hospitalized for acute medical illness at high risk of VTE

\*FDA approved for VTE prevention after hip replacement surgery

\*\*Off-label use in cancer patients

contraindication exists. LMWH is quite effective and safe with the benefit of long-term experience with these agents. Low-dose DOACs have shown comparable efficacy to enoxaparin in this population with a similar low absolute risk of bleeding. Low-dose apixaban (2.5 mg twice daily), rivaroxaban (10 mg daily), and dabigatran (150 mg daily) appear safer than higher doses. Prophylaxis should continue at least 10 to 14 days, and prolongation up to a month should be considered for major orthopedic surgery. Low-dose aspirin has been shown to be effective for extended prophylaxis after initial acute phase of therapy (~5 days) with standard anticoagulant in patients undergoing total hip or knee arthroplasty; however, anticoagulants are generally favored for high-risk patients. IPCs should be used during

the inpatient stay in addition to pharmacologic prophylaxis. If bleeding risk is high, IPCs should be used until pharmacologic agents can be safely administered. For arthroscopic procedures of the knee and other low-risk procedures, prophylaxis is generally not indicated unless other risk factors exist. A summary of available agents and recommendations for prophylaxis is provided (Table 7).

### Acute Medical Illness

For hospitalized patients with medical illnesses, the risk of VTE is ~8 fold higher than the general population. Patients expected to be hospitalized with reduced mobility >3 days, a previous history of VTE, active infection or malignancy, recent surgery or trauma, heart failure or respiratory failure should be considered for prophylaxis. The Padua score is a prospectively validated risk assessment model that stratifies patients into groups with high (~11%) or low (0.3%) incidence of VTE. Current prophylaxis options for medical patients include LMWH, low-dose UFH, and fondaparinux. When bleeding risk is considered moderate to high, mechanical prophylaxis using IPCs or GCS should be used until it is safe to add anticoagulants. For low-risk patients admitted for short duration or remaining ambulatory, withholding prophylaxis may be appropriate. Clinical context and bleeding risk assessment should also impact these decisions.

Although pharmacologic prophylaxis is typically limited to the acute illness during the inpatient stay, analysis of population-based data suggests that ~75% of VTE events occur well after discharge, at a median of almost 3 weeks. Furthermore, increased compliance with inpatient prophylaxis over time has not resulted in the expected decrease in the rate of VTE. The effect of extended DOAC prophylaxis (35–42 days) has been examined in medical patients for apixaban, rivaroxaban, and betrixaban. Reduced-dose apixaban and rivaroxaban demonstrated similar VTE prevention to standard enoxaparin prophylaxis but increased bleeding events. Evaluation of betrixaban in a select patient group (elevated D-dimer and elderly) demonstrated modestly better VTE prevention relative to enoxaparin, with an increase in nonmajor but not major bleeding. Extended prophylaxis is an area of ongoing investigation with unresolved issues that include appropriate patient selection and discerning the impact of specific anticoagulants versus prophylaxis duration on outcomes.

### CURRENT DIAGNOSIS

#### Influenza (human, avian, swine)

- Mild influenza A or B presents acutely with headache, fever, sore throat, plus/minus rhinorrhea.
- Severe influenza A presents with an acute onset (patients often able to name the hour the influenza began) and rapidly become bed bound.
- Headache, myalgias, and prostration may be severe.
- With swine influenza, gastrointestinal symptoms (e.g., nausea/vomiting or diarrhea) may be prominent.
- Auscultation of the lungs is quiet, disproportionate to the degree of respiratory distress. Influenza is an interstitial process and not alveolar, which explains the absence of rales.
- With severe influenza, patients rapidly become hypoxemic. Hypoxemia is accompanied by an A-a gradient >35, which indicates a interstitial oxygen diffusing defect.
- Severe tracheobronchitis is common and manifested by hemoptysis.
- Relative lymphopenia with monocytosis occurs early followed by thrombocytopenia and later leukopenia. Low titer elevations of cold agglutinins are not infrequent ( $\geq 1:18$ ).
- Patients may have chest pain exacerbated by breathing mimicking pleuritic chest pain. This is the result of direct intracostal muscle involvement with the influenza virus, which results in myositis and pain on inspiration.
- The chest radiograph in early influenza in mild to moderate cases is normal or near normal, with minimal, if any, increase in interstitial markings. The chest radiograph in fulminant cases shows symmetrical bilateral patchy infiltrates without pleural effusion in 48 hours.
- Severe influenza A is accompanied by severe hypoxemia cyanosis, and may be followed by an early fatal outcome.
- Influenza pneumonia most often presents alone without bacterial superinfection, but bacterial infection may accompany (e.g., MSSA/CA-MRSA) or follow influenza (e.g., *S. pneumoniae* or *H. influenzae*).
- Purulent sputum with influenza indicates concurrent bacterial pneumonia usually caused by *S. aureus* (methicillin-susceptible *Staphylococcus aureus* [MSSA]/methicillin-resistant *Staphylococcus aureus* [MRSA]). Bacterial pneumonia following influenza (after 1–2 weeks), is suggested by leukocytosis, focal or segmental pulmonary infiltrates, and purulent sputum; the pathogens are not *S. aureus*, but most commonly are *S. pneumoniae* or *H. influenzae*.
- A laboratory diagnosis may be made by multiplex polymerase chain reaction (PCR) of respiratory secretions.

#### COVID-19

- COVID-19 is caused by a novel  $\beta$ -coronavirus (different than the novel  $\beta$ -coronaviruses causing severe acute respiratory syndrome [SARS] and Middle East respiratory syndrome [MERS]) identified as SARS-CoV-2.
- Common nonspecific laboratory abnormalities include leukopenia, relative lymphopenia, thrombocytopenia, and mildly elevated serum transaminases.
- Chest x-ray (CXR) early resembles that of influenza pneumonia (i.e., essentially unremarkable, without definite/discreet infiltrates).
- As COVID-19 pneumonia progresses, the CXR shows bilateral interstitial fuzzy/fluffy peripheral infiltrates.

- Chest computed tomography (CT) scans may show bilateral peripheral infiltrates with or without consolidation.
- Diagnosis of COVID-19 is by reverse transcription PCR (RT-PCR) of respiratory tract specimens or antigen testing. RT-PCR usually becomes positive early in the disease course (days).
- COVID-19 seems to preferentially affect adults, with relative sparing of young children. Elderly patients with advanced lung/cardiac disease are particularly predisposed to severe disease/complications.

#### *Mycoplasma pneumoniae*

- In a patient with community-acquired pneumonia (CAP) who has a dry, nonproductive cough without severe headache or myalgias, the most likely diagnosis is *M. pneumoniae*. *M. pneumoniae* CAP is commonly accompanied by nonexudative pharyngitis and/or loose stools or watery diarrhea.
- The temperature is usually less than 102°F (38.9°C) and is not accompanied by frank rigors or pleuritic chest pain.
- Relative bradycardia and elevations in the serum transaminases are not features of *M. pneumoniae* CAP.
- Respiratory viruses are often associated with mild elevations of cold agglutinins ( $\leq 1:16$ ) but *M. pneumoniae* is the only pathogen causing CAP associated with highly elevated cold agglutinin titers ( $\geq 1:64$ ). Elevated cold agglutinin titers occur in up to 75% of patients with *M. pneumoniae*, and occur early and transiently.
- In a patient with CAP, elevated cold agglutinin titers ( $>1:8$ ) effectively rule out the typical pathogens, as well as *Legionella* species and *C. pneumoniae*.
- Elevated *M. pneumoniae* ELISA IgG titers indicate past exposure/infection and not current infection or co-infection with another pathogen.
- In the absence of an antecedent respiratory tract infection (e.g., nonexudative pharyngitis, otitis, etc., in the preceding 3 months), the presence of an increased *M. pneumoniae* ELISA IgM titer is diagnostic of acute infection.

### CURRENT THERAPY

#### Viral Influenza

- The aim of the therapy is to inhibit the influenza virus and prevent its attachment/spread to uninfected respiratory epithelial cells.
- The neuramidase inhibitors shorten the course of influenza by 1 to 2 days and have antiviral activity. These agents are active against both influenza A and B.
- Most strains of human and avian flu, but not swine flu, are resistant to amantadine (Symmetrel) or rimantadine (Flumadine).
- Amantadine and rimantadine may have an important therapeutic effect in severe influenza A by increasing distal airway dilation and increasing oxygen action.
- Peramivir (Rapivab) may be useful in those unable to take oral neuraminase inhibitors.

#### COVID-19

- Oral agents are now available to treat outpatient COVID-19 patients: Nirmatrelvir/ritonavir (Paxlovid, approved for Emergency Use Authorization by the FDA) is more effective than molnupiravir (Lagevrio, approved for Emergency Use Authorization by the FDA) in preventing disease progression.
- Effective therapy for hospitalized patients with COVID-19 pneumonia is with remdesivir (Veklury) 200 mg (IV) for the first dose, then 100 mg (IV) q24h for 5 to 10 days.
- Dexamethasone<sup>1</sup> 6 mg IV/ PO daily for 10 days should be considered in patients who are hospitalized and require supplemental oxygen.

***Mycoplasma pneumoniae***

- Monoclonal antibodies have been shown to be effective in limiting severity of disease and preventing progression/need for hospitalization if given early.
- The agents active against *M. pneumoniae* are macrolides, tetracyclines, quinolones, and ketolides.  $\beta$ -Lactam antibiotics are not active against *M. pneumoniae* because it does not contain a bacterial cell wall.
- Goals of therapy of *M. pneumoniae* CAP are to eradicate the infection, decrease the shedding of *M. pneumoniae* in respiratory secretions posttherapy, and to prevent post-treatment asthma.
- Therapy is equally efficacious with macrolides, doxycycline (Vibramycin), or a respiratory quinolone intravenously, orally, or in combination for 1 to 2 weeks.
- The mode of administration is determined by the severity of the CAP and the setting. Outpatients are usually treated orally. Patients hospitalized with severe CAP are initially treated intravenously and then changed to an oral agent.
- Macrolide resistance to *M. pneumoniae* has been described in children and reported in adults.

<sup>1</sup>Not FDA approved for this indication.

Influenza pneumonia is the most important cause of viral pneumonia in adults. Influenza A is the predominant type of influenza found in adults, and influenza B is more common in children. Influenza A has the potential for severe disease, occurs seasonally, and is the predominant type involved in influenza pandemics. *M. pneumoniae* CAP was first recognized decades ago as distinctive from bacterial and viral pneumonias. It was originally described by Eaton as “Eaton agent” pneumonia caused by a pleuropneumonia-like organism (PPLO), later shown to be caused by *M. pneumoniae*. *M. pneumoniae* is a common cause of pneumonia in all age groups, but the peak incidence of *M. pneumoniae* CAP is in young adults. *M. pneumoniae* CAP is a common cause of ambulatory CAP.

The term *atypical pneumonia* was first applied to viral pneumonias because the clinical laboratory and radiologic findings were different from those caused by typical bacterial pulmonary pathogens. In influenza pneumonia, the clinical findings are confined to the trachea, bronchi, lung parenchyma, and central nervous system. *M. pneumoniae* CAP is a systemic infection with a pulmonary component. Over the years, atypical pneumonia has come to refer to pneumonia caused by systemic nonviral/nonbacterial pathogen agents that have a pulmonary component. Viral pneumonias are no longer considered atypical pneumonias. Atypical pneumonias may be divided into nonzoonotic and zoonotic atypical CAPs. Nonzoonotic CAPs are most commonly caused by *M. pneumoniae*, *Chlamydia pneumoniae*, or *Legionella* species, whereas the three most common zoonotic atypical pneumonias are caused by *Chlamydia psittaci* (psittacosis), *Francisella tularensis* (tularemia), or *Coxiella burnetii* (Q fever). All of the atypical pneumonias are distinct clinical entities that may be differentiated on the basis of their characteristic pattern of extrapulmonary organ involvement. Although some viruses may occasionally have extrapulmonary manifestations (i.e., influenza, adenovirus with viral pneumonias), the primary clinical features are confined to the lungs. *M. pneumoniae* is a critical cause of nonzoonotic atypical CAP, particularly in the ambulatory setting. *M. pneumoniae* CAP may be severe in patients with impaired host defenses or those with severe, preexisting cardiopulmonary disease.

**Influenza (Human, Avian, and Swine)**

Viral influenza pneumonia affects children and adults. Influenza B is the primary cause of mild influenza in children and adults. Influenza A is primarily an infection of adults that may be mild to severe. Influenza A has the potential for pandemic spread (e.g., swine influenza [H<sub>1</sub>N<sub>1</sub>]).

Influenza occurs during the winter months, usually peaking in February. Influenza is spread by aerosolized droplet infection from person to person and via fomites. Influenza A is classified into subtypes based on hemagglutinin (H) and neuramidase (N) surface proteins. An important characteristic of the influenza A virus is antigenic drift, which refers to minor changes in surface protein shift in the neuramidase or hemagglutinin receptors. With influenza A, these surface receptor proteins are important in cellular adherence of the influenza virus and spread of influenza from respiratory epithelial cells. The vaccine for the flu season most often includes the influenza hemagglutinin and neuramidase types seen at the end of the preceding year’s season. Prevention of attachment and spread of the virus is helpful in controlling the spread of influenza; vaccine protection conferred by specific antibody response to influenza A is highly protective (approximately 80% in noncompromised hosts).

During the years when influenza B has been prevalent, vaccines for the subsequent year contain an influenza B component.

Clinical manifestations of influenza A in adults varies considerably from mild to fatal infection. Mild infection is usually manifested as an acute febrile illness characterized by headache and myalgias with dry, unproductive cough and rhinorrhea. Mild influenza may be caused by influenza A or B and usually resolves in a few days without complications in normal hosts who have good cardiopulmonary function.

Severe influenza A (human, avian, swine) occurs in normal healthy adults and may be fatal. The onset of severe influenza A (human, avian, swine) is sudden, and the patient often recalls the exact hour of onset. The patient is febrile, with early/extreme prostration rendering the patient bedridden. Fever rapidly rises and may be accompanied by chills. Neck soreness, severe headache, and myalgias are typical. Sore throat, eye pain, conjunctival injection, and hemoptysis are frequently present. Chest pain worsened by deep inspiration is not truly pleuritic but rather reflects influenza A myositis of the intracostal muscles. Shortness of breath is related to the degree of hypoxemia. Severe influenza A causes an oxygen diffusion defect as manifested by an increased A-a gradient (>35). Profound hypoxemia may be accompanied by cyanosis. Hypotension caused by hypoxemia and vascular collapse may follow. The course of fulminant viral influenza A is of short duration.

Physical findings are few in viral influenza (i.e., conjunctival suffusion). Auscultation reveals absolutely quiet lungs because the infectious process is interstitial and not alveolar. Routine blood tests are usually unremarkable except for leukopenia, relative lymphopenia, and thrombocytopenia. Atypical lymphocytes are not present, but low titers of cold agglutinins may be present. Cold agglutinins (if present) have titers less than or equal to 1:18. In fatal cases, a pale blue hue of the skin may be noted, and there may be bleeding from multiple orifices before death. The chest radiograph in uncomplicated influenza A is unremarkable, with minimal perihilar bilateral increased prominence of interstitial markings possible. In severe influenza A pneumonia, the chest radiograph shows bilateral symmetrical perihilar infiltrates without pleural effusions in <48 hours.

Patients may die from severe influenza A without superimposed bacterial pneumonia. Most deaths during the 1918–1919 pandemic were young military recruits who died of influenza A pneumonia without bacterial pneumonia. Influenza may be complicated by bacterial pneumonia. Bacterial pneumonias complicating influenza may occur concurrently at presentation or may occur after an interval of improvement 1 to 2 weeks after the presentation of influenza. Influenza A presenting concurrently with bacterial pneumonia is caused by *Staphylococcus aureus*. In contrast to influenza alone, MSSA/CA-MRSA is manifested by an increase in fever, shaking chills, leukocytosis, purulent sputum, localized rales on auscultation, bacteremia, and focal/segmental infiltrates on chest radiograph that rapidly cavitate in less than 72 hours. Alternatively, patients with influenza A may develop a secondary bacterial infection 1 to 2 weeks later. Secondary bacterial pneumonia is less severe and is usually caused by *Streptococcus pneumoniae* or *Haemophilus influenzae*.

Viral influenza-like illnesses (ILIs) most often present during the winter months or influenza season. For clinical and therapeutic purposes, it is important to differentiate influenza A from viral ILIs in hospitalized adults. Some clinical features may point to a specific ILI viral etiology, but a specific viral diagnosis can be made by viral respiratory PCR of nasopharyngeal swab specimens. The only viral ILI likely to mimic influenza A presenting with a fulminant severe viral CAP is MERS. The mimics of ILIs

are presented (Table 1). The main nonviral mimic of influenza A in hospitalized adults is Legionnaire's disease (LD). LD may be differentiated from influenza A and other viral ILIs by CXR findings and characteristic nonspecific laboratory tests. With LD CAP, the CXR shows one or more nonfocal infiltrates. Fever, usually greater than 102° F, is accompanied by relative bradycardia. With LD, the ESR is highly elevated (>90 mm/h), the ferritin is highly elevated (>2 times normal), and the serum phosphorus

**TABLE 1** Mimics of Influenza A in Hospitalized Adults Presenting with Influenza-like Illnesses (ILIs)

INFLUENZA-LIKE ILLNESSES (ILIS)	CHEST FILM FEATURES	CLINICAL CLUES
MERS	Ill-defined infiltrates (early) Bilateral dense interstitial nodular infiltrates (late) Severe cases often develop ARDS	Recent travel to Middle East or contact with MERS case Dry cough and sore throat Hemoptysis (in some) Diarrhea (common) WBC count normal, thrombocytopenia Elevated LDH
COVID-19	CXR: Ill-defined infiltrates (early) Bilateral, peripheral dense interstitial infiltrates. Severe cases often develop ARDS	Fever and dry cough Diarrhea (common) Myocarditis (late, in some) ARDS (in some) Leukopenia Relative lymphopenia Thrombocytopenia Mildly elevated serum Transaminases (early) Elevated CPK (in some) Elevated D-dimer may herald coagulopathy
RSV	Clear CXR (early) Bilateral ill-defined infiltrates on CXR (late) Chest CT: GGO (non-specific)	Antecedent/concurrent rhinorrhea Hoarseness Lymphocyte/monocyte ratio >2
HPIV-3	Clear CXR (early) Bilateral ill-defined infiltrates on CXR (late)	Hoarseness Prolonged lymphocyte/monocyte ratio <2 Monocytosis
EV-D86	Clear CXR (early) Bilateral ill-defined infiltrates on CXR (late)	Diarrhea (common) Flaccid paralysis
Legionnaire's disease	Rapidly progressive, asymmetric, ill-defined infiltrates on CXR Consolidation and small pleural effusions (common) Cavitation (rare)	High fevers (>102 °F) Highly elevated ESR (>90 mm/h) Ferritin (>2 xn) Leukocytosis with relative lymphopenia Elevated CPK (in some) Mild transient elevated transaminases common (early) Microscopic hematuria (early)

*Abbreviations:* MERS = Middle East respiratory syndrome; COVID-19: Coronavirus disease; RSV = respiratory syncytial virus; HPIV = human parainfluenza virus; EV = enterovirus; GGO = ground glass opacity; CXR = chest x-ray; ARDS = acute respiratory distress syndrome.

**TABLE 2** Mimics of *Mycoplasma pneumoniae* in Community Acquired Pneumonia (CAP) Hospitalized Adults

MYCOPLASMA CAP MIMICS	CHEST FILM FEATURES	CLINICAL CLUES
<i>C. pneumoniae</i>	Ill-defined lower lobe infiltrates (often ovoid) No consolidation, cavitation or effusion	No seasonal predisposition Hoarseness Prolonged dry cough Mycoplasma-like illness that doesn't respond to erythromycin Wheezing (in some) No diarrhea No cold agglutinins Rhinorrhea precedes dry cough (1–2 weeks)
Pertussis	Perihilar illdefined infiltrates ("shaggy heart" sign) No consolidation, cavitation or effusions	Prolonged dry cough Persistent cough (without typical "whoop" of children) Afebrile or minimal fevers Marked lymphocytes (> 60%) No cold agglutinins

is decreased early, as is serum sodium. Although an elevated CPK and mild transaminitis often accompany LD, these findings are not uncommon in influenza A and some viral ILIs. There are few infections that may mimic the dry, productive cough of *M. pneumoniae* CAP. Pertussis is most likely to mimic mycoplasma. Pertussis, unlike mycoplasma, is not accompanied by watery diarrhea. The distinguishing laboratory feature of *M. pneumoniae* CAP is elevated cold agglutinins not found with pertussis. The key non-specific laboratory finding in pertussis is marked lymphocytosis (Table 2).

COVID-19 emerged from Wuhan, China in 2019 and spread worldwide early in 2020, resulting in a pandemic. COVID-19 is caused by a novel  $\beta$ -coronavirus (different than the novel  $\beta$ -coronaviruses causing SARS and MERS) identified as SARS-CoV-2. SARS-CoV-2 is thought to have been contracted from wild animals in food markets. COVID-19 spreads rapidly via airborne transmission, and may be spread from asymptomatic individuals.

Patients most commonly present with fever, headache, sore throat, dry cough, shortness of breath, and diarrhea (in some).

Clinically, the spectrum of COVID-19 ranges from asymptomatic cases to symptomatic cases. Symptomatic COVID-19 most often presents as a mild ILI; in more severe cases, it presents as a viral pneumonia (not unlike influenza pneumonia). Severe COVID-19 pneumonias have severe hypoxemia caused by an oxygen diffusion defect (high A-a gradient). Fatal cases are due to ARDS and/or myocarditis. Common nonspecific laboratory abnormalities include leukopenia, relative lymphopenia, thrombocytopenia, and mildly elevated serum transaminases. Serum LDH or CPK are often elevated. Elevated D-dimers also present frequently and may herald a subsequent coagulopathy.

Early CXR resembles that of influenza pneumonia (i.e., essentially unremarkable without definite/discrete infiltrates). As COVID-19 pneumonia progresses, the CXR shows bilateral interstitial peripheral infiltrates. CXR demonstrates no/small bibasilar effusions. Chest CT scans may show bilateral nodular infiltrates with or without consolidation. Cavitation is not a feature of COVID-19 pneumonia. Co-infection or superinfection is a rare occurrence in COVID-19.

Diagnosis of COVID-19 is by RT-PCR of respiratory tract specimens. A positive RT-PCR result may be present early in the disease course, although it may not become positive for a few days. If clinical suspicion is high, serial testing may reveal RT-PCR + after 2 to 3 repeat tests. The RT-PCR should not be used as a test of cure. RT-PCR + may persist for 1 to 2 weeks after clinical recovery, although transmission should not occur during this time period. Antibody testing may become positive after several weeks.

COVID-19 seems to preferentially affect adults, with relative sparing of young children. Elderly patients with advanced lung/cardiac disease are particularly predisposed to severe disease/complications.

### Anti-Influenza Therapy

Therapy of viral influenza is directed at inhibiting viral replication and preventing further infection of respiratory epithelial cells. The neuramidase inhibitors zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir (Rapivab) have anti-influenza A and B activity. Neuramidase inhibitors decrease the severity and duration of influenza symptoms by 1 to 2 days. Current flu strains are resistant to amantadine and rimantadine, but these drugs may still be useful to increase peripheral airway dilation and oxygenation, which may be of critical importance in severe influenza A with severe hypoxemia. Mild influenza A/B may be treated with neuramidase inhibitors. Mild cases of influenza A should be treated at the onset of the illness. For severe influenza A, neuramidase inhibitors provide optimal anti-influenza therapy (Table 3). For human and avian influenza (H<sub>5</sub>N<sub>1</sub>), these antiviral drugs may be ineffective, but are effective against swine influenza.

**TABLE 3** Adult Anti-Influenza Antivirals

ANTIVIRAL	TREATMENT DOSE	PROPHYLACTIC DOSE
<b>Mild Influenza A/B</b>		
Zanamivir (Relenza)*	2 inhalations (5 mg per inhalation) q12h × 5 d	2 inhalations (5 mg per inhalation) q24h × 5 d
<b>Influenza</b>		
Baloxavir (Xofluza)	80 mg (PO) × 1 dose	80 mg (PO) × 1 dose
Oseltamivir (Tamiflu)*	75 mg (PO) q12h × 5 d <sup>†</sup>	75 mg (PO) q24h × 7 d
Peramivir (Rapivab)	600 mg (IV) over 30 min × 1 d	None

\*Currently most human and avian influenza strains are resistant.

<sup>†</sup>For avian (H5N1) influenza, 150 mg (PO) q12h may be effective.

### COVID-19 Therapy

At the time of writing, optimal therapy of COVID-19 continues to evolve. Effective therapy for hospitalized patients with COVID-19 pneumonia who require oxygen is remdesivir (Veklury) 200 mg (IV) for the first dose, then 100 mg (IV) q24h for 5 to 10 days. Oral therapy for COVID-19 is now available for certain high-risk patients. Nirmatrelvir with ritonavir (Paxlovid, approved for Emergency Use Authorization by the FDA) is currently the most effective PO agent available. Due to the ritonavir component, drug-drug interactions need to be considered when prescribing this medication. Molnupiravir (Lagevrio, approved for Emergency Use Authorization by the FDA) is an alternate PO option but has lower efficacy than Paxlovid or monoclonal antibodies in preventing serious disease in high risk patients. Monoclonal antibodies, when given early, reduce rate of hospitalization, particularly in high risk patients. Dexamethasone<sup>1</sup> has a role in limiting mortality in patients admitted with COVID-19 who require supplemental oxygen. Interleukin inhibitors (IL-6 in particular) have a role in select patients with COVID-19. Vaccines play a critical role in prevention of COVID-19, although the increasing number of genetic variants may blunt the effectiveness of existing vaccines.

### Mycoplasma Pneumoniae

*M. pneumoniae* is a common cause of ambulatory CAP. It affects all age groups, and in normal hosts with intact cardiopulmonary function, *M. pneumoniae* CAP is usually a mild, self-limiting infection. However, *M. pneumoniae* derives its importance from difficulty in diagnosis, the necessity for non- $\beta$ -lactam therapy, and because of its effect on peripheral airways.

*M. pneumoniae* CAP is one of the nonzoonotic causes of CAP (the others being *Legionella* and *Chlamydia pneumoniae*). *M. pneumoniae* is an atypical pneumonia that is a systemic infectious disease with a pulmonary component. It may be distinguished from other atypical pneumonias by its characteristic pattern of extrapulmonary organ involvement. *M. pneumoniae* CAP most closely resembles *C. pneumoniae* CAP clinically, but is very different from LD in terms of its epidemiology, age distribution, pattern of extrapulmonary organ involvement, and severity.

Clinically, *M. pneumoniae* presents as a subacute febrile illness. Temperatures rarely exceed 102°F (38.9°C). Rigors are not a feature of *M. pneumoniae* CAP, but patients may complain of chilly sensations. Mild headache and/or myalgias are not uncommon. The most common presenting symptom in *M. pneumoniae* CAP is the prolonged, nonproductive, dry cough. Patients with *M. pneumoniae* CAP often complain of

<sup>1</sup>Not FDA approved for this indication.

or have mild nonexudative pharyngitis. Rhinorrhea and conjunctivitis are not features of *M. pneumoniae* CAP. Watery diarrhea is commonly present in *M. pneumoniae* CAP, but abdominal pain is not a clinical finding. Other extrapulmonary manifestations are uncommon or rare (e.g., meningococcal meningitis, pericarditis, hemolytic anemia, glomerular nephritis, Guillain-Barré syndrome, erythema multiforme). *M. pneumoniae* has a distinctive pattern of extrapulmonary organ involvement that does not include cardiac involvement (relative bradycardia) or hepatic involvement, including normal serum glutamate-oxaloacetate transaminase (SGOT) or serum glutamate-pyruvate transaminase (SGPT). The distinguishing laboratory feature of *M. pneumoniae* CAP is elevated cold agglutinin titers. Although a variety of infectious and noninfectious diseases are associated with cold agglutinin elevations, they are usually of low titer (i.e., <1:16). There are no pulmonary infections presenting as CAP that are associated with high elevations of cold agglutinin titers (i.e., ≥1:64). Although elevated cold agglutinins occur early in up to 75% of patients with *M. pneumoniae* CAP, they are still diagnostically important when present. In a patient with CAP and a cold agglutinin titer greater than or equal to 1:64, the diagnosis of *M. pneumoniae* CAP is very likely.

*M. pneumoniae* may be differentiated from the typical bacterial pneumonias because of the presence of extrapulmonary findings, including nonexudative pharyngitis, loose stools or watery diarrhea, erythema multiforme, and high cold agglutinin. Patients with typical bacterial CAP usually have a more acute onset of presentation, a productive cough, and temperatures that may exceed 102°F (38.9°C), often accompanied by chills. Patients with typical pneumonia often have pleuritic chest pain, which is not a feature of *M. pneumoniae* CAP. Among the atypical pneumonias, the zoonotic pneumonias (i.e., tularemia, psittacosis, Q fever) may be eliminated from consideration if there is a recent zoonotic contact history with the appropriate vector.

*C. pneumoniae* CAP resembles closely *M. pneumoniae* CAP. *C. pneumoniae* may be distinguished by the absence of cold agglutinins and the presence of hoarseness, which is a feature of *C. pneumoniae* CAP but not *M. pneumoniae* CAP. Loose stools or watery diarrhea are not usual features of *C. pneumoniae* CAP. The most common clinical problem is differentiating *Legionella* from *Mycoplasma* CAP; this may be done by appreciating the differences in the pattern of extrapulmonary organ involvement with each of these pathogens. *Legionella* may be clinically differentiated from *Mycoplasma* by acuteness of onset or severity, the presence of relative bradycardia, temperatures greater than 102°F (38.9°C), and the presence of abdominal pain. From a laboratory standpoint, highly elevated cold agglutinin titers argue strongly against the diagnosis of *Legionella* and point to *M. pneumoniae*. Nonspecific laboratory tests in a patient with CAP that suggest *Legionella* and argue against *M. pneumoniae* include otherwise unexplained hypophosphatemia, hyponatremia, microscopic hematuria, and increased creatinine. *Legionella* does not affect the upper respiratory tract as does *Mycoplasma* (e.g., nonexudative pharyngitis). Ear findings are not a feature of Legionnaires' disease but are common in *M. pneumoniae* CAP. The finding most likely to cause confusion between *M. pneumoniae* and *Legionella pneumophila* is the presence of loose stools or watery diarrhea, which is found in both.

*M. pneumoniae* may be cultured from the throat in viral culture media, but the diagnosis is usually made serologically. An elevated enzyme-linked immunosorbent assay (ELISA) or enzyme immuno-assay (EIA) IgM titer suggests acute or recent infection, but an elevated IgG titer indicates past exposure but not acute infection. Elevated IgG titers regardless of degree of elevation are not diagnostic of current infection with *M. pneumoniae* and only indicate previous antigenic exposure. *M. pneumoniae* ELISA IgM levels may take up to 3 months to decrease. Therefore, clinicians should take into account recent antecedent respiratory illness to properly interpret elevated IgM

titers, including patients with nonexudative pharyngitis within 3 months prior to the presentation of CAP. The combination of an increased *M. pneumoniae* IgM titer and highly elevated cold agglutinin titers is virtually diagnostic of acute infection. Cold agglutinin titers are elevated transiently early and rapidly fall; the simultaneously elevated cold agglutinins and IgM titers of *M. pneumoniae* indicate active or current infection. In patients with CAP caused by another organism (e.g., *S. pneumoniae*), the presence of elevated *Mycoplasma* IgG titers does not indicate co-infection but only preexisting serologic exposure to *M. pneumoniae*.

#### *M. pneumoniae* Therapy

*M. pneumoniae* has a predilection for the respiratory epithelial cells and resides on their surface. Mycoplasmas have no definite cell wall like the typical pathogens causing CAP. Their position on the surface of the respiratory epithelium and their absence of a cell wall necessitates the therapeutic approach, which includes non-β-lactam antibiotics with the capacity to penetrate into the *Mycoplasma* organisms. Traditionally, macrolides and tetracyclines have been used successfully to treat *M. pneumoniae*. Both tetracyclines and macrolides are effective against *Mycoplasma* because they interfere with intracellular protein synthesis at the ribosomal level. Tetracyclines penetrate intracellularly better than macrolides, with the exception of penetration into the alveolar macrophage, which is relevant in *Legionella* but not *M. pneumoniae* infections. Macrolides and tetracyclines are both active against *Mycoplasma*. Patients treated with macrolides or tetracyclines defervesce rapidly over 24 to 48 hours. Clinical defervescence manifests by an increased feeling of well-being and a decrease in fever. The dry cough persists during and after therapy regardless of the anti-*Mycoplasma* antimicrobial used.

There are important differences in the shedding rates of *Mycoplasma* from respiratory epithelial cells posttherapy when using tetracyclines instead of macrolides. Tetracycline therapy is associated with a more rapid decrease in shedding. Tetracyclines with better ability to penetrate intracellularly, such as doxycycline (Vibramycin), are the most rapid at decreasing *Mycoplasma* shedding, which is an important public health consideration. Mycoplasmas are transmitted by aerosolized droplet infection. Because patients with *Mycoplasma* have a prolonged cough, organisms not eliminated from respiratory epithelial cells may be aerosolized during coughing for weeks following the acute infection, spreading the infection to susceptible individuals via aerosolized droplets. The aim of therapy is to rapidly treat the patient's pneumonia and extrapulmonary sites of involvement. The secondary goal is to rapidly decrease shedding and aerosolization to prevent the spread of *Mycoplasma* to other individuals. An additional therapeutic goal is to decrease the incidence of post-*Mycoplasma* asthma seen in some patients. *M. pneumoniae* CAP may exacerbate preexisting asthma, but may also cause permanent post-CAP asthma in some individuals.

Until recently, doxycycline was the most active antimicrobial to use against *M. pneumoniae*. Currently, the "respiratory quinolones," levofloxacin (Levaquin) and moxifloxacin (Avelox), are highly active anti-*M. pneumoniae* antimicrobials. The respiratory quinolones and doxycycline penetrate cells efficiently and interfere with intracellular enzymes or protein synthesis of intracellular organisms. Respiratory quinolones and doxycycline are highly effective anti-*Mycoplasma* agents and rapidly decrease shedding of *M. pneumoniae* in respiratory secretions.

Therapy for *M. pneumoniae* is ordinarily 1 to 2 weeks. Patients who have impaired cardiopulmonary disease or are immunocompromised may require 2 full weeks of therapy. In patients with borderline cardiopulmonary function, *M. pneumoniae* as with other relatively low virulence pathogens may present as severe CAP. Antimicrobial therapy for typical or atypical CAP should be directed against the presumed pathogen

**TABLE 4** Antibiotics Effective Against *M. pneumoniae*

ANTIBIOTIC	DOSE (ADULT)
<b>Mild/Moderate CAP</b>	
Doxycycline	100 mg (IV/PO) q12h
Erythromycin	500 mg (base, estolate, stearate) (PO) q6h
Erythromycin lactobionate	1 g (IV) q6h
Clarithromycin (Biaxin)	500 mg (PO) q12h
Azithromycin (Zithromax)	500 mg (IV) q24h x 2 doses, followed by 500 mg (PO) q24h
<b>Severe CAP</b>	
Levofloxacin (Levaquin)	500 mg (IV/PO) q24h, or 750 mg IV/PO q24h (may allow for shorter duration of therapy)
Moxifloxacin (Avelox)	400 mg (IV/PO) q24h

CAP, Community-acquired pneumonia.

and not based on co-morbidities. Normal healthy hosts are treated with the same antimicrobial as patients hospitalized with severe CAP. Patients hospitalized with compromised cardiopulmonary function caused by severe *M. pneumoniae* CAP are most often initially treated intravenously with doxycycline (Vibramycin), a macrolide, or a respiratory quinolone. Most patients with *M. pneumoniae* CAP present in the ambulatory setting, which permits therapy with oral doxycycline, a macrolide, or a respiratory quinolone (Table 4).

## VIRAL RESPIRATORY INFECTIONS

Method of

Robert C. Welliver Sr., MD

### CURRENT DIAGNOSIS

- Rapid diagnostic kits are available for many common respiratory viruses. These tests are used increasingly to establish that antibiotic therapy is not necessary in many patients with febrile respiratory illnesses or with lower respiratory tract infections.
- The presence of wheezing on physical examination virtually excludes bacterial infection from consideration in subjects with lower respiratory disease.

### CURRENT THERAPY

- The management of most viral respiratory infections consists of rest, adequate caloric and fluid intake, and management of fever and malaise.
- Corticosteroids are essential in the management of croup.
- Specific antiviral therapy is available only for influenza virus infection, and beneficial effects have been more readily achieved in prevention rather than treatment.

Viral infections of the respiratory tract are among the most common infections in humans, and they account for significant morbidity at all ages. Infants and young children can sustain six to eight such infections annually, and adults have an average of nearly two such infections per year.

Rhinoviruses are the most commonly identified etiologic agents and cause illness year-round. Other common causative agents during winter months include influenza viruses and respiratory syncytial virus, and enteroviruses predominate in summer months. The parainfluenza viruses also commonly cause respiratory infection, particularly in autumn (type 1) and late spring or summer (type 3). Coronaviruses, metapneumoviruses, adenoviruses, and other agents are identified less often.

Although each of these agents can cause a common cold, some viral infections are associated with characteristic patterns of respiratory disease. Most of these viruses can also exacerbate asthma, cystic fibrosis, and chronic obstructive pulmonary disease (COPD).

### Common Colds

Colds are the most common of the viral respiratory illnesses. Pharyngitis is usually the earliest sign of a cold, beginning a few days after infection has taken place. Nasal congestion and clear or slightly cloudy rhinorrhea usually follow within 24 to 48 hours. Cough occurs in approximately 30% to 40% of those infected, and fluid can accumulate in middle ear or sinus cavities that have become blocked as a result of mucosal swelling. Ear and sinus cavity infections occur when this fluid is trapped for a week or more. Treatment with antibiotics is ineffective before this time, and they are ineffective especially in the absence of other clinical signs of ear and sinus infections.

Colds are a frequent cause of missed school and work, and even of mild morbidity, but they are rarely serious in otherwise healthy persons. The most appropriate approach to treatment therefore entails rest, with adequate nutrition and hydration. Agents that inhibit the activity of cyclooxygenase probably represent the most effective form of pharmacologic intervention. These compounds include acetaminophen (Tylenol) and the nonsteroidal anti-inflammatory agents (NSAIDs) such as ibuprofen (Motrin). They are effective in reducing fever and, perhaps more importantly in most colds, reducing malaise, headache, and pharyngitis.

Nasal congestion and some rhinorrhea during colds are related to dilation of blood vessels in the nose and sinuses. Vasoconstrictors have therefore been used extensively to attempt to reverse these symptoms. Oral decongestants such as pseudoephedrine (Sudafed) have minimal effect on nasal congestion, and can result in systemic hypertension, anxiety, and difficulty sleeping. The propensity for these compounds to cause cardiac arrhythmias in the very young child has led to recommendations against their use in the first year or two of life. Nasal sprays containing vasoconstricting agents such as oxymetazoline (Afrin) can result in mild temporary relief of nasal obstruction. However, the use of these compounds for more than 3 or 4 days can result in rebound vasodilation and paradoxically increased rhinorrhea.

Numerous investigations have evaluated the role of antihistamines in colds. The release of histamine itself is not associated with fever, cough, or malaise, so effects on these symptoms would not be expected. Furthermore, nasal congestion and discharge may be more related to the release of kinins, and not histamine. Indeed, the administration of antihistamines in adults and, particularly, in children has not demonstrated strikingly positive results. As many as 40% of subjects treated with placebo report beneficial effects. Side effects of histamine use, primarily sedation and dry mouth, are commonly encountered.

Cough can be one of the most irritating symptoms during colds. Cough during colds is principally caused by secretions entering the airway (postnasal drip) and not by inflammation of the airway itself. Therefore, it is not surprising that cough suppressants, especially codeine, have little effect on cough induced by colds. Antihistamines have also been found to be ineffective in relief of cough during colds.

### Influenza-Like Illness

The influenza syndrome is defined as the abrupt onset of fever, headache, and striking degrees of malaise and prostration, often with intense myalgia. Respiratory symptoms can occur concurrently, but they might not be prominent features. The principal cause is, of course, influenza virus, although infection with many other viruses can cause similar (although not as intense) symptoms. The illness is generally self-limited, and most symptoms resolve over 4 or 5 days. Lassitude can persist for up to 2 weeks.

Influenza virus infection and influenza-like illness are best treated symptomatically, relying on rest, adequate intake of fluids and calories, and appropriate analgesic therapy. Compounds referred to as *M2 inhibitors* such as amantadine (Symmetrel) and rimantadine (Flumadine) have been approved for therapy. Positive outcomes from therapy with these agents are observed only when therapy is instituted within 48 hours after the onset of symptoms, and benefits are not striking. In recent years, resistance to *M2 inhibitors* has been commonly observed among circulating epidemic strains of influenza virus.

More recently, inhibitors of the activity of influenza viral neuraminidase have been used in treatment and prevention of influenza virus infection in adults and children. The first such compound released, zanamivir (Relenza), was administered by inhalation but was unpopular because of its irritating effects on the airway. An oral compound, oseltamivir (TamiFlu), has been used to prevent and to treat influenza virus infection. As with *M2 inhibitors*, it is believed that treatment should be started within the first 48 hours of symptoms and that prophylaxis should be instituted within 48 hours of exposure. Treatment with oseltamivir shortens the

duration of subsequent illness by only about 24 hours. Treatment can prevent some of the complications of influenza infection, including pneumonia. The drug may be more effective as a therapeutic agent, because it may be up to 90% effective in preventing culture-positive symptomatic influenza illness. The recommended dose for adults is 75 mg orally every 12 hours for 5 days. In children, the appropriate dose based on body weight is 30 mg twice daily for children weighing less than 15 kg, 45 mg twice daily for children weighing 15 to 23 kg, 60 mg twice daily for children weighing 23 to 40 kg, and 75 mg twice daily for children weighing more than 40 kg. The principal side effect is nausea, which can be reduced by taking the drug with food.

A new type of antiviral (baloxavir marboxil [Xofluza]) was released for treatment of influenza infections in 2018. This drug acts by a different mechanism than previous antivirals used to treat influenza infections. The advantages are that it is given as a single dose for the entire course of treatment, and reduces the duration of influenza illness by approximately 24 hours. It does not seem more effective than oseltamivir in reducing influenza-related symptoms. The appropriate doses are 40 mg for individuals age 12 years or greater and weighing less than 40 kg (88 lbs.) to less than 80 kg (176 lbs), and 80 mg for individuals weighing greater than or equal to 80 kg (176 lbs.).

In 2009, a novel H1N1 strain of influenza caused a worldwide pandemic. At the time of this writing, both this epidemic H1N1 strain as well as the seasonal influenza A/H3N2 and type B strains continue to circulate in the world. The considerable majority of these epidemic and seasonal strains continue to show sensitivity to oseltamivir, while most are resistant to *M2 inhibitors*. All strains continue to show sensitivity to zanamivir.

### Croup

Croup is defined by the occurrence of hoarseness or laryngitis, a deep, brassy or barking cough, and inspiratory stridor. Airway obstruction in croup is caused by constriction in the subglottic area, often noted on radiographs by a steple-shaped narrowing of the air column in this region. Affected children are usually afebrile and nontoxic in appearance.

Parainfluenza virus type 1 is the primary cause of croup, although infection with many different viruses can produce this illness, and influenza virus can cause a particularly severe form of croup. Bacterial secondary infection occurs uncommonly, but it can result in fever and severe obstruction of the airway. Administration of dexamethasone (Decadron)<sup>1</sup> at 0.6 mg/kg either orally or intramuscularly markedly reduces the rate of hospitalization, admission to the intensive care unit, and intubation for croup.

### Bronchiolitis

Bronchiolitis represents the most common cause for hospitalization of infants in developed countries. Infants present with a history of several days of upper respiratory symptoms, followed by the rapid onset of wheezing and labored breathing. Respiratory syncytial virus (RSV) is the most common cause and is the agent found in the most severe cases that result in respiratory failure. Contrasting with asthma, obstruction of the airway in bronchiolitis is a result of plugging of bronchioles with detached epithelium and inflammatory cells. Mucus plugging and constriction of smooth muscle are not prominent. Also in contrast with asthma is the absence of a sustained response to bronchodilators and corticosteroids among infants with bronchiolitis.

Therapy of bronchiolitis primarily consists of administration of supplemental oxygen and replacement of fluid deficits as needed. Ribavirin (Virazole)<sup>1</sup> is a compound with antiviral activity against RSV, but controlled studies have not demonstrated meaningful differences in outcomes between treated and untreated subjects. The compound is quite expensive and must be delivered via a special aerosol generator.

<sup>1</sup>Not FDA approved for this indication.

Palivizumab (Synagis), a preparation consisting of a monoclonal antibody against the fusion protein of RSV, has proved to be effective in reducing the rate of hospitalization for RSV infection by approximately 50% when given to high-risk infants. Infants who may be considered candidates for therapy include those with chronic lung disease, those born prematurely, and those with hemodynamically significant congenital heart disease. Doses of palivizumab (15 mg/kg) are given on a monthly basis throughout the local RSV season, usually November through March.

### Severe Acute Respiratory Syndrome Coronavirus-2 (SARS-CoV-2)

The appearance of SARS-CoV-2 has profoundly affected health-care worldwide. While symptoms are generally milder in children, respiratory illness can, at times, be severe or even fatal. Symptoms are not readily distinguishable from other respiratory viral infections early on but may become severe as the illness progresses. Numerous antivirals and antibody formulations have been developed, but only remdesivir (Veklury) has been approved by the FDA for use in children. Remdesivir may be considered in children older than 12 years of age who have risk factors for severe disease (obesity, diabetes mellitus, immune compromising conditions, or defects in immunity) and have an emergent or increasing need for supplemental oxygen. In children older than 16 years of age, remdesivir is recommended for use if they have an emergent or increasing need for supplemental oxygen, even without high-risk underlying factors. In consultation with a pediatric infectious disease expert, remdesivir may be considered for use in any child regardless of age if they have an emergent or increasing need for supplemental oxygen or mechanically assisted ventilation. Also, in consultation with a pediatric infectious disease specialist, dexamethasone<sup>1</sup> may be administered to children who require high-flow oxygen, noninvasive ventilation, or extracorporeal membrane oxygenation. The recommended doses for remdesivir are as follows:

- For children 12 years of age and older and weighing 40 kg or more: 200 mg IV on day 1, followed by 100 mg IV on subsequent days (maximum expected duration is 10 days).
- For children younger than 12 years of age weighing 3.5 to less than 40 kg: 5 mg/kg IV on day 1, followed by 2.5 mg/kg IV on subsequent days (maximum expected duration is 10 days).
- For children younger than 12 years of age but weighing more than 40 kg: 200 mg IV on day 1, followed by 100 mg/Kg IV on subsequent days (maximum expected duration is 10 days)

Remdesivir therapy is not recommended if serum levels of alanine transferase are greater than 5 times the upper limit of normal.

The dose for dexamethasone is 0.15 mg/kg IV or IM QD for a maximum of 10 days.

## AXIAL SPONDYLOARTHRITIS

Method of

Atul A. Deodhar, MD, MRCP; and Sonam S. Kiwalkar, MD

### CURRENT DIAGNOSIS

- *Axial spondyloarthritis (axSpA)* is an umbrella term that includes ankylosing spondylitis (AS) and nonradiographic axial spondyloarthritis (nr-axSpA). The presence or absence of definitive sacroiliitis on radiographs differentiates AS (also called *radiographic axSpA*) from nr-axSpA. The latter is a condition with the same clinical features and similar disease burden, except that definitive radiographic features of sacroiliitis are lacking.
- In the absence of diagnostic criteria, the diagnosis of AS is made by the presence of definitive sacroiliitis on sacroiliac (SI) joint radiographic imaging plus either chronic (>3 months) inflammatory back pain or restriction in spinal movements or chest expansion (Modified New York Criteria for Classification of AS).
- Because definitive sacroiliitis may take up to 10 years to appear on a radiograph from the start of chronic inflammatory back pain (the most common first symptom), early or mild disease can be missed.
- When AS is suspected with features of inflammatory back pain (usually starting before 45 years of age) along with other clinical features of spondyloarthritis—such as uveitis, psoriasis, enthesitis, asymmetric peripheral inflammatory arthritis, family history of spondyloarthritis, high C-reactive protein (CRP), inflammatory bowel disease, favorable response to nonsteroidal antiinflammatory drugs (NSAIDs)—but a radiograph of the SI joints is negative or uncertain for definitive sacroiliitis, magnetic resonance imaging (MRI) of the SI joints and/or human leukocyte antigen (HLA)-B27 typing may help in making the diagnosis of axSpA.

### CURRENT THERAPY

- Nonpharmacologic interventions include active physical therapy, self-directed physical exercise, patient education, and smoking cessation.
- NSAIDs are the first line of pharmacologic treatment.
- In patients who do not respond adequately to NSAIDs, treatment with a tumor necrosis factor- $\alpha$  inhibitor (TNFi), interleukin-17 inhibitor (IL-17i), or Janus kinase inhibitor (JAKi) is recommended.
- Retrospective analysis in cohorts of patients with AS using long-term TNFi therapy has shown a reduced rate of new bone formation in the spine, although no pharmaceutical agents have shown “disease-modifying” ability in placebo-controlled prospective studies to date.
- Conventional synthetic antirheumatic drugs such as sulfasalazine (Azulfidine)<sup>1</sup> or methotrexate<sup>1</sup> can be used to treat peripheral arthritis in axSpA patients, but they do not have efficacy in axial disease.

<sup>1</sup>Not FDA approved for this indication.

### Definition and Spectrum of the Disease

Axial spondyloarthritis (axSpA) is an umbrella term that includes ankylosing spondylitis (AS) and nonradiographic axial spondyloarthritis (nr-axSpA). The presence or absence of definitive sacroiliitis on radiographic imaging differentiates AS (also called *radiographic axSpA*) from nr-axSpA.

AxSpA is a chronic, immune-mediated inflammatory disorder involving the sacroiliac (SI) joints, the spine, and often the hips. In some, spinal bony fusion develops gradually over several years and may lead to reduced spine and neck flexibility. The axial skeleton is always involved, and involvement of the peripheral joints occurs in approximately 30% of patients. Enthesitis is a common occurrence. Extraarticular manifestations (EAMs) include osteoporosis, psoriasis, acute anterior uveitis, and inflammatory bowel disease (IBD) (i.e., Crohn disease or ulcerative colitis).

### Epidemiology

Based on the 2009 to 2010 National Health and Nutritional Examination Survey (NHANES), the estimated prevalence of axSpA in the U.S. population is about 1.0%, of which 0.5% of patients are reported to have AS. The prevalence of nr-axSpA is thus assumed to be the other 0.5%, as pelvic radiographs and SI magnetic resonance imaging (MRI) examinations were not carried out in this population-based study. Based on 2006 to 2014 data from the U.S. Medicare Fee-for-Service and IBM MarketScan databases, a retrospective observational cohort study showed an increase in the diagnostic prevalence of AS and axSpA, which could possibly be attributed to increased disease awareness.

The prevalence of axSpA varies with geographic region and, in general, depends on the prevalence of human leukocyte antigen (HLA)-B27. Prevalence of HLA-B27 is less than 1% in Japan, 3% in African Americans, and more than 20% in some native populations of eastern Siberia and Alaska; it is 8% in western Europe and 10% to 16% in Scandinavian countries. AxSpA is thus rare in Japanese and African-American populations. The prevalence of axSpA is about 0.5% in persons of European descent and 1.4% in those of Scandinavian ancestry, whereas it increases to 2% to 3% in natives of eastern Siberia and Alaska. The risk of axSpA is increased among those with an affected first-degree relative. The male-to-female ratio is 2:1 for the diagnosis of AS. In contrast, there is hardly any difference in the prevalence of nr-axSpA among males and females, suggesting that male sex is a prognostic indicator for progression from nonradiographic to radiographic axSpA.

### Pathogenesis

Genetics plays a major role in the pathogenesis of spondyloarthritis, and the *HLA-B27* gene has a major association with AS. *HLA-B27* is present in about 70% to 90% of patients with AS in most ethnic groups. The risk of disease in family members of patients with AS is 63% in monozygotic twins, 20% in dizygotic twins, 8.2% in first-degree relatives, 1% in second-degree relatives, and 0.7% in third-degree relatives. The overall contribution to AS heritability by *HLA-B27* is estimated to be approximately 20%. Some other genes associated with AS—such as endoplasmic reticulum aminopeptidases (ERAP-1 and ERAP-2) and interleukin-23 receptor (IL-23R)—have been implicated to play a role in the pathogenesis.

The following hypotheses have been put forth to explain the role of *HLA-B27* in the pathogenesis of AS:

1. Arthritogenic peptide presentation. Certain antimicrobial peptides have molecular mimicry to self-peptides found in the joints, and it is hypothesized that *HLA-B27* presents these to

cytotoxic T cells. The activated T-cell lymphocytes then lead to autoreactivity, arthritis, and spondylitis.

2. HLA-B27 heavy chain homodimer. The heavy chains of the HLA-B27 molecule can form homodimers when they are expressed on the cell surface, resulting in their recognition by natural killer cell receptors. This can enhance the survival and proliferation of CD-4 T cells and increase the production of IL-17 in vivo.
3. HLA-B27 misfolding and unfolded protein response. HLA-B27 assembly takes place in the endoplasmic reticulum (ER) before it is expressed on the cell surface. The misfolded HLA-B27 molecules accumulate in the ER, leading to cellular stress secondary to the unfolded protein response. This then activates the IL-23/IL-17 pathway of inflammation.
4. HLA-B27 shaping of the human gut microbiome. The human body contains a large community of commensals and symbiotic bacteria, fungi, and viruses called *microbiota*. The term *microbiome* refers to the genomes of these microorganisms. The composition of the gut microbiome is influenced by genes and other environmental factors. It is postulated that HLA-B27 predisposes to AS by influencing the gut microbiome. Studies have shown that the microbiota composition of patients with AS differs from that of rheumatoid arthritis patients as well as healthy controls. Further, HLA-B27–positive healthy individuals have a microbiome that differs from that of HLA-B27–negative subjects.

In animal models of spondyloarthritis, HLA-B27 transgenic rats and mice did not develop spondyloarthritis when raised in a germ-free environment, but they developed spondyloarthritis-like disease when they were housed in a typical laboratory environment, suggesting a role for microbes in the pathogenesis of spondyloarthritis. More than 60% of patients with AS have subclinical acute or chronic intestinal inflammation. This loss of architectural and functional integrity in the intestinal epithelium enables the passage of microbial products into the submucosa and then into the systemic circulation. Innate and adaptive immune cells recognize these microbial products and produce proinflammatory cytokines. These microbial products and the immune cells travel from the gut to distant sites, such as peripheral joints and entheses, causing inflammation.

### Clinical Manifestations

The most common manifestations of axSpA include chronic inflammatory low back, hip, and/or buttock pain. The typical characteristics of inflammatory back pain include age of onset before 40 years, insidious onset without any identifiable cause, improvement with exercise or activity and no improvement with rest, and pain in the second half of the night. Neck pain is rarely the presenting feature due to involvement of the cervical spine; when this is present, it is more commonly seen in women.

The limitation of spinal motion is initially the result of axial inflammation and later is secondary to the ossification of ligamentous structures, bony fusion of apophyseal joints, and outer fibers of the annulus fibrosus of the intervertebral disks, leading to the development of syndesmophytes.

Hip involvement is seen in up to 40% of patients. The typical symptoms are pain in the groin or radiation of pain to the medial thigh or the knee. Hip involvement is associated with significant functional impairment. Other peripheral joints—such as the ankles, knees, shoulders, and, to a lesser extent, the sternoclavicular joint, the temporomandibular joint, and small joints of the hands and feet—may also be involved.

Enthesitis is a classic feature of axSpA. Enthesitis presents as pain, stiffness, and tenderness at the sites of insertions of ligaments, muscles, or tendons to a bone. Typical areas of enthesitis include the Achilles tendon, plantar fascia attachment to the calcaneum, costochondral junctions, and the paraspinal muscle attachment to the pelvic rim. Diffuse swelling of the toes or fingers, called *dactylitis* (“sausage digits”), is occasionally seen in axSpA.

EAMs associated with axSpA include psoriasis, IBD, uveitis, and osteoporosis. A large epidemiologic study found that 42% of axSpA patients had one or more EAMs; uveitis was present in 27%, IBD in 10%, and psoriasis in 11%. Uveitis seen in association with axSpA presents as eye discomfort during

the prodromal phase followed by an acute onset of eye redness, pain, photophobia, and miosis. The usual characteristics of uveitis associated with axSpA are acute in onset, unilateral, and involve the anterior part of the uvea. Even though overt IBD is seen in only 10% of axSpA patients, more than 60% have subclinical mucosal inflammation in the gut.

### Diagnosis

Within the United States, there is a significant delay of 10 to 14 years in the diagnosis of axSpA from symptom onset. There are many reasons for this, including the commonality of back pain in the general population and the rarity of axSpA as a cause of back pain. There are no specific physical findings or laboratory tests to diagnose axSpA; the diagnosis is based on pattern recognition and clinical reasoning. Patients with back pain are generally seen by nonrheumatologists who may not be familiar with features of inflammatory back pain and may not suspect axSpA. In the optimal clinical setting with a patient complaining of onset of chronic (>3 months) inflammatory back pain starting before 45 years of age, the presence of other features of spondyloarthritis (as described earlier), a positive HLA B-27 test, and a plain radiograph of the SI joint showing sacroiliitis, the diagnosis of AS would be straightforward. Radiographic findings such as sclerosis; joint erosions; or widening, narrowing, or ankylosis of the SI joint suggest sacroiliitis.

During this early stage of disease (also known as *nr-axSpA*), MRI (without contrast) of the SI joints may show evidence of active inflammation and may also show structural changes such as sclerosis, fatty metaplasia, or erosions that aid in making the diagnosis. The required sequence of MRI and the features that suggest a diagnosis of nr-axSpA include the following:

1. T1-weighted sequence. Structural changes such as erosions and ankylosis can be seen. Fat metaplasia appears hyperintense.
2. Fat-suppressed T2-weighted (short-TI inversion recovery [STIR]) sequence, osteitis, representing active inflammation and reported as bone marrow edema; appears hyperintense.

When the clinical suspicion of axSpA is high but radiographic imaging of the SI joints is negative or inconclusive for sacroiliitis, the presence of the features previously noted on MRI of the SI joints may help in confirming a diagnosis of nr-axSpA.

The changes of inflammation on STIR imaging (i.e., “osteitis”) can be seen in professional athletes, military recruits, and even in normal individuals because of mechanical stress (“false-positive MRI”). It is therefore important to emphasize that ruling out common causes of back pain, pattern recognition, and clinical reasoning is the key to a diagnosis of axSpA.

Plain radiographs of the spine may show characteristic changes in AS. Romanus lesions or the *shiny corner sign* and squaring of the vertebral body are seen as a result of erosions at the attachments of the spinal ligaments at the vertebral corners in early disease. This is followed by ossification of the outer layer of annulus fibrosus, leading to syndesmophyte formation on plain radiographs. In the late stages, ankylosis of the spine, also known as *bamboo spine*, may be seen in a small percentage of AS patients. The role of low-dose computed tomography (CT) in the diagnosis of axSpA is currently being researched.

An elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) is seen in only 30% to 40% of patients with active AS.

### Differential Diagnosis

Chronic nonspecific back pain is common in the general population (19% according to the NHANES study); hence mechanical causes of back pain should be considered first.

Diffuse idiopathic skeletal hyperostosis (DISH) is sometimes mistaken for “bamboo spine of AS.” DISH is a noninflammatory condition affecting the spine. It is more commonly seen in obese, diabetic males, often older than 50 years of age. Radiographically, DISH is characterized by calcification of the anterior longitudinal ligament involving at least four contiguous vertebral bodies, sometimes referred to as *flowing osteophytes*. The flowing osteophytes are bulky and typically appear on the right side of the spine. SI joints are not involved in patients with DISH.

Osteitis condensans ilii (OCI) can be mistaken for sacroiliitis but is usually an asymptomatic benign disorder of multiparous women. OCI is characterized by radiographic findings of a triangular area of dense sclerosis on the lower and inferior part of iliac side of the SI joint. OCI is not associated with erosions or ankylosis of the SI joints.

Inflammatory back pain with sclerotic changes on SI joint radiographs can also be seen in conditions such as (1) postpartum insufficiency fracture of the sacrum; (2) septic sacroiliitis from tuberculosis, brucellosis, fungi, and other infectious agents; and (3) rarely malignancies such as acute lymphoblastic leukemia.

### Treatment

The goals of treatment of axSpA are to reduce symptoms, improve and maintain spinal flexibility and normal posture, reduce functional limitations, and decrease complications of the disease. The mainstay of treatment has been NSAIDs, exercise and physical therapy, biologics such as tumor necrosis factor- $\alpha$  inhibitors (TNFi) and interleukin-17 inhibitors (IL-17i), and small-molecule drugs such as Janus kinase inhibitors (JAKi).

Treatment of axSpA can be divided into nonpharmacologic, pharmacologic, and surgical interventions.

### Nonpharmacologic Interventions

Nonpharmacologic interventions include active physical therapy (on land or aquatic), self-directed physical exercise, patient education, and smoking cessation. These are recommended during all stages of the disease.

### Pharmacologic Interventions

Box 1 outlines pharmacologic interventions for the treatment of axSpA. In clinical practice, most of the treatment recommendations for nr-axSpA are extrapolated from studies based on AS. Based on a 52-week placebo-controlled trial, certolizumab pegol (Cimzia) was approved by the U.S Food and Drug Administration (FDA) for the treatment of nr-axSpA in the United States.

The use of biologics and small molecules has been associated with an increased risk of serious infections. While bacterial infections are seen in both classes of drugs, herpes zoster is seen mostly with JAKi while reactivation of latent tuberculosis is mostly seen with TNFi. Therefore, screening for latent tuberculosis should be performed before these therapies are initiated.

Some of the side effects of TNFi and IL-17 therapy include injection-site reactions with subcutaneous preparations or infusion reactions with infliximab (Remicade) or golimumab (Simponi). Some of the other adverse effects of TNFi are the development of demyelinating disease, worsening of heart failure, recurrence of lymphoma or malignant melanoma, and paradoxical development of psoriasis-like skin lesions. Adverse events associated with IL-17i therapy include leukopenia, candidiasis, and the development or worsening of IBD. The ORAL Surveillance Study, a postmarketing safety trial ordered by the FDA, showed a higher risk of major adverse cardiac events (fatal and nonfatal myocardial infarctions and nonfatal strokes) and a higher risk of cancers (excluding non-melanoma skin cancers) in those on JAKi therapy compared with those on TNFi therapy. As a result, the FDA called a black box warning on tofacitinib (Xeljanz) and extended the warning to upadacitinib (Rinvoq)<sup>1</sup> because it is in the same class of drugs.

### Surgical Interventions

Total hip arthroplasty should be considered in patients with refractory hip pain or functional decline in the presence of radiographic evidence of structural damage. Spinal corrective osteotomies are occasionally necessary for fixed kyphotic deformities seen in advanced AS but should be undertaken only in centers of expertise.

### Monitoring

Patients should be monitored regularly for disease activity, functional impairment, and medication safety. The frequency of

## BOX 1 Pharmacologic Interventions for the Treatment of Ankylosing Spondylitis

1. Nonsteroidal antiinflammatory drugs (NSAIDs) are used in full doses either continuously or on an as-needed basis, depending on the severity of symptoms, comorbidities, and patient preferences. No particular NSAID is preferred over any other.
2. If patients continue to have symptoms despite a 4-week trial of full-dose NSAIDs, therapy is escalated to TNFi. Currently five TNFi agents are FDA approved for the treatment of AS (and for nr-axSpA in certain countries):
  - a. Soluble receptor of TNF—Etanercept (Enbrel) 50 mg, SC injection once weekly
  - b. TNFi monoclonal antibodies
    - i. Adalimumab (Humira) 40 mg SC every 2 weeks
    - ii. Golimumab (Simponi) 50 mg SC once a month or (Simponi Aria) 2 mg/kg intravenous (IV) at weeks 0, 4, and then every 8 weeks thereafter
    - iii. Certolizumab pegol (Cimzia) 200 mg SC twice a month or 400 mg SC once a month
    - iv. Infliximab (Remicade) 5 mg/kg IV infusion every 6 weeks
  - c. No TNFi is preferred over any other, except in patients with concomitant uveitis or IBD, in whom monoclonal antibodies are preferred over soluble receptor TNFi therapy.
3. In case of secondary failure of TNFi therapy (failing after initial benefit), an alternative TNFi can be used. In case of primary failure of TNFi therapy (no response), an IL-17i, secukinumab (Cosentyx), can be used. Secukinumab is given SC as 150 mg at weeks 0, 1, 2, 3, and 4, followed by 150 mg or 300 mg every 4 weeks. Ixekizumab (Taltz), another IL-17i, can also be used. It is given subcutaneously as 160 mg once, followed by 80 mg every 4 weeks. Another option could be tofacitinib (Xeljanz), a recently FDA approved medication for AS. It is given orally as 5 mg two times a day.
4. Upadacitinib (Rinvoq)<sup>1</sup>, a JAKi, and bimekizumab (Bimzelx)<sup>2</sup>, an IL-17A and IL-17F inhibitor, have shown promising results in phase III trials.
5. Conventional synthetic DMARDs like sulfasalazine (Azulfidine),<sup>1</sup> up to 3 g/day, and methotrexate,<sup>1</sup> up to 25 mg/week, are effective in the treatment of peripheral joint involvement, but not of axial disease in AS.
6. Local glucocorticoid injections for enthesitis or intraarticular injections for active peripheral arthritis can provide relief for flareups. However, injection of inflamed weight-bearing tendons such as the Achilles tendon is not recommended because of the risk of rupture.
7. Systemic glucocorticoids do not have any benefit in AS and should be avoided.

<sup>1</sup> Not FDA approved for this indication.

<sup>2</sup> Not available in the United States.

monitoring is individualized. Assessment of disease activity can be performed by the following methods:

1. Use of the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI): This is a patient-administered questionnaire with six questions answered on a visual analog scale of 0 to 10. A BASDAI score of greater than or equal to 4 is indicative of active disease. Clinically significant improvement is defined as an absolute change greater than or equal to 2.
2. Use of the Ankylosing Spondylitis Disease Activity Score (ASDAS): This incorporates three questions used in the BASDAI, a patient global assessment of disease activity, and CRP. An ASDAS score below 1.3 is defined as inactive disease; a score of 1.3 to 2.1 is low disease activity; 2.1 to 3.5 is high disease activity, and greater than 3.5 is very high disease activity. A reduction of greater than or equal to 1.1 in ASDAS is considered a significant improvement.

<sup>1</sup>Not FDA approved for this indication.

Structural damage resulting from axSpA can be measured using the modified Stoke Ankylosing Spondylitis Spine Score. This score correlates with disease activity as measured with the ASDAS.

Functional impairment can be measured by the Bath Ankylosing Spondylitis Functional Index. This is a patient-administered questionnaire that includes 10 activities of daily living. The Bath Ankylosing Spondylitis Metrology Index is an index of spinal and hip mobility in patients with AS. It includes lateral lumbar flexion, tragus-to-wall distance, modified Schober test, maximal intermalleolar distance, and cervical rotation.

The ESR and CRP may be useful in monitoring disease activity. MRI of the SI joints or spine is expensive and is not indicated to monitor disease activity of AS. Spine radiographs are not used for monitoring purposes in daily practice, although they may be used to counsel patients about lifestyle changes (such as stopping smoking) or to start biologic therapy.

### Complications

The prevalence of osteoporosis is approximately 25% after 10 years of axSpA. Vertebral fractures are seen in about 10% of patients with AS. The lower cervical spine is the most commonly involved area, where there is often also neurologic compromise. One should consider vertebral fractures in patients with neck and back pain that has changed in intensity or character from baseline. Another rare complication is the cauda equine syndrome from long-standing AS resulting from inflammation of the lumbosacral nerve roots caused by arachnoiditis. Cardiac manifestations include aortic valve insufficiency and conduction abnormalities. Pulmonary manifestations are rare and include chest expansion restriction from ossification of costovertebral joints and upper lobe–predominant interstitial lung disease. Patients with AS can have IgA nephropathy or, in late stages, renal amyloidosis if the disease is left untreated. Cardiovascular disease is being recognized as a common comorbidity in patients with AS and is linked to chronic inflammation. All patients with AS should be counseled about the traditional risk factors for cardiovascular disease, and appropriate treatment should be instituted if necessary.

## BURSITIS AND TENDINOPATHY

Method of  
Kyle Goerl, MD

### CURRENT DIAGNOSIS

#### Tendinopathy

- Tendinitis is an inflammatory condition only present within the first weeks of a tendon injury.
- Tendinosis is a degenerative condition usually developing weeks after the initial injury.
- The diagnosis is typically made clinically with a thorough history and physical examination.
- Most tendinopathies occur secondary to overuse, and can be acute, chronic, or recurrent.
- Tendinopathies are usually characterized by pain, possible swelling, and dysfunction of the affected tendon.
- If the diagnosis is in question, magnetic resonance imaging and ultrasound are helpful diagnostic aides.

#### Bursitis

- Bursitis is an inflammatory reaction of a bursa.
- Bursitis is typically the result of overuse or trauma, but systemic illnesses can also cause bursitis.
- The olecranon, prepatellar, and trochanteric bursa are particularly susceptible to traumatic bursitis because of their location immediately under the skin with minimal subcutaneous fat for protection.
- Bursitis rarely occurs alone, so a search should be conducted for an associated condition such as tendinopathy or a tendon tear.
- Imaging studies demonstrate that lateral hip pain is usually tendinopathy, not “trochanteric bursitis,” a term that should be reserved for image-proven bursitis.
- Septic bursitis usually only affects the olecranon and prepatellar bursa, and care must be taken to distinguish it from aseptic bursitis.
- Common pathogens in septic arthritis include *Staphylococcus aureus* and  $\beta$ -hemolytic *Streptococcus*.
- If the diagnosis of septic bursitis is in question, aspiration should be performed, and the aspirate sent for Gram stain, cell count and differential, culture and crystal analysis, and blood should be sent for culture, complete blood count, C-reactive protein, and erythrocyte sedimentation rate.

### CURRENT THERAPY

#### Tendinopathy

- Given that tendonitis is an inflammatory condition, NSAIDs should be considered. Ice, activity modification, and rest are also effective.
- Tendinosis is not an inflammatory condition, so NSAIDs are not usually a part of the treatment regimen.
- Tendinosis responds well to physical therapy and, in particular, eccentric exercises. Deep tissue massage with tools is also an effective treatment modality.
- Steroid injections can be effective for short term pain relief, but not for long-term healing, and should not be a routine part of the treatment plan. Steroid injections can be considered if the patient is in too much pain to perform physical therapy.
- Injections of blood products such as whole blood and platelet-rich-plasma, prolotherapy and sclerotherapy have

varying levels of evidence supporting their effectiveness, but are reasonable alternatives to surgery.

- When conservative measures fail, more invasive procedures such as tenotomy, tendon scraping, and open débridement should be considered, but are rarely needed.

#### Bursitis

- Early treatment should include NSAIDs, ice, activity modification, and rest.
- If an associated condition like tendinopathy is discovered, appropriate treatment should target that condition as well, and typically involves physical therapy.
- In the event of septic bursitis, antibiotic treatment should be initiated. Parenteral medication should be heavily considered, given the high failure rate of oral antibiotics.
- Surgery is rarely needed for bursitis.

## Tendinopathy

### Background

Tendon is a connective tissue used to attach muscle to bone. Normal tendon tissue is dense and has a highly regular and fibrillar pattern. Tendinopathy is the term used to describe a clinical syndrome typically resulting from overuse of a tendon. Traditionally the term tendonitis has been used to describe all tendon injuries, but the suffix “-itis” indicates the presence of inflammation, and inflammation is only present early on in the tendinopathy disease process. Inflammation may have resolved and inflammatory cells may no longer be present, but the patient may still have pain. At that point the disease process has changed from one of inflammation to a degenerative problem more appropriately termed tendinosis (Table 1).

Tendinopathies are characterized by pain, swelling, and impairment of functional activities of the affected region. They can be acute, chronic, or recurrent. The diagnosis is usually clinical based on history and physical examination. Typically, there is a history of repetitive motion, which can be anything from painting a wall to playing a sport like tennis. If this historical information is lacking, then a systemic medical condition should be considered.

With repetitive activities and inadequate recovery time tenocytes will begin producing inflammatory substances, and the load-bearing matrix of the tendon will begin to breakdown and become fibrotic. The collagen matrix becomes disorganized with fibers separating and healing in an erratic, disorganized manner. There is an increase in mucoid ground substance, hypercellularity, and pathologic vessel and sensory afferent nerve formation. The abnormal nerve formation likely contributes to the sensation of pain. This histopathological degenerative process is more appropriately called tendinosis. The degenerative mechanism appears to be multifactorial, with contributions from:

1. Classic inflammatory mediators like interleukins, prostaglandins, and substance P.
2. Altered load bearing on a tendon as in shoulder impingement.
3. Systemic influences such as aging.

Tendinopathy is occurring at higher rates in the developed world secondary to an increase in recreational sport participation. Lower extremity tendons, like the Achilles and patellar

tendons, bear a large amount of tensile force (Table 2). Thirty percent of runners will suffer Achilles tendinopathy in their lifetime, with an odds ratio of 31:2 when compared with age matched controls, and repetitive exposure is a risk factor. One in 3 patients with Achilles tendinopathy do not participate in sports. With respect to patellar tendinopathy, jumping sports like volleyball and basketball are risk factors. Historically, most lateral hip pain was labeled “trochanteric bursitis.” Research using imaging techniques, including magnetic resonance imaging (MRI) and ultrasound (), has concluded that lateral hip pain around the greater trochanter is more likely caused by tendon tears or tendinopathy of the gluteus medius and gluteus minimus muscle-tendon complex than inflammation of the trochanteric bursa. Rarely is there an actual bursitis present, so the diagnosis “trochanteric bursitis” should no longer be used regularly unless there is documented bursitis on an imaging study. This is important because the patient is more likely to benefit long-term from physical therapy (PT) as opposed to nonsteroidal antiinflammatory drugs (NSAIDs), or steroid injections, attributable to the underlying pathology being more likely tendon related than bursa related. Without an imaging study, the better term for lateral hip pain at this time is greater trochanteric pain syndrome (GTPS).

Many upper extremity tendons, such as those of the wrist, are adapted to gliding through synovial sheaths. The most commonly affected tendons in the upper extremity are the rotator cuff, specifically the supraspinatus tendon, and the common extensor tendon (more precisely the extensor carpi radialis brevis) involved in lateral epicondylopathy, commonly known as *tennis elbow*. Despite names like tennis elbow and golfer’s elbow, upper extremity tendinopathies (see Table 2) are more likely the result of repetitive motion from work or hobby related activities. When sports are a cause of upper extremity tendinopathy, they are typically sports requiring overhead motion like baseball, volleyball, and tennis. Up to 35% to 50% of adult tennis players will develop an elbow tendinopathy during their lifetime. A common cause of tendinopathy in the wrist is De Quervain tenosynovitis. De Quervain tenosynovitis affects the first dorsal compartment of the wrist containing the abductor pollicis longus and extensor pollicis brevis tendons. As the term “tenosynovitis” suggests, this condition results in irritation and swelling of not only the tendons themselves, but also of the synovial sheath encapsulating those tendons.

Some patients will develop tendinopathies without repetitive activity. Diseases of glucose metabolism and atherosclerosis are associated with a higher incidence of tendinopathy. Some common medications are also associated with tendinopathy including statins, fluoroquinolone antibiotics, and steroids, especially when steroids are injected intratendinously, which should be avoided.

### Evaluation

On physical examination the affected tendon will sometimes appear swollen, and it is typically tender to palpation. The affected tendon-muscle complex may exhibit restricted flexibility, and stretching it or activating it against resistance may reproduce the patient’s pain.

**TABLE 1** Tendinopathy Progression

	TENDONITIS	TENDINOSIS
Pathology	Inflammatory	Degenerative
Timing	Days to weeks	Weeks to years
Imaging	Typically unnecessary	Radiographs initially Ultrasound or magnetic resonance imaging for persistent symptoms

**TABLE 2** Common Tendinopathy Sites

#### Upper Extremity

- Rotator cuff (especially supraspinatus)
- Medial epicondyle
- Lateral epicondyle (especially extensor carpi radialis brevis)
- First dorsal compartment of the wrist (De Quervain)

#### Lower Extremity

- Gluteus medius and gluteus minimus
- Iliopsoas
- Patellar
- Achilles

**Figure 1** A, AP of the patient's shoulder demonstrating a calcific lesion near the humeral head. B, Long axis view; C, short axis view both by ultrasound of the same patient's supraspinatus tendon (outline) near its attachment at the humeral head. The humeral cortex shows as hyperechoic on the bottom of the tendon. The calcification is noted to be within the tendon near the attachment. Acoustic shadowing is noted underneath the calcification, which prevents viewing the entire calcific structure and the underlying humeral cortex. Abbreviations: CALC=calcification, SS=supraspinatus.

When the diagnosis of a tendinopathy is in question, imaging can be helpful. Radiographs of the affected area should be considered, to look for abnormalities such as large calcifications within tendons (Figure 1, A). When the diagnosis is in question or the patient has failed a course of physical therapy, advanced imaging should be considered. This is usually accomplished by either ultrasound or MRI. Ultrasound can reveal thickening or structural changes within the tendon consistent with degeneration and other abnormalities such as calcification. As tendinopathies are commonly associated with bursitis, bursal thickening consistent with bursitis may also be seen (Figures 1, B-C, 2, and 3). Similar findings may be demonstrated on MRI (Figure 4).

**Figure 2** A, Long axis view; B, short axis view both by ultrasound of a patellar tendon (outline) demonstrating tendinosis as evidence by the hypoechoic heterogeneous region outline, which represents the degeneration and irregularity of tendinosis. Abbreviations: DIST=distal, HFP=Hoffa's fat pad, MED=medial, LAT=lateral, LAX=long axis, P=patella, PROX=proximal, SAX=short axis.

**Figure 3** A, long axis view; B, short axis view both by ultrasound of a supraspinatus tendon with a subacromial-subdeltoid bursitis. The tendon is hyperechoic and fibrillar, which is in contrast to the overlying hypoechoic bursa. Abbreviations: ANT=anterior, GT=greater tuberosity, HH=humeral head, LAX=long axis, POST=posterior, SAX=short axis, SUPRA T=supraspinatus tendon.

**Figure 4** MRI appearance of tendinopathy. Sagittal T1-weighted image of the knee in a professional basketball player demonstrates abnormal signal and increased size in the patellar tendon, consistent with severe tendinopathy (*arrow*). The tendon is normally devoid of signal. (From Grainger RG, Allison DJ, Adam A, Dixon AK. *Grainger and Allison's Diagnostic Radiology*, 4th ed. Philadelphia: Churchill Livingstone; 2001.)

Determining which imaging modality to use can be challenging. MRI is considered the gold-standard for diagnosing tendinopathies and has the advantage of demonstrating an anatomic overview of the affected area, in addition to providing soft tissue contrast. However, in trained hands, the advantages of ultrasound include ease of use, point-of-care examination, dynamic evaluation of the tendon and muscles, better resolution than MRI, and guidance for injections and procedures.

#### Prevention

Prevention is always the best option. Tendons do not respond well to acute changes in routine or long periods of rest. This should be kept in mind by athletes during the off-season, someone taking on a new labor job on an assembly line, or a secretary with a new work space. These “potential patients” should be eased into their new routines, because all of these scenarios are classic setups for the development of a tendinopathy. Maintaining activity during the off-season and preparing one’s self for changes in the workplace will help to mitigate the risk of tendinopathy development.

#### Treatment

Medications are rarely employed in the treatment of tendinosis because the patient usually does not present to the clinician’s office until long after the disease process has begun. If the patient is caught early enough, for example within a week or two of the offending event (eg, lateral epicondylitis a week after painting a house), then the disease process is still likely an inflammatory one, and appropriately termed a tendonitis. In this case, NSAIDs are appropriate to try to stop the inflammatory process and ultimately try to prevent it from progressing to a degenerative process. Other effective treatments for tendonitis include activity modification, rest, and ice. However, if the patient has had pain for months, the process has likely progressed to tendinosis. The use of NSAIDs has been shown to negatively affect the repair

mechanism involved in tendinosis, thus they should be used cautiously in this situation.

Expectations about healing tendinosis should be addressed early. To begin with, tendon healing takes significant time and effort on the part of the patient. Additionally, many of the treatment modalities used to heal tendons will produce a reasonable amount of pain in and of themselves. This is actually a good thing as it indicates the patient is working hard enough to heal and that the healing process is occurring. It is not uncommon to have minor setbacks during the rehabilitation process. There should be an overall trend from a state of disease to health, but the path to recovery is not typically linear. The initial management of tendinopathy should be rehabilitation through PT. The patient should be informed that the “work” of PT is not done at the therapist’s office, but it is done at home on their own. Failing to adhere to the treatment program will almost ensure a lack of recovery.

The exercises performed in PT aim to reorganize the degenerative matrix, reduce tenocyte activity, improve tendon compliance, and provide analgesia. Specifically, eccentric exercises have proven to be an effective treatment. An eccentric exercise is one that strengthens the muscle-tendon complex while lengthening the complex. For example, if a patient is being treated for lateral epicondylitis, the eccentric exercise would be to move the wrist from extension to flexion against resistance, lengthening the common extensor tendon. Strengthening exercises also work to hypertrophy the muscle, which is commonly atrophied after long periods of abnormal use from compensatory movement by the patient to try to reduce pain. The time needed for the exercises to work well is 3 months, which correlates with the time needed to form new fibroblasts, the presumed mechanism by which eccentric exercises work.

PT exercises should be done bilaterally as there is a proven crossover effect for tendinopathies, whereby exercising the non-affected side actually improves the affected side. Adding static stretching to eccentric exercises has been shown to improve outcomes over eccentric exercises alone in patellar tendinopathy, and should be included in an effective rehabilitation program. Before releasing an athlete back to sports activity, the final components of an optimal rehabilitation program includes explosive concentric movements (e.g., weightlifting or box jumps), higher eccentric loading exercises (e.g., jumping from an elevated surface like a box and landing on the ground), and sports-specific movements like sprinting and cutting.

The other treatment modality commonly employed by a physical therapist in tendinosis is deep soft tissue massage with tools. These tools are used to scrape along the pathologic tendon, which promotes blood flow and inflammation leading to the breakdown of the degenerative tissue and ultimately healing of that tissue.

When these conservative measures fail, more aggressive treatment methods should be considered. It is important to point out that the following treatment options are supported by limited high quality evidence, but are nonetheless reasonable alternatives to a surgical procedure. Less invasive methods include extracorporeal shockwave therapy and low-intensity pulsed ultrasound. Glyceryl trinitrate patches are sometimes used to promote blood flow, and have been shown to provide some pain relief. Injections are common treatment modalities in tendinopathies. Steroid injections are commonly used, but usually provide short-term pain relief at best. There is evidence for long-term negative effects of steroids, so they should be used judiciously. A reasonable time to try a steroid injection is when the patient is experiencing so much pain that they are unable to perform therapy. Ultrasound guidance in the hands of a trained physician can help ensure that the injection is placed properly, and specifically not intratendinously. Other treatment options requiring a more trained physician, such as a sports medicine specialist, include prolotherapy, sclerotherapy, and biological blood product injections. Prolotherapy, the injection of hypertonic glucose, is thought to work by inducing a local inflammation-repair mechanism. In sclerotherapy, a sclerotic agent, typically polidocanol, is injected to degrade the tendinopathy pain generators,

namely the abnormal vessels and sensory nerves within the tendinopathic tissue. Blood products, including whole blood and platelet-rich-plasma, are used with the intent to deliver a high concentration of growth factors to the tendinopathic tissue, where blood flow is typically low.

If the tendinopathy does not respond to these treatment options, then more invasive measures are typically considered. A tenotomy procedure uses a sharp object, typically a large bore needle, to repetitively fenestrate the degenerated portion of tendon tissue, as noted on ultrasound guidance, to cause bleeding, and stimulate tissue healing. There is a newer technique, whereby the outside of tendon is scraped with a needle or scalpel. The procedure is guided by increased color Doppler signal on ultrasound indicating high vascularity and presumed nerve formation. The recovery from these techniques is usually a minimum of 6 weeks, so they should be reserved for recalcitrant cases. Finally, an open procedure can be performed to remove macroscopically abnormal tissue through an incision in the tendon; unfortunately the recovery for this sort of a procedure is in the time frame of 4 to 12 months.

## Bursitis

### Background

Bursas are fluid filled sacs designed to reduce friction between various tissues including bones, skin, tendons, and muscles. Typically, there is little fluid within a bursa, but with irritation from overuse or trauma, the bursa may swell with fluid leading to pain and dysfunction. This is referred to as bursitis because of the inflammatory nature of the condition.

There are multiple locations in the body where bursitis more commonly occurs, including the shoulder, elbow, hip, and knee. Bursitis usually develops from either trauma or overuse, but systemic illnesses like rheumatoid arthritis, diabetes mellitus, gout or pseudogout, and immunosuppression may also lead to bursitis. Bursas that are more susceptible to traumatic bursitis include the prepatellar, olecranon, and trochanteric bursas; they are closer to the skin and have little subcutaneous fat over them, thus they are more likely to sustain a direct impact. Both the olecranon and prepatellar bursa are also at risk for chronic irritation and trauma. Olecranon bursitis is seen in patients who frequently rest on their elbows, as in desk workers and truck drivers. Prepatellar bursitis is seen in patients who kneel for work like carpet layers and house cleaners.

Septic bursitis is rare, and it most commonly affects the olecranon and prepatellar bursa. This occurs via direct inoculation from the traumatic event. The most common organisms isolated are *Staphylococcus aureus* followed by  $\beta$ -hemolytic *Streptococcus*, with about 10% being polymicrobial infections.

The other bursas in the body are more susceptible to overuse injuries. The bursas around the shoulder most commonly affected include the subacromial-subdeltoid bursa, and the scapulothoracic bursa. Athletes who perform overhead movements in sports like baseball, softball, tennis, volleyball, and swimming are at greater risk for irritating these bursas. Of course, athletes are not the only people at risk for bursitis. Manual laborers working with their arms, especially when flexed or abducted regularly can also develop bursitis around the shoulder.

The hip and pelvis have multiple bursas, but the more commonly affected include the bursas around the greater trochanter and iliopsoas. As stated in the tendinopathy section, lateral hip pain is rarely caused by “trochanteric bursitis,” but there are bursa present under the gluteus maximus, gluteus medius, and gluteus minimus muscle-tendon complexes. Bursitis in this region is rarely found without an associated problem like gluteal tendinopathy, or iliotibial (IT) band syndrome. In fact, it is likely that one of these underlying problems led to the bursitis. There is also

a bursa under the iliopsoas muscle as it crosses the iliopectineal eminence and anterior hip joint.

Rare causes of knee bursitis include irritation of the suprapatellar bursa, deep infrapatellar bursa, pes anserine bursa, semimembranosus bursa, and medial collateral ligament bursa (Voshell bursa). Bursitis at these locations is almost always from chronic overuse. In the ankle, the retrocalcaneal bursa may also be irritated from overuse.

### Evaluation

Evaluation of a patient with suspected bursitis should always begin with a thorough history. Usually the clinician will discover a history of either trauma or overuse, but the patient should also be questioned about the presence of systemic illness. Physical exam of the affected region should include inspection for erythema and swelling. Warmth may be noted on palpation. Range of motion may be limited, but is not a consistent finding. Strength is rarely affected. The appearance of decreased strength may only reflect pain, not true weakness. True weakness would suggest an associated concern like tendinopathy or a tendon tear.

Patients with the presenting symptom of shoulder pain should be evaluated for rotator cuff tendinopathy and scapulothoracic dysfunction and winging, which predispose the athlete to impingement and bursitis. For patients complaining of hip pain, another symptom they may complain of is snapping. The patient should be questioned if the snap is reliably reproducible. If so, then have the patient demonstrate the snap. Snapping laterally is typically the gluteus maximus muscle or the iliotibial band snapping over the greater trochanter, and this is a risk factor for bursitis. If the snapping is anterior in the hip, it is likely the iliopsoas tendon snapping over the iliopectineal eminence or anterior femoral head, which can lead to iliopsoas bursitis.

For the olecranon and prepatellar bursas, special attention must be given to the fact that they are more likely to develop into a septic bursitis from a bacterial infection. If there is evidence of an abrasion in these particular areas, the physician needs to ensure there is not an associated infection. Erythema, progressive swelling, and painful range of motion may point towards the presence of an infection, but these symptoms are often present in aseptic bursitis as well, making the diagnosis difficult. Fever may be present, but its absence does not rule out infection. If there is any concern for infection, the bursa needs to be aspirated and fluid sent for cell count and differential, crystal analysis, gram stain, and culture before starting antibiotics. Blood should also be sent for a complete blood count, C-reactive protein, erythrocyte sedimentation rate, and cultures.

Imaging is not always necessary to diagnose bursitis. Swelling and erythema over a known bursa may be enough to make a diagnosis, but if the diagnosis is in question, then imaging typically begins with radiographs. Radiographs can evaluate for bony abnormalities that may suggest an underlying reason for bursitis. For example, spurring on the undersurface of the acromion can be a risk factor for subacromial-subdeltoid bursitis. Radiographs can also be used to rule out fracture or to evaluate for a foreign body, especially in the setting of olecranon or prepatellar bursitis.

Further evaluation is typically done with either MRI or ultrasound. MRI offers the advantage of global assessment of the affected region, in addition to allowing enhancement of soft tissues. In skilled hands, ultrasound is an effective tool to demonstrate bursitis throughout the body (see [Figure 3](#)). Ultrasound also has the distinct advantage of real-time imaging during a dynamic examination of the affected tissue. If aspiration or injection is needed, ultrasound can help guide the procedure. Both MRI and

ultrasound modalities are useful in assessing for associated diagnoses like tendinopathy.

### Treatment

Bursitis treatment usually begins with conservative measures like rest or activity modification, NSAIDs, compression, padded splinting, and ice. If the bursitis is acute, it is typically responsive to these basic treatments. As stated previously in this chapter, it is common to find associated problems with the bursitis. These include rotator cuff tendinopathy, gluteal tendinopathy, and iliotibial band syndrome. It is imperative that these issues be treated as well or the bursitis will likely reoccur. This typically requires a home exercise plan usually best directed by a physical therapist.

If these problems fail to respond to this conservative approach, including rehabilitation, then a steroid injection can be considered. There is reasonable evidence that doing the injection under ultrasound guidance will lead to better outcomes, especially for the subacromial-subdeltoid bursa, but blind injections are certainly reasonable if ultrasound is not available. Research reveals that steroid injections for greater trochanteric pain syndrome demonstrate clinically relevant relief at 3 months postinjection when compared with usual care, but that difference disappears by 12 months. This is a common finding with steroid injections. Thus, it is reasonable to consider a steroid injection for pain relief, especially if the patient is unable to participate in PT, but it is unlikely to “fix” the patient’s problem long-term.

For olecranon and prepatellar bursitis, the clinician must first differentiate between septic and aseptic bursitis. If the bursa is infected, following aspiration and lab collection, antibiotics must be initiated. The decision about whether to use oral versus parenteral antibiotics and whether admission is warranted depends upon the severity of the infection and the reliability of the patient. Oral therapy should be used cautiously, as treatment failure has been seen in up to 39% to 50% of patients. The duration of antibiotic treatment is usually 10 to 14 days. Surgical intervention is rarely necessary, but should be considered in patients who fail to respond to incision and drainage and appropriate antibiotics, if there is suspicion of a foreign body, or there is an inability to adequately drain the bursa.

With aseptic bursitis of the prepatellar and olecranon bursas, the clinician should resist the urge to aspirate and inject with steroids. Aspiration and injection is a possible treatment option, but should only follow a failed conservative approach. The reason for this is that once drained, the bursa is likely to fill with fluid again quickly, and there is a risk for an iatrogenic infection. Steroids are also known to cause skin atrophy. A 6- to 8-week trial of the conservative approach is reasonable.

## COMMON SPORTS INJURIES

Method of

Andrew S.T. Porter, DO

### CURRENT DIAGNOSIS

- **Lateral Ankle Sprain**—Pain over lateral ankle ligament(s) with localized swelling. Often associated with laxity and pain with anterior drawer and/or talar tilt test. Obtain x-rays based on the Ottawa ankle and foot rules.
- **Medial Ankle Sprain**—Less common than lateral ankle sprain. Pain in the deltoid ligament with localized swelling. Obtain x-rays based on Ottawa ankle and foot rules.
- **High Ankle Sprain**—Syndesmotic injury. Pain with squeeze test and/or dorsiflexion with external rotation.
- **Osteochondral Ankle Injuries**—Most commonly seen in the talar dome. Associated with an ankle inversion injury and ankle pain. Often have a joint effusion and soft tissue swelling and can have mechanical symptoms (catching, locking, crepitus, and a feeling of giving way). Obtain x-rays initially and then magnetic resonance imaging (MRI) to grade degree of injury.
- **Anterior Cruciate Ligament (ACL) Injuries**—Most common after noncontact injuries. Physical examination reveals a diffuse knee effusion, positive Lachman, and/or anterior drawer test. Obtain x-rays then MRI for further evaluation.
- **Posterior Cruciate Ligament (PCL) Injuries**—Occur with varus/valgus stress with the knee in full extension. Physical examination reveals a positive posterior drawer and sag sign. Obtain x-rays then MRI for further evaluation.
- **Medial Collateral Ligament (MCL) Injuries**—Occur with valgus stress or twisting with or without contact. Physical examination reveals localized effusion and a positive valgus stress testing and tenderness to palpation along the MCL. Graded 1 to 3.
- **Osteochondral Knee Injuries**—Most commonly seen in the femoral condyle. Associated with a knee injury. Knee pain and, often, mechanical symptoms of the knee. Palpation of the femoral condyles with the knee in flexion reproduces pain. Obtain x-rays initially and then MRI to grade degree of injury.
- **Mallet Finger**—Disruption of the extensor mechanism insertion into the distal phalanx.
- **Jersey Finger**—Occurs after avulsion of the flexor digitorum profundus tendon from its insertion on the distal phalanx.
- **Proximal Interphalangeal (PIP) Joint Dorsal Dislocation**—Injury to the volar plate with or without an avulsion fracture.
- **Scaphoid Fracture**—Pain over the scaphoid with or without a fall on an outstretched hand injury is a scaphoid fracture until proven otherwise. Obtain wrist x-rays with a scaphoid view.
- **Tendinosis**—Repetitive chronic tendon injuries result in scarring, disorganization of fibers, degeneration, and are without an inflammatory component.
- **Stress Fractures**—Most often seen in active patients as a result of excessive stress on normal bone from overactivity or normal stress on a bone that is deficient (osteoporotic, poor nutrition, or in female athlete triad). History is positive for bone pain, and physical examination reveals tenderness to palpation in the affected bone and often a positive tuning fork test, hop test, and fulcrum test. Obtain x-rays first, then MRI or bone scan if needed.
- **Spondylolysis/Spondylolisthesis**—Most often seen in young athletes with insidious onset low back pain and history of repetitive extension. Positive stork test. X-rays initially, and if negative, may proceed with limited CT and SPECT scan or MRI.

## CURRENT THERAPY

- Lateral Ankle Sprain—Treat with RICE (rest, ice, compression, elevation) and early rehab. Return to play (RTP) is generally 1 to 4 weeks and is based on functional progression. RTP with ankle brace.
- Medial Ankle Sprain—Treat with RICE and early rehab. RTP with ankle brace.
- High Ankle Sprain—Treat with RICE and boot for 1 to 3 weeks and then rehab. RTP takes a longer time compared with lateral ankle sprain.
- Osteochondral Ankle Injuries—Degree of injury is graded via MRI, and this guides treatment and RTP.
- ACL Injuries—ACL tears often need reconstruction that is individualized in active patients who require knee stability.
- PCL Injuries—Isolated PCL injuries often heal conservatively with protected weight bearing in an extension brace and knee rehab.
- MCL Injuries—Often heal conservatively with bilateral hinged knee brace and knee rehab. Generally, RTP in 2 to 6 weeks.
- Osteochondral Knee Injuries—Degree of injury is graded via MRI, and this guides treatment and RTP.
- Mallet Finger—Treat with continuous full-extension stack splinting of the distal interphalangeal joint for 6 weeks and then nighttime splinting and activity splinting for 6 weeks.
- Jersey Finger—Treatment is referral to orthopedic surgeon for surgical intervention.
- PIP joint dorsal dislocation—Reduce dislocation and obtain x-rays. Treat with progressive extension blocking splint with 30° to 40° of flexion and decrease by 10° per week.
- Scaphoid Fracture—If x-rays with scaphoid view are negative, place in a short-arm thumb spica cast and follow up in 2 weeks. If x-rays remain negative but pain persists, obtain a CT or MRI. Treat nondisplaced scaphoid fractures with short-arm thumb spica cast: proximal-third fractures 12 to 20 weeks, middle-third fractures 10 to 12 weeks, and distal-third fractures 4 to 6 weeks.
- Tendinosis—Treat by creating inflammation to facilitate healing.
- Stress Fractures—Treat with general treatment for stress fractures plus specific treatment based on stress fracture site.
- Spondylolysis/Spondylolisthesis—Treat with extension blocking brace, rest, rehabilitation with core strengthening and lower extremity flexibility, and gradual RTP.

### Ankle Injuries

The ankle is the most common joint injured in athletes. Ankle sprains are common, as they represent 25% of all sports-related injuries. The Ottawa ankle and foot rules help in the decision to obtain x-rays (Box 1). In general, treatment will consist of RICE (rest, ice, compression, elevation), early mobilization, and rehab. Prevention of ankle injuries is important and consists of ankle braces, ankle taping, neuromuscular training program, and regular sport-specific warm-up exercises.

### Lateral Ankle Sprain

The most common ankle sprain is a lateral inversion sprain that results from landing on an inverted foot with or without plantarflexion. The lateral ankle ligaments are the anterior talofibular ligament (ATFL), calcaneofibular ligament, and the posterior talofibular ligament. The ATFL is the most commonly sprained ligament. Lateral ankle sprains are most commonly treated with RICE initially, then early ambulation, range of motion, progression into strengthening, and then proprioception rehabilitation. Proprioception rehabilitation includes balancing on one leg and performing balancing exercises on a wobble board. For example, patients can balance on one leg when brushing their teeth.

## BOX 1 Ottawa Ankle and Foot Rules

- An ankle x-ray series is indicated if there is pain in the malleolar zone and any of these findings are made:
  - Tenderness over the lateral malleolus
  - Tenderness over the medial malleolus
  - Inability to bear weight four steps immediately after the injury or in the emergency department or physician's office
- A foot x-ray series is indicated if there is pain in the midfoot zone and any of these findings are made:
  - Tenderness over the base of fifth metatarsal
  - Tenderness over the navicular bone
  - Inability to bear weight four steps immediately after the injury and in the emergency department or physician's office

\*X-rays are indicated if any of these criteria are met.  
Data from Bachmann and colleagues (2003) and Tiemstra (2012).

Athletes should return to play (RTP) with a lace-up/velcro ankle brace after injury with or without taping. This added stability will help prevent future ankle injuries and also decrease the severity of ankle injuries. Most athletes will RTP in a few days to 4 weeks; this return is based on pain, obtaining full active range of motion and full strength, and functional stability.

### Medial Ankle Sprain

Medial ankle ligament sprains are rare, account for < 10% of ankle injuries, and are often accompanied with a lateral malleolar fracture or syndesmotic injury. The medial ankle ligament is the deltoid ligament and is injured via external rotation or eversion. These ankle sprains are treated similarly to lateral ankle sprains.

### High Ankle Sprain

High ankle sprains, also known as syndesmotic ankle sprains, occur through forced external rotation of a dorsiflexed foot most commonly but also occur by forced internal rotation of a fixed plantar flexed foot. The syndesmotic ligaments connect and stabilize the distal tibia to the distal fibula. The syndesmotic ligaments are the anterior tibiofibular ligament, posterior tibiofibular ligament, transverse tibiofibular ligament, interosseous ligament, and the interosseous membrane. Palpate the fibular head for pain. Pain on palpation of the fibular head might indicate a Maisonneuve fracture, a fracture of the proximal third of the fibula associated with syndesmotic disruption. A high ankle sprain has a longer healing time compared to a lateral ankle sprain. Often these need immobilization with a boot or cast for 1 to 4 weeks to help with healing before beginning rehab. RTP after a high ankle sprain depends on pain, achieving a full active range of motion, full strength, and functional stability. Incomplete healing of a high ankle sprain can result in distal tibia and fibula instability.

### Osteochondral Ankle Injuries

Osteochondral injuries are injuries to the articular surface of a joint. These injuries range from small undisplaced depressions and cracks in the osteochondral surface to small pieces of articular cartilage and bone that break off of the articular surface and float within the joint. Osteochondral injuries occur most commonly on weight-bearing articular surfaces. In osteochondral injuries, osteonecrosis of subchondral bone occurs, resulting in separation of cartilage and subchondral bone from underlying, well-vascularized bone. The term *osteochondral lesion* (OCL) is favored over the previously used term *osteochondritis desiccans* because there might not be an inflammatory component of the injury. OCLs are often associated with repeated trauma or overuse in athletes. OCLs typically present with pain in the affected joint and can develop with a specific injury or over several months in highly active athletes. OCLs are more

**Figure 1** X-rays of the left ankle, AP and mortise views, which demonstrate a grade 2 osteochondral lesion (OCL) along the medial talar dome.

**Figure 2** X-ray of the left ankle, mortise view, which demonstrates a grade 4 OCL along the lateral talar dome.

**Figure 3** CT scan without contrast. Sagittal image of ankle, which demonstrates a grade 4 OCL of the talar dome.

common in younger patients with open physes (growth plates) and are referred to as juvenile OCLs. Adult OCLs describe this condition in skeletally mature patients.

Osteochondral injuries are a cause for pain in up to 25% of ankle injuries and need to be considered when a patient presents with ankle pain. Acute osteochondral injuries in the ankle most commonly affect the talar dome (Figures 1–3) but can also be

found in the distal tibia (Figure 4). OCLs are first evaluated by x-rays (see Figures 1 and 2) and then graded by magnetic resonance imaging (MRI) (Table 1). CT scan (see Figure 3) is sometimes utilized as well. Grade 1 to 3 juvenile OCLs and grade 1 to 2 adult OCLs are treated conservatively. Conservative treatment consists of no weight bearing (NWB) in a cast or boot for 6 to 10 weeks followed by partial weight bearing (PWB) to full weight bearing (FWB) over 2 to 6 weeks, followed with an ankle brace for 3 months, and ensuring adequate calcium and vitamin D intake to facilitate healing. Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided because they can slow bone healing, and OCLs are probably not an inflammatory process. For grade 4 juvenile OCLs, grade 3 and 4 adult OCLs, and those that have not clinically healed with conservative care operative treatment is required. Operative treatment options depend on OCL size and type and include removal of the OCL followed by transchondral drilling and microfracture to stimulate fibrocartilage

**Figure 4** CT scan without contrast. Coronal image of ankle, which demonstrates a grade 1 OCL of the distal lateral tibia.

**TABLE 1** Classification of Osteochondral Lesions

STAGE	PLAIN X-RAY FINDINGS	MRI FINDINGS
1	Depressed osteochondral fragment	Articular cartilage thickening and low signal changes in subchondral bone
2	Osteochondral fragment attached by bone	Articular cartilage breached, no synovial fluid around fragment
3	Detached nondisplaced fragment	Articular cartilage breached, synovial fluid around fragment
4	Displaced fragment	Loose foreign body

formation, fixation of the OCL with an osteochondral allograft, osteochondral autograft transfer, and autologous chondrocyte implantation.

Knee injuries—The knee joint lacks intrinsic bone stability, so most stability is from the major knee ligaments.

### Anterior Cruciate Ligament Injuries

The anterior cruciate ligament (ACL) is the key stabilizer of the knee and is one of two major intraarticular knee ligaments, the other being the posterior cruciate ligament (PCL). Most ACL tears occur from noncontact injuries. Women experience ACL tears up to nine times more often than men do. The main function of the ACL is to prevent excessive anterior tibial translation relative to the femur. Patients who sustain an injury to their ACL often describe hearing a pop, feeling instability in their knee, experiencing pain immediately after the injury, and develop an associated knee effusion. On-the-field evaluation is ideal in an ACL injury, as the hamstrings will often start to tighten up shortly after the injury, preventing anterior tibial translation. This will prevent an isolated test of the ACL and give the false impression that an ACL endpoint is present when in fact the ACL is completely torn. The anterior drawer (Figure 5) and Lachman test (Figure 6) are the main physical examination tests to evaluate the ACL. Obtain x-rays and then MRI if an ACL tear is suspected. The blood supply to the ACL is poor and is provided by the middle geniculate artery off of the popliteal artery. Because of the poor blood supply, ACL tears often need reconstruction if

**Figure 5** Anterior drawer test for ACL laxity. Patient's knee is flexed 90°. Examiner applies anterior force to the tibia in relation to the patient's femur to evaluate for laxity.

**Figure 6** Lachman test for ACL laxity. Patient's knee is flexed 20°–30°. Examiner grasps the distal femur and proximal tibia and applies anterior force to the tibia and posterior force to the femur to evaluate for ACL laxity.

athletes want to return to a high level of activity and knee stability is needed. ACL reconstruction timing is important and often will occur 3 to 4 weeks after injury to allow for swelling to decrease, ROM and strength to improve, and inflammation to decrease. Also during this presurgical time, it is important to have patients perform pre-hab (presurgical rehabilitation), focusing on AROM and knee strengthening. A knee effusion will cause the quadriceps muscles to weaken and atrophy. Hamstring tendon autograft, patella tendon autograft, quadriceps tendon autograft, and allograft are all used for ACL reconstruction. Each graft has advantages and disadvantages and should be discussed with the orthopaedic surgeon before reconstruction and individualized for each patient. Continuing to participate in high-level activity after an ACL tear if undiagnosed can lead to a knee dislocation and further intraarticular knee injury.

### PCL Injuries

The PCL is the other major intraarticular knee ligament. Isolated PCL injuries are much less common than ACL injuries and make up only 3.5% of ligamentous knee injuries in sports, with the remaining 96.5% of PCL injuries associated with multiligamentous knee injuries. PCL injuries, unlike ACL injuries, are the result of external forces (e.g., a soccer player sliding into the goal post and tearing his or her PCL). The main function of the PCL is to resist posterior tibial translation. Posterior drawer testing (Figure 7) and a sag sign test (Figure 8) are the physical examination tests used to evaluate the PCL. Obtain x-rays then MRI if a PCL tear is suspected. The blood supply to the PCL is better than the blood supply to the ACL. Isolated PCL injuries (grades 1 and 2) are treated conservatively because surgical reconstruction has not been shown to be helpful. Conservative treatment consists of protected weight bearing in an extension brace followed by quadriceps rehabilitation and ROM exercises. RTP is generally 4 to 6 weeks after a PCL injury. Surgical intervention is recommended for associated injuries to the ACL, medial collateral ligament (MCL), and posterior lateral corner (grade 3 PCL injury).

**Figure 7** Posterior drawer test for PCL laxity. Patient's knee is flexed 90°. Examiner applies posterior force to the tibia in relation to the patient's femur to evaluate for laxity.

**Figure 8** Sag sign test for PCL laxity. Examiner views the tibia condyles from the lateral side to evaluate for a posterior sag (displacement) in the appearance that would indicate a PCL injury.

### MCL Injuries

The MCL is an extraarticular ligament that resists knee valgus forces. An MCL sprain results from a valgus stress to a partially flexed knee. Athletes will present with localized pain and swelling along the medial aspect of the knee. Most MCL injuries are isolated ligament injuries, but more severe MCL injuries can involve tears of the medial meniscus and ACL, commonly referred to as the “terrible triad.” The MCL is examined by palpation and valgus stress testing at 0° and 30° of knee flexion. MCL injuries are graded 1, 2, or 3 depending on severity of injury. A patient with a grade 1 MCL sprain has pain in the MCL but no valgus stress testing laxity. A grade 2 MCL sprain has valgus stress testing laxity but a solid endpoint. A grade 3 MCL sprain has no endpoint with valgus stress testing. Thankfully, the MCL has a rich vascular supply and can often heal conservatively. Treatment consists of RICE for the first 1 to 2 weeks and a bilateral hinged

**Figure 9** X-ray of the bilateral knees, AP view, which demonstrates a grade 1 OCL along the right knee medial femoral condyle.

**Figure 10** Magnetic resonance imaging (MRI) of the right knee, without contrast. Coronal T2 fat saturation image, which demonstrates a grade 4 OCL of the medial femoral condyle.

knee brace to facilitate healing. Weight bearing and ROM and strengthening exercises are started when they are tolerable. RTP after an MCL injury depends on the grade and generally takes 2 to 6 weeks.

### Osteochondral Knee Injuries

Osteochondral injuries occur in the knee as well as in the ankle. Osteochondral injuries of the knee most commonly affect the lateral aspect of the medial femoral condyle but can be found anywhere along the medial or lateral femoral condyle, patella, or trochlea. History is significant for knee pain, with or without swelling and mechanical symptoms (catching, locking, crepitus, and feeling of giving way). On palpation, patients can have pain in the affected area with knee flexion with or without crepitus. Obtain x-rays initially (Figure 9) and then grade the OCL severity by MRI (Figure 10). CT scans are also utilized sometimes. Grade 1 to 3 juvenile knee OCLs and grade 1 to 2 adult knee OCLs are

**Figure 11** X-ray of the left hand, lateral view, which demonstrates a mallet finger of the fifth finger. Note the flexion of the DIP joint and avulsion fracture of the distal phalanx that involves about 30% of the joint space.

**Figure 12** Stack splint with Coban wrap added for stability that immobilizes the DIP joint at neutral to 5° of hyperextension.

treated conservatively. Grade 4 juvenile OCLs, grade 3 to 4 adult OCLs and all OCLs that have failed conservative care are treated operatively.

## Hand Injuries

### Mallet Finger

A mallet finger occurs after forced flexion of an actively extended distal interphalangeal (DIP) joint, resulting in disruption of the extensor mechanism insertion into the distal phalanx. Patients with a mallet finger are unable to actively extend the DIP joint. This injury can be associated with an avulsion fracture (Figure 11). For acute injuries, general treatment consists of continuous extension splinting of the DIP joint (0° to 10° of hyperextension) for at least 6 weeks. The 6-week clock starts over if the DIP joint is allowed to flex at all during the initial 6 weeks of treatment or if, at the end of the 6 weeks, the mallet finger is not completely healed. After the initial 6 weeks, it is recommended to continue with nighttime splinting and activity splinting for another 6 weeks to ensure adequate healing and avoidance of surgery. To perform this splinting, a stack splint is well tolerated and is protective (Figure 12). Orthopaedic referral is indicated if the patient is unable to obtain full passive extension of the DIP joint or if the avulsion fracture involves over 30% of the joint space.

### Jersey Finger

A jersey finger results from the avulsion of the flexor digitorum profundus tendon from its insertion on the distal phalanx. This commonly occurs in football and rugby players when the tip of their flexed finger is caught in a jersey and the DIP joint of the finger is then forcefully extended. After this injury occurs, the patient is unable to actively flex the DIP joint. Treatment is urgent referral to an orthopaedic surgeon for surgical intervention.

### Proximal Interphalangeal Joint Dorsal Dislocation

Proximal interphalangeal (PIP) joint injuries are the most common joint injuries in sports. Most PIP dislocations are dorsal and

**Figure 13** X-ray of the left hand, oblique view, which demonstrates a proximal interphalangeal (PIP) joint dorsal and lateral dislocation.

result from hyperextension with an axial load. Dislocations are described by the position of the distal fragment in relation to the proximal fragment. PIP dorsal dislocations cause injury to the volar plate with or without avulsion fracture. Pre-reduction x-rays are preferred if they can be obtained promptly (Figure 13). X-rays of the finger with at least one view being a true lateral view should be obtained to rule out fracture. However, many PIP dorsal dislocations occur on the playing field and it is reasonable to reduce these dislocations, buddy tape the affected finger, and allow the patient to RTP with x-rays obtained after the athletic competition. Reduction is usually uncomplicated and is performed urgently via hyperextending the joint, applying traction in plane with the finger, then flexing the joint. Post reduction films are a necessity (Figure 14). Stability testing of the collateral ligaments should be performed after the reduction. Full flexion and extension of the PIP joint will be possible if the joint is stable. A stable joint without a large avulsion fragment should be treated with a progressive extension blocking splint (Figures 15 and 16). Start with 30° to 40° of flexion and decrease by 10° per week over 3 to 4 weeks, then buddy tape the injured finger with activity PRN (8). Some PIP dorsal dislocations have a lateral component to them and these are treated similar to pure dorsal dislocations (see Figure 13). Orthopaedic surgeon referral is indicated if there is a large avulsion fracture or the joint is unstable.

### Scaphoid Fracture

The scaphoid bone is the most common carpal bone that is fractured and is a common injury that is encountered in primary care. Interestingly, scaphoid fractures occur most commonly in young men. Scaphoid fractures occur less commonly in young children and the elderly because of the relative weakness of the distal radius compared with the scaphoid in these age groups. Often a scaphoid fracture is caused by a FOOSH (fall on an outstretched hand) injury. On physical examination, if the patient has pain over the scaphoid tubercle or in the anatomical snuffbox with or without a history of a FOOSH injury, the clinician needs to have a high index of suspicion for a scaphoid fracture when evaluating the wrist

**Figure 14** X-ray of the left hand, lateral status postreduction view, which demonstrates a relocated proximal interphalangeal (PIP) joint. Note the avulsion fracture of the middle phalanx.

**Figure 15** Dorsal extension blocking splint at 30°–40° of flexion at the PIP joint. Note that there is no pressure over the PIP joint volar plate and that flexion and extension at the DIP joint is possible.

x-rays. Obtain the standard wrist x-rays (AP, lateral, and oblique views) plus a dedicated scaphoid view (AP with ulnar deviation) and be aware that early imaging with x-rays is often unrevealing for a scaphoid fracture (Figure 17). If a fracture is not seen on x-rays, the clinician needs to have a high index of suspicion for a scaphoid fracture, place the patient in a short-arm thumb spica cast, and have the patient follow up in 2 weeks. If repeat x-rays remain negative and the patient continues to have scaphoid pain, proceed with an MRI of the wrist with T2 fat saturation views or a CT scan. If a scaphoid fracture is noted on imaging, the location

**Figure 16** Dorsal extension blocking splint at 30°–40° of flexion at the PIP joint. This figure illustrates the freedom of motion that is possible at the PIP joint (full flexion and limited extension) and the DIP joint (full flexion and extension).

of the scaphoid fracture will guide treatment. Because the blood supply to the scaphoid is distal to proximal, scaphoid fractures are harder to heal than other carpal fractures. Nondisplaced middle-third or proximal-third scaphoid fractures are treated with a long- or short-arm thumb spica cast with the wrist at 20° to 30° of extension and the thumb in slight extension and abduction for 10 to 20 weeks. Middle-third fractures should be immobilized for 10 to 12 weeks. Proximal-third fractures should be immobilized from 12 to 20 weeks. It is much easier to regain flexion in the wrist after casting than it is to regain extension. If the elbow is incorporated in the cast, it should be casted at 90° of flexion. A long-arm cast may decrease healing time, but it does not improve nonunion rates. A nondisplaced distal-third fracture should be treated in a short-arm thumb spica cast for 4 to 6 weeks. For displaced fractures or non-healing fractures, a referral to an orthopedic surgeon is recommended. Use acetaminophen for pain control and avoid nonsteroidal antiinflammatory drugs (NSAIDs) because NSAIDs can impair bone healing. Ensure adequate energy availability via diet and adequate calcium and vitamin D intake, and avoid tobacco exposure to help heal the fracture. Bone health and bone nutrition are a part of the big picture in fracture healing.

## Overuse Injuries

### Tendinosis

The paradigm and management of tendon overuse injuries is changing. The term *tendinitis* is generally used to refer to painful overuse tendon conditions and implies that inflammation is present. However, the most common pathology in chronic painful tendons is tendinosis. Tendinosis occurs after repetitive injuries to a tendon results in intertendinous scarring, disorganization of tendon fibers, and degeneration. Tendinosis does not have an inflammatory component. Early on in a tendon injury, there is inflammation resulting in tendinitis, but after about 6 weeks this generally evolves into tendinosis. Early activity modification and treatment of tendinitis with NSAIDs and rehabilitation may prevent the development of tendinosis. Tendinosis is a problematic condition that affects many active people, young and old. To address these more chronic tendon injuries, healing is facilitated by creating an inflammatory response. To create inflammation, treatments such as eccentric strengthening (Figure 18), deep soft tissue massage with tools (e.g., gua sha or Graston, or ASTYM) (Figure 19), nitroglycerin patches (Nitro-Dur),<sup>1</sup> and musculoskeletal ultrasound-guided percutaneous needle tenotomy (with or without injection of autologous blood, prolotherapy, or platelet-rich plasma) have all been utilized and have been shown to be effective (Table 2). It is important to avoid NSAIDs when trying to create inflammation because NSAIDs will prevent the

<sup>1</sup> Not FDA approved for this indication.

inflammatory response. This concept of tendinosis diagnosis and treatment can be utilized for tendons throughout the body and is most commonly applied to the Achilles tendon, patella tendon, iliotibial (IT) band, piriformis, gluteus medius, hamstrings, biceps, common elbow flexor tendon, and common elbow extensor tendon.

### Stress Fractures

Stress fractures occur when osteoclastic activity overwhelms osteoblastic activity. Bone injury unfolds over a continuum of time, starting with normal bone that progresses to stress reaction, then stress fracture, and finally fracture if the bone continues to be injured. This can occur as a result of excessive stress on normal bone from overactivity or normal stress on a bone that is deficient (osteoporotic, poor nutrition, or in female athlete triad).

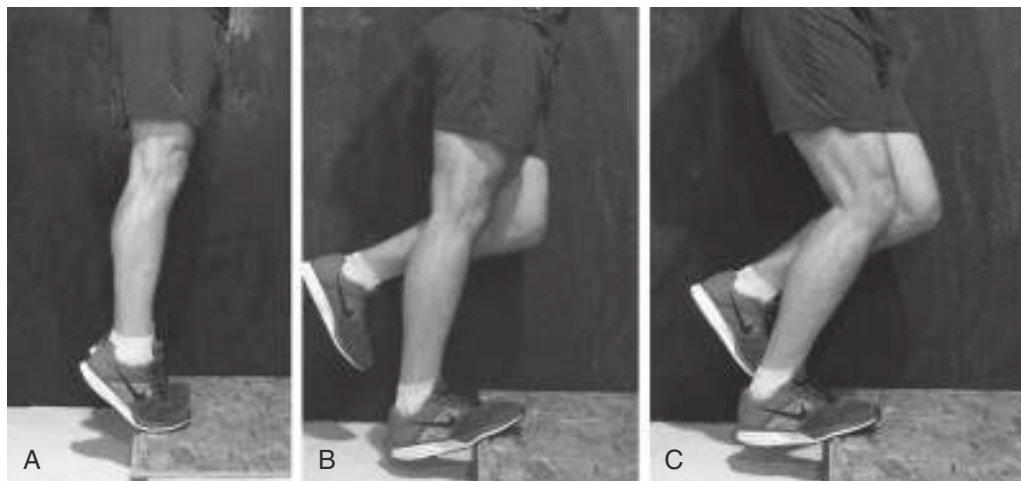

**Figure 17** Scaphoid view x-ray (AP view with ulnar deviation) is important to obtain in addition to your standard wrist views (AP, lateral, and oblique) when scaphoid fracture is suspected. This scaphoid fracture was not seen on the x-rays on the day of the injury. Patient continued to have wrist pain and then presented 10 weeks later, and x-rays were obtained demonstrating the scaphoid fracture.

Stress fractures are common injuries in athletes and occur most often in the lower extremities. Running sports account for 69% of stress fractures. Stress fractures should be considered in someone who is active, presents with bone pain, and who performs repetitive activities with limited rest or with a recent increase in activity. Physical examination tests to perform in the area of interest are palpation, the tuning fork test, the fulcrum test, and the hop test (Table 3). If a stress fracture is suspected, x-rays should be obtained, keeping in mind that it takes 2 to 3 weeks for signs of stress fracture (i.e., periosteal reaction, callus formation, fracture line) to show up on an x-ray, and often stress fractures do not show up on x-rays. If x-rays are negative and a diagnosis is needed to help guide care and RTP, a bone scan or MRI with T2 fat saturation views (Figures 20 and 21) should be obtained. The bone scan and MRI are equally sensitive, but an MRI is more specific and avoids patient radiation exposure. An MRI is more expensive. Because a bone scan can stay positive for up to 18 months, clinical progress should not be monitored with a bone scan.

To prevent stress fractures, athletes should distribute loading forces on the bone with cross training and biomechanical adjustments (i.e., orthotics, proper shoes, stretches, strengthening, running mechanics), consume sufficient calories to maintain adequate energy availability, and ensure appropriate intake of calcium and vitamin D. A study by Lappe of female Navy recruits showed reductions in stress fractures in those consuming 2000 mg of calcium<sup>1</sup> and 800 IU vitamin D<sup>1</sup> daily, either as a supplement or through consumption of dairy products. Tobacco should be avoided. Additionally, women of child bearing age should try to maintain regular menses by consuming adequate calories and avoiding a negative energy balance.

General treatment for stress fractures can be grouped into nutrition, medication, and biomechanical recommendations. Nutrition recommendations include optimizing energy availability in the diet, ensuring adequate calcium and vitamin D intake, and avoidance of tobacco exposure. Medication recommendations include using acetaminophen as needed for pain control and avoidance of NSAIDs. Biomechanical recommendations are to offload the affected bone and reduce activity to pain-free functioning and pain-free cross-training. Crutches may be needed to offload the injured area even more than a walking boot/cast or steal shank. The patient may require complete non-weight bearing (NWB) with the overall goal being to obtain pain-free ambulation during the initial treatment. Tables 4 and 5 outline recommended guidelines for protected weight bearing for specific stress fracture sites. Additional recommendations are to begin a rehabilitation program when tolerated and to stretch and strengthen supporting

<sup>1</sup> Not FDA approved for this indication.

**Figure 18** Eccentric exercises for Achilles tendinosis. (A) Patient begins with the injured leg straight and the ankle in flexion. The assistance of the uninjured leg was utilized to get in this starting position. (B) The ankle of the injured leg (right leg, in this case) is slowly lowered in a controlled fashion to full dorsiflexion to eccentrically strengthen (while lengthening the calf muscles) the right Achilles tendon. The left leg is then brought back down, and full plantarflexion in both ankles is performed, recruiting the uninjured leg to assist with getting back to position (A). (C) The eccentric exercise from (B) is repeated with the knee bent at 45°.

structures. Start a gradual increase in activity when the patient is pain-free.

Because of their propensity for delayed healing and nonunion, certain stress fractures are considered high risk, necessitate prompt treatment, and may ultimately require surgical fixation.

Low-risk stress fractures have a lower incidence of delayed healing and nonunion. High-risk stress fractures that appear stable and nondisplaced can be treated nonoperatively with close follow-up. Consider referral to an orthopaedic surgeon for failed

Figure 19 ASTYM® tools.

TABLE 2 Treatment of Tendinosis

TREATMENT MODALITY	DESCRIPTION
Deep soft tissue massage with tools (gua sha, Graston, ASTYM) (Figure 19)	One to three times per week for 4–6 wk; most common with athletic trainer certified or physical therapist
Nitroglycerin patches (Nitro-Dur) <sup>1</sup>	0.1 mg/h patch, apply Q24 h to a different location on tendon for at least 6 wk
Eccentric strengthening (Figure 18)	3 sets of 15 exercises, twice daily, for 12 wk
Musculoskeletal ultrasound-guided percutaneous needle tenotomy with or without autologous blood injection, prolotherapy, or platelet-rich plasma	Referral to primary care sports medicine physician

<sup>1</sup>Not FDA approved for this indication.

TABLE 3 Stress Fracture Physical Exam Tests

PHYSICAL EXAM TEST	POSITIVE TEST
Palpation	Pain over affected bone with palpation
Stork test (Figure 22)	Back extension with rotation while standing on one leg increases pain in the pars interarticularis region
Fulcrum test	Pain in fracture site while applying a bending force (e.g., over the exam table) to distal extremity while proximal extremity is kept relatively immobilized
Hop test	Hopping 10 times on affected leg reproduces pain at fracture site
Tuning fork test	Vibrating tuning fork over fracture site results in pain at site

Figure 20 MRI of the right hip without contrast. Coronal T2 fat saturation image demonstrates a compression-sided femoral neck stress fracture (note surrounding bone edema in white).

Figure 21 MRI of the right hip without contrast. Axial T2 fat saturation image that demonstrates a compression sided femoral neck stress fracture (note edema in white and probable fracture line in black that measures up to 11 mm).

**TABLE 4** High-Risk Stress Fracture Initial Treatment

HIGH-RISK STRESS FRACTURE	INITIAL TREATMENT (IF STABLE AND NONDISPLACED)
Femoral neck (compression side) (Figures 20 and 21)	NWB for 6–8 wk then PWB to FWB over next 6–8 wk
Anterior tibia (tension side)	NWB for 6–8 wk then PWB to FWB over next 6–12 wk
Medial malleolus	Pneumatic lower leg boot for 6–8 wk
Navicular	NWB cast/boot for 6 wk then 6-wk RTP progression
Base of fifth metatarsal (Jones)	NWB cast/boot 6–8 wk
May consider surgery for quicker RTP	
Sesamoids	NWB cast/boot 6 wk

Abbreviations: NWB = non-weight bearing; PWB = partial weight bearing; FWB = full weight bearing.

**TABLE 5** Low-Risk Stress Fracture Initial Treatment

LOW-RISK STRESS FRACTURE	INITIAL TREATMENT
Sacrum/pelvis	WBAT 7–12 wk
Femoral shaft	WBAT 6–8 wk
Posterior medial tibia (compression side)	WBAT boot 2–12 wk (longer time with cortical break) then transition to pneumatic tibial brace
Fibula	WBAT 1–4 wk
Metatarsal (2nd–5th)	Steel shank/walking boot 3–6 wk

Abbreviations: WBAT = weight bearing as tolerated.

conservative treatment. Biomechanical forces along the bone with activity are used to classify tibia and femur stress fractures. For example, during running, the tibia and femur have different forces exerted on different parts of the bone. The tibia compresses posteriorly, so there is more compression along the posterior tibia and more tension along the anterior aspect of the tibia. The femoral neck compresses inferiorly and medially with running, so there is more compression along the inferior medial aspect of the femoral neck and more tension along the superior lateral aspect of the femoral neck. These variable forces on different parts of the bone affect the potential for delayed healing and nonunion.

### Spondylolysis and Spondylolisthesis

Spondylolysis is a nondisplaced stress fracture of the pars interarticularis. Spondylolisthesis occurs when there is bilateral spondylolysis with listhesis (slippage) of the vertebral body. Spondylolisthesis is graded 1 to 4 depending on how much slippage is present with each grade, accounting for 25% (i.e., grade 1 = 0–25%).

When a young athlete presents with low back pain, spondylolysis needs to be considered: this can be the cause of their pain up to 47% of the time. Spondylolysis is an overuse injury caused by repetitive hyperextension and/or rotation and has increased incidence in ballet dancers, gymnasts, divers, soccer players, and football linemen. L5 is the most common level for a spondylolysis. The history is significant for insidious onset of deep pain in the low back exacerbated by extension. Physical examination shows a positive Stork test (see Table 3), often with reproduction of pain on the side of weight bearing (Figure 22). If history and physical exam are suggestive of a pars interarticularis injury, x-rays of the lumbar spine, including

**Figure 22** Stork test: To assess localized spondylolysis pain, a single leg hyperextension rotation test (stork test) is performed. The patient stands on one leg and hyperextends and rotates the spine. Reproduction of the patient's pain is suggestive of a spondylolysis.

**Figure 23** Oblique view x-ray of the lumbar spine, which demonstrates a L3 and L4 spondylolysis.

oblique views, should be obtained. Oblique view x-rays provide the best view to identify a spondylolysis even though they only demonstrate spondylolysis about 30% of the time when it is present (Figure 23). If x-rays are negative, proceed with

**Figure 24** SPECT scan lumbar spine, PA view, which demonstrates an acute bilateral L3 and L4 spondylolysis.

**Figure 26** CT scan without contrast. Axial image at L4 shows bilateral pars interarticularis fractures. Right L4 pars fracture appears more chronic in appearance, with sclerotic fracture edges on the lateral aspect. Left L4 pars fracture appears more acute, with more jagged-appearing edges.

**Figure 25** CT scan without contrast. Axial image at L3 shows bilateral pars interarticularis fractures that appear acute with jagged and nonsclerotic fracture edges.

MRI or with SPECT scan. If the SPECT scan is positive (Figure 24), then proceed with limited CT scan (Figures 25 and 26). If radiation exposure is a concern, or if high-definition MRI is readily accessible, thinly sliced stacked axial cuts with T2 fat saturation views in all planes using a high-definition MRI is the test of choice (Figure 27). A spectrum of recommended treatments and conservative approaches that allow for a prompt and safe RTP are reasonable. For acute spondylolysis, the recommended treatment consists of a warm and form-extension-blocking back brace worn all day except for showering and bathing (23–24 hours per day) for the first month of treatment in conjunction with rest from activity. During the second month, use of the brace during the day with rehabilitation is suggested. Rehabilitation consists of core strengthening

**Figure 27** MRI lumbar spine without contrast. Axial T2 fat saturation image at L5 that demonstrates a right L5 spondylolysis signified by right pars interarticularis bone edema in white at L5.

and lower extremity flexibility. The third month consists of a gradual return to activity, continuing core strengthening and flexibility, and wearing the brace with activity. When treating spondylolysis, a healed pars interarticularis injury is defined as pain-free activity that may include bony union of the pars interarticularis stress fracture or fibrous nonbony union. Generally, the patient should wear the brace for at least 1 year with activity and sometimes longer depending on the severity of

**Figure 28** Lateral view x-ray of the lumbar spine, which demonstrates a grade 1 L5 spondylolisthesis.

injury. Utilize acetaminophen for pain, avoid NSAIDs, ensure adequate energy availability, maximize calcium and vitamin D intake, and avoid tobacco exposure to facilitate bone healing.

The general goal for spondylolisthesis treatment is to prevent further slippage; treatment is similar to that for spondylolysis. Surgical referral is indicated for grade 2, 3, or 4 spondylolisthesis (Figure 28).

## CONNECTIVE TISSUE DISORDERS

Method of

Molly A. Hinshaw, MD; and Susan Lawrence-Hylland, MD

### CURRENT DIAGNOSIS

#### Lupus Erythematosus

- The erythematous-violaceous and variably pruritic, tender, or scaly eruption is photosensitive.
- Mild to moderate systemic involvement may include arthritis and pleurisy.
- Severe systemic involvement may include nephritis, cerebritis, vasculitis, and severe cytopenias.
- Associated findings include antiphospholipid antibodies associated with thromboembolism or stroke, Raynaud's phenomenon, and sicca symptoms.

#### Dermatomyositis and Polymyositis

- Photosensitive, violaceous-erythematous, poikilodermatous, and variably scaly patches occur around eyes, on extensor extremities (especially over joints), upper back, scalp, and dystrophic nail folds with prominent telangiectasias.
- Patients may have or develop myositis or pulmonary involvement.
- Age-appropriate cancer screening is required for adults.

#### Scleroderma

- Patients have firm, variably pruritic, and indurated plaques.
- Localized scleroderma (i.e., morphea or asymmetric sclerotic plaques) may be seen.
- Limited systemic sclerosis is characterized by symmetric sclerosis of distal extremities, and patients may have systemic disease.
- Diffuse systemic sclerosis is characterized by symmetric sclerosis of the trunk and proximal extremities, and patients may have systemic disease.
- Sclerodactyly (i.e., thickening of skin of digits) may occur in patients with systemic sclerosis.
- Pulmonary, cardiac, and gastrointestinal screening should be done for patients with systemic sclerosis.
- Patients with systemic sclerosis should be evaluated and monitored for renal crisis.
- Raynaud's phenomenon may develop in patients with systemic sclerosis.

### CURRENT THERAPY

#### Lupus Erythematosus

- Patients should be counseled on photoprotection measures.
- Localized cutaneous disease is treated with medium- to high-potency topical corticosteroids, and intralesional triamcinolone acetonide 10 mg/mL (Kenalog-10) is added if needed.
- Mild to moderate systemic involvement is treated with low- to medium-potency prednisone 5 to 20 mg/day and with antimalarials.
- Severe disease is treated with prednisone 1 mg/kg/day with a taper based on clinical response. Steroid-sparing agents include azathioprine (Imuran),<sup>1</sup> mycophenolate mofetil (CellCept),<sup>1</sup> methotrexate (Rheumatrex),<sup>1</sup> and cyclophosphamide (Cytoxan).<sup>1</sup>
- Thromboembolism or stroke is treated by anticoagulation with warfarin (Coumadin), aspirin, or heparin.

- Sicca syndrome is treated with frequent water intake, saliva replacement, artificial tears, routine dental care, and pilocarpine (Salagen).

#### Dermatomyositis and Polymyositis

- Patients should be counseled on photoprotection measures.
- Medium-potency topical corticosteroids and calcineurin inhibitors are used for cutaneous disease.
- Prednisone 1 mg/kg/day is first-line therapy for muscle or pulmonary disease.
- Methotrexate<sup>1</sup> 10 to 25 mg/week is a steroid-sparing agent used for muscle involvement.
- Hydroxychloroquine (Plaquenil)<sup>1</sup> 200 mg/day is used for persistent skin involvement.

#### Scleroderma

- For localized scleroderma, UVA<sup>1</sup> 20 to 60 J/cm<sup>2</sup> or psoralen plus UVA (PUVA) is used to resolve established lesions; high-potency corticosteroids and calcipotriene (Dovonex)<sup>1</sup> may help to reduce pruritus and inflammation in new lesions; and systemic prednisone<sup>1</sup> or methotrexate<sup>1</sup> may be used for rapidly progressive new lesions.
- Treatment of systemic sclerosis is primarily aimed at limiting complications.
- Physical therapy is used for contractures.
- Systemic sclerosis is treated with cyclophosphamide (Cytosan),<sup>1</sup> mycophenolate mofetil (CellCept),<sup>1</sup> methotrexate<sup>1</sup> 10 to 25 mg/week, and photopheresis.
- Renal crisis is treated with captopril (Capoten)<sup>1</sup> 6.25 mg three to six times/day and titrated to effect.
- Raynaud's is treated with warming techniques, calcium channel blockers, antiadrenergic agents, antiplatelet drugs, and topical vasodilators.

<sup>1</sup>Not FDA approved for this indication.

## Lupus Erythematosus

Lupus erythematosus is an autoimmune connective tissue disease that may localize to the skin or involve several organ systems. A complete review of systems with evaluation of positive findings is necessary to thoroughly assess patients for signs of systemic lupus as defined by the American Rheumatism Association. Cutaneous lupus erythematosus manifests in chronic, subacute, and acute forms. A punch biopsy from within an erythematous lupus lesion is useful for confirming the diagnosis.

### Clinical Features

Discoid lupus and tumid lupus are the two forms of chronic cutaneous lupus erythematosus. Discoid lupus lesions are tender or pruritic, erythematous to violaceous, scaly plaques that typically occur on sun-exposed skin. The lesions resolve with scarring, and when the lesions affect the scalp, they cause scarring alopecia. Tumid lupus manifests as pruritic, erythematous to violaceous, nonscaly plaques that typically preferentially affect the face and trunk.

The lesions of subacute cutaneous lupus erythematosus occur as erythematous to violaceous, scaly macules and as annular or polycyclic patches. These lesions are commonly located on sun-exposed skin and heal without scarring.

Acute cutaneous lupus erythematosus is exemplified by malar erythema (i.e., butterfly rash) and by poikiloderma (i.e., hyperpigmentation, telangiectasias, and epidermal atrophy). It is a manifestation of systemic lupus erythematosus (SLE). Cutaneous lesions may be widespread. In addition to the American Rheumatism Association criteria, patients with SLE may also develop Raynaud's phenomenon, hypercoagulability, and overlap syndromes with Sjögren's disease, dermatomyositis, and other conditions.

Hydrochlorothiazide (HydroDIURIL), terbinafine (Lamisil), minocycline (Minocin), procainamide (Pronestyl), hydralazine (Apresoline), and isoniazid (Nydrazid) are a few of the pharmaceutical agents that cause drug-induced lupus. This disease manifests with synovitis, photosensitivity, and positive serology results, and it may

have cutaneous lesions that do not necessarily abate with cessation of the medication.

## Management

### Prevention

All patients with lupus erythematosus should be counseled on photoprotection, including protecting skin from sunlight and avoiding sun exposure during peak hours (i.e., between 10 AM and 2 PM). Ultraviolet A and B wavelengths may cause lupus to flare. Broad-spectrum sunscreen with an SPF of 30 or higher and that contains titanium, zinc, Mexoryl (L'Oreal), or Helioplex (Neutrogena) should be used whenever patients are outdoors. Photoprotective clothing, available from multiple vendors, is useful for limiting sun exposure.

Patients with lupus are relatively immunosuppressed by their disease. Vaccinations should be kept up to date, although there is a debate about the necessity and safety of vaccination against meningococcal disease (*Neisseria meningitidis*) (Menactra, Menomune), varicella-zoster virus (Zostavax), and *Streptococcus* (Pneumovax).

### Treatment of Cutaneous Lupus Erythematosus

Medium-potency topical corticosteroids should be used for lupus localized to the skin, and they are used as adjunct treatment for patients with systemic lupus. Use of triamcinolone 0.1% cream (Flutex) for lesions on the head and neck until symptoms subside or up to 2 weeks continuously is an appropriate starting strength. Ointment-based vehicles are useful for lesions on the trunk and extremities. They are also the vehicles of choice on the scalp of patients of African American descent. Foam or liquid- or lotion-based corticosteroids work well in the scalp of other ethnic groups and can be used on the trunk and extremities. If lesions persist, the corticosteroid can be occluded, or intralesional injections with triamcinolone can be repeated monthly as needed. Intralesional triamcinolone acetone at concentrations of 5 mg/mL (Kenalog) can be injected into lesions on the face or neck and doses of 10 to 20 mg/mL (Kenalog-10, Kenalog) into lesions on the trunk or extremities. Intralesional corticosteroids may cause mild discomfort, atrophy of the skin or subcutis, or stretch marks. Topical calcineurin inhibitors such as pimecrolimus (Elidel)<sup>1</sup> or tacrolimus (Protopic)<sup>1</sup> may be used for maintenance treatment but are not recommended for new or active lesions because they do not work quickly. Recurrent or refractory cutaneous lesions require systemic treatment.

### Treatment of Systemic Lupus Erythematosus

Antimalarials, including hydroxychloroquine (Plaquenil),<sup>1</sup> are disease-modifying agents that limit the progression of lupus. Hydroxychloroquine, chloroquine (Aralen),<sup>1</sup> and quinacrine<sup>2</sup> (at compounding pharmacies) raise the pH of inflammatory cells, inhibiting inflammatory pathways that cause end-organ damage in patients with SLE.

Hydroxychloroquine is typically used first at 200 mg daily for 2 weeks and then increased to 400 mg daily. Patients need laboratory monitoring and a baseline and then yearly eye examination because the medication may be deposited in the retina over time. Hydroxychloroquine exerts its effects within 2 to 3 months of beginning treatment. Its effects are diminished in smokers.

Depending on end-organ involvement in SLE, immunosuppression with systemic corticosteroids such as prednisone at doses of 1 mg/kg/day is appropriate. Steroid-sparing drugs such as methotrexate (Rheumatrex),<sup>1</sup> acitretin (Soriatane),<sup>1</sup> or mycophenolate mofetil (CellCept)<sup>1</sup> are added. After signs of inflammation subside, prednisone is tapered.

### Treatment of Musculoskeletal Manifestations

Arthralgia is a common complaint that can usually be managed with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs). For true arthritis unresponsive to the previously described measures,

<sup>1</sup> Not FDA approved for this indication.

<sup>2</sup> Not available in the United States.

hydroxychloroquine<sup>1</sup> 200 mg twice daily can be added. After that, treatments similar to those used for rheumatoid arthritis can be added, although the antitumor necrosis factor agents usually are avoided in lupus. Methotrexate<sup>1</sup> 7.5 to 25 mg PO once weekly may be used along with folic acid<sup>1</sup> 1 mg daily to help limit side effects. Routine toxicity monitoring includes frequent complete blood cell counts and liver tests. Azathioprine (Imuran)<sup>1</sup> 0.5 to 2 mg/kg can be used with frequent monitoring of complete blood cell counts and liver tests. A sample for testing the thiopurine methyltransferase activity level should be drawn before initiating therapy because a genetic deficiency can lead to severe pancytopenia. Leflunomide (Arava)<sup>1</sup> 10 to 20 mg PO once daily can be used with frequent blood cell counts and liver tests. Low-dose glucocorticoids (prednisone 5–10 mg/day) may be used as a bridge to steroid-sparing therapy and to treat intermittent flares.

### Treatment of Hematologic Manifestations

Autoimmune cytopenias are common and are often a defining feature of SLE. Lymphopenia (absolute lymphocyte count <1500 cells/microliter) does not require therapy. Hemolytic anemia in SLE is the result of antierythrocyte antibodies that activate complement, and it is treated with prednisone at a dose based on clinical severity. Typically, 1 mg/kg/day, or approximately 60 mg, is used for 4 to 6 weeks, with gradual tapering as long as the response is maintained. For severe hemolytic anemia, pulse methylprednisolone (Solu-Medrol) 1 g IV for 3 consecutive days can be tried, followed by the previously described standard dosing. For patients who do not respond to glucocorticoids or are unable to taper prednisone to low doses, other treatments can be used. They may include azathioprine<sup>1</sup> 1.5 to 2.5 mg/kg/day, mycophenolate mofetil<sup>1</sup> 1000 to 2000 mg/day in divided doses, danazol (Danocrine)<sup>1</sup> 300 to 600 mg/day in divided doses, intravenous immunoglobulin,<sup>1</sup> or rituximab (Rituxan)<sup>1</sup> 375 mg/m<sup>2</sup> weekly for four doses.

Immune thrombocytopenia results from antiplatelet antibodies that identify platelets for early destruction. Treatment is indicated when patients have signs or symptoms of spontaneous bleeding or when the platelet count drops below 50,000/mL. The initial treatment approach with glucocorticoids is similar to that used for hemolytic anemia. For patients with chronic thrombocytopenia or for those who cannot achieve an acceptable long-term dose of prednisone, steroid-sparing agents, including azathioprine,<sup>1</sup> mycophenolate mofetil,<sup>1</sup> danazol,<sup>1</sup> rituximab,<sup>1</sup> and intravenous immunoglobulin<sup>1</sup> can be used in doses similar to those used for hemolytic anemia. Dapsone,<sup>1</sup> cyclosporine (Sandimmune, Neoral),<sup>1</sup> and cyclophosphamide (Cytoxan)<sup>1</sup> have also been used.

Thrombotic thrombocytopenia purpura may occur in SLE, and it must be differentiated from immune thrombocytopenia because treatment requires emergent plasmapheresis. Manifestations of thrombotic thrombocytopenia purpura include fever, microangiopathic hemolysis, and central nervous system and renal abnormalities.

Antiphospholipid antibodies include the lupus anticoagulant, anticardiolipin antibodies, and  $\beta_2$ -glycoprotein. They are associated with coagulopathy, thrombocytopenia, late-trimester miscarriage, and heart valve abnormalities. Antiphospholipid antibodies that can be determined with blood testing but are not associated with thromboembolism do not require treatment. Low-dose aspirin<sup>1</sup> may be considered but has not been shown to prevent future thrombosis. Hydroxychloroquine<sup>1</sup> 200 mg twice daily has been shown to reduce the risk. Patients with antiphospholipid antibodies who develop thromboembolism need lifelong treatment with warfarin (Coumadin). A goal international normalized ratio (INR) remains controversial because different studies advocate for high-intensity warfarin (INR >3) or low-intensity therapy (INR >2). For women who have suffered a miscarriage determined to be related to antiphospholipid antibodies, low-dose aspirin and heparin 5000 units SQ twice daily may increase the likelihood of a successful pregnancy.

### Treatment of Renal Manifestations

Many patients with SLE have mild to severe renal involvement. Diagnosis by renal biopsy is important to establish the type of

kidney involvement. Lupus nephritis is considered one of the more severe manifestations of the disease, and treatment is aimed at preventing renal failure. Treatment should be coordinated with a rheumatologist or nephrologist.

Class I disease requires no specific therapy. The class IIb pattern with more than 1 g of proteinuria can be treated with moderate-dose prednisone (20 mg/day for 6 weeks to 3 months), followed by tapering. Class III and IV patterns of disease have the same prognosis and are treated similarly with high-dose prednisone (1 mg/kg/day) for at least 6 weeks before tapering, based on clinical response, by 10 mg a week to a maintenance of 10 to 15 mg/day. In addition to prednisone, cytotoxic therapy is initiated with cyclophosphamide<sup>1</sup> 0.5 to 1 g/m<sup>2</sup> of body surface area monthly for 6 months and tapered to every 3 months, based on clinical response, for a total of 2 to 3 years. Cyclophosphamide has serious toxicities, including hemorrhagic cystitis, bone marrow suppression, infertility, teratogenicity, and increased risk of malignancy. 2-Mercaptoethane sulfonate sodium (Mesna)<sup>1</sup> can be given with each infusion to minimize bladder toxicity. Class V disease can be treated with prednisone alone, similar to class IIb disease, unless there are coexisting features of class III or IV disease, for which treatments outlined previously should be implemented.

An acceptable alternative to cyclophosphamide for class III and IV disease is mycophenolate mofetil<sup>1</sup> 2 to 3 g/day in divided doses combined with corticosteroids (dosing outlined earlier). This appears to be an effective therapy with fewer side effects than traditional therapy.

### Treatment of Nervous System Manifestations

Neuropsychiatric involvement is common in patients with lupus. Symptoms can range from mild to severe and include headache, aseptic meningitis, neuropathy, myelopathy, cognitive dysfunction, seizures, cerebritis, and stroke. A thorough evaluation is necessary to define the cause of nervous system dysfunction and differentiate it from a medication side effect. For seizures, antiepileptic therapy is used, preferably in coordination with a neurologist. Lupus cerebritis and transverse myelitis are two of the more serious manifestations that need to be treated emergently with aggressive immunosuppression in coordination with a rheumatologist or neurologist. Treatment includes high-dose corticosteroids and cyclophosphamide,<sup>1</sup> similar to treatment for lupus nephritis.

## Dermatomyositis and Polymyositis

### Clinical Features

Dermatomyositis may affect skin and muscle. Cutaneous dermatomyositis manifests with violaceous erythema of characteristic areas, including the periorbital skin (i.e., heliotrope rash), upper back (i.e., shawl sign), dorsal hands (i.e., Gottron's papules), scalp, lateral thighs (i.e., Holster sign), and periungual skin, where dilated capillary loops and erythema are observed. Patients may report muscle weakness. As in lupus, a punch biopsy of an actively inflamed cutaneous lesion shows characteristic features.

Evaluation of patients with cutaneous dermatomyositis is not complete without assessment for systemic involvement. Serum aldolase is the most specific marker for myositis, and it can be used as a measure of response to treatment. Creatinine kinase and alanine aminotransferase levels may be elevated but are not specific indicators. An electromyogram shows dampening of signals, and a muscle biopsy shows a characteristic pattern of myositis. Inflammatory lung disease, diagnosed by the characteristic pattern on chest computed tomography, bronchoalveolar lavage, or biopsy, may be life limiting and therefore should be treated aggressively, similar to lung disease in scleroderma. Adult patients should have age-appropriate cancer screening because dermatomyositis is a paraneoplastic phenomenon in 10% to 50% of patients.

Some patients present with characteristic cutaneous dermatomyositis but no systemic involvement (i.e., dermatomyositis sine myositis). The risk of concurrent or subsequent cancer development is thought to be increased. These patients require monitoring for systemic involvement that may develop over time.

<sup>1</sup> Not FDA approved for this indication.

<sup>1</sup> Not FDA approved for this indication.

## Treatment

Patients with dermatomyositis need photoprotection similar to patients with lupus. Periodic evaluation by clinical examination and review of systems allows for early intervention for developing visceral or muscle involvement.

Cutaneous dermatomyositis is treated the same as lupus (see earlier). Dermatomyositis with systemic involvement is initially treated with immunosuppression using prednisone at doses of 1 mg/kg/day. Steroid-sparing agents are incorporated early in the disease and include antimalarials (methotrexate,<sup>1</sup> azathioprine,<sup>1</sup> and mycophenolate mofetil<sup>1</sup>) at doses that are used in treating lupus.

## Scleroderma

### Clinical Features

Scleroderma is a sclerosing condition of skin or viscera, or both. The cause is unknown, but transforming growth factor- $\beta$  plays a role. Type I and III collagens are excessively produced, as are other substances, including glycosaminoglycans, tenascin, and fibronectin.

Cutaneous scleroderma without Raynaud's phenomenon or clinically relevant systemic involvement is also known as *morphea*. Morphea has different distribution patterns, including guttate, linear, segmental, or diffuse distribution, but it is always characterized by indurated plaques that are inflammatory initially, have an advancing inflammatory ("lilac") border as they progress, and then become hyperpigmented. The cutaneous lesions may restrict movement of joints and can cause restricted growth of underlying structures, particularly when they develop in childhood.

Systemic sclerosis may affect the respiratory, renal, cardiovascular, genitourinary, and gastrointestinal systems and vascular structures. Raynaud's phenomenon may be the first presenting symptom of systemic sclerosis, and it can be severe, leading to digital ulcerations and autoamputation. The American College of Rheumatology has defined criteria for the diagnosis.

Tests for antinuclear antibodies are positive in approximately 95% of patients, who typically present with a homogeneous or speckled pattern. A nucleolar pattern is more specific for systemic sclerosis. Anticentromere antibodies are present in 60% to 90% of patients with limited disease but are rare in diffuse disease. Topoisomerase I (Scl-70) antibodies are positive in 30% of patients with diffuse disease and are associated with pulmonary fibrosis. Anti-PM-Scl antibodies are present in overlap syndromes and are associated with myositis and renal involvement.

## Treatment

### Treatment of Limited Scleroderma

For limited scleroderma, treatment with topical medium-potency corticosteroids such as triamcinolone 0.1% ointment (Kenalog) plus calcipotriene (Dovonex)<sup>1</sup> 0.005% cream or intralesional triamcinolone<sup>1</sup> 20 mg/mL may slow progression of active lesions or improve the pruritus and cutaneous stiffness that typify cutaneous scleroderma. For rapidly evolving disease, prednisone<sup>1</sup> 1 mg/kg/day and methotrexate<sup>1</sup> 15 to 20 mg/week may help slow progression of disease. UVA<sup>1</sup> given over 36 treatments at doses of 30 to 60 mJ/cm<sup>2</sup> or PUVA (oral methoxsalen [8-MOP] 10 mg taken 2 hours before treatment with UVA light) can soften the existing plaques of morphea.

### Treatment of Systemic Sclerosis: Raynaud's Phenomenon

First-line treatment for Raynaud's phenomenon is preventive, with cold avoidance and the use of warming techniques. If pharmacotherapy is required, extended-release calcium channel blockers such as nifedipine (Procardia XL)<sup>1</sup> starting at 30 mg/day or amlodipine (Norvasc)<sup>1</sup> starting at 5 mg/day may be useful. If this is not helpful, the  $\alpha$ -blocker prazosin (Minipress)<sup>1</sup> 1 mg three times daily or the angiotensin receptor blocker losartan (Cozaar)<sup>1</sup>

50 mg daily may be helpful. Antiplatelet therapy with low-dose aspirin<sup>1</sup> (81 mg/day) or dipyridamole (Persantine)<sup>1</sup> 50 to 100 mg three or four times daily may be useful. Topical vasodilators such as nitroglycerin ointment (Nitro-Bid)<sup>1</sup> applied to the base of the affected finger three times daily can be helpful in refractory disease. Digit-threatening ischemia may be treated with an intravenous prostaglandin such as alprostadil (Prostin VR)<sup>1</sup> or iloprost (Ilomedine),<sup>5</sup> which require peripheral or central access. Patients with severe recurrent digital ischemia may ultimately benefit from surgical sympathectomy.

### Treatment of Gastrointestinal Manifestations

The most common gastrointestinal manifestation is esophageal reflux caused by esophageal dysmotility. Proton pump inhibitors such as omeprazole (Prilosec)<sup>1</sup> 20 mg twice daily should be used and may prevent the development of esophageal strictures. Prokinetic drugs such as metoclopramide (Reglan)<sup>1</sup> 10 mg four times daily can be helpful. Erythromycin<sup>1</sup> 500 mg three or four times daily can help esophageal and gastric hypomotility. Small bowel hypomotility can lead to bacterial overgrowth, resulting in malabsorption and diarrhea. Rotating antibiotics that include metronidazole (Flagyl),<sup>1</sup> ciprofloxacin (Cipro),<sup>1</sup> and amoxicillin/clavulanate (Augmentin)<sup>1</sup> can be used.

### Treatment of Pulmonary Manifestations

Inflammatory lung disease occurs commonly in patients with scleroderma and can be life limiting. Cyclophosphamide<sup>1</sup> at doses of up to 2 mg/kg/day for up to 2 years may slow progression of pulmonary disease. Pulmonary hypertension occurs more commonly in limited systemic sclerosis than in diffuse disease. Symptomatic patients may receive treatment with prostacyclin analogues, which require continuous infusions. The endothelin receptor antagonist bosentan (Tracleer)<sup>1</sup> can be given orally starting at 62.5 mg twice daily. Liver tests should be monitored frequently. At this point, care is typically coordinated with a cardiologist to monitor disease progression and treatment response. Anticoagulation for pulmonary hypertension may improve survival because of the frequent occurrence of pulmonary arterial thrombosis.

### Treatment of Renal Manifestations

Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril [Capoten]<sup>1</sup>) beginning at 6.25 mg three to six times daily and titrated for blood pressure control) have dramatically reduced the incidence of renal failure and death due to renal crisis. Avoidance of prednisone at doses greater than 15 mg/day is also important in reducing the risk of renal crisis.

<sup>5</sup> Investigational drug in the United States.

## FIBROMYALGIA

Method of

Timothy Sowder, MD; Jeffrey Michael Foster, DO; and Andrea L. Nicol, MD, MSc

### CURRENT DIAGNOSIS

- Fibromyalgia (FM) is a common condition, seen in 2% to 8% of the population, depending on the diagnostic criteria used.
- Hallmark symptoms of FM typically include widespread body pain, cognitive difficulties (“fibro fog”), poor sleep, and fatigue. Other associated symptoms may also include headaches, abdominal or pelvic pain, and symptoms of depression or anxiety.
- FM may occur independently of any other medical conditions, but is also known to associate with other painful conditions such as osteoarthritis and autoimmune disorders such as lupus and rheumatoid arthritis.
- No blood tests or imaging modalities are useful for diagnosing FM; however, tender point examination and questionnaires are available for aiding in diagnosis.

### CURRENT THERAPY

- Treatment should be multidisciplinary and focus on symptom management, lifestyle modifications, and psychological interventions.
- A variety of on-label and off-label medications are available to mechanistically address the altered pain processing underlying FM.
- Physical therapy, exercise, and psychological treatments such as cognitive behavioral therapy are of the utmost importance in adequate management of FM symptoms.
- Seeing patients frequently to monitor medications, address side effects, and provide motivational interviewing and care is important to providing optimal patient pain relief and minimizing poor outcomes.

### Epidemiology

The global prevalence of fibromyalgia (FM) has been estimated to be 2.7% (4.2% female, 1.4% male), but studies have produced varying results. Historically, studies have been conducted using the 1990 American College of Rheumatology (ACR) diagnostic criteria, which required pain to be present on palpation of at least 11/18 tender points to confirm a diagnosis of FM. Using these criteria, prevalence estimates range from 0.4% to 8.8% with 2.0% in the USA (3.4% of females and 0.5% of males, ratio ~7:1). The problems with these criteria include difficulty reproducing tender points, significantly higher rates in women (possibly due to increased number of tender points in women or a higher pressure pain threshold in males), and a strong correlation with various measures of distress and negative affect. In 2010 the ACR released updated criteria that do not require a tender point assessment. These new criteria have yielded prevalence estimates of 7.7% in women and 4.9% in men for a ratio of 1.6:1, which is similar to that seen in other chronic pain conditions. The prevalence is similar in different countries, cultures, and ethnic groups; there is no evidence that FM has a higher prevalence in industrialized countries and cultures. There are also concerns about underdiagnosis of FM with only 12% to 28% of subjects identified

during population-based surveys as fulfilling the ACR 1990 criteria having ever been diagnosed with FM.

### Risk Factors

There are both genetic and environmental risk factors associated with the development of FM. FM has been thought to affect mostly women with initial studies predicting that women were up to seven times more likely to develop FM. More recent studies using updated criteria have found less of a discrepancy but still indicate an increased risk with women being 1.5 to 2 times more likely to be affected than men. FM can affect people of all ages, including children. Many patients are diagnosed when they are young or middle aged, but studies show that prevalence rises with age, peaking in people greater than 60 years old. It is postulated that perhaps widespread chronic pain in older patients is more likely to be attributed to osteoarthritis or other degenerative conditions instead of FM, however, the two conditions are known to coexist. Patients diagnosed with certain conditions like rheumatoid arthritis and lupus have been noted to be more likely to develop FM than others. Obesity, poor sleep, low physical activity levels, and decreased job or life satisfaction are potentially modifiable risk factors. There are many other conditions associated with FM, though the degree of contribution to actual disease development has yet to be determined. Individuals with FM are more likely have psychiatric disorders, including depression, anxiety, obsessive-compulsive disorder, and posttraumatic stress disorder. A history of childhood, adolescent, or adulthood abuse or traumatic events have also been linked with the development of FM and other centralized pain syndromes. Maladaptive cognitive features are poor prognostic factors for FM and can include catastrophizing and fear-avoidance of movement and activity. Lower education and other indicators of lower social status have been thought to place patients at an increased risk for FM, though other studies did not find a significant difference in developed and wealthy areas versus rural and poor areas.

### Pathophysiology

FM can be thought of as a centralized pain state, where “centralized” refers to amplification of pain emanating from the central nervous system. Evidence suggests that dysfunction in central nervous system pain processing mechanisms underlie this condition and include central amplification of pain and nonpainful stimuli (including auditory, visual, and olfactory). Typical manifestations of central amplification include allodynia (pain resulting from a non-noxious stimulus) and hyperalgesia (increased sensitivity to a painful stimulus), and temporal summation (progressive increase in the pain response to repetitive painful stimulus). This term “centralized pain” does not exclude that an individual’s peripheral nervous system and its nociceptive input may be contributing to the patient’s overall pain symptoms, but rather that they feel greater levels of pain than would be normally expected based on the degree of peripheral nociceptive input. However, it must be noted that many patients with FM do not have any identifiable structural or functional abnormalities in the periphery that would explain their widespread pain and associated symptoms. The concept of central amplification helps describe the heterogeneous clinical features of FM as many of the same neurotransmitters that control sensory sensitivity and pain also control mood, memory, fatigue, and sleep. A variety of quantitative research methods have been employed to establish that central amplification is involved in the pathophysiology of FM, including quantitative sensory testing and functional, chemical, and structural brain neuroimaging. Functional magnetic resonance imaging (MRI) has corroborated that nonnoxious stimuli such as mild pressure activates brain regions involved

in pain processing compared with healthy controls. It has also been found that endogenous pain inhibitory pathways do not effectively operate in patients with FM. This defective inhibition is postulated to exist due to altered homeostasis of inhibitory and excitatory neurotransmitters.

### Clinical Manifestations

The patient with FM can experience a wide variety of symptoms, including pain, fatigue, sleep disturbance, cognitive dysfunction, and mood alterations. These patients typically present with chronic widespread pain for at least 3 months that is not fully explained by injury or inflammation. This pain is typically identified as being “all over,” but drawings by patients show various localized areas of pain, which may migrate in intensity from time to time. Somatic pain is typically the dominant feature; however, visceral pain (including abdominal and pelvic pain) and headaches are also commonly seen. Most frequently, the affected areas include the shoulders, arms, lower back, buttocks, and thighs. Widespread pain in the joints is also common. The patients most generally experience pain that is throbbing, aching, and tender. This pain is often accompanied by generalized hypersensitivity, allodynia, and hyperalgesia, which is indicative of the underlying central amplification. Other symptoms can include numbness, tingling, burning, cramps, and sensitivity to light and sound. Exacerbating factors for these patients’ pain include emotional distress, weather changes, sleeping problems, and strenuous activity. A total of 70% to 90% of patients with FM sleep fewer hours, have more frequent waking, and report nonrestorative sleep. They also suffer from significant fatigue, weakness, and stiffness that are worse in the morning and improve as the day progresses. A total of 76% of patients report mental confusion, forgetfulness, and concentration difficulties. This cognitive dysfunction is frequently described as being more bothersome than their widespread pain. These symptoms are so pervasive and disruptive that they are commonly referred to as “fibro fog.” In addition, there is an affective component to the cognitive dysfunction that is usually described by patients as feeling fatigued and exhausted all the time, irrespective of how much sleep they get. Depression, anxiety, and posttraumatic stress disorder are comorbidities with high prevalence in this patient population, and their various symptoms can also be present in the patient with FM.

### Diagnosis

FM is a condition with distinctive clinical characteristics that allow for it to be diagnosed in the primary care setting. Although many practitioners may have concern that the diagnosis of FM is controversial or that it may label patients in a negative manner, studies suggest that the opposite is true. Establishing the diagnosis of FM can actually provide substantial validity and relief for patients for their previously unexplained symptoms. Prompt diagnosis is a vital component of effective FM management and is linked with patients having greater satisfaction in health, which in turn leads to decreased health care utilization and its associated costs.

In the clinical setting, FM should be considered as a diagnosis in any patient presenting with chronic widespread or multifocal pain. It is commonly comorbid in patients with other chronic pain syndromes, those with thyroid dysfunction, and patients with rheumatic diseases. There exists other co-occurring pain syndromes that have been linked to the same pathophysiology as FM that may also spark a clinician’s suspicion for FM such as irritable bowel syndrome, interstitial cystitis, migraine headache, temporomandibular disorder, and chronic pelvic or genitourinary pain (e.g., interstitial cystitis, vulvodynia). It is very important to note that FM should *not* be considered a diagnosis of exclusion.

A thorough history including asking about pain during childhood and adolescence, other comorbid pain symptoms, a history of childhood or adulthood abuse, or other traumatic events will help elucidate whether FM should be considered in the differential diagnosis. An excellent physical exam including musculoskeletal, neurologic, assessment of tenderness or significant pain to palpation, and allodynia should always be performed. Laboratory tests are not necessary or useful to establish the diagnosis of FM, besides possibly helping sort through the differential diagnoses. Basic laboratory evaluation may include vitamin D levels, thyroid panels, erythrocyte sedimentation rate, C-reactive protein, and blood count or blood chemistries to guide an assessment of potentially treatable causes of diffuse musculoskeletal pain. Detailed serologic studies are not necessary unless the patient has other signs and symptoms of other potential comorbid diseases. No imaging studies are specific in diagnosing FM, and one must be careful in performing radiographs or other imaging studies, as these can have findings that are associated with the degenerative aging process, but may not be the actual cause of the patient’s ongoing pain symptoms.

The 1990 ACR tender point exam has been historically used to “diagnose” FM; however, it was originally developed to be used for research and was never intended to be used in clinical practice. Revised versions of diagnostic criteria were published in 2010 and again in 2016. These revised criteria do not require a tender point exam to elucidate a diagnosis and may be ascertained with a self-report questionnaire (Table 1). These criteria rapidly assess widespread pain symptoms and associated symptoms of poor sleep, cognitive difficulties, fatigue, and mood problems. Once diagnosed, treatment for FM can be initiated immediately, even if further tests or referrals to specialists are pending.

### Differential Diagnosis

While the diagnosis of FM can be difficult and time-consuming, providing the patient with an answer to their issues can decrease healthcare costs by decreasing biological testing and imaging, decreasing the number of visits, and decreasing the number and dosage of drugs prescribed. With such a wide variety of possible symptomatic expressions of FM, it is important to address the differential diagnoses in a systematic way. Arthralgias are commonly seen in osteoarthritis and spondyloarthritis, but are also seen in rheumatic diseases like rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus, and polymyalgia rheumatica. Inflammatory, metabolic, and drug-induced myopathies and myalgias should also be ruled out. Myofascial pain syndrome, tendonitis, and bursitis are common pathologies that cause pain in localized areas. Neurologic disorders such as multiple sclerosis and myasthenia gravis should be considered in addition to radiculopathies, and both peripheral and compressive neuropathies that could complicate the picture. Viral infections and Lyme disease should be considered as potential infectious causes. Endocrinopathies like hypothyroidism, Cushing syndrome, and hyperparathyroidism can cause weakness, but are unlikely to cause the significant widespread pain seen in FM. There are other disorders that frequently overlap or co-occur with FM that should be optimally treated in conjunction. These include depression, anxiety, obsessive-compulsive disorder, posttraumatic stress disorder, tension headaches, migraines, temporomandibular disorder, chronic fatigue syndrome, irritable bowel syndrome, interstitial cystitis (painful bladder syndrome), chronic prostatitis, and vulvodynia. It is important for any clinician to distinguish that the patient’s symptoms are not explained by another pathology or systemic disorder because treatment of these entities can vary greatly. However, the 2016 Revised Fibromyalgia Criteria does not exclude the diagnosis of FM if other conditions are present. Each of these problems should be

**TABLE 1** American College of Rheumatology 2016 Revised Fibromyalgia**Criteria**

A patient satisfies modified 2016 fibromyalgia criteria if the following three conditions are met:

- (1) Widespread pain index (WPI)  $\geq 7$  and symptom severity scale (SSS) score  $\geq 5$  OR WPI of 4–6 and SSS score  $\geq 9$ .
- (2) Generalized pain, defined as pain in at least 4 of 5 regions, must be present. Jaw, chest, and abdominal pain are not included in generalized pain definition.
- (3) Symptoms have been generally present for at least 3 months.

**Ascertainment**

- (1) WPI: note the number of areas in which the patient has had pain over the last week. In how many areas has the patient had pain? Score will be between 0 and 19.

Left upper region (Region 1)

- Jaw, left
- Shoulder girdle, left
- Upper arm, left
- Lower arm, left

Right upper region (Region 2)

- Jaw, right
- Shoulder girdle, right
- Upper arm, right
- Lower arm, right

Left lower region (Region 3)

- Hip (buttock, trochanter), left
- Upper leg, left
- Lower leg, left

Right lower region (Region 4)

- Hip (buttock, trochanter), right
- Upper leg, right
- Lower leg, right

Axial region (Region 5)

- Neck
- Upper back
- Lower back
- Chest
- Abdomen

- (2) SSS score

- Fatigue
- Waking unrefreshed
- Cognitive symptoms

For the each of the 3 symptoms above, indicate the level of severity over the past week using the following scale:

- 0 = No problem
- 1 = Slight or mild problems, generally mild or intermittent
- 2 = Moderate, considerable problems, often present and/or at a moderate level
- 3 = Severe: pervasive, continuous, life-disturbing problems

The SSS score: is the sum of the severity scores of the 3 symptoms (fatigue, waking unrefreshed, and cognitive symptoms) (0–9) plus the sum (0–3) of the number of the following symptoms the patient has been bothered by that occurred during the previous 6 months:

- (1) Headaches (0–1)
- (2) Pain or cramps in lower abdomen (0–1)
- (3) And depression (0–1)

The final symptom severity score is between 0 and 12

The fibromyalgia severity (FS) scale is the sum of the WPI and SSS

A diagnosis of fibromyalgia is valid irrespective of other diagnoses.

A diagnosis of fibromyalgia does not exclude the presence of other clinically important illnesses.

considered as variables and optimally treated when attempting to diagnose this complex syndrome.

**Treatment**

FM is best approached by using an integrated, multidisciplinary approach where pharmacologic and nonpharmacologic treatments are provided in parallel. Engaging and motivating the patient toward their treatment goals as an active participant in their care is vital for success. As stated before, FM can be diagnosed and treated in the primary care setting. Referral to specialists should only be necessary when pain is refractory to therapy (e.g., comprehensive pain management clinic), those in whom the diagnosis is uncertain (e.g., to a rheumatologist or neurologist depending on symptoms), or those with significant comorbid mood or psychiatric disturbances. Forming treatment teams can be very useful and should include clinicians with expertise in exercise/physical activity (e.g., physical therapists), patient education, and pain psychology.

Most comprehensive guidelines on treatment of FM generally recommend that all patients should receive education on their condition, the importance of being an active participant in their care, and that setting reasonable and attainable goals and expectations for treatment. Patients need to be informed that instead of searching for treatments to cure the condition, that management of the condition should focus on pain reduction (not complete pain relief), increased physical functioning, and improved quality of life. This management should rely heavily on stress reduction, exercise and physical activity, adequate sleep, and improving function through cognitive restructuring (e.g., reducing catastrophizing, increasing self-efficacy). Pharmacologic treatments can be effective in alleviating some of the symptoms of FM, but rarely will patients achieve significant improvements without embracing these essential self-management strategies.

In the United States, there are three drugs currently approved by the US Food and Drug Association (FDA) for the treatment of FM: (1) pregabalin (Lyrica), (2) milnacipran (Savella), and (3) duloxetine (Cymbalta). These drugs mechanistically treat FM through either increasing the activity of inhibitory neurotransmitters (milnacipran and duloxetine) or to decrease the activity of excitatory neurotransmitters (pregabalin). [Table 2](#) highlights the FDA-approved medications in the pharmacologic treatment of FM. Careful initiation and titration are recommended to improve patient compliance and response, given the incidence of side effects or drug-drug interactions. There are a variety of commonly utilized drugs other than those listed previously, although none of them have an FDA approval for the FM indication. These other medications have been shown in a variety of research studies to provide pain and symptom relief in FM and include gabapentin (Neurontin)<sup>1</sup>, tricyclic antidepressants (e.g., nortriptyline [Pamelor]<sup>1</sup>, amitriptyline [Elavil]<sup>1</sup>), cyclobenzaprine (Flexeril)<sup>1</sup>, and venlafaxine (Effexor)<sup>1</sup>. Basic analgesics such as acetaminophen and nonsteroidal antiinflammatories (NSAIDs) have little evidence supporting effectiveness for FM. Other emerging therapies such as low-dose naltrexone (ReVia, Vivitrol)<sup>1</sup> warrant further investigation and should only be used in refractory cases by those who are familiar with its use. There exists no evidence that mu-opioid agonists are helpful in the long-term treatment of FM and ultimately increase central amplification overtime, thereby increasing the potential for worsening pain and functioning whilst placing the patient at risk for dependence and addiction. Clinicians and patients should recognize that in many cases, treatment with pharmacologic agents may

**TABLE 2** Comparison of FDA-approved Pharmacologic Therapies for Fibromyalgia

DRUG	DATE OF FDA APPROVAL	MECHANISM OF ACTION	AVAILABLE STRENGTHS	DOSING	COMMON SIDE EFFECTS
Duloxetine (Cymbalta)	June 16, 2008	Serotonin norepinephrine reuptake inhibition	20 mg; 30 mg; 60 mg	<ul style="list-style-type: none"> <li>60 mg/day recommended total dose (doses higher than 60 mg rarely helpful for pain)</li> <li>Start 30 mg/day for 1 week or longer and then may increase to 60 mg/day</li> </ul>	Dry mouth, somnolence, nausea, constipation, decreased appetite, hyperhidrosis
Milnacipran (Savella)	January 14, 2009	Serotonin norepinephrine reuptake inhibition	12.5 mg; 25 mg; 50 mg; 100 mg; convenience starter pack	<ul style="list-style-type: none"> <li>Convenience starter pack dosing: Start 12.5 mg daily × 1 day, then 12.5 mg bid × 2 days, then 25 mg bid × 4 days, then 50 mg bid</li> <li>Max dose 100 mg bid (200 mg/day)</li> </ul>	Nausea, constipation, hot flush, hyperhidrosis, vomiting, palpitations, increased heart rate, dry mouth, hypertension
Pregabalin (Lyrica)	June 21, 2007	Non-selective alpha-2-delta calcium channel blocker	25 mg; 50 mg; 75 mg; 100 mg; 150 mg; 200 mg; 225 mg; 300 mg	<ul style="list-style-type: none"> <li>Start at 75 mg bid (can start much lower in sensitive or older patient population)</li> <li>May increase to 150 mg bid within 1 week</li> <li>Max dose 225 mg bid (450 mg/day)</li> </ul>	Dizziness, somnolence, dry mouth, peripheral edema, blurred vision, weight gain, abnormal thinking/cognitive difficulties

be ineffective. The choice of drug should always be discussed with the patient and should focus on targeting the most bothersome symptoms. Oftentimes multiple types of drugs/drug combinations are needed. If a drug is trialed and does not lead to clinically meaningful relief after four weeks at the full recommended dose, it should be tapered or stopped, and an alternative drug trialed.

Nonpharmacologic treatment for FM consists of psychological and educational interventions, in addition to physical modalities and should be an integral part of a comprehensive FM treatment plan. Education should be a foundational intervention applied immediately with diagnosis or early in the patient's treatment plan, and should consist of information on the underlying pain mechanisms causing clinical pain and associated symptoms (e.g., central nervous system pain and sensory amplification) and information on the nature of the condition (e.g., nonprogressive, chronic, and lifelong with episodic flares, risk of other comorbid conditions). This will provide a strong foundation to then add psychological therapies, which are typically behavioral based and focused on acceptance theories. Cognitive behavioral therapy has been shown to be effective for the treatment of FM and focuses on the link between pain, mood, thoughts, and behavior, and trying to unravel negative coping mechanisms such as catastrophizing and poor self-efficacy. Mind-body therapies, including stress reduction, biofeedback, and mindfulness, have also shown good benefit for FM.

Physical activity, including active and passive modalities, is perhaps the most important nonpharmacologic treatment for FM. Physical therapy, including warm-water aquatherapy, can be utilized initially to help patients improve their conditioning and obtain education on how to incorporate movement and activity into their daily lives. Among different exercise interventions, aerobic exercise has been shown to be the most beneficial. Patients should start with low-to-moderate intensity activities (such as walking, stationary cycling, or swimming).

Over time, patients can increase their intensity and duration over time to a goal of at least 20 min/day at least two to three times weekly. It is important to counsel patients on pacing themselves and that initially they may have more soreness or pain as they gradually build their physical conditioning and strength. Continuation of the exercise regimen is of paramount value as ongoing exercise has been associated with maintenance of improvements in FM. Passive forms of physical activity such as balneotherapy (heated spa treatments), manipulation, massage, transcutaneous electrical stimulation, and ultrasound have only weak evidence to support their use. Complementary and alternative medicine options that may be considered include acupuncture, yoga, tai chi, and qi gong meditation, but there are few high-quality evidence studies to support their use as first-line therapy.

### Monitoring

No laboratory or imaging monitoring is required in the treatment of FM. Regular/frequent outpatient engagement with patients is recommended—to discuss the comprehensive care plan and focus on patient goals for treatment, as increased outpatient engagement has been shown to reduce morbidity and mortality (including risk of suicide) in patients with FM.

## JUVENILE IDIOPATHIC ARTHRITIS

Method of  
Ashley Cooper, MD

### CURRENT DIAGNOSIS

- Juvenile idiopathic arthritis (JIA) is a clinical diagnosis. JIA is diagnosed when objective signs of arthritis persist in a child for at least 6 weeks in the absence of another identifiable cause.
- Children who present with musculoskeletal pain without accompanying objective signs of joint inflammation (swelling or painful, limited range of motion) are unlikely to have arthritis. In many children with JIA, swelling and joint limitation are more prominent than pain.
- Laboratory testing has limited value in diagnosing JIA. In some cases, no laboratory tests are needed to make the diagnosis. When clinically indicated, laboratory tests are used to exclude other causes of arthritis such as infection (including Lyme disease in endemic areas), malignancy, or underlying systemic autoimmune disease.
- The antinuclear antibody (ANA), rheumatoid factor (RF), and anticitrullinated peptide (anti-CCP) have prognostic but **not** diagnostic value in JIA. These tests should not be drawn to evaluate musculoskeletal pain in children in the absence of objective signs of arthritis.

### CURRENT THERAPY

- Medical therapy is individualized for each child based on severity and number of affected joints and comorbidities. The goal of treatment is to completely control joint inflammation to minimize symptoms and prevent damage.
- Many rheumatologists use a step-up treatment approach, titrating medication until inactive disease is achieved. In children with severe arthritis, early combination therapy is sometimes used. With appropriate use of currently available medications, most children with JIA can achieve clinically inactive disease.
- Current treatment options include scheduled nonsteroidal antiinflammatory drugs (NSAIDs), intraarticular corticosteroid injections, disease-modifying antirheumatic drugs (DMARDs, most commonly methotrexate), and biologic response modifiers (such as antitumor necrosis factor alpha, anti-interleukin-1, or anti-interleukin-6 therapy).
- With the currently available medications, many children with JIA do not require systemic corticosteroids. Steroids should not be prescribed to a child presenting with joint pain or swelling of unclear etiology.
- Optimal timing and approach to medication discontinuation in patients who have achieved inactive disease are unclear. Relapse rates are high after medication discontinuation in most JIA subtypes.
- A partnership between the child's rheumatologist and primary care provider is key to safe use of immune-modulating medications. Optimal management includes:
  - Medication toxicity monitoring with periodic laboratory studies;
  - Prompt evaluation of infectious symptoms in immunosuppressed patients;
  - Administration of age-appropriate vaccines (with avoidance of live virus vaccines in patients on immunosuppression);
  - Counseling of adolescents to avoid alcohol while on methotrexate and pregnancy while on teratogenic medications.

- Children with JIA should remain physically active and be allowed to continue participating in sports and leisure activities as tolerated. Physical and/or occupational therapy is indicated for patients with limited mobility, deconditioning, or compromised activities of daily living.
- Regular screening for uveitis is an essential part of JIA management to allow prompt treatment of this sight-threatening complication.

Juvenile idiopathic arthritis (JIA) is an umbrella term that encompasses multiple forms of chronic, immune-mediated arthritis that begin in childhood. The classification system currently used for JIA was established in 1995 by the International League of Associations for Rheumatology (ILAR). By replacing the term *juvenile rheumatoid arthritis* with *juvenile idiopathic arthritis* and defining additional subtypes, the ILAR criteria better reflect the clinical heterogeneity among children with arthritis. Absence of the term "rheumatoid" from the current nomenclature appropriately highlights that most cases of juvenile arthritis are not simply early onset rheumatoid arthritis (RA), as only 5% of all children with JIA have rheumatoid factor (RF) positive polyarticular disease.

The subtypes of JIA are summarized in [Table 1](#) and include oligoarticular, polyarticular (RF negative and RF positive), enthesitis-related (a childhood-onset spondyloarthropathy closely related to ankylosing spondylitis), psoriatic, and systemic arthritis.

Although each of these conditions has a distinct phenotype, the presence of chronic inflammatory arthritis is the unifying feature and sine qua non of JIA. A careful history and physical exam are the most important tools in diagnosis. A complete exam of all joints should be performed in children with possible JIA as the pattern of affected joints impacts disease classification. Additional affected joints are often identified on exam that have not been apparent to patients and parents. Common pitfalls in diagnosis of arthritis in children include the following:

- *Diagnosing JIA in the absence of objective clinical signs of arthritis (joint inflammation).* Most children who present to the primary care office with joint pain (even chronic pain) do not have JIA. Isolated pain in the absence of objective findings of arthritis such as swelling predicts against JIA or other chronic rheumatic disease.
- *Attempting to rule in JIA with laboratory studies.* ANA tests can be positive in up to 30% of healthy children, and the most common cause of a positive RF in children is recent viral infection. Due to the high frequency of positive results in children without rheumatic disease, these tests should not be drawn to evaluate for arthritis in the setting of normal exam findings.
- *Attempting to rule out JIA with laboratory studies.* Arthritis is a clinical diagnosis. If a child presents with chronic joint swelling, limited range of motion or contractures, one should not be falsely reassured by normal labs. Many children with arthritis have completely normal inflammatory markers and a negative ANA, and 95% of children with JIA are RF negative.

### Risk Factors/Prevention

All JIA subtypes are generally thought to result from an aberrant immune response to an environmental trigger in a genetically predisposed person. A monozygotic twin concordance of 25% to 40% and increased autoimmunity in family members of children with JIA suggest a significant genetic contribution to disease development. Recent genome-wide association studies have revealed susceptibility loci for JIA, though differences in genetic factors exist between clinical JIA subtypes. Strong genetic associations are rare for most JIA subtypes and many identified risk loci are associated with multiple autoimmune diseases. The exception is that 80% to 90% of children with enthesitis-related arthritis (ERA) are human leukocyte antigen (HLA) B27 positive. Testing for specific HLA alleles currently has no diagnostic utility in JIA. For the interested reader, Hersh and Prahalad recently

**TABLE 1** International League of Associations for Rheumatology Classification Criteria for Juvenile Idiopathic Arthritis

**JIA CLASSIFICATION CRITERIA**

JIA Definition: Inflammatory arthritis in at least one joint that begins before age 16, persists at least 6 weeks, and has no other identifiable cause.

JIA SUBTYPE	DESCRIPTION
Oligoarthritis	Arthritis affects 1–4 joints in the first 6 months
<ul style="list-style-type: none"> <li>• Persistent</li> <li>• Extended</li> </ul>	Never extends beyond 4 joints Extends to affect 5 or more joints after first 6 months
Polyarthritis	Arthritis affects 5 or more joints in the first 6 months
<ul style="list-style-type: none"> <li>• RF negative</li> <li>• RF positive</li> </ul> Enthesitis-Related Arthritis	Arthritis and enthesitis, OR Arthritis or enthesitis with at least 2 of the following: <ul style="list-style-type: none"> <li>• Signs of sacroiliitis,</li> <li>• Positive HLA-B27,</li> <li>• Onset in a boy age 6 or older,</li> <li>• Acute anterior uveitis,</li> <li>• HLA-B27-related disease in a first-degree relative.</li> </ul>
Psoriatic Arthritis	Arthritis and psoriasis, OR Arthritis and at least 2 of the following: <ul style="list-style-type: none"> <li>• Dactylitis,</li> <li>• Nail pitting or onycholysis,</li> <li>• Psoriasis in a first-degree relative.</li> </ul>
Systemic JIA	Arthritis in at least 1 joint with at least 2 weeks of fever that is daily for at least 3 days, with at least one of the following: <ul style="list-style-type: none"> <li>• Evanescent erythematous rash,</li> <li>• Generalized lymphadenopathy,</li> <li>• Hepatomegaly and/or splenomegaly,</li> <li>• Serositis.</li> </ul>
Undifferentiated	Fulfills criteria for no category or 2 or more categories

JIA, Juvenile idiopathic arthritis.

Data from Petty RE, Southwood TR, Manners P, et al. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001. *J Rheumatol.* 2004;31(2):390–392.

reviewed the genetics of JIA, and Yasin and Schulert published a detailed review of the genetics and pathophysiology of systemic JIA (SJIA).

There is no known prevention for JIA.

**Pathophysiology**

Synovitis in JIA is characterized by synovial hypertrophy, edema, and hypervascularity. A mixed inflammatory infiltrate of T and B lymphocytes, plasma cells, macrophages, and dendritic cells is found in the synovial lining of affected joints. Infiltrating mononuclear cells produce proinflammatory cytokines and chemokines that contribute to bone and cartilage erosion and perpetuate recruitment of inflammatory cells.

SJIA is uniquely characterized by significant innate immune activation, including increased production of the proinflammatory cytokines interleukin-1 (IL-1) and 6 (IL-6). Some experts suggest that SJIA may be better classified as an autoinflammatory disease.

Given their unique clinical phenotypes, the epidemiology, clinical manifestations, diagnosis, and management of the JIA subtypes will each be discussed separately. Some general principles of diagnosis and management reviewed in “Current Diagnosis and Therapy”, previously discussed, and introduced in the oligoarticular JIA section are applicable to all JIA subtypes.

**Oligoarticular Juvenile Idiopathic Arthritis**

**Epidemiology**

Oligoarticular JIA is the most common JIA subtype, comprising 40% to 50% of all cases, with an incidence of approximately 1 in 10,000 children per year. Peak age of onset is 1 to 4 years, with a female predominance. It is most commonly seen in children of Northern European descent.

**Clinical Manifestations**

Children with oligoarticular JIA present with arthritis in one to four joints, without spread to more than four joints in the first 6 months of disease. Oligoarthritis typically affects large joints in an asymmetrical pattern. The most common presentation is arthritis of a single knee. Swelling is the predominant symptom, often with little or no apparent pain early in the disease course. Affected joints may have a limited range of motion or contractures. A relatively painless limp is common, and is sometimes the first symptom apparent to parents. Stiffness is worse in the morning or after inactivity, though may be difficult for children to describe. Children with oligoarthritis may experience a persistent oligoarticular course (limited to four or fewer affected joints throughout the child’s life) or an extended articular course (spread to five or more joints after the first 6 months of disease).

**Diagnosis**

A careful history and exam are key to diagnosis. Persistent joint swelling for more than 6 weeks, joint contracture, and/or gait disturbance are the most common presenting symptoms of oligoarticular JIA. Physical exam reveals joint effusion or thickened synovium indicating joint inflammation. Some children may also have warmth, decreased range of motion, contracture, or pain with range of motion on exam. Atrophy of adjacent muscles can be seen in chronic arthritis. Children with oligoarticular JIA are otherwise well-appearing. Severe pain (especially with nighttime waking), extremely red or hot joints, *migratory* swelling, fevers, rash, pallor, or a generally ill-appearing child suggest an alternative diagnosis.

All forms of JIA are diagnosed on the basis of objective signs of arthritis, a history of at least 6 weeks of persistent symptoms, and exclusion of alternative diagnoses *as appropriate based on the patient’s clinical picture*. As there is no single test that can confirm the diagnosis of JIA, the value of lab testing is limited to excluding other diagnoses and for prognostic purposes in confirmed cases of JIA (see “Complications”). Radiographs have limited diagnostic value with the exception of detecting other conditions such as malignancy. MRI or musculoskeletal ultrasound can be useful in cases of equivocal or challenging physical exam (such as in obese patients).

**Differential Diagnosis**

In some patients with a classic clinical picture, no specific workup for other diagnoses is needed. Prompt evaluation by a pediatric rheumatologist is key to confirming the presence of arthritis, determining an appropriate individualized workup, and rapidly initiating treatment if a diagnosis of JIA is established.

Features that suggest the need to evaluate for alternative diagnoses include the following:

- Atypical demographics (age, ethnicity)—may suggest a different JIA subtype such as ERA in older children (see “Enthesitis-Related Arthritis”).
- Travel history—may suggest the need to evaluate for Lyme arthritis or tuberculosis in patients residing in or traveling to endemic areas.
- Atypical clinical features—severe pain, constitutional symptoms such as weight loss, fevers, fatigue, or an ill appearance should prompt consideration of infection, malignancy, inflammatory bowel disease, or systemic collagen vascular disease such as lupus in a child with arthritis. Acute, subacute, or migratory arthritis suggests an infectious or postinfectious cause (including rheumatic fever). Episodic joint swelling, especially after trauma, may suggest a bleeding disorder or intra-articular vascular malformation.

## Treatment

Treatment of JIA aims to completely control joint inflammation to control symptoms and mitigate the risk of joint damage. In oligoarticular JIA, either scheduled nonsteroidal antiinflammatory drugs (NSAIDs) or intraarticular corticosteroid injections are used as first line therapy. NSAIDs must be administered at anti-inflammatory doses on a scheduled basis to control inflammation, and may take 6 to 8 weeks to be effective. Naproxen (Naprosyn) is often preferred due to twice daily dosing and available liquid formulation. Steroid joint injections can control inflammation rapidly and are often used for patients with contractures or severe arthritis to more rapidly restore physical function. Intraarticular steroid injections should not be repeated more frequently than every 3 months. In patients with arthritis refractory to NSAIDs or steroid injections, traditional or biologic disease modifying antirheumatic drugs (DMARDs), such as methotrexate (Trexall) and tumor necrosis factor (TNF) inhibitors, can be used (some are off-label) in a stepwise fashion until disease control is achieved. DMARDs should be prescribed and monitored by a rheumatologist.

## Monitoring

JIA disease control is monitored by a rheumatologist on the basis of history and physical exam. The frequency of follow-up visits varies depending on the patient's disease course and medications. Assessments of functional status should be performed to identify patients who would benefit from physical and occupational therapy service or school accommodations. Eye screening for uveitis is a critical part of JIA monitoring (see "Complications"). Medication toxicity monitoring depends on the medication used:

- Daily NSAIDs: complete blood count (CBC), comprehensive metabolic panel (CMP), and urinalysis every 6 to 12 months.
- Methotrexate: CBC and CMP at baseline, 1 month after starting or dose escalation, and then every 3 months on stable doses. Urine pregnancy screening should be considered in girls of reproductive age.
- Biologic DMARDs: Similar lab screening to methotrexate, with some variation depending on medication. Testing for tuberculosis should be performed prior to starting biologic medications.

Patients on immunosuppressive medications should be evaluated promptly for symptoms of infection. They should avoid live virus vaccines, but receive all other age-appropriate vaccinations including an annual flu vaccine.

## Complications

Articular complications include joint limitation, contractures, and muscle atrophy, leading to chronic disability and pain, though these complications are less common with currently available treatments. A complication of arthritis unique to the growing child is local growth disturbance, most commonly seen as leg length discrepancy as a result of knee arthritis. Inflammation near the open growth plate can cause overgrowth of the affected limb in young children or premature growth plate closure leading to a shorter limb in adolescents.

Chronic anterior uveitis is a common complication of JIA, particularly oligoarticular and RF negative polyarticular JIA. Chronic uveitis is treatable but carries a high risk of morbidity including cataract, glaucoma, synechiae (adhesions leading to an irregular pupil), band keratopathy (corneal calcium deposits), and blindness. Chronic uveitis is often completely asymptomatic until damage has occurred. Because it can only be detected by slit lamp exam performed by an eye doctor, regular screening is critical to early detection, treatment, and prevention of permanent damage. Uveitis is more likely to occur early in the course of disease, in patients who are ANA positive, and who have an early age of arthritis onset. Well-established screening recommendations guide the frequency of eye exams, ranging from every 3 to 12 months, depending on risk factors. Risk stratification for uveitis is the only use of ANA testing in patients with JIA. Uveitis may occur independent of active arthritis, so eye screening is a critical

part of health maintenance for people with JIA throughout their lives. All children diagnosed with uveitis should see an ophthalmologist with experience treating uveitis. Topical corticosteroids are first-line therapy for anterior uveitis, though long-term use is not advisable given the risk of cataracts and glaucoma. Methotrexate<sup>1</sup> and the TNF inhibitors adalimumab (Humira) and infliximab (Remicade)<sup>1</sup> are used widely in children with refractory uveitis. Some patients require more aggressive treatment for uveitis than for arthritis.

## Polyarticular Juvenile Idiopathic Arthritis

### Epidemiology

Polyarticular arthritis has two subtypes. RF negative polyarthritis has two peaks of onset (at 1 to 4 years and in adolescence) and comprises 20% of all JIA. It is more common in girls and occurs in all ethnicities. RF positive polyarthritis makes up only 5% of JIA, has a peak onset of 9 to 11 years, and is more common in girls and in nonwhites.

### Clinical Manifestations

Children with polyarthritis present with evidence of arthritis (swelling, morning stiffness, pain, limited range of motion) in five or more joints. Young children may present with gait disturbance or loss of milestones, while older children may present with prolonged morning stiffness or difficulty with activities of daily living and fine motor tasks. Large and small joints in the extremities are affected (often symmetrically). Long-standing disease can produce bony overgrowth of the small joints in the hands or joint deformities including wrist subluxation and boutonniere deformities of the fingers. Arthritis of the cervical spine (presenting with limited extension) and temporomandibular joint (TMJ; presenting with decreased mouth opening, jaw deviation, or micrognathia) are common and cause significant morbidity. Mild to moderate systemic symptoms, including fatigue and weight loss, may be present; however, high grade fevers should not occur.

### Diagnosis

Diagnosis hinges on the presence of arthritis in five or more joints on physical exam (typically with some degree of wrist and hand involvement), at least 6 weeks of symptoms, and exclusion of other causes. There are no confirmatory tests; however, in patients with polyarticular JIA diagnosed clinically, the RF and anticitrullinated peptide (anti-CCP) have prognostic value. RF and anti-CCP positivity are associated with a more severe, erosive course. Some children with polyarticular JIA have normal inflammatory markers, while others have a moderately elevated erythrocyte sedimentation rate (ESR) and anemia of chronic disease. These findings are more useful for assessing overall health and monitoring response to therapy than in establishing an initial diagnosis, as they are nonspecific.

### Differential Diagnosis

Reactive arthritis may present with polyarticular joint swelling, but is typically acute in onset and characterized by more pain than is seen in JIA. The arthritis of acute rheumatic fever is typically exquisitely painful and has a unique migratory pattern. While patients with polyarticular JIA may experience an *additive* arthritis pattern early in the disease course, *migratory* arthritis (i.e., swelling resolving completely in one joint and moving to another) is not seen in JIA. In patients with extreme pain, bone pain, pallor, or severe fatigue, malignancy such as leukemia or neuroblastoma should be considered.

Polyarthritis can occur as a manifestation of other underlying autoimmune diseases, including systemic lupus erythematosus, mixed connective tissue disease, or inflammatory bowel disease. The best approach to evaluating for these conditions is a thorough history and physical exam. Oral ulcers, Raynaud phenomenon, or malar or discoid rashes raise concern for lupus. Because ANA tests are nonspecific and have a high positive rate in both the healthy and JIA populations, an ANA test in isolation is not helpful in evaluating for lupus unless it is negative (which

essentially excludes lupus). In cases in which the history or physical raises concern for lupus, using a combination of several laboratory studies is more helpful. A reasonable initial workup for lupus when clinical suspicion is high includes an ANA, specific lupus antibodies (Smith, double-stranded DNA), ESR, C3 and C4 levels, CBC to evaluate for cytopenias, a urinalysis, creatinine, and blood pressure measurement.

Inflammatory bowel disease can present with inflammatory arthritis. Inflammatory bowel disease (IBD) should be considered in patients with significant oral ulcers, chronic abdominal pain and/or diarrhea, weight loss, significantly elevated ESR, or anemia.

### Treatment

The goals of treatment are the same as for oligoarticular disease, although children with polyarticular JIA often require more aggressive medical therapy to attain inactive disease. Scheduled NSAIDs are often started first line or in conjunction with other medications for pain relief, but rarely are effective as monotherapy. Intraarticular steroid injections may be used in combination with systemic therapy for severely affected or critical joints, but monotherapy with steroid injections is not a viable approach to treating this disease.

Most children with polyarticular JIA require treatment with DMARDs for disease control. There are two general approaches to initiation of medications: step-up therapy and early aggressive (combination) therapy. The choice of approach may be driven by provider and/or patient preference or severity of disease. In a step-up approach, methotrexate is most commonly used as the first DMARD. Methotrexate (10 to 15 mg/m<sup>2</sup> or 0.4 to 1 mg/kg) once weekly is administered orally or subcutaneously, with subcutaneous dosing preferred by many pediatric rheumatologists on the basis of possible improved absorption and mitigation of side effects.

Biologic medications shown to be effective in JIA refractory to methotrexate include TNF inhibitors (etanercept [Enbrel], adalimumab [Humira], golimumab [Symponi], and infliximab [Remicade]<sup>1</sup>), the IL-6 inhibitor tocilizumab (Actemra), the T cell costimulation inhibitor abatacept (Orencia) and the Janus kinase inhibitor tofacitinib [Xeljanz]. Selection of an initial biologic medication can be driven by a variety of factors including patient/parent preference, logistics of administration, side effects, comorbid medical conditions, and (in our current health system) insurance restrictions. The anti-CD20 medication rituximab (Rituxan)<sup>1</sup> is sometimes used in patients with RF positive disease, usually after failure of other medications.

Early aggressive approach, such as first-line combination therapy with methotrexate and a TNF inhibitor with or without adjunctive NSAIDs, intraarticular steroid injections, or a short oral steroid bridge, is sometimes used. With earlier aggressive use of DMARDs, treatment with systemic corticosteroids can now be limited to short courses or avoided altogether in most children. While systemic steroids can produce rapid improvements in pain, symptoms return quickly after discontinuation and their side effect profile makes long-term use unacceptable. Systemic steroids should *never* be initiated in a child presenting with musculoskeletal pain of unknown etiology, given the danger of corticosteroids in undiagnosed infection or malignancy.

### Monitoring

Monitoring of clinical disease and medications (NSAIDs, methotrexate, TNF inhibitors) is the same as described for oligoarthritis. Other biologic medications have similar monitoring requirements, including testing for latent tuberculosis (TB) prior to initiation. Some biologics have additional recommended laboratory monitoring parameters. Given the expertise needed to safely prescribe and monitor DMARDs, these medications should only be prescribed to children with JIA by a rheumatologist. In patients with systemic inflammation or anemia at presentation, these labs should be followed as adjunctive markers of disease activity, but normalization should not falsely reassure that arthritis is well

controlled if the joint exam indicates otherwise. Children with polyarticular JIA who develop fever while on immunosuppression should be assessed promptly for infection.

### Complications

Articular complications in polyarticular JIA include joint contractures, deformities, growth disturbances, and progressive, erosive disease. Cervical spine, TMJ, hip, and wrist involvement are associated with higher morbidity. Fortunately, with earlier aggressive treatment, severe joint destruction and severe physical disability are now less common. Surgical interventions are sometimes required for patients with severe micrognathia (mandibular distraction or reconstruction techniques), joint destruction (joint replacements), or severe growth disturbances (limb inequality procedures).

Children with polyarticular JIA can also develop chronic uveitis. Similar to oligoarticular JIA, age of onset, duration of disease, and ANA status are risk factors for development of uveitis and direct frequency of eye screening. The exception is that uveitis is rare in RF positive polyarticular JIA; thus eye screening is needed only once yearly in this subtype.

### Enthesitis-Related Arthritis

#### Epidemiology

ERA is the only JIA subtype more common in boys, makes up 9% to 19% of all JIA, and has a peak age of onset of 10 to 13 years.

#### Clinical Manifestations

ERA is a childhood form of spondyloarthropathy and closely related to ankylosing spondylitis. Spondyloarthropathies are characterized by axial arthritis, although in children peripheral arthritis precedes axial disease, sometimes by years. Peripheral arthritis in ERA preferentially affects the lower extremities, often asymmetrically. Arthritis of the hips and sacroiliac joints, tenosynovitis (inflammation of tendon sheaths), and *enthesitis* (inflammation at the bony insertions of tendons, ligaments, or fascia) are common findings. *Tarsitis*, diffuse swelling of the dorsum of the foot, is relatively unique to ERA. Pain is more prominent in ERA than other JIA subtypes. Axial arthritis develops in some patients in late adolescence or adulthood. Uveitis in ERA is acute and symptomatic (with a red, photophobic eye), distinct from uveitis in other forms of JIA.

#### Diagnosis

ERA usually presents as monoarthritis or oligoarthritis in the lower extremities (hips, knees, ankles). Diagnosis is made on the basis of arthritis on exam with a history supporting a chronic course. HLA-B27 positivity can support the diagnosis, though the HLA-B27 is not a diagnostic test (as some ERA patients are B27 negative and many B27 positive individuals are healthy). Though most children do not have sacroiliitis or spinal arthritis at presentation, findings of inflammatory spinal arthritis on radiographs or magnetic resonance imaging strongly suggest this diagnosis.

#### Differential Diagnosis

School-aged children with ERA often present with arthritis of a single knee or ankle. In addition to the diagnostic considerations outlined above for oligoarthritis, ERA must be distinguished from oligoarticular JIA itself. Clues to diagnosis in this clinical scenario are older age (recall that the peak age of onset of oligoarticular JIA is age 1 to 4), male gender, and supporting clinical features if present (tenosynovitis, enthesitis, acute uveitis).

In children presenting with hip symptoms, infectious and orthopedic conditions (including slipped capital femoral epiphysis or Perthes) should be considered. Rarely, older adolescents present with sacroiliitis. Low back stiffness, worse in the morning, helps distinguish from infectious and orthopedic conditions, though imaging is usually required to make this distinction with confidence. The vast majority of children with chronic low back pain have mechanical rather than inflammatory pain.

## Treatment

The general approach to treatment of ERA is similar to polyarticular JIA, though for patients with sacroiliitis or spinal arthritis, TNF inhibition should be considered early in the disease course.

## Monitoring

Monitoring is very similar to polyarticular JIA with a few exceptions:

1. Children with ERA should be monitored closely for development of axial arthritis. This may include a combination of the following approaches: querying symptoms of inflammatory back pain, eliciting sacroiliac pain on exam, measuring spine mobility (with a modified Schober test), and/or imaging sacroiliac joints with x-ray or magnetic resonance imaging (MRI).
2. Eye exams are only required once yearly and as indicated based on symptoms as uveitis in ERA is usually symptomatic.

## Complications

Acute uveitis occurs in some patients with ERA, and often responds to topical corticosteroids. Patients who develop a red or photophobic eye should be evaluated promptly by an eye doctor. Arthritis of the spine, sacroiliac joints, and hips can be difficult to control, sometimes leading to joint destruction, even in the setting of prompt and aggressive therapy. In adulthood, these patients are at risk for progressive, ascending ankylosis of the spine.

## Juvenile Psoriatic Arthritis

### Epidemiology

Juvenile psoriatic arthritis comprises approximately 10% of JIA, is more common in girls, and has two peaks of onset: preschool and late childhood.

### Clinical Manifestations

Psoriatic arthritis usually presents with peripheral joint involvement and can occur in a monoarticular, oligoarticular, or polyarticular pattern. Both small and large joints can be affected, often in an asymmetrical pattern. *Dactylitis*, or a sausage digit, is a unique feature of psoriatic arthritis not seen in other forms of JIA. Dactylitic fingers and toes exhibit diffuse swelling that extends beyond individual joints. Arthritis of the distal interphalangeal (DIP) joints is also unique to psoriatic arthritis among children with JIA. There is some clinical overlap between psoriatic arthritis and ERA. Enthesitis and tenosynovitis are prevalent features and sacroiliitis can occur in up to 30% of adolescents. Nail changes, including pitting, horizontal ridges, and onycholysis, are common, and overt psoriasis occurs in about half of children. Both chronic uveitis (with risk factors similar to patients with oligo- and polyarticular JIA) and acute uveitis (in HLA-B27 positive patients) can occur.

### Diagnosis

Unlike adults, children with psoriatic arthritis often present with arthritis prior to skin disease. In patients with chronic arthritis and psoriasis, the diagnosis is relatively straightforward. In those with chronic arthritis without psoriasis, clinical clues to diagnosis include dactylitis, psoriatic nail changes (pitting or onycholysis), or a first-degree relative with psoriasis.

### Differential Diagnosis

Depending on the pattern of joint involvement, differential diagnosis includes other forms of JIA (oligoarticular, polyarticular, ERA) and other conditions listed previously in the differential of these JIA subtypes. Small joint involvement or dactylitis help distinguish psoriatic from oligoarticular JIA in young children with less than five affected joints.

### Treatment

The treatment approach is similar to polyarticular JIA, though for patients with sacroiliitis, enthesitis, or dactylitis, TNF inhibition has the most well-established efficacy.

## Monitoring

Monitoring is similar to other forms of JIA including eye screening for chronic uveitis described for oligo- and polyarthritis and monitoring for axial arthritis described for ERA. In addition, patients who have not developed skin manifestations should be monitored for development of psoriasis.

## Complications

Articular and ocular complications are similar to other JIA subtypes, though children with psoriatic arthritis often have poorer functional outcomes and lower rates of remission off medication than those with oligo- or polyarticular JIA.

## Systemic Juvenile Idiopathic Arthritis

### Epidemiology

SJIA occurs in children of all ages and into adulthood (Still disease in adults). It is the only form of JIA that affects boys and girls equally. SJIA makes up 10% to 20% of JIA. It occurs in all ethnicities, with increased prevalence in some Asian countries including Japan.

### Clinical Manifestations

SJIA is characterized by fever, rash, and arthritis. Fevers in SJIA are high grade, typically spiking once (quotidian) or twice (double quotidian) daily with return to normal temperature between fevers. The rash seen in SJIA is salmon-colored or erythematous, macular or urticarial, sometimes with associated Koebner phenomenon. A unique feature of the SJIA rash is its *evanescent* nature: it appears with fever and resolves or fades during afebrile periods. The arthritis in SJIA can affect any number of joints, in any pattern, and is not always present at disease onset. In some patients, the latent period between onset of systemic features and arthritis is weeks or months. Many patients exhibit nonspecific symptoms, including fatigue, irritability, and myalgia during fevers.

Children with SJIA have significant systemic inflammation during periods of disease activity. Profoundly elevated white blood count, platelet count, ESR, CRP, and anemia are common.

SJIA is truly a systemic disease, with some patients exhibiting lymphadenopathy, hepatosplenomegaly, and serositis (pleural or pericardial effusions). The most feared complication of SJIA is macrophage activation syndrome (MAS; see “Complications”).

### Diagnosis

SJIA is diagnosed based on the presence of quotidian fevers, evanescent Stills rash, arthritis, and systemic inflammation, with exclusion of similar conditions. SJIA often leads to inpatient evaluation, given patients' high grade fevers and ill appearance. Children who lack arthritis at the time of presentation are challenging to diagnose. In practice, SJIA is often presumptively diagnosed before arthritis has been present for 6 weeks (and sometimes in the absence of arthritis), as the severity of this disease can necessitate urgent treatment.

### Differential Diagnosis

SJIA has a broad differential diagnosis that includes infectious (viral, bacterial), oncologic (leukemia, neuroblastoma), and inflammatory conditions (Kawasaki, polyarteritis nodosa, inflammatory bowel disease, among others). Involvement of infectious disease and oncology consultants can help exclude these mimics, particularly if treatment with corticosteroids is being considered. Additional workup, including infectious studies and bone marrow biopsy, is appropriate in cases of diagnostic uncertainty.

### Treatment

The treatment paradigms have evolved more for SJIA than any other JIA subtype over the last decade. Traditionally, children with SJIA were treated with systemic corticosteroids, resulting in the full spectrum of anticipated morbidities (growth delay, infections, osteoporosis, etc.). Traditional DMARDs and TNF inhibitors are significantly less effective than for other JIA subtypes.

Targeted therapy with inhibition of IL-1 (with anakinra [Kineret]<sup>1</sup> or canakinumab [Ilaris]) or IL-6 (with tocilizumab [Actemra]) is the emerging standard of care, though optimal timing of these medications is unclear. Many pediatric rheumatologists are now using IL-1 or IL-6 blockade first line or after a failed NSAID trial to avoid or minimize corticosteroids. Systemic corticosteroids continue to have a role in severe disease or MAS. Other treatments for MAS include cyclosporine (Neoral)<sup>1</sup> and etoposide (Toposar)<sup>1</sup>.

### Monitoring

Monitoring is similar to polyarticular JIA, with a few exceptions. As uveitis is rare in SJIA, eye exams are needed only annually. Laboratory markers of systemic inflammation are useful in monitoring disease activity and evaluating for impending MAS, which can develop even when disease otherwise appears well controlled. Given the serious and life-threatening nature of this disease, all children with SJIA should be followed closely by a pediatric rheumatologist or an adult rheumatologist with experience managing SJIA.

### Complications

Articular complications of SJIA are similar to polyarticular JIA, though the arthritis of SJIA is often aggressive and destructive. There is emerging evidence that earlier treatment with targeted biologics may prevent progression to chronic polyarthritis.

MAS is a serious complication of SJIA, characterized by unregulated production of proinflammatory cytokines, macrophage proliferation, and hemophagocytic activity in the bone marrow and other organs. MAS is a potentially fatal rheumatologic emergency. It is often suspected on the basis of rapidly worsening clinical status and the development of continuous fever. Laboratory findings include a profoundly elevated ferritin, elevated lactate dehydrogenase and transaminases, falling blood cell counts, and paradoxically low or falling ESR and fibrinogen in the setting of other signs of systemic inflammation. MAS is currently considered a secondary form of hemophagocytic lymphohistiocytosis (HLH).

<sup>1</sup> Not FDA approved for this indication.

## OSTEOARTHRITIS

Method of

Rachel Chamberlain, MD; Jacob Christensen, DO; and Christopher Bossart, MD

### CURRENT DIAGNOSIS

- Risk factors for osteoarthritis (OA) include age, gender, genetics, and anatomic factors, which are nonmodifiable; modifiable risk factors include body mass index (BMI), tobacco use, trauma, physical activity, and muscle strength.
- OA is diagnosed using both clinical and radiologic information.
- Clinical signs and symptoms include joint pain, crepitus, mild swelling, and joint line tenderness to palpation. Symptoms wax and wane and may be related to activity but can be present at varying times of day.
- The Kellgren-Lawrence Classification system can help determine the grade of OA, but the ultimate determination of the severity is based on clinical factors.

### CURRENT THERAPY

- First-line therapy for OA includes exercise, physical therapy, and weight loss (if the patient is overweight or obese).
- Nonsteroidal antiinflammatory drugs (NSAIDs) are the best studied pharmacologic treatment for OA pain. Their use must be balanced by their side effects and the patient's comorbid conditions.
- Injections of corticosteroids may be used for OA pain management, but their pain relief effects are not long term.
- Hyaluronic acid injections can be considered in patients with mild to moderate OA of the knee, but this is an expensive therapy and evidence of effectiveness is mixed.
- No current treatment either in systemic medications or injections alters the course of OA. Research in the long-term benefits of biologic agents is ongoing.
- Total joint replacement is an expensive but definitive treatment for many patients with OA. The referring clinician should consider the patient's overall health and help optimize the patient's health for a successful outcome when referring for a total joint replacement.

Osteoarthritis (OA), also known as degenerative joint disease, is the most common form of arthritis worldwide. OA is a significant cause of morbidity, disability, and decreased quality of life. It is one of the leading contributors to global years lived with disability (YLDs) by Global Disease Burden studies. It is the leading cause of lower extremity disability. OA affects about one in eight people in the United States, or 27 to 31 million, and about 250 million people worldwide, with the most commonly affected joints being the knees, hips, hands, feet, and spine. As the age of the population and the rates of obesity increase, the economic impact of OA also increases. It is estimated that OA costs 1% to 2.5% of GDP in developed countries, with the majority of cost for treatment (85%) coming from joint replacement surgeries.

OA has been previously characterized pathologically by varying levels of cartilage involvement. One may find fissures and microfibrillations in mild or early disease, and erosive destruction of the joint surfaces may be seen in more advanced disease. However, it is recognized that the effects of OA can be seen throughout the entire joint including the bone, synovium, menisci, and ligaments.

## Pathogenesis

The pathogenesis of OA remains unclear. For decades, the traditional belief was that OA was a “wear and tear” condition associated with the cumulative stress of aging. This theory has not been shown to be true, or at least it is not an accurate depiction of “the whole story.” Research investigating other possible mechanisms is gaining traction. More recent research areas of focus include what role inflammatory mediators, genetics, metabolic factors, proteases, and biomarkers may play in the development of OA.

## Risk Factors

Despite the pathogenesis of OA being unclear, a number of factors have been identified to be associated with increased risk. These risk factors include age, gender, body mass index (BMI), genetics, tobacco smoking, trauma, chronic overuse, anatomic factors, and muscle strength.

**Age**—There is a clear correlation between aging and development of OA. It is also clear that the aging of joint tissues and the development of OA are separate and distinct processes. There are a number of aging changes within the joint that may contribute to development of OA including: thinning of articular cartilage, reduced hydration, accumulation of advanced glycation end-products (AGEs), and abnormal calcification (“chondrocalcinosis”). Based on population based radiographic surveys from the Framingham study, the prevalence of knee OA in patients aged 63 to 94 was 33%, and symptomatic knee OA was 9.5%.

**Gender**—OA is more common in women than men. Some have postulated that the correlation between age and OA explains the why OA is more common in the postmenopausal years; however, there is some evidence to suggest decreased estrogen exposure in women could also be a contributing factor.

**BMI**—Being overweight or obese has been well documented as a strong risk factor for development of OA. This is likely both related to increased mechanical forces and metabolic changes associated with obesity. Weight loss has also been shown to reduce the risk of developing knee OA.

**Genetics**—Twin studies have shown a genetic contribution of about 40% to 70% depending on the site of OA. There exists substantial heterogeneity depending on the site of involvement, and there is also racial variation, which makes studying this genetic component more difficult.

**Trauma and chronic overuse**—Trauma, which includes both major injuries and surgery, increases the risk of OA. For example, history of anterior cruciate ligament (ACL) tear in the knee is associated with increased risk of OA development regardless of whether surgical reconstruction is done. The mechanism for this is not completely understood. Chronic overuse as is seen in some occupations carries an increased risk of development of OA. For example, professional soccer players have an increased risk of developing knee OA, and professional baseball pitchers have a higher risk of developing elbow OA.

**Biomechanical factors**—Joint structural abnormalities may increase the risk of developing OA. The understanding of the role of muscle strength in OA is expanding. It is known that patients with knee and hip OA have reduced muscle strength in the surrounding muscles. However, it has been thought previously that this was a consequence of the symptoms of OA causing decreased activity, muscle atrophy, and subsequent weakness. There is more recent evidence to suggest that muscle weakness may actually predate the onset of knee OA.

## Clinical Features

OA is characterized clinically by insidious onset, usage-related joint pain, which can be accompanied by mild stiffness. Pain can be present at varying times of day. Mild swelling may be present in OA; however, large effusion and history of trauma or injury should prompt further workup. Patients may complain of limitation in range of motion, as well as a sensation of giving way or buckling (particularly in knee OA). Tenderness to palpation along the joint lines is a common physical exam finding. Joint

deformity is a sign of advanced disease. Symptoms are typically slowly progressive as is the disease course.

OA severity can be graded based on radiographic criteria or a combination of radiographic criteria and symptom severity. Perhaps the most commonly used radiographic criteria is the Kellgren-Lawrence method, classifying OA severity into grades 0 to 4 based on presence of joint space narrowing, osteophyte formation, and sclerosis of subchondral bone (Table 1). This method is certainly useful, though it should be mentioned that there are limitations to this method—namely, that there is somewhat poor correlation between radiographic findings and symptoms. It is estimated that up to 50% of people with radiographic findings of OA do not have any symptoms.

## Current Therapy

Treatment for OA is individualized based on patient symptoms, values, needs, goals, and response to therapies. There is no single treatment for OA, which reliably and consistently manages symptoms on its own. Therefore, a combination of therapeutic approaches is used in order to optimize function, minimize pain, and in some cases modify the process of damage to the joint. In general, safer treatments should be considered first before trying other treatments with higher risk profiles. Treatments can be placed into four categories: nonpharmacologic, pharmacologic, nonsurgical, and surgical interventions.

## Nonpharmacologic Therapies

Nonpharmacologic therapies represent the mainstay of treatment for OA initially. These therapies include education, exercise, weight management, braces, assistive devices, psychologic therapies, manual medicine, and alternative therapies.

**Education**—It is important to inform patients about their diagnosis, the modifiable risk factors for their specific case, and their expected prognosis. Information should be provided regarding the various treatment options including their risks, benefits, costs, and alternatives. Doing this helps encourage active shared decision making and combat some of the common misconceptions about OA management. Patient involvement in setting goals and self-managing their condition improves adherence and can make a significant difference in patients’ view of their disease.

**Exercise**—The goal of exercise therapy is reduction in pain and improvement in joint function. Various forms of exercise exist, and physical activity in general should be encouraged, providing it is done with patient symptoms as a guide. The forms of exercise with the best evidence for improvement, particularly in knee OA, are aerobic exercise and resistance strength training. Perhaps the most readily available form of aerobic exercise is walking, and formal walking programs have been shown to significantly improve OA symptoms, as well as quadriceps strength. Aquatic exercise has also been shown to be beneficial, and has the added benefit of decreased weight-bearing stress on joints.

**Weight loss**—In overweight and obese patients (BMI > 25), a reduction of 10% of baseline body weight has been shown to

**TABLE 1** Kellgren Lawrence Radiographic Classification of Osteoarthritis of the Knee

Grade 1	Doubtful joint space narrowing, possible osteophytic lipping
Grade 2	Definite osteophytes, possible joint space narrowing
Grade 3	Moderate osteophytes, definite joint space narrowing, some sclerosis, possible bone-end deformity
Grade 4	Large osteophytes, marked joint space narrowing, severe sclerosis, definite bone ends deformity

Data from Kellgren JH, Lawrence JS. Radiological assessment of osteo-arthritis. *Ann Rheum Dis*. 1957;16:494–502.

decrease OA-related joint pain. This is true of patients with knee and hip OA, but may also be beneficial in patients with OA of the hands in light of evidence that increased BMI is a risk factor for development of hand OA. Again, this may be partially related to metabolic changes.

**Braces and assistive devices**—Walking aids, such as a walking stick or cane, as well as knee braces for patients with joint malalignment, may be helpful, and should be considered as an adjunct treatment in appropriate patients. OA of the thumb is particularly amenable to splinting to improve pain.

**Psychologic therapies**—Chronic pain from OA can have significant effects on a patient's ability to function. Often as patients feel less able to perform the activities they enjoy, their mood is adversely affected, which in turn negatively affects their pain symptoms. There is some evidence that psychological interventions, such as cognitive behavioral therapy, are helpful in this regard.

**Manual medicine**—Manual techniques, whether performed by a physical therapist, doctor of osteopathic medicine (DO), massage therapist, or chiropractor, typically focus on improvement/maintenance of range of motion as well as joint mobility. There is some limited evidence to suggest manual manipulation may improve pain scores, particularly when combined with exercise therapy. However, more research in this area is needed.

**Alternative therapies**—There is currently insufficient evidence to recommend the use of acupuncture, therapeutic ultrasound, and neuromuscular electrical stimulation for treatment of OA.

## Pharmacotherapy

Despite the fact that nonpharmacologic agents are first line, many patients with OA require drug therapy. Although no available medications predictably reverse or halt the inexorable progression of the disease, some medications do reduce pain and inflammation, enhancing the patient's quality of life.

**Analgesics**—The most common nonnarcotic analgesic agent currently used for OA is acetaminophen (Tylenol). The recommended dose for OA is 1 g administered every 8 hours or three to four times daily (not to exceed 4 g/day). However, even at a high dose, studies are mixed if acetaminophen is effective for OA pain. Adverse effects are rare, but caution must be exercised in patients who have preexisting renal or liver conditions. Duloxetine (Cymbalta) 60 mg daily is approved by the US Food and Drug Administration (FDA) for mild to moderate pain resulting from OA. In a double-blind, randomized, placebo-controlled study of patients with chronic pain due to OA of the knees, there was significant improvement with duloxetine versus the placebo. In treating OA, the regular use of opioids is not recommended or supported. Tramadol (Ultram) is commonly used, particularly in patients who have contraindications to nonsteroidal antiinflammatory drugs (NSAIDs), but we suggest caution in prescribing even this medication given potential for tolerance. While for years it has been suggested that opioids improve quality of life and function in patients with chronic pain from OA, there is no evidence to support this in OA. Opioids may be needed occasionally for intense pain, but the benefits are limited compared to the risks of tolerance, opioid misuse, addiction, overdose, and death.

**Nonsteroidal antiinflammatory drugs**—Pain in OA patients is often not adequately controlled with pure analgesics, whereas NSAIDs in adequate dosage can provide significant clinical improvement. The 2013 AAOS Guidelines on nonsurgical management of knee OA recommend NSAIDs with a strong strength of recommendation. If simple analgesics fail to provide adequate relief, one of the many currently available NSAIDs may be tried. Clinical trials with naproxen (Anaprox), diclofenac (Voltaren), and sulindac (Clinoril) showed significantly greater improvement when compared with high-dose acetaminophen. The chief limiting factor in the use of NSAIDs is the possible induced gastric pathologic changes, disturbed renal function, and potential increased cardiac events. In addition, many patients with OA may be on other platelet inhibiting medications and interactions should be

taken into consideration. For patients ages 75 and above, topical NSAIDs are advised over oral given less toxicity and adverse effects. Cost and compliance also must be given consideration. Many of the NSAIDs are now available in dosage forms that can be given once or twice daily, which helps overcome the issue of noncompliance.

**Cyclooxygenase 2 inhibitors**—COX-2 inhibitors block prostaglandin synthesis and inflammatory mediators without the COX-1 effect of inhibiting gastric mucosal protection. In the United States, the COX-2-specific inhibiting NSAID that is FDA approved is celecoxib (Celebrex). It is equivalent to the older nonselective NSAIDs with regard to therapeutic effectiveness, but the risk of gastrointestinal injury and adverse effects on platelet aggregation is lessened. The risk of renal side effects is probably comparable with that of the conventional NSAIDs. A trial assessing the effect of celecoxib on cardiovascular events found a slightly higher risk of cardiovascular events, but primarily only at higher doses (400 mg/day or greater). In addition, celecoxib can be used with low-dose aspirin (81 mg) daily and anticoagulants, including warfarin. It is important to take into consideration that the cost of Celebrex is several times that of traditional NSAIDs.

**Glucosamine and chondroitin sulfate**—Glucosamine and chondroitin sulfate are over-the-counter dietary supplements that have gained moderate press touting their possible symptom-modifying effects. However, there is no significant evidence demonstrating that either of these used alone or in combination prevents or reduces arthritis in the knee. A Cochrane review shows mild improvement in pain scores at short-term follow-up with glucosamine compared with placebo, however only with certain preparations of the product. At this point, multiple organizations including the American College of Rheumatology and American Academy of Orthopedic Surgeons cannot recommend their use in treating OA.

**Turmeric**—Turmeric<sup>7</sup> has been used for treatment of many inflammatory disease processes, including OA, with modest improvement in pain. Curcumin<sup>7</sup> is the primary constituent within turmeric, and there is thought that regular intake can protect joints in individuals with OA. The studies to date are small and limited in number, but they do show modest reduction in pain among those with OA. Larger studies would be needed in order for a definitive recommendation to be made but given its low side effect profile and risk of adverse effects it seems to be a reasonable addition to treatment. However, turmeric may interact with other antiplatelet therapies, and this should be considered individually for each patient.

**Disease-modifying drugs**—To date, there are no known medications that reliably slow or stop the disease process of OA, and disease modifying antirheumatic drugs (DMARDs) are not recommended in the treatment of OA.

## Intra-articular Injections

**Corticosteroid injections (CSI)**—Early in symptomatic OA it is preferable to attempt to control symptoms by nonpharmacologic therapy and with oral therapy, rather than by local injection. CSI are commonly used for OA. Steroids are strong antiinflammatory medications, and there is reasonable evidence that CSI decreases pain in the short term. There remain concerns that CSI may damage cartilage and therefore hasten the advancement of OA. Clinical trials remain mixed. However, when noninvasive therapies are not controlling OA pain or a patient has an OA flair, CSI can provide relief. CSI is thought to be relatively safe to be given three to four times per year, although this is an expert opinion and not based in sound evidence. The remote risk of introducing infection from the procedure is minimized by adhering to a meticulous aseptic technique. CSI is thought to be less problematic than systemic steroids when it comes to side effects such as raising blood sugar, but caution should be used in patients with diabetes, particularly uncontrolled DM. While arthrocentesis of

<sup>7</sup> Available as dietary supplement.

a painful arthritic joint is commonly done, there is little evidence that this is an effective therapy, particularly after the short term.

**Hyaluronic acid**—Intra-articular hyaluronic acid (HA) injections have been approved by the FDA since 1997 as a medical device for OA of the knee. The clinical use of intra-articular HA in painful OA of the knee was introduced in Europe in the 1990s. The mechanism of action of HA is not completely understood, but it is thought to restore normal viscoelastic properties to the pathologically altered synovial fluid. Other possible beneficial effects include protection of the chondrocytes, antiinflammatory effects, and possible improvement of the mechanics of joint motion. Unfortunately, in non-industry-funded studies, head-to-head comparisons often fail to show superiority over cortisone and placebo injections. In addition, HA does not change the course of OA. Numerous preparations of FDA-approved HA products are in wide use in the United States. Initially, all HA products were extracted from rooster combs; however, that is no longer the case. In approximately 2% to 8% of patients injected with avian derived product, a subsequent pseudoseptic reaction can occur, mimicking an infected joint. Newer HA products are not animal-derived preparations but rather are developed from biological fermentation of streptococcal bacteria. In the United States, these products are only approved for knee OA. Drawbacks of intra-articular HA products include mixed evidence, cost, and less efficacy in patients with morbid obesity or severe (Kellrigan Lawrence Grade 4) OA.

**Platelet rich plasma (PRP)**—PRP injections have become popular in recent years. However, as many of these procedures are not covered by insurance, their use has been limited secondary to the expense of these treatments. There are some studies suggesting increased efficacy in functional improvement when compared to HA products. However, the data are still lacking, and it is hard to make clear conclusions at this point.

**Stem cells**—Stem cell injections have become an intriguing area of research. The thought that intra-articular injections of stem cells can help improve/restart chondrogenesis, and regeneration of damaged cartilage is actively being researched. However, a recent systematic review of the literature shows only a low level of evidence for its use, all of which were studies deemed to be at high risk for bias. At this time, it is not considered a mainstay treatment for OA in the United States.

### Surgical Management of Osteoarthritis

Surgical management of arthritis varies by which joint is affected, with knee arthritis being most common, followed by hip. Knee arthroscopy should not be used to manage knee OA and/or degenerative meniscus tears in the setting of OA, as there is little to no improvement compared with exercise. Additionally, arthroscopic partial meniscectomy for degenerative meniscus tears may increase risk of developing OA. Hemiarthroplasty can be considered in patients with unicompartamental knee arthritis, and may carry less risks than total knee arthroplasty (TKA). In addition, a valgus-producing proximal tibial osteotomy may be beneficial in patients with symptomatic medial compartment knee OA. Total joint arthroplasty is an expensive surgery, though often well covered by insurance companies. The surgeries carry significant risks, including cardiovascular events, deep vein thrombosis, and prosthesis infection, which can lead to long hospitalizations for intravenous antibiotics and repeat surgeries. Not all patients have the pain relief and function improvement expected from total joint arthroplasty (TJA).

When referring a patient to orthopedic surgery for consideration of a total hip or knee arthroplasty, the clinician may be able to help prepare the patient to optimize their surgical outcome. This includes, but is not limited to, helping a patient with

smoking cessation, weight loss, and diabetes control. Ideally, a patient would be tobacco/nicotine free for at least 8 weeks prior to surgery, would have a BMI less than 40, and would have a hemoglobin A1C  $\leq 7.0$ . In addition, the referring clinician should take into consideration that patients with chronic pain and/or opioid use, depression and anxiety, liver cirrhosis/hepatitis C, and other chronic conditions may not have optimal outcomes from total joint replacement. It is acceptable to delay total knee arthroplasty up to 8 months to improve these modifiable risk factors without decreasing the patient's benefit from total joint arthroplasty. Arthroplasty procedures are also performed for arthritis of the shoulder, elbow, wrist, thumb, and ankle with varying degrees of evidence for pain and quality of life improvement. Surgical techniques and prostheses are undergoing advancements and improving patient outcomes for the less commonly done arthroplasty surgeries, and clinicians can expect this technology to continue to advance in the future.

### Conclusions

OA remains a very common source of pain and disability throughout the world and also carries a significant financial burden. The pathophysiology of OA is more complex than previously believed, and is not fully understood. OA has both modifiable and nonmodifiable risk factors. Nonmodifiable risk factors include age, gender, and genetic risk/family history. Modifiable risk factors include weight loss in patients who are overweight or obese, eliminating tobacco exposure, trauma and overuse, and control of metabolic syndrome.

Nonpharmacologic therapy for OA is first-line treatment and includes education and management of patient expectations, weight loss, exercise, and physical therapy. Braces and assistive devices, cognitive behavioral therapy, manual therapy, and alternative therapy may also be considered but have less definitive evidence.

Pharmacologic therapy is usually required for OA, with acetaminophen being first line. Clinicians should educate patients on high dose acetaminophen and safe amounts to take to achieve therapeutic effect without danger to liver. NSAIDs are often more effective at controlling pain from OA, but do carry a higher risk profile for gastrointestinal bleeding, renal dysfunction, and cardiovascular events. Herbal medications such as glucosamine chondroitin and turmeric may also be beneficial but studies are mixed. Opioids should be avoided in management of OA pain, as there is no evidence that they improve function and quality of life (as previously proposed) but do carry very serious side effects.

Nonsurgical interventions such as intra-articular injections can be beneficial in managing pain from OA. It is important to counsel patients that none of the current injection therapies have data that they change the course of the disease process; they only help control pain and improve function. Corticosteroid injections often give the patient good pain relief but are often not long lasting. HA injections may also be beneficial, but many studies show equivocal pain improvement compared with cortisone and the cost is much greater. Studies are still ongoing at biologic agent injections such as PRP and stem cell therapies, and data is mixed. It is unclear if these expensive, non-FDA-approved therapies are beneficial at this time.

Total joint arthroplasty is the definitive treatment for OA, with the best data in hip followed by knee arthroplasty. These surgeries carry significant risks, especially in the older population that OA most commonly affects. In addition, surgery is very expensive and associated with significant time loss from work. Patients' chronic medical conditions should be well controlled prior to a total joint arthroplasty, to minimize risks of poor outcomes or adverse effects.

## OSTEOPOROSIS

Method of

Alexei O. DeCastro, MD; Scott Bragg, PharmD; and Peter J. Carek, MD, MS

### CURRENT DIAGNOSIS

- Evaluate risk factors for falls and osteoporotic fractures.
- Screen for osteoporosis with bone mineral density (BMD) testing in women age 65 years and older.
- Recommend screening for osteoporosis in postmenopausal women younger than 65 years at increased risk of osteoporosis.
- Current evidence is insufficient to recommend screening for osteoporosis in men.
- Determination of BMD is helpful for those with clinical osteoporotic fractures to determine the severity of the disorder and to help guide future treatment decisions.
- Consider clinical and laboratory workup of secondary causes of osteoporosis.
- Current evidence is insufficient to recommend routine vertebral fracture assessment and trabecular bone scores, although they may improve fracture risk assessment.

### CURRENT THERAPY

- Recommend a comprehensive nutritional assessment targeting normal body weight and adequate ingestion of calcium and vitamin D.
- Evidence does not support taking calcium and vitamin D for primary prevention of osteoporotic fracture in adults over age 50. For secondary prevention, recommend at least 1200 mg/day of calcium and 800 to 1000 IU/day of vitamin D. Dietary sources are preferred, but supplements may be necessary to meet goals.
- Mind-body, resistance, and aerobic exercise are important tools to reduce the risk of falls and fracture.
- Pharmacologic osteoporosis treatment may reduce fracture risk in patients with a fragility fracture (i.e., low-trauma fracture to the vertebrae, proximal femur, distal radius, humerus, pelvis, ribs) or radiographic evidence of osteoporosis (i.e., BMD T-scores  $\leq -2.5$  at the lumbar spine, femoral neck, or total hip).
- Pharmacologic treatment may also reduce fracture risk in patients with low bone mass and high 10-year fracture risk. The 10-year fracture risk is high if the 10-year hip fracture probability is  $\geq 3\%$  or if the 10-year probability of a major osteoporosis-related fracture is  $\geq 20\%$ . To assess fracture risk, use the fracture risk assessment tool (FRAX) from the US-adapted algorithm from the World Health Organization.
- Treatment of premenopausal women and men younger than 50 years old with osteoporosis therapy is controversial. Z-scores  $\leq -2.0$  indicate osteoporosis. However, osteoporosis treatment is often reserved for glucocorticoid-induced osteoporosis in patients at high fracture risk or patients with multiple fragility fractures.
- Drug treatment for osteoporosis should prioritize treatments with better patient-oriented evidence like alendronate (Fosamax), risedronate (Actonel), zoledronic acid (Reclast), denosumab (Prolia), teriparatide (Forteo), abaloparatide (Tymlos), and romosozumab (Evenity).

Osteoporosis is a skeletal disease characterized by low bone mass and structural deterioration of bone tissue, which is associated with decreased bone strength and increased susceptibility to fractures. Its clinical relevance is increasing because of the rapid population growth of older adults and because of the high morbidity

and mortality associated with the disease. Osteoporosis is asymptomatic until the patient has a fracture, so identifying patients at high fracture risk and prevention is important. Once a vertebral fracture is present, patients may develop back pain, height loss, and/or thoracic kyphosis. Hip fractures are associated with thigh or groin pain and typically limit a patient's mobility. Primary or secondary prevention of fracture in patients with osteoporosis is a challenge because screening can be difficult and treating osteoporosis has many risks and benefits.

The World Health Organization (WHO) has defined osteoporosis as a condition in which bone mineral density (BMD) assessed by dual-energy x-ray absorptiometry (DEXA) at the lumbar spine or hip is decreased. Osteoporosis is seen in postmenopausal women or men over age 50 with a BMD of 2.5 standard deviations (SDs) below normal ( $T$ -score  $\leq -2.5$ ) compared with young-adult reference population. Low bone mass, previously known as osteopenia, is a milder degree of bone loss seen in the same populations ( $T$ -score of  $-1.0$  to  $-2.4$ ). Although the risk of fracture increases significantly with decreasing BMD, large observational studies have demonstrated that osteoporotic fractures can occur across a wide spectrum of BMDs. Osteoporotic fractures may be caused by low bone quantity or poor bone quality which are not measured by DEXA scans. Qualitative determinants of bone strength include trabecular bone scores, microcracks, mineralization defects, bone geometry, cell death, changes in bone size, and changes in bone turnover. Even though a low BMD defines osteoporosis, a fragility fracture (i.e., fracture without trauma or a low-trauma fall) may lead to a clinical diagnosis of osteoporosis.

The U.S. Preventive Services Task Force (USPSTF) recommends screening for osteoporosis in women greater than 65 years old and in women younger than 65 who are at equal or increased risk of osteoporosis compared with an average 65-year-old woman (Grade B recommendation). To identify patients at increased risk, multiple decision support tools exist, but the most widely used tool is the fracture risk assessment tool (FRAX), which helps calculate the 10-year risk of a hip fracture and a major osteoporotic fracture. The FRAX considers several major independent risk factors including BMD of the femoral neck, previous fracture history, family history of fracture, age, sex, ethnicity, glucocorticoid use, alcohol abuse, current smoking status, and possible secondary osteoporosis causes. Inclusion of race in FRAX is controversial and may perpetuate inequities in care considering it may underestimate risk in non-Caucasian patients. Despite these recommendations, many women with osteoporosis go unrecognized and untreated. In one study from an insurance claims database, less than 50% of women with a fragility fracture had an osteoporosis diagnosis within 1 year of the fracture and less than 30% were treated with pharmacologic therapy.

### Epidemiology

Osteoporosis is the most common metabolic disorder of the skeleton. Based on 2018 data in the United States of adults over age 50, the prevalence of osteoporosis in women was 19.6% and in men was 4.4%. The estimated prevalence of osteoporosis is highest in Mexican Americans, followed by non-Hispanic Whites, and lowest in non-Hispanic Blacks. Worldwide, 200 million women suffer from osteoporosis, and those women have an estimated 65% lifetime risk of a fragility fracture. In men with osteoporosis, the estimated lifetime risk of a fragility fracture is 42%. Hip fractures are the most feared fragility fracture because they cause a mortality rate of 10% to 20% at 12 months, and up to 25% of those with hip fractures require long-term nursing care.

### Screening

Evaluating risk factors for osteoporosis is important at annual well visits or during all visits in high-risk individuals. Universal screening in all women older than 65 years or those at comparable risk is important. Nonmodifiable risk factors are genetic background, advancing age, female sex, low socioeconomic status, personal history of fracture, and family history of fracture

in a first-degree relative. Modifiable risk factors consist of low body weight, hormonal deficiencies, smoking, alcohol abuse, inactive lifestyle, and a diet low in calcium and vitamin D. In addition, certain medications affect skeletal homeostasis and increase fracture risk. Routine assessment and minimizing high-risk medications (e.g., glucocorticoids, immunosuppressive medications, anticonvulsants, sex hormone deprivation therapy, proton pump inhibitors, antidepressants, loop diuretics), when possible, can lower fracture risk. Other comorbid illnesses (e.g., chronic kidney disease, hyperthyroidism, rheumatoid arthritis) increase the risk of secondary osteoporosis, but better control of the underlying condition may reduce risk.

Several decision support tools are available to help identify patients who are at high risk for osteoporosis and fracture. The most common risk assessments include FRAX, the simple calculated osteoporosis risk estimation, the osteoporosis self-assessment tool, and the osteoporosis risk assessment instrument. However, many clinicians prefer using FRAX because it incorporates easy-to-identify risk factors, helps determine the appropriateness of a DEXA, and provides a 10-year absolute fracture risk. While FRAX incorporates DEXA results, it does not require this information to estimate fracture risk. The USPSTF recommends screening with a DEXA scan in all women 65 years and older and postmenopausal women less than 65 years old if their 10-year fracture risk with FRAX is 9.3% or higher. The other decision support tools to assess the need for a DEXA scan may be reasonable as well because they rely on fewer factors and have comparable sensitivity.

The National Osteoporosis Foundation (NOF) and the International Society for Clinical Densitometry recommend screening all men 70 years and older and men 50 to 69 years of age based on risk factors. However, the USPSTF guidelines state that insufficient evidence is available to support screening for osteoporosis in men. Other screening risk assessments, such as vertebral imaging and trabecular bone scores, may be considered in addition to DEXA scans to help identify asymptomatic vertebral fractures or to quantify bone microarchitecture. These techniques may help better characterize 10-year fracture risk or guide pharmacologic treatment decisions, although neither vertebral imaging nor trabecular bone scores are discussed in the USPSTF guidelines because of limited data with these screening modalities relevant to improved risk assessment or patient-oriented outcomes.

The optimal rescreening interval remains unclear after an initial DEXA scan. Most guidelines recommend rescreening after 2 to 3 years of antiresorptive therapy or in high-risk individuals not taking therapy. In patients receiving antiresorptive therapy, a baseline DEXA and a repeat at 3 years may be a cost-effective strategy to minimize the number of DEXA scans if a patient improves as expected and is then able to start a drug holiday. There is some evidence that waiting for 15 years to rescreen is a reasonable strategy in low-risk individuals with an initial normal  $T$ -score. Shared decision making should be used to determine when to stop screening because evidence has not identified a clear time to stop, and patient risk factors vary significantly.

### Pathophysiology

Although osteoporosis is often thought of as synonymous with decreased BMD, this association is not always present. Several factors can lead to decreased bone strength, including small bone size, increased length of the femoral neck, cortical porosity, decreased viability of osteocytes, and others.

Peak bone mass typically occurs in an individual's third decade of life. Differences in the peak bone mass may be secondary to genetic, hormonal, and environmental variables. Increases in body size and skeletal load also play a role in determining peak bone mass. Physical activity during childhood also enhances bone mass, whereas chronic diseases during childhood may decrease BMD. The contribution of genetic variants is unclear because osteoporosis is a polygenic disease and genetic variants seem to have small effect on BMD and fracture risk. A patient's BMD

correlates strongly with fracture risk, but other factors also influence fracture risk.

Age-related bone loss is a significant factor in the development of osteoporosis. Bone resorption begins to overtake bone formation with advancing age. Hormonal deficiency causes bone loss because testosterone and estrogen help determine bone homeostasis (i.e., osteoclast-induced bone resorption vs. osteoblast-supported bone formation). In women, rapid estrogen loss after menopause initially affects trabecular bone density. After a few years, bone loss continues to occur more slowly and primarily affects cortical sites. This slower phase is associated with a decreased number of osteoblasts and a slower bone formation rate as a result. Men, however, are less likely to develop bone loss because of greater bone gain during puberty and no sudden loss of sex hormones. In addition, there is evidence that aging itself is an independent risk factor for bone loss. Another contributing factor is loss of muscle strength and coordination, which increases the risk for falls and fragility fractures.

### Clinical Manifestations

There are typically no clinical manifestations of osteoporosis until a patient actually has a fracture. The signs and symptoms associated with osteoporosis correspond to direct or indirect manifestations of these fractures. Patients may have height loss, back pain, and thoracic kyphosis after experiencing a vertebral fracture. Moreover, manifestations from thoracic kyphosis could include dyspnea, from pulmonary restrictive lung disease, or constipation. Significant pain is often seen with both vertebral fractures and hip fractures although some patients may present with asymptomatic vertebral fractures that can be clinically inconspicuous. Functional disability is common after a fracture and many times requires rehabilitation to improve long-term functional status.

### Diagnosis

Osteoporosis can be diagnosed radiographically or after a fragility fracture, which is a low-trauma fracture to the vertebrae, proximal femur, distal radius, humerus, pelvis, or ribs resulting from a fall from at standing height or lower. The initial evaluation includes a history to assess for clinical risk factors for fracture, evaluation for secondary conditions that contribute to bone loss, a physical examination, laboratory and imaging tests, and assessment of medications that increase fracture risk. Most cases of osteoporosis are diagnosed by a DEXA scan of the total hip, femoral neck, or lumbar spine, with a *T*-score of  $-2.5$  or below. Bone mass measurements by DEXA must be interpreted in relation to the patient's age, ethnicity, fracture history, family history, previous medication use, timing of menopause, and other concomitant disorders.

Other techniques for measuring bone mass include ultrasound of the calcaneus, wrist, and finger; computed tomography of the spine; or peripheral quantitative computed tomography of the wrist and tibia. However, these tests have limited availability, increase radiation exposure, and are expensive so they are rarely used. Vertebral fracture assessment is another imaging modality that may augment risk assessment decisions when performed during a DEXA. A vertebral fracture assessment involves an radiograph of the spine and may help identify asymptomatic vertebral fractures, which strongly correlate with future symptomatic vertebral fractures.

DEXA results are expressed as a *T*-score and a *Z*-score. The WHO established the *T*-score as a standard deviation (SD) difference between an individual's BMD and a sex- and ethnicity-matched young-adult reference population. The *T*-score should be used in the evaluation of men age 50 and older and postmenopausal women. The *T*-score provides an indication of the risk for developing fractures because of the association of fractures with decreasing BMD. A *T*-score that is  $-2.5$  SD or more is diagnostic of osteoporosis; a *T*-score that is between  $-1.0$  and  $-2.4$  SD below the mean is defined as low bone mass, also known as *osteopenia*. A *T*-score of  $-2.5$  SD or

below plus a fragility fracture is termed *severe osteoporosis*. BMD measurements may be different across various bone sites in the same patient. These discrepancies may likely be related to differences in skeletal compartments (trabecular vs. cortical) at distinct sites. To classify the degree of osteoporosis use the lowest *T*-score from the lumbar spine, femoral neck, or total hip.

The *Z*-score is the SD difference between the patient's BMD and a reference population matched for age, sex, and ethnicity. A low *Z*-score of  $-2.0$  SD or below indicates osteoporosis and can identify patients in need of further workup or even osteoporosis treatment. *Z*-scores should be used in the evaluation of adult men younger than age 50, premenopausal women, and children. Less evidence exists for characterizing the severity of disease or need for osteoporosis treatment in these populations, making patient care decisions difficult. Further research is needed to identify appropriate groups to screen with *Z*-scores and whether osteoporosis treatment changes patient-oriented outcomes.

Biochemical bone turnover markers (e.g., procollagen type 1 N-terminal propeptide, pyridinoline, deoxypyridinoline) reflect the activity of the bone-remodeling unit. However, their roles in the management of osteoporosis are not clear. Future use of these biochemical markers may be helpful in determining risk and for monitoring patients response to antiresorptive therapies.

Identifying secondary causes of osteoporosis is important when making a diagnosis to help make treatment decisions. Approximately 66% of men and 20% of women will have secondary causes of osteoporosis. Common causes of osteoporosis in men are long-term use of glucocorticoids, hypogonadism, alcohol abuse, myeloma, and comorbid causes (e.g., celiac disease, hyperthyroidism, hyperparathyroidism). Stopping medications associated with osteoporosis is reasonable after having a shared decision-making discussion with a patient to identify the benefits of the drug and if treatment alternatives exist.

### Prevention

Prevention of osteoporosis is important because bone loss with aging is difficult to correct. Lower peak bone mass established in early adulthood may determine bone strength and fracture risk decades later. Therefore prevention starts with good nutrition, maintenance of a healthy body weight, and weight-bearing exercise to optimize bone mass during bone-forming years. Avoiding smoking and excessive alcohol intake are other important lifestyle factors to emphasize with patients. Medications that may be harmful to bone health should be monitored and re-evaluated when possible. Prevention with antiresorptive treatment in patients with low bone mass may increase BMD, restore bone strength, and reduce fracture risk in high-risk patients.

Calcium and vitamin D are both physiologically vital in bone formation. Studies are conflicting on the benefits of calcium and vitamin D<sup>1</sup> for primary prevention of fracture in older adults. Several studies with high potential for bias have shown increases in BMD and reduction of fracture risk in high-risk adult patients given both calcium and vitamin D. As a result, the NOF recommends 1200 mg of elemental calcium and 800 to 1000 IU of vitamin D daily for postmenopausal women. However, recent studies with low potential for bias do not support calcium or vitamin D to reduce the risk of fractures or to increase BMD in older adults when used in primary prevention. Concerns about renal adverse events, particularly nephrolithiasis, exist with excessive dietary and/or supplemental calcium. There is also theoretical concern that excessive calcium administration could increase the risk of myocardial infarction via coronary calcification, although no strong data support this concern.

<sup>1</sup> Not FDA approved for this indication.

## Treatment

### Nonpharmacologic Therapy

Nondrug therapy for preventing osteoporosis and, more worrisome, fractures includes addressing risk of falls, eating a balanced diet, incorporating routine exercise, and avoiding excessive alcohol intake or smoking. Vision deficits, gait abnormalities, cognitive impairment, dizziness, and balance problems are common but preventable causes of falls. Performing a formal home safety evaluation and modifying the patient's living environment by improving lighting and removing loose rugs can reduce risk of fall. Physical therapy evaluation and treatment can address both balance and gait issues. Regular physical activity with mind-body, aerobic, and resistance exercises are effective in increasing spine BMD. Patients should exercise at least 30 minutes three times per week. However, there is no evidence that high-intensity exercise provides greater benefit. Frequent medication assessment is also important and may reduce the risk of falls if stopping ineffective or potentially inappropriate medications like those outlined by the Beers Criteria.

Eating a balanced diet with adequate calcium, vitamin D, and kilocalories should be emphasized from an early age. Studies showing the efficacy of calcium on fracture primary prevention in older adults are mixed, with some meta-analyses showing benefit and others showing no effect. Although primary prevention benefit is unclear, adequate calcium and vitamin D consumption should be encouraged when used with bisphosphonates and denosumab (Prolia) to reduce the risk of hypocalcemia and to ensure optimal effectiveness. Because optimal doses are not established, a daily intake of at least 1200 mg of calcium and 800 to 1000 IU of vitamin D<sup>1</sup> is recommended for all women with osteoporosis by the NOF based on the historic recommended dietary allowance. Calcium and vitamin D supplements are often used because of low dietary consumption and reduced vitamin D creation with decreased sun exposure in older adults. Both calcium carbonate and calcium citrate can be used, but caution should be used because of constipation and gastrointestinal upset.

The appropriate vitamin D level remains unclear, with mixed evidence and different experts advocating for different goal values. Some studies suggest that a serum 25-hydroxyvitamin D

level of at least 30 ng/mL is needed to reduce falls and to improve physical function in the elderly. However, many experts advocate for treating only severely low 25-hydroxyvitamin D values <20 ng/mL because of mixed evidence with slightly low vitamin D values. In patients with confirmed vitamin D insufficiency, administration of 50,000 IU of oral ergocalciferol (vitamin D<sub>2</sub> [Drisdol])<sup>1</sup> once-weekly for 8 to 12 weeks was thought to be safe and effective. However, a more recent study has shown that high-dose vitamin D may increase the risk of falls, so these high intermittent doses should be reevaluated. A repeat serum 25-hydroxyvitamin D value is often obtained, but the ideal value remains unclear.

### Pharmacologic Treatment

All drugs approved by the FDA for treating osteoporosis reduce vertebral fracture risk. The antifracture effects of these medications are due to an increase in BMD and an improvement in qualitative measures of bone strength. For a summary of commonly used drug treatments, see [Table 1](#).

The mechanisms of each class of osteoporosis agent are slightly different and primarily work through decreasing bone resorption by inhibiting osteoclasts or increasing bone formation by stimulating osteoblasts. The bisphosphonates (e.g., alendronate [Fosamax], risedronate [Actonel], ibandronate [Boniva], zoledronic acid [Reclast]) impair osteoclastic resorption through the inhibition of farnesyl diphosphate synthase, a key enzyme that supports osteoclast activity. Raloxifene (Evista), conjugated equine estrogen (Premarin), and bazedoxifene/conjugated equine estrogen (Duavee) inhibit osteoclast apoptosis and secretion of osteoprotegerin on osteoblasts, which reduce osteoclast production. Denosumab (Prolia), a monoclonal antibody, works similarly to estrogen by stopping osteoclast formation through inhibition of the receptor activator of nuclear factor κB ligand system. Calcitonin (Miacalcin) works through a different mechanism by inhibiting osteoclast activity through the calcitonin receptor. Parathyroid hormones (i.e., teriparatide [Forteo], abaloparatide [Tymlos]) stimulate osteoblast bone formation and increase serum calcium absorption in the gastrointestinal tract and reabsorption through the renal tubules. Lastly, romosozumab (Evenity), a new class

**TABLE 1** Osteoporosis Treatment Dosing and Effectiveness on Fracture Risk Reduction

MEDICATION	ROUTE	DOSE/FREQUENCY	CLINICAL EVIDENCE OF EFFICACY		
			VERTEBRAL	HIP	NONVERTEBRAL
Alendronate (Fosamax)	Oral	Oral 10 mg daily or 70 mg weekly	+	+	+
Risedronate (Actonel)	Oral	5 mg daily or 35 mg weekly	+	+	+
Zoledronic acid (Reclast)	IV	5 mg yearly	+	+	+
Ibandronate (Boniva)	Oral	150 mg monthly	+	–	+
	IV	3 mg every 3 months	+	–	+

<sup>1</sup>Not FDA approved for this indication.

of monoclonal antibody, inhibits sclerostin, which is a protein that regulates bone metabolism. By inhibiting sclerostin, romosozumab will increase osteoblast activity and reduce osteoclast activity.

Bisphosphonates are often considered first line medications because they work to reduce all types of osteoporotic fracture, are reasonably safe, can be taken orally, and are relatively inexpensive. Alendronate (Fosamax) and risedronate (Actonel) are the preferred oral bisphosphonates based on the evidence of benefit and ideally should be taken weekly to improve effectiveness. Ibandronate (Boniva) is another oral bisphosphonate, but its antifracture data are weaker, considering there is no evidence that it prevents against hip fractures. Zoledronic acid (Reclast), an intravenous (IV) bisphosphonate, is approved for once-yearly treatment of postmenopausal osteoporosis or alternatively can be administered once every other year if used to prevent osteoporosis. Zoledronic acid is the only osteoporosis therapy shown to reduce all-cause mortality and may be a preferred option in those who cannot tolerate or are nonadherent with oral therapy. In patients with an osteoporotic hip fracture, it is essential that they receive treatment with a bisphosphonate after surgery to modify the subsequent risk of fracture at any site. There have been concerns that bisphosphonates started soon after surgery could disrupt bone remodeling and fracture healing, but current evidence shows that early administration of bisphosphonates does not delay fracture healing. Therefore they should be given soon after surgery to reduce subsequent fractures.

The ideal duration of bisphosphonate therapy is unknown. Low-risk patients may consider discontinuing therapy after 3 to 5 years once the risks and benefits are weighed. Low-risk patients are typically defined as those that have a *T*-score that improves into a low bone mass range or normal range and have not had recent fragility fractures. In low-risk individuals, benefits from the initial bisphosphonate course may last for another 5 years or longer. High-risk patients (e.g., patients with a *T*-score still below  $-2.5$ , having recent fragility fractures) could have the continued benefit of reducing vertebral fractures with bisphosphonates up to 10 years, but other types of fractures do not seem to be reduced and the risk of long-term complications (e.g., atypical fractures, osteonecrosis of the jaw, atrial fibrillation, myocardial infarction, esophageal cancer) may increase.

Side effects of oral bisphosphonates include esophageal and gastric irritation, musculoskeletal pain, and hypocalcemia. They must be taken with a full glass of water, and a 30- to 60-minute wait is required before eating or reclining to improve drug absorption and reduce gastrointestinal adverse effects. Intravenous bisphosphonates are associated with hyperthermia, episcleritis, uveitis, and hypocalcemia. Atypical femur fractures with bisphosphonates appear rare but are seen more frequently when used longer than 5 years. Young women are particularly prone to these fractures, which often require surgical intervention. Prodromal symptoms that have been linked to this syndrome include proximal femur pain and evidence of previous stress fracture or cortical thickness on x-ray. Osteonecrosis of the jaw is the other most feared complication with long-term bisphosphonate use, but again it is very rare. The actual incidence of both atypical fractures and osteonecrosis of the jaw are difficult to predict because these are largely point estimates from cohort studies with so few events seen in randomized trials.

Denosumab (Prolia) is approved for treatment of men and postmenopausal women with osteoporosis who are at high risk for fracture. It is given as a subcutaneous injection every 6 months. Similar to alendronate, risedronate, and zoledronic acid, denosumab may significantly reduce the risk of vertebral, nonvertebral, and hip fractures compared with placebo. Common side effects include skin rash, upper respiratory tract infections, arthralgias, back pain, diarrhea, and hypocalcemia. Long-term risks of atypical fractures and osteonecrosis of the

jaw have been reported with denosumab similar to bisphosphonates, so it is recommended to reevaluate the need for continued treatment after 3 to 5 years. Starting sequential therapy with another osteoporosis treatment after stopping denosumab is recommended to avoid posttreatment decline in bone mineral density, which starts around 9 to 10 months after the last dose.

Conjugated equine estrogen (Premarin) is an effective therapy at reducing all types of fractures, but is often reserved for women unable to use other options because of potential serious consequences. Complications associated with estrogen include thromboembolism, stroke, myocardial infarction, and some types of cancer. Raloxifene (Evista), on the other hand, improves BMD and reduces the risk of vertebral fractures but not nonvertebral or hip fractures. Unfortunately, raloxifene can exacerbate the vasomotor symptoms of menopause and increase the risk of thromboembolic events. Raloxifene may be considered in postmenopausal women with osteoporosis who cannot tolerate bisphosphonates, need sequential therapy after stopping an osteoporosis treatment, or in patients with a high breast cancer risk. A combination of bazedoxifene (a new selective estrogen receptor modulator) with conjugated equine estrogens (Duavee) has been approved for prevention of postmenopausal osteoporosis and treatment of vasomotor symptoms associated with menopause. It might prove to be an alternative to raloxifene, but it is still associated with many of the serious precautions seen with estrogen therapy.

Parathyroid hormones (i.e., teriparatide [Forteo], abaloparatide [Tymlos]) have recognized antifracture effects on both vertebral and nonvertebral sites. There are mixed data on whether teriparatide reduces the risk of hip fracture. Currently, therapy with either treatment should be limited to 2 years and reserved for patients at the highest fracture risk or refractory to other antiresorptives. Parathyroid hormone analog therapy can only be used for 2 years based on concerns for osteosarcoma, which has only been seen in laboratory animals exposed to high doses. Consequently, parathyroid hormones are contraindicated in patients with risk of osteosarcoma, such as those with Paget's disease of the bone, previous skeletal radiation, or unexplained elevations of alkaline phosphatase. Adverse effects may include orthostatic hypotension, hypercalcemia, nausea, arthralgia, risk of renal stones, and leg cramps. In addition to its approved indications, some experts recommend using one of the treatments that stimulate bone production via osteoblast activity in patients who experience an atypical fracture or for patients who have not improved on bisphosphonates. No evidence exists for combining multiple osteoporosis treatments at the same time. However, it is recommended that after a period of 2 years of using parathyroid hormones, sequential therapy with an antiresorptive should be started to avoid posttreatment bone loss.

Romosozumab (Evenity) is a monoclonal antibody that works by binding and inhibiting sclerostin. Sclerostin is a glycoprotein that inhibits osteoblast bone formation and, to a lesser degree, increases osteoclast bone resorption. There is robust evidence showing better effectiveness at reducing hip, vertebral, and nonvertebral fractures when compared head-to-head with alendronate over 24 months. The FDA rejected romosozumab at first because of concern for increasing the risk of myocardial infarction and stroke, but it was approved in April 2019 for postmenopausal women at high fracture risk. The increased risk of cardiovascular events is still a concern, but long-term safety studies are ongoing. Romosozumab should be reserved for patients at high fracture risk because of safety concerns and high costs. When romosozumab is used, it is given as two consecutive subcutaneous injections (total dose of 210 mg) once every month for up to 1 year. Similar to other treatments except bisphosphonates, sequential therapy with another antiresorptive medication is recommended to avoid bone loss after stopping treatment.

## PAGET'S DISEASE OF BONE

Method of

Ian R. Reid, MD

### CURRENT DIAGNOSIS

- Suspect the presence of Paget's disease in those patients with bone pain, bone deformity, isolated elevation of alkaline phosphatase, or lytic/sclerotic lesions on radiographs.
- Paget's disease is diagnosed from plain radiographs.
- Bone scintigraphy identifies the affected bones and allows some assessment of disease activity.
- Biochemical markers of bone turnover allow more precise assessment of turnover and response to therapy.
- Serum total alkaline phosphatase activity is the most cost-effective marker, although bone-specific alkaline phosphatase and procollagen type I N-terminal propeptide (PINP) are marginally more sensitive.

### CURRENT THERAPY

- Zoledronate (zoledronic acid, Reclast) 5 mg given as a single infusion over 15 minutes; retreatment is seldom required within 5 years.
- Alendronate (Fosamax) 40 mg/day for 6 months; retreatment may be required between 2 and 6 years.
- Risedronate (Actonel) 30 mg/day for 2 months; retreatment may be required between 1 and 5 years.

Paget's disease is a focal skeletal condition in which one or more bones has a clearly circumscribed area of increased turnover (Figure 1A). Either osteoblasts or osteoclasts may predominate at a given time, resulting in sclerosis or lysis, respectively. Areas that are initially lytic often become sclerotic later, and it is common to see both changes within the same bone (see Figure 1B). Unaffected areas of the skeleton are completely normal, in marked contrast to some rare congenital conditions which are sometimes (inappropriately) referred to as early-onset or juvenile Paget's disease. Such conditions (e.g., familial expansile osteolysis, idiopathic hyperphosphatasia) have different etiologies, clinical presentations, and responses to treatment when compared to Paget's disease.

### Etiology

Within pagetic bone, there is a loss of the usual tight control of bone cell function, and the bone-resorbing cells (osteoclasts) and bone-forming cells (osteoblasts) both exhibit overactivity. In the case of osteoclasts, this leads to local areas of bone loss, which can result in deformity or fracture. Osteoblast overactivity leads to the random laying down of new bone, which is disorganized in its structure, mechanically inadequate, and prone to deformity. Osteoblast overactivity can also lead to bone expansion, resulting in bone pain, premature arthritis (if it affects articular surfaces), and nerve compression (e.g., in the spine or skull). Figure 1B shows the effects of osteoblast and osteoclast overactivity on the structure of an affected tibia. The disease progresses along a long bone at a rate of about 1 cm per year, so most patients have had active disease for 1 or more decades before presentation. Typically, the disease progresses until the entire bone is involved. However, Paget's disease does not spread from one bone to another, so the number of affected bones remains constant throughout the disease course.

Paget's disease sometimes runs in families, and about 10% of patients are reported to have an affected relative. This observation has led to much work seeking genetic associations of the

**Figure 1** A, Bone scintigram in a patient with Paget's disease, demonstrating the multifocal nature of the condition and the presence of normal bone at other sites. B, Tibia affected by Paget's disease. The upper tibia is of increased density and width as a result of osteoblast overactivity, whereas the lower part of the affected bone shows a lytic region (between arrows) resulting from osteoclastic bone resorption. Below this, the bone is normal. Copyright I. R. Reid, used with permission.

condition. It is now apparent that mutations of the gene for sequestosome 1 are associated with Paget's disease in some families. Other research has focused on possible environmental causes, and a slow viral infection has been suggested. Evidence that the prevalence of Paget's disease has decreased in recent decades would be consistent with altered exposure to an environmental agent. However, both the genetic and environmental hypotheses fail to account for the focal nature of the condition, which in some ways resembles a benign neoplasm.

Altered gene expression in osteoblasts and bone marrow stromal cells from pagetic bone has been demonstrated recently, including increased levels of dickkopf-1, interleukin-1, and interleukin-6. These changes are likely to result in stimulation of osteoclast proliferation and inhibition of osteoblast growth, leading to development of the characteristic lytic bone lesions. This work suggests that the key abnormality may reside in the osteoblast, rather than the osteoclast, as was assumed in the past. Uncertainties remain regarding the primary abnormality giving rise to this condition.

### Epidemiology

Paget's disease is classically a condition of older adults, most patients being older than 60 years of age at diagnosis. There is a male preponderance in some studies. It is overwhelmingly a condition of individuals with European forebears, particularly from the United Kingdom and Western Europe (excluding Scandinavia), where about 6% to 7% of the older population have been affected. Among older white Americans, the prevalence was about 2%. There is evidence that prevalence and disease severity are both declining, possibly reflecting change in an environmental etiologic factor. It is extremely uncommon in individuals with predominantly Asian or Polynesian ancestry, although it is observed in some black populations.

### Clinical Presentation

The most common symptoms attributable to Paget's disease are bone and joint pain. The bone pain is typically worse at rest and may trouble patients particularly at night. With skull involvement, pounding headaches can result. If Paget's disease leads to deformity of joint surfaces, premature arthritis occurs. This is particularly common at the hips. Deformity in long bones can occur, and involvement of the

radius or weight-bearing bones of the lower limb often manifests in this way. Microfractures, which can be very painful, sometimes occur over the convexity of a deformed, weight-bearing bone. These can progress to complete fractures. Fractures can also occur through an area of active lytic disease in a weight-bearing bone.

Deafness is a common manifestation of Paget's disease and is caused by involvement of the bones of the middle ear or compromise of the eighth cranial nerve. More rarely, other neurologic syndromes can arise from nerve entrapment, including paraplegia as a result of spinal cord involvement.

Some pagetic patients are asymptomatic and are diagnosed because of an incidental finding of elevated circulating levels of alkaline phosphatase. The diagnosis may also result from an incidental radiographic finding, such as in studies of the urinary tract. Commonly, only one or two bones are involved, although disease may be more widespread. The pelvis, vertebral bodies, long bones, and skull are the most common sites, but almost any bone can be involved.

### Diagnosis

Serum alkaline phosphatase, the most widely available marker of osteoblast activity, is usually elevated; however, if only one bone is involved, this test can be normal. In any patient with an elevation of alkaline phosphatase, it is important to determine whether this is coming from liver or bone. This question is usually addressed by other liver function tests, although assays of bone-specific alkaline phosphatase and of other osteoblast-specific markers (e.g., procollagen type I N-terminal propeptide [PINP]) are available. If the elevation of alkaline phosphatase is bony in origin, it is important to rule out other bone conditions such as metastatic cancers (e.g., breast, prostate). This is usually done by identifying the sites of skeletal abnormality on a bone scintigram and then obtaining plain radiographs of the abnormal areas.

Paget's disease has a characteristic appearance on plain radiographs, showing either bony rarefaction or sclerosis (depending on whether the osteoclastic or osteoblastic phase is predominating), disorganization of trabecular architecture, and the other abnormalities already discussed (e.g., deformity). Bone biopsy is not usually necessary to confirm the diagnosis.

Other biochemical markers of osteoblast or osteoclast activity, such as breakdown products of bone collagen, have been used in Paget's disease. Total alkaline phosphatase, bone alkaline phosphatase, PINP or N-terminal telopeptide of type I collagen (NTX) identified more than 95% of pagetic subjects in one cohort of pagetic subjects, although the poorer precision of NTX reduced its utility in monitoring the effects of treatment. Osteocalcin, C-telopeptide of type I collagen, and urinary free deoxypyridinoline are less useful for assessment of baseline activity and monitoring response to therapy. Total alkaline phosphatase remains the most widely used test because of its low cost and wide availability.

### Treatment

Treatment of Paget's disease almost always relies on the potent bisphosphonates, primarily zoledronate (Reclast). These compounds have a very high affinity for the bone surface, where they remain for years. They are ingested by osteoclasts when bone is resorbed and inhibit a key enzyme in the mevalonate pathway, farnesyl pyrophosphate synthase. This results in disruption of the osteoclast cytoskeleton and cell death. Bisphosphonates are preferentially taken up at sites of high bone turnover, which accounts for their utility as bone scintigraphy agents, and therefore target active pagetic bone.

The preferred treatment at present is the potent intravenous bisphosphonate zoledronate (Reclast, generic), which is administered in a single dose of 5 mg over 15 minutes. It has been compared with the standard 2-month course of risedronate (Actonel) in two randomized, controlled trials. At 6 months, 96% of patients receiving zoledronate had a therapeutic response, compared with 74% of those randomized to risedronate ( $P < 0.001$ ). Alkaline phosphatase levels normalized in 89% of patients in the zoledronate group and in 58% of those in the risedronate group ( $P < 0.001$ ). Zoledronate showed a more rapid onset of action and superior effects on quality-of-life measures. Perhaps the most impressive data with zoledronate have been those from the open follow-up of responders in these studies. Six years after drug administration, relapse had occurred

in 0.7% of those receiving zoledronate but in 20% of risedronate-treated patients. Therefore, zoledronate produces much more sustained responses to therapy than have hitherto been possible.

Potent oral bisphosphonates such as alendronate (Fosamax, generic) and risedronate (Actonel, generic) have been widely used, but are usually less effective than zoledronate. These are administered daily over periods of 2 to 6 months and produce good disease control. The duration of treatment chosen in the pivotal clinical trials was arbitrary to some extent, and individual patients may require longer or shorter initial courses to achieve remission. Oral bisphosphonates have a very low bioavailability. Therefore, they must be taken in a fasting state, with a glass of water, and at least 30 minutes before consumption of food or other fluids. Positively charged ions (including calcium supplements, antacids, and mineral supplements) bind avidly to bisphosphonates and impair their absorption, so they must be taken at a different time of day. Potent bisphosphonates can cause irritation to the upper gastrointestinal tract and should not be prescribed to patients with inflammation or ulceration in that region. Patients should remain upright for 30 minutes after taking oral bisphosphonates to minimize the risk of reflux and associated esophagitis or ulceration.

The injectable bisphosphonate pamidronate (Aredia, generic) has been used in the past for treatment of Paget's disease. It is typically given as a series of infusions of 60 to 90 mg, each administered over a period of 1 to 2 hours. Pamidronate produces partial or complete remissions of disease activity that last for up to several years. The first administration of the drug may be accompanied by mild flu-like symptoms, which settle over 24 to 48 hours and usually do not recur. Their resolution can be hastened by the use of paracetamol (acetaminophen, Tylenol) or similar agents.

Potent bisphosphonates can cause mild hypocalcemia, which is usually asymptomatic and not a cause for concern. However, in patients with marked vitamin D deficiency, hypocalcemia can be more severe and sustained. Therefore, it is important to ensure that patients are vitamin D sufficient before receiving these drugs—a serum 25-hydroxyvitamin-D level greater than 40 nmol/L is more than adequate. Some physicians prescribe calcium to patients receiving bisphosphonate therapy (given in the evening if the oral bisphosphonate is given in the morning) as a further protection against hypocalcemia.

In the past, the weak bisphosphonate etidronate (Didronel) was used to treat Paget's disease. This is much less effective than the agents discussed previously. If used in high doses or for more than a few months, it carries the risk of producing osteomalacia, which can lead to bone pain and fractures. Therefore, it no longer has a place in the treatment of Paget's disease. Calcitonin (Miacalcin Injection) has also been relegated to an historical role only, because its efficacy is much less than that of the potent bisphosphonates and its effects are rapidly reversed after cessation of therapy. Denosumab (Prolia)<sup>1</sup> has some efficacy, but also appears to be inferior to zoledronate.

There are several philosophical approaches to Paget's disease management, none of which is strictly evidence based. There is general agreement that patients with symptoms attributable to Paget's disease should receive treatment. This is clear-cut in patients who have bone pain at the site of a pagetic lesion, but it is a common observation that antipagetic drugs can produce variable degrees of improvement in pain from joints adjacent to pagetic bone. Patients with neurologic complications from spinal cord or other nerve entrapments also improve with antipagetic therapy.

Treatment aimed at preventing complications of Paget's disease is variably endorsed, because there is no clinical trial evidence that treatment prevents the progression of deformity, the development of pagetic symptoms, or fracture. However, it is clear that treatment leads to a restoration of normal bone histology (Figure 2) and radiographic healing of lytic lesions and that, in the absence of such intervention, both bone lysis and deformity progress. It seems unreasonable to withhold safe therapies that are able to halt histologic and radiologic disease progression. Therefore, many experienced physicians endorse the provision of antipagetic therapy for individuals with lytic lesions in long bones; lesions at sites that are likely to lead

**Figure 2** Section of a bone trabecula affected by Paget's disease, viewed under polarized light to show orientation of lamellae. In the center of the trabecula, the collagen fibers are chaotically laid down (woven bone), consistent with active Paget's disease. Over the outer surfaces, collagen is organized in parallel lamellae, indicating the restoration of normal bone microarchitecture after treatment with alendronate. Reprinted with permission from: Reid IR, Nicholson GC, Weinstein RS, et al: Biochemical and radiologic improvement in Paget's disease of bone treated with alendronate: A randomized, placebo-controlled trial. *Am J Med* 1996;101:341-48.

to neurologic complications, arthritis, or deformity; or involvement of the skull that could compromise hearing. Expert opinion also supports the use of antipagetic therapy before elective surgery on pagetic bone, because this approach reduces the vascularity of pagetic bone and results in less perioperative blood loss. On the other hand, Paget's disease in asymptomatic patients whose future risk of complications is thought to be low (e.g., with involvement of the ilium) is commonly managed without specific pharmaceutical intervention, although the availability of a safe, single-dose treatment with zoledronate is increasing the inclination to treat.

When providing treatment targeted at these goals, it is important to consider how adequacy of therapy can be judged. In the case of patients with pain, maximal relief of pain is an important endpoint. Lytic lesions should be treated and monitored with sequential radiographs until healing is apparent. Activity at other sites can be assessed indirectly with biochemical markers of bone turnover, although these are much less sensitive in patients with monostotic disease. In this context, there can be considerable residual activity at a single affected site without the markers being abnormal. Bone scintigrams provide the most sensitive method of assessing local disease activity.

In the past, Paget's disease caused substantial morbidity in the elderly population. However, it is now possible to achieve adequate and sustained disease control with use of intravenous zoledronate. Prompt use of these agents, when indicated, can be expected to halt disease progression and to effectively prevent the development of significant complications from this condition.

# POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

Method of

Mark A. Matza, MD, MBA; and Sebastian H. Unizony, MD

## CURRENT DIAGNOSIS

### Primary Polymyalgia Rheumatica

- Age is greater than 50 years.
- Symptoms include pain and stiffness involving the shoulder and hip girdles, and sometimes the neck and lower back. Symptoms are worse after immobilization (e.g., morning) and improve with activities.
- Constitutional symptoms such as fever, fatigue, and weight loss can be present. Peripheral arthralgias or arthritis (e.g., wrists) occasionally occur.
- Only 15%–20% of patients with primary or isolated polymyalgia rheumatica (PMR) develop giant cell arteritis (GCA).
- Upon disease onset, acute-phase reactants (erythrocyte sedimentation rate and C-reactive protein concentration) are typically elevated but can rarely be normal.
- Ultrasound can be used to assess for synovitis, tenosynovitis, or bursitis in the shoulders and hips.

### Giant Cell Arteritis

- Age is greater than 50 years.
- Acute-phase reactants (erythrocyte sedimentation rate and C-reactive protein concentration) are elevated in approximately 95% of the cases before treatment with glucocorticoids is initiated.
- Symptoms include new-onset headaches (often temporal), scalp tenderness, jaw or tongue claudication, and vision impairment such as diplopia, amaurosis fugax, episodic blurry vision, and/or blindness.
- Approximately 50% of patients with GCA also have PMR symptoms.
- Constitutional symptoms such as fever, fatigue, and weight loss are often present. In addition, about 10% of GCA cases present only with fever and without other cranial or PMR manifestations.
- Temporal arteries may be prominent, beaded, or tender on examination, but they may also be normal. Vascular bruits and decreased pulses can be auscultated in the presence of large-vessel disease.
- Temporal artery biopsy is the diagnostic test of choice for patients presenting with cranial symptoms, but false-negative results may occur.
- Ultrasound can also be diagnostic in the appropriate clinical scenario when hypoechoic circumferential mural thickening (i.e., halo sign) is identified in the temporal arteries.
- Noninvasive cross-sectional imaging, including computed tomography angiography, magnetic resonance angiography, or positron emission tomography, can be used to evaluate for large-vessel involvement (e.g., aorta, subclavian arteries, axillary arteries).

## CURRENT THERAPY

### Primary Polymyalgia Rheumatica

- Prednisone at a dose of 15–20 mg/day (or equivalent glucocorticoid) is used initially. The starting dose should be continued for 1 full month to suppress the disease effectively and then tapered to 10 mg by the end of month 2 of treatment. Prednisone can then be tapered off at the rate of 1 mg/month for a total prednisone duration of approximately 1 year.

- Should symptoms recur with tapering, the glucocorticoid dose should be increased temporarily, followed by a new tapering attempt.
- Methotrexate<sup>1</sup> and tocilizumab (Actemra)<sup>1</sup> can be considered for relapsing patients or patients at high risk for glucocorticoid toxicity (e.g., poorly controlled diabetes mellitus).

### Giant Cell Arteritis

- Treatment should not be delayed while awaiting confirmatory testing (e.g., temporal artery biopsy), given the risk of blindness (15%–20%) in untreated patients.
- Prednisone<sup>1</sup> at a dose of 1 mg/kg or approximately 60 mg (or equivalent glucocorticoid) should be started immediately if the diagnosis is suspected.
- Pulse dose methylprednisolone<sup>1</sup> (1 g daily for 3 days) should be considered if vision changes occur (e.g., amaurosis fugax, monocular permanent vision loss).
- Tocilizumab (Actemra) is an effective drug for remission maintenance and glucocorticoid-sparing in GCA patients both with new-onset and relapsing disease.
- Once the disease activity is controlled, glucocorticoids are tapered off gradually.
- In patients receiving only glucocorticoids, tapers usually last 12 to 24 months, but relapses are common (up to 70% of cases), requiring dose adjustments and prolongation of glucocorticoid therapy.
- In patients receiving tocilizumab, glucocorticoid tapers are typically shorter (e.g., 6 months), and disease relapses are seen in only approximately 30% of the patients within 1 year.
- Approximately 40% of GCA patients in remission after treatment with tocilizumab (162 mg weekly) for 1 year may be able to discontinue tocilizumab and remain in remission for at least 2 more years.
- The use of low doses of aspirin<sup>1</sup> to prevent ischemic complications of GCA is controversial.
- Prophylaxis for glucocorticoid-induced osteoporosis with bisphosphonates, calcium, and vitamin D should be considered in all patients receiving glucocorticoids.
- Immunizations according to the national guidelines (influenza and pneumococcus) should be administered to all GCA patients, especially when they receive glucocorticoids and tocilizumab.

<sup>1</sup>Not FDA approved for this indication.

Primary polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are related and often overlapping systemic inflammatory disorders that typically affect patients older than 50 years of age. Women are more commonly affected than men, and Caucasians more so than African Americans, Asians, and Hispanics. Symptoms range from proximal muscle aching in primary PMR to blindness in GCA. Both conditions are characterized by elevated serum inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]). Most patients quickly respond to glucocorticoids (e.g., prednisone), but many of them fail to maintain long-term disease control during or after glucocorticoid tapers. Interleukin (IL)-6 receptor blockade with tocilizumab (Actemra) in combination with up to 6 months of prednisone has demonstrated efficacy for remission maintenance, glucocorticoid sparing, and quality-of-life improvement in GCA randomized clinical trials. Preliminary evidence suggests that tocilizumab<sup>1</sup> might also be beneficial in some patients with primary PMR.

### Primary Polymyalgia Rheumatica

#### Clinical Presentation

Primary or isolated PMR is characterized by symmetric proximal joint pain and stiffness (i.e., shoulders and hips). The lifetime

<sup>1</sup>Not FDA approved for this indication.

risks for primary PMR in women and men older than 50 years of age are 2.4% and 1%, respectively. Disease onset can be acute or subacute, but patients sometimes delay seeking medical attention for days to weeks. Symptoms are classically worse early in the morning and after periods of immobilization (e.g., a “long commute”). Morning stiffness is generally prolonged greater than 45 minutes. Involvement of the peripheral joints (e.g., wrists, knees, and ankles) is rare. Weight loss, fatigue, anorexia, and low-grade fever can be seen. Physical examination is usually unrevealing. However, some patients may demonstrate tenderness and limited active range of motion of the shoulder and hip girdles, but synovitis (e.g., joint swelling, effusion, or erythema) is absent. Range of motion with passive limb movements is typically better.

Apart from occurring in isolation (i.e., primary PMR), PMR symptoms can be seen in nearly 50% of patients with GCA (as discussed later).

### Diagnosis

Diagnosis is made based on the clinical presentation and the exclusion of other conditions (e.g., rheumatoid arthritis, GCA, and regional noninflammatory rheumatism [such as rotator cuff tendinopathy]). Almost all patients demonstrate increased serum ESR and/or CRP at disease onset before treatment is started. Patients have negative rheumatoid factor and anti-CCP antibodies. The response to glucocorticoids (e.g., prednisone) is also often a telling indication of PMR: most patients experience dramatic clinical improvements within 24 to 48 hours. Ultrasound can be used to detect synovitis, tenosynovitis, or bursitis in the shoulders and hips. GCA occurs in approximately 15% to 20% of patients with primary PMR. Therefore, these patients should be queried closely to detect any symptoms that suggest GCA—namely headaches, scalp tenderness, jaw claudication, and visual disturbances.

A minority of patients with presentations of PMR eventually declare their true underlying disorder to be rheumatoid arthritis. Such patients can convert from seronegative to seropositive (i.e., positive rheumatoid factor or anti-CCP antibodies) at some point during follow-up. The presence of distal joint symptoms (e.g., small joints of the hands) might help predict the evolution to rheumatoid arthritis (RA), but the development of RA cannot be predicted if seronegative at baseline. Rarely, late-onset spondyloarthritis initially can be confused with PMR.

### Treatment

Patients with primary PMR are treated with glucocorticoids. Prednisone at a dose of 15 to 20 mg is often used to induce disease remission. Symptoms should dramatically improve within 1 to 2 days. Infrequently, patients require higher doses (e.g., 25 to 30 mg) over a longer period (e.g., 5 to 7 days) to achieve clear responses. However, in cases that do not demonstrate classic responses to glucocorticoids, ruling out other conditions (e.g., GCA) is mandatory. The initial glucocorticoid dose is maintained for about 4 weeks to ensure clear sustained resolution of the clinical manifestations and normalization of the inflammatory marker values. A gradual glucocorticoid taper is then begun to maintain the disease in remission. Patients usually taper the daily prednisone dose by 2.5 to 5 mg every 2 to 4 weeks until the dose of 10 mg is achieved. Subsequently, the taper progresses at a rate of 1 to 2.5 mg every 2 to 4 weeks until glucocorticoid discontinuation. The total duration of the treatment in the absence of a disease flare is about 12 to 18 months. Unfortunately, many patients relapse and require an increased prednisone dose and renewed tapering attempt once the disease is again controlled.

Most patients can eventually taper off prednisone completely; however, in some, a low dose of prednisone may be required to prevent the recurrence of symptoms. For patients with primary PMR who require excessive prednisone exposure to maintain disease control, methotrexate<sup>1</sup> or IL-6 blockade therapy with tocilizumab (Actemra)<sup>1</sup> should be considered.

<sup>1</sup> Not FDA approved for this indication.

## Giant Cell Arteritis

### Clinical Presentation

GCA is the most frequent form of primary vasculitis in adults. The disease causes granulomatous inflammation in the large arteries, including the aorta and its primary branches—particularly the vessels of the head and neck. The epidemiology of GCA is identical to the one of primary PMR, with the exception that GCA is three times less frequent. The lifetime risks for GCA in women and men older than 50 years are 1% and 0.5%, respectively. The incidence of GCA increases with each decade and peaks around 73 years of age.

The onset of GCA is often subacute or acute. The most frequent clinical manifestations of this condition can be divided into four not mutually exclusive categories: cranial manifestations, PMR symptoms, constitutional symptoms, and signs and symptoms of large artery involvement.

The cranial manifestations of GCA include headache, jaw claudication, scalp tenderness, temporal artery abnormalities (e.g., prominent arteries, palpable beading, decreased pulsation, or tenderness), and visual symptoms (e.g., diplopia, amaurosis fugax, transient blurred vision, and blindness). The most frequent cranial manifestation is headache (60% to 70% of cases), which may involve not only the temporal region but also other cranial locations. The only unique feature of the GCA-related headache is that it is new for the patient. Jaw claudication, which is reported by 30% to 50% of patients, is very specific of GCA. Typically, patients with jaw claudication notice pain when eating foods that require vigorous chewing, such as meats. Jaw pain is exertional and resolves with mandibular rest. Less frequently, patients may report tongue or pharyngeal pain during mastication and swallowing.

About one-third of patients with GCA have visual manifestations, including diplopia, blurred vision, amaurosis fugax, and the most serious GCA complication—permanent vision loss or blindness. Unlike the slowly progressive blurred vision seen in elderly patients with cataracts, the blurred vision reported by GCA patients is usually monocular (although it can be bilateral), acute, and short lived (e.g., minutes to hours). Blindness, which develops in 8% to 20% of patients, occurs in greater than 90% of the cases before GCA is suspected and treatment with glucocorticoids is initiated. This complication can develop abruptly but, more often, is preceded by episodes of blurred vision or amaurosis fugax. By the time blindness occurs, most patients have increased inflammatory markers in serum and also report other clinical manifestations (headaches, jaw claudication, PMR symptoms, etc.). The mechanism of vision loss in GCA is in the great majority of the cases ischemia of the head of the optic nerve (so-called anterior ischemic optic neuropathy). Unfortunately, blindness is generally irreversible.

Approximately 50% of patients with GCA also have PMR symptoms. In addition, most patients with GCA and primary PMR report nonspecific manifestations such as fever, malaise, fatigue, anorexia, or weight loss. At times, fever is the only presenting symptom of GCA, and high clinical suspicion is required to order confirmatory tests to make the diagnosis (e.g., temporal artery biopsy). Finally, despite the fact that nearly all patients have some degree of large-vessel involvement at least histologically, only about 30% of patients develop clinical manifestations related to it. Vascular inflammation can cause structural damage of the walls of elastic arteries, leading to dilation and dissection, as well as narrowing of the lumens of muscular arteries resulting in stenosis, occlusion, and distal ischemia. The most frequently affected vessels include the thoracic and abdominal aorta, and the vertebral, carotid, subclavian, axillary, and brachial arteries. Signs and symptoms related to the involvement of limb arteries may include extremity claudication, decreased peripheral pulses, blood pressure asymmetries, and vascular bruits. Involvement of the vertebral and, less often, the carotid circulation may cause transient ischemic attack and stroke. Aortic disease may lead to aortic aneurysm (mainly in the thoracic aorta) and less frequently

aortic dissection. In most patients, however, large artery inflammation and subsequent arterial damage are clinically silent and only detected by vascular imaging.

### Diagnosis

GCA is diagnosed based on a combination of clinical presentation, laboratories, imaging, and biopsy. The temporal arteries may be bulging, irregular, or tender on examination; however, they may also be normal, even if temporal artery biopsy subsequently confirms the presence of GCA. The laboratory hallmark of GCA is the elevation of the inflammatory markers ESR and CRP, which is seen in ~95% of untreated patients with new-onset disease. Although elevation of the inflammatory markers is highly sensitive for the diagnosis of GCA, the specificity of these tests is low (~30%).

A characteristic pattern of inflammation in a temporal artery, with granulomatous infiltrates composed of lymphocytes, macrophages, and giant cells, is the most specific test for the diagnosis of GCA. Because skipped lesions (i.e., diseased segments alternating with normal-appearing tissue) are common, multiple sections of biopsies of at least 1 to 2 cm should be examined to increase the diagnostic yield. In addition, simultaneous or sequential bilateral temporal artery biopsies may decrease the false-negative biopsy rate in up to 13% of cases.

Vascular imaging (i.e., ultrasound, MRA, CTA, and PET) has been increasingly incorporated into the care of patients with GCA. Changes suggestive of vasculitis can be found in the arterial walls and/or lumens. Characteristic mural lesions may include circumferential wall thickening or edema, contrast enhancement, and <sup>18</sup>fluorine-2-deoxy-D-glucose (FDG) uptake. Luminal lesions may include stenosis, occlusion, and aneurysmal dilatation. Temporal artery ultrasound scanning may reveal a characteristic “halo sign,” caused by edema within and around the blood vessel wall. Several studies and meta-analyses have estimated the sensitivity (55% to 100%) and specificity (75% to 100%) of the halo sign for the diagnosis of GCA compared with clinical diagnosis as the gold standard.

### Treatment

Treatment with high-dose glucocorticoids should not be delayed to obtain a temporal artery biopsy or ultrasound. A dose of prednisone<sup>1</sup> 1 mg/kg or approximately 60 mg (or prednisone equivalent) should be initiated promptly when a diagnosis of GCA is considered. Lower doses (e.g., 40 mg/day) can be used for individuals who are frail and elderly. If visual involvement has occurred, pulse dose methylprednisolone<sup>1</sup> 1000 mg daily for 3 days can be initiated, followed by high-dose oral glucocorticoids. The optimal duration of a prednisone taper in GCA is not certain. In one randomized clinical trial, the percentage of patients achieving sustained disease remission at 1 year was essentially the same regardless of whether patients received a 6-month or 12-month prednisone taper. Sustained remissions were achieved in only 14% and 18% of patients, respectively. Thus, although high-dose glucocorticoids are effective at controlling GCA and inducing remission in most patients, the great majority of patients experience disease flares whenever prednisone is tapered to a lower dose (e.g., <15 mg/day) or discontinued.

The interleukin-6 receptor blocker tocilizumab (Actemra) is now approved worldwide for the treatment of GCA in combination with glucocorticoids. The addition of tocilizumab leads to substantial improvement in the rate of glucocorticoid-free remissions at 1 year and a reduction in the cumulative prednisone dose by approximately 50%. Tocilizumab can be administered either intravenously (8 mg/kg each month)<sup>1</sup> or subcutaneously (165 mg each week). The high rate of treatment failure with regimens involving prednisone alone suggests that all patients without contraindications to tocilizumab (e.g., history of diverticulitis) should be treated with the combination

of tocilizumab and prednisone initially, followed by an aggressive prednisone taper designed to discontinue prednisone within 4 to 6 months. In a trial of the interleukin-6 receptor blocker tocilizumab, 42% of patients who completed 1 year of weekly tocilizumab in disease remission were able to discontinue treatment and maintain treatment-free remissions for at least 2 more years. Some patients, on the other hand, may require ongoing tocilizumab or even tocilizumab plus prednisone to maintain disease control. Patients who are not able to discontinue prednisone entirely can usually be controlled well with the combination of tocilizumab and low-dose prednisone.

Aspirin<sup>1</sup> (81 mg/day), which has been shown in some retrospective studies and a meta-analysis to reduce the incidence of vision loss, should be considered in all patients without contraindications. Prophylaxis for glucocorticoid-induced osteoporosis with bisphosphonates, calcium, and vitamin D should be implemented, particularly since GCA tends to afflict elderly individuals, many of whom have significant comorbidities at baseline, including osteoporosis. Prophylaxis for *Pneumocystis jiroveci* pneumonia may also be considered in appropriate clinical circumstances, particularly when prolonged or recurrent courses of high-dose glucocorticoids are required in patients with underlying chronic pulmonary conditions (e.g., emphysema).

## PSORIATIC ARTHRITIS

Method of

William Tillett, MD; and Laura C. Coates, MBChB, PhD

### CURRENT DIAGNOSIS

- Psoriatic arthritis (PsA) is a form of inflammatory arthritis genetically associated with the spondylarthritides (SpA) (e.g., ankylosing spondylitis, reactive arthritis [ReA], inflammatory bowel disease [IBD], arthritis).
- It is usually diagnosed in the presence of psoriasis (personal or family history), negative rheumatoid factor, and other typical features such as dactylitis and nail involvement.
- Presentation is highly heterogeneous with potential involvement in multiple domains (arthritis, enthesitis, dactylitis and axial disease, skin plaques, and nail dystrophy) as well as SpA-related extraarticular manifestations (IBD and uveitis).

<sup>1</sup> Not FDA approved for this indication.

## CURRENT THERAPY

- Therapy for PsA aims to control musculoskeletal inflammation (arthritis, enthesitis, dactylitis, and axial disease) and cutaneous manifestations (skin plaques and nail dystrophy).
- Treatment usually follows a step-up approach with non-steroidal antiinflammatory drugs (NSAIDs), topical therapies (for skin plaques), conventional synthetic disease-modifying antirheumatic drugs (DMARDs; e.g., methotrexate [Trexall], leflunomide [Arava]<sup>1</sup>) and biologics (TNF, IL12/23, IL17, and IL23 inhibitors), and targeted synthetic DMARDs (apremilast [Otezla] and Janus kinase [JAK] inhibitors).
- PsA is commonly associated with comorbidities such as depression and increased cardiovascular risk with elements of the metabolic syndrome, which may affect therapeutic choice.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Psoriatic arthritis (PsA) is a destructive inflammatory arthritis occurring in up to 20% people with psoriasis. Psoriasis affects approximately 2% to 3% of the U.S. population. The exact prevalence of PsA among the general population has been difficult to estimate because of the heterogeneous nature of the disease and variety of different classification criteria. The lowest prevalence estimates come from Japan (0.001%), and the highest come from Italy (0.42%). Data from recent studies have been more consistent with prevalence estimates of 0.16% in North America and 0.19% in the United Kingdom. PsA affects men and women equally and can develop at any age, but it typically occurs in the 10 to 15 years after the diagnosis of psoriasis, usually between 30 and 50 years of age. The incidence of developing PsA among people with psoriasis is approximately 2% per year. In a recent prospective study of patients with psoriasis, 51 of 464 patients developed PsA over an 8-year follow-up period.

### Risk Factors

A number of risk factors have been identified that appear to increase the risk of developing PsA. The presence of HLAB27 is an established genetic risk factor. Increased rates of PsA are seen among those with more severe psoriasis (relative risk [RR] 5.4,  $P = 0.006$ ). The site of psoriasis may also be important, and some reports suggest that intergluteal and scalp psoriasis confer an increased risk of developing PsA. Nail psoriasis (pitting, onycholysis, subungual hyperkeratosis, and oil drop discoloration) is also associated with an increased likelihood of developing PsA. Nail dystrophy occurs in 80% of patients with PsA but only 20% of patients with psoriasis alone. Obesity is a well-documented risk factor for developing both psoriasis and PsA. The higher the body mass index (BMI), the higher the risk of developing arthritis. Alcohol is a potentially modifiable risk factor with associated increased rates of both psoriasis and arthritis. Data relating to smoking as a risk factor are mixed, with reports suggesting both increased risk and a potentially protective effect.

### Pathophysiology

#### Genetics

The exact etiology of PsA remains uncertain. Genetics are known to play a central role. However, the number of genes identified do not account for the strong heritability seen clinically. Approximately 40% of people with PsA will have a first-degree relative with the condition. PsA appears to have a stronger association with *HLA-B* and *HLA-C* alleles, whereas psoriasis is associated with the *HLA-C* allele. The *HLA-Cw6*, *B57*, *DR7*, and *B17* alleles are all associated with early-onset psoriasis. The *HLA-B7*, *HLA-B27*, *DR4*, *38*, and *DR7* alleles are associated with PsA.

The *HLA-B39*, *B27*, and *DR7* alleles are associated with more progressive/destructive disease, whereas the *HLA-B22* allele appears to be protective.

### Immunopathology

Tissue-specific autoantibodies have not yet been identified. The inflammatory arthritis is characterized by hypervascularity, hypertrophy/tissue proliferation, and inflammatory cell infiltrate. Lymphocytes (particularly Th17 cells) and dendritic cells are known to play an important role. The cytokine profile for PsA shows a predominance of TNF- $\alpha$ , IL-1, and IL-10.

### Infection and Trauma

The temporal link between infections and the development of PsA raises the possibility of a pathologic role of bacteria or viruses. There are higher rates of both psoriasis and PsA in HIV-endemic areas, and psoriasis is often more extensive among patients with HIV. The gut microbiome is an area of current interest in which disturbance of the normal microbiota is being investigated as a possible immunologic trigger. Finally, a small number of epidemiologic studies have made the association with trauma and the subsequent development of PsA, but reports are inconclusive.

### Prevention

There are no proven strategies to prevent the development of PsA, but observational studies have suggested that biologic use may delay or prevent the onset of arthritis, and ongoing research is focusing on this question. Current preventive strategies focus on early diagnosis and prevention of damage accumulation, loss of function, and disability. The treatment of comorbid conditions, pre-drug-treatment screening, and drug dose optimization to minimize drug exposure are important prevention strategies.

Early diagnosis and treatment strategies focus on the prevention of damage and subsequent disability. Untreated inflammation results in damage to the articular surface and surrounding tissues with subsequent loss of movement, pain, limitation of function, and reduced quality of life. Erosion of the surface of the bone, narrowing of the joint space, and new bone formation (osteoproliferation) cause pain, reduced movement, and physical dysfunction. Observational studies have suggested that delay of diagnosis by as little as 6 months results in more damage and poorer physical function.

In the United Kingdom, annual screening of patients with psoriasis for arthritis is recommended using the Psoriasis Epidemiology Screening Tool (PEST) questionnaire. The questionnaire asks patients with psoriasis if they have ever had pain in their joints, if a doctor has ever told them they have arthritis, if they have had nail pitting, if they have had pain in their heel, and if they have ever had a completely sausage-like swelling of a finger or toe without reason. A score of 3 or more is positive.

### Clinical Manifestations

PsA is classified with the seronegative spondyloarthropathies that include axial spondyloarthritis (axSpA), reactive arthritis (ReA), and inflammatory bowel disease (IBD) arthritis. The seronegative spondyloarthropathies share many of the clinical and genetic features, such as *HLAB27* association, enthesopathy (inflammation at the tendon and ligament insertion to the bone), association with uveitis, spondyloarthritis, and asymmetric peripheral arthritis.

The following are classical patterns of PsA, although there is often overlap among these groups:

- Polyarthritis (five or more joints)
- Oligoarthritis (four or fewer joints)
- Monoarthritis (one joint)
- Spondyloarthritis (axial disease)
- PsA mutilans (digital shortening/telescoping caused by onycholysis)

Polyarthritis is the most common form, occurring in approximately 60% cases, whereas mutilans only occurs in 5% cases.

The signs of PsA are heterogeneous and include psoriasis, nail dystrophy, joint disease, enthesitis, dactylitis, and spondyloarthritis. These are discussed in the following sections.

## Psoriasis

In its most common plaque form, the skin lesions of psoriasis are characterized by scaly plaques on the extensor surfaces. Psoriasis can be hidden in the scalp, ear, natal cleft, and umbilicus. Most patients develop psoriasis before developing arthritis, but a small proportion, approximately 10%, will develop psoriasis after the arthritis. A proportion of patients present with musculoskeletal symptoms but are unaware that they have skin psoriasis, which can be subtle in sites such as the hairline, intergluteal region, behind the ear, or umbilicus. Other patterns of psoriasis include guttate (small spots that can be widespread), palmar-plantar (palms and soles), and inverse (affecting the flexural creases).

## Nail Dystrophy

Pitting (fine pits), onycholysis (lifting of the distal nail plate), hyperkeratosis (thickening of the nail plate), and oil drop discoloration (salmon-colored spots) are the most common nail manifestations of psoriasis. Other features include leukonychia, Beau lines, and longitudinal ridging. Nail pitting can be a clinically subtle but helpful sign to distinguish PsA from other types of arthritis. Nail dystrophy itself is associated with an increased risk of developing arthritis and can be the only manifestation of psoriasis.

## Joint Disease

Inflammatory arthritis is the hallmark of PsA. The joints appear swollen and hot and are stiff and painful. The recognized patterns of joint involvement are inflammatory polyarthritis (five or more joints involved, which may be symmetric or asymmetric in distribution), oligoarticular (fewer than five joints), monoarticular (one joint), axial (spondyloarthritis), and mutilans (digital shortening caused by onycholysis).

## Enthesitis

Inflammation at the insertion of the tendon or ligament to the bone (rather than the mid-portion of the tendon, which is more likely to be an overuse tendinopathy) may be a sign. Many sites can be affected by enthesitis. However, the most readily assessable are the Achilles insertion to the calcaneus, the lateral epicondyle of the elbow, and the medial condyle of the femur. Enthesitis is not commonly seen in rheumatoid arthritis and can be a useful distinguishing sign. The assessment of enthesitis can be challenging, as many enthesal insertions correlate anatomically with myofascial tender points seen in fibromyalgia. Ultrasonography can be helpful to examine for sonographic features of enthesitis, such as insertional hypervascularity, osteoproliferation, and erosion.

## Dactylitis

Also known as *sausage finger*, dactylitis is the swelling of an entire digit. Dactylitis occurs on 50% of patients with PsA at some point in their disease. The inflammation is at the joint, tendon, and extracapsular tissues.

## Spondyloarthritis

Spondyloarthritis affects up to 50% of patients with PsA, but cohort studies have suggested that only one-half of these patients have symptoms of inflammatory back pain. Inflammatory back pain typically occurs before 40 years of age, will wake people in the second half of the night, are characteristically stiff in the morning, and feel better with exercise and nonsteroidal antiinflammatory drugs (NSAIDs). The radiographic features are of sacroiliitis (sclerosis, erosions, and fusion), which can be asymmetrical, and syndesmophytes (bone formation that can be fine or chunky), which can flow between vertebrae, causing fusion.

Other manifestations include uveitis (approximately 30% patients, RR 3.5 compared with the general population), metabolic syndrome (elevated BMI, hypertension, and dyslipidemia), IBD (Crohn disease, RR 2.9 compared with the general population), and depression.

## BOX 1 Classification Criteria for Psoriatic Arthritis

Confirmed inflammatory articular disease (joint, spine, or enthesal) with at least three points from the following features:

1. Current psoriasis (two points)
2. Past personal history or family history of a first- or second-degree relative with psoriasis (one point each)
3. Dactylitis (one point)
4. Juxtaarticular new bone formation (ill-defined ossification near joint margins—excluding osteophyte formation—on plain hand and feet radiographs; one point)
5. Rheumatoid factor negativity (one point)
6. Psoriatic nail dystrophy (onycholysis, pitting, and hyperkeratosis observed on current physical examination; one point)

## Diagnosis

In the absence of specific antibodies, the diagnosis of PsA remains clinical. The Classification Criteria for Psoriatic Arthritis (CASPAR) criteria were developed for use in clinical trials to ensure a consistent trial population and were also shown to apply in the clinical setting as diagnostic criteria (Box 1).

## Differential Diagnosis

The other seronegative spondyloarthropathies are in the primary differential diagnosis. The absence of an infectious trigger or concurrent IBD discount ReA and IBD arthritis. The presence or history of psoriasis (or a first-degree relative with psoriasis) is the most useful distinguishing feature in differentiating from axial spondyloarthritis.

Osteoarthritis is a common and clinically challenging differential, particularly in the hands. Young age of onset, the presence of nail psoriasis at the affected ray, and radiographic features of PsA are the most useful distinguishing features.

Gout is an important differential for two reasons. First, a history of a swollen toe is often mistaken as gout (or podagra). Second, uric acid is commonly mildly elevated in patients with PsA. A careful history and examination for other clinical features of PsA can be helpful, such as history of psoriasis, nail dystrophy at the affected toe, enthesitis, or axial symptoms. Ultrasonography to examine for sonographic features of crystal deposition or aspiration to examine for crystals may be required. Concurrent gout and PsA are rare but recognized.

Investigations to support the diagnosis include the following:

- Rheumatoid factor (RhF) and anticyclic citrullinated peptide (ACPA or Anti-CCP) are usually negative.
- Inflammatory markers such as C-reactive protein (CRP), plasma viscosity (PV), and erythrocyte sedimentation rate (ESR) can often be normal and do not exclude inflammatory joint disease.
- Plain radiographs can be helpful to distinguish PsA from rheumatoid arthritis (RA) or osteoarthritis (OA). The plain radiographic features of PsA are erosions, joint space narrowing, osteoproliferation (bone formation), ankyloses (fusion), and, in the mutilans form of the disease, osteolysis (bone resorption).
- Magnetic resonance imaging (MRI) and ultrasonography are both frequently used to assess for spondyloarthritis and articular and enthesal inflammation, respectively.

## Therapy (or Treatment)

The treatment of PsA aims to control inflammation related to the disease to improve symptoms, maximize function, and prevent long-term complications. Different therapies may be chosen dependent on the domains of disease (arthritis, skin, nails, enthesitis, dactylitis, axial disease) that are active in any one individual patient. In general, treatment of PsA follows a step-up

approach with treatment escalated in case of nonresponse to the previous therapy. Ideally, treatment should follow a treat-to-target approach in which a treatment target, such as minimal disease activity (MDA), is reassessed at each visit, and therapy is assessed if the target is not met. This approach has been shown to improve disease control in the Tight Control of Inflammation in Early Psoriatic Arthritis (TICOPA) trial.

NSAIDs are used frequently to help manage pain and stiffness but do not seem to have a significant effect on the disease course. Particularly in the early stages of disease or in the case of disease flares, parenteral steroids (intraarticular or intramuscular) are used to control inflammation quickly, although there can be a risk of psoriasis flare on withdrawal of systemic steroids. The mainstay of therapy in PsA are disease-modifying antirheumatic drugs (DMARDs), which are grouped into three categories:

1. Conventional synthetic DMARDs (methotrexate, sulfasalazine [Azulfidine],<sup>1</sup> leflunomide [Arava]<sup>1</sup>)
2. Biologic DMARDs (tumor necrosis factor [TNF] inhibitors, interleukin 12/23, 17, or 23 inhibitors)
3. Targeted synthetic DMARDs (phosphodiesterase 4 [PDE4] and Janus kinase [JAK] inhibitors)

Conventional synthetic DMARDs (csDMARDs) are commonly used to treat skin psoriasis and peripheral arthritis. The use of these drugs is based on their efficacy in psoriasis and in rheumatoid arthritis, although the data supporting their efficacy in PsA are relatively lacking. The most commonly used csDMARD is methotrexate, although the placebo-controlled Methotrexate In PsA (MIPA) trial did not show a significant effect of methotrexate over placebo. Many rheumatologists discounted these data because of flaws in the study design (low target dose used, poor completion rate). Interestingly, in the supplementary data from the study, it seemed that patients with polyarticular disease responded much better to methotrexate than those with oligoarthritis. This may be caused by a differential response in different forms of arthritis, but it most likely relates to the sensitivity of the outcome measures used. The Study of Etanercept and Methotrexate in Combination or as Monotherapy in Subjects with Psoriatic Arthritis (SEAM-PsA) study compared first-line etanercept versus methotrexate and showed superiority for etanercept, but with 23% achieving MDA on methotrexate alone. Given that there is proven efficacy for the use of methotrexate in psoriasis, this drug is useful to manage patients with both peripheral arthritis and active psoriasis. Sulfasalazine (Azulfidine)<sup>1</sup> is also commonly used and has a number of studies supporting its efficacy. However, a Cochrane review in 2000 summarized the results of these studies and concluded that although it was effective, the effect size was relatively small. Leflunomide (Arava)<sup>1</sup> is the conventional DMARD with the strongest trial data. The Treatment of Psoriatic Arthritis Study (TOPAS) in 2004 confirmed the efficacy of leflunomide versus placebo but came shortly before breakthrough trials with biologic therapies with superior results.

Despite the mixed data on the csDMARDs and their effect on clinical measures of disease activity, none of them have any proven effect on disease progression in the form of radiographic damage. Observational studies have suggested that early use of therapies and higher dosages used in more recent years may be associated with less radiographic damage, but this has not been formally tested. Recent studies have compared conventional and biologic drugs in early PsA. The Comparison Between Adalimumab Introduction and Methotrexate Dose Escalation in Patients with Inadequately Controlled Psoriatic Arthritis (CONTROL) study took patients with active disease despite moderate (15 mg) doses of methotrexate and compared methotrexate dose escalation with addition of adalimumab (Humira)<sup>1</sup>. This showed superiority in MDA responses for adalimumab at week 16. There are very limited data in treating other domains of PsA, such as enthesitis and dactylitis, for which only small open-label studies are available. In axial PsA, as in other axial spondylarthritides,

there is no evidence of efficacy of conventional drugs, and treatment algorithms rely on biologic therapies.

A number of biologic DMARDs (bDMARDs) have proven efficacy in PsA, and four have been licensed for use in this condition. There are five different TNF inhibitors (adalimumab [Humira]<sup>1</sup>, certolizumab [Cimzia], etanercept [Enbrel], infliximab [Remicade], and golimumab [Simponi]), which have all shown efficacy across the key domains of PsA, including arthritis, enthesitis, dactylitis, skin disease, and nail disease. They have all shown long-term efficacy and retardation of radiographic damage, confirming their effect on structural progression. In most of the studies, around 50% of the patients were also receiving a concomitant csDMARD (usually methotrexate). However, in PsA, in contrast with rheumatoid arthritis, there was no significant difference in efficacy seen with combination treatment over monotherapy biologics. A randomized trial recently addressed this point, comparing methotrexate monotherapy, etanercept monotherapy, and the combination in a placebo-controlled trial. This study confirmed superiority of both etanercept arms over methotrexate monotherapy but did not find a difference in effect with concomitant use of csDMARDs.

As a secondary outcome in the PsA studies, there has been a significant difference seen in enthesitis and dactylitis using clinical measures. In the PsA studies and in specific psoriasis studies, the efficacy of TNF inhibitors has been proven for both skin and nail disease. As yet, there are no specific studies in axial PsA, but data in axial spondyloarthritis and/or ankylosing spondylitis have confirmed the efficacy of TNF inhibitors for spinal symptoms.

A number of interleukin inhibitors have been licensed for the treatment of PsA. Ustekinumab ([Stelara]; a p40 antibody that blocks the action of IL-12 and IL-23) is particularly effective for psoriasis, with proven superiority over TNF inhibitors. It also has evidence of efficacy for peripheral arthritis, enthesitis, and dactylitis. Surprisingly, however, despite a small positive open-label study, a randomized trial in axial spondyloarthritis was halted early, with no evidence of efficacy over placebo. Thus the phenotype of disease must be considered when choosing a therapy.

IL-17A inhibitors (secukinumab [Cosentyx] and ixekizumab [Taltz]) are now licensed for PsA and ankylosing spondylitis, providing an alternative biologic option for those with PsA. A specific study in axial PsA has also shown efficacy of secukinumab. These drugs showed even higher responses in skin psoriasis, with head-to-head studies confirming superiority over ustekinumab and TNF inhibitors. Brodalumab (Siliq)<sup>1</sup>, a human antibody against the IL-17 receptor, also blocks different forms of IL-17. It is licensed for the treatment of psoriasis and has positive phase III data in PsA. Additional drugs targeting the Th17 pathway are in development. Bimekizumab (Bimzelx)<sup>5</sup> blocks both IL-17A and IL-17F and has positive phase II trial results. Further studies will show if dual blockade is superior to blocking IL-17A alone.

A number of specific IL-23 inhibitors have been approved for treatment of PsA, including guselkumab (Tremfya) and risankizumab (Skyrizi), which are also licensed for psoriasis. These bind to the p19 subunit, providing specific blockade of IL-23 only, and have been shown to have impressive efficacy in skin psoriasis. Phase III trial data are available in PsA, with evidence of efficacy in peripheral arthritis, but again studies in ankylosing spondylitis and axial spondyloarthritis have been halted because of lack of efficacy in the spinal domain. Further studies will investigate the efficacy of these drugs, specifically in axial PsA.

In recent years, a third class of drugs, the targeted synthetic DMARDs (tsDMARDs), have also become available for the treatment of PsA. Apremilast (Otezla) is a phosphodiesterase 4 inhibitor with proven modest efficacy in the treatment of peripheral arthritis, psoriasis, enthesitis, and dactylitis, but not in axial PsA. Although responses seem lower than with the biologic drugs, apremilast has a very reassuring safety profile with no requirement for regular blood monitoring. The other group

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

of tsDMARDs in development focus on targeting the JAK pathway. Tofacitinib (Xeljanz) and upadacitinib (Rinvoq) are licensed for treatment of peripheral arthritis and showed improvements in arthritis, enthesitis, and dactylitis outcomes that were comparable with adalimumab (Humira),<sup>1</sup> which was included in both studies as either an internal control or head-to-head comparison. Tofacitinib showed modest efficacy on skin psoriasis, with seemingly higher responses seen in the upadacitinib PsA trial, although they are not specifically licensed for psoriasis. Studies in AS have confirmed that JAK inhibitors are also efficacious for axial disease with a license for tofacitinib in AS. Other JAK and TYK inhibitors, with different selectivity for JAK pathways, are in phase II and III studies. A recent study identified safety concerns with tofacitinib when compared with a TNF inhibitor, showing an increased risk of malignancy, cardiovascular disease, and venous thromboembolism, particularly in patients older than 65 years of age or those with preexisting cardiovascular risk factors. Caution is advised with JAK inhibitors, particularly in this population.

In all cases, the aim of treatment should be to minimize disease activity. The choice of therapy can be difficult, as there are few head-to-head comparison studies, and many of the newer bDMARDs and tsDMARDs appear to have similar efficacy in arthritis. In cases with significant psoriasis, an argument could be made for IL12/23, IL17, or IL23 inhibitors, for which superior efficacy has been shown in psoriasis and PsA trials. For those with axial disease, proven efficacy is limited to TNF, IL17, and JAK inhibitors. In other cases, the choice of medication often depends on comorbidities, and therapies may be contraindicated (IL17 inhibitors worsening active IBD) or helpful (TNF inhibitors).

## Monitoring

Monitoring of PsA may include assessment of clinical disease activity measures, patient-reported outcomes, laboratory testing, and imaging. The majority of day-to-day disease monitoring consists of clinical outcome measures, often combined with patient-reported outcomes.

Ideally all domains of the disease should be assessed to allow optimal choice of therapy. To assess arthritis, a full 68/66 joint count is required, rather than the reduced joint counts used in rheumatoid arthritis. Dactylitis is usually evident when joints are examined. Enthesitis can be assessed clinically, looking for tenderness and swelling at the site of key tendon attachments. In cases of doubt, ultrasound imaging can be helpful to look for inflammation and increased blood flow. Although rheumatologists are focused on musculoskeletal signs, when treating patients with PsA, they should also assess skin and nail manifestations. This can be a relatively brief assessment, such as a body surface area of skin psoriasis affected; it is important not to underestimate the impact of skin involvement on a patient's quality of life.

Multiple patient-reported outcomes are available to measure the patient perspective in PsA, including questionnaires assessing pain, function, work disability, and other impacts. The majority of these are research tools, and they are often combined with physician-assessed clinical measures to form composite scores. In clinical practice, some questionnaires may be used to assess the patient perspective and encourage dialogue with patients.

As mentioned previously, treatment recommendations now state that a treat-to-target approach should be implemented in routine care of PsA. Recommendations state that the treatment target should ideally be remission, with the alternative target of low disease activity if remission is not feasible. Additional recommendations on treat to target have highlighted that the target of therapy should include both musculoskeletal and skin manifestations of disease. Thus the MDA criteria have been recommended for the target of treatment, as these include measures of arthritis, psoriasis, enthesitis, and patient-reported pain, global activity, and functional ability.

## Management of Complications

PsA is associated with a number of comorbidities. It is part of the spectrum of spondyloarthritis and has associated extraarticular manifestations (EAMs), including potential overlap with IBD and uveitis. The involvement of these other systems is important to recognize to aid diagnosis and then manage patients to optimize outcome. Often therapies for PsA are also licensed for treatment of EAMs, allowing treatment of the disease as a whole.

Other comorbidities, not directly related to the disease complex, are also prominent in patients with psoriasis and PsA. Depression and anxiety are prevalent in up to one-half of the population and are important to address to maximize quality of life and to aid with adherence to therapy. Patients with psoriasis and PsA also have a much higher risk of metabolic syndrome and associated cardiovascular comorbidity. There are higher rates of obesity, diabetes, hypertension, hyperlipidemia, and associated complications such as nonalcoholic fatty liver disease and cardiovascular events. The cardiovascular risk seems to be higher in those with severe active disease and provides another argument for effective control of inflammation. Beyond controlling disease, patients need support and interventions to manage their other risk factors such as weight, smoking, blood pressure, and lipid control.

## RHEUMATOID ARTHRITIS

Method of

Megan Krause, MD

### CURRENT DIAGNOSIS

- Clinical diagnosis based on combination of history, examination, and supporting laboratory studies.
- Presentation is typically chronic symmetric polyarticular inflammatory arthritis.
- While not required for diagnosis, supporting laboratory studies include positive rheumatoid factor (RF), positive anticitrullinated protein antibodies (ACPA), elevated C-reactive protein (CRP), and elevated sedimentation rate (ESR).
- Radiographs can be normal at diagnosis. Findings of periarticular osteopenia and erosions are supportive of diagnosis of rheumatoid arthritis (RA).

### CURRENT THERAPY

- Methotrexate (Otrexup, Rasuvo, Rheumatrex) initial dose typically 10 to 15 mg weekly with an increase based on disease activity up to 25 mg weekly orally or subcutaneously in conjunction with daily folic acid<sup>1</sup> 1 mg orally daily.
- Hydroxychloroquine (Plaquenil) 5 mg/kg orally per day with maximum of 400 mg daily.
- Sulfasalazine (Azulfidine-EN) initially dose typically 500 mg orally once daily or 500 mg twice daily, increasing up to goal dose of 1000 to 1500 mg twice daily.
- Leflunomide (Arava) 10 to 20 mg orally once daily.
- Azathioprine (Imuran) initial 1 mg/kg/day orally with increasing dose based on response to maximum of 2.5 mg/kg/day.
- Janus kinase inhibitors
  - Tofacitinib (Xeljanz) immediate release 5 mg orally twice daily or extended release 11 mg orally once daily.
  - Baricitinib (Olmiant) 2 mg orally once daily.
  - Upadacitinib (Rinvoq) 15 mg orally once daily.
- Tumor necrosis factor (TNF) inhibitors
  - Adalimumab (Humira) 40 mg subcutaneous every other week.
  - Certolizumab (Cimzia) 400 mg subcutaneous at week 0, 2, and 4, then 200 mg every other week or 400 mg every 4 weeks.
  - Etanercept (Enbrel) 50 mg subcutaneous every week.
  - Golimumab (Simponi, Simponi Aria)
    - Simponi: 50 mg subcutaneous every 4 weeks
    - Simponi Aria: 2 mg/kg intravenous at week 0, 4, and then every 8 weeks
  - Infliximab (Remicade) 3 mg/kg intravenous at week 0, 2, and 6 and then every 8 weeks but, if persistent disease activity, dose can be adjusted between 3 and 10 mg/kg every 4 to 8 weeks.
- Interleukin 6 (IL6) receptor inhibitors
  - Tocilizumab (Actemra)
    - Subcutaneous: if less than 100 kg: 162 mg every other week, increase to weekly if persistent disease activity; if more than 100 kg: 162 mg every week.
    - Intravenous: 4 mg/kg every 4 weeks, can be increased to 8 mg/kg every 4 weeks if persistent disease activity.
  - Sarilumab (Kevzara) 200 mg subcutaneous every 2 weeks.
- T cell co-stimulation inhibitors
  - Abatacept (Orencia)
    - Subcutaneous: 125 mg once weekly (with or without IV loading dose).
    - Intravenous: if less than 60 kg: 500 mg; if 60 to 100 kg: 750 mg; if more than 100 kg: 1000 mg with initial dosing at week 0, 2, and 4, and then every 4 weeks.

- B cell inhibitor
  - Rituximab (Rituxan) 1000 mg IV day 1 and 15, subsequent doses can be repeated at 24 weeks.
- Interleukin 1 receptor inhibitor
  - Anakinra (Kineret) 100 mg subcutaneous every day.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Individuals can develop rheumatoid arthritis (RA) at any age, but a peak incidence is between 50 and 75 years. Women are affected at a frequency of two to three times greater than men. It is estimated that the prevalence is approximately 1% in the United States.

### Risk Factors

The exact pathogenesis of RA is not completely understood. It is likely the consequence of the interplay of multiple factors, including genetic predisposition and epigenetic factors, along with environmental exposures that result in the systemic inflammatory process. The environmental factors are diverse and are likely not the same in all individuals. Cigarette smoking has been identified as a significant risk factor. Periodontal disease also is associated with development of RA. Silica is an example of an associated occupational exposure.

Multiple genetic risk factors have been identified. The shared epitope, referring to a specific sequence at the HLA-DRB1 locus, which is involved with antigen presentation, has been one of the most studied. Other genetic factors have been identified but individually contribute a small increase in risk.

### Pathophysiology

The combination of genetics, epigenetic factors, and environmental exposures lead to downstream consequences of loss of tolerance to self. Both the innate and adaptive immune systems are activated in this process. Diverse immune cells including T cells, B cells, macrophages, and dendritic cells are involved in the pathogenesis. The production of cytokines contributes to the wide variety of downstream tissue targets that lead to the diverse clinical manifestations of RA. While RA frequently is diagnosed based on presentation of inflammatory arthritis, the production of cytokines and interplay of multiple cell types leads to the multiorgan dysfunction.

### Prevention

It is not understood how to prevent the development of RA. Limiting known risk factors such as smoking and maintaining periodontal health would be reasonable recommendations.

### Clinical Manifestations

#### Articular Manifestations

Classically, individuals will present with symmetric inflammatory polyarthritis (affecting five or more joints) frequently affecting the wrists, metacarpophalangeal joints (MCPs), proximal interphalangeal joints (PIPs), and metatarsophalangeal joints (MTPs). Both small and large joints can be affected. The distal interphalangeal joints (DIPs) and lumbar spine are spared.

On examination, the joints can be warm, erythematous, swollen, and tender. Range of motion of joints is frequently limited. The synovitis on exam can be described as boggy in contrast to bony hypertrophic changes of osteoarthritis.

#### Extraarticular Manifestations

One of the consequences of the systemic nature of RA is that the symptoms are not limited to the joints. The extraarticular manifestations can have significant impact both in terms of morbidity and mortality. High clinical suspicion is required, and evaluation is necessary to differentiate toxicity of medications versus a

manifestation of RA. More data are required to understand how the advances in therapy will impact extraarticular manifestations.

Individuals with RA can develop subcutaneous nodules, which sometimes can be independent of disease activity. Rarely, individuals can develop a paradoxical increase in rheumatoid nodules with methotrexate.

Individuals can present with significant dryness of the mouth consistent with secondary Sjögren syndrome. Some of these individuals will have positive autoantibodies, such as SSA/Ro and SSB/La.

Pulmonary manifestations can be quite varied and have important implications for treatment. Pleural disease can be seen and can include pleural effusions and pleurisy. Pulmonary nodules can also be present. Interstitial lung disease can present in wide ranging patterns, including usual interstitial pneumonia (UIP), nonspecific interstitial pneumonia (NSIP), organizing pneumonia, and constrictive bronchiolitis.

Cardiac manifestations can include accelerated coronary artery disease. If the joint symptoms preclude significant exertion, patients may not present with classic angina. Pericardial disease can range from pericarditis, pericardial effusion, and constrictive pericarditis. Depending on the location, rheumatoid nodules affecting the heart can be associated with valve dysfunction and conduction abnormalities.

Episcleritis and scleritis can be associated with RA. A dreaded ocular complication of RA is peripheral ulcerative keratitis and corneal melt; this requires emergent ophthalmologic evaluation.

Frequently hematologic abnormalities can be associated with RA. Anemia of chronic disease, leukocytosis, and thrombocytosis can be frequently seen. A minority of individuals will develop Felty syndrome, which includes clinical manifestations of splenomegaly, leukopenia (frequently neutropenia), and frequent infections.

Entrapment syndromes such as carpal tunnel syndrome can be a presenting symptom of RA or develop over the course of the disease. In the case of carpal tunnel syndrome, it is the result of compression of the median nerve due to swelling of the flexor tendons.

RA can affect the cervical spine. The atlantoaxial joint can be prone to subluxation, which can result in myelopathy. A high clinical suspicion is required, as individuals may not present with neck pain and joint damage can obscure examination findings such as reflexes.

An increasingly rare manifestation is vasculitis secondary to RA. This can have multiple manifestations but can include cutaneous ulcers and mononeuritis multiplex.

## Diagnosis

Rheumatoid arthritis is a clinical diagnosis based on the pattern of clinical and laboratory findings. Rarely at presentation, individuals can present with monoarticular (one joint) or oligoarticular (two to four joints), but typically when observed over time, individuals will have polyarticular involvement.

Tests to aid diagnosis include the RF, which refers to an immunoglobulin M (IgM) directed against immunoglobulin G (IgG). It is a nonspecific test and can be elevated related to age, as well other diseases that can mimic RA, such as hepatitis C. ACPA have the advantage of being more specific than RF with specificity as high as 95%. Individuals are considered to have seropositive RA when either RF or ACPA is positive; this occurs in approximately 70% to 80% of individuals. Acute phase reactants including CRP and ESR, when elevated, are supportive of the diagnosis but not required for the diagnosis. Anemia of chronic disease, thrombocytosis, and leukocytosis can also be supportive of the diagnosis but are nonspecific.

The American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) have developed classification criteria. Domains included the pattern of joint involvement, serology status (RF and ACPA), acute phase reactants (CRP and ESR), and duration of symptoms (cutoff of 6 weeks).

At presentation, x-rays can be normal. The earliest abnormality in RA on x-ray evaluation of the joints includes soft tissue swelling and periarticular osteopenia. Additional changes on x-rays include symmetric joint space narrowing and marginal erosions. If erosions are present at diagnosis, this is associated with a worse prognosis.

## Differential Diagnosis

The differential diagnosis is broad for RA. Multiple infections can cause polyarticular joint pain. Viral etiologies can include hepatitis B, hepatitis C, and HIV. Parvovirus B19 can also be a mimic of RA; joint pain can be a prominent feature in adults in contrast to children who rarely have joint involvement. Typically the arthritis of parvovirus B19 will resolve spontaneously over a few weeks. Travel history is also an important element of the history; for example, Chikungunya and Dengue can present with arthritis symptoms. Rubella, both the illness and vaccine, can be associated. Bacterial infection such as endocarditis and Lyme disease can present with oligoarticular/polyarticular joint pain. Rheumatic fever is also in the differential and can present with migratory joint pain.

Inflammatory arthritis can be a manifestation of other systemic rheumatologic conditions including seronegative spondyloarthritis (psoriatic arthritis, arthritis secondary to inflammatory bowel disease, reactive arthritis, and ankylosing spondylitis/axial spondyloarthritis). The pattern of involvement can be helpful, as seronegative spondyloarthritis frequently presents in an asymmetric, large joint predominant, and lower extremity predominant fashion. Inflammatory arthritis can develop secondary to connective tissue disease such as systemic lupus erythematosus and systemic sclerosis. ANCA-associated vasculitis can also present with arthritis. Paraneoplastic syndromes can present with joint pain including hypertrophic osteoarthropathy.

## Treatment

The goals of treatment of RA are to address both the short term and long term complications of RA. The overarching principle is “treat to target.” The goal of therapy should be to achieve clinical remission or low disease activity. The treatment approach must be individualized and consider the comorbidities of the patient. The significant cost of the medications must also be considered in therapy decisions.

### Analgesics and Nonsteroidal Antiinflammatory Drugs

Analgesics and nonsteroidal antiinflammatory agents can be utilized to help address breakthrough pain. However, these agents should not be the foundation of treatment. Their role can be used to help control symptoms while a maintenance strategy with conventional disease-modifying antirheumatic drugs (DMARDs) and/or biologics is being established, as there is delay to the full clinical benefit of these medications. Since these medications do not alter the natural history of the disease, they should not be used in isolation.

In patients with extensive damage related to RA, these medications can have a role in helping address pain. DMARDs and biologics are unable to address pain related to damage.

### Glucocorticoids

Glucocorticoids are frequently used due to their rapid onset of action, which distinguishes them from DMARDs and biologics. These are frequently utilized at initial diagnosis or with flares of established disease. However, the side effects of corticosteroids limit their use. Corticosteroids should not be utilized in isolation to treat RA. Corticosteroids can be given in multiple administration forms, including oral, intramuscular, and intraarticular. The choice of which to use is dependent on the individual patient’s scenario.

### Conventional Disease Modifying Antirheumatic Drugs

Conventional DMARDs are immunosuppressants with the goal of inducing and maintaining remission of patients with RA.

### Methotrexate

Methotrexate (Otrexup, Rasuvo, Rheumatrex), in the absence of contraindications, is typically the first-line medication utilized for RA. The exact mechanism specifically for RA is incompletely understood. Methotrexate inhibits dihydrofolate reductase which results in reduction of DNA synthesis and, as a result, cell replication. However, this is not the role in isolation as daily folic acid<sup>1</sup> is prescribed to help counter the side effects and does not reverse the therapeutic benefit. Methotrexate also increases the release of adenosine which leads to reduction of inflammation.

Methotrexate can be given in both oral and subcutaneous administration forms. Typically, the starting dose is 10 to 15 mg weekly with titration depending on clinical response, up to 25 mg weekly. At higher doses, gastrointestinal absorption can be limited, and this can be a situation to prefer the subcutaneous form.

Common side effects can include oral ulcers, nausea, fatigue, increased infection risk, cytopenias, and hepatotoxicity. Methotrexate requires routine blood monitoring specifically for cytopenia and hepatotoxicity. The toxicity of methotrexate is increased in the setting of renal dysfunction, and in this setting there should be consideration of dose reduction versus choosing an alternative agent.

Methotrexate is a teratogen. The recommendation is to wait 3 months from stopping methotrexate before trying to conceive.

### Hydroxychloroquine

Hydroxychloroquine (Plaquenil) has multiple mechanisms of action including inhibition of antigen presentation via interference of toll-like receptors and acidification of lysosomes.

It is an oral medication with the dose range of 200 to 400 mg daily. It is a weight-based regimen, and when using real body weight, the dose is 5 mg/kg with the maximum of 400 mg daily.

Side effects can include photosensitive rash, hypoglycemia, hearing loss, and retinal toxicity. Hydroxychloroquine can deposit in the retina which can ultimately lead to vision loss if not identified. Individuals are recommended to have routine eye examinations so changes related to hydroxychloroquine, including bull's eye maculopathy, can be identified and hydroxychloroquine can then be discontinued if necessary. Eye comorbidities, such as macular degeneration, may complicate the ability to monitor for hydroxychloroquine toxicity and would need to be discussed with patient's eye provider.

### Sulfasalazine

The exact mechanism of action of sulfasalazine (Azulfidine-EN) in RA is not currently well understood.

It is an oral medication that is utilized twice daily. The dose is typically started at 500 mg once or twice daily with titration of dose to 1000 to 1500 mg twice daily.

Side effects include rash, gastrointestinal side effects, cytopenias, and hepatotoxicity. Laboratory monitoring is required to monitor for cytopenia and hepatotoxicity.

### Leflunomide

Leflunomide (Arava) inhibits dihydroorotate dehydrogenase, which results in the reduction of pyrimidine synthesis and ultimately reduction of cellular replication.

It comes in an oral form. A loading dose is not required and frequently not used, as it can result in a side effect of diarrhea. Leflunomide has a very long half-life due to its entrance in the enterohepatic circulation.

Side effects include diarrhea, cytopenias, hepatotoxicity, and increased infection risk. It requires routine laboratory monitoring for cytopenia and hepatotoxicity. It is contraindicated in pregnancy.

A cholestyramine (Questran)<sup>1</sup> washout procedure can be utilized to eliminate leflunomide when needed for a time sensitive scenario, such as a woman wanting to pursue pregnancy.

### Azathioprine

Azathioprine (Imuran) is an inhibitor of purine synthesis and as a result of cellular replication.

It is an oral medication and the dosing is weight based. Azathioprine is typically started at 1 mg/kg/day and can be escalated up to a maximum of 2.5 mg/kg/day.

Side effects can include cytopenias, rash, nausea, diarrhea, and pancreatitis. Azathioprine requires routine monitoring for cytopenias and hepatotoxicity. A thiopurine methyltransferase (TPMT) level can be checked prior to initiation for assessment of the metabolism of azathioprine. If there are reduced levels of TPMT activity, then one would need to consider using a reduced dose or an alternative agent.

Azathioprine has been less commonly used as other agents have become available. Interstitial lung disease secondary to RA is one scenario in which it is still utilized.

## Synthetic Disease Modifying Antirheumatic Drugs

### Janus kinase (JAK) Inhibitors

Tofacitinib (Xeljanz), baricitinib (Olumiant), and upadacitinib (Rinvoq) are targeted small molecules that inhibit Janus kinases (JAKs). Inhibition blocks intracellular signaling of cytokine receptors and results in decreased gene activation.

The JAK inhibitors are oral medications. Side effects can include cytopenia, hepatotoxicity, and cholesterol elevation. The U.S. Food and Drug Administration (FDA) updated warnings in 2021 regarding serious heart-related events, cancer including lymphoma and lung cancer, and thrombosis. Individual patient risk factors should be given attention. Routine lab monitoring is required to monitor for these complications. There are rare reports of bowel perforation, and currently there is a recommendation to avoid in the setting of diverticulitis.

### Biologics

Biologics refer to the complex chemical structure of these medications. Biologics can be used in combination with conventional DMARDs.

### TNF Inhibitors

TNF inhibitors inhibit the effect of TNF alpha, a proinflammatory cytokine. There are five different TNF inhibitors: etanercept (Enbrel), adalimumab (Humira), certolizumab (Cimzia), golimumab (Simponi), and infliximab (Remicade). Etanercept has a component of the TNF receptor, allowing it to bind TNF alpha, and prevents it from binding to TNF receptors. The remaining are monoclonal antibodies targeting TNF alpha. Etanercept, adalimumab, certolizumab, and golimumab come in a subcutaneous form. Golimumab and infliximab are available as an infusion. Biosimilars, referencing their similar structure and as a result function but not identical to their corresponding biologic, are becoming increasingly available for some of the TNF inhibitors (e.g., Avsola [infliximab-axxq], Inflectra [infliximab-dyyb], and Renflexis [infliximab-abda] are biosimilars to infliximab).

Side effects include injection site/infusion reactions. Patients must be counseled on infection risk to wide-ranging organisms, ranging from bacterial, viral, fungal, and mycobacterial. Individuals must undergo tuberculosis testing prior to initiation of therapies. There were initial concerns regarding lymphoma in the setting of TNF inhibitor use, but also underlying RA plays a role in the risk. TNF inhibitors can be associated with exacerbations of congestive heart failure. Multiple sclerosis would be a contraindication to TNF inhibitors.

### Interleukin 6 Receptor Inhibitor (Tocilizumab and Sarilumab)

Tocilizumab (Actemra) and sarilumab (Kevzara) are both interleukin 6 (IL6) receptor inhibitors, which prevents activation of the receptors of IL6. This prevents the downstream activation of targets of IL6, a proinflammatory cytokine.

Tocilizumab comes as both infusion and subcutaneous versions. Sarilumab comes as a subcutaneous version.

<sup>1</sup> Not FDA approved for this indication.

Side effects include cytopenia, particularly neutropenia and thrombocytopenia, hepatotoxicity, and elevated cholesterol. Routine monitoring is necessary. Injection site/infusion reactions are also a risk. The infection concerns are similar to TNF inhibitors, with the risk pertaining to diverse organisms. Due to rare reports of bowel perforations, it is recommended to be avoided in the setting of diverticulitis.

### T Cell Coactivation Inhibition

Abatacept (Orencia) prevents T cell coactivation by binding the costimulating signal (CD80/86) on antigen presenting cells and preventing it from binding T cells. Administration forms include subcutaneous injection and intravenous infusions. Side effects include injection/infusion site reactions. Infection risk is also a concern with abatacept.

### B Cell Inhibition

Rituximab (Rituxan) depletes B cells by targeting CD20, which is present on B cells.

It is an intravenous medication. The timing of subsequent doses is typically every 6 months.

The risks of rituximab include infusion reactions. Infection risk is a concern with rituximab, particularly considering the long timeframe of effect. Careful attention must be given to prevent hepatitis B reactivation. Even patients with evidence of natural immunity via cleared infection would be a candidate for hepatitis B reactivation prophylaxis. Progressive multifocal leukoencephalopathy (PML) related to JC virus has been reported in patients receiving rituximab for the indication of RA. The risk is very low, and in multiple reports, patients were also on additional immunosuppressants such as chemotherapy.

### Interleukin 1 Inhibition

Anakinra (Kineret) is an inhibitor of the IL1 receptor preventing the downstream activation of IL1, a proinflammatory cytokine. Risks are similar to other biologics in terms of infection, injection site reaction, cytopenia, and nausea. It is a daily subcutaneous injection.

### Combination Therapy

Combination therapy is frequently utilized for treatment of RA. An indication to proceed with combination therapy is when disease activity is persistent despite therapeutic dosing with a single agent. A frequently used combination therapy is termed “triple therapy.” This refers to the combination of methotrexate, sulfasalazine, and hydroxychloroquine. A single biologic can be utilized in combination with conventional DMARDs, most frequently methotrexate. Two biologics are not recommended to be utilized together, due to concern with increased infection risk.

### Choice of Therapy

Multiple factors must be weighed in terms of the choice of therapy for RA. If there are no contraindications, methotrexate is typically used as the first choice. If there is an insufficient response to a maximized dose of methotrexate, including use of subcutaneous methotrexate, then combination therapy is frequently utilized. If methotrexate is unable to be tolerated, then leflunomide could be considered in its place. The combination therapy to be utilized with methotrexate could include triple therapy versus methotrexate in combination with a biologic or synthetic DMARD (JAK inhibitors). Triple therapy has been compared with methotrexate plus biologic therapy in multiple studies and overall thought to be equivalent in terms of achieving clinical response. The choice between the two is dependent on discussion with the patient. Consideration for the forms of administration would need to be taken into account. Comorbidities of the patient can restrict choices. Another consideration is cost and insurance coverage for different medications. Currently, there is not available testing to inform choice of therapy in a personalized manner beyond consideration of comorbidities.

When patients have consistently achieved clinical remission, there can be consideration for reduction in treatment. There is

increased risk of flare of disease when reducing medications. Patients would need to be counseled regarding this risk and monitored closely.

### Special Scenarios

#### Pregnancy

As RA can affect women of childbearing age, the goals in terms of pregnancy must be understood for patients with RA. Methotrexate and leflunomide would be contraindicated in the setting of pregnancy. Methotrexate is associated with known congenital abnormalities. The recommendation would be to stop methotrexate 3 months prior to contraception. Leflunomide has a much longer half-life and the level could be checked and, if elevated, then could use cholestyramine<sup>1</sup> washout. If there is a possibility of pregnancy, then hydroxychloroquine or sulfasalazine are frequently used options in this setting. TNF inhibitors have been utilized in pregnancy. The recommendations would be to stop TNF inhibitors over the course of pregnancy with the specific TNF inhibitors having different recommendations; certolizumab is not thought to cross the placenta due to its chemical structure, and in some individuals, this is continued throughout the pregnancy. Less information is available about the safety of other biologics in pregnancy and, if possible, would be avoided until further information is known.

Patients frequently have improvement in their clinical symptoms during pregnancy, which emphasizes the importance of an individualized approach during pregnancy. Patients should be counseled on the risk for flare in the postpartum setting.

#### Breastfeeding

Data is limited regarding the effects of medications for RA and breastfeeding. The potential benefits of breastfeeding would need to be weighed with potential risk. Methotrexate and leflunomide are avoided during breastfeeding. An individualized approach is necessary in conjunction with the patient and obstetrician.

#### Malignancy

Data is limited regarding the ideal choice of therapy in the setting of a history of malignancy. DMARDs are frequently preferred over biologics in the setting of prior malignancy. Specifically in the setting of lymphoproliferative disorders, if a biologic is indicated due to disease activity, rituximab is preferred over other biologic choices. Individualized decisions must be made in conjunction with the patient and their hematologist/oncologist.

#### Preoperative Management

Due to the risk of atlantoaxial instability in RA, particularly in long-standing disease, patients prior to surgery should be screened for this complication. Cervical spine x-rays with flexion and extension views would be recommended. The results should be reviewed with an anesthesiologist to assist with planning for positioning during surgery.

Management of immunosuppressant medications must be reviewed with the surgeon and take into account the nature of surgery as well as the pharmacokinetics of the immunosuppressants. Data are limited on the ideal management of immunosuppressants in this setting. Guidelines have been published in the setting of total hip and knee arthroplasty.

#### Monitoring

There are two components of monitoring for patients with RA. The first is to assess for disease activity both from the standpoint of the joints as well as extraarticular manifestations. From the joint perspective, there are multiple disease activity scores that can be utilized. Some rely solely on patient reported outcomes. Others are a combination of patient reported outcomes, exam findings, and provider global assessment. Swollen joint counts and tender

<sup>1</sup>Not FDA approved for this indication.

joint counts are frequently utilized. Specifically for laboratory monitoring of disease activity, ESR and CRP can be utilized but do not trend with disease activity in all patients. ACPA and RF do not trend with disease activity and thus the values do not need to be repeated if positive.

Separately, drug toxicity must be assessed including clinical symptoms and laboratory monitoring. In addition, monitoring for development of infection is also necessary.

### Management of Complications

If drug toxicity develops, depending on the nature of toxicity, the medication dose should either be reduced or discontinued. If the side effect likely reflects a class effect, consider an agent in a different drug class. If infection occurs while on immunosuppressant therapy, these medications should be held at least until the infection has resolved. Restarting would be dependent on the clinical scenario, including the nature of the infection and the specific treatment for RA.

## Sexually Transmitted Diseases

### CHLAMYDIA TRACHOMATIS

Method of  
Tracy L. Williams, MD

#### CURRENT DIAGNOSIS

- Screen all sexually active woman 25 years of age or younger for *C. trachomatis* annually regardless of symptoms per the CDC recommendations.
- Symptomatic patients should be tested regardless of gender.
- Reinfection with *C. trachomatis* is common.
  - Retest all patients who have a history of *C. trachomatis* or *N. gonorrhoea* at 3 to 6 months following treatment, regardless of whether their partner(s) were treated.
  - If the patient does not follow up at 3 to 6 months, then retest upon presentation for medical care within the first 12 months posttreatment.
- Patients who screen positive for *C. trachomatis* need to be screened for gonorrhea, syphilis, and HIV.
- Perform test of cure on pregnant patients at 3 to 4 weeks posttreatment and repeat in 3 to 6 months, preferably in the third trimester if the pregnant woman was diagnosed during the first trimester.
- Rescreen pregnant patients for other sexually transmitted infections (STIs) 3 months posttreatment including gonorrhea, syphilis, and HIV.

#### CURRENT THERAPY

- Azithromycin (Zithromycin) 1 g orally in a single dose or doxycycline (Vibramycin) 100 mg orally twice a day for 7 days are the recommended regimens for nonpregnant patients and for presumptive treatment for *C. trachomatis*.
- All of the patient's recent sexual partners need referral and treatment.
  - The patient's last sexual contact should be referred and treated if it has been more than 60 days since the patient had a sexual partner.
  - The partner needs to be treated for *C. trachomatis* even if his or her personal STI results are negative.
- Counsel patients and their partners to abstain from sexual contact until 7 days after one-dose therapy or after the final dose of the 7-day regimen.
- The CDC recommends patients who test positive for *N. gonorrhoea* only be treated for *C. trachomatis* when coinfection is not excluded.

#### Epidemiology

*Chlamydia trachomatis* is the most common notifiable sexually transmitted infection (STI) in the United States, with an incidence of over 1.8 million cases per year according to the Centers for Disease Control and Prevention (CDC) in 2018. Women

age 15 to 19 years are the most commonly affected, followed by women age 20 to 24. The incidence of *C. trachomatis* has steadily climbed yearly since it became a federally mandated notifiable disease; part of this is an artifact of improved screening practices that are discovering disease in asymptomatic patients.

*C. trachomatis* costs an estimated \$2.4 billion annually. Cost-benefit analyses have consistently shown prioritizing screening efforts in asymptomatic women to be cost-effective.

#### Risk Factors

The risk of contracting *C. trachomatis* increases with: multiple sexual partners; unprotected sex including vaginal, oral, and anal intercourse; anal-receptive intercourse; and men having sex with men. The risk increases in the presence of other coinfections including human immunodeficiency virus (HIV) or herpes simplex virus (HSV). African Americans have a fourfold higher incidence compared to their white counterparts (13% versus 2.4%, respectively).

#### Pathophysiology

*Chlamydia trachomatis* is an obligate intracellular parasite. It is found only in human cells, but can live on fomites for up to 30 hours. Previous infections do not yield protection against future infections with *C. trachomatis*. *C. trachomatis* does not infect the squamous epithelium of the vaginal vault, but can infect the urethra, the squamocolumnar junction of the cervix, the rectal mucosa, and the oropharynx.

#### Prevention

Prevention depends on screening of asymptomatic patients, who make up a large portion of the infected population. The United States Preventive Task Force (USPSTF) recommends annual screening of all sexually active women younger than 25 years of age and for older women at increased risk.

The CDC and the USPSTF found insufficient evidence to recommend routine screening of men based on cost-effectiveness, efficacy, and practicality, but screening of symptomatic men or men in areas with high prevalence of *Chlamydia*, including men having sex with men, men in correctional facilities, and men visiting STI clinics, is recommended. Overall, screening of men is recommended so long as it does not detract resources from the screening of women. Symptomatic patients should be tested regardless of gender.

Men who have sex with other men are at high risk for bacterial and viral STI. The CDC STI screening recommendation in this group is an annual test for urethral infection with *C. trachomatis* and *N. gonorrhoea*. The preferred methodology is testing the urine using nucleic acid amplification technique (NAAT). Men who have receptive anal intercourse are recommended to have annual anal screening for both *C. trachomatis* and *N. gonorrhoea*. Men who have oral receptive sex are also advised to have pharyngeal screening for *N. gonorrhoea* but not *C. trachomatis*. The NAAT is only Food and Drug Administration (FDA)-approved on urine in the above scenarios but is used off-label in laboratories that have met all regulatory requirements.

Patients who screen positive for *Chlamydia* need to be screened for other STIs, including gonorrhea, syphilis, and HIV.

Abstinence and monogamous relationships are ideal to help prevent the transmission of *C. trachomatis*. Safer sex practices to limit the spread of *C. trachomatis* include the consistent use of

condoms. Epidemiologic studies show that people often base their decision to use condoms on their perception of their partner's risk. Given the high prevalence of asymptomatic *C. trachomatis* infections in certain American populations, selective condom use is not an effective strategy.

### Clinical Manifestations

Most infections are asymptomatic. However, some women will report vaginal discharge, postcoital or intermenstrual bleeding, or lower abdominal pain. Men are more commonly symptomatic than women and may report dysuria or urethral discharge.

Untreated *C. trachomatis* in women has significant health sequelae. Approximately 40% of women with untreated *Chlamydia* go on to develop pelvic inflammatory disease (PID). Women with PID may become infertile (20%), develop debilitating chronic pelvic pain (18%), or suffer ectopic pregnancy (9%).

Men do not tend to suffer as severe sequelae from *C. trachomatis*. The most common illness is urethritis, but men may also suffer epididymitis, proctitis, and conjunctivitis. Reactive arthritis is also more common in men.

### Diagnosis

Tests used for detection of *C. trachomatis* can be divided into molecular (NAAT, DNA probing, and hybrid capture), antigen detection (direct immunofluorescence and enzyme immunoassay), and cell culture.

The most reliable method of testing for *C. trachomatis* is NAAT. It is FDA-approved for use on vaginal/endocervical secretions, male intraurethral swabs, and first-catch urine. It is not FDA-approved for rectal or oropharyngeal use but is used off label in laboratories as described above. The primary benefit of NAAT is the lack of a need for viable organisms to induce a positive test result; this increases its sensitivity to more than 95% because of the ability to detect *C. trachomatis* even if only one copy of the targeted RNA or DNA is present. Its specificity is also desirable at 99%.

*C. trachomatis* cell culture is used as the reference standard for all testing but has many limitations, including expense, long turnaround time (72 hours), and transport and specimen storage requirements. Its sensitivity is 80% to 85%. It is not readily available.

Limiting barriers to screening is important. If testing in the clinic is difficult to arrange, self-collected vaginal swab specimens perform at least as well as other approved specimens using NAAT. First-catch urine NAAT testing is also more acceptable to many patients, particularly asymptomatic men and women who do not otherwise need a pelvic examination.

### Differential Diagnosis

Infection with *Chlamydia* is often asymptomatic but is included in the differential diagnosis of various organ system complaints. It should be ruled out in any sexually active patient presenting with urethritis, mucopurulent cervicitis, epididymitis, and proctitis. There is significant overlap in the symptoms caused by *C. trachomatis* with *N. gonorrhoea*, so testing for both bacteria with NAAT is preferred. Other agents that are included in the differential diagnosis after *C. trachomatis* and *N. gonorrhoea* have been ruled out include: *Trichomonas vaginalis*, HSV, adenovirus, *Mycoplasma* species, and *Ureaplasma*. More specifically, persistent urethritis after treatment with doxycycline (Vibramycin) can be caused by infection with *T. vaginalis* or doxycycline-resistant *Urea urealyticum* or *Mycoplasma genitalium*.

*C. trachomatis* should be ruled out in newborn infants with conjunctivitis in the first 30 days of life or pneumonia at 1 to 3 months of life, especially if they were born to mothers with untreated chlamydial infections.

### Treatment

Recommendations for treatment regimens are summarized in **Box 1**. The benefit of using single-dose azithromycin (Zithromycin) is the ability to directly observe the patient taking the therapy.

#### BOX 1 *Chlamydia trachomatis*: Recommended Treatment Regimens by Clinical Syndrome

Cervicitis or urethritis or for presumptive treatment in nonpregnant patient\*

- Azithromycin (Zithromycin) 1 g orally in a single dose
- or
- Doxycycline (Vibramycin) 100 mg orally twice a day for 7 days

#### Alternative regimens (one of the following)

- Erythromycin base (E-Mycin) 500 mg orally four times a day for 7 days
- or
- Erythromycin ethylsuccinate (EES) 800 mg orally four times a day for 7 days

- or
- Levofloxacin (Levaquin)<sup>†</sup> 500 mg orally once daily for 7 days

- or
- Ofloxacin (Floxin) 300 mg orally twice a day for 7 days

#### Pregnant patient with cervicitis or urethritis\*

- Azithromycin 1 g orally in a single dose
- or
- Amoxicillin 500 mg orally three times a day for 7 days

#### Alternative regimens

- Erythromycin base 500 mg orally four times a day for 7 days
- or
- Erythromycin base<sup>‡</sup> 250 mg orally four times a day for 14 days
- or

- Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days

or

- Erythromycin ethylsuccinate<sup>†</sup> 400 mg orally four times a day for 14 days

#### Epididymitis

- Ceftriaxone (Rocephin) 250 mg IM in a single dose

plus

- Doxycycline 100 mg orally twice a day for 10 days

#### Ophthalmia neonatorum or *C. trachomatis* pneumonia

- Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into 4 doses daily for 14 days<sup>‡</sup>

#### Recommended regimen for children who weigh <45 kg

- Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into 4 doses daily for 14 days

#### Recommended regimen for children who weigh ≥45 kg but who are <8 years old

- Azithromycin 1 g orally in a single dose

#### Recommended regimens for children aged ≥8 years

- Azithromycin 1 gram orally in a single dose
- or
- Doxycycline 100 mg orally twice a day for 7 days

#### Inpatient and outpatient PID

- Please refer to PID chapter for treatment regimens

Providers should consult the Centers for Disease Control and Prevention's website at <http://cdc.gov/std/treatment> for up-to-date treatment recommendations.

\*Consider concurrent treatment for gonococcal infection if prevalence of gonorrhea is high in the patient population under assessment.

<sup>†</sup>Not FDA approved for this indication

<sup>‡</sup>The lower-dose and longer-treatment option with erythromycin can be considered if gastrointestinal tolerance is an issue.

<sup>‡</sup>Infants <6 weeks of age who are treated with erythromycin should be followed for signs and symptoms of infantile hypertrophic pyloric stenosis.

The 7-day course of doxycycline (Vibramycin) has comparable cure rates to azithromycin, but decreased compliance.

Presumptive treatment for *C. trachomatis* should be considered for high-risk patients with cervicitis. High-risk patients include women up to 25 years old, those with new or multiple sexual partners, those who engage in unprotected sex, especially if follow-up cannot be ensured, and those for whom a relatively insensitive diagnostic test is used in place of NAAT.

The CDC only recommends presumptive treatment for *C. trachomatis* for patients being treated for *N. gonorrhoea* when coinfection is not excluded. Coinfection is common, as illustrated in a study that found 20% of men with *N. gonorrhoea* and 42% of women with *N. gonorrhoea* were also infected with *C. trachomatis*. Cotreatment is also recommended in the hope that it will impede the development of antimicrobial-resistant *N. gonorrhoea*.

*Chlamydia trachomatis* is a reportable infectious disease. The patient is instructed to refer all of his or her sexual partners for testing and treatment if they have had sexual contact during the previous 60 days. If the patient has not been sexually active for the last 60 days, then the patient is to refer his or her most recent sexual contact. The patient's recent sexual partners should be treated empirically even if their personal STI evaluation returns negative results. The patient and his or her sexual partners should be counseled to abstain from sexual activity for 7 days post treatment. Reinfection, rather than recurrence, is the more common etiology of repeat *C. trachomatis* infection.

Expedited partner therapy is an option in certain cases. This entails the patient delivering the antibiotic to his or her partner(s) without a physician first seeing the patient. Patients are to give their partners written materials on the importance of following up with a physician if any signs of complications occur (e.g., pelvic pain in women or testicular pain in men). It can be used effectively in certain situations but is not routinely recommended in men who have sex with men because of the high risk for coexisting infections, especially undiagnosed HIV infection, in their partners. Please refer to the CDC website ([www.cdc.gov/std/ept](http://www.cdc.gov/std/ept)) to check on legality in individual states. In general, utilizing the traditional patient-physician model is preferred.

Infants born to women with untreated *C. trachomatis* infection are at increased risk for vertical transmission. Prophylactic treatment with oral erythromycin (E-Mycin) for *C. trachomatis* is not recommended. The state-mandated standard erythromycin eye ointment (Ilotycin) that all newborns receive is still indicated. Overall, infants born to infected mothers need to be closely monitored for any signs and symptoms of infection and treated appropriately.

Intrauterine devices (IUDs) have regained popularity in the United States after they were implicated in causing PID in the 1970s. The IUD has evolved and now the risk of PID appears increased only in the first three weeks postinsertion. If *C. trachomatis* or PID is contracted with an IUD in place, practitioners must decide if the IUD should be removed. Research has found insufficient evidence to mandate removal, but close follow-up is mandatory.

## Monitoring

Repeat testing is recommended for all patients, including pregnant women, treated for *C. trachomatis* at 3 months regardless

of the treatment status of the patient's partner(s) because reinfection is so common. If the patient does not follow up at 3 months, he or she should be retested upon presentation for medical care within the first 12 months posttreatment.

Test of cure, which is testing at 3 to 4 weeks posttreatment, is recommended only for pregnant patients. Testing for cure earlier than 3 to 4 weeks increases the rate of false positive results. The pregnant woman who is treated for *C. trachomatis* during the pregnancy also qualifies to be rescreened in the third trimester for *N. gonorrhoea*, HIV, and syphilis in addition to *C. trachomatis*.

## Complications

*C. trachomatis* is a major public health concern because it results in serious health complications and sequelae. In women it can cause PID, endometritis, ectopic pregnancy, infertility, salpingitis, and perihepatitis (Fitz-Hugh-Curtis syndrome). In men it is associated with postgonococcal or nongonococcal urethritis and epididymitis. Reactive arthritis can occur in both men and women.

*C. trachomatis* is especially problematic in pregnancy because it is associated with an increased risk of preterm labor and preterm premature rupture of membranes. Infants born to women infected with *Chlamydia* risk suffering pneumonia and conjunctivitis.

*C. trachomatis* pneumonia can present as an afebrile pneumonia often with a staccato cough without wheezing between 1 and 3 months of life. *C. trachomatis* conjunctivitis, also known as ophthalmia neonatorum, is uncommon in the United States, but worldwide it is the number one cause of blindness. It usually presents within the 5th and 12th day of life but can present at up to 1 month of age. State-mandated prophylactic eye ointment given to babies at birth mainly helps prevent gonococcal ophthalmia; it does not prevent perinatal transmission of *Chlamydia* from mother to infant. Therefore the screening of pregnant women and ultimate treatment of their *Chlamydia* during pregnancy is the best method of preventing complications in newborn infants.

## CONDYLOMATA ACUMINATA

Method of

M. Chantel Long, MD

### CURRENT DIAGNOSIS

- Condylomata acuminata are usually flesh-colored, brown, or gray and can be flat, plaque-like, or exophytic papules, giving them the classic “cauliflower” appearance.
- The lesions may be single or multiple and can range in size from minute to several centimeters in diameter.
- When the appearance of the lesion is typical, confirmatory tests are usually unnecessary.
- Suspicious lesions or uncertain diagnoses warrant biopsy to rule out malignancy.

### CURRENT THERAPY

- In the absence of dysplasia, treatment of subclinical human papilloma virus infection is not recommended.
- The goal of therapy is to eliminate symptoms, namely clinically apparent warts, rather than address the underlying HPV infection.
- Common treatment options include podofilox (Condylox), imiquimod (Aldara, Zyclara), sinecatechins (Veregen), trichloroacetic acid (Tri-Chlor), cryotherapy, and surgery.

### Epidemiology

Condylomata acuminata, commonly known as genital warts, is a sexually transmitted disease caused by the human papilloma virus (HPV). It is estimated that 43 million people are infected with HPV in the United States, with the highest prevalence in adolescents and young adults. Lifetime incidence of HPV infection is greater than 50% and appears to be increasing, making it the most common sexually transmitted disease.

### Risk Factors

Risk factors associated with HPV infection include sex with an infected partner, early age at first sexual intercourse, multiple sexual partners, history of sexually transmitted infections, cigarette smoking, and lack of condom use. The majority of patients whose sexual partner has condyloma will themselves develop condyloma within 3 months. An even larger percentage of people are believed to develop subclinical infection.

### Pathophysiology

About 90% of warts are caused by HPV types 6 and 11; condyloma can be coinfecting with types 16, 18, 31, 33, 35, and 45, which have oncogenic potential, especially in patients with HIV infection. Genital skin appears to be less susceptible to the oncogenic potential of HPV compared to the transformation zones of the cervix and anal canal.

The virus is easily transmitted via sexual contact. Vertical transmission and autoinoculation are possible. The average incubation period between infection and appearance of condyloma ranges from 3 months to several years. Condyloma can persist or recur after therapy, undergo malignant transformation, or spontaneously regress.

### Prevention

Prevention options include HPV vaccination, abstinence, routine condom use, and limiting sexual partners. Once patients have condyloma, they should be encouraged to use condoms

consistently. Educate patients that condoms can decrease transmission but might not completely prevent infection.

One HPV vaccine series is currently available in the United States. Gardasil 9 is a 9-valent HPV vaccine indicated for male and female patients aged 9 to 26 years for prevention of cervical cancer and genital warts. It may also be given to patients age 27 to 45 years based on shared clinical decision-making between the patient and clinician.

### Clinical Manifestations

Most genital warts are asymptomatic on presentation, although patients can present with complaints of a “bump.” Localized irritation, pruritus, pain, or bleeding can occur, and symptoms may vary based on the location and size of the lesions. Usually, the warts appear flesh-colored, brown, or gray and can be flat, plaque-like, or exophytic papules, giving them the classic “cauliflower” appearance. The lesions may be single or multiple and range in size from minute to several centimeters in diameter. Flat HPV lesions might not be grossly visible.

The majority of HPV infections are either subclinical or unrecognized. Clinically apparent disease might represent only a small portion of the actual infected area.

### Diagnosis

When the clinical appearance of the lesion is typical, confirmatory tests are usually unnecessary. The entire anogenital tract should be examined because of the widespread nature of HPV. A magnifying glass and anoscopy may be helpful for thorough detection and examination. Application of dilute 3% to 5% acetic acid solution to the skin surface can help detect subtle HPV lesions by producing an acetowhitening of the condyloma; however, this is not a specific test and is not routinely recommended. Pap smears or tissue biopsy can provide histopathologic confirmation of the diagnosis. Biopsy is recommended to rule out malignancy in any suspicious lesions, such as large or rapidly growing condyloma; pigmented, atypical, friable, bleeding, or ulcerated lesions; sites of previous treatment failure; areas of recurrence; acetowhite lesions; or lesions in immunocompromised patients. Although costly and not recommended, HPV identification via DNA testing can be performed.

### Differential Diagnosis

Table 1 outlines the differential diagnosis for condylomata acuminata.

**TABLE 1** Differential Diagnosis

LESION	APPEARANCE
Verruca vulgaris	Occurs anywhere Tends to be thicker, drier, and hyperkeratotic
Molluscum contagiosum	Occurs anywhere Smooth, round papules with central umbilication
Seborrheic keratoses	Occurs anywhere Multiple waxy, rough, hyperpigmented papules
Condyloma latum	Moist, rounded, white papules of syphilis
Pearly penile papules	Smooth, uniform, small, 1–2mm at corona, benign
Vestibular papillae	Both sides of vulva, female equivalent of pearly penile papules
Lichen planus	Purplish, pruritic rash or flat-topped polygonal papules
Nonpigmented nevi	Occurs anywhere Flat or raised, reddish or flesh colored

**TABLE 2** Treatment Regimens

DRUG	USE ON	ADVANTAGES	DISADVANTAGES	INSTRUCTIONS
<b>Patient Applied</b>				
Podoflox 0.5% gel or solution (Condylox)	Moist warts	Relatively inexpensive	Avoid in pregnancy Avoid on mucous membranes Do not exceed 10cm <sup>2</sup> area Do not exceed 0.5mL daily; can have systemic side effects	Apply bid × 3d, then 4d off Repeat weekly May use for 4–6 cycles <sup>3</sup>
Imiquimod 5% cream (Aldara)	Dry or moist warts		Avoid with large warts >10cm <sup>2</sup> Requires compliance Hypo- or hyperpigmentation of treated skin can occur Local inflammatory skin reaction	Apply nightly, 3 times per week Use up to 16 weeks Wash off after 6–10h
Sinecatechins 15% ointment (Veregen)	Dry warts		Avoid in pregnancy and genital herpes Avoid in immunocompromised patients	Apply tid Use up to 16wk Do not wash off
<b>Provider Applied</b>				
Trichloroacetic acid (TCA) (Tri-Chlor) or bichloroacetic acid (BCA) <sup>2</sup> 80%–90% solution	Small, few Moist warts	May use on vagina, cervix May use on anal warts May use in pregnancy	Avoid with dry and large warts	Apply sparingly with cotton tip Air dry Repeat weekly to every other week Do not allow to “run” on normal skin Neutralize with soap or sodium bicarbonate
Cryotherapy	Small, few, flat Dry or moist	May use in pregnancy May use liquid nitrogen in vagina, meatus, anus	Avoid with large warts Avoid cryoprobe use in vagina or anus	Freeze q1–2wk Freeze 1–2mm border May offer/need local anesthesia
Surgery	Small or large Dry or moist	May use on anal warts Use on large warts and large treatment areas	Avoid in patients with bleeding disorder	Scissors, shave biopsy, punch excision, curettage, cautery, laser
Interferon-α-2b injections (Intron A)	Refractory warts		Expensive Flulike side effects	Multiple intralesional injections Several times a week Often requires specialty referral
Laser vaporization	Refractory warts	May use on intraurethral and large warts as well as large treatment areas	Expensive	Requires specialty referral

<sup>2</sup>Not available in the United States.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

## Treatment

In the absence of dysplasia, the Centers for Disease Control and Prevention recommends no treatment of subclinical HPV infection. The goal of treatment is to eliminate symptoms, namely clinically apparent warts, rather than address the underlying HPV infection. Current treatments do not eradicate the virus.

Ideally, treatment of condyloma should continue until all warts are gone. A repeated course of therapy is often required to achieve a wart-free state. Recurrence may be due to latent HPV in the surrounding normal tissue, HPV reinfection, or improper selection or use of a therapy modality. Nearly all treatment regimens have similar efficacy and rates of intolerance and toxicity. All are known to cause local pain and irritation. Any given treatment has a 40% to 80% rate of wart clearance and up to a 50% recurrence rate. It is unknown whether eliminating warts will decrease infectivity of current or future sexual partners.

The factors to consider when deciding on treatment include location and size of the warts, the patient's tolerance and preference, cost, convenience, and the clinician's preference. Patient-applied options allow the patient greater control; however, this requires good compliance, and the warts must be accessible by the patient or caregiver. Provider-applied treatments are good choices for large

treatment areas. Data regarding the efficacy of using more than one modality at a time are lacking. It is common practice for health care providers to combine treatment modalities. Table 2 outlines current therapy regimens. Podophyllin resin (Podocon-25) is no longer recommended. Failure to respond after four treatments or failure to clear within 3 months warrants a change in therapy modality and possible reevaluation of the diagnosis.

Advise patients to abstain from sexual activity while undergoing treatment for genital warts.

## Monitoring

Counseling of patients regarding prevention and recognition of condyloma as well as screening and treatment of sexual partners should be part of the comprehensive management plan. One should consider testing for other sexually transmitted diseases because they often coexist with HPV. Encourage patients to discuss their HPV diagnosis with sexual partners. Asymptomatic partners likely harbor a subclinical infection, and examination for genital warts is appropriate if lesions are suspected. Discuss the need for smoking cessation and regular physician examinations, including Pap smears, as ways to prevent early HPV-related neoplasm.

## Complications

Anogenital HPV infection with high-risk genotypes is associated with squamous cell carcinoma of the cervix, vagina, vulva, penis, and anus. Persistent HPV infection is the most important risk factor for development of cervical intraepithelial neoplasia and cancer.

## GENITAL ULCER DISEASE: CHANCROID, GRANULOMA INGUINALE, AND LYMPHOGRANULOMA

Method of  
Todd Stephens, MD

Chancroid, granuloma inguinale, and lymphogranuloma venereum (LGV) are important genital ulcer diseases that should be included in the differential diagnosis of patients presenting with anal or genital ulcers with or without inguinal adenopathy. Syphilis and herpes simplex virus testing should be considered on all such patients because of similarities in clinical presentation. Testing or treatment for other potential sexually transmitted infections (STIs), including HIV, should be considered given the high risk for concomitant infection.

### Chancroid

#### History

Chancroid, also called soft sore, was first distinguished from the hard chancre of syphilis by Ricord in 1838. Ducrey, in Naples, demonstrated that inoculation of material from the chancroid ulcer into the skin of the forearm could reproduce the ulcer, and he went on to identify the causative organism, which bears his name.

#### Epidemiology

Chancroid is an important cause of genital ulceration in most countries of the developing world, accounting for about 10 million cases annually. Chancroid was diagnosed in 60% of patients who had genital ulcers and who presented to STI clinics in Africa before the HIV epidemic. Now, herpes simplex lesions represent a higher percentage. The prevalence of this disease is highest among commercial sex workers, and the presence of chancroid lesions significantly increases the risk of transmission of HIV. Although generally rare in industrialized countries, there have been several well-documented outbreaks in urban centers of North America, particularly among men who have sex with men.

**Figure 1** Chancroid. This photo shows an early chancroid ulcer on the penis along with accompanying regional inguinal adenopathy. (Courtesy of Dr. Pirozzi, Centers for Disease Control and Prevention.)

#### Etiology

Chancroid is caused by *Haemophilus ducreyi*, a small anaerobic Gram-negative bacillus that forms streptobacillary chains on Gram stain and grows only on enriched media.

#### Clinical Features

After an incubation of 3 to 7 days, a papule appears that soon ulcerates, leaving a soft ulcer with an undermined edge and a purulent base. Vesicles are not seen. About half of patients develop unilateral inguinal adenopathy (Figure 1). Both the adenopathy and the lesions are very painful. Lesions can be single or multiple, and atypical presentations occur. Kissing lesions often occur on adjacent cutaneous surfaces. Not infrequently, a giant ulcer develops with several smaller satellite ulcers around the periphery, which can mimic the ulcerative phase of herpes simplex. More than half of the lesions occur on the prepuce, particularly in uncircumcised men. In women, the majority of lesions are on the fourchette, labia, and perianal area. Adenopathy can progress to bubo formation with tender, overlying erythema. These buboes can rupture and produce inguinal abscesses.

#### Diagnosis

Gram stain of smears obtained from the ulcer base has been advocated in the past for diagnosis, but this lacks both sensitivity and specificity. The preferred diagnostic modality is swabs for culture from the ulcer base or undermined edge. These are plated directly on enriched media (GC agar and Mueller-Hinton agar base) and incubated for 72 hours in an atmosphere of 5% carbon dioxide at 33°C. Polymerase chain reaction (PCR) and immunochromatography tests are also available.

#### Treatment

The Centers for Disease Control and Prevention (CDC) recommend a syndromal management approach in which a positive diagnosis is suggested if the patient has one or more painful ulcers and no evidence of syphilis or herpes simplex virus. Ulcers with painful adenopathy are pathognomonic (Table 1 lists antimicrobial treatment). The safety and efficacy of azithromycin (Zithromax) for pregnant and lactating women have not been established. Ciprofloxacin (Cipro)<sup>1</sup> is contraindicated during pregnancy and lactation. No adverse effects of chancroid on pregnancy outcome have been reported. Serologic testing for syphilis, HIV, and other appropriate STIs should be performed.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Clinical Features and Treatment Summary of Chancroid, Granuloma Inguinale, and Lymphogranuloma Venereum

FEATURES AND TREATMENT	CHANCROID	GRANULOMA INGUINALE	LYMPHOGRANULOMA VENEREUM
<b>Clinical Features</b>			
Incubation period	3–7 days	3–40 days	1–28 days
Primary lesion	Papule	Papule	Papule or vesicle
Ulcerative lesion painful	Yes	No	No
Lymphadenopathy	Yes (unilateral)	No	Yes (unilateral or bilateral)
Base	Purulent	Raised, easily bleeds	Nonvascular
Border	Round, raised, undermined edges	Irregular, expansion along skin folds	Irregular, ragged
<b>Treatment</b>			
Treatment of choice (any of the options listed)	Azithromycin (Zithromycin) 1g Ciprofloxacin (Cipro) <sup>1</sup> 500mg bid × 3d Ceftriaxone (Rocephin) <sup>1</sup> 250mg IM once	Azithromycin <sup>1</sup> 1g PO once a week or 500 mg qd for >3 weeks until all lesions have completely healed Doxycycline (Vibramycin) 100mg bid × 3 wks	Azithromycin <sup>1</sup> 1g weekly × 3wk Doxycycline 100mg bid × 3wk
Alternative treatment (any of the options listed)	Erythromycin (Ery-Tab) <sup>1</sup> 500mg qid × 7d	Azithromycin <sup>1</sup> 1g PO qwk × 3 wk Erythromycin <sup>1</sup> 500mg qid × 3 wk Ciprofloxacin <sup>1</sup> 750mg bid × 3 wk Ceftriaxone <sup>1</sup> 1 gm IM daily for at least 3 weeks and until all lesions have completely healed.	Erythromycin <sup>1</sup> 500mg qid × 3wk

<sup>1</sup>Not FDA approved for this indication.

Chancroidal ulcers should be kept clean with regular washing in soapy water and kept dry. Fluctuant buboes might require incision and drainage, which is preferable over needle aspiration. Treatment of all sexual partners within 60 days should be pursued, and treatment is similar to that for the source patient. Patients should not engage in sexual activity until the ulcers are healed.

### Granuloma Inguinale (Donovanosis)

#### History

Granuloma inguinale was first recognized in India, where Donovan observed, in an oral lesion of the disease, the bodies that bear his name. There is considerable confusion about terminology between this disease and LGV, because various similar synonyms have been used inconsistently. Adding to the confusion, Donovan's name is associated with two tropical diseases that he discovered: leishmaniasis, with the discovery of intracellular protozoan inclusions that bear his name (Leishman-Donovan bodies), and granuloma inguinale (whose intracellular inclusions were believed to be caused by protozoa but are now known to be caused by bacteria).

#### Epidemiology

Endemic areas are localized to a few specific areas of the tropics, particularly India, Papua New Guinea, Brazil, and the eastern part of South Africa, particularly Durban. Commercial sex workers and men are primarily involved.

#### Etiology

The disease is caused by an encapsulated Gram-negative coccobacillus *Klebsiella granulomatis* (previously known as *Calymmatobacterium* or *Donovania granulomatis*).

#### Clinical Features

A firm, painless papule or nodule is the presenting sign of granuloma inguinale. The incubation period is variable from 3 to 40

**Figure 2** Granuloma inguinale. (Source: NEHC [http://www.nhec.med.navy.mil/hp/sharp/std\\_pictures.htm](http://www.nhec.med.navy.mil/hp/sharp/std_pictures.htm))

days from inoculation. This nodule quickly ulcerates, and the base is highly vascular, is beefy red, and bleeds easily. Lymphadenopathy is not part of the clinical presentation of this disease, distinguishing granuloma inguinale from chancroid and LGV. However, the ulcer can be easily confused with chancroid, condyloma lata, ulcerated verrucous warts, and squamous carcinoma. Untreated, the ulcers slowly expand, particularly along skin folds toward the inguinal region or anus (Figure 2). The ulcers are flat and raised and have slightly hypertrophic margins, but the bases are typically free of pus and necrotic debris. Less-common presentations include extragenital lesions involving the neck and mouth; cervical lesions that resemble carcinoma; and involvement of the uterus, tubes, and ovaries, producing hard masses, abscesses, or frozen pelvis.

## Diagnosis

Diagnosis requires the demonstration of intracellular Donovan bodies from Giemsa or Wright staining of smears taken from a swab of the ulcer base or from biopsy material.

## Treatment

See [Table 1](#) for antimicrobial treatment. Treatment should be continued until lesions are resolved and, if possible, a little longer to reduce the risk of relapse.

## Lymphogranuloma Venereum

### History

LGV was first differentiated from syphilis in 1906 by Wasserman, though the first full description of the disease was given by Durand, Nicolas, and Favre in 1913. In 1925, Frei developed an intradermal skin test that gave positive responses in most LGV patients. The term “tropical bubo” was associated with the disease later.

### Epidemiology

LGV is largely confined to the tropics and is not a common STI. The global overall incidence is in a decline. It is seen more commonly in men, but since 2004, there has been a resurgence manifesting as proctitis in North America and Europe among HIV-positive men who have sex with men.

### Etiology

LGV is a chlamydial infection caused by the invasive L1, L2, and L3 serovars of *Chlamydia trachomatis*, an intracellular gram-negative bacterium.

### Clinical Features

LGV is essentially a systemic disease whose natural course is divided into three distinct phases. The initial phase of LGV is normally an inconspicuous genital lesion beginning as a typically small, painless papule or vesicle occurring 1 to 28 days after inoculation. This papule or vesicle quickly ulcerates and heals without a scar, and it often goes unrecognized by the patient ([Figure 3](#)). However, the second phase of LGV is the development of increasingly painful lymphadenopathy, often with fever and malaise. The lymphadenopathy progresses to bubo formation over 1 to 2 weeks. When a sexually active adult patient presents with an inguinal bubo not associated with genital ulcers, LGV is an important diagnosis to consider. The infected nodes are usually unilateral (bilateral in a third of cases) and often coalesce into a matted mass that can project outwards above or below the inguinal ligament, producing the pathognomonic groove sign present in 20% of patients with LGV. The buboes are likely to rupture, forming multiple sinuses. Untreated, LGV can cause extensive lymphatic damage, resulting in elephantiasis of the genitalia. Anal involvement, likewise, can lead to perirectal abscesses, fistulas, and rectal strictures. These complications represent the late phase of LGV.

### Diagnosis

The diagnosis of LGV can only be confirmed using PCR methods of smears, scrapings, or aspirated material. Alternatively, the ability to perform micro-immunofluorescence serology testing using a fluorescein-conjugated monoclonal antibody and viewing the slide with a fluorescence microscope can demonstrate the inclusion bodies within the cytoplasm of macrophages. Gram staining by itself lacks appropriate sensitivity or specificity. Additional laboratory findings include leukocytosis, elevated erythrocyte sedimentation rate, and increases in immunoglobulin G and cryoglobulins.

### Treatment

Antimicrobial treatment is summarized in [Table 1](#). Needle aspiration or incision and drainage of fluctuant buboes may be required for symptomatic relief but are not routinely recommended for treatment because drainage can delay healing. Fistula openings should receive sterile dressings. One of the primary goals of treatment of LGV is to prevent long-term complications such as

**Figure 3** Lymphogranuloma venereum. **A**, Small ulcerative lesion near corona of penis (*arrow*). **B**, Bilateral inguinal adenopathy, with developing groove sign as adenopathy expands above and below the inguinal ligament. (**A** courtesy Ronald Ballard, Reproduced with permission from *The Diagnosis and Management of Sexually Transmitted Infections in South Africa*, 3rd ed., Johannesburg, South African Institute for Medical Research, 2000. **B** courtesy Connexions ([http://cnx.org/content/m14883/latest/Case\\_10-pres1-1.jpg](http://cnx.org/content/m14883/latest/Case_10-pres1-1.jpg).)

anogenital strictures or fistulas. Plastic surgical operations may be of benefit in cases with extensive rectal strictures or elephantiasis of the genitalia. However, these surgical interventions should only be performed after a prolonged course of antibiotics. Scars should be monitored to detect malignant change.

### Management of Sex Partners

Any person having had sexual contact with a patient with LGV within 60 days before the onset of the patient’s symptoms should be examined and presumptively treated with azithromycin<sup>1</sup> 1gram orally as a single dose or doxycycline 100mg orally twice a day for seven days. Symptomatic patients should be treated with longer treatment regimens.

<sup>1</sup>Not FDA approved for this indication.

## GONORRHEA

Method of

John Brill, MD, MPH

### CURRENT DIAGNOSIS

- Gonorrhea is caused by the gram-negative diplococcus *Neisseria gonorrhoeae*.
- Asymptomatic gonococcal infections are common in men and women, particularly in extragenital locations.
- Molecular tests are more sensitive than culture for diagnosis, particularly in extragenital locations.
- All patients diagnosed with gonorrhea should be tested for other sexually transmitted infections, including human immunodeficiency virus (HIV).
- Annual screening for *N. gonorrhoeae* infection is recommended for all sexually active women aged less than 25 years and for older women at increased risk for infection.

### CURRENT THERAPY

- Ceftriaxone (Rocephin) 500 mg IM is the first-line treatment for gonorrhea, with the addition of doxycycline (100 mg PO BID × 7 days) if concomitant chlamydia has not been ruled out. Persons weighing over 150 kg should be given a dose of ceftriaxone 1.0 g IM.
- The higher dosing of ceftriaxone compared with prior recommendations reflects a small increase in resistance. Doxycycline is now preferred over azithromycin due to a sevenfold increase in azithromycin resistance from 2014 to 2018.
- Only immunoglobulin E-mediated allergic reaction to penicillin (PCN) or cephalosporins (anaphylaxis, Stevens-Johnson syndrome, or toxic epidermal necrolysis) should contraindicate the use of ceftriaxone. Due to limited options, infectious disease consultation is recommended in this situation.

### Epidemiology

Gonorrhea (GC) is the second most common reportable human infection in the United States, with an estimated 1,568,000 new infections occurring each year. After a historic low in 2009, rates have progressively increased in all US regions, with western US states showing the greatest increase over the last 5 years (79.9%) (Figure 1). Cases in men who have sex with men (MSM) drive most of this escalation (Figure 2). Regional rates vary widely from 43 (Vermont) to 611 (District of Columbia) per 100,000 population (Figure 3). The estimated annual US healthcare cost related to GC infections is \$162 million.

### Risk Factors

Risk factors for infection include unprotected intercourse, adolescent and young adult age, new/multiple sexual partners, and exchanging sex for money or drugs (Figure 4). Gonococcal infection is strongly associated with other STIs. In fact, at a county population level, the human immunodeficiency virus (HIV) infection rate carries the highest association with GC rates, superseding all other socioeconomic and demographic risk factors. Additional risk factors for gonorrhea include inconsistent condom use among persons who are not in mutually monogamous relationships, previous or coexisting STIs, and exchanging sex for money or drugs. Military recruits, incarcerated persons, and persons receiving care at public STI clinics are also at high risk. A significant ethnic disparity in GC rates is seen, with rates in Black men 8.9 times higher than those in White men and Black women and 8.4 times higher than in White women in

2016; however, these proportions have been decreasing since 2011.

### Pathophysiology

*N. gonorrhoeae* infects noncornified epithelial cells such as the urethra, endocervix, rectum, oropharynx, and conjunctiva. The bacteria divide by binary fission every 20 to 30 minutes, thus the rapid emergence of symptoms. *N. gonorrhoeae* attaches to different types of mucus-secreting epithelial cells via a number of alterable structures located on the surface of gonococci and additionally uses several mechanisms to counter the immune system. *N. gonorrhoeae* is primarily spread by infected secretions (oral, urethral) coming into contact with mucosal surfaces. Mother-to-child transmission is well established, hence, the recommendation to treat all newborns prophylactically with erythromycin (Ilotycin) 0.5% ophthalmic ointment.

### Screening and Prevention

The US Preventive Service Task Force recommends annual screening for *N. gonorrhoeae* infection in all sexually active women aged less than 25 years and in older women at increased risk for infection (e.g., those who have a new sex partner, more than one sex partner, a sex partner with concurrent partners, or a sex partner who has an STI)—a “B” recommendation. The US Preventive Service Task Force concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for gonorrhea in men—an “I” recommendation. A 2021 draft update maintains the same recommendations.

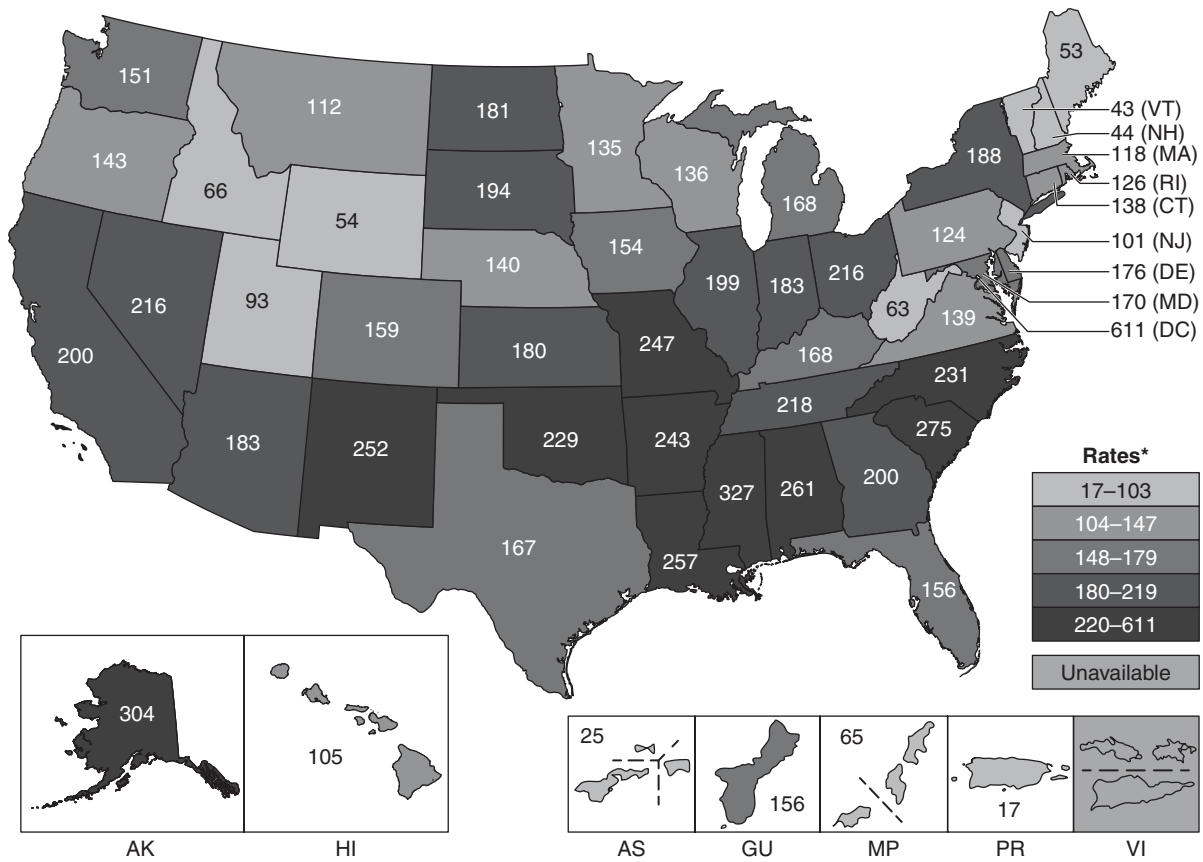

MSM without consistent condom use are at high risk for gonorrhea infection; the Centers for Disease Control and Prevention (CDC) recommends that sexually active MSM be screened at least annually at anatomic sites of exposure. Mucosa that is infected by GC is more susceptible to HIV, even in asymptomatic states, raising the impetus for screening and treatment. Because the bacterium is an obligate human pathogen with adult transmission only via sexual contact, avoidance of intimate contact with an infected person is the optimal mode of prevention. Male latex condoms, used correctly and consistently, are highly effective at preventing GC transmission; polyurethane male and female condoms are effective when intact but have higher breakage rates.

### Clinical Manifestations

The most common symptom of genital GC infection is a mucopurulent urethritis or cervicitis. In men, genital GC typically manifests with urethral discharge and dysuria 2 to 5 days after exposure; however, approximately 30% of urethral infections are asymptomatic. About half of genitally infected women will show symptoms, most commonly vaginal discharge, dysuria, and itching, generally 5 to 10 days after exposure. The great majority of rectal and pharyngeal infections are asymptomatic. GC can also present as ocular and disseminated infection. Except for neonatal infections, believed to arise from perinatal transmission, diagnosis of gonococcal infection in infants and children should trigger a sexual abuse investigation, including multisite testing.

### Diagnosis

Laboratory diagnosis of GC can be made by gram staining of urethral secretions in symptomatic men, by culture of endocervical or urethral specimens, or by nucleic acid amplification testing (NAAT) of urine or the target location. Gram staining of urethral discharge showing leukocytes with intracellular gram-negative diplococci is extremely specific and sensitive. Gram staining is not sensitive enough to rule out infection in symptom-free men or in extraurethral locations. NAAT has largely replaced culture and appears to be more than twice as sensitive as culture in extragenital locations. The increased sensitivity of NAATs is due to their ability to produce a positive test result from as little as a single copy of the target DNA. False-positive test results can occur with NAAT, especially if NAAT has not been cleared by the US Food and Drug Administration (FDA) for use with these specimens or if it is ordered too soon after treatment because NAATs do not

\* Per 100,000.

**NOTE:** See Section A1.11 in the Appendix for more information on interpreting reported rates in US territories.

**Figure 1** Gonorrhea—Rates of reported cases by state and territory, United States, 2018. From CDC: Sexually Transmitted Disease Surveillance 2018. <https://www.cdc.gov/std/stats18/gonorrhea.htm>. Accessed March 21, 2021.

require viable organisms. Although this higher sensitivity has allowed the use of less invasively collected specimens, such as first-catch urine, specific site testing (pharyngeal or rectal specimens) will detect up to 80% more infections than urine screening alone, highlighting the importance of a careful exposure history and consideration of multiple-site screening in high-risk populations. Recent literature has also demonstrated that approved self-collection vaginal swabs are accurate and highly acceptable to patients.

### Differential Diagnosis

Differential diagnosis of gonorrheal genital infections includes *Chlamydia trachomatis* (CT), *Mycoplasma genitalium*, *Trichomonas vaginalis*, and herpes simplex infection. In women, yeast vaginitis and bacterial vaginosis should be considered. Coinfection is common and cannot be ruled out on clinical grounds; therefore cotesting for CT and *Trichomonas* should be done in all patients, and all patients should be offered testing for HIV, syphilis, and hepatitis.

Gonococcal conjunctivitis is typically purulent and unilateral but again cannot be distinguished clinically from other bacterial infections. Because gonococcal eye infections in adults generally result from autoinoculation, this diagnosis should prompt testing at other exposure sites.

### Therapy

The 2021 CDC guidelines recommend a single intramuscular dose of ceftriaxone (Rocephin) 500 mg for the treatment of uncomplicated gonorrhea in persons weighing less than 150 kg, with the addition of oral doxycycline (100 mg BID for 7 days) if concomitant

**Figure 2** Gonorrhea—Estimated rates of reported gonorrhea cases by MSM, MSW, and women. STD Surveillance Network (SSuN), 2010 to 2018. From CDC: Sexually Transmitted Disease Surveillance 2018. <https://www.cdc.gov/std/stats18/gonorrhea.htm>. Accessed March 21, 2021.

chlamydial infection has not been excluded. For persons weighing over 150 kg, a single 1 g IM dose of ceftriaxone should be used. During pregnancy, azithromycin (Zithromax) 1 g as a single dose is recommended to treat chlamydia or as concomitant therapy to ceftriaxone if chlamydial infection has not been excluded. If administration of IM ceftriaxone is not available, a single 800 mg oral dose of cefixime (Suprax) is an alternative regimen.

\* Per 100,000.

**Figure 3** Rates of reported gonorrhea cases by age group and sex, United States, 2018. From CDC: Sexually Transmitted Disease Surveillance 2018. <https://www.cdc.gov/std/stats18/gonorrhea.htm>. Accessed March 21, 2021.

\* Per 100,000.

**Figure 4** Gonorrhea—Rates of reported cases by race/ethnicity, United States, 2014 to 2018. From CDC: Sexually Transmitted Disease Surveillance 2018. <https://www.cdc.gov/std/stats18/gonorrhea.htm>. Accessed March 21, 2021.

The higher dosing in ceftriaxone in the 2021 CDC guidelines reflects a small increase of Minimum Inhibitory Concentration (MIC) of isolates versus the 250 mg dose suggested previously, while azithromycin resistance increased over sevenfold between 2014 and 2018, leading to the recommended switch to doxycycline.

The risk for penicillin cross-reactivity is markedly lower with third-generation cephalosporins such as ceftriaxone (<1%) than first-generation cephalosporins. Only immunoglobulin E-mediated allergic reaction to penicillin (PCN) or cephalosporins (anaphylaxis, Stevens-Johnson syndrome, or toxic epidermal necrolysis) should contraindicate the use of ceftriaxone. Gentamicin 240 mg IM x1 PLUS azithromycin 2g orally x1 is an alternative regimen.

Expedited partner therapy (EPT) is a strategy of treating sex partners of patients with GC or chlamydia without examining the partner. EPT is advocated by the CDC to decrease reinfection rates, particularly where the likely alternative is no care. In 2019 all US states and territories except South Carolina allowed EPT as an exception to scope-of-practice legislation requiring an established clinician-patient relationship. A challenge for EPT with gonorrhea is the need for parental administration of the preferred therapy, ceftriaxone. If oral therapy seems to be the only option for a partner to be treated, cefixime<sup>1</sup> 800 mg (Suprax, two

400-mg single-dose tablets) should be used, again in conjunction with doxycycline 100 mg BID x 7 days if chlamydial infection has not been excluded.

### Monitoring

The 2021 CDC monitoring guidelines contained several changes from prior recommendations:

- Because reinfection is common, occurring in 7% to 12% of patients, men and women with gonorrhea should be retested 3 months after treatment of the initial infection, regardless of whether they believe that their sex partners were successfully treated.
- If the 3-month retesting does not occur, clinicians should retest whenever the individual next presents for care within 1 year of initial treatment.
- A test-of-cure is needed 7 to 14 days after treatment for people who are treated for a throat infection, as ceftriaxone levels are more variable in the pharynx.
- Pregnant women treated early in pregnancy should have a test of cure as well as retest in third trimester.
- Those with persistent symptoms 3 weeks or more after treatment should have a test of cure.

Testing with NAAT in a shorter interval after treatment may result in false-positive test results because of the presence of DNA fragments. In this situation, testing should be repeated for CT and *Trichomonas* to reduce the potential for false-negative initial test results. For continued symptomatic genital infections despite appropriate therapy, culture with sensitivity testing is recommended.

### Management of Complications

In men younger than 40, GC causes about 30% of cases of epididymitis, marked by unilateral testicular pain and swelling. Uncommon male complications of *N. gonorrhoeae* include inguinal lymphadenitis, penile edema, periurethral abscess or fistula, accessory gland infection (Tyson glands), balanitis, urethral stricture, and perhaps prostatitis. Female complications of gonorrhea are more frequent and burdensome; they include pelvic inflammatory disease, potentially leading to infertility or ectopic pregnancy. Disseminated gonococcal infections may occur in up to 2% of untreated patients. Certain gonococcal strains are more likely to cause disseminated gonococcal infections. Although patients are bacteremic, many appear nontoxic. Symptoms and signs may include fevers, myalgias, arthralgias, asymmetric polyarthritits, and a characteristic dermatitis consisting of a small number (<30) of skin lesions on the distal extremities that begin as papules and progress to pustules and ulcerations. Rarely, meningitis and endocarditis may occur. Hospitalization and consultation with an infectious disease specialist are recommended.

## NONGONOCOCCAL URETHRITIS

Method of

Shannon Dowler, MD

### CURRENT DIAGNOSIS

- The gold standard for rapid diagnosis of nongonococcal urethritis (NGU) in a clinic setting is a Gram stain of urethral discharge positive for greater than 2 WBC/hpf and negative for gram-negative diplococci (diagnostic for *Neisseria gonorrhoea*). Microscopic diagnosis of this nature is often immediately available only in dedicated sexual health clinics.
- The majority of patients with NGU present to primary or urgent care, so clinical presentation in a male with symptoms of penile discharge and/or dysuria, with a positive sexual history, is adequate for presumptive diagnosis while awaiting confirmatory testing.
- A urine sample (the first portion of urine stream results in the highest yield) should be sent for nucleic-acid amplification testing (NAAT).
- It is important to take a thorough sexual history and test exposed extragenital sites of infection (such as the throat and anus).
- In adolescents and young adults, a test of reinfection is recommended 12 weeks after treatment. In select patients where there is concern for nonadherence, or in pregnant patients with positive NAAT, test of reinfection/cure (TOR/C) is recommended in 4 weeks. All patients with a positive NAAT should have TOR/C in 3 to 4 months.
- Patients with recurrent infection or persistent symptoms should be evaluated for reinfection, drug resistance, or causes of NGU other than *Chlamydia*, such as *Trichomonas vaginalis* or *Mycoplasma genitalium*.

### CURRENT THERAPY

- If immediate test results are not available, empiric treatment to cover both *Chlamydia trachomatis* and *Neisseria gonorrhoea* is recommended with ceftriaxone (Rocephin) 500 mg IM × 1 (1 g for patients ≥150 kg) and doxycycline 100 mg BID × 7 days. An alternate regime in place of doxycycline is azithromycin (Zithromax) 1 g PO × 1.
- Stocking medications for the immediate treatment of *C. trachomatis* and *N. gonorrhoea* in the clinic is best practice and strongly recommended.
- Expedited partner therapy (EPT) is recommended, though local state law should dictate this practice. Guttmacher Institute maintains an active database of EPT rules by state.

## Epidemiology

There are several etiologies of NGU in the United States, the most common being *Chlamydia trachomatis*. In 2019, the CDC estimates that in the United States there were 1.8 million *C. trachomatis* infections reported—up 19% from 2015. This represents yearly increases since 2000. The second most common cause is *Mycoplasma genitalium*, an infection that is increasingly recognized as a contributor to NGU. Only in 2019 was the first FDA-approved diagnostic laboratory test for *M. genitalium* available commercially. Men who have sex with women are at higher risk for *Trichomonas vaginalis* than men who have sex with men, and the prevalence varies geographically. Historically poor testing options for men have made it difficult to quantify the prevalence of NGU due to *T. vaginalis*, though new tests are now readily available. Other less common causes include *Ureaplasma urealyticum*, herpes simplex virus (HSV), and adenovirus.

## Risk Factors

The risk factors for NGU include sexual activity without using barrier method protection, younger age (<25 years), high-risk sexual partners, multiple sex partners, and a history of sexually transmitted disease (STD). Other contributing factors include low socioeconomic status and racial and ethnic minority status.

## Pathophysiology

NGU as a broad term describes the inflammation of the male urethra usually caused by infection other than *Neisseria gonorrhoea*. Inflammation as a result of the infection causes a penile discharge that ranges in consistency from mucoid to mucopurulent and a range of dysuric symptoms from none to marked burning. While the cause of NGU is most often bacterial (e.g., *C. trachomatis* and *M. genitalium*), it can also be caused by protozoa, *T. vaginalis*, viral etiologies (HSV), and other etiologies.

## Prevention

The mainstay of public health primary prevention efforts includes the education of adolescents and young adults about the inherent risks of unprotected sex, multiple partners, and high-risk sexual partners. Efforts at “abstinence-only” education have resulted in poor outcomes. Encouraging the use of barrier methods, limiting the number of sexual partners, and avoiding high-risk partners are primary prevention strategies. Secondary prevention is geared toward making sexual health clinics widely available and affordable for all people, regardless of insurance status, and ensuring primary care practices are equipped for screening for, treatment of, and education on signs and symptoms of infection.

## Clinical Manifestations

Most men with NGU present with symptoms of dysuria and urethral discharge. Dysuria can range from intermittent and episodic discomfort to persistent pain. Discharge ranges from clear to mucoid to mucopurulent. Frankly purulent and abundant discharge should alert the clinician to strongly consider *N. gonorrhoea*. Many men may not be aware of discharge, so asking questions about “crusting” on the penis or underwear can be helpful. The clinical examination is critical. “Milking” the penis can allow for urethral discharge to manifest at the tip of the penis. At times, the urethral meatus can be inflamed and red. In men with *T. vaginalis*, the symptoms are often more mild and vague, such as “a tingling feeling” or “itching inside the penis” with urination; discharge is less common. Clinicians should pay attention to the presence of significant findings such as enlarged lymph nodes, ulcers, warts, rashes, and scrotal/testicular pain, as patients may present with more than one infection.

## Diagnosis

While Gram stain of the urethral discharge is the gold standard for immediate diagnosis, this modality is rarely available in standard clinical practice. If Gram stain is available, the absence of gram-negative diplococci and the presence of greater than 2 WBC/hpf suggest a diagnosis of NGU. For all patients, further testing by nucleic-acid amplification testing (NAAT) should be undertaken.

A urine sample should be collected after physical examination (ideally limited to the “first” portion of the stream). The NAAT test has high specificity and sensitivity, and results are often available in hours or within a day for many labs. There is not an indication for culture of any causes of NGU. In men who have sex with women, *T. vaginalis* should be strongly considered as an etiology, and testing for *T. vaginalis* is now available to add to *N. gonorrhoea* and *C. trachomatis* NAAT tests. Alternatively, a urine sample can be spun for microscopy, and in experienced labs, *T. vaginalis* can be diagnosed with microscopy. Wet prep testing is not a reliable test for *T. vaginalis* in men. In January 2019, the first FDA-approved NAAT for *M. genitalium* was introduced to the US market. Current CDC guidelines do not routinely recommend screening for *M. genitalium* at this time, though with the availability of new, rapid testing guidelines, it should be monitored. For patients who have refractory or recurrent symptoms, the diagnosis of *M. genitalium* should be considered, but testing is indicated for patients with persistent or recurrent symptoms when NAAT testing is negative for other etiology.

Increasingly, nongenital sites of asymptomatic infection are being identified, particularly in the throat and anus. A thorough sexual history should include sites of sexual contact, and screening should be performed at those sites when a patient presents with symptoms or risk for sexually transmitted infections. Routine screening should also include sampling from extragenital sites. Numerous studies have confirmed that many patients with negative urine NAATs will have asymptomatic *C. trachomatis* or *N. gonorrhoea* infections in other sites of sexual contact.

### Therapy/Treatment

Patients with characteristic symptoms who have a Gram stain performed that rules out *N. gonorrhoea* should be treated for NGU empirically with doxycycline 100 mg BID × 7 days. This guidance in the 2021 CDC STI guidelines reflects a significant change. Alternatively, azithromycin (Zithromax) 1 g by mouth in one dose can be given; unfortunately, due to emerging drug resistance, this should be reserved for patients where the likelihood of treatment non-adherence is very high. In the absence of Gram stain testing availability, empiric treatment coverage with both azithromycin and ceftriaxone (Rocephin) should be considered in patients with a history of recent infection, high-risk contacts, or symptoms of urethritis. All clinical locations that test and treat for sexually transmitted infections should maintain a supply of oral azithromycin and metronidazole (Flagyl), as well as intramuscular ceftriaxone to provide immediate treatment and reduce barriers to care such as transportation to a pharmacy, pharmaceutical insurance coverage, cost, and concerns about confidentiality, particularly in younger patients.

If trichomonas is suspected, new guidelines recommend men receive a one time 2 g dose of metronidazole but women receive 500 mg BID × 7 days, a marked change from prior guidelines. Of note, the new guidelines also disabuse the historical potential for the interaction between alcohol and metronidazole and no longer list this as a contraindication. Additional regimens are available at the free-of-charge STD treatment guidelines page on the CDC website ([cdc.gov](http://cdc.gov)). The STD treatment guideline app is an excellent public source tool for treatment guidelines.

If a patient presents with persistent symptoms despite appropriate treatment, the clinician must consider reinfection or drug resistance. If the patient had negative tests for *N. gonorrhoea* and *C. trachomatis*, the clinician should consider empiric treatment for *T. vaginalis* with metronidazole 2 g PO ×1 or tinidazole (Tindamax) 2 g PO ×1 if the patient is a male who has sex with females. The possibility of *M. genitalium* should be considered in patients with NGU, particularly those with recurrent or persistent symptoms. *M. genitalium* has developed rapid drug resistance, with more than a third of infections now resistant to azithromycin. Performing NAAT testing for recurrent or persistent symptoms in the absence of a confirmatory *C. trachomatis* or *N. gonorrhoea* result should be undertaken. The guidelines for treatment are different based on whether resistance testing is available from your

lab. If it is not available, the recommended treatment is doxycycline 100 mg BID × 7 days followed by moxifloxacin (Avelox)<sup>1</sup> 400 mg daily for 7 days. CDC recommends testing partners for *M. genitalium* and treating if positive; alternatively, if testing not an option for partners of positive cases, then the same drug regimen can be used.

All patients treated for NGU should be advised to abstain from sex for 1 week to allow for clearance of infection. Known sexual partners should be treated with expedited partner therapy when allowed by state law. The patient should not resume sexual activity until the partner is adequately treated. Positive tests should be reported to the health authority as indicated by state law.

### Monitoring

Partner treatment is recommended for all confirmed causes of NGU. Test of reinfection closely after treatment (4 weeks) is recommended in high-risk patients and test of cure after treatment (3 months) for all patients with a positive NAAT for *C. trachomatis* or *N. gonorrhoea*. TOR/C is not routinely recommended for *T. vaginalis*.

### Complications

Untreated *C. trachomatis* infection in men can cause epididymitis, prostatitis, and reactive arthritis. Autoinoculation to the eyes is a potential complication in untreated urethral infections and requires immediate treatment.

<sup>1</sup>Not FDA approved for this indication.

## SYPHILIS

Method of

Jennifer Frank, MD

### CURRENT DIAGNOSIS

- Serologic testing includes both nontreponemal-specific testing (VDRL and RPR) and treponemal-specific testing (FTA-Abs [fluorescent treponemal antibody absorption] and TP-PA [*Treponema pallidum* particle agglutination]).
- Cerebrospinal fluid testing (VDRL [Venereal Disease Research Laboratory], protein, cell count) is performed to diagnose neurosyphilis.

### CURRENT THERAPY

- Penicillin is first-line therapy for all types and stages of syphilis.
- Penicillin is the only recommended treatment for pregnant women and for congenital syphilis. Penicillin-allergic patients should undergo desensitization.

**Figure 1** *Treponema pallidum* on darkfield microscopy.

**Figure 2** Syphilis skin lesion.

### Epidemiology

The rate of primary and secondary syphilis reached a low point (2.1 per 100,000) in 2000 and has increased since that time, with the most recent data indicating a continued increase of 11% from 2018 to 2019. Rates are increasing in both men and women, among all racial/ethnic groups, and in all areas of the United States. Men who have sex with men (MSM) continue to have the highest rates of syphilis. Rates in women have increased by 30% from 2018 to 2019. Congenital syphilis cases also continue to increase with a rate of 48.5 cases per 100,000 live births in 2019, which is a 41% increase from 2018. The number of stillbirths and infant deaths secondary to congenital syphilis is also on the rise.

### Risk Factors

MSM and HIV-positive persons are at highest risk for primary and secondary syphilis. Other risk factors include living in the certain geographic areas in the United States or an urban area, and being born to a mother infected with syphilis.

### Pathophysiology

Syphilis is caused by infection with the spirochete *Treponema pallidum* subspecies *pallidum* (Figure 1). The average incubation period is 21 days (range 3-90 days). Primary infection manifests with signs and symptoms at the site of infection; secondary and tertiary syphilis manifest with systemic signs and symptoms. Syphilis is primarily sexually transmitted but may be transmitted perinatally or through nonsexual cutaneous transmission. Previous infection does not confer long-term immunity.

### Prevention

Prevention includes both avoiding initial infection and preventing disease progression through early detection and treatment. Transmission of syphilis can be reduced (although not eliminated) by using condoms. Screening for syphilis in pregnancy combined with treatment of infected women reduces perinatal transmission. The two most common missed opportunities in prevention of congenital syphilis are maternal treatment in a woman who is diagnosed with syphilis and timely prenatal care with appropriate syphilis screening. Screening high-risk populations may prevent spread of infection.

### Screening

The US Preventive Services Task Force recommends screening people at increased risk for syphilis. This includes women and men who have sex with women who are at increased risk based on incarceration, sex work, geography, race or ethnicity, and age. Men who have sex with men should be screened annually and more frequently if at increased risk. People with HIV should be screened at their first evaluation and then annually. Gender diverse people should be screened based on risk factors. All pregnant women should be screened for syphilis at the first prenatal visit. Women at increased risk should be rescreened in the third trimester, at delivery, and after any potential exposure to an infected partner.

### Clinical Manifestations

Primary syphilis manifests as a chancre at the site of inoculation. The chancre, a painless ulcer with sharp borders, is usually solitary and associated with regional lymphadenopathy. Atypical presentations include extragenital location (most commonly oral or anal) and the presence of pain or multiple lesions. Secondary syphilis characteristically manifests with a generalized rash with variable features four to eight weeks after onset of primary syphilis (Figure 2). The palms and soles are affected in the majority of patients. Typically, the rash is maculopapular or papulosquamous and nonpruritic. Other clinical manifestations include highly infectious flat lesions (condyloma lata), fever, malaise, sore throat, headache, myalgias, alopecia, and, rarely, renal, bone, eye, or liver involvement. Latent syphilis, by definition, has no clinical manifestations. Neurologic, otologic, and ocular symptoms can occur during any stage of syphilis. People should be screened for neurologic, otologic, and ocular involvement; the presence of any symptoms warrants additional evaluation, which may include CSF examination, ocular examination, or evaluation by otolaryngology.

Tertiary syphilis, which is rare, is a late manifestation in untreated people and includes late neurosyphilis, cardiovascular, and gummatous disease. Gummas are nodular lesions that vary in size and location. They can ulcerate and cause local tissue destruction. Cardiovascular syphilis most commonly manifests as aortitis of the ascending aorta. The clinical manifestations of neurosyphilis are numerous and include meningitis with or without vascular involvement, dementia, tabes dorsalis (posterior column involvement with ataxia and bowel and bladder dysfunction), and ocular or otologic involvement.

Congenital syphilis has early (birth to 2 years) and late (2 to 20 years) clinical manifestations. Early signs include hepatosplenomegaly, rash, fever, neurosyphilis, pneumonitis, rhinitis, generalized lymphadenopathy, hepatitis, ascites, hematologic disease, renal disease, periostitis, and osteochondritis. Late manifestations (present in 40% of untreated patients) include skeletal deformities, neurologic disease (deafness), dental abnormalities, and ocular abnormalities.

### Diagnosis

Primary syphilis is optimally diagnosed by specific testing of the skin lesion or exudate as it can take several weeks for antibodies to develop. There are three methods for testing of exudate: direct fluorescent antibody testing, PCR testing, and darkfield microscopy; all have limited availability. Serologic testing is done using nontreponemal (VDRL or RPR) and treponemal testing (multiple types, including FTA-ABS and TPPA) because both tests have limitations. Nontreponemal testing may be falsely positive with other medical conditions, but antibody titers correlate with disease activity and therefore can indicate response to treatment. Nontreponemal tests usually become nonreactive after successful treatment. A serofast reaction can occur in which the nontreponemal test stays reactive. Treponemal tests are specific for syphilitic infection but

**TABLE 1** CDC Recommendations for Treatment of Syphilis

STAGE	RECOMMENDED PENICILLIN TREATMENT	
	PENICILLIN	DOSAGE
Primary and secondary syphilis	Benzathine penicillin G (Bicillin LA)	2.4 million U IM once
Early latent syphilis (acquired within previous 12 mo)	Benzathine penicillin G	2.4 million U IM once
Late latent syphilis	Benzathine penicillin G	2.4 million U IM weekly × 3 doses
Tertiary syphilis	Benzathine penicillin G	2.4 million units IM weekly × 3 doses
Neurosyphilis	Aqueous crystalline penicillin G <i>or</i> Continuous infusion	3–4 million U q4h 18–24 U daily IV × 10–14 d (preferred)
	Procaine penicillin (Wycillin) <i>plus</i> Probenecid	2.4 million U IM 500 mg PO qid
<b>Congenital Syphilis</b>		
Proven or highly probable disease	Aqueous crystalline penicillin G <i>or</i> Procaine penicillin G	100,000–150,000 U/kg/d (divided 50,000 U/kg/dose) IV q12h × first 7 d of life, then q8h for total of 10 d of treatment 50,000 U/kg/dose IM daily × 10 d
Normal examination but mother inadequately treated	Aqueous crystalline penicillin G <i>or</i>	100,000–150,000 U/kg/d (divided 50,000 U/kg/dose) IV q12h × first 7 d of life, then q8h for total of 10 days of treatment
	Procaine penicillin G <i>or</i>	50,000 U/kg/dose IM daily × 10 d
	Benzathine penicillin G	50,000 U/kg/dose IM once
Normal examination, serologic titers ≤4× the maternal titer, and mother adequately treated during pregnancy	Benzathine penicillin G	50,000 U/kg/dose IM once

Abbreviation: CDC = Centers for Disease Control and Prevention.

stay reactive in the majority of people regardless of treatment or disease status. Treponemal test antibody titers do not match the level of disease activity and therefore cannot be used to monitor treatment response. Reverse sequence testing has been used in which a treponemal specific test is the initial screening test, followed by a non-treponemal test. Reverse sequence testing has a higher false-positive rate with the initial screening step of testing but identifies more cases of syphilis, particularly early infection, previously treated infection, or long-standing infection. If reverse sequence screening is used, a third treponemal specific test using different antigens should be used to confirm the results.

Neurosyphilis is diagnosed based on clinical signs and symptoms using laboratory testing to support a clinical diagnosis. No single test can be used to diagnose all patients with neurosyphilis, which means that neurosyphilis is usually diagnosed by a combination of serologic testing, testing of cerebrospinal fluid (CSF), and clinical evaluation. Laboratory testing includes reactive serologic testing; cerebrospinal fluid (CSF) VDRL (Venereal Disease Research Laboratory) testing, which is specific but not sensitive; and CSF positive for white blood cells or protein, or both. The CSF FTA-ABS (fluorescent treponemal antibody absorption) test is sensitive but less specific than CSF VDRL testing. Patients with latent, tertiary, or neurosyphilis should be tested for HIV infection.

### Differential Diagnosis

Syphilis, which can affect every organ system, has historically been called the great mimicker. Syphilis is on the differential diagnosis of, most commonly, conditions causing genital ulcers or lesions, conditions causing systemic rashes affecting the palms and soles, conditions causing ocular and otologic manifestations (uveitis, sudden visual changes, hearing loss), and conditions causing dementia, meningitis, or ataxia.

### Treatment

Penicillin G is the preferred treatment for all stages of syphilis; other forms of penicillin (oral penicillin, combinations of benzathine and procaine [Bicillin CR]) are not effective. The stage and extent of clinical disease determine which preparation is used, the dosage, and the length of treatment (Table 1). In penicillin-allergic patients, antibiotic alternatives exist for all types and stages of syphilis except for syphilis in pregnancy and congenital syphilis. Consider consultation with infectious disease for nonpenicillin treatment regimens for patient with latent, tertiary, ocular, otic, or neurosyphilis.

In people with a penicillin allergy and primary or secondary syphilis, doxycycline (100 mg orally twice daily for 14 days) or tetracycline (500 mg orally four times per day for 14 days) can be used. Ceftriaxone (Rocephin) 1 g daily IM or IV for 10 days<sup>1</sup> has also been used, although the optimal dose and duration are not known. Azithromycin (Zithromax)<sup>1</sup> should not be used given the potential for resistance.

The treatment of latent syphilis in penicillin-allergic people can include doxycycline (100 mg twice daily) or tetracycline (500 mg four times daily) for 28 days. Neither ceftriaxone nor azithromycin are indicated.

The Jarisch-Herxheimer reaction is an acute febrile reaction (with accompanying headache, myalgias, and other symptoms) occurring within 24 hours of treatment of syphilis. It is more common in early stages of syphilis and rare in newborns.

### Monitoring

No definite criteria exist for either cure of syphilis or treatment failure. It is recommended that nontreponemal antibody titers be followed every 6 months, and patients should be periodically reexamined for clinical signs or symptoms of syphilitic

<sup>1</sup>Not FDA approved for this indication.

infection. Treatment failure is probable in patients with either persistent or recurrent clinical signs or symptoms or a sustained fourfold increase in nontreponemal antibody titer (compared to maximum titer at time of treatment). Treatment failure is possible if nontreponemal antibody titers fail to decline fourfold within 6 months after treatment. Suspected treatment failure warrants retesting for neurosyphilis and HIV infection. Patients with HIV infection, with congenital syphilis, who are pregnant, or who have neurosyphilis warrant closer and more-specific laboratory and clinical follow-up. Full recommendations can be found in the Centers for Disease Control and Prevention (CDC) treatment guidelines (<http://www.cdc.gov/std/treatment-guidelines/syphilis.htm>).

### Complications

Complications of syphilis are primarily related to neurologic involvement, tertiary syphilis, or late manifestations of congenital syphilis.

**ACNE VULGARIS**

Method of

Lisa M. Johnson, MD; and Daniel J. Van Durme, MD, MPH

**CURRENT DIAGNOSIS**

- Acne vulgaris (AV) is primarily found in teenagers and young adults and is characterized by microcomedones that develop into open and closed comedones (blackheads and whiteheads), inflammatory papules and pustules, or nodules and cysts.
- AV lesions are primarily on the face, neck, upper arms, back, and chest.
- Acneiform lesions are typically found in various stages, with many patients having a predominant type.

**CURRENT THERAPY**

- Acne therapy targets abnormal hyperkeratinization, excess sebum production, colonization by *Propionibacterium acnes*, and inflammation. Therapy involves prevention of new lesions and control over a long period of time with response generally seen in 6 to 8 weeks.
- Numerous topical and oral medications have demonstrated efficacy for patients with acne; there is little evidence for which is best.
- Benzoyl peroxide is an excellent starting agent because of extensive safety and efficacy studies, its demonstrated benefit in controlling *P. acnes*, and some benefits in controlling abnormal keratinization and inflammation.
- Topical retinoids should also be considered starting agents because of their demonstrated benefits in controlling abnormal keratinization leading to microcomedones, a primary lesion in acne.
- Topical antibiotics such as clindamycin (Cleocin-T) and erythromycin (Akne-Mycin) should be used in combination with topical retinoids for more efficacy or with benzoyl peroxide to decrease the likelihood of bacterial resistance.
- Oral antibiotics such as the class of tetracycline should be used if acne is widespread or unresponsive to topical agents.
- Oral contraceptives have proven benefits for most types of acne.
- Oral isotretinoin (Accutane, Claravis) can be very effective and even cures many patients, but the teratogenic and other side effects are profound and mandate use with extreme caution.

Acne (or acne vulgaris [AV]) and rosacea (previously called *acne rosacea* and sometimes *adult acne*) are often thought of together. However, they actually represent different pathophysiologic processes and require different therapeutic approaches.

**Epidemiology**

Acne is a chronic inflammatory dermatosis that is most common in adolescents, affecting approximately 85% of teenagers with the average age of onset being 11 to 12 years of age, peaking at

ages 15 to 17. It can occur, however, in most age groups and can persist into adulthood. It is typically worse in male patients. The severity varies widely. There is no mortality associated with acne, but there is often significant physical and psychological morbidity, such as permanent scarring, poor self-image, depression, and anxiety. More severe forms of acne are found in those with a genetic predisposition and those with earlier onset.

**Prevention**

There is some evidence to suggest that high glycemic index diets may be associated with acne. In 2007, a randomized controlled trial with 23 Australian males, aged 15 to 25 years, examined the impact of a low glycemic diet on acne. Those randomized to follow the low glycemic load (LGL) diet had significant improvement in acne severity, a significant reduction in weight and body mass index (BMI), a significant decrease in free androgen index, and improved insulin sensitivity at the end of 12 weeks. The study was limited by its small sample size and the fact that both the intervention and control groups lost weight.

There is some evidence that dairy products (particularly skim milk) might contribute to acne, but others have questioned the strength of these studies. Although some small preliminary studies have examined the role of antioxidants (including oral zinc), probiotics, and fish oil on acne, the existing evidence is not strong enough, at this time, to support any recommendations regarding these dietary factors.

**Pathophysiology**

The pathophysiology of acne involves androgens as a major contributing factor, and thus acne starts with puberty. Four intersecting pathophysiologic processes are involved in acne, and the sequence and degree of contribution of each factor is still under study. The lesions begin with abnormal keratinization of the pilosebaceous glands that are more concentrated on the face, neck, and trunk. The keratin that lines the opening of the glands becomes more cohesive; this blocks the gland from being able to adequately excrete the sebum, and the plugged opening dilates. This leads to a closed comedone (whitehead) or open comedone (blackhead). Additional factors include the proliferation of the gram-positive *Propionibacterium acnes* (*P. acnes*) and an increase in inflammatory mediators, such as cytokines, leukotrienes, lymphocytes, and macrophages, which lead to the papules and pustules of inflammatory acne. Finally, the abnormal and excess production of sebum, particularly triggered by androgens, can play a key role as well, notably in nodulocystic acne.

**Diagnosis**

Diagnosis is generally straightforward, especially in teenagers. Dermatologic lesions include open and closed comedones, pustules, inflammatory papules, nodules, and cysts. Lesions are primarily found on the face, neck, upper arms, back, and chest. They are typically found in various stages, and many patients have a predominant type.

**Clinical Manifestations**

Clinical manifestations include open and closed comedones (blackheads and whiteheads), inflammatory papules and pustules, and, in severe cases, nodules and cysts. There are several proposed classification schemes to help identify the numbers and

types of lesions. Perhaps the most useful combines an estimate of the numbers of lesions with a descriptor of the lesions and location. Thus a patient can have mild (few lesions) papulopustular acne of the face and severe (many lesions) comedonal acne on the back and shoulders. This classification helps identify optimal treatment and provides a better description to assess response to therapy.

### Differential Diagnosis

Differential diagnosis should include drug-induced acne (especially from steroids), which can be identified by seeing all lesions at nearly the same stage of development. Rosacea should also be considered in the differential diagnosis of AV, though the age of onset and symptomatology are usually distinguishing.

### Treatment

The topical therapy of AV includes the use of agents that are available over the counter or via prescription. Therapy choice may be influenced by age of the patient, site of involvement, extent and severity of disease, cost, and patient preference. Topical therapies may be used as monotherapy in combination with other topical agents or in combination with oral agents in both initial control and maintenance.

Additionally, it is key to set realistic expectations about how acne can be controlled with the regular use of a variety of agents and how it can take 6 to 8 weeks to see improvement. If these issues are not addressed, the likelihood of adherence and long-term improvement are low.

Commonly used topical acne therapies include benzoyl peroxide, salicylic acid, antibiotics, combination antibiotics with benzoyl peroxide, retinoids, retinoid with benzoyl peroxide (BP), retinoid with antibiotic, azelaic acid, and sulfone agents.

BP is an antibacterial agent that kills *P. acne* through the release of free oxygen radicals and is also mildly comedolytic. No resistance to this agent has been reported, and the addition of BP to regimens of antibiotic therapy enhances results and may reduce development of drug resistance. BP is available as topical washes, foams, creams, or gels and can be used as leave-on or wash-off agents. Strengths available for acne therapy range from 2.5% to 10%. Benzoyl peroxide therapy is limited by skin irritation, staining and bleaching of fabric, and uncommon contact allergy. Total skin contact time and formulation can also affect efficacy. Lower concentrations (e.g., 2.5–5%), water-based, and wash-off agents may be better tolerated in patients with more sensitive skin. Results may be noted in as soon as 5 days.

Topical antibiotics for acne accumulate in the follicle and have been postulated to work through antiinflammatory mechanisms and via antibacterial effects. These agents are best used in combination with BP, which increases efficacy and decreases the development of resistant bacterial strains. Monotherapy with topical antibiotics in the management of acne is not recommended because of the development of antibiotic resistance.

Clindamycin 1% solution or gel is currently the preferred topical antibiotic for acne therapy. Topical erythromycin in 2% concentration is available as a cream, gel, lotion, or pledget but has reduced efficacy in comparison with clindamycin because of resistance of cutaneous *Staphylococci* and *P. acnes*.

Topical retinoids (tretinoin [Retin-A, Renova, Avita], adapalene [Differin], or tazarotene [Tazorac]) are all extremely effective for abnormal keratinization and comedone development and thus treat existing lesions and prevent the development of new lesions. These can be irritating and come in a variety of strengths. Patients might need to start at the lowest strength with every-other-day dosing and work up to the highest strength needed and tolerated. Some formulations of tretinoin (primarily generic products) are not photo stable and should be applied in the evening. All are contraindicated in pregnancy.

Topical retinoids enhance other topical acne regimens and allow for maintenance of clearance after discontinuation of oral therapy. Retinoids are ideal for comedonal acne and, when used in combination with other agents, for all acne variants. Three

topical agents are available that contain retinoids in combination with other products: adapalene 0.1%/ BP 2.5% (Epiduo), approved for use in patients  $\geq 9$  years of age, and 2 agents with fixed combination clindamycin phosphate 1.2%/tretinoin 0.025% gel (Veltin, Ziana), approved for patients  $\geq 12$  years of age.

Salicylic acid preparations are comedolytic and can be used for patients who cannot tolerate either benzoyl peroxide or topical retinoids, although salicylic acid preparations have not been shown to be as effective. Azelaic acid 20% cream (Azelex) is mildly effective as a comedolytic, antibacterial, and antiinflammatory agent; it is also a category B in pregnancy.

The sulfone agent, dapsone 5% gel (Aczone), is available as a twice-daily agent for the therapy of AV. In clinical trials, topical dapsone showed modest to moderate efficacy, primarily in the reduction of inflammatory lesions. Combination with topical retinoids may be indicated if comedonal components are present. Topical dapsone may be oxidized by the coapplication of BP, causing orange-brown coloration of the skin, which can be brushed or washed off.

Topical dapsone 5% gel is pregnancy category C and has efficacy and safety data down to patients 12 years of age. Aluminum chloride<sup>1</sup> possesses antibacterial activity and therefore has been investigated in the treatment of acne. There is some evidence to suggest the efficacy of sodium sulfacetamide (Klaron, Ovace Plus). Topical niacinamide (nicotinamide)<sup>7</sup> 2% to 4% gel is available over the counter.

For patients with moderate inflammatory and comedonal lesions, it can be appropriate to start both BP and topical retinoids at the initial visit; however, the applications should be separated in time because the BP will inactivate the retinoid. An effective regimen (if tolerated) is a BP wash in the morning and topical retinoid at bedtime.

Antibiotics should be added if response to topical BP and retinoids is inadequate at the 6- to 8-week follow-up visit. Topical clindamycin (Cleocin-T) and erythromycin (Akne-Mycin) have demonstrated efficacy and can be used twice a day at the same time as the BP. There are also combination agents that conveniently add the two agents into a single preparation: clindamycin 1% plus BP 5% gel (BenzaClin, Duac) and erythromycin 3% plus BP 5% gel (Benzamycin). They are more expensive, however.

Oral antibiotics should be started if the acne is moderate to severe, if it is too widespread to reasonably cover with topical antibiotics, or if there is an inadequate response after 6 to 8 weeks of topical antibiotics. The tetracycline class of antibiotics should be considered first-line therapy in moderate to severe acne, except when contraindicated because of other circumstances (i.e., pregnancy,  $< 8$  years of age, or allergy).

Minocycline in an extended-release form (Ximino) appears safest (at 1 mg/kg once daily), but no dose response was found for efficacy. Doxycycline appears effective in the 1.7 to 2.4 mg/kg dose range. Subantimicrobial dosing of doxycycline (i.e., 20 mg twice daily [immediate release] to 40 mg daily [delayed release]) has also shown efficacy in patients with moderate inflammatory acne. Adverse events with the tetracycline class vary with each medication. Photosensitivity can be seen with the tetracycline class, doxycycline being more photosensitizing than minocycline. Doxycycline is more frequently associated with gastrointestinal disturbances. Doxycycline is primarily metabolized by the liver and can be used safely in most patients with renal impairment. Minocycline has been associated with tinnitus, dizziness, and pigment deposition of the skin, mucous membranes, and teeth. Minocycline-induced skin pigmentation is more common in patients taking higher doses for longer periods of time. The rare serious events associated with minocycline include autoimmune disorders, such as drug reaction with eosinophilia and systemic symptoms (DRESS), drug-induced lupus, and other hypersensitivity reactions. Finally, pseudo tumor cerebri is a rare phenomenon associated with the tetracycline class of antibiotics.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement

Erythromycin<sup>1</sup> and azithromycin<sup>1</sup> have also been used in the treatment of acne. Azithromycin has been primarily studied in the treatment of acne with different pulse dosing regimens ranging from 3 times a week to 4 days a month, with azithromycin being an effective treatment in the time span of usually 2 to 3 months. However, a recent study compared using azithromycin 3 times per month to daily doxycycline use and showed that doxycycline had superior results. The macrolide class of antibiotics is most commonly associated with gastrointestinal disturbances. Erythromycin is associated with a higher incidence of diarrhea, nausea, and abdominal discomfort than azithromycin.

TMP-SMX (trimethoprim-sulfamethoxazole [Bactrim, Septra DS])<sup>1</sup> taken twice daily also has side effects to consider but can be useful when other agents are not tolerated. The adverse events of TMP/SMX include gastrointestinal upset, photosensitivity, and drug eruptions. Multiple skin reactions have been observed with patients on this medication, the most severe eruptions being Stevens-Johnson syndrome and toxic epidermal necrolysis. Other adverse effects can include blood dyscrasias, such as neutropenia, agranulocytosis, aplastic anemia, and thrombocytopenia. Although these are rare adverse events, patients on long-term therapy with this medication should be periodically monitored with a complete blood cell count.

Penicillins and cephalosporins are sometimes used in the treatment of acne and can be used as an alternative treatment when circumstances dictate. In particular, these medications represent a useful option in patients who may be pregnant or who have allergies to the other classes of antibiotics.

All oral agents should be used in combination with BP and/or a topical retinoid but not in combination with topical antibiotics. If significant improvement is noted, oral agents should be decreased after 3 to 4 months or stopped in order to attempt maintenance control with topical agents. Limiting systemic antibiotic use is urged because of the reported associations of inflammatory bowel disease, pharyngitis, *C. difficile* infection, and the induction of *Candida vulvovaginitis*.

Combined oral contraceptives can be very helpful in female patients with moderate acne because of their antiandrogenic effects, which decrease sebum production. There are currently four combined oral contraceptives (COCs) approved by the FDA for the treatment of acne. They are ethinyl estradiol/norgestimate (Ortho Tricyclen), ethinyl estradiol/norethindrone acetate/ferrous fumarate (Erostep Fe, Tilia Fe, Tri-Legest Fe), ethinyl estradiol/drospirenone (Yasmin, Yaz), and ethinyl estradiol/drospirenone/levomefolate (Beyaz, Rajani).

COC use is associated with cardiovascular risks. Venous thromboembolic events (VTEs) have been the center of an ongoing debate regarding COCs. Traditionally, higher doses of ethinyl estradiol have been linked to increased risks of VTE. However, in recent years, some progestins have been implicated as risk factors for VTE. A recent Cochrane meta-analysis evaluated 25 publications reporting on 26 studies focused on oral contraceptives and venous thrombosis. The analysis concluded that all COC use increases the risk of VTE compared with nonusers. The relative risk of venous thrombosis for COCs with 30 to 35 micrograms of ethinyl estradiol and gestodene desogestrel, cyproterone acetate, or drospirenone was similar and about 50% to 80% higher than for COCs with levonorgestrel. To put this increased risk into perspective, it is important to note that the baseline risk of VTE in nonpregnant, nonusers of COCs is 1 to 5 per 10,000 woman-years. Users of COCs have a VTE risk of 3 to 9 per 10,000 woman-years. Users of drospirenone containing COCs have a VTE risk of about 10 per 10,000 woman-years. Pregnant women have a VTE risk between 5 and 20 per 10,000 woman-years, and women within 12 weeks postpartum have a VTE risk of between 40 and 65 per 10,000 woman-years.

Oral isotretinoin (Accutane, Claravis) has demonstrated marked benefit for patients with severe recalcitrant acne, even inducing a

full remission. It is a potent teratogen; therefore every woman of child-bearing potential taking isotretinoin should be carefully counseled regarding various contraceptive methods (including long-acting reversible contraception) that are available. Isotretinoin has a host of other significant side effects, including cheilitis, epistaxis, photosensitivity, and many others. Prescribed at 0.5 to 2 mg/kg per day over 20 weeks, it is like chemotherapy for acne. It is extremely tightly regulated, and both prescribers and patients must register with the iPledge program to write for the medicine and to receive the prescriptions. See [www.ipledgeprogram.com](http://www.ipledgeprogram.com). When all the precautions are managed, it can be an extremely effective option for the patients with the worst cases of acne.

## ATOPIC DERMATITIS

Method of

Peck Y. Ong, MD

### CURRENT DIAGNOSIS

- Itch must be present for the diagnosis of atopic dermatitis. In addition, the diagnosis must include three or more of the following criteria (U.K. Working Party's Diagnostic Criteria for Atopic Dermatitis):
  - History of generalized dry skin
  - Visible flexural dermatitis
  - Onset of the skin condition before 2 years (not used for patients younger than 4 years)
  - History of itchy skin involving the following areas: elbows, behind knees, front of ankles, or around the neck
  - History of asthma or allergic rhinitis (or for children younger than 4 years, history of atopic disease in a first-degree relative)

### CURRENT THERAPY

- Bathe or shower for 10 to 20 minutes daily and pat dry gently.
- Follow immediately by applying an emollient on unaffected areas and an antiinflammatory medication on affected areas.
- Use topical corticosteroids as a first-line antiinflammatory medication; alternative medications are topical calcineurin inhibitors, topical phosphodiesterase 4 inhibitor topical or oral janus kinase (JAK) inhibitors and monoclonal antibodies targeting IL-13 or IL4/IL-13.
- Avoid environmental triggers such as extreme heat, humidity, or dryness.
- Avoid food allergens that may cause anaphylaxis. Consult an allergist regarding the interpretation of serum-specific IgE tests or food challenge.
- Treat skin infection only when clinical signs are present (e.g., oozing, impetigo).
- Severe, generalized infection or vesicular lesions may indicate herpes simplex virus infection; persistent fever may indicate invasive *S. aureus* infection.

<sup>1</sup>Not FDA approved for this indication.

Atopic dermatitis (AD) is a chronic inflammatory skin disease that is characterized by itch and a predilection of eczema on extensor areas in young infants or flexural areas in older children and adults. In the United States, AD affects about 15% of children and 2% of adults. For more than 85% of patients, AD begins during the first 5 years, but 50% of the children with AD improve significantly or outgrow the disease by age 7. The persistence of AD depends on various factors: early onset, severity, family history of AD, personal history of asthma, and food or inhalant allergies.

The itch associated with AD causes significant discomfort in these patients and often leads to sleep loss and to poor school or work performance. The quality of life of children with generalized AD is worse than that for children with diabetes, epilepsy, asthma, cystic fibrosis, or renal disease. The maternal stress in taking care of children with moderate to severe AD is equivalent to that associated with care of children with diabetes, Rett syndrome, profound deafness, or the need for enteral feeding.

### Pathophysiology

AD is caused by a combination of genetic and environmental factors. Patients with AD have a defective skin barrier. This leads to a loss of skin hydration and susceptibility to environmental triggers. There is evidence that the skin barrier defects of AD are caused by genetic mutations. Studies have shown that many AD patients carry a genetic mutation in filaggrin, a protein with important barrier function.

Potential external triggers of AD include microbial pathogens and environmental allergens. Almost 100% of AD skin lesions are colonized by *Staphylococcus aureus*, which may produce toxins that trigger immune response in the skin. As a result, AD patients produce an increased amount of pro-allergic cytokines, such as interleukin-4 (IL-4), IL-5, and IL-13, in their skin. These cytokines lead to an increased infiltration of inflammatory T cells and eosinophils. IL-4 and IL-13 also are important for the production of serum IgE, the level of which is elevated in AD patients.

### Diagnosis and Clinical Assessment

Most AD patients can be diagnosed by clinical history and physical examination. Typical presentation includes itch, dryness, flexural dermatitis, early age of onset, and atopy such as multiple food allergies. Patients with generalized eczema or adult-onset eczema can present as a diagnostic challenge. The differential diagnosis includes immunodeficiency (e.g., hyper-IgE syndrome, Omenn syndrome), malignancy (e.g., cutaneous T-cell lymphoma), zinc deficiency (i.e., acrodermatitis enteropathica), and celiac-associated dermatitis (i.e., dermatitis herpetiformis) (Table 1). AD children seldom present with failure to thrive, unless they are under severe dietary restriction. Failure to thrive should therefore prompt further investigation. Punch skin biopsies may be needed when the diagnosis is still unclear.

The prevalence of mild, moderate, and severe AD is 80%, 18%, and 2%, respectively. Most patients with mild to moderate disease have flexural, extensor, or facial involvement, whereas patients with severe disease often present with total-body involvement with or without erythroderma (Figure 1). Validated scales for assessing the severity of AD include validated Investigator Global Assessment (vIGA; [https://www.eczemacouncil.org/assets/docs/Validated-Investigator-Global-Assessment-Scale\\_vIGA-AD\\_2017.pdf](https://www.eczemacouncil.org/assets/docs/Validated-Investigator-Global-Assessment-Scale_vIGA-AD_2017.pdf)), patient-oriented Eczema Measure (POEM; <https://www.nottingham.ac.uk/research/groups/cebd/documents/methodological-resources/poem-for-self-completion-or-proxy-completion.pdf>), Scoring of Atopic Dermatitis (SCORAD) and Eczema Area and Severity Index (EASI). These scoring systems or a simplified diagram documenting the extent of dermatitis are useful for more objective follow-up of the patient's progress.

### Management of Atopic Dermatitis and Associated Conditions

#### Daily Maintenance Care

Changes in humidity can adversely affect AD symptoms. Dry conditions lead to increased transepidermal water loss and dry AD skin. Extreme heat, humidity, and sweating may lead to irritation

**TABLE 1** Differential Diagnoses of Atopic Dermatitis

DISEASE CATEGORY	DIFFERENTIAL DIAGNOSES
Dermatologic diseases	Contact dermatitis, seborrheic dermatitis, psoriasis, dyshidrotic eczema, eosinophilic pustular folliculitis, ichthyosis vulgaris
Neoplastic diseases	Cutaneous T-cell lymphoma, Langerhans cell histiocytosis
Immunodeficiencies	Hyper-IgE syndrome, severe combined immunodeficiency, Omenn syndrome, IPEX (immune dysregulation, polyendocrinopathy, enteropathy X-linked) syndrome
Infectious diseases	Scabies, cutaneous candidiasis, tinea versicolor
Nutritional deficiencies	Acrodermatitis enteropathica (zinc deficiency), essential fatty acid deficiency, biotin deficiency
Multisystemic disorders	Netherton syndrome, dermatitis herpetiformis

**Figure 1** Generalized atopic dermatitis.

of AD skin. AD patients are at increased risk for contact or irritant dermatitis, which may occur with over-the-counter topical skin medications that contain multiple ingredients. Wool or synthetic acrylic fabrics may also be irritating to AD skin.

To improve barrier function, AD patients should bathe or shower for 10 to 20 minutes once or twice daily, followed immediately by gently drying the skin and applying an emollient on the unaffected areas and a topical antiinflammatory medication on the affected areas. A petrolatum-based emollient is recommended in infants and young children because of its occlusive property. In older children and adults, the ointment may not be tolerated well because of its greasy feel, and another emollient or moisturizer may be chosen based on the patient's preference or experience.

Itch may continue to be a problem even if the rash has improved. The mechanisms of itch in AD are not fully understood but do not appear to be mediated solely by histamine. The use of first-generation antihistamines (diphenhydramine [Benadryl]<sup>1</sup> and hydroxyzine [Vistaril]) in AD largely depend on their sedative effects and are best used at bedtime. The second-generation, nonsedating antihistamines such as loratadine (Claritin)<sup>1</sup> and cetirizine (Zyrtec)<sup>1</sup> have not proved helpful in treating AD. Low-dose doxepin<sup>1</sup> has been used anecdotally to treat itching in AD.

### Topical and Systemic Medications

The first-line medication for AD is a topical corticosteroid (TCS). For mild AD, a TCS with group VI and VII potency (Table 2) may suffice. However, for moderate to severe AD, a TCS with at least group III to V potency is chosen to increase efficacy and to shorten the duration of need for these medications.

The use of TCS is confronted with various obstacles, including rare side effects such as skin atrophy, but mostly patients' or parents' misunderstanding of TCS. Studies have shown that twice-daily use of fluticasone propionate (Cutivate) 0.05% cream (group V) and desonide (DesOwen, Tridesilon) 0.05% ointment or aqueous gel (group V and VI, respectively) continuously up to 1 month in young children with AD results in no significant adverse effect. It is therefore important to clarify for patients or parents the safety and side effects based on the potency of the TCS.

Topical calcineurin inhibitors (TCI) (pimecrolimus [Elidel] 1% cream and tacrolimus [Protopic] ointment) are alternative nonsteroidal antiinflammatory medications for AD. Elidel is indicated for mild to moderate AD in patients older than 2 years, whereas 0.03% and 0.1% Protopic are indicated for moderate to severe AD in patients 2 to 15 years old and in patients 16 years old or older, respectively. Both Elidel and Protopic have an FDA black box warning saying that their long-term use may be associated with cancer risk. However, a recent large longitudinal study has failed to confirm this risk. These medications continue to be useful alternatives for skin areas that are prone to atrophy, including the face, axillae, and groins.

A third class of topical medication, phosphodiesterase 4 inhibitor (crisaborole [Eucrisa] 2% ointment), is approved for patients 2 years and older with mild to moderate AD.

A fourth class of topical medication, topical janus kinase (JAK) inhibitor, has been approved for patients with mild to moderate AD in the US. Ruxolitinib cream (Opzelura) is currently the only medication in this class that is approved for  $\geq 12$  years. The use of this medication is limited to 20% or less of the body surface areas.

For patients with moderate to severe AD, there are four recently-approved systemic medications. Dupilumab (Dupixent), a monoclonal antibody that targets IL-4/IL-13, is approved for  $\geq 6$  years; Tralokinumab (Adbry), a monoclonal antibody that targets IL-13, is approved for  $\geq 18$  years. Both dupilumab and tralokinumab are administered subcutaneously. Two oral JAK inhibitors, upadacitinib (Rinvoq) and abrocitinib (Cibinqo), are approved for  $\geq 12$  years and  $\geq 18$  years, respectively. As JAK inhibitors are immunosuppressants, topical ruxolitinib, oral upadacitinib, and oral abrocitinib carry the boxed warnings of serious infections, mortality, malignancy, major adverse cardiovascular events and thrombosis.

Wet-wrap treatment, phototherapy, and systemic immunosuppressive therapies (e.g., cyclosporine [Sandimmune, Neoral],<sup>1</sup> azathioprine [Imuran],<sup>1</sup> methotrexate [Trexall],<sup>1</sup> and mycophenolate mofetil [CellCept])<sup>1</sup> are alternatives, but these systemic immunosuppressants are not approved by FDA for AD patients.

Systemic corticosteroids are not recommended for long-term control of AD because of their known adverse effects, including stunted growth in children, adrenal suppression, osteoporosis, and cataracts. A rebound of AD symptoms is common after the medication is stopped. If a systemic corticosteroid is used, it should be tapered over a short period while nonsteroidal antiinflammatory treatment is intensified.

The efficacy and side effects of the following medications have not been established in AD: intravenous immunoglobulin

**TABLE 2** Classification of Topical Corticosteroids Based on Potency

GROUP	TOPICAL CORTICOSTEROIDS
I (most potent)	Clobetasol propionate 0.05% (Temovate) (cream, ointment, gel), betamethasone dipropionate, augmented 0.05% (Diprolene) (cream, ointment), diflorasone diacetate 0.05% (Psorcon) (ointment)
II	Amcinonide 0.1% (Cyclocort) (ointment), betamethasone dipropionate 0.05% (Diprosone) (ointment), mometasone furoate 0.1% (Elocon) (ointment), halcinonide 0.1% (Halog) (cream), fluocinonide 0.05% (Lidex) (gel, cream, ointment), desoximetasone (Topicort) (0.05% gel, 0.25% cream, 0.25% ointment)
III	Fluticasone propionate 0.005% (Cutivate) (ointment), amcinonide 0.1% (Cyclocort) (lotion, cream), diflorasone diacetate 0.05% (Florone) (cream), betamethasone valerate 0.1% (Valisone) (ointment)
IV	Flurandrenolide 0.05% (Cordran) (ointment), mometasone furoate 0.1% (Elocon) (cream), triamcinolone acetonide 0.1% (Kenalog) (cream), fluocinolone acetonide 0.025% (Synalar) (ointment), hydrocortisone valerate 0.2% (Westcort) (ointment)
V	Flurandrenolide 0.05% (Cordran) (cream), fluticasone propionate 0.05% (Cutivate) (cream), hydrocortisone butyrate 0.1% (Locoid) (cream), fluocinolone acetonide 0.025% (Synalar) (cream), desonide 0.05% (Tridesilon) (ointment), betamethasone valerate 0.1% (Valisone) (cream), hydrocortisone valerate 0.2% (Westcort) (cream), prednicarbate 0.1% (Dermatop) (cream)
VI	Alclometasone dipropionate 0.05% (Aclovate) (cream, ointment), fluocinolone acetonide 0.01% (Synalar) (solution, cream) (Derma-Smoother/FS Oil), Desonide 0.05% (Tridesilon) (cream and aqueous gel)
VII (least potent)	Hydrocortisone 1%/2.5% (lotion, cream, ointment).

(IVIG),<sup>1</sup> anti-IgE (omalizumab [Xolair]),<sup>1</sup> probiotics,<sup>7</sup> montelukast (Singulair),<sup>1</sup> Chinese medicinal herbs,<sup>7</sup> and fish oils.<sup>1</sup>

### Food Allergies

At least 30% of children with moderate to severe AD have one or more food allergies, compared with 4% to 6% of the general population. Accurate diagnosis of food allergies in AD patients is crucial because it can prevent life-threatening anaphylaxis or unnecessary food restriction.

The diagnosis of food allergy involves history taking and food challenge. History taking is helpful in the diagnosis of food allergy in most patients. It is often useful to begin by asking the patients whether they have any problems or reactions with any of the seven food allergens: milk, egg, peanut, wheat, soybean, seafood, and tree nuts. These foods account for more than 90% of food allergies. Almost all food allergic reactions occur in the first hour. AD patients may complain of immediate worsening of itching after ingestion. Symptoms of anaphylactic reactions include throat-clearing, cough, shortness of breath, vomiting, dizziness, fainting, and headache, which may be attributed to hypotension. Most food allergic reactions also manifest with skin symptoms, including hives, swelling, or generalized itching.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

Skin tests and serum specific IgE are useful in the context of negative or undetectable test results because they have a negative predictive value of more than 95%. The level of a positive test result (i.e., skin test wheal size or serum-specific IgE level), which correlates with the chance of a reaction, should be interpreted in the context of a clinical reaction. Consider consultation with an allergist regarding food challenge if there are still concerns regarding positive serum-specific IgE. More accurate epitope-specific IgE assays may be available to clinicians in the near future.

Patients with confirmed food allergy should avoid any amount of the food allergen. Parents or patients should be instructed to read food allergen labels carefully. All packaged foods in the United States are required to label the contents of milk, eggs, peanuts, wheat, soybeans, fish, shellfish, or tree nuts. Organizations, such as the Food Allergy Research & Education, can provide patients and parents with useful information on potential hidden food allergens and alternative food sources.

AD children often have multiple food allergies, including cow's milk and soy, and the use of a hydrolyzed or amino acid–based formula can provide an alternative source of nutrition. For these patients, consultation with a dietitian can be helpful in managing food avoidance and nutrition needs.

Patients or parents of children with anaphylactic reactions should be prescribed and instructed on the use of an epinephrine autoinjector (EpiPen or Auvi-Q 0.15 mg for patients who weigh more than 15 kg but less than 30 kg; 0.3 mg for patients who weigh 30 kg or more, while Auvi-Q 0.1 mg for patients who weigh 7.5–15 kg).

Infants with severe AD who consume peanut products early have a 86% relative risk reduction in the development of peanut allergy. For any infants with AD under a year, clinicians should consider introducing peanut products early in their diet according to the guidelines of National Institute of Allergy and Infectious Disease, or consult an allergist.

### Infections

Most AD patients are colonized by *S. aureus* on their skin lesions or in their nostrils. The frequency of colonization increases with AD severity. Exacerbation of AD is frequently associated with secondary *S. aureus* skin infections. Other common skin pathogens in AD include group A  $\beta$ -hemolytic *Streptococcus* and herpes simplex virus (HSV), which causes eczema herpeticum (Figure 2). Many reports have documented invasive *S. aureus* infections such as bacteremia, septic arthritis, osteomyelitis, and endocarditis in AD patients. Persistent fever or focal limb pain should alert the physician to the possibility of these infections.

The reasons for the high rate of bacterial colonization and skin infections in AD are not completely understood. A defective skin barrier and decreased cutaneous innate immunity (i.e., deficiency in natural skin antibiotics) likely contribute to the frequency of skin infections in patients with AD.

Because of the concern about increasing bacterial resistance, antibiotics are not recommended unless clinical infection is confirmed. The use of dilute bleach in treating AD remains controversial.

### Inhalant Allergies and Asthma

Eighty-five percent of AD infants have concurrent respiratory allergies or are at risk for allergic rhinitis or asthma. However, whether inhalant allergens lead to a worsening of AD remains controversial. Randomized, double-blind, placebo-controlled studies have shown positive and negative effects of house dust mites (HDM) as a trigger for AD symptoms. Because there is no serious side effect associated with the use of HDM-proof bed and pillow encasings, unless cost is an issue, these encasings are recommended for AD patients with HDM sensitization. Further research is needed to confirm the

Figure 2 Eczema herpeticum.

role of inhalant allergens, including furry pets and pollens, as triggers for AD.

### Referral to Specialists

Patients who have failed topical treatments or who have been limited by their eczema in daily activities should be considered for referral to specialists in allergy/immunology or dermatology for systemic treatments.

## AUTOIMMUNE BULLOUS DISEASES

Method of

Dominic J. Wu, MD; and Anand Rajpara, MD

### CURRENT DIAGNOSIS

- There is a significant overlap between the major autoimmune bullous diseases, which include pemphigus vulgaris, bullous pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, and more.
- Biopsy is usually required for diagnosis, including routine hematoxylin and eosin stain (H&E) histology and other special tests including direct immunofluorescence (DIF), indirect immunofluorescence (IIF), and ELISA.
- Preferred biopsy sites include edge or entire intact blister/bulla (H&E), perilesional “normal” appearing skin (DIF).
- Different staining patterns on DIF, salt-split skin, and IIF can help differentiate between diseases that appear similar on routine histology.
- It is important to evaluate for other causes of blistering disease, including infectious causes such as bullous impetigo, herpes simplex virus, varicella zoster virus, and noninfectious causes such as severe contact allergic dermatitis, poison ivy dermatitis, and others.

### CURRENT THERAPY

- Immunosuppressive medications are the mainstay treatment for autoimmune bullous diseases.
- Specific treatments for each diagnosis are listed under each section. Many of the treatment regimens are not Food and Drug Administration (FDA)-approved treatments and should only be attempted by experienced clinicians familiar with each medication and their side effect profiles and monitoring parameters.
- Traditional first-line therapy is with oral corticosteroids to induce remission, with or without adjunctive steroid-sparing therapy.
- Topical corticosteroids should be attempted for milder cases of bullous pemphigoid prior to initiation of systemic corticosteroids because of side effects and risks for systemic steroids and efficacy of topicals.
- Adjunctive steroid-sparing therapy may help clinicians lower and eventually taper the doses of corticosteroids.
- Patients on higher doses of corticosteroids and/or longer courses of treatment with corticosteroids may require prophylaxis or treatment of osteoporosis and peptic ulcer disease.
- Early involvement of relevant specialties is critical given the complex nature of the disease and treatment options.

### Epidemiology

The autoimmune bullous diseases are a heterogeneous group of diseases, mostly occurring in the elderly. Please see each section for specific epidemiologic comments.

### Pathophysiology

Specific antibodies and pathophysiology will be discussed under specific diseases discussed in this chapter.

### Diagnosis

There is significant clinical overlap between the major autoimmune bullous diseases. In addition to obtaining a detailed clinical history, biopsies are usually required for diagnosis. Ideal sample sites for routine histology (H&E) are of the

blister/bullae (intact if possible, or the edge of the bulla), and normal-appearing perilesional skin for direct immunofluorescence (DIF). Punch biopsies (usually 4 mm punch tool) or deeper shave biopsies are common biopsy methods. Specific staining patterns are noted under each individual disease entity below. Indirect immunofluorescence (IIF) may also be helpful, although it is beyond the scope of this chapter and will not be discussed in detail.

### Pemphigus

#### Pathophysiology

In normal skin tissue, epithelial cells are held together by adherens and desmosome protein junctions. In pemphigus diseases, different desmosomal proteins are targeted by autoantibodies, causing a loss of connection between adjacent cells, resulting in splitting of skin layers. The causes of pemphigus diseases vary, including idiopathic, drug-induced cases (traditionally penicillamine and ACE inhibitors such as captopril), underlying conditions such as thymoma, myasthenia gravis, autoimmune thyroiditis, and more. Epidemiologic studies have shown higher incidence in people of Jewish ancestry. Certain genetic predispositions have also been identified, including HLA-DRB1, HLA-DR4, and HLA-DR6.

The pemphigus group of bullous diseases includes (1) pemphigus vulgaris and pemphigus vegetans, (2) pemphigus foliaceus and pemphigus erythematosus, and (3) paraneoplastic pemphigus. Pemphigus vulgaris and pemphigus vegetans are caused by circulating IgG autoantibodies, primarily against desmoglein 3 (Dsg3), which is mostly found on the lower portion of the epidermis. Desmogleins are desmosomal cadherin proteins that form desmosomes, which join cells together. Patients with pemphigus foliaceus have autoantibodies directed against desmoglein 1 (Dsg1). As its name denotes, paraneoplastic pemphigus is a paraneoplastic syndrome associated with an underlying neoplastic disorder (most frequently non-Hodgkin's lymphoma, CLL, Castleman's disease, thymoma, sarcoma, and Waldenström's macroglobulinemia). In paraneoplastic pemphigus, patients may have circulating autoantibodies against nearly all the different components of the desmosome junction including plakin family proteins and both Dsg1 and Dsg3.

#### Clinical Manifestations

Pemphigus vulgaris presents with painful flaccid skin blisters/bullae and erosions in the oral cavity. Oral involvement is typically seen in cases of pemphigus vulgaris, which can be quite helpful in distinguishing between pemphigus foliaceus (typically no oral involvement) and other autoimmune bullous diseases such as bullous pemphigoid, in which a smaller subset of patients have oral mucosal involvement. Nikolsky sign (shearing of skin with slight pressure or rubbing of perilesional skin) and Asboe-Hansen (pressure placed on intact bulla results in spreading of bulla to surrounding skin) are both found in cases of pemphigus vulgaris.

Pemphigus foliaceus (including the Brazilian endemic variant Fogo Selvagem and pemphigus erythematosus) typically present with impetigo-like crusted erosions involving the face, scalp, and upper trunk. Blisters tend to be more superficial and fragile, creating what is frequently described as a cornflake-like scale and crust. Nikolsky sign also is typically positive. Pemphigus foliaceus typically spares mucosal surfaces, differentiating it from pemphigus vulgaris.

Paraneoplastic pemphigus presents as a more severe-appearing form of pemphigus. In addition to pemphigus vulgaris-like skin findings, paraneoplastic pemphigus typically presents with severe mucosal involvement with extensive crusted stomatitis extending onto the vermilion lip and scarring conjunctivitis. There may also be erosions in the esophagus, genitalia, and nasopharynx. Palms and soles may also be affected, distinguishing this entity from pemphigus vulgaris.

## Diagnosis

In addition to classic clinical findings, biopsy is usually required to confirm diagnosis with routine H&E histology, DIF, and other workup as indicated (including IIF, ELISA, and immunoprecipitation/immunoblotting).

Pemphigus vulgaris biopsies initially show eosinophilic spongiosis, followed by suprabasilar acantholysis without keratinocyte necrosis. Classically, one would also expect to find a tombstoning pattern of vertically oriented keratinocytes of the basal layer attached to the basement membrane zone (BMZ). DIF shows intercellular IgG deposition (with or without C3) in a chicken-wire appearance, with greater concentration in the lower epidermis.

Pemphigus foliaceus and its variants appear similarly to pemphigus vulgaris on histology, but on DIF one would expect to find higher concentration of IgG +/- C3 deposition in the upper epidermis. Pemphigus erythematosus may also have granular to linear IgG and C3 deposition along the BMZ.

Paraneoplastic pemphigus histology demonstrates intercellular IgG and C3 deposition, in addition to linear IgG and C3 deposition along the BMZ. Gold standard of diagnosis of paraneoplastic pemphigus is immunoprecipitation or immunoblotting for antibodies against plakins, and ELISA detection of anti-DsG antibodies.

## Treatment and Monitoring

Pemphigus can be a severe and deadly disease requiring immunosuppressive treatment. Because of the complex nature of the disease and treatment, early involvement of relevant specialists including but not limited to dermatology, rheumatology, gastroenterology, otolaryngology, oral medicine, and ophthalmology is critical. Clinicians prescribing immunosuppressive medications must be comfortable and familiar with the medications, including their side effect profile and monitoring parameters.

First-line treatment of pemphigus diseases is systemic corticosteroids for rapid disease control in conjunction with steroid-sparing immunosuppressive medications such as azathioprine (Imuran),<sup>1</sup> mycophenolate mofetil (CellCept),<sup>1</sup> or rituximab (Rituxan only for pemphigus vulgaris). Although numerous systemic steroids may be used, most frequently clinicians use prednisone 1 mg/kg/day. Higher doses of prednisone (100–150 mg daily) may sometimes be needed for more severe diseases, but prolonged use of higher doses may result in greater morbidity and mortality. In our practice, we aim to taper patients completely off of corticosteroids within 3 to 6 months. However, low-dose regimens such as prednisone 5 mg daily may be required for several years. For patients on long-term corticosteroid therapy vitamin D, calcium supplementation, and especially bisphosphonate therapy can help prevent or treat osteoporosis, while H<sub>2</sub> blockers (e.g., famotidine [Pepcid]<sup>1</sup>, ranitidine [Zactac]<sup>2</sup>) or PPIs (e.g., omeprazole [Prilosec]<sup>1</sup>) are recommended to prevent or treat peptic ulcer disease in patients taking concomitant nonsteroidal antiinflammatory drugs (NSAIDs).

Corticosteroid therapy should be initiated in combination with a steroid sparing agent because these agents typically take 3 to 6 months to take full effect. First-line steroid sparing agents include azathioprine<sup>1</sup> (2–3 mg/kg/day based on the patient's thiopurine methyltransferase [TPMT] levels), mycophenolate mofetil<sup>1</sup> (1–1.5 g twice daily), and rituximab (Rituxan only for pemphigus vulgaris). In our practice we dose rituximab IV 1000 mg once every 2 weeks for 2 doses, followed by maintenance dose of 500 mg at months 12 and 18, and every 6 months thereafter based on clinical response. Milder cases may be treated with dapsone<sup>1</sup> (25 mg daily for 1 week, then increase dose in 25 mg increments weekly based on clinical response up to maximum 100 mg daily), niacinamide<sup>1</sup> (nicotinamide), and tetracycline.<sup>1</sup> Topical corticosteroids such as triamcinolone 0.1% ointment or clobetasol 0.05% ointment twice daily may be helpful in milder cases for pruritic

or painful skin lesions. Second-line steroid-sparing agents with varying levels of efficacy described include methotrexate<sup>1</sup> (10–25 mg once weekly with folic acid supplementation<sup>1</sup> on days not taking methotrexate), cyclophosphamide,<sup>1</sup> and TNF- $\alpha$  inhibitors.<sup>1</sup> Severe refractory cases may be treated with IV immunoglobulin (IVIG)<sup>1</sup> therapy, or with rituximab or cyclophosphamide,<sup>1</sup> with or without plasmapheresis.

Treatment response should be monitored with IIF or ELISA levels, which can help detect quantitative levels of circulating antibodies.

Patients with paraneoplastic pemphigus may also have improvement in cutaneous lesions with systemic steroids, with or without adjunctive steroid-sparing agents. Excision of benign neoplasms such as thymomas and localized Castleman's disease may lead to resolution within months. Cases of paraneoplastic pemphigus from underlying malignancies are highly recalcitrant to treatment and carry a poor prognosis of up to a 90% mortality rate.

## Bullous Pemphigoid

### Pathophysiology

Bullous pemphigoid (BP) is the most common autoimmune blistering disorder and typically affects elderly patients. Patients with BP have circulating autoantibodies against different proteins, along the BMZ. The most common and important antigenic targets in BP include IgG autoantibodies targeted against the hemidesmosomal proteins BP180 (also referred to as BPAG2 and type XVII collagen) and BP230 (also referred to as BPAG1). BP180 is the primary mediator of BP. Complement activation causes eosinophilic and neutrophilic infiltration to the tissues, release of mediators and degradatory enzymes resulting in subepidermal blisters. Drug-induced cases of BP are most frequently because of furosemide, ACE inhibitors, NSAIDs, and antibiotics including cephalosporins, beta-lactams, and D-penicillamine.

### Clinical Manifestations

BP initially presents as pruritic urticarial papules and plaques on the trunk, abdomen, and flexures of extremities. This progresses to tense fluid-filled blisters and bullae on a urticarial base. Patients often complain of intense pruritus. After the bullae and blisters rupture, denuded areas of erosions and crusted areas remain.

### Diagnosis

In addition to clinical findings and history, biopsy is required for diagnosis. On histology, lesions of the urticarial phase demonstrate eosinophilic spongiosis with eosinophils lining up at the dermoepidermal junction (DEJ). During the bullous phase, lesions demonstrate subepidermal split with numerous eosinophils in the blister cavity and dense inflammation in the dermis. DIF is the most sensitive test for BP and shows linear IgG and C3 deposition along the DEJ. Salt-split skin DIF is a special type of modified DIF study that uses NaCl solution to split the biopsy specimen at the lamina lucida, allowing for localization of the bound antibodies. BP antibodies classically show staining on the top of the blister cavity. Unlike in pemphigus vulgaris, IIF levels do not correlate well with BP disease activity and are not useful for determining treatment response.

### Treatment

Although BP carries lower mortality risk compared with pemphigus vulgaris, treatment is indicated for its significant morbidity.

There have not been many controlled trials performed for BP therapies, and recommendations tend to be based on consensus opinion and clinician experience. Most frequently used first-line therapy includes high-potency topical corticosteroids or systemic corticosteroids and steroid-sparing immunosuppressive medications. Some studies have shown that topical clobetasol propionate (Temovate, Clobex) 0.05% may have better response than oral prednisone 0.5–1 mg/kg/day, with fewer side effects. Although prednisone has traditionally been

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

the standard approach to oral therapy, side effects should be weighed highly, and topical steroids should be attempted first in mild to moderate cases. Dapsone<sup>1</sup> (see pemphigus vulgaris section on treatment) or tetracycline<sup>1</sup> (500 mg four times daily) given with niacinamide<sup>1</sup> (500 mg three times daily) may also be efficacious as first-line treatment. There have been increasing reports of successful treatment with dupilumab (Dupixent)<sup>1</sup> (600 mg subcutaneous injection loading dose, followed by 300 mg every other week) and prednisone. We have implemented this successfully in patients with BP in our institution.

Immunosuppressive medications may be necessary in severe or recalcitrant cases. Azathioprine<sup>1</sup> and mycophenolate mofetil<sup>1</sup> have shown similar efficacy. Rituximab,<sup>1</sup> methotrexate,<sup>1</sup> cyclophosphamide,<sup>1</sup> IVIG,<sup>1</sup> and cyclosporine<sup>1</sup> (4–5 mg/kg/day) are potentially effective second-line options. IVIG may be especially helpful in steroid-resistant cases. Dosing regimens for these medications are similar to those of pemphigus. There have been several case reports of omalizumab (Xolair)<sup>1</sup> (monoclonal anti-IgE antibody) showing good response in some patients.

In our practice, for patients with severe bullous pemphigoid and no contraindications, we start prednisone at 0.5 mg/kg/day along with mycophenolate mofetil. We aim to taper the patient off of steroids in 3 to 6 months while increasing mycophenolate mofetil to a max dose of 1.5 gm twice daily if needed. For patients with mild to moderate disease, or in patients with severe disease but contraindications to corticosteroids and/or immunosuppressants, we treat with topical steroids in conjunction with doxycycline/nicotinamide, IVIG, and/or dapsone.

Denuded, eroded areas tend to heal spontaneously and may not require further treatment other than appropriate wound care. BP is considered a chronic condition, although some cases may be self-limited over a period of about 5 years. High levels of BP180 at the time of discontinuing therapy are associated with a higher risk of relapse.

## Mucous Membrane Pemphigoid

### Pathophysiology

Mucous membrane pemphigoid (MMP), also referred to as *cicatricial pemphigoid*, is a rare autoimmune bullous disease with numerous targets in the anchoring filament zone including epiligrin (also referred to as laminin 332),  $\alpha_6\beta_4$  integrin (specifically the  $\beta_4$  subunit), and c-terminus of BP180. Antiepiligrin MMP has a strong association with underlying malignancy, most frequently adenocarcinoma. Patients with antibodies against the  $\alpha_6\beta_4$  integrin may have exclusive ocular involvement. MMP most frequently affects the elderly, with a female predominance.

### Clinical Manifestations

As its name denotes, MMP mostly involves the mucosa, most commonly the oral and conjunctival mucosa. Patients with oral involvement present with numerous painful chronic erosions of the oral mucosa including the gingiva, buccal mucosa, palate, and lips. Eye involvement is typically bilateral, initially presenting as a relatively nonspecific conjunctivitis, which progresses to fibrosis and eventual formation of adhesions of the bulbar and palpebral conjunctiva (symblepharon), ectropion, dry eyes, and inward facing eyelashes (trichiasis). Skin involvement is less common and tends to be more limited. The most common extramucosal sites include the scalp, face, neck, and upper trunk. Skin lesions may heal with atrophic scars, which may help distinguish this entity from BP.

## Diagnosis

In addition to clinical history<sup>1</sup> and examination findings, biopsy is required for diagnosis including routine histology, DIF, and salt-split skin. IIF may also be helpful. Routine histology findings are similar to BP with fewer eosinophils. DIF staining shows linear IgG, IgA, +/- C3 deposition along the BMZ. Salt-split skin testing shows an epidermal staining pattern, except for antiepiligrin, which shows dermal staining pattern.

## Treatment

For patients with mild, limited oral disease, treatment with topical triamcinolone acetonide (Oralene) 0.1% dental paste twice daily to oral lesions can be quite effective. Dapsone<sup>1</sup> (start 25 mg daily and titrate slowly based on response after 1 week) is our first-line systemic treatment for mild-moderate oral mucosal disease. Limited cutaneous disease can be treated with topical corticosteroids such as triamcinolone 0.1% ointment or clobetasol 0.05% ointment twice daily to affected areas on the body. Tetracycline<sup>1</sup> (500 mg four times daily) with niacinamide<sup>1</sup> (500 mg three times daily) may also be effective.

In patients with more severe oral disease and/or ocular disease, treatment with systemic steroids and cyclophosphamide is often needed. Most frequently oral prednisone 1 mg/kg/day is started with cyclophosphamide<sup>1</sup> (1–2 mg/kg/day), and therapy may continue after clinical remission for maintenance. Clinicians should attempt to taper prednisone after remission is achieved if possible, although some patients may continue to require low doses of prednisone to prevent recurrence. Ocular disease may result in scarring, and early involvement of an experienced ophthalmologist is essential.

MMP is a chronic condition which may result in scarring, disfigurement, and even blindness.

## Linear IgA Bullous Dermatitis/Chronic Bullous Disease of Childhood

### Pathophysiology

Adult-onset linear IgA bullous dermatosis (LABD) is a rare autoimmune subepidermal bullous disease affecting elderly patients greater than 60 years old. Chronic bullous disease of childhood (CBDC) is typically a self-limited bullous disease affecting young children beginning around 2 or 3 years old and may remit by teenage years. Patients with LABD/CBDC have circulating IgA autoantibodies targeting antigens derived from BPAG2, and some patients may have both IgA and IgG autoantibodies. Medication-induced LABD/CBDC is most frequently caused by vancomycin, followed by penicillin and cephalosporin antibiotics, captopril, NSAIDs, phenytoin, and many more offending medications.

### Clinical Manifestations

Both adult-onset LABD and CBDC present with tense blisters/bullae and urticarial plaques that may be arranged in an annular or polycyclic formation, often described as *crown of jewels arrangement*. Individual lesions may appear quite similar to that of bullous pemphigoid and dermatitis herpetiformis. The most frequently affected sites include the trunk, flexures of extremities, groin, buttocks, and the face (in children). Patients may or may not have mucosal involvement.

## Diagnosis

Biopsies of early urticarial lesions may show diffuse neutrophilic infiltrate along the BMZ. Biopsies of bullous lesions show subepidermal blisters/bullae filled with neutrophils and a neutrophil-predominant infiltrate in the papillary dermis. DIF of perilesional skin is the gold standard for diagnosis and shows linear IgA deposition along the BMZ. Salt-split skin testing may show epidermal staining.

<sup>1</sup>Not FDA approved for this indication.

## Treatment

Dapsone<sup>1</sup> is considered first-line therapy for cases of LABD and CBDC. We recommend starting at 25 mg daily, which may be increased weekly by increments of 25 mg based on clinical response (maximum dose varies by age). Second-line agents for those who cannot tolerate dapsone include colchicine<sup>1</sup> (up to 0.6 mg two times daily in pediatric patients and up to three times daily in adult patients) and sulfapyridine<sup>2</sup> (500 mg twice daily starting dose, titrated appropriately based on clinical response).

In cases of drug-induced LABD/CBDC, the offending medication should be discontinued. Lesions are expected to resolve within a few weeks of stopping the medication.

## Epidermolysis Bullosa Acquisita

### Pathophysiology

Epidermolysis bullosa acquisita (EBA) is a very rare acquired bullous disease, most commonly found in adults of East Asian and African American descent. It is frequently associated with inflammatory bowel disease (especially Crohn's disease), multiple myeloma, systemic lupus erythematosus, diabetes mellitus, hepatitis C infection, and other underlying diseases.

Patients may have IgG autoantibodies targeting type VII collagen, which is a major component of anchoring fibrils in the basement membrane zone.

### Clinical Manifestations

The noninflammatory, or mechanobullous, variant of EBA is the most commonly recognized subtype. Patients present with hemorrhagic bullae and erosions on trauma-prone sites including the dorsal hands and feet, elbows, and knees. Lesions may heal with scarring, milia, and nail dystrophy. Inflammatory EBA clinically is indistinguishable to BP. Lesions of inflammatory EBA may also heal with scarring and milia. Patients may also have oral and ocular erosions which may appear similarly to MMP.

### Diagnosis

In addition to clinical findings, biopsy is required for diagnosis of EBA to distinguish it from other subepidermal bullous diseases. Routine histology shows subepidermal blisters with varying degrees of neutrophilic and eosinophilic infiltrates. DIF of perilesional skin shows linear IgG and C3 deposition along the BMZ. Unlike BP, DIF of EBA lesions tend to show more linear IgG deposition rather than C3. Salt-split skin technique shows dermal staining.

### Treatment Options

Some patients may have good response to prednisone (0.5–1 mg/kg/day), with or without dapsone. Dapsone<sup>1</sup> monotherapy may also be effective for patients (initiated at 25 mg daily and increased appropriately based on clinical response). This dose should be maintained for several months prior to tapering attempts. Colchicine<sup>1</sup> (0.6 mg twice to thrice daily) may be effective. Patients with resistant or severe disease may have more rapid relief with cyclosporine<sup>1</sup> (4–5 mg/kg/day). Other agents with reported success include rituximab,<sup>1</sup> IVIG,<sup>1</sup> infliximab (Remicade),<sup>1</sup> minocycline,<sup>1</sup> plasmapheresis, and PDE-4 inhibitors.<sup>1</sup>

Unfortunately, cases of EBA tend to be quite resistant to treatment relative to BP and other subepidermal bullous diseases. The disease is usually chronic and waxes and wanes. Patients should avoid trauma as much as possible because it may contribute to further blister formation. The inflammatory subtype of EBA may have better response to therapy compared with the mechanobullous noninflammatory subtype.

## Dermatitis Herpetiformis

### Pathophysiology

Dermatitis herpetiformis (DH) is a chronic and relapsing bullous disease which is strongly associated with celiac disease. People of Northern European descent are most commonly affected, and it is quite rare in patients of Asian and African American descent. More than 97% of patients with DH and celiac disease have one or both HLA-DQ2 and HLA-DQ8 alleles. In addition to celiac disease, DH is also associated with other autoimmune conditions including Hashimoto's thyroiditis, type 1 diabetes mellitus, and pernicious anemia.

Gluten is a grain protein found in many foods containing wheat, rye, and barley. Gluten is broken down into gliadin during digestion, which is then transported across the gastrointestinal (GI) mucosa to the lamina propria, where it binds with tissue transglutaminase 2 (TTG2). This complex is recognized by HLA-DQ2 or HLA-DQ8 on antigen presenting cells (APCs) and activating the T-cell and B-cell activated autoinflammatory cascade to form IgA autoantibodies against TTG2 or the TTG2-gliadin complex. These bound IgA antibodies lead to neutrophil recruitment, resulting in damage to intestinal villi. Epitope spreading (diversification of epitope specificity) results in production of IgA autoantibodies against epidermal transglutaminase (TTG3), which then binds to TTG3 within dermal papillae. Neutrophils recruited by this process release elastase and other proteolytic enzymes, resulting in the formation of subepidermal blisters seen in DH.

### Clinical Manifestations

Patients with DH classically present with extremely pruritic herpetiform vesicles on an urticarial base. The vesicles can be ruptured very easily, so excoriations, rather than intact vesicles, are more frequently seen on examination. Lesions are typically distributed on the symmetric extensor extremities (elbows and knees), buttocks, back, neck, face, and scalp. A minority of approximately 20% of patients with DH have symptomatic gastrointestinal disease; however, the majority of patients have evidence of gluten-sensitive enteropathy on gastrointestinal biopsy samples.

### Diagnosis

Clinical history can be particularly helpful in cases of DH. A history of worsening of disease with gluten-containing diets is a useful clue, although patients are not always aware of their specific dietary habits unless they keep a careful food diary.

Biopsy samples should be obtained on early blisters if possible. Routine histology shows subepidermal bullae most pronounced above the dermal papillae, and neutrophilic infiltrates in the dermal papillae. These findings can be quite similar to LABD, so DIF testing and serologic testing can be helpful. DIF of perilesional skin shows granular IgA deposits with or without C3 deposition in the dermal papillae. Serologic testing for DH and celiac disease can be helpful, including serum antitissue transglutaminase or antiendomysial antibodies (present in approximately 80% of patients with DH and greater than 95% of patients with celiac disease); however, it is important to keep in mind that tests can also be falsely negative if the patient has been keeping a gluten-free diet. Patients with IgA deficiency may also have falsely negative testing for anti-TTG antibodies, so IgA levels should be assessed concurrently.

### Treatment Options

Dapsone is the treatment of choice in patients with DH. Patients tend to have a rapid response to dapsone (within 2–3 days) with improvement in cutaneous disease. The usual dose of dapsone in DH is to start at 50 mg daily and increase in increments of 25 mg based on clinical response to a maximum of to a maximum of 100–200 mg daily. Typically, patients are well controlled on

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

50–100 mg daily. Patients do not typically see an effect on their GI disease, if present. Prior to initiating dapson, it is important to evaluate for G6PD deficiency. Sulfapyridine<sup>2</sup> is an effective second-line therapy with less risk of hemolysis.

Gluten-free diets (avoiding wheat, rye, and barley) can be effective to control both cutaneous and gastrointestinal disease. It may also reduce the risk of development of GI lymphomas associated with celiac disease. DH is typically a lifelong, chronic, relapsing disease. It is important to involve relevant specialties including dermatology, nutrition, and gastroenterology to help manage patients with DH.

<sup>2</sup>Not available in the United States.

## BACTERIAL DISEASES OF THE SKIN

Method of

Karissa Gilchrist, MD

### CURRENT DIAGNOSIS

- The large variety of bacterial skin infections can usually be distinguished by history, physical exam, and clinical presentation.
- Bacterial infections can range from those affecting the superficial layers of skin to the deep layers and soft tissue.
- Many infections are precipitated by a breach in the normal skin barrier.
- Infection can vary in severity depending on how extensive and invasive it is.
- Deep infection can lead to systemic toxicity.
- Necrotizing infection can rapidly progress and cause extensive tissue damage and even death.

### CURRENT THERAPY

- Antibiotic therapy is selected based on knowledge of the most likely causative pathogen or based on culture results.
- When a loculated abscess is identified, procedural incision and drainage should be performed.
- Broad-spectrum empiric antibiotic coverage should be initiated when a rapidly progressing necrotizing infection is suspected.
- Delay in surgical consultation and debridement of necrotizing infection may result in tissue damage, limb loss, and/or death.
- Tissue culture of necrotizing infection can guide antibiotic choice.

**TABLE 1** Primary Pathogen for Common Bacterial Skin Infections

DIAGNOSIS	ORGANISM
Cellulitis	Streptococci ( <i>Staphylococcus aureus</i> less common)
Impetigo	<i>S. aureus</i> Group A beta-hemolytic streptococci
Folliculitis	<i>S. aureus</i> Gram-negative bacteria
Abscess	<i>S. aureus</i> , predominantly MRSA

MRSA, Methicillin-resistant *S. aureus*.

Bacterial infections of the skin can manifest in a broad range of clinical presentations. Bacterial skin diseases can occur both superficially and in the deep layers. They can also range from mild to aggressive and life-threatening infection. Skin infections have increased in prevalence and severity in part due to the development of resistant bacterial organisms. For this reason, it is critical for clinicians to be able to promptly recognize and manage bacterial infections of the skin.

## Common Infections

### Cellulitis

Cellulitis is an acute bacterial skin infection that causes poorly demarcated areas of erythema, warmth, tenderness, and edema of the skin involving the deep dermal and subcutaneous layers. Depending on the extent of edema and inflammation, the affected skin may develop bullae, ecchymosis, or maceration. Cellulitis may occur on any area of the skin but is typically found on the lower extremities and is almost always unilateral. Cellulitis develops when there is a break in the skin and pathogens are able to breach the surface. It most commonly arises from infection with streptococci. *Staphylococcus aureus* is a less common cause of cellulitis but should be considered in special circumstances such as bite wounds, penetrating trauma, intravenous drug use, or in immunocompromised patients (Table 1).

Culture or biopsy of the affected skin is not routinely recommended for the diagnosis of cellulitis. Cultures often yield negative or unhelpful results as the rapidly spreading skin manifestations may be more likely related to a strong inflammatory response to the inciting pathogen and may not be representative of the bacterial load. Blood cultures may be considered if there are systemic signs of infection. Diagnosis of cellulitis should be made clinically. Labs and imaging may be obtained to help distinguish cellulitis from other diagnoses and rule out complications such as underlying abscess, deep venous thrombosis, osteomyelitis, or necrotizing fasciitis. Stasis dermatitis is commonly mistaken for cellulitis and can be differentiated by its bilateral appearance and lack of skin trauma.

In the treatment of mild cases of uncomplicated nonpurulent cellulitis without systemic signs of infection, an oral antibiotic agent that is active against streptococci—such as cephalexin (Keflex), dicloxacillin<sup>1</sup>, or amoxicillin/clavulanate (Augmentin)—should be used. If the patient has a penicillin allergy, clindamycin can be used as an alternative. The typical treatment duration is 5 days, but this may be extended in the case of residual symptoms. In patients who fail oral antimicrobial treatment or in those with systemic signs of infection, an intravenous regimen with an agent such as cefazolin (Ancef), ceftriaxone (Rocephin), or clindamycin should be considered. In cases where there is increased risk of methicillin-resistant *S. aureus* (MRSA) infection, such as

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>1</sup>Not FDA approved for this indication.

penetrating trauma or intravenous drug use, intravenous vancomycin should be added (Table 2).

### Erysipelas

For some, the term *erysipelas* is synonymous with cellulitis. However, erysipelas refers to infection that is limited to the upper dermis; cellulitis extends into the deeper dermis. The borders of the erysipelas rash are more clearly demarcated than those of cellulitis. Erysipelas is always nonpurulent. The treatment outlined earlier for cellulitis can be applied to erysipelas with antibiotics targeted against streptococci and, if systemic signs or symptoms are present, parental agents can be used.

### Impetigo

Impetigo is a common bacterial skin infection that can occur at any age but is most commonly seen in children. It is most prevalent in hot, humid conditions and is highly contagious. It is transmitted by direct contact and may develop secondarily after a disruption of the skin occurs from an insect bite or other underlying disease such as eczema or psoriasis.

Impetigo can be classified into two major categories: bullous and nonbullous. Bullous impetigo is a result of *S. aureus* infection. Strains of this organism produce a factor that cleaves the junction between the epidermal and dermal skin layers. This causes a delicate vesicle to form, which may break open, leaving behind a crusted erosion. Nonbullous impetigo is most commonly caused by *S. aureus*, group A beta-hemolytic streptococci, or a combination of both (see Table 1). This form of impetigo typically begins as erythematous papules or pustules. These lesions develop a discharge that dries and forms a classic honey-colored crust.

Treatment for both bullous and nonbullous impetigo consists of antibiotic therapy aimed at both staphylococcal and streptococcal organisms (see Table 2). Either topical or oral antibiotics can be used for treatment of impetigo depending on the severity

and extent of infection. Topical treatment with mupirocin (Bactroban) ointment 2% three times daily for 5 days can be effective for mild cases of impetigo. Over-the-counter topical bacitracin<sup>1</sup> or triple antibiotic ointments are not as effective as mupirocin in the treatment of impetigo. If an oral agent is desired for more severe or extensive cases, therapy should consist of an antibiotic medication that is active against *S. aureus*, such as cephalexin (Keflex) or dicloxacillin<sup>1</sup> for 7 days. *S. aureus* isolates from impetigo are typically methicillin-susceptible *S. aureus* (MSSA); however, if MRSA is suspected or confirmed with direct culture of an impetiginous lesion or its drainage, treatment with doxycycline, clindamycin, or sulfamethoxazole-trimethoprim (Bactrim DS)<sup>1</sup> for 7 days is recommended.

### Ecthyma

Ecthyma is a form of impetigo that infects deeper layers of the skin into the dermis. Lesions appear as “punched out” ulcerations with an overlying crust and surrounding erythematous edema. Ecthyma differs from impetigo in that it heals with scarring due to the deep skin involvement. The principal pathogen causing ecthyma is group A streptococcus (GAS). Treatment of ecthyma differs from that of impetigo and always requires oral antibiotic therapy. Penicillin is the first-line choice of antibiotic agent. With both impetigo and ecthyma, care should be taken to use contact precautions and frequent handwashing to prevent spread.

### Ecthyma Gangrenosum

Ecthyma gangrenosum is a skin eruption that classically arises in immunocompromised patients with *Pseudomonas aeruginosa* bacteremia. An ecthyma gangrenosum lesion typically begins as an erythematous macule or pustule and quickly develops into a gangrenous ulcer. This lesion results from bacterial invasion of the vascular wall and subsequent tissue ischemia and necrosis. There may be one single eruption or several. Lesions can occur in any location, with the axilla and genital regions most commonly affected. Although it is possible for lesions to occur in an immunocompetent patient without any signs of systemic illness, the presence of ecthyma gangrenosum should definitely raise the clinician’s suspicion for bacteremia, especially with *P. aeruginosa*. Treatment involves empiric antibiotic therapy with an antipseudomonal agent. Blood cultures should be obtained, and lesions can be swabbed for culture to help guide antibiotic narrowing.

### Folliculitis

Folliculitis is the infection and inflammation of hair follicles. It typically presents as erythematous papules or pustules in hair follicles. As with most inflammatory skin diseases, pruritus is the most frequent symptom. Lesions may be painful. Folliculitis is typically infectious, with the most common etiology being bacterial. It can also be caused by viral, fungal, or parasitic infection. Bacterial folliculitis is most frequently caused by *S. aureus* but may also result from infection with gram-negative bacteria (see Table 1). Multiple factors may predispose a patient to develop folliculitis; these include underlying immunodeficiency, frequent scratching (from underlying eczema or other pruritic skin disease), nasal colonization with *S. aureus*, shaving in the opposite direction of hair growth, hyperhidrosis, or prolonged use of topical corticosteroids. Exposure to underchlorinated heated water is the classic risk factor for developing “hot tub folliculitis,” which is caused by *P. aeruginosa* infection. In this example of gram-negative folliculitis, pustules appear on the areas of hair-bearing skin that were exposed to the contaminated water. Onset may occur up to 48 hours after exposure.

Diagnosis is typically made clinically, and the distribution of lesions may be suggestive of a pathogenic etiology. Folliculitis occurring primarily on the face or scalp is most likely due to *S. aureus*. Culture of pustule contents may be considered if the diagnosis is unclear. Pseudomonal folliculitis is often self-limiting but

<sup>1</sup>Not FDA approved for this indication.

may necessitate treatment with oral ciprofloxacin (Cipro)<sup>1</sup> in the setting of immunodeficiency or in severe cases. Topical mupirocin (Bactroban)<sup>1</sup> or topical clindamycin<sup>1</sup> is an effective treatment for cases of superficial folliculitis thought to be caused by *S. aureus*. In very mild and localized cases of *S. aureus*, lesions may even resolve spontaneously. If the disease is extensive, refractory to topical treatment, or appears to involve the deep areas of the follicles, an oral antibiotic should be used for treatment. First-line agents include cephalexin (Keflex) or dicloxacillin treatment for 7 to 10 days. If MRSA is suspected or confirmed on culture, oral trimethoprim/sulfamethoxazole (Bactrim DS)<sup>1</sup>, clindamycin, or doxycycline should be used for treatment (see Table 2). It is important to try to minimize or eliminate any predisposing factors identified in order to prevent recurrence.

### Abscess

An abscess is a collection of pus within the skin or soft tissue. It presents as an erythematous, painful nodule that is fluctuant, sometimes with an overlying pustule. *S. aureus* is responsible for the majority of abscesses (see Table 1), with a large portion being due to methicillin-resistant strains (MRSA). Immunosuppression or any disruption of the normal skin barrier may predispose a patient to develop one or multiple abscesses. Procedural incision and evacuation of the abscess debris should be performed for treatment. Care should be taken to probe the cavity and release loculated areas within the abscess. Proper wound care should follow with application of a dry gauze dressing with or without packing of the wound space. Systemic antibiotics should be used in addition to incision and drainage in cases of multiple lesions, abscesses larger than 2 cm, immunosuppression, signs of systemic toxicity, refractory lesions, extensive surrounding cellulitis, or presence of implanted medical devices. It is reasonable to forgo antibiotic therapy in an otherwise healthy patient with a single small abscess, especially in the setting of numerous antibiotic allergies. However, there is now evidence to suggest that treatment with trimethoprim/sulfamethoxazole (Bactrim DS)<sup>1</sup> or clindamycin for any patient who has undergone incision and drainage may improve cure rates and decrease the risk of recurrence (see Table 2).

### Furuncle and Carbuncle

When an abscess forms at the base of a hair follicle, it is referred to as a furuncle. This is different from folliculitis, where infection does not extend deeper than the epidermis. A carbuncle develops when several furuncles occur in multiple adjacent follicles and the infection coalesces into a larger mass of pus. Carbuncles commonly occur on the back of the neck and in the axilla. As in the case of cutaneous abscesses, the principal pathogen for furuncles and carbuncles is *S. aureus*. Many furuncles will rupture spontaneously, allowing the pus to drain. The application of moist heat may also help to encourage spontaneous drainage. Carbuncles and larger furuncles should be treated with incision and drainage.

### Invasive Infections

#### Necrotizing Soft Tissue Infection

Necrotizing cellulitis is an aggressive, rapidly spreading life-threatening bacterial infection of the skin. When there is involvement of the fascia or muscle, the descriptive term becomes *necrotizing fasciitis* or *necrotizing myositis*, accordingly. These infections result in significant tissue destruction and have a high mortality rate. Necrotizing infections may be precipitated by varying degrees of disruption of the skin barrier due to anything from insect bites to intravenous drug use or major penetrating trauma. Diabetes increases the risk of developing a necrotizing soft tissue infection.

Necrotizing infection presents as skin erythema, edema, and warmth with underlying crepitus that develops quickly over the course of hours and progresses rapidly. Skin findings are usually

**TABLE 3** Suggested Antibiotic Agents for Invasive Bacterial Skin Infections

DIAGNOSIS	ANTIBIOTIC
Necrotizing soft tissue infection	1. Vancomycin, linezolid (Zyvox), or daptomycin (Cubicin)
Group A streptococcal infection with toxic shock syndrome	plus 2. Piperacillin-tazobactam (Zosyn) or a carbapenem or Ceftriaxone (Rocephin) plus metronidazole (Flagyl) or Fluoroquinolone plus metronidazole (Flagyl)
Invasive	1. Clindamycin plus 2. Penicillin
Staphylococcal scalded skin syndrome	Intravenous oxacillin, nafcillin, cefazolin (Ancef), or vancomycin
Tularemia	Mild or moderate disease: • Oral fluoroquinolone or doxycycline Severe disease: • IV/IM gentamicin <sup>1</sup> or IM streptomycin

<sup>1</sup>Not FDA approved for this indication.

associated with severe pain, which may be out of proportion to findings on examination. Signs of systemic toxicity, such as fever or hemodynamic instability, may also appear. Delayed clinical recognition can result in extensive tissue damage, limb loss, or death. Prompt surgical consultation should be made if a necrotizing soft tissue infection is suspected. If the diagnosis is unclear, a computed tomography scan may be helpful in revealing the presence of gas in the soft tissues, but it should not delay surgical intervention. Treatment should include emergent surgical debridement as well as empiric antibiotic administration. Care should be taken to provide hemodynamic support as needed. Blood cultures would ideally be obtained prior to the administration of antibiotics. Empiric therapy should consist of a polymicrobial approach with a combination of agents aimed at treating MRSA, aerobes, and anaerobes (Table 3). Antibiotic therapy can be tailored according to culture results from tissue obtained during surgical debridement.

#### Fournier Gangrene

Fournier gangrene is a form of necrotizing soft tissue infection involving the perineal region. It is typically seen in middle-aged adults, particularly those who have diabetes mellitus. Potential predisposing factors may include recent urologic procedures, chronic use of an indwelling urinary catheter, or urethral trauma. However, this condition can develop without these risk factors. Cutaneous and systemic findings are similar to those of other necrotizing soft tissue infections, and prompt surgical debridement with broad-spectrum empiric antibiotic coverage is critical.

#### Invasive Group A Streptococcal Infection with Toxic Shock Syndrome

GAS is a common cause of superficial skin infections, as outlined earlier in this chapter. However, this pathogen can sometimes lead to invasive disease and result in necrotizing infection. Toxic shock syndrome is a complication that may arise when invasive GAS produces a toxin that induces the subsequent release of inflammatory cytokines. Skin manifestations include induration and erythema of the affected areas, eventually giving rise to hemorrhagic skin sloughing. It is often associated with signs of systemic toxicity and multiorgan failure. Toxic shock syndrome may also develop as a result of invasive postpartum endometritis. It is a rapidly progressive disease and prompt treatment should be provided along with hemodynamic support. Antibiotic treatment includes coverage with both clindamycin and penicillin (see Table 3). Clindamycin has the

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

additional benefit of helping to suppress the toxin-mediated inflammatory response. Dual coverage with penicillin is important due to potential clindamycin resistance.

### Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome is a complication that can arise from any infection caused by *S. aureus*, such as impetigo, for example. It typically occurs in children and develops as a result of exotoxins produced by the bacteria. Skin findings include painful erythema and desquamation; the mucous membranes are spared. Fever and generalized malaise usually accompany the cutaneous findings. Diagnosis can usually be made clinically; however, culture of the suspected primary infection can be collected for confirmation. One should keep in mind that areas of desquamation or bullae in scalded skin syndrome will be sterile, as these lesions are a result of the exotoxins and not direct bacterial infection. Therefore culture of these areas is unlikely to be helpful.

Patients with staphylococcal scalded skin syndrome are typically treated in an inpatient setting with intravenous antibiotics and supportive care. First-line antibiotic agents include oxacillin, nafcillin, cefazolin (Ancef), and vancomycin (see Table 3). Clindamycin is not a recommended first-choice agent due to high rates of resistance.

### Tularemia

Tularemia is an uncommon infection caused by *Francisella tularensis*; it occurs after exposure to an infected insect or animal, most commonly a tick or rabbit. Clinical manifestations vary in severity. The most common form of tularemia is ulceroglandular disease. Symptom onset typically occurs within 3 to 5 days following exposure and begins with nonspecific constitutional symptoms such as fever, headache, myalgias, and generalized malaise. Cutaneous manifestations commonly begin with a single erythematous ulceration with or without a central eschar. Location of the skin lesion is based on the site of inoculation, and the anatomic distribution of findings is regional. Rarely, there may be multiple skin lesions. Ulceroglandular tularemia is associated with localized tender lymphadenopathy. Glandular tularemia has the same characteristics as ulceroglandular tularemia without the ulcerations.

When tularemia is suspected clinically, serology should be sent for diagnosis. It generally takes 2 weeks for antibodies to *Francisella* to reach diagnostic levels, and serology may need to be repeated if clinical suspicion is high. Polymerase chain reaction (PCR) testing can be completed more rapidly depending on lab availability of the test. Blood or tissue cultures are rarely positive; if such specimens are collected, laboratory staff should be notified in advance of tularemia suspicion in order to optimize conditions for culture growth as well as for infection control precautions. Treatment consists of selecting an effective antibiotic regimen. In general, an oral fluoroquinolone or doxycycline would be a reasonable initial treatment for patients with mild or moderate disease. If the infection is severe, intravenous or intramuscular gentamicin<sup>1</sup> or intramuscular streptomycin is recommended (see Table 3). Of note, *F. tularensis* has the potential to be used as a bioterrorism agent, as it is easily disseminated and infection can occur at low exposure. In such a case, recognition and reporting are critical.

<sup>1</sup>Not FDA approved for this indication.

## CONTACT DERMATITIS

Method of

Yul W. Yang, MD, PhD; and James A. Yiannias, MD

### CURRENT DIAGNOSIS

- Gather a detailed history on skin exposures, including use of the following items:
  - Irritants
  - Alkalis: soaps, detergents, cleansers
  - Acids
  - Hydrocarbons: petroleum, oils
  - Solvents
  - Potential allergens including:
    - Metals: nickel sulfate; cobalt chloride (e.g., jewelry, makeup, personal products)
    - Fragrances: balsam of Peru (*Myroxylon pereirae*; fragrance); fragrance mix
    - Methylisothiazolinone, methylchloroisothiazolinone (preservatives)
    - Benzalkonium chloride (preservative)
    - Formaldehyde and formaldehyde-releasing preservatives such as quaternium-15
      - Topical antibiotics such as neomycin, bacitracin
- Examine the skin for the location and pattern of eruption:
  - Eyelid: nail polish
  - Postauricular scalp: perfume
  - Perioral area: chewing gum, toothpaste
  - Trunk: dyes, clothing finish
  - Wrist: nickel, chrome
  - Waistline: rubber
  - Feet: shoes
  - Wounds: topical antibiotic ointment
- Perform patch testing:
  - T.R.U.E. TEST with 35 allergens (note: two common allergens, benzalkonium chloride and propolis, are not included in this panel)
  - Customized series with 70 or more allergens

### CURRENT THERAPY

- Avoid irritants and allergens, using the prepared patient handout.
- Consult the SkinSAFE shopping list of skin care products free from the top 10 most common allergens (if patch testing is not performed).
- Consult a customized SkinSAFE shopping list of skin care products free from the patient's contact allergens, based on patch test results.
- Topical corticosteroids can be applied.
- Hydrocortisone 2.5% (Hytone) can be applied twice daily on the face, neck, axillae, groin, and intertriginous areas.
- Triamcinolone 0.1% (Kenalog) can be applied twice daily on the body.
- For severe reactions, short-term, higher-potency steroids can be applied (e.g., clobetasol [Clobex] 0.05% twice daily).
- Sedating antihistamines can be taken: doxepin (Sinequan)<sup>1</sup> 10 to 20 mg qhs.
- Steroid-sparing topical agents can be applied twice daily to any skin surface (but may be more expensive than topical corticosteroids): tacrolimus 0.1% (Protopic),<sup>1</sup> pimecrolimus 1% (Elidel),<sup>1</sup> crisaborole 2% (Eucrisa),<sup>1</sup> ruxolitinib 1.5% (Opzelura)<sup>1</sup>
- For severe, acute episodes, systemic corticosteroids can be taken in a several-week tapering course (e.g., prednisone 60 mg for 5 days, 40 mg for 5 days, and 20 mg for 5 days).

- Longer-term systemic therapy is possible for severe or recalcitrant disease.
- Phototherapy with narrow-band ultraviolet B is suggested.
- Azathioprine (Imuran)<sup>1</sup> can be taken 1 to 3 mg/kg qd.
- Mycophenolate mofetil (CellCept)<sup>1</sup> can be taken 2 to 3 g qd.
- Methotrexate<sup>1</sup> can be taken 10 to 25 mg per week.
- Cyclosporine (Neoral)<sup>1</sup> can be taken 2.5 to 5 mg/kg qd short term.
- Dupilumab (Dupixent)<sup>1</sup> can be taken by injection at 600 mg initially and then 300 mg every other week.
- Tralokinumab (Adbry)<sup>1</sup> can be taken by SQ injection at 600 mg initially and then 300 mg every other week.
- Upadacitinib (Rinvoq)<sup>1</sup> can be taken 15 to 30 mg qd.
- Abrocitinib (Cibinqo)<sup>1</sup> can be taken 100 to 200 mg qd.

<sup>1</sup>Not FDA approved for this indication.

Dermatitis typically manifests as papules and vesicles with weeping and oozing that can become lichenified and scaly when chronic. When this clinical picture is secondary to an exogenous substance coming into contact with the skin, it is termed *contact dermatitis*. Further delineation leads to irritant versus allergic contact dermatitis, although in practice these often overlap.

Irritant contact dermatitis is not an allergic process. It represents damage to the skin from repeated and cumulative exposure to an agent. Irritants do not require prior sensitization. A decreased barrier function of the skin (e.g., with frequent handwashing) can predispose to the condition or exacerbate it. Examples include alkalis (in soaps, detergents, and cleansers), acids (in germicides, dyes, and pigments), hydrocarbons (in petroleum and oils), and solvents.

Allergic contact dermatitis is an immunologic process classified as a type IV cell-mediated delayed hypersensitivity reaction. Poison ivy is a classic example. It requires an initial exposure to the contactant in which sensitization occurs but without outward physical effect. Subsequent exposure can elicit a striking response that is independent of the amount of the contactant.

From 1994 to 2016, the most common contact allergens have changed little. Based on studies performed by the North American Contact Dermatitis Group (NACDG) and the Mayo Clinic Contact Dermatitis Group (MCCDG), the allergens most consistently in the top 10 were nickel sulfate, balsam of Peru, fragrance mix, quaternium-15, neomycin, bacitracin, formaldehyde, and cobalt chloride (Box 1). However, in the past few years, two additional preservatives have gained prominence: methylisothiazolinone (MI) and benzalkonium chloride. Common sources of exposure to nickel include costume jewelry, snaps, zippers, and other metal objects. Balsam of Peru and fragrance mix are markers for fragrance sensitivity. Sources of exposure to formaldehyde include skin care products, household products, and the resins in plastics and clothing. Quaternium-15 is a formaldehyde-releasing preservative and may be found in items such as skin care products, paper, inks, and photocopier toner. Neomycin and bacitracin are topical antibiotics available alone and in combination with polymyxin (Neosporin), antifungals, and corticosteroids. Cobalt is found with other metals, including zinc, and in items such as jewelry, crayons, hair dye, and antiperspirants. MI is a common preservative found in personal care products and may be used in combination with another preservative, methylchloroiso-thiazolinone (MCI). Benzalkonium chloride is commonly used in the healthcare field as a cleanser, antiseptic, and preservative, but it is also found in personal care products such as wipes and an increasing number of skin care products.

Others less consistently in the top 10 during that period were methyl-dibromo glutaronitrile, gold sodium thiosulfate, potassium dichromate, *p*-phenylenediamine, thiuram mix, MI/MCI, and propolis. Methyl-dibromo glutaronitrile is a preservative and can be found in healthcare and personal products. Clinically relevant sources of gold may be found in jewelry and dental appliances. Potassium dichromate is used in cement, leather, and steel surfaces. Permanent hair dyes are the usual source of *p*-phenylenediamine. Thiuram mix is in rubber and some personal products. Propolis is another marker of fragrance sensitivity.

## BOX 1 Top 10 Most Common Allergens

### North American Contact Dermatitis Group

- Nickel sulfate
- Methylisothiazolinone (MI)
- Fragrance mix
- Formaldehyde 2%
- Methylisothiazolinone/methylchloroiso-thiazolinone (MI/MCI)
- Balsam of Peru
- Neomycin
- Bacitracin
- Formaldehyde 1%
- *p*-Phenylenediamine

### Mayo Clinic Contact Dermatitis Group

- Nickel sulfate
- MI
- Balsam of Peru
- Neomycin
- Cobalt chloride
- Benzalkonium chloride
- Fragrance mix I
- Potassium dichromate
- Bacitracin
- MI/MCI

Data from DeKoven JG, Warschaw EM, Zug KA, et al. North American Contact Dermatitis Group Patch Test Results: 2015–2016. *Dermatitis*. 2018;29(6):297–309; Veverka KK, Hall MR, Yiannias JA, et al. Trends in patch testing with the Mayo Clinic standard series, 2011–2015. *Dermatitis*. 2018;29(6):310–315.

Each year since 2000, the American Contact Dermatitis Society has designated an allergen of the year, designed to spotlight allergens, common or not, that are increasing in significance. For 2022, aluminum was chosen. Aluminum is a common metal used both as a metal in industry/everyday life (e.g., construction, packaging, electronic equipment, household goods, dentistry) and also as a salt in cosmetics, sunscreen, food, tattoos, medicine (vaccines, antiperspirants), and water purification. Other designated allergens of the year have been alkyl glucosides, cobalt chloride, benzophenones, MI, acrylates, dimethyl fumarate, neomycin, mixed dialkyl thioureas, nickel, fragrance, *p*-phenylenediamine, corticosteroids, cocamidopropyl betaine, bacitracin, thimerosal, gold, disperse blue, propylene glycol, nonallergen parabens, isobornyl acrylate, and acetophenone azine. Alkyl glucosides are surfactants that are pervasive in consumer products, including cosmetics. Benzophenones, such as oxybenzone, are chemical ultraviolet light filters that are found in sunscreens and personal care products. Artificial nails, dentures, and bone cement contain acrylates, but these substances are only allergenic when in the liquid, powder, or paste forms. Dimethyl fumarate is a biocide in furniture, shoes, and textiles. It is often placed in little paper packets with these items. Rubber products and shoe glue are common sources of mixed dialkyl thioureas. Shampoos often contain cocamidopropyl betaine as a lathering agent. Thimerosal is a preservative for medications and personal care products, including contact lens solution. Disperse blue is a fabric dye. Patients with an allergy to disperse dyes may also react to *p*-phenylenediamine. Propylene glycol is a common ingredient in personal care products, topical corticosteroids and other medications, and foods. Parabens are preservatives commonly found in cosmetics, foods, pharmaceuticals, dentifrices, and suppositories. Isobornyl acrylate, an adhesive, is often used in medical devices, such as insulin pumps, and can also be found in acrylic nails. Acetophenone azine is found in shin pads and footwear that contain cushioning foam made of ethyl vinyl acetate.

### Diagnosis

The evaluation of a patient with suspected contact dermatitis begins with the history. Specific questions directed at the patient's

## Introduction

Eczema, also known as dermatitis, is an inflammation of the skin due to dryness, irritation, or possible external allergy. Eczema/dermatitis is not contagious.

Some skin care products contain fragrance even though the package says "fragrance free" or "unscented." Therefore, please choose the skin care products as listed below by their *exact brand name*.

## Suggestions

### Soaps/Cleansing

- Vanicream cleansing bar
- Free and Clear liquid cleanser
- Aveeno moisturizing bar for dry skin fragrance Free or Aveeno advanced care body wash
- Oilatum unscented soap
- Neutrogena original formula fragrance-free (bar or liquid)

*Any of the shampoos listed in this brochure may be used as your hand or body soap.*

- Vanicream shave cream for sensitive skin

### Moisturizers

- Vanicream, Vanicream Lite
- Aveeno daily moisturizing lotion fragrance Free
- Plain Vaseline, Vaniply
- DML unscented
- Use moisturizers twice daily.
- All of the above are OK to use on the face.
- After showering, blot excess water with hands and apply cream. Do not use a towel to dry.
- Robathol bath oil

### Deodorants

- Almay unscented antiperspirants
- Plain cornstarch from the grocer can be used.

### Shampoo

- Free and Clear shampoo and conditioner
- DHS clear shampoo and DHS conditioner
- If you have dandruff, use DHS sal shampoo or Neutrogena T-SAL shampoo (not T-Gel).
- Conditioners can be used as "leave on" hair gel.

### Hairspray

- Fragrance-free hairspray such as Free and Clear hairspray
- Caution: Hairsprays labeled as "unscented" may not be fragrance free.

### Laundry and Home Care

- Unscented laundry detergents (Tide free, Cheer free and gentle, All free clear, Arm & Hammer unscented, Wisk free, Purex unscented)
- Wash all new clothes and linens five times before using.
- Old clothes and fabrics are preferred.
- Use white vinegar in rinse cycle to help remove soap.

### Hand, Nail, and General Skin Care Tips

- Wear cotton gloves under rubber/vinyl gloves for any activities where hand-wetting is expected.
- Trim nails short. Long nails are dangerous to skin, especially when sleeping.

### Sunscreens

- Vanicream sunscreen #30 or #60

### Make-ups/cosmetics

- If you would like a list of make-ups and cosmetics that are free of the most common allergy-causing ingredients, ask your provider about "virtual patch testing" using the Mayo SkinSAFE program, [www.SkinSafeProducts.com](http://www.SkinSafeProducts.com)

### Avoid

#### Soaps/Cleansing

- No hot water (use lukewarm).
- Avoid hot tubs.
- No rubbing alcohol.

#### Moisturizers

- No creams, lotions, oils or powders other than those recommended in this brochure.
- No Neosporin, triple antibiotic, or bacitracin antibiotic ointments.

#### Fragrances

- No perfumes, colognes, after shave, or pre-shave on any part of body/clothing.

#### Laundry and Home Care

- No fabric softener in washer.
- Bounce unscented fabric softener sheets in dryer if desired.
- No washing machine water softener such as Calgon (in-house water softeners are acceptable).
- White vinegar may be used as a general household cleaner.

#### Hand, Nail, and General Skin Care Tips

- No wetting of hands more than five times a day.
- Avoid tight-fitting clothes unless your doctor has advised you to wear a pressure garment such as support hose.
- No scrubbing! No loofah! No pumice stone!
- Do not pull off dead skin. Snip with scissors instead.

**Figure 1** Sample of prepared handout (used at the Mayo Clinic Arizona) with recommendations for the patient on hypoallergenic skin care products.

occupation, hobbies, and home routine will be helpful. Examination should note the location and pattern of the eruption. Although eyelid dermatitis may be seen in the atopic patient, nail polish may be the source of the offending allergen. Dyshidrotic eczema occurs as vesicles along the lateral aspects of the fingers, whereas eczematous changes along the dorsal hands are more commonly caused by an allergen. Other distributions as clues include postauricular scalp (perfume), perioral area (chewing gum, toothpaste), trunk (dyes or clothing finish), wrist (nickel or chrome), waistline (rubber), feet (shoes), and history or presence of wounds (topical antibiotic ointment).

Patch testing can confirm or reveal a contact allergy. It involves placement of allergens against the skin of the patient's back for 48 hours. An initial reading is then done, with follow-up readings typically at 96 hours. Prepared series include the thin-layer, rapid-use epicutaneous (TRUE) test, which consists of 35 allergens and 1 negative control (<https://mytruetest.com/>). Customized series, such as the NACDG Standard Series with 70 allergens and the Mayo Clinic's Standard Series with 80 allergens, must be manually assembled. The majority of dermatologists performing patch testing use the TRUE test. Note that benzalkonium chloride, MI, and propolis are not included in this panel. Overall, the NACDG estimates that 25% to approximately 40% of allergic reactions would have been missed by the TRUE test based on their data for 2015 to 2016.

In addition to ascertaining degree of positivity, relevance must be determined. This involves collaborating with patients to assess the likelihood that they are currently exposed to the positive antigen.

## Treatment

Ideally, the allergen or allergens will be identified and avoided. Realistically, compliance is a challenge. To assist patients in avoiding antigens in skin care products, SkinSAFE was created in 1999. It includes 14,847 ingredients and 81,833 individual over-the-counter and prescription skin care products as of August 9, 2022. Once the patient's allergens have been identified with patch testing, they can be entered into the database, and a list of products free from those substances is generated. The patient should

be reminded that even small and infrequent exposures can perpetuate the eczema.

Topical corticosteroids applied twice daily are helpful in hastening resolution and may also be used for disease control when the allergen is unknown. Low-potency corticosteroids such as 2.5% hydrocortisone (Hytone) are recommended for the thinner skin of the face, neck, axillae, groin, and intertriginous areas. Midpotency steroids such as triamcinolone 0.1% (Kenalog, Kenonel) are appropriate for the thicker skin of the body. Short-term use of higher-potency steroids may be necessary if the reaction is severe. If there is significant pruritus, sedating antihistamines such as doxepin (Sinequan)<sup>1</sup> 10 to 20 mg taken nightly 2 hours before bedtime can provide relief. Steroid-sparing topical immunomodulators such as tacrolimus (Protopic),<sup>1</sup> pimecrolimus (Elidel),<sup>1</sup> crisaborole (Eucrisa)<sup>1</sup> and ruxolitinib 1.5% (Opzelura)<sup>1</sup> may be helpful adjuncts, but they may be more expensive. Treatment for severe acute episodes can entail a several-week tapering course of systemic corticosteroids, especially if the eruption is widespread. Other longer-term systemic therapies for severe or resistant disease include phototherapy or systemic immunosuppressants such as azathioprine (Imuran),<sup>1</sup> mycophenolate mofetil (CellCept),<sup>1</sup> methotrexate,<sup>1</sup> cyclosporine (Neoral),<sup>1</sup> or dupilumab (Dupixent).<sup>1</sup> Newer agents include tralokinumab (Adbry),<sup>1</sup> upadacitinib (Rinvoq),<sup>1</sup> and abrocitinib (Cibinqo).<sup>1</sup>

It may take many weeks before the skin reverts to a normal appearance despite successful avoidance of antigens. A prepared handout with concrete recommendations for the patient on truly hypoallergenic skin care is beneficial. A sample of that used at Mayo Clinic Arizona is shown in [Figure 1](#).

If patch testing is not performed, an initial approach may be to instruct the patient on avoiding the most common contact allergens via a handout and prescribing symptomatic treatment including topical and oral therapies. SkinSAFE can generate a shopping list of products free from the top 10 allergens as identified by

<sup>1</sup>Not FDA approved for this indication.

the NACDG and the MCCDG. Patients may access SkinSAFE independently (at <https://www.skisafeproducts.com>, the Apple App Store, or the Google Play Store under SkinSAFE) to generate this list or build customized lists free from fragrances, common preservatives, parabens, nickel, lanolin, coconut, and topical antibiotics. In 35% of patients, simply using products free from the top 10 allergens can prompt clearance. Some physicians follow these measures for several months, especially if the eruption is mild, before pursuing formal patch testing.

An excellent primer for the physician interested in learning more about contact allergy diagnosis and management is *Contact and Occupational Dermatology*.

## CUTANEOUS T-CELL LYMPHOMAS, INCLUDING MYCOSIS FUNGOIDES AND SÉZARY SYNDROME

Method of

Gary S. Wood, MD

### CURRENT DIAGNOSIS

For Cutaneous T-cell Lymphomas, obtain the following:

- History: duration and pace of lesion development
- Skin examination: extent of patches, plaques, tumors, and ulcers
- Extracutaneous examination: status of lymph nodes, liver, and spleen
- Laboratory: complete blood cell count, differential, and lesional biopsy results
- Imaging: CT or fused PET/CT scans of the chest, abdomen, and pelvis (not needed for early stage mycosis fungoides)

### CURRENT THERAPY

Guidelines Are Primarily for Mycosis Fungoides and Sézary Syndrome:

- Stages IA–IIA: skin-directed therapy with potent topical corticosteroids, topical mechlorethamine (Valchlor), or phototherapy; radiation therapy or topical bexarotene (Targretin) in selected cases
- Stages IIB–IVB: skin-directed therapy plus one or more systemic therapies, such as pegylated interferon alfa-2a (Pegasys),<sup>1</sup> bexarotene (Targretin), romidepsin (Istodax), targeted antibodies, or methotrexate; photopheresis for erythrodermic cases
- Combination therapies are often used in intermediate- and advanced-stage disease.
- Multiagent chemotherapy is usually not an effective long-term treatment strategy.

<sup>1</sup>Not FDA approved for this indication.

### Cutaneous T-Cell Lymphomas Classification

Virtually every subtype of T-cell lymphoma involves the skin primarily or secondarily. The principal types of primary cutaneous T-cell lymphomas (CTCLs) recognized in the World Health Organization and European Organization for Research and Treatment of Cancer classification include mycosis fungoides (MF) and its leukemic variant, the Sézary syndrome (SS); CD30<sup>+</sup> large cell lymphoma and lymphomatoid papulosis (LyP); CD30<sup>-</sup> large cell lymphoma; and pleomorphic CD4<sup>+</sup> small or medium cell variants (Table 1). All other primary CTCLs comprise only a few percent of the total. This discussion focuses on MF and SS because they account for up to 75% of primary cutaneous cases.

### Standard Diagnosis and Staging Methods

The evaluation of CTCL patients begins with a thorough clinical history and physical examination. Key elements of the history include the pace and nature of disease development, the presence or absence of spontaneous regression of lesions, prior therapy, and ingestion of drugs (e.g., anticonvulsants, antihistamines, other agents with antihistaminic properties) that have been associated with pseudolymphomatous skin eruptions that can mimic CTCLs. The review of systems should establish the presence of lymphoma-associated constitutional symptoms (e.g., fever of

**TABLE 1** Simplified Classification of Primary Cutaneous T-Cell Lymphomas

CTCL TYPE	PROPORTION OF PRIMARY CTCL (%)	5-YEAR SURVIVAL RATE (%)
MF and variants	60	85
SS	3	35*
CD30 <sup>+</sup> large cell/LyP	25	<95
Pleomorphic small/medium cell**	8	99
Miscellaneous	<1	Variable

Abbreviations: CTCL = cutaneous T-cell lymphoma; MF = mycosis fungoides; SS = Sézary syndrome.

Complete classification in Willemze R, Cerroni L, Kempf W, et al. The 2018 update of the WHO-EORTC classification for primary cutaneous lymphomas. *Blood* 133(16):1703–1714, 2019.

\*The 5-year survival rate depends on the criteria used to define SS, and it may be as low as 10%.

\*\*Now regarded as a lymphoproliferative disorder, not lymphoma.

unknown origin, night sweats, weight loss, fatigue). In addition to general aspects, the physical examination should document the type and distribution of skin lesions and whether there is lymphadenopathy, hepatosplenomegaly, or edema of extremities (i.e., potential sign of lymphatic obstruction).

Histopathologic analysis of representative lesional skin biopsy specimens is the primary means of confirming the clinical diagnosis. Biopsy specimens should be deep enough to include the deepest portions of the cutaneous lymphoid infiltrates because these areas often exhibit the most diagnostic features. Putative extracutaneous involvement should be confirmed by biopsy if it is relevant to clinical management.

Routine blood tests include a complete blood cell count, differential review, and general chemistry panel. A “Sézary prep” is used to assess peripheral blood involvement.

Internal nodal and visceral involvement by lymphoma usually is assessed with chest radiography, computed tomography (CT), or combined positron emission tomography and CT (PET/CT) scans of the chest, abdomen, and pelvis. These radiologic studies usually are not needed for patients with early forms of MF (i.e., nontumorous skin lesions without evidence of extracutaneous involvement assessed by physical examination); however, they are usually obtained during the work-up of other types of CTCLs. The role of immunopathologic and molecular biologic assays in the diagnosis and staging of CTCLs is discussed later.

An algorithm for the diagnosis of early MF has been proposed by the International Society for Cutaneous Lymphomas (ISCL) (see Pimpinelli et al. in References). It relies on a combination of clinical, histopathologic, immunopathologic, and clonality criteria. This differs from former approaches that have been based primarily on histopathologic criteria.

### Mycosis Fungoides, Sézary Syndrome, and Variants

#### Clinical Features

MF classically manifests as erythematous, scaly, variably pruritic, flat patches or indurated plaques, often favoring the most sun-protected areas. The patches or plaques may progress to cutaneous tumors and involvement of lymph nodes or viscera, although this usually does not occur as long as the skin lesions are reasonably well controlled by therapy. SS manifests as total-body erythema and scaling (i.e., erythroderma), generalized lymphadenopathy, hepatosplenomegaly, and leukemia. Large-plaque parapsoriasis is essentially the prediagnostic patch phase of MF. Lesions may exhibit poikiloderma (i.e., atrophy, telangiectasia, and mottled hyperpigmentation and hypopigmentation) and have then been referred to as *poikiloderma atrophicans vasculare*.

Follicular mucinosis refers to a papulonodular eruption in which hair follicles are infiltrated by T cells and contain pools of mucin. In hairy areas, this may result in alopecia. Follicular mucinosis may exist as a lesional variant of MF (i.e., follicular MF) or as a clinically benign entity (i.e., alone or associated with other lymphomas).

Granulomatous slack skin is a variant of MF that manifests with pendulous skin folds in intertriginous areas. Lesional skin biopsy specimens contain atypical T cells in a granulomatous background.

Pagetoid reticulosis manifests as a solitary or localized, often hyperkeratotic plaque containing atypical T cells that are frequently confined to a hyperplastic epidermis. Some authorities regard it as a variant of unilesional MF, whereas others think it is a distinct entity.

Other variants of MF include hypopigmented, palmoplantar, bullous, and pigmented purpuric forms. The latter form shows clinicopathologic overlap with the pigmented purpuric dermatoses. *Tumor d'emblée* MF is an outmoded concept used in the past to refer to supposed cases of MF that manifested as cutaneous tumors in the absence of patches or plaques. Most experts now prefer to classify such cases as other forms of CTCL, depending on their histopathologic features.

#### Histopathologic and Cytologic Features

A well-developed plaque of MF contains a bandlike, cytologically atypical lymphoid infiltrate in the upper dermis that infiltrates

the epidermis as single cells and cell clusters known as Pautrier's microabscesses. The atypical lymphoid cells exhibit dense, hyperchromatic nuclei with convoluted, cerebriform nuclear contours and scant cytoplasm. The term *cerebriform* comes from the brain-like ultrastructural appearance of these nuclei. In more advanced cutaneous tumors, the infiltrate extends diffusely throughout the upper and lower dermis and may lose its epidermotropism. In the earlier patch phase of the disease, the infiltrate is sparser, and lymphoid atypia may be less pronounced. In some cases, it may be difficult to distinguish early patch-type MF from various types of chronic dermatitis. The presence of lymphoid atypia and absence of significant epidermal intercellular edema (i.e., spongiosis) help to establish the diagnosis of early MF.

Involvement of lymph nodes by MF begins in the paracortical T-cell domain and may progress to complete effacement of nodal architecture by the same types of atypical lymphoid cells that infiltrate the skin. These cells can be seen in low numbers in the peripheral blood of many MF patients; however, those with SS develop gross leukemic involvement, usually defined as at least 1000 tumor cells/mm<sup>3</sup>. These cells are known as Sézary cells, and they are traditionally detected by manual review of the peripheral blood smear (the so-called Sézary prep). They may also be defined by various immunophenotypic criteria.

#### Immunophenotyping

Cellular antigen expression is usually assessed by immunoperoxidase methods for tissue biopsy specimens and by flow cytometry for blood specimens. Almost all cases of MF or SS begin as phenotypically and functionally mature CD4<sup>+</sup> T-cell neoplasms of skin-associated lymphoid tissue (SALT). MF and SS express homing markers consistent with “effector memory” and “central memory” T cells, respectively. They express the SALT-associated homing molecule cutaneous lymphocyte antigen (CLA) and most mature T-cell surface antigens, with the exceptions of CD7 and CD26, which are often absent. As disease progresses, the tumor cells often dedifferentiate and lose one or more mature T-cell markers, such as CD2, CD3, or CD5.

Cases typically express the  $\alpha/\beta$  form of the T-cell receptor. At least in advanced cases, the cytokine profile is consistent with the T<sub>H</sub>2 subset of CD4<sup>+</sup> T cells (i.e., production of interleukin [IL]-4, IL-5, and IL-10 rather than T<sub>H</sub>1 cytokines such as IL-2 and interferon- $\gamma$ ). Expression of the high-affinity IL-2 receptor (CD25, TAC) ranges widely, with most cases showing a variable minority of lesional CD25<sup>+</sup> cells. Tumor cells can be induced to express a regulatory T-cell phenotype (Treg) in vitro. MF cases that express CD8<sup>+</sup> or other aberrant phenotypes occur occasionally but behave like conventional cases. They should not be confused with rare aggressive CTCLs exhibiting cytotoxic T-cell differentiation.

In addition to tumor cells, MF and SS lesions contain a minor component of immune accessory cells (i.e., Langerhans cells and macrophages) and CD8<sup>+</sup> T cells with a cytolytic phenotype. This presumed host response correlates positively with survival and tends to decrease as lesions progress. A favorable response to therapy such as photopheresis appears to correlate with normal levels of circulating CD8<sup>+</sup> cells.

#### Molecular Biology

Well-developed MF or SS is a monoclonal T-cell lymphoproliferative disorder. Southern blotting or polymerase chain reaction (PCR) assays demonstrate monoclonal T-cell receptor gene rearrangements. The greater sensitivity of PCR assays allows the demonstration of dominant clonality in many early patch-type lesions of MF. These assays sometimes detect dominant clonality in lesional skin showing only chronic dermatitis histopathologically. These cases are called *clonal dermatitis* and may represent the earliest manifestation of MF because several have progressed to histologically recognizable MF within a few years. However, some cases of clinicopathologically defined early-phase MF lack a detectable monoclonal T-cell population until later in their clinical course. Next generation high throughput T-cell receptor sequencing is emerging as a more sensitive and quantitative alternative to other molecular assays of T-cell clonality.

In addition to aiding initial diagnosis, gene rearrangement analysis has facilitated staging and prognosis. Because some patients without MF or SS can have low levels of circulating Sézary-like cells and because not all cases of peripheral blood involvement in MF or SS exhibit morphologically recognizable tumor cells, the demonstration of dominant clonality that matches the clone in lesional skin has proved to be a useful diagnostic adjunct. The same holds true for assessing lymph node involvement. T-cell receptor gene rearrangement analysis of MF and SS lymph nodes is more sensitive than histopathology and possesses at least some prognostic relevance. Mutations in more than 80 genes can occur in MF/SS, including those involving T-cell receptor related pathways, *TP53* and *PD1*. In addition to providing insights into pathogenesis and prognosis, these mutations will form the basis of future precision medicine-based treatments.

### TNMB Staging

Although several proposed methods have used a weighted extent approach to more accurately determine the MF or SS tumor burden, the preferred approach is the tumor-node-metastasis-blood (TNMB) system, which is detailed in Tables 2 and 3. The original tumor (skin), lymph nodes, and metastasis (visceral organs) version of this system has been modified by the ISCL to incorporate the extent of blood involvement (B classification) into the staging process. Table 2 shows the TNMB classification relevant to MF and SS, and Table 3 shows how this information is used to determine the stage of disease. The prognostic relevance of this staging system has been supported by numerous studies, and use of the TNMB helps to guide the selection of therapies. For example, early-stage MF is the most amenable to control with topically directed treatments, whereas advanced MF or SS with extracutaneous involvement usually requires systemic therapies or topical plus systemic combinations.

### Treatment

Treatment guidelines for CTCL published by the National Comprehensive Cancer Network can be found at [www.nccn.org](http://www.nccn.org). Rather than cure, which is attained in less than 10% of cases, the goal of MF and SS therapy is to reduce the impact of the skin disease on quality of life. For most patients, this is achieved by reducing pain, itch, and infection and improving clinical appearance. Appearance is affected by the disfigurement of the eruption and by the profound degree of scale shedding in some patients. Because the natural history of early-stage MF predicts a virtually normal life span, the goal of treatment must be directed at quality of life. For more advanced stages, prolongation of life expectancy may be a reasonable treatment goal.

Regardless of presentation, relief of symptoms should be addressed early. For dryness and scaling, the use of emollient ointments is indicated. These include petrolatum, Aquaphor, and commercially available shortening such as Crisco (an inexpensive alternative).<sup>1</sup> For modest dryness, creams (e.g., Nivea, Cetaphil, Eucerin) can be adequate and more acceptable to patients. Mild superfatted soaps such as Dove and Oil of Olay are recommended. Soap substitutes such as Cetaphil are also acceptable. Pruritus can be addressed with oral agents such as hydroxyzine (Atarax) or diphenhydramine (Benadryl)<sup>1</sup> 2 to 5 mg/kg/day and divided into four daily doses. Antipruritics work better when used on a regular basis rather than on an as-needed basis. Nonsedating antihistamines tend to be less effective. Measures to reduce dryness also help to reduce pruritus. Secondary infection needs to be treated with appropriate antibiotics. Their selection is guided by results of skin cultures but usually involves coverage of gram-positive organisms.

### Phototherapy

Two main phototherapeutic regimens are used to treat CTCLs. Ultraviolet B radiation (290–320-nm broad band or 311-nm narrow band) can be used for patients with patches but not those

**TABLE 2** TNMB Classification of Mycosis Fungoides and Sézary Syndrome

Skin (T)	
T1	Patches and/or plaques; <10% body surface area
T2	Patches and/or plaques; ≥10% body surface area
T3	Tumors with/without other skin lesions
T4	Generalized erythroderma
Lymph Nodes (N)	
N0	Not clinically enlarged; histopathology not required
N1	Clinically enlarged; histopathologically negative
N2	Clinically enlarged; histopathologically equivocal
N3	Clinically enlarged; histopathologically positive
Visceral Organs (M)	
M0	No involvement
M1	Involvement
Peripheral Blood (B)	
B0	Atypical cells ≤5% of lymphocytes
B1	Atypical cells >5% of lymphocytes
B2	Atypical cells ≥1000/mm <sup>3</sup>

T1 and T2 can be subclassified as patch only vs. plaque +/- patch. N and B categories can be subclassified as clone positive or negative. For updates, see [www.nccn.org](http://www.nccn.org).

**TABLE 3** TNMB Staging System for Mycosis Fungoides and Sézary Syndrome

STAGE	SKIN	LYMPH NODES	VISCERA	BLOOD
IA	T1	N0	M0	B0–1
IB	T2	N0	M0	B0–1
IIA	T1–2	N1–2	M0	B0–1
IIB	T3	N0–2	M0	B0–1
IIIA	T4	N0–2	M0	B0
IIIB	T4	N0–2	M0	B1

IVA-2	T1–4	N3	M0	B0–2
IVB	T1–4	N0–3	M1	B0–2

Modified from Olsen E, Vonderheid E, et al: Revisions to the staging and classification of mycosis fungoides and Sézary syndrome: A proposal of the International Society for Cutaneous Lymphomas (ISCL) and the cutaneous lymphoma task force of the European Organization of Research and Treatment of Cancer (EORTC). *Blood* 2007;110(6):1713–1722. For updates, see [www.nccn.org](http://www.nccn.org).

with well-developed plaques or tumors. Seventy percent of patients achieve total clinical remission, usually within about 3 to 5 months. Another 15% achieve partial remission. Narrow-band UVB usually is more effective than broadband UVB and achieves maximal responses more rapidly. A synthetic form of hypericin

<sup>1</sup>Not FDA approved for this indication.

(HyBryte)<sup>5</sup> applied topically and activated by visible fluorescent light has undergone clinical trials and is currently being evaluated by the FDA.

Psoralen-ultraviolet A (PUVA) photochemotherapy uses oral 8-methoxypsoralen (8-MOP)<sup>1</sup> 0.6mg/kg as a photosensitizer before UVA (320–400nm) exposure. Sixty-five percent of patients with patch or plaque disease achieve complete remissions, and 30% have partial responses to this modality. For most patients, maximal responses are achieved within 3 months, and after 5 months, it is unlikely that further improvement will be gained. Limitations of these modalities include actinic damage, photocarcinogenesis, retinal damage (if eyes are not protected), and the inconvenience of getting to phototherapy centers. PUVA also has the risk of nausea and a theoretical risk of cataract induction without proper eye protection.

During the clearing phase of treatment, phototherapy treatments usually are administered three times per week. After resolution of skin lesions, treatment frequency is usually tapered gradually to once weekly for UVB and once every 4 to 6 weeks for PUVA. These maintenance regimens are often continued for months to years because abrupt cessation of phototherapy is commonly associated with rapid relapse, which is probably related to the persistence of microscopic disease after clinical clearing.

### Topical Therapy

Like phototherapeutic regimens, topical therapies are appropriate for disease confined to the skin (stage I). Topical corticosteroids are frequently used for CTCLs, often before diagnosis. Low-potency formulations are useful on the face and skin folds. Medium-potency preparations are appropriate for the trunk and extremities. High-potency formulations are useful for recalcitrant lesions; however, prolonged use of such potent agents can cause local atrophy and adrenal suppression. Roughly half of patients achieve complete remissions, and most others have partial remissions. Response duration varies widely with the individual pace of disease and patient compliance. Topical corticosteroids are particularly useful as a means to relatively quickly ameliorate severe signs and symptoms and as an adjuvant therapy in combination with other primary treatments.

Mechlorethamine (nitrogen mustard, HN<sub>2</sub>, Mustargen) is applied topically in an aqueous solution or in an ointment, such as Aquaphor. Although these forms are not FDA approved for this indication, a 0.016% gel formulation (Valchlor) is now commercially available and FDA approved. The aqueous form is prepared at home and involves a daily dose totaling 10 mg in 60 mL water. The ointment form is prepared by a pharmacist in 1-pound lots at a concentration of 10 mg mechlorethamine per 100 g ointment. Only the amount of ointment needed to apply a thin layer is used. Either formulation is usually applied at bedtime to lesional skin for limited disease or to the entire skin surface (excluding the head unless it is also involved) for more extensive disease. It is then showered off every morning using soap and water. Results are similar to those from PUVA. Advantages include therapy at home and availability in all regions of the country. Disadvantages are daily preparation (aqueous form only), daily application, and possible allergic contact dermatitis (more common with the aqueous preparation). Maximal efficacy is expected within 6 months. Mild flare-ups of disease may occur during the first few months of treatment and probably represent inflammation of subclinical skin lesions, analogous to the clinical accentuation of actinic damage during topical therapy with 5-fluorouracil (Efudex). As with phototherapy, topical mechlorethamine is tapered gradually after remission is achieved in an effort to delay clinical relapse.

Carmustine (BCNU, BiCNU)<sup>1</sup> is applied to the total skin surface as an alcohol/aqueous solution (10–20mg in 60mL).<sup>6</sup> Complete responses are seen in 85% of patients with stage IA disease (<10% involvement) and 50% of patients with stage IB disease (>10% involvement). Another 10% of patients obtain partial responses.

Advantages include those described for nitrogen mustard and reports of success with application only to lesional skin. Disadvantages include skin irritation followed by telangiectasia formation and possible bone marrow suppression necessitating blood monitoring.

A topical gel formulation of the retinoid X receptor (RXR)-specific retinoid, bexarotene (Targretin), is useful for localized or limited skin lesions. The principal side effect is local irritation.

### Radiotherapy

Conventional radiotherapy for mycosis fungoides therapy has been used for approximately 100 years. It is useful in the treatment of isolated, particularly problematic lesions such as recalcitrant tumors or ulcerated plaques. In addition to benefit from the photons delivered by radiotherapy, electron beam therapy (0.4Gy per week for 8–9 weeks) is also useful for CTCL therapy. An approximately 85% complete response rate of skin disease with a median duration of 16 months is expected with electron beam therapy. An advantage is an excellent rate of complete response. Disadvantages include limited access to required equipment and expertise and cutaneous toxic effects, such as alopecia, sweat gland loss, radiation dermatitis, and skin cancers. As with other skin-directed therapy, the benefit for internal disease is limited. Cumulative toxicity also limits the number of courses a patient may receive. Localized electron beam therapy is also useful for treating cases of limited-extent MF and in treating selected problematic MF lesions in patients who are otherwise responding to therapy. After completion of total-skin electron beam therapy, patients require maintenance therapy such as topical mechlorethamine<sup>6</sup> or phototherapy to prolong remission. Low dose radiotherapy is emerging as an effective alternative to conventional regimens.

### Apheresis-Based Therapy

Leukapheresis and particularly lymphocytapheresis (6000–7000mL of blood treated three times per week initially, then according to response) have been used in the treatment of SS patients. Benefit has been reported in several case reports and small case series; however, response rates are not possible to determine. Photopheresis (i.e., extracorporeal photochemotherapy) describes an apheresis-based therapy in which circulating lymphocytes are first exposed to a psoralen (orally or extracorporeally) and then exposed to UVA extracorporeally. In contrast to leukapheresis, in which leukocytes are discarded, all cells are returned to the patient's circulation during photopheresis. Response rates in erythrodermic patients are 33% to 50%, and median survival for SS patients is prolonged from 30 months to more than 60 months. In recent years, extracorporeal photochemotherapy has been used increasingly in conjunction with one or more systemic therapies to enhance efficacy. The toxicity of the systemic agents is diminished because they are often used in combination at reduced doses.

### Cytokine Therapy

Pegylated interferon alfa-2a (Pegasys)<sup>1</sup> has replaced interferon alfa-2a and alfa-2b, both of which have been discontinued. 90 to 180 µg is given subcutaneously or intralesionally once weekly. Response rates are approximately 55%, with complete responses occurring in 10% of patients. Advantages include the relative ease of delivery. Disadvantages include anorexia, fever, malaise, leukopenia, and risk of cardiac dysrhythmia. An alternative treatment is interferon gamma-1b (Actimmune)<sup>1</sup> (1-2 MU) injected three times weekly. Interferon combined with narrow-band UVB or PUVA is effective for many patients with generalized skin lesions unresponsive to phototherapy alone.

### Tumor-Associated Antigen-Directed Therapies

Various specific tumor-associated antigens have been targeted with antibody-based therapy. Less specific targets are CD4, CD5, and IL-2 receptors. Of this class of agent, an improved version

<sup>5</sup>Investigational drug in the United States.

<sup>6</sup>May be compounded by pharmacists.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

of the now discontinued denileukin diftitox (Ontak, DAB389 IL2, known as E7777 [I/ONTAK]<sup>2</sup>) is approved for CTCL in Japan. Additional approvals are pending. This agent is a fusion protein combining IL-2 and diphtheria toxin. Cells bearing the IL-2 receptor (in the lesions of at least one half of MF patients) bind and internalize the drug. The drug also may destroy Treg cells that are CD25<sup>+</sup> and suppress immune responses. Inside the cell, the toxin portion of the molecule disrupts protein synthesis, leading to cell death. Total response rates of about 33% have been reported. Adverse events include capillary leak syndrome, flulike symptoms, and allergic reactions. Alemtuzumab (Campath)<sup>1</sup> is an antibody directed against CD52. It has shown benefit in advanced-stage disease. This agent can be used alone or in conjunction with multiagent chemotherapy. Brentuximab vedotin (Adcetris)<sup>1</sup> is an anti-CD30 antibody linked to the microtubule toxin monomethyl auristatin E. It can be effective in those cases of MF that express sufficient CD30. Mogamulizumab (Poteligeo) is an antibody directed against CCR4. It is approved for relapsed or refractory MF or SS after at least one other systemic therapy. Pembrolizumab (Keytruda)<sup>1</sup> is an antibody directed against PD1. It can be of benefit for relapsed or refractory MF or SS.

### Systemic Chemotherapy

Various regimens of single-agent and multiagent chemotherapy have been used in the treatment of MF and SS. Oral methotrexate, chlorambucil (Leukeran)<sup>1</sup> with or without prednisone,<sup>1</sup> and etoposide (VePesid)<sup>1</sup> have shown therapeutic activity. The best response has been in erythrodermic patients treated with methotrexate (5 to 12.5 mg weekly),<sup>3</sup> who have shown a 58% response rate. The combination of low-dose methotrexate and interferon alfa has been reported to yield a high response rate in advanced-stage MF and SS.

The use of multiagent regimens is controversial because of the small number of patients treated with any given regimen. There is even some evidence that for some populations of CTCL patients, survival may be reduced. For individual patients with advanced disease, however, cyclophosphamide (Cytoxan),<sup>1</sup> doxorubicin (Adriamycin),<sup>1</sup> vincristine (Oncovin),<sup>1</sup> and prednisone<sup>1</sup> (CHOP regimen) can provide some short-term palliation. In some cases, CHOP has successfully eradicated large cell transformation of MF and returned patients to their more clinically indolent patch or plaque baseline disease. Idarubicin (Idamycin)<sup>1</sup> in association with etoposide, cyclophosphamide, vincristine, prednisone, and bleomycin (Blenoxane)<sup>1</sup> (VICOP-B regimen) has demonstrated response rates of 80% (36% complete response rate) for patients with stage II through IV disease and 84% for MF patients, with a median duration of response longer than 8 months. Other regimens have been used with more modest success.

Several purine nucleoside analogues have been used for CTCL treatment, including erythrodermic variants. These include 2-chlorodeoxyadenosine (cladribine [Leustatin]),<sup>1</sup> with a response rate of 28%, 2-deoxycoformycin (pentostatin [Nipent]),<sup>1</sup> with a response rate of 39%, and fludarabine (Fludara).<sup>1</sup> Toxicities include pulmonary edema, bone marrow and immune suppression, and neurotoxicity.

### Retinoids

Retinoids have therapeutic activity against MF and SS alone and in combination with other therapies, such as interferon alfa or PUVA (the latter combination is called Re-PUVA). Arotinoid,<sup>5</sup> acitretin (Soriatane),<sup>1</sup> and 13-*cis*-retinoic acid (isotretinoin [Accutane])<sup>1</sup> have various degrees of efficacy, and they typically are used in conjunction with other modalities. A newer RXR-specific retinoid, bexarotene, has an overall response rate of about 40% and can be used alone or in combination with phototherapy and

other systemic agents such as interferon alfa-2. Disadvantages of bexarotene therapy include signs of hypothyroidism and vitamin A toxicity, particularly hyperlipidemia.

### Enzyme Inhibitors

Vorinostat (Zolinza) is the first histone deacetylase inhibitor to be FDA approved for MF and SS. The overall response rate approaches 40% using a standard oral dose of 400 mg/day. Side effects include gastrointestinal symptoms, thrombocytopenia, and cardiac conduction abnormalities. Romidepsin (Isotodax) is an intravenously administered histone deacetylase inhibitor recently approved by the FDA for MF and SS. Forodesine<sup>5</sup> is a purine nucleoside phosphorylase inhibitor that preferentially affects T cells because they contain relatively high concentrations of this enzyme. Forodesine has undergone clinical trials for MF and SS in the United States and appears to have a response rate of about 40%.

### Miscellaneous Therapies

Various other therapies have been tried for MF and SS with modest success. Nonmyeloablative allogeneic stem cell transplantation has led to favorable responses in some patients; however, the total number treated is small. Cyclosporine (Sandimmune)<sup>1</sup> has been used for MF and SS. Transient improvement is followed by worsened survival due to immunosuppression, and it is not a recommended therapy. Thymopentin<sup>5</sup> has given excellent results in SS patients (i.e., 40% complete response rate and 35% partial response rate, with a median duration of response of 22 months). The lack of follow-up reports in recent decades leaves the status of this therapy in question. Inhibitors of JAK/STAT and other signal transduction pathways may be useful in patients bearing relevant activating mutations.

### Selection of Therapy

Initial choices among conventional treatments for MF and SS depend on the types of lesions and the stage of disease. Disease subsets are followed by recommended initial treatments in parentheses: unilesional or localized MF (local radiation therapy), patch MF (broad- and narrow-band UVB, PUVA, mechlorethamine), patch/plaque MF (PUVA, mechlorethamine), thick plaque/tumor MF (electron beam radiation therapy, interferon alfa-2, bexarotene, histone deacetylase inhibitors), erythrodermic MF/SS (photopheresis), and nodal or visceral MF or SS (interferon alfa-2, bexarotene, histone deacetylase inhibitors, experimental systemic therapies, systemic chemotherapy).

Second-line therapeutic choices often involve interferons, retinoids, or histone deacetylase inhibitors, usually in combination with primary modalities. Multimodality combinations, often at reduced doses, are used commonly to treat patients with stage IIB or more advanced disease. Medium-potency topical corticosteroids, such as 0.1% triamcinolone cream or ointment (Kenalog),<sup>1</sup> are useful adjuncts to many different therapies. The optimal use of newer therapeutic agents in various subtypes and stages of MF and SS is still being established. Evidence-based guidelines for MF and SS therapy have been developed by the National Comprehensive Cancer Network (NCCN) ([www.nccn.org](http://www.nccn.org)).

## Lymphoproliferative Disorders Associated with Mycosis Fungoides and Sézary Syndrome

### Types and Clinical Features

Patients with MF or SS are at increased risk for large T-cell lymphomas, lymphomatoid papulosis, and Hodgkin's disease. Molecular biologic analysis has shown that these disorders and MF often share the same clonal T-cell receptor gene rearrangement when they arise in the same individual. As a consequence, they are considered to be subclones of the original MF tumor clone. The development of large T-cell lymphoma in a patient with MF or SS is referred to as *large cell transformation of MF*.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>5</sup>Investigational drug in the United States.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

This occurs in up to 20% of cases in some series and is associated with a median survival of only 1 to 2 years. One half of these large T-cell lymphomas are CD30<sup>+</sup>; however, the generally favorable prognosis of primary cutaneous CD30<sup>+</sup> anaplastic large cell lymphoma may not extend to these secondary forms of CD30<sup>+</sup> lymphoma. These patients may need to be treated with systemic chemotherapy such as CHOP or with experimental systemic therapy appropriate for advanced-stage CTCL.

Lymphomatoid papulosis manifests as recurrent, usually generalized crops of spontaneously regressing, erythematous papules that can exhibit crusting or vesiculation before resolution. It is the clinically benign end of a disease continuum that has primary cutaneous CD30<sup>+</sup> anaplastic large cell lymphoma at its other extreme. Intermediate forms of disease can occur. Histopathologically, lesions contain a mixed-cell infiltrate, including large, atypical T cells that resemble Reed-Sternberg cells and their mononuclear variants (so-called type A) or large MF-type cells (so-called type B). Type A cells are CD30<sup>+</sup>. A type C form is also recognized. It has sheets of type A cells histologically mimicking CD30<sup>+</sup> large T-cell lymphoma but is different from it clinically. A type D variant containing CD8<sup>+</sup> CD30<sup>+</sup> large atypical cells has also been described recently, as well as a few other rare subtypes. All types of lymphomatoid papulosis behave similarly. Patients with lymphomatoid papulosis sometimes respond to tetracycline<sup>1</sup> or erythromycin<sup>1</sup> (500 mg PO bid), presumably on the basis of antiinflammatory activity. Most cases improve within 1 month with low-dose methotrexate (10–20 mg PO every week). PUVA and narrow-band UVB given three times per week are other therapeutic options.

### Treatment

In most cases, non-MF/SS CTCLs are treated with radiation therapy (with or without complete surgical excision) if they are localized or with various multiagent systemic chemotherapy regimens if they are generalized. The roles of other agents remain to be defined, except that studies have proved that methotrexate (10–40 mg PO every week) is effective therapy for most cases of primary cutaneous CD30<sup>+</sup> anaplastic large cell lymphoma. Therapies being investigated for this lymphoma include anti-CD30 antibodies, alone or conjugated to toxins. One of these antibody conjugates (brentuximab vedotin [Adcetris]) is FDA approved for primary cutaneous anaplastic large cell lymphomas and CD30<sup>+</sup> MF. Denileukin diftitox (now discontinued) and histone deacetylase inhibitors have been reported to be effective against some subcutaneous panniculitic T-cell lymphomas. The recent discovery of JAK fusion mutations in aggressive epidermotropic cytotoxic CTCL (Berti's lymphoma) suggests that JAK inhibitors might be beneficial in this rare disorder.

<sup>1</sup>Not FDA approved for this indication.

## CUTANEOUS VASCULITIS

Method of

Molly A. Hinshaw, MD; and Susan Lawrence-Hylland, MD

### CURRENT DIAGNOSIS

- Cutaneous vasculitis can be limited to skin (leukocytoclastic vasculitis) or associated with systemic disease.
- Perform punch biopsy of intact, nonulcerated skin lesion.
- “Vasculitis” on skin biopsy describes vessel appearance and is not a clinical diagnosis.
- Thorough review of systems and physical examination are necessary to evaluate for systemic vasculitis.

### CURRENT THERAPY

#### Leukocytoclastic Vasculitis

- First identify instigating factors: infection, medications.
- Care is symptomatic. Lesions typically remit without treatment.
- If needed, short course of prednisone may be given and tapered over 3 to 6 weeks.

#### All Forms of Vasculitis

- Treat underlying systemic vasculitis.

Vasculitis is an inflammatory-mediated destruction of blood vessels. The systemic vasculitides have historically been differentiated by their involvement of small, medium, or large blood vessels. Names used to describe isolated cutaneous vasculitis have included hypersensitivity vasculitis and leukocytoclastic vasculitis (LCV). In 1990, the American College of Rheumatology proposed five criteria for the classification of hypersensitivity vasculitis: age older than 16 years, possible drug trigger, palpable purpura, maculopapular rash, and skin biopsy showing neutrophils around vessel. At least three out of five criteria yield a sensitivity of 71% and specificity of 84%. In 1994, a new nomenclature proposed at the Chapel Hill International Consensus Conference in North Carolina further classified vasculitis (Box 1). The term “hypersensitivity vasculitis” was not used, because most vasculitides that would have previously been in this category fall into either microscopic polyangiitis or cutaneous LCV. LCV is vasculitis restricted to the skin without involvement of vessels in other organs. Cutaneous vasculitis may be a clue to systemic vasculitis and guides the clinician to a comprehensive evaluation (Table 1).

Vasculitis can affect almost any organ, and once affected, end organs can become dysfunctional. Such dysfunction may be as innocuous as cutaneous, tender, transient papules or as devastating as a stroke. A thorough evaluation of the patient with a complete review of systems, physical examination, laboratory evaluation, and clinical follow-up allows a distinction to be made between the different forms of vasculitis.

### Leukocytoclastic Vasculitis

#### Epidemiology

LCV is common. The incidence and prevalence are unknown. Mean age of onset ranges from 34 to 49 years of age. The female-to-male ratio ranges from approximately 2:1 to 3:1.

#### Risk Factors

LCV is often secondary to a known trigger including infection, drug ingestion, or malignancy. LCV can also be a presenting feature of autoimmune disease.

**Large-Vessel Vasculitis**

- Giant cell arteritis
- Takayasu's arteritis

**Medium-Vessel Vasculitis**

- Classic polyarteritis nodosa
- Kawasaki's disease

**Small-Vessel Vasculitis**

- Churg-Strauss syndrome
- Cutaneous leukocytoclastic vasculitis
- Essential cryoglobulinemia
- Henoch-Schönlein purpura
- Microscopic polyangiitis (polyarteritis)
- Wegener's granulomatosis

**Pathophysiology**

LCV is best characterized as immune complex-mediated inflammatory destruction of the postcapillary venules of any organ. The exact mechanisms of vascular destruction is unknown.

**Clinical Manifestations**

LCV typically manifests as nonblanchable macules that evolve to papules or, less commonly, pustules and ulcers (Figure 1). Clues to the diagnosis include a monomorphous, ruddy-brown appearance owing to leakage of hemosiderin pigment from vessels. Lesions measure a few millimeters to a few centimeters in diameter. LCV is often localized to the lower extremities but may be diffuse. Pruritus, pain, or burning of the skin lesions are indicators that the patient might have a vasculitis extending beyond LCV.

**Diagnosis**

To confirm a clinical impression of LCV, perform a punch biopsy in the center of a nonulcerated cutaneous lesion that is less than 24 to 48 hours old and submit the sample in 10% formalin (standard medium). It is important to biopsy an intact, nonulcerated active lesion (Figure 2) because ulcers can show histologic features simulating vasculitis regardless of whether the patient has true vasculitis or not.

Pathology reveals a mononuclear or polymorphonuclear inflammation of the small blood vessels (called LCV), most prominent in the postcapillary venules. The appearance may be necrotizing or non-necrotizing.

**Differential Diagnosis**

LCV manifests as erythematous papules or occasionally as papulopustules that can simulate a variety of entities (see Table 1). The review of systems and physical examination should be directed to evaluate for diseases that have cutaneous vasculitis as a component of their presentation (see Table 1). All patients with LCV should have a urinalysis to evaluate for hematuria as a sign of kidney involvement, with subsequent evaluation and management if identified.

**Treatment**

The primary goal in the management of LCV is to identify and treat instigating factors, including infection and medications. Supportive treatment includes resting, elevating legs, and wearing support hose. When review of systems, physical examination, and urinalysis do not reveal associated systemic diseases, treatment of LCV is generally not necessary. Lesions typically remit without treatment. In rare patients with symptomatic, extensively pustular, or progressive lesions, a short course of prednisone<sup>1</sup> dosed at 1 mg/kg/day initially and tapered over 3 to 6 weeks may be used,

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Diseases with Cutaneous Vasculitis as a Component of Their Presentation

DISEASE	SKIN LESIONS	CLUES AND CONFIRMATION
Urticarial vasculitis	Individual lesions look like urticaria but last >24 h; typical urticaria last a few hours, always <24 h Pruritus, burning of skin lesions	May be associated with connective tissue disease, medications, low complement, viral infections (e.g., hep B, hep C, EBV) Skin biopsy
Henoch-Schönlein purpura	Wheals progress to petechia, ecchymoses and palpable purpura Lesions are in gravity-dependent or pressure-dependent areas such as legs or the buttocks in toddlers	Arthralgia or arthritis, hematuria, abdominal pain, melena Skin biopsy and DIF for IgA
Essential mixed cryoglobulinemia	Palpable purpura	Peripheral neuropathy, GN Hep C positive Serum cryoglobulins
Wegener's granulomatosis	Palpable purpura, hemorrhagic lesions, petechiae, skin ulcers	c-ANCA >80% Pulmonary hemorrhage, GN Biopsy affected organ
Churg-Strauss syndrome	Maculopapular rash, palpable purpura, hemorrhagic lesions, subcutaneous nodules, livedo reticularis or Raynaud's disease	ANCA (50%) Asthma, allergic rhinitis Eosinophilia >1.5 × 10 <sup>9</sup> /L Pulmonary infiltrates, pulmonary neuropathy Biopsy affected organ
Microscopic polyangiitis	Palpable purpura, hemorrhagic lesions, petechiae, skin ulcers, splinter hemorrhages	p-ANCA >60% Pulmonary hemorrhage, GN Biopsy affected organ
Polyarteritis nodosa	Livedo reticularis, tender nodules, skin ulcers, bullae or vesicles	Hypertension, elevated creatinine, abdominal pain, constitutional symptoms (fever) Abnormal angiogram Biopsy affected organ

*Abbreviations:* c-ANCA = classic antineutrophil cytoplasmic antibody; DIF = direct immunofluorescence; EBV = Epstein-Barr virus; GN = glomerulonephritis; hep = hepatitis; Ig = immunoglobulin; p-ANCA = protoplasmic-staining antineutrophil cytoplasmic antibody.

**Figure 1** Leukocytoclastic vasculitis: palpable, purpuric, nonblanching, erythematous to ruddy-brown thin papules. Additional secondary changes include small pustules (pustular vasculitis) or shallow, small ulcerations.

**Figure 2** Biopsy of intact clinical lesion of leukocytoclastic vasculitis. Histology shows destruction of postcapillary venules with fibrin deposition, degenerate inflammatory cells, and extravasated erythrocytes.

although no controlled trials have been performed using oral corticosteroids for isolated LCV. Rapid steroid taper can lead to rebound. Systematic evaluation of the use of other medications, such as colchicine<sup>1</sup> or dapsone,<sup>1</sup> to treat isolated LCV has not been performed.

### Monitoring

Patients with LCV are at risk for recurrent or chronic vasculitis. In addition, apparent LCV can occur as a systemic disease that is not recognizable at the first episode. Patients with persistent or recurrent LCV require follow-up to ensure disease clearance, to monitor for medication side effects, and to evaluate for evolving disorders known to be associated with cutaneous vasculitis (see [Table 1](#)).

### Complications

Isolated LCV generally resolves without sequelae. However, pustular or ulcerative LCV may be complicated by local sequelae such as cutaneous ulcerations and scars.

### Cutaneous Vasculitis Associated with Systemic Vasculitis

Cutaneous vasculitis may be a component of the presentation of multiple diseases (see [Table 1](#)). When a clinician reads a pathology report from a biopsy of a skin lesion that states “vasculitis,” it is important to realize that this term is a descriptor of the histopathology. It is the clinician’s challenge to determine whether “vasculitis” is as potentially innocuous as LCV or part of a more severe systemic disease. Symptoms that are clues

to a systemic process can include fever, arthralgias, myalgias, anorexia, abdominal pain, pulmonary abnormalities, or neurologic symptoms.

Skin biopsy may aid in the diagnosis of a systemic vasculitis (Henoch-Schönlein purpura), but biopsy of an affected end organ may be necessary to confirm a diagnosis. Pathology focuses on the confirmation of vasculitis in a small, medium, or large vessel.

Aside from Henoch-Schönlein purpura, treatment of systemic vasculitis is typically much more aggressive than treatment of LCV and should be pursued in conjunction with involvement of a rheumatologist, nephrologist, or pulmonologist. Systemic disease leads to severe complications including renal failure, pulmonary damage, permanent vascular disease, or neurologic insult depending on the viscera affected.

## DISEASES OF THE HAIR

Method of

Dirk M. Elston, MD

### CURRENT DIAGNOSIS

- A sudden increase in shedding most commonly represents telogen effluvium.
- Hair thinning is more likely to represent pattern alopecia.
- Scarring alopecia generally requires a biopsy for diagnosis.
- Most medically significant hirsutism results from polycystic ovarian syndrome.
- New-onset virilization suggests the possibility of a tumor.

### CURRENT THERAPY

- Pattern alopecia in men is treated with oral finasteride (Propecia), topical minoxidil (Rogaine), or both.
- Pattern alopecia in women is treated with antiandrogens (such as spironolactone [Aldactone]<sup>1</sup>) and oral<sup>1</sup> or topical minoxidil. Platelet-rich plasma injections may be of benefit in both men and women.
- Alopecia areata can require intralesional corticosteroid injections, topical immunotherapy, or therapy with agents such as methotrexate (Trexall)<sup>1</sup> or Janus kinase (JAK) inhibitors.
- A scalp biopsy is critical to guide therapy in scarring alopecia.
- Hirsutism may be treated with laser epilation or systemic antiandrogens. Topical eflornithine (Vaniqa) can slow regrowth of hair.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Hair disorders are common, with more than half of the population affected by pattern alopecia and the prevalence of hirsutism varying significantly by ethnicity.

### Risk Factors

Most causes of alopecia and hirsutism are genetically determined.

## Pathophysiology

Pattern alopecia relates to increased sensitivity to dihydrotestosterone. Telogen effluvium relates to an alteration in the normal hair cycle, with many hairs shedding synchronously. Alopecia areata represents an inflammatory insult directed against melanocytes in the hair bulb. There is strong evidence that the disease is mediated by Th1 lymphocytes. Polycystic ovarian syndrome is an insulin-resistance syndrome resulting in excess production of androgens.

## Prevention

Little can be done to prevent hair disorders, so the focus is generally on diagnosis and treatment.

## Clinical Manifestations

Pattern alopecia manifests with apical scalp thinning. In men, receding of the hairline at the temples is typical, whereas women demonstrate widening of the part but retain the anterior hairline. Telogen effluvium manifests with diffuse shedding of telogen hairs (hairs with a nonpigmented bulb). Alopecia areata typically occurs with patchy hair loss. Shed hairs demonstrate tapered fracture at the base. Syphilitic alopecia resembles alopecia areata but often affects smaller areas, with only partial hair loss, resulting in a moth-eaten appearance. Scarring alopecia shows permanent areas of smooth alopecia lacking follicular openings.

Polycystic ovarian syndrome manifests with evidence of anovulation and excess androgen production. Signs of virilization suggesting a possible tumor include new onset of hirsutism, deepening of the voice, change in body habitus, and clitoromegaly.

## Diagnosis

### Alopecia

The first step is to determine whether a hair shaft abnormality exists (Box 1). This is particularly important in Black patients, in whom trichorrhexis nodosa is a common cause of hair loss. Trichorrhexis nodosa results from overprocessing of the hair. Hair density is normal at the level of the scalp, but hairs break off, leaving patches of short hair.

The next step is to determine whether telogen effluvium exists. Telogen effluvium manifests with increased shedding of hairs with a blunt nonpigmented bulb (Figure 1), and it commonly follows an illness, surgery, delivery, or crash diet by 3 to 5 months. Hairs can often be easily extracted with a gentle hair pull or 1 minute of combing. The presence of tapered fracture suggests alopecia areata, syphilis, or heavy metal poisoning. Alopecia areata can result in diffuse hair loss, but it more commonly manifests with well-defined round patches of hair loss. The skin is either normal or salmon pink. Syphilis more often shows a moth-eaten pattern of alopecia (Figure 2).

Most patients with hair loss need only limited laboratory testing or none at all. Thyroid disorders and iron deficiency are common, and testing for them is relatively inexpensive. I recommend them when telogen effluvium is present. Their presence can also accelerate the course of pattern alopecia, and it is reasonable to test for them in women with this disorder. Thyroid-stimulating hormone is the best screen for thyroid disorders. The role of iron deficiency in telogen hair loss is controversial, but iron deficiency is common, easily established, and inexpensive to correct. Iron status also serves as an indicator of overall nutritional status. Although a low ferritin level proves iron deficiency, ferritin behaves as an acute phase reactant and a normal level does not rule out iron deficiency. Therefore, I recommend measurement of ferritin, serum iron, iron binding capacity, and saturation.

A scalp biopsy is required in any patient with scarring alopecia. It may also be necessary in other patients if history and physical examination do not establish a diagnosis and the alopecia is progressive. The scalp biopsy should be performed with a 4-mm biopsy punch oriented parallel to the direction

## BOX 1 Diagnosis of Alopecia

### Trichodystrophy

#### Types

- Trichorrhexis nodosa
- Inherited trichodystrophies
- Fractures

#### Causes

- Alopecia areata
- Chemotherapy
- Heavy metal

#### Determine Type

##### Anagen Effluvium

Tapered fractures can be caused by

- Alopecia areata
- Chemotherapy
- Heavy metal

Loose anagen can be caused by

- Loose anagen syndrome
- Easily extractable anagen in scarring alopecia

##### Telogen Effluvium

Increased shedding of club hairs can be caused by

- Diet, illness
- Pregnancy
- Medication
- Papulosquamous disorders
- Pattern alopecia

### Diagnosis

#### Laboratory Studies

- Iron
- Thyroid-stimulating hormone
- Endocrine studies in virilized women

#### Biopsy

Nonscarring types

- Telogen effluvium
- Pattern alopecia
- Alopecia areata

Scarring types

- Lupus erythematosus
- Lichen planopilaris
- Folliculitis decalvans

#### Other Permanent Alopecia

- Idiopathic pseudopelade
- Morphea

of hair growth. Collagen hemostatic sponge (Gelfoam and others) can be placed into the resulting hole to stop bleeding and eliminate the need for sutures. The biopsy should be done in a well-established but still active area of inflammation if one can be identified. A combination of vertical and transverse sections increases the diagnostic yield and is usually recommended. In patients with scarring alopecia, half of the vertically bisected specimen should be sent for direct immunofluorescence. An additional biopsy of an end-stage scarred area can demonstrate characteristic patterns of scarring with an elastic tissue stain. This can help distinguish among causes of scarring alopecia such as lupus erythematosus (Figure 3), lichen planopilaris, pseudopelade, and folliculitis decalvans.

### Hirsutism

Patients with *new-onset* virilization should be evaluated to rule out an ovarian or adrenal tumor. Ovarian and adrenal imaging

**Figure 1** Telogen hair on *left*, anagen hair on *right* for comparison.

**Figure 2** Moth-eaten syphilitic alopecia.

**Figure 3** Scarring alopecia secondary to chronic cutaneous lupus erythematosus.

### Differential Diagnosis

Syphilis can mimic alopecia areata, and serologic testing should be performed in any sexually active patient with a new diagnosis of alopecia areata. Correct diagnosis of scarring alopecia depends of a thorough examination for other cutaneous signs of lupus erythematosus or lichen planus as well as the results of a skin biopsy.

Tinea capitis can occur as inflammatory boggy areas with hair loss (kerion) or with subtle seborrheic-type scale and black-dot areas of hair loss. A potassium hydroxide (KOH) examination can be performed by rubbing the affected area with moist gauze and examining broken hairs that cling to the gauze.

Hirsutism should be distinguished from hypertrichosis. Hirsutism is a male pattern of hair growth occurring in a woman and is hormonal in nature. Hypertrichosis is excess hair growth that occurs outside of an androgen-dependent distribution. It can be found in metabolic disorders such as porphyria or may be a sign of internal malignancy (Figure 4).

Nonclassic 21-hydroxylase deficiency accounts for up to 10% of patients with medically significant hirsutism. Screening with a baseline morning 17-OH-progesterone is associated with many false positive results. A stimulated 17-OH-progesterone is more specific, but the results of testing seldom affect management because outcomes with dexamethasone (Decadron)<sup>1</sup> are no better than with spironolactone (Aldactone).<sup>1</sup>

### Treatment

#### Alopecia

Telogen effluvium commonly resolves spontaneously once the cause has been eliminated. Poor diet and papulosquamous diseases of the scalp such as seborrheic dermatitis and psoriasis can perpetuate a telogen effluvium and should be treated. The importance of a diet containing adequate protein and trace minerals should be emphasized. Deficiencies and thyroid abnormalities should be addressed. Seborrheic dermatitis responds to topical corticosteroids. Medicated shampoos containing selenium sulfide (Selsun Blue) or zinc pyrithione (T-gel Daily Control) can be helpful. Scalp psoriasis can require more potent topical steroids such as fluocinonide solution (Lidex) and calcipotriene (Dovonex) applied on weekends or daily. Systemic agents such as methotrexate (Trexall)<sup>1</sup> at doses of 7.5 to 20 mg once weekly may be required to control severe scalp psoriasis.

Pattern alopecia in men is mediated by dihydrotestosterone (DHT). Men with pattern alopecia may be treated with daily topical minoxidil 2% to 5% (Rogaine), oral minoxidil (Loniten)<sup>1</sup> in doses from 0.5 to 5 mg daily, and oral finasteride (Propecia) at a dose of 1 mg daily. In women, the pathogenesis

studies and a total testosterone level are the best screens. A total testosterone more than 200 ng/dL or dehydroepiandrosterone sulfate (DHEAS) more than 8000 ng/dL suggests tumor. In patients with physical signs of Cushing disease, a 24-hour urine cortisol should be obtained. Most patients with *chronic* medically significant hirsutism have polycystic ovarian syndrome (PCOS). The diagnosis is established by means of history and physical examination, and the most important laboratory tests are serum lipids and fasting glucose to establish associated cardiac risk factors. A clinical diagnosis of PCOS requires the presence of hirsutism, acne or pattern alopecia, and evidence of anovulation (fewer than nine periods per year or cycles longer than 40 days). Ratios of luteinizing hormone (LH) to follicle-stimulating hormone (FSH) have poor sensitivity and specificity for diagnosing PCOS. Imaging for ovarian cysts seldom affects management.

<sup>1</sup>Not FDA approved for this indication.

**Figure 4** Malignant hypertrichosis secondary to ovarian cancer.

is complex, and adrenal androgens may play a larger role. Finasteride<sup>1</sup> is of less benefit in the majority of women with pattern alopecia. Spironolactone<sup>1</sup> 100 mg twice daily can be helpful and may be combined with oral minoxidil.<sup>1</sup> In women of childbearing potential, spironolactone should always be used in conjunction with an oral contraceptive. Side effects are uncommon but can include urinary frequency, irregular periods, dyspareunia, and nausea. Most patients demonstrate a minor increase in serum potassium. Those with kidney failure are at risk for life-threatening potassium retention. Topical 2% minoxidil can also be of benefit, and some women derive added benefit from the 5% formulation. All patients with pattern alopecia should be evaluated for superimposed causes of telogen effluvium such as inadequate diet and seborrheic dermatitis.

Tinea capitis is often overlooked in adults and Black children, in whom the manifestations of inflammation can be subtle. Black dot and seborrheic tinea are common in Black children. Patchy hair loss is an important clue to the diagnosis. Treatment is summarized in [Table 1](#).

Localized patches of alopecia areata respond to intralesional injections of triamcinolone hexacetonide (Aristospan) (2.5–5 mg/mL) given once per month. Approximately 0.1 mL/cm<sup>2</sup> is injected to a maximum of 3 mL during any one session. Minoxidil solution produces slow regrowth in some patients who cannot tolerate other treatments. Anthralin (Dritho-Scalp 0.5%)<sup>1</sup> is sometimes used in children. It is applied 30 minutes before showering. It can stain skin and anything else it touches.

Topical immunotherapy with dinitrochlorobenzene (DNCB)<sup>1</sup>, squaric acid dibutylester (SADBE),<sup>1</sup> or diphenylcyclopropenone (DPCP)<sup>1</sup> is more effective than either minoxidil or anthralin. DNCB is mutagenic in the Ames assay and none of the topical immunotherapies are currently approved for human use. A 2% solution of the sensitizer is applied to the arm in acetone to induce initial sensitization. Subsequently, diluted solutions, starting at about 0.001%, are applied weekly to the scalp with a cotton-tipped applicator. Roughly 20% to 60% of patients have responded to this regimen in various studies.

Tofacitinib (Xeljanz)<sup>1</sup> and other JAK inhibitors are often effective in patients with refractory alopecia areata. Biologic agents have shown mixed results. Methotrexate<sup>1</sup> in psoriatic doses (7.5–20 mg weekly for an adult) can be effective. Sulfasalazine (Azulfidine)<sup>1</sup> is sometimes effective in doses ranging from 500 to 1500 mg three times a day.<sup>3</sup> Patients should be encouraged to read about new therapies on the National Alopecia Areata Foundation website (<https://www.naaf.org>).

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

**TABLE 1** Treatment of Tinea Capitis

ANTIFUNGAL AGENT	DOSAGE	USUAL DURATION OF THERAPY
Griseofulvin (Fulvicin U/F)	Required dosages are often higher than reflected in the product label; 4–10 mg/kg/day is a good starting dosage	1 month or more
Fluconazole (Diflucan) <sup>1</sup>	5–6 mg/kg/day; adult: 200 mg/day	1 month or more
Itraconazole (Sporanox) <sup>1</sup>	3–5 mg/kg/day; adult: 200 mg/day	1 week, repeated monthly until cured
Terbinafine (Lamisil)	Patient <20 kg: 62.5 mg/day Patient 20–40 kg: 125 mg/day Patient >40 kg: 250 mg/day	1 month or more

<sup>1</sup>Not FDA approved for this indication.

Early, aggressive therapy for discoid lupus erythematosus is recommended to prevent permanent scarring. Topical corticosteroids are rarely sufficient. Intralesional injections are performed in a manner similar to that described above. Initial control of severe disease can be achieved with a single 3-week tapered course of oral prednisone at a dose of 60 mg daily for the first week, 40 mg daily for the second week, and 20 mg daily for the third week. Intralesional steroid injections or a systemic steroid-sparing agent are required for maintenance therapy. Systemic agents that can be effective include antimalarials, dapsone,<sup>1</sup> methotrexate,<sup>1</sup> mycophenolate mofetil (CellCept),<sup>1</sup> and thalidomide (Thalomid).<sup>1</sup> I generally begin treatment with hydroxychloroquine (Plaquenil)<sup>1</sup> at a dose of 400 mg daily for an adult. Dapsone is used at a dose of 100 mg daily for an adult. Thalidomide has been used effectively at doses of 50 to 100 mg daily, but peripheral neuropathy and teratogenicity limit its use. Mycophenolate mofetil is used at a dose of 1 g twice daily, and methotrexate is used at doses of 7.5 to 20 mg weekly. Background pattern (androgenetic) alopecia should be treated as well.

End-stage cicatricial alopecia is best treated by scalp reduction and hair transplantation. The disease can flare up in response to surgery, and it is best to plan a 3-week tapered course of prednisone<sup>1</sup> or a month of cyclosporine (Neoral)<sup>1</sup> to help prevent the flare.

Lichen planopilaris is treated in a manner similar to lupus, except that hydroxychloroquine<sup>1</sup> is of less benefit and oral retinoids (acitretin [Soriatane])<sup>1</sup> at doses of 25 to 50 mg daily are more likely to be successful. Topical calcineurin inhibitors can be effective in achieving and maintaining remission. A few months of pioglitazone (Actos)<sup>1</sup> can induce remission in a subset of patients and the frontal fibrosing alopecia variant can respond to dutasteride (Avodart).<sup>1</sup> Patients should be aware of the risks associated with each of these treatments, including bladder cancer and hypospadias in a male fetus. Mycophenolate mofetil (CellCept)<sup>1</sup> 1 g twice daily or a JAK inhibitor may be effective when other treatments fail, and excimer laser can also be effective for lichen planopilaris. It is contraindicated in lupus erythematosus.

Folliculitis decalvans manifests with crops of pustules that result in permanent scarring. Patients respond to weekend applications of clobetasol (Clobex, Olux) together with prolonged use of antistaphylococcal antibiotics such as doxycycline (Doryx)<sup>1</sup> 100 mg twice daily.

<sup>1</sup>Not FDA approved for this indication.

## Hirsutism

Treatment options include laser epilation, eflornithine (Vaniqa) cream to reduce the rate of hair growth, or spironolactone<sup>1</sup> at a starting dose of 100 mg twice daily as described for pattern alopecia. Cyproterone acetate is used in some countries but is not available in the United States. Other options that are less commonly used include insulin sensitizers, flutamide (Eulexin),<sup>1</sup> metformin (Glucophage),<sup>1</sup> and leuprolide (Lupron)<sup>1</sup> plus estrogen.<sup>1</sup>

## Monitoring

Patients treated with topical or intralesional corticosteroids should be monitored for cutaneous atrophy. Patients on JAK inhibitors should have quarterly evaluations of blood count, chemistries, and lipids. Those on hydroxychloroquine should be monitored for ocular toxicity, including corneal deposits and retinal damage, although these are very rare at usual doses. They should also be monitored periodically for thrombocytopenia, agranulocytosis, and hepatitis. Patients beginning dapsone therapy should be screened for G6PD deficiency. Potential side effects include hemolysis, methemoglobinemia, and neuropathy. Monitoring includes periodic blood count assessment and measurement of strength and sensation. Mycophenolate mofetil can produce pancytopenia, and blood counts should be monitored. Methotrexate is cleared by the kidneys, and kidney function should be assessed at baseline. Periodic assessment of liver-function tests and blood count is warranted, as is a yearly chest radiograph. I also monitor procollagen 3 terminal peptide levels quarterly to assess the risk of hepatic fibrosis. Patients on antiandrogen therapy should be monitored for dyspareunia resulting from vulvar atrophy.

## Complications

Patients with pattern alopecia and PCOS have a greater risk of metabolic syndrome with cardiac complications. They should be evaluated for lipid abnormalities and glucose intolerance and treated appropriately.

<sup>1</sup>Not FDA approved for this indication.

## DISEASES OF THE MOUTH

Method of

Lisa Simon, MD, DMD; and Hugh Silk, MD, MPH

## CURRENT DIAGNOSIS

### High-risk conditions

- Ludwig angina: Spread of infection most commonly from a mandibular molar into the sublingual and submaxillary spaces that surround the airway, causing urgent respiratory compromise.
- Cavertous sinus thrombosis: Ascending infection and thrombosis of intracranial vessels that can be caused by a maxillary dental infection. Requires urgent neurologic and neurosurgical evaluation.
- Lesions concerning for oral cancer: Most commonly squamous cell carcinoma (SCC) may present as sessile or fungating, with red or white shading. Usually asymptomatic, may feature fixed, painless lymph nodes. Associated with alcohol and tobacco use.

### Common conditions

- Dental caries: Most common infectious disease globally, near 100% prevalence. Dental pain indicates that the tooth will require root canal therapy or extraction to resolve the infection.
- Periodontal disease: Inflammatory loss of the tooth's attachment structure, which can cause pain, tooth mobility, and eventual tooth loss.

### Oral ulcers

- Acute ulcers most likely infectious (herpes simplex virus [HSV], Coxsackie) or aphthous ulcers, tend to resolve within 7 to 10 days.
- Chronic ulcers will appear more desquamative and widespread within the oral cavity. They are more likely to be due to a dermatologic condition (pemphigus vulgaris, mucous membrane pemphigoid, lichen planus) and should prompt investigation of other dermatologic findings.

### Oral lesions and masses

- Cessation of triggering activity (e.g., use of chewing tobacco) and evaluate for resolution.
- Refer for biopsy if lesions persist for more than 14 days.

### Xerostomia

- Perception of dry mouth, which can make speaking and swallowing more difficult and predisposes patients to rampant dental decay.
- Associated with polypharmacy, especially drugs with known anticholinergic properties.
- Can also be due to autoimmune destruction of salivary glands from SICCA syndrome.

### Osteonecrosis of the jaw

- Antibiotics for purulent exudate.
- Refer to oral surgeon or oral medicine specialist for monitoring and possible resection of necrotic bone.

### Antibiotic prophylaxis for dental procedures

- For infective endocarditis prevention, this is necessary only in individuals with prosthetic valves or implants, unrepaired cyanotic congenital heart disease or repair with residual defect, history of cardiac transplant with valvular regurgitation, or history of infective endocarditis.
- No prophylaxis necessary for individuals with prosthetic joints.
- Prophylaxis necessary only for procedures that involve manipulating the gingiva.
- Prophylaxis can be taken up to 2 h after a procedure with equivalent efficacy.

## CURRENT THERAPY

### Management of painful odontogenic or periodontal infections

- Definitive resolution requires dental treatment.
- Penicillin VK 500 mg qid or amoxicillin<sup>1</sup> 500 mg tid for 7 days
- If penicillin allergic: clindamycin<sup>1</sup> 300 mg qid for 7 days

### Management of oral ulcers

- For herpetic ulcers: Treat as early as possible with acyclovir (Zovirax) 400 mg tid for 5 to 10 days
- For aphthous ulcers or other autoimmune etiologies: If focal, triamcinolone 0.1% in orabase (Kenalog Orabase), apply topically after each meal and at bedtime; if extensive, dexamethasone (Decadron)<sup>1</sup> 0.5 mg/5 mL elixir, rinse for 2 min after each meal and at bedtime, then expectorate.
- Pain relief can be achieved with diphenhydramine (Benadryl)<sup>1</sup> liquid 12.5 mg/5 mL blended 1:1 with a coating agent such as Kaopectate<sup>1</sup> or Maalox<sup>1</sup>; can be used to rinse every 2 h.

### Management of oral candidiasis

- Clotrimazole (Mycelex) troches five times a day for 14 days
- Nystatin (Mycostatin 100,000 U/mL), 400,000 to 600,000 U, rinse daily for 14 days; may soak denture overnight if applicable
- For angular cheilitis or focal infection: Nystatin/triamcinolone 1% (Mycolog) cream daily for 14 days

### Management of xerostomia

- Reduce or stop medications that cause xerostomia
- Ensure access to water or ice chips throughout the day
- Sialogogues such as Biotène rinse or gel
- Cholinergic agonist such as pilocarpine (Salagen) 5 to 10 mg tid before meals

### Management of osteonecrosis

- Antibiotics for purulence (see infections, earlier).
- Chlorhexidine gluconate (Peridex) rinse to reduce bacterial burden (*off-label use*): Rinse with 15 mL bid and expectorate.
- Pain medication if needed; avoid opioids when possible.
- Refer to oral surgeon or oral medicine provider for extensive necrosis and possible resection.

### Antibiotic prophylaxis for dental procedures

- Amoxicillin<sup>1</sup> 2 g 30 to 60 min before procedure
- If penicillin allergic: Clindamycin<sup>1</sup> 600 mg, cephalexin (Keflex)<sup>1</sup> 2 g, azithromycin (Zithromax)<sup>1</sup>, or clarithromycin (Biaxin)<sup>1</sup> 500 mg

<sup>1</sup>Not FDA approved for this indication.

## Caries

Dental caries are the most prevalent infectious disease in the world, affecting more than 90% of the population. Caused primarily by the acidogenic species *Streptococcus mutans* and lactobacilli, fermentation of dietary sugars produces acids that create holes in the teeth. Diets high in sugar—including both fermentable carbohydrates, sugary foods, and sugar-sweetened beverages—increase caries risk.

The prevalence and severity of caries has decreased substantially in the United States since the introduction of fluoride into community water sources. For pediatric patients ages 6 months to 16 years who primarily drink well water or reside in communities without water fluoridation, fluoride supplementation should be offered according to the guidelines set by the American Academy of Pediatrics.

Saliva is basic in nature and can reduce acid in the mouth and remineralize teeth to counteract the caries process. Consequently individuals with xerostomia, a common side effect of many medications, are at higher risk of caries, which are more likely to develop at the base of the tooth (the cervical aspect) in xerostomic mouths (see xerostomia, further on) (Figure 1).

Caries initially appear as chalky white spots on the tooth enamel. Eventually, decay will expand into a visible lesion, which may appear dark yellow, brown, or black. Interproximal decay (caries between the teeth) may be visible only radiologically until quite advanced. Patients may report sensitivity to sweet foods, progressing to sensitivity to hot and cold. Spontaneous pain caused by tooth decay indicates that the bacterial infection has spread to the neurovascular supply within the tooth (the pulp) and should be managed as a dental abscess (see later).

Patients with visibly carious dentition should be urged to visit a dentist as promptly as possible. If available, topical 5% sodium fluoride varnish can be applied off label by a provider to slow the progression of caries. Patients should also be counseled to reduce the quantity and frequency of dietary sugar intake.

Prevention includes twice daily brushing of teeth with proper technique and fluoridated toothpaste, daily flossing, and limiting sugary drinks and snacks. Children should be assisted with brushing until approximately age 8 and should use only a smear of fluoride-containing toothpaste until age 3. Fluoride should be offered (as noted previously) in communities with nonfluoridated water, and fluoride varnish should be offered at medical visits until age 5. Everyone with teeth should visit a dental provider regularly for cleanings, radiographs, and advice, usually twice annually, more or less based on risk. Individuals without teeth should still have regular dental visits to evaluate denture fit.

## Periodontitis

Periodontal disease is a polymicrobial infection of primarily anaerobic, gram-negative pathogens within the *periodontium*, the attachment apparatus between the tooth and the alveolar bone. Proliferation of bacteria in the periodontal space causes local inflammation, which leads to sensitive and friable gingival tissue and eventual tooth mobility from inflammatory damage to the periodontal ligament and bone. Periodontal disease is extremely common, present in approximately 40% of all adults worldwide and in 20% of middle-aged US adults, and prevalence increases with age. Patients with diabetes are at especially high risk of periodontal disease. Note that periodontitis is associated with other conditions including worsening heart disease, uncontrolled diabetes, and preterm labor. Severe congenital forms of periodontal disease are known to be caused by disorders of neutrophil adhesion.

Accumulation of bacteria near or within the periodontal space may initially present with gingivitis, or inflammation of the gingiva without bone or attachment loss. Patients may report friable gingiva (bleeding when eating, brushing, or flossing the teeth) and sensitivity. As the disease progresses, the loss of bone will cause the teeth to appear to lengthen. Teeth with reduced attachment may become spaced apart or splayed due to the impact of repeated occlusal forces on unstable teeth. In advanced stages, teeth may be freely mobile on examination. The gingiva will appear boggy and friable, and bleeding or suppuration may be noticed when the teeth or gingiva are manipulated. Patients presenting with an acute onset of new bleeding and expansile gingiva should be evaluated for a hematologic abnormality suggestive of malignancy prior to referral for dental treatment.

Definitive diagnosis, including the severity of the periodontal disease and whether individual teeth can be maintained or must be extracted, must be made by a dentist using clinical exam and radiographic findings. Dental professionals will perform probing to evaluate loss of attachment between bone and tooth. The primary treatment to prevent further attachment loss is *scaling and root planing* to remove the bacterial concretions below the gingiva that are causing the inflammatory response.

Topical and occasionally systemic antibiotic therapy may be prescribed by a dental professional as part of surgical treatment for periodontitis. Patients presenting with an acute abscess (e.g., fluctuant swelling, pain, constitutional symptoms) should be managed in the same manner whether the abscess is periodontal or dental in origin, as noted in the section titled “Odontogenic Infections,” later.

Prevention of periodontitis is similar to caries prevention in terms of dental hygiene, diet, and professional dental care. For adults,

**Figure 1** Basic anatomy of the tooth and periodontium. (From Walls R, et al: *Rosen's Emergency Medicine: Concepts and Clinical Practice*, ed 9. Philadelphia, 2018, Elsevier.)

electric toothbrushes may reduce plaque and gingivitis compared with manual toothbrushing, especially for patients with manual dexterity limitations. Tobacco use also contributes to periodontal disease; thus avoidance or cessation should be encouraged.

### Necrotizing Ulcerative Gingivitis

An uncommon presentation of gingival disease is necrotizing ulcerative gingivitis (NUG), also referred to as Vincent angina or “trench mouth” for its prevalence among young soldiers during World War I. More common in young people, NUG presents with fever, malaise, and severe gingival pain without loss of bone or attachment. It is caused by mixed bacterial infection that includes anaerobes. Clinical exam will reveal exquisitely tender gingiva throughout the mouth, possibly more severe in the anterior teeth, with inflammation and the appearance of “punched out” gingival papillae between the teeth, with a fetid odor.

Patients require source control in the form of dental scaling, but topical antibiotic treatment with chlorhexidine gluconate (Peridex) as well as empiric treatment with penicillin or metronidazole (Flagyl)<sup>1</sup> can dramatically improve symptoms. Individuals presenting with NUG should be evaluated for a potential underlying source of immunocompromise, such as human immunodeficiency virus (HIV) infection. Other risk factors include nutritional deficiencies and stress.

### Odontogenic Infections

Progression of untreated dental disease, both periodontitis and dental caries, can result in focal infection. Infection may be due to a periodontal abscess or spread of infection from a necrotic tooth into the supporting bone. Patients will often have globally poor dentition on exam and report a history of prior dental pain that may have resolved spontaneously.

Patients most often present with severe localized pain that may be worse at night. Involved teeth may be localized by evaluating for focal fluctuance, tooth mobility, or pain produced by percussion of the tooth with a tongue depressor. Visible drainage of exudate through a fistula or the gingival cuff of a tooth may be associated with relief of pain due to reduced buildup of pressure.

Most dental infections do not result in systemic compromise; however, providers should be proactive in ruling out more serious complications. Ludwig angina is a form of airway compromise resulting from spread of infection, most commonly from the mandibular molars, into the submandibular and submaxillary fascial spaces that ring the trachea, causing urgent airway compromise.

Patients will appear acutely ill with trismus, submandibular swelling, and difficulty managing secretions. Patients require imminent transfer to a tertiary care facility for airway management and surgical source control. Cavernous sinus thrombosis, most commonly resulting from the ascending infection from maxillary anterior teeth, initially manifests with loss of the nasolabial fold, periorbital swelling, and ophthalmoplegia; it can lead to vision loss, elevated intracranial pressure, and stroke and requires urgent transfer. Descriptions of these two conditions are given in [Table 1](#).

For stable patients, evidence of systemic spread such as fever, tachycardia, or descending lymphadenopathy are indications for antibiotic treatment. Although not medically indicated, patients who do not have timely access to a dentist may benefit from antibiotic prescription as a palliative measure to reduce infection burden and pain until they can receive definitive treatment. Most infections are polymicrobial, with a predominance of aerobic, gram-positive organisms and a low prevalence of antibiotic resistance. A 1-week course of penicillin VK, amoxicillin, or clindamycin<sup>1</sup> for patients with penicillin allergy should be enough to provide several weeks of pain relief.

For acute pain relief, patients should be offered a local anesthetic injection if possible. Bupivacaine (Marcaine, Sensorcaine, generic) provides the longest-lasting relief, but lidocaine with 1:100,000 epinephrine can also be effective. Combined analgesia with a nonsteroidal antiinflammatory drug (NSAID) and a non-NSAID is effective in reducing dental pain, and adult patients without contraindications may take up to 800 mg tid of ibuprofen and 1000 mg tid of acetaminophen concurrently for relief. Providers may consider short courses (3 days) of opioid analgesia for unremitting pain.

Definitive treatment of all oral infections requires source control, whether from extraction of the involved tooth, root canal treatment, or periodontal therapy. Referral to a dentist as soon as feasible should be a primary goal, and it should be emphasized to patients that infection will recur even if their symptoms resolve transiently.

### Oral Ulcers

Ulcerated lesions within the oral cavity may be due to multiple possible etiologies, including infectious or autoimmune causes. The likely etiology can often be determined by a careful history and physical exam.

About 90% of the population is ultimately infected with oral herpes simplex virus (HSV), most commonly HSV-1, with rarer infection by HSV-2. Initial presentation of HSV infection (primary herpetic gingivostomatitis) is more likely to involve severe

<sup>1</sup>Not FDA-approved for this indication.

**TABLE 1** Complications of Dental Infection Requiring Emergent Transfer and Their Clinical Presentation

Ludwig angina	<ul style="list-style-type: none"><li>• History of toothache in a mandibular molar</li><li>• Fever and malaise, submandibular swelling, trismus, drooling, muffled voice, elevated floor of mouth, stridor</li></ul>
Cavernous sinus thrombosis	<ul style="list-style-type: none"><li>• History of toothache in a maxillary tooth</li><li>• Fever and malaise, loss of nasolabial fold, periorbital swelling, confusion, obtundation</li></ul>

ulceration of the oral mucosa as well as constitutional symptoms such as fever. Adults are more likely to present with nonspecific symptoms such as pharyngitis, whereas children are more likely to have the classic presentation. If ulceration is severe enough to prevent adequate fluid intake, those presenting with more severe symptoms should be evaluated for risk of dehydration. Symptoms generally resolve within 1 to 2 weeks without severe complications such as encephalitis.

Following initial infection, HSV remains dormant in the sensory nerve ganglia, with rate and severity of recurrence varying considerably among individuals. Recurrence may be activated by periods of stress, including local trauma or systemic illness. Recurrent HSV-related ulcerations favor fixed keratinized tissue such as the gingiva or lips (herpes labialis). Symptoms typically present with a prodromal burning or tingling sensation followed by the appearance of painful small vesicles that rupture. The ulcer may appear purple or gray on the periphery, and a yellow layer of keratin overlying the ulcer may be present. Patients who present with prodromal symptoms may have a shortened course if they are prescribed acyclovir (Zovirax), either as a capsule or a topical cream, very early in the presentation of symptoms. Patients with repeat recurrence may benefit from a “pill in pocket” approach to treatment. Recurrence is usually seen one to six times a year and generally becomes less severe and frequent with time. If recurrences are frequent, antivirals can be given orally for suppression with the patient reevaluated annually. Treatment of first episodes requires a longer duration of treatment with oral antivirals.

Aphthous stomatitis is an immune complex-mediated condition that can also result in recurrent oral ulceration. Patients may similarly report that ulcers are induced by stress or local trauma and share a similar prodrome of pain or pruritus at the site of ulcer formation. Ulcers are most commonly less than 10 mm in size, though they can be larger. Aphthous ulcers may be distinguished from HSV-related ulcers due to their predilection for less keratinized oral surfaces such as the buccal, sublingual, and palatal mucosa and for presenting with multifocal lesions. Ulcers resolve within 7 to 10 days without treatment. Aphthous ulcers can be quite painful, and patients may find relief from topical benzocaine 20% (Orabase or Orajel), although patients should be cautioned to forego excessive use in order to avoid the risk of methemoglobinemia. Exceedingly painful ulcers may resolve more quickly with topical corticosteroids. Triamcinolone 0.1% in orabase (Kenalog Orabase) can be applied topically after each meal and at bedtime; if ulcers are extensive, dexamethasone (Decadron)<sup>1</sup> 0.5 mg/5 mL elixir can be prescribed as a rinse for 2 minutes (and then expectorated) after each meal and at bedtime.

Symptomatic relief of oral ulcers from any cause may be obtained from a mouth rinse with a combination of diphenhydramine (Benadryl)<sup>1</sup> and a coating agent such as bismuth subsalicylate (Kaopectate)<sup>1</sup> or aluminum/magnesium antacid (Maalox)<sup>1</sup>. This formulation is sometimes colloquially referred to as “magic mouthwash.”<sup>6</sup>

Several other conditions may initially present with oral ulceration. Simple trauma such as biting the buccal mucosa can lead to a local ulceration. Oral lichen planus may present with oral

ulcerations or peeling of keratinized gingiva around the teeth as well as reticulated white “Whickham striae” on the mucosa. Generalized sloughing of the mucous membranes should prompt high concern for a systemic source and demands a more complete dermatologic exam. Onset within weeks of beginning a new medication could indicate the onset of Stevens-Johnson syndrome or toxic epidermal necrolysis, which may present first with mucosal involvement. Mucous membrane pemphigoid or pemphigus vulgaris may also present with mucosal sloughing. Such presentations should be referred for biopsy and further workup. Behçet disease also presents with genital and oral ulcerations; there are usually multiple ulcers and systemic symptoms, including eye inflammation, skin ulcers, and arthralgias. Coxsackie virus presenting as “hand, foot, and mouth disease” is usually more obvious, as many of the lesions are outside of the mouth on and around the lips and the classic round lesions on the hands, feet, and occasionally the buttocks. Coxsackie is also much more common in children and rare in adults.

Last, mucositis may be induced by chemotherapy or head and neck radiation. Such ulcerations are often widespread and exquisitely painful and may impair patients’ ability to take in adequate fluids and nutrition. These symptoms should be managed jointly with a patient’s oncology team, including prevention, which can involve the following treatments: aloe vera,<sup>7</sup> amifostine (Ethyol),<sup>1</sup> granulocyte colony stimulating factor (G-CSF),<sup>1</sup> honey, keratinocyte growth factor (palifermin, Kepivance), polymyxin/tobramycin/amphotericin (PTA)<sup>1</sup>, antibiotic pastille/paste<sup>6</sup>, and sucralfate (Carafate)<sup>1</sup>.

### Oral Soft Tissue Lesions

Lesions within the oral cavity can be extremely heterogenous in appearance, ranging from fungating to sessile, white to red and even pigmented, and ulcerated or smooth. White coloration often indicates increased keratinization, whereas increased red shading indicates increased vascularity. Oral SCC is the most common malignancy of the oral cavity, representing 90% of all intraoral cancers. Malignant lesions are more likely to manifest with raised/irregular borders, be fixed or indurated, be painless, and feature painless lymphadenopathy. The highest-risk sites for malignant transformation are the lateral aspect of the tongue, the floor of the mouth, and the junction of the hard and soft palate. Both alcohol and tobacco use are risk factors, and both behaviors together increase the risk of SCC up to 300-fold. Rising rates of HPV infection have increased the prevalence of HPV-associated SCC of the throat (including tonsils and base of tongue); however, there has not been a similar rise in rates of oral SCC. The HPV vaccine may help to reduce oropharyngeal cancer rates.

Detection of an intraoral lesion should prompt examination for possible traumatic causes (e.g., a recent burn or tongue bite) and removal of potential causative factors (e.g., smoking cessation). Bilateral lesions are more likely to be benign and this can be a reassuring finding. Any lesion that fails to resolve after 2 weeks of observation should be biopsied and/or referred for definitive diagnosis. Note that brush biopsy should be used cautiously due to a positive predictive value of only 58%; tissue biopsy should be used for all all negative biopsies. The differential diagnosis for common oral soft tissue lesions is listed in Table 2.

Treatment of oral squamous cell carcinoma (SCC) is multidisciplinary and often requires both surgical resection/excision as well as chemotherapy and radiation. Five-year survival rates remain around 60%. Unfortunately, no preventive measures have been widely successful, with even routine oral examination being given a designation of insufficient evidence to support implementation (“I”) and not recommended by the US Preventive Services Task Force. However, providers should consider periodic thorough examinations of high-risk patients.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

**TABLE 2** Differential Diagnosis of Common Oral Soft Tissue Lesions

Red or White Lesions	
Traumatic/frictional keratosis	Benign thickening of keratin layer due to repeated trauma
Leukoedema	Variant of normal; bilateral whitening of the buccal mucosa, which disappears when the mucosa is stretched
Oral candidiasis	Fluffy white patches that will reveal an erythematous base when scraped
Oral papilloma	Related to infection with low-risk HPV strain; may be fungating or pedunculated, most commonly on tongue
Oral lichen planus	Reticulations, Wickham striae, and desquamation of buccal mucosa and gingiva
Leukoplakia/erythroplakia/erythroleukoplakia	Irregular, usually unilateral change in coloration, risk of malignant transformation, biopsy needed
Squamous cell carcinoma	May appear as white, red, or ulcerative lesion; biopsy any lesion that persists after 2 weeks
Ulcerations	
Aphthous ulcers	Immune-mediated ulcers on nonkeratinized oral mucosa
Herpetic ulcers	Ulcers most prominent on gingiva and lips
Angular cheilitis	Ulcerations at corners of the lips; may be associated with nutrient deficiency, ill-fitting dentures, or fungal infection
Mucous membrane pemphigoid	Desquamation of gingiva; associated with desquamation of other body mucosal surfaces
Pemphigus vulgaris	Desquamation of mucosa to vermillion border; may present months or years before presentation on the skin

HPV, Human papillomavirus.

Lesions that may appear benign, such as leukoplakia or erythroplakia, should be monitored closely and biopsied if not resolving. Mild forms of these lesions will resolve on their own, whereas persisting lesions can be precancerous. They are often thickened, painless, on the buccal mucosa (inside cheek), on the tongue or floor of mouth, and either white or red in color. The smoking of tobacco is a risk factor for these lesions.

### Oral Candidiasis

Oral candida infections are heterogenous in presentation. Other than in extremely rare cases, all are caused by *Candida albicans*, which is also a common colonizer of asymptomatic individuals. Recent antibiotic use is a risk factor, as is uncontrolled diabetes and the use of inhaled corticosteroids. Of note, although immunocompromised patients are at higher risk, oral candidiasis is *not* considered indicative of immunocompromise.

Most commonly, patients will report the presence of white patches that may appear on the buccal mucosa and palate. Such patches can be scraped away with a tongue depressor or gauze, and irritated, bleeding tissue will be present beneath. Patients may report some mouth dryness, irritation, or discomfort when swallowing, but they will not be constitutionally ill.

In addition to the more classic presentation of oral thrush, candida may colonize macerated tissue in contact with dentures (atrophic candidiasis), or in the moist regions at the labial corners (angular cheilitis). Atrophic candidiasis may be asymptomatic, or patients

may report worsening discomfort with denture use. The candida infection will be evident as a bright red outline in the shape of the patient's dental prosthesis. White patches are usually not present. Angular cheilitis may cause pain with wide mouth opening and will reveal erythematous, sometimes weeping tissue at the corners of the mouth. Although angular cheilitis is associated with some B vitamin deficiencies, it can also be caused by ill-fitting dentures, causing the collapse of the facial tissues and producing a moist environment suitable for fungal superinfection. A nutritional history and evaluation for other signs or symptoms of nutrient deficiency can rule out the need for further evaluation; regardless, a topical antifungal treatment should be prescribed. New properly fitting dentures and vitamin supplementation are the other necessary treatments.

The choice of anticandidal treatment should be based on the extent of infection. More widespread infection such as thrush or atrophic candidiasis should be treated with clotrimazole (Mycexel) troches or nystatin (Mycostatin) pastilles or rinse. Nystatin rinse is more suitable for patients with xerostomia, who may find the troches difficult to dissolve, and for patients who wear dentures, who should be instructed to soak their dentures overnight in the nystatin solution in addition to receiving intraoral treatment. For patients with angular cheilitis, a nystatin ointment or clotrimazole cream applied to the affected area may be more comfortable. Systemic antifungals such ketoconazole (Nizoral) or fluconazole (Diflucan) should be considered only for immunocompromised patients or those who cannot tolerate topical treatment.

To prevent the development of candidiasis, patients with partial or complete dentures should be advised to brush their dentures twice daily and to remove them during sleep, when they can be soaked in an over-the-counter denture cleansing solution or a mouthwash such as Listerine. Dentures should not be brushed or cleaned with toothpaste, which can scratch the surface. Management of xerostomia can prevent the development of candidiasis in these patients (see later). Individuals using corticosteroid inhalers should be advised to rinse their mouths with water after use and expectorate. There is some evidence that probiotic prescription concurrently with oral antibiotics may reduce risk of candidiasis development, especially for denture wearers.

### Xerostomia

Xerostomia refers to the subjective feeling of a dry mouth due to reduced salivary flow. This may be due to autoimmune conditions such as SICCA (e.g., Sjögren syndrome) or a history of head and neck radiation but is more commonly due to the anticholinergic effects of numerous medications, with polypharmacy putting individuals at particularly high risk. Behavioral factors such as tobacco, marijuana, and methamphetamine use can also increase risk.

As saliva plays a critical role in remineralizing the dentition after acidic insults from dietary sugar intake, xerostomia is associated with higher caries risk; widespread caries at the base of the tooth nearest the gingiva is a common finding. Saliva also has antibacterial and antifungal properties, thus xerostomia places patients at higher risk for other oral infections.

Patients may report a feeling of "cotton mouth," which makes it difficult or even painful to eat, swallow, or talk. Physical exam will reveal dry, shiny oral tissues with thickened, ropy white saliva that may aggregate at the corners of the lips. Severity of reported symptoms may not correlate fully with physical findings.

Patients for whom the xerostomia is possibly a pharmacologic adverse reaction should undergo a thorough medication review, with reduction in dose or elimination of any unnecessary medications, especially those with known anticholinergic side effects. Following this and for individuals with a known cause of xerostomia (e.g., head and neck radiation), treatment is symptomatic. Many patients report improvement with frequent small sips of water throughout the day. Symptoms should first be managed with over-the-counter salivary replacement rinses or gels (such as Biotène). Sucking candy can increase salivary flow, although it is essential to select sugar-free candies. Patients should be advised to avoid sugar-rich foods, including sugar-sweetened beverages, if at all possible, given their heightened caries risk.

If this fails to cause improvement, prescription of a cholinergic agonist such as cevimeline (Evoxac), pilocarpine (Salagen), or bethanechol (Urecholine)<sup>1</sup> can be considered. Although these medications successfully increase salivary output, the inevitability of undesired cholinergic agonism causing excessive sweating, gastritis, and other symptoms often results in discontinuation of the medications. Patients considering systemic treatment with a cholinergic agonist should be warned of these adverse effects as well as the increased risk of acute angle-closure glaucoma.

### Osteonecrosis of the Jaw

Osteonecrosis of the jaw (ONJ) most commonly occurs in individuals with a history of head and neck radiation or with bisphosphonate exposure. Intravenous bisphosphonates put patients at much higher risk of ONJ (95% of cases) compared with those on an oral bisphosphonate regimen. Because it has a relatively lower vascular supply, the mandible is more prone to osteonecrosis.

Individuals should be warned of the risk of ONJ and advised to complete necessary dental work, especially dental extractions, prior to beginning radiation or bisphosphonate therapy when appropriate. Due to the prolonged half-life of bisphosphonates, drug holidays prior to dental treatment for patients already taking them are not recommended. Patients with a history of head and neck radiation in need of oral surgery, especially in the mandible, may benefit from adjunctive hyperbaric oxygen therapy, which may require close collaboration with the treating dentist or oral surgeon.

Lesions may appear spontaneously due to occlusal forces. Patients may report an area of roughness or mild discomfort, most commonly on the medial aspect of the mandible, near the tongue. Alternately, patients may present with nonhealing sockets after a tooth extraction or other dental procedure. Such areas of necrosis may expand over time. Diagnosis is empiric but may benefit from confirmation by an oral medicine practitioner or oral surgeon.

Management is largely symptomatic. Patients should be prescribed antibiotics if the area is purulent (see the earlier section titled “Odontogenic Infections”), and extensive areas of necrosis may need to be resected. Chlorhexidine gluconate (Peridex) rinses may assist with reducing the bacterial burden within the areas of necrosis, thus reducing rates of superinfection.

### Antibiotic Prophylaxis Before Dental Procedures

Changes to guidelines by the American Dental Association and the American Heart Association within the last 7 years have greatly restricted recommendations for the use of antibiotic prophylaxis prior to dental procedures. Currently, the only patients who require antibiotic prophylaxis for the prevention of infectious endocarditis are those with prosthetic valves or prosthetic materials used for valve repair, a history of cardiac transplant with ongoing valvular regurgitation, unrepaired cyanotic congenital heart disease or repaired heart disease with a residual defect or regurgitation adjacent to a prosthetic patch or device, and individuals with a prior history of infective endocarditis. Children within 6 months of repair of a congenital cardiac condition or with a residual defect should also be prescribed prophylactic antibiotics. Patients without these conditions who may have received antibiotic prophylaxis in the past should be reassured that the potential risks of antibiotic prescription (including *Clostridium difficile* infections) outweigh the extremely low risk of infective endocarditis caused by dental procedures.

It is currently not recommended that patients with a history of prosthetic joint replacement receive prophylactic antibiotics.

Only those dental procedures that involve manipulation of the gingiva (e.g., a dental cleaning or dental extraction) require antibiotic prophylaxis. Patients should be advised to discuss the necessity of prophylaxis with their dentist, who may also be the prescriber of any necessary antibiotics. One dose of antibiotic should be taken 30 to 60 minutes before the procedure. In the event they forget to take a dose before a dental appointment,

patients should also be informed that the prophylactic efficacy of antibiotics is equivalent up to 2 hours after a dental procedure.

Amoxicillin<sup>1</sup> is the antibiotic of choice for most patients. For those with an allergy to penicillins, cephalexin (Keflex)<sup>1</sup>, clindamycin<sup>1</sup>, azithromycin (Zithromax)<sup>1</sup>, or clarithromycin (Biaxin)<sup>1</sup> can be used, though care should be taken for potential cross-reactivity of cephalosporins in penicillin-allergic patients. Generally doses are as follows: amoxicillin 2 g; if penicillin allergic, clindamycin 600 mg, cephalexin 2 g, azithromycin or clarithromycin 500 mg.

<sup>1</sup>Not FDA approved for this indication.

## DISEASES OF THE NAIL

Method of

Jonathon Firnhaber, MD, MAEd, MBA

### CURRENT THERAPY

#### Ingrown nail

- Ingrown nails with mild acute inflammation may be treated with antiseptic soaks and a moderate-potency topical steroid. The distal anterior tip and lateral edges of the ingrown toenail can be elevated with cotton or wool to allow the nail to advance without further penetrating the nail fold.
- Ingrown nails with moderate or greater inflammation generally require surgical intervention. Partial nail plate removal is performed under local anesthesia.
- If the ingrown nail is recurrent, liquid phenol or a radiofrequency surgical electrode can be used to permanently ablate the lateral portions of the nail matrix and germinal tissue.

#### Onychomycosis

- Physicians should not prescribe oral antifungal therapy for suspected onychomycosis without confirmation of infection.
- Terbinafine (Lamisil) is the preferred agent for onychomycosis. It offers a higher cure rate and fewer drug interactions than alternative antifungal agents.
- Topical agents for onychomycosis offer limited efficacy as primary treatments. Efficacy may be improved by thorough debridement of the affected nail or nails prior to treatment and at multiple points during treatment.
- The risk of recurrent onychomycosis may be reduced by preventing and treating tinea pedis.

<sup>1</sup>Not FDA-approved for this indication.

## CURRENT DIAGNOSIS

### Onychomycosis

- The vast majority of onychomycosis is caused by dermatophytes, typically *Trichophyton rubrum* and *Trichophyton mentagrophytes*.
- Dermatophyte onychomycosis typically presents with invasion of the hyponychium or lateral nail folds, causing onycholysis, nail plate thickening, and subungual debris.
- Superficial white onychomycosis is also caused by dermatophytes and presents as a powdery white discoloration of the nail surface.
- Nordermatophyte organisms are responsible for 10% to 20% of cases of onychomycosis but may be clinically indistinguishable from disease caused by common dermatophytes.
- *Candida* onychomycosis is uncommon and may present as proximal nail changes in association with paronychia.
- Accurate diagnosis of onychomycosis depends on the collection of an adequate sample for evaluation. The affected nail plate and subungual debris should be sent for fungal culture.

### Nail Anatomy

The nail unit includes several clinically important components (Figure 1). The nail plate is made of keratin, which is hard and translucent. The skin of the lateral and proximal nail folds surrounds the nail plate, and the proximal nail fold overlies the matrix. The keratin layer of the proximal nail fold extends over the nail plate to form the cuticle. The tip of the proximal nail fold has capillary loops, which are typically inapparent but may become visible in connective tissue diseases such as systemic lupus erythematosus (SLE) and scleroderma.

The nail plate is primarily synthesized by the matrix epithelium. The distal aspect of the nail matrix is visible as the lunula and is continuous with the nail bed. The nail bed extends from the distal nail matrix to the hyponychium and consists of parallel longitudinal ridges. Splinter hemorrhages, which are visible through the nail plate, represent bleeding at the base of these ridges. The hyponychium begins at the distal edge of the nail bed and is a short segment of keratinized skin that is not covered by the nail plate.

Fingernails grow 0.5 to 2 mm per week and thus take approximately 6 months to grow from the proximal matrix to the distal free edge. Toenails grow much more slowly, taking 12 to 18 months for complete replacement of the nail. Although nails grow continuously, their growth rate slows with age and with decreased capillary perfusion.

### Noninfectious Nail Disorders

#### Psoriasis

##### *Clinical Features and Diagnosis*

Although multiple inflammatory skin diseases may affect the nail unit, nail changes are seen in up to 90% of patients with psoriasis over the course of their disease. Nail involvement typically occurs in conjunction with skin disease and is particularly common in patients with psoriatic arthritis involving the distal digits. Nail changes may, however, occur as an isolated finding and support a diagnosis of psoriasis when skin changes are equivocal or absent.

Nail psoriasis has multiple presentations, depending on the portion of the nail unit that is affected. Most commonly, nail matrix psoriasis presents as nail plate pitting. More extensive nail matrix involvement leads to leukonychia (white discoloration of the nail) and loss of integrity of the nail plate, with crumbling and fragmentation. Psoriasis of the hyponychium leads to an accumulation of scaly yellow debris that may elevate the nail plate. Psoriasis of the nail bed may trigger irregular separation of the nail plate and nail thickening, resulting in yellow discoloration of the nail plate. Both

Figure 1 Surface anatomy of the nail unit.

of these changes may be mistaken for onychomycosis, and onychomycosis may occur in psoriatic nails, emphasizing the importance of verifying the presence of a fungal infection prior to treatment.

#### Treatment

Topical treatments for psoriatic nail disease include high-potency topical steroids, vitamin D analogues, and topical retinoids; however, relatively poor penetration of the nail plate by these agents limits their potential benefit. Systemic therapy is rarely indicated for nail disease without skin or joint involvement.

#### Onychogryphosis

Onychogryphosis, or “ram’s horn nail,” affects the great toes and causes marked thickening, discoloration, and curvature of the nail plate. The condition may be triggered by repeated minor trauma from poorly fitting shoes and can eventually make it impossible for the patient to wear shoes. This deformity may be complicated by pain, distal onycholysis, subungual hemorrhage, or onychomycosis. Treatment primarily involves mechanical debridement of the thickened nail plate with a high-speed rotary burr. Surgical removal of the entire nail is associated with prolonged healing of the nail bed, which is generally not well tolerated. Onychogryphosis is more commonly seen in older patients and is also associated with self-neglect, homelessness, dementia, and peripheral vascular disease.

#### Pincer Nails

Inward deformation of the lateral edges of the nail plate results in a tube- or pincer-shaped nail. The nail bed is drawn into and pinched by the nail, often causing significant pain. Triggers for pincer nails include onychomycosis, psoriasis, and local tumors. Most commonly, however, biomechanical or arthritic changes cause the nail matrix to widen, and the nail ultimately becomes too wide for the nail bed. In extreme cases, removal of the medial, lateral, or both nail margins with ablation of the associated nail matrix, in a manner similar to treatment of an ingrown nail, is indicated to relieve the compression of the nail bed.

#### Spoon Nails

Spoon-shaped nails, with lateral elevation and a central depression of the nail plate, is termed koilonychia. Although spoon nails may be seen in healthy children and adults, the spontaneous onset of spoon nails is associated with iron deficiency anemia and may be seen in 50% of patients with idiopathic hemochromatosis. The spoon deformity resolves once the anemia has been corrected.

#### Beau Lines

Beau lines are transverse depressions in the nail plate that arise from the temporary interruption of nail growth within the nail

matrix. Acute systemic events may trigger Beau lines in all nails, whereas localized trauma or paronychia will limit the finding to the traumatized nail or nails. The grooves have been associated with multiple systemic conditions including zinc deficiency, pemphigus, Raynaud disease, and myocarditis as well as with illnesses accompanied by high fever, such as rheumatic fever, measles, mumps, hand-foot-and-mouth disease, and malaria. They may also be triggered by chemotherapeutic agents cytotoxic to the nail matrix.

The distance of a Beau line from the proximal nail fold can allow the clinician to estimate the time of the triggering event based on an average growth rate of 3 mm per month for fingernails and 1 mm per month for toenails.

### Habit-Tic Deformity

Habit-tic deformity is triggered by chronic biting or picking at a section of the proximal nail fold, usually of the thumb. The resulting nail plate deformity consists of a longitudinal band of horizontal grooves that often extend from the proximal nail fold to the tip of the nail. Habit-tic deformity may be confused with Beau lines associated with chronic paronychia or chronic eczema of the proximal nail fold. Habit-tic deformity produces closely spaced sharp grooves, whereas Beau lines tend to be more smooth and undulating. Formal treatment is not necessary, and the deformity resolves once the chronic irritation ceases and the nail grows out.

### Ingrown Nail

#### *Clinical Features and Diagnosis*

Ingrown nails (onychocryptosis) are common, painful conditions, most often affecting the great toe. The nail plate of the great toe extends several millimeters beyond the medial and lateral nail folds. In properly trimmed nails, its margin should be apparent at the distal portion of the nail. Excessive or improper trimming of the lateral nail plate will often leave behind a sharp spike of nail that is covered by the lateral nail fold. Lateral pressure from poorly fitted shoes or trauma may exacerbate the problem. The nail pierces the lateral or medial nail fold and enters the dermis, acting as a foreign body. Initial pain and swelling give way to a robust inflammatory response with edema, purulent drainage, and granulation tissue surrounding the penetrating nail.

#### *Treatment*

Ingrown nails with mild acute inflammation may be treated conservatively with antiseptic soaks and a moderate-potency topical steroid. If visible, the distal anterior tip and lateral edges of the ingrown toenail can be elevated from the adjacent soft tissue with cotton or wool, which both withdraws the foreign body and allows the nail to advance without further penetrating the nail fold. If collodion is available, it can help fix the cotton or wool in place, so that it will require less frequent replacement. Antibiotics are of limited value, as purulent drainage is associated with the foreign body reaction and is less indicative of an acute bacterial infection.

Ingrown nails with greater-than-mild inflammation generally require surgical intervention. The toe is anesthetized with 1% or 2% lidocaine without epinephrine, either with a digital block or local infiltration of the proximal and lateral nail fold. A narrow periosteal elevator is inserted under the ingrown nail parallel to the lateral nail fold and advanced with upward pressure against the nail plate to minimize risk of damage to the underlying nail bed. The surgeon must ensure that the periosteal elevator is fully advanced to the base of the nail plate, which is 3 to 5 mm proximal to the proximal nail fold. Once the elevator reaches the base of the nail, a sudden decrease in resistance will be noted and care should be taken to not advance it further into the toe. The elevated nail is clipped longitudinally, again taking care to include the most proximal portion of nail, and removed. Residual granulation tissue can be removed with iris scissors or a curette.

If the ingrown nail is recurrent, liquid phenol can be used to permanently ablate the lateral portions of the nail matrix and germinal tissue. Once the nail bed has dried, a phenol-soaked cotton

swab is applied for 3 minutes, followed by a thorough wash with 70% isopropyl alcohol, which neutralizes the phenol. Alternatively, a radiofrequency surgical electrode can be used to cauterize the nail matrix and germinal tissue. A flattened tip coated with Teflon on one side is used to protect the proximal nail fold. Regrowth of the nail occurs in up to 25% of patients following phenol cauterization, but the rate of regrowth is less than 5% with radiofrequency cauterization.

### Subungual Hematoma

Subungual hematoma is most often caused by direct trauma to the nail plate, which causes bleeding and separation of the nail plate from the nail bed. Hematomas that are fully contained under the nail plate can be exquisitely painful. Drainage, whether spontaneous or by clinician intervention, relieves the pain immediately. The quickest and most effective method of draining the hematoma is by puncturing the nail plate with a hot-tip electrocautery or with a red-hot paperclip tip, taking care not to advance the instrument into the nail bed. Anesthesia is not required for this procedure. Trephination of the nail with a fine-point scalpel blade or large-bore needle tip can be painful, as pressure is required to puncture the nail. Trauma to the proximal nail fold or underlying nail matrix can cause bleeding that is not apparent until the nail plate emerges from the nail fold with blood stains. Staining will be present until the nail fully grows out.

### Acute Paronychia

Trauma or manipulation of the proximal and lateral nail fold may trigger acute, painful swelling and erythema of the proximal and/or lateral nail folds, which is termed acute paronychia. Most superficial infections will present with a collection of purulent material about the cuticle or lateral nail fold. These superficial abscesses can quickly be drained with a 1- to 2-mm nick from the tip of an 18- or 21-gauge needle or #11 scalpel blade. Alternatively, the instrument may be inserted between the proximal nail fold and the nail plate, lifting the nail fold to achieve drainage. Neither anesthesia nor oral antibiotics are required. More diffuse erythema and swelling without any superficial abscess suggest a deeper infection. Antibiotics active against *Staphylococcus* and a deeper incision may be required. Acute and chronic paronychias are distinctly different processes.

### Chronic Paronychia

Chronic paronychia is triggered by chronic exposure to contact irritants and moisture. Clinically, it presents with tenderness, mild erythema, and mild swelling about the proximal and lateral nail folds of most or all fingers. Typically, many or all fingers are involved simultaneously. The primary pathophysiologic change is separation of the cuticle from the nail plate, which allows bacteria and fungal organisms to colonize the space between the nail plate and proximal nail fold. Manipulation of the cuticle further disrupts the barrier and accelerates the process. Culture of purulent material expressed from the proximal nail fold may show polymicrobial growth and will often include *Candida*. In this case, *Candida* is a colonizer rather than a true pathogenic cause of chronic paronychia, and it disappears once the integrity of the cuticle barrier has been restored. If the colonizing organisms include *Pseudomonas aeruginosa*, the nail plate may develop a green discoloration. The nail plate itself is not infected but may develop Beau lines as a result of the chronic inflammation.

Chronic paronychia is slow to resolve; its treatment hinges on eliminating exposure to contact irritants, limiting exposure to moisture, and treatment of the associated inflammation and infection. Low- to midpotency topical steroid creams may be used for 2 to 4 weeks. Because of the broad polymicrobial colonization typical of chronic paronychia, oral or topical antibiotics are unlikely to affect the time to resolution. Topical antifungal agents, such as ciclopirox (Loprox)<sup>1</sup> applied to the

<sup>1</sup>Not FDA approved for this indication.

proximal nailfold two or three times per day, or oral fluconazole (Diflucan)<sup>1</sup> 200 mg daily for 1 to 4 weeks, may help to mitigate the chronic inflammation.

### Myxoid Cysts

Digital mucous, or myxoid, cysts present as solitary dome-shaped nodules 2 to 6 mm in diameter located at the distal interphalangeal joint (DIP) or proximal nail fold. They are contiguous with the DIP joint capsule and contain synovial fluid, which is viscous, gelatinous, and clear to light yellow in color. Myxoid cysts most commonly occur in the 40- to 70-year age group and are twice as common in women as in men. When the lesion extends to the proximal nail fold, it can compress the matrix, causing a longitudinal groove on the nail plate. Myxoid cysts may be triggered by a reactive process or by herniation of the synovium; they are typically associated with a joint affected by osteoarthritis. Although most lesions are asymptomatic and do not require intervention, they may cause pain or decreased range of motion. In those cases, simple incision and drainage with the tip of a large-bore needle often provides relief. Recurrent lesions may require excision by a hand surgeon.

### Nail Infections

#### Fungal Nail Infections

##### Clinical Features and Diagnosis

Tinea of the nails, or tinea unguium, affects 2% to 14% of the general population; prevalence increases with age.

About 90% of toenail and virtually all fingernail onychomycosis is caused by dermatophytes, typically *Trichophyton rubrum* and *Trichophyton mentagrophytes*. *Epidermophyton* and *Microsporum* species are less frequent causes. The most common clinical presentation of dermatophyte onychomycosis is fungal invasion of the hyponychium or lateral nail folds, which causes onycholysis, nail plate thickening, and subungual debris. Fungus may also invade the nail plate from above; superficial white onychomycosis causes a powdery white patchy discoloration of the nail surface. Least commonly, fungus will invade through the proximal margin, giving the appearance of infection emerging from beneath the nail as it grows. This presentation—proximal subungual onychomycosis—is a marker for lack of resistance to dermatophyte infection and is more prevalent in individuals with immunodeficiency.

Dermatophytes invade normal keratin, whereas molds invade altered keratin. Onychomycosis, therefore, can be caused by other fungal species, including *Candida* and nondermatophyte molds such as *Acremonium*, *Alternaria*, *Aspergillus*, *Fusarium*, *Onycholiza*, *Scopulariopsis*, and *Scytalidium* species. Nondermatophyte organisms are responsible for 10% to 20% of cases of onychomycosis. The distinction is important because treatment may differ from that for dermatophyte infection. Candidal onychomycosis is uncommon and may present as proximal nail changes in association with paronychia or as onycholysis with typical nail plate thickening and subungual debris. Nondermatophyte infection

most commonly presents with distal-lateral subungual onychomycosis and may be difficult to distinguish from typical dermatophyte onychomycosis.

At least half of patients with onychomycosis will experience some degree of pain or discomfort. As a result, patients may choose less than ideal footwear or have difficulty with ambulation, increasing the risk of falls, particularly among the elderly. Additionally, dystrophic nails may disrupt the surrounding cutaneous barrier, creating a point of entry for skin bacteria or leading to toe or foot ulceration.

Accurate diagnosis of onychomycosis depends on the collection of an adequate sample for evaluation. The onycholytic portion of the affected nail plate should be trimmed as far proximally as possible. Subungual debris is then collected from the nail bed using a curette, taking care to sample from different parts (proximal and distal) of the infected nail. Fungi collect in the nail plate and in the cornified cells of the nail bed. Superficial nail samples are unlikely to produce a high fungal yield.

All national guidelines recommend that physicians not prescribe oral antifungal therapy for suspected onychomycosis without confirmation of infection. Direct microscopy of nail scrapings using potassium hydroxide (KOH) can quickly confirm the presence of fungal hyphae, but the procedure does not identify the exact infectious organism. Formal culture may take 4 weeks or longer to produce a result and offers a sensitivity of only about 50%.

#### Treatment

Oral antifungal agents—including terbinafine (Lamisil), itraconazole (Sporanox), and fluconazole (Diflucan)<sup>1</sup>—penetrate keratinizing tissue and produce higher drug levels in the nail plate than in plasma. Therapeutic levels may remain in the nails for at least a month after the discontinuation of therapy. Periodic debridement of the infected nail during the course of treatment may increase the cure rate. Treatment with systemic antifungals must be weighed against the risk of hepatic toxicity and the potential for interactions with multiple other medications.

Despite adequate treatment, recurrence of onychomycosis is seen in 40% to 70% of patients and is more likely in patients with extensive involvement of the proximal nail, immunosuppression, or peripheral vascular disease. Oral antifungal agents for onychomycosis are outlined in Table 1.

Three topical drugs for onychomycosis are available in the United States: ciclopirox (Penlac), efinaconazole (Jublia), and tavaborole (Kerydin). Fingernails are treated daily for 24 weeks; toenails are treated daily for 48 weeks. Once weekly, the lacquer should be removed with acetone and any residual diseased nail material filed or clipped away. Complete cure rates typically do not exceed 15% but may be enhanced by thorough debridement of a thickened, lytic nail prior to treatment.

Toenails take 12 to 18 months to be replaced; fingernails take 4 to 6 months for the same process. Therefore, immediately after completion of therapy, the nail will not appear to be completely

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Oral Antifungal Agents for Onychomycosis

DRUG	DOSING	INDICATIONS	POTENTIAL COMPLICATIONS
Terbinafine (Lamisil)	250 mg daily for 12 weeks (toenails); 6 weeks (fingernails)	First-line treatment for typical dermatophytes	Hepatic toxicity
Itraconazole (Sporanox)	200 mg bid for 7 days, then 21 days off for two courses (8 weeks total) (fingernails); 200 mg daily for 12 weeks (toenails)	Preferred for nondermatophyte molds Treatment option for <i>Candida</i>	Hepatic toxicity Multiple drug interactions Lower cure rate than terbinafine
Fluconazole (Diflucan) <sup>1</sup>	150–300 mg weekly for 6 months	Treatment of choice for <i>Candida</i>	Hepatic toxicity Multiple drug interactions Lower cure rate than terbinafine

<sup>1</sup>Not FDA approved for this indication.

normal. Rather, a proximal segment of newly formed, fungus-free, and normal-appearing nail will be present and will gradually extend distally as a new nail is produced.

The risk of recurrent onychomycosis may be reduced by preventing and treating tinea pedis. Prolonged use of a topical antifungal agent, such as terbinafine (Lamisil), may prevent nail reinfection after successful treatment with oral medication. Avoidance of trauma to the tips of the nails from tight-fitting shoes may also decrease the risk of recurrence. Foot powder and the use of moisture-wicking socks can limit the moisture surrounding the foot, preventing the warm, dark, moist environment that is conducive to fungal growth.

### **Pseudomonas Nail Infection**

*Pseudomonas* is the bacterium that is most likely to infect the nail unit, and such infections are characterized by blue-green discoloration beneath the nail and onycholysis. Typically, only one nail is involved. Risk factors include chronic nail trauma, nail disease such as psoriasis, and chronic paronychia. Topical treatment, such as fluoroquinolone or aminoglycoside solutions, or anti-septic soaks with dilute bleach or chlorhexidine (Hibiclens), are often curative. Response rates are enhanced by trimming away any diseased or lytic nail prior to treatment.

### **Periungual Verrucae**

Verruca vulgaris—common warts—are caused by human papillomavirus infection and can involve the periungual and subungual skin of the nail unit. Fingers are more commonly affected than toes. Periungual verrucae present the same as warts at other cutaneous sites, with a hyperkeratotic papule, associated thrombosed capillaries, and disruption of epidermal architecture. Verrucae do not typically involve the nail matrix, but lesions of the proximal nail fold can compress the matrix and lead to nail plate dystrophy.

Periungual verrucae are notoriously difficult to treat. Topical agents are appropriate initial therapeutic options for periungual verrucae, typically including the use of a keratolytic such as salicylic acid. Success rates with topical agents are enhanced with occlusion of the lesion, but several months of daily treatment may be required. Cryotherapy is an additional first-line option and is more efficacious if the lesion is debulked with scissors or scalpel prior to treatment. Longer freeze times may also improve efficacy. Aggressive cryotherapy at the proximal nail fold may damage the underlying nail matrix and lead to permanent nail dystrophy. Intralesional treatment with candida antigen<sup>1</sup>, mumps antigen<sup>1</sup>, or bleomycin<sup>1</sup> has demonstrated success in the treatment of refractory periungual verrucae. Surgical approaches such as excision and electrosurgery have a moderate potential for scarring and are associated with higher recurrence rates. Squamous cell carcinoma of the nail unit presents as a hyperkeratotic lesion that may be indistinguishable from a wart. Therefore lesions that are recalcitrant to conventional therapy warrant biopsy.

<sup>1</sup>Not FDA approved for this indication.

## **ERYTHEMA MULTIFORME**

Method of

**Chad Douglas, MD, PharmD**

### **CURRENT DIAGNOSIS**

- Acute cutaneous target-like papules, plaques, and bullae
- Oral mucosal lesions can be present
- Predominance in young adults
- Most often associated with acute or chronic herpes simplex virus (HSV-1) infection
- Less commonly associated with medications such as sulfonamide and penicillin antibiotics

### **CURRENT THERAPY**

- Treat any underlying infection, and discontinue any potential offending medications.
- Mild disease: Provide symptomatic care with oral antihistamines, topical corticosteroids.
- Severe and persistent disease: Treatment includes prednisone, cyclosporine (Neoral and Sandimmune),<sup>1</sup> azathioprine (Imuran).<sup>1</sup>
- Recurrent episodes: Provide prophylaxis with HSV antiviral agents.

### **Epidemiology**

Erythema multiforme (EM) is an acute, mucocutaneous, immune-mediated hypersensitivity disorder. This rare self-limiting disorder has an estimated incidence of 0.01% to 1% and predominately occurs in young adults between 20 and 40 years of age. Up to 20% of cases occur in children and adolescents. The median age of onset of recurrent EM in children is 9 years of age.

### **Risk Factors**

EM is most commonly associated with viral, fungal, and atypical bacterial infections. More than 60% of infection-associated cases of EM occur with herpes simplex virus (HSV), most commonly HSV-1. *Mycoplasma pneumoniae* is the second most common infectious organism associated with EM, and up to 5% of patients with this atypical pneumonia develop EM. Most cases of recurrent EM are associated with acute HSV infection or reactivation of chronic HSV infection. The second most common cause of EM are medications. Medications account for 10% to 20% of EM cases and is referred to as *drug-induced erythema multiforme* (DIEM). The most common medication classes and agents in DIEM are sulfonamides, penicillins, erythromycin, nitrofurantoin, tetracyclines, nonsteroidal anti-inflammatory drugs, and aromatic amine anticonvulsants such as carbamazepine, phenytoin, and phenobarbital. DIEM is considered a separate and distinct entity from hypersensitivity and cutaneous adverse drug reactions such as maculopapular erythema, Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN).

### **Pathophysiology**

The pathophysiology of EM has been extensively delineated in herpes-associated erythema multiforme (HAEM). HSV DNA fragments are transported to distant skin sites by peripheral blood mononuclear cells. HSV genes within these fragments express various enzymes including DNA polymerase that leads to recruitment of CD4+ TH1 cells. These CD4+ TH1 cells release interferon-gamma (INF-gamma), which initiates an inflammatory cascade with the sequestration of circulating monocytes, natural killer (NK) cells, and lymphocytes as well as recruitment of autoreactive T cells. This extensive immune response leads to keratinocyte destruction. In contrast, the pathophysiology of DIEM involves tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) production that leads to epidermal destruction. Human leukocyte antigen polymorphisms

have not been extensively characterized in DIEM as they have been in more classic immune-mediated cutaneous drug hypersensitivity reactions such as SJS and TEN.

### Prevention

There is no current prevention for EM; however, the knowledge of infectious agents and medications that can cause EM can help one identify patients who could be at risk for development of this condition. Future studies in the advancement of pharmacogenetics may potentially identify human leukocyte antigen polymorphisms that could predispose patients to HAEM or DIEM.

### Clinical Manifestations and Diagnosis

EM is a self-limiting eruption that most often appears in a symmetric distribution on the distal extremities with frequent involvement of dorsal surfaces of the hands and extensor surfaces of the extremities. Prodromal syndrome such as fever, chills, malaise, and arthralgia can occur but are rare. Lesions often burn or itch and progress from distal areas of the body toward proximal regions. Initial lesions are usually sharply demarcated red or pink macules that can resemble hives or early stages of SJS. Unlike hives, these lesions become fixed and do not migrate. Mucosal involvement and skin sloughing is less common than with SJS. The macules become papular and may gradually enlarge into plaques that are several centimeters in diameter. Lesions often contain three concentric zones including a central darker red region, a pale pink edematous zone, and a peripheral red ring. These characteristic “target” or “iris” lesions may only contain a central dark red region with a lighter peripheral ring and may not appear until several days after onset of the eruptions. Lesions of multiple morphology are usually present, thus the name *multiforme*. Mucosal lesions, when present, are red and edematous and often involve blister formation. These lesions are usually limited to the oral cavity and affect the lips, inside of the cheeks, and the tongue. Typically, lips are swollen with hemorrhagic crusting. EM associated with *Mycoplasma pneumoniae* may present with mucosal lesions alone without cutaneous manifestations. Diagnosis is most often made clinically in patients with characteristic lesions and a preceding or concurrent infection that is known to be commonly associated with EM. A clinical diagnosis can also be made in patients with characteristic lesions who are taking a commonly associated medication. Rarely, a skin biopsy is needed to rule out other conditions, although there is no single diagnostic histologic feature or immunofluorescence finding specific to EM. EM usually resolves spontaneously within 3 to 5 weeks.

### Differential Diagnosis

Early EM lesions can resemble urticaria, drug eruptions, viral exanthem, maculopapular erythema, and the early stages of SJS and toxic epidermal necrosis. Bullous lesions may resemble bullous pemphigoid, and target lesions may resemble pityriasis rosea or vasculitis.

### Treatment

Although EM is self-limiting, early identification and treatment of the causative infectious agent or immediate discontinuation of an offending medication can reduce the severity and duration of the condition. Symptomatic treatment with oral first-generation antihistamines (diphenhydramine [Benadryl] 25 to 50 mg po q 6 hours prn or hydroxyzine [Atarax] 25 to 100 mg po q 6 hours prn) and mid-potency topical corticosteroids (triamcinolone [Kenalog] 0.1% cream) will usually suffice for mild disease. More severe disease including cases with mucosal involvement as well as recurrent EM can be treated with prednisone, cyclosporine (Neoral, Sandimmune),<sup>1</sup> or azathioprine (Imuran).<sup>1</sup> The use of dapsone<sup>1</sup> and antimalarial agents in severe disease has demonstrated varying success. Recurrent EM is most often associated with HSV-1, and herpes viral suppressive therapy with acyclovir (Zovirax)<sup>1</sup> or valacyclovir (Valtrex)<sup>1</sup> has been shown to be effective. Valacyclovir (Valtrex) is given once daily until the patient is recurrence free for 4 months. The valacyclovir dose is then reduced with eventual

<sup>1</sup>Not FDA approved for this indication.

discontinuation. Although reintroduction of an offending medication does not frequently cause recurrence of EM, caution should still be advised when considering the future use of such medication or other medications within the same drug class.

### Monitoring and Complications

Mucosal involvement may limit a patient’s ability to eat or drink, and close monitoring is advised in such cases. This can be of particular concern in pediatric patients. Skin lesions are usually not associated with scarring, but postinflammatory hyperpigmentation can occur and often takes several months to resolve.

## FUNGAL INFECTIONS OF THE SKIN

Method of

Therese Holguin, MD

### CURRENT DIAGNOSIS

- Dermatophyte infections
  - Non-hair-bearing (glabrous) skin diagnostic techniques include scraping the leading edge of scale with a glass slide onto glass slide, placing a cover slip, and applying 10% potassium hydroxide (KOH) to the edge of the coverslip. Then the bottom of the slide is slightly heated, cleaned with a tissue, and viewed under a microscope without condenser. Counterstaining with chlorazol black E or Parker blue-black ink may help visualize hyphae.
  - Hair-bearing skin may require a tissue biopsy with special fungal stains to confirm diagnosis.
  - Culture of scale, hair, and nail fragments sent to the laboratory in a sterile urine cup and clearly marked “for dermatophyte culture” is an additional testing method. Nail fragments can be sent in formalin for periodic acid-Schiff (PAS) staining (a quick-turnaround test).
- Tinea versicolor
  - Diagnostic techniques include stratum corneum removal with a glass slide against a glass slide and KOH examination as noted earlier for dermatophyte infections. Cultures require a special media, and the laboratory must be notified that this is the organism suspected.
- Candida cutaneous infections
  - Unroofing a pustule by scraping gently with a No. 15 blade and spreading contents onto a glass slide for KOH evaluation will review the characteristic yeast and pseudohyphae. Culture is usually not necessary.

## CURRENT THERAPY

- Dermatophyte infections
  - Mild non-hair-bearing skin infections are treated with topical agents if severe and widespread; systemic and topical agents together will provide a higher cure rate. Measures to prevent reinfection of feet include wearing sandals when possible, especially in public places, alternating shoes, and keeping feet dry. Measures to prevent reinfection of groin infections include drying well after showering and putting socks on before underwear.
  - Hair-bearing skin and hair infections require systemic therapy for cure. Nail infections may be cured with newer topical agents.
- Tinea versicolor
  - Topical treatment with topical agents such as selenium sulfide lotion applied for 10 minutes for 2 weeks, neck to knees, is a cheap and effective treatment. Systemic agents may be needed for resistant cases. Prevention may require maintenance therapy with topical agents during warm and humid months.
- Candida cutaneous infections
  - Topical agents such as nystatin or ketoconazole cream are an effective choice. Prevention of intertrigo is somewhat successful if routine care is taken to dry body fold areas thoroughly after showering. Zinc-talc shake lotion may be used once or twice daily.

Dermatophyte (tinea) infections are a group of filamentous fungal infections of the skin, hair, and nails and can be non-inflammatory or inflammatory. The route of acquisition for dermatophytes is either person-to-person (anthropophilic) or from animals (zoophilic). Geophilic dermatophytes grow in soil and are a rare source of infection in humans. The causative organisms are of three genera: *Microsporum*, *Trichophyton*, and *Epidermophyton*.

Dermatophytoses are the most common fungal infections worldwide, affecting 20% to 25% of the world population. The predominant agents have changed over time by geography and population based on migration of populations, hygiene practices, and therapeutic breakthroughs (griseofulvin [Gris-PEG]). Clinical classification is based on the site of infection. Tinea pedis refers to infection of the feet, tinea manuum to the hands, tinea cruris to the groin, and tinea corporis to the skin excluding the aforementioned sites plus the scalp and nails. Tinea unguium (onychomycosis) refers to nail infection, tinea barbae to the beard area, tinea faciei to the face, and tinea capitis to the scalp and hair. Virulence of the infection is dependent on underlying factors suppressing immunity (diabetes, cancer, HIV infection). Dissemination can be seen in the immunosuppressed.

Superficial infections of the skin and mucous membranes caused by yeasts are caused by *Candida* species. Also common are infections caused the lipophilic yeast fungus *Malassezia*.

### Superficial Mycoses Dermatophytes

#### Tinea Capitis

The populations most at risk are children, with boys more commonly affected than girls. The onset of puberty and change in the relative composition of unsaturated fatty acids in sebum is protective. African Americans and Hispanics have an increased incidence of *Trichophyton tonsurans*. Pet exposure is associated with infections of *Microsporum canis*. Infection with *Trichophyton schoenleinii* (*favus*), still seen in less-developed countries, is of characteristic cup-shaped crusts, or scutula.

The usual presentation of tinea capitis is of scale and itch on the scalp with broken-off hairs with a “black dot” appearance (Figure 1) or an inflamed boggy plaque, referred to as a *kerion*. Inflammatory presentations are most often seen in zoophilic infections. Patches of alopecia are common.

Figure 1 Black dot tinea.

Tools for diagnosis include potassium hydroxide (KOH) preparation of scale or microscopic examination of hair tweezed from the affected patch. A Wood’s lamp will show fluorescence with ectothrix infections (organism on outside of the shaft) but not endothrix infections (spores on inside of the shaft). Samples for culture are obtained by rubbing a wet cotton-tipped applicator over the affected area and applying this or pulled hairs onto the dermatophyte test medium or other medium if species identification is required in resistant cases. The differential diagnosis includes seborrheic dermatitis, psoriasis, folliculitis, pediculosis, secondary syphilis, discoid lupus erythematosus, lichen planus, lichen simplex chronicus, trichotillomania, alopecia areata, and other inflammatory follicular conditions.

#### Tinea Faciei and Barbae

Frequently misdiagnosed, infection of the face or beard is rare. Beard infections (tinea sycosis or barber’s itch) can be deep and inflammatory and are seen in agricultural workers, especially those working with farm animals. Discoid lupus is a commonly mistaken diagnosis, and biopsies are sometimes required to differentiate.

#### Tinea Corporis

*Ringworm* is the layperson’s descriptive term of the characteristic clinical findings of dermatophyte infections. The term accurately portrays the appearance of an erythematous annular plaque with a scaly, raised, leading edge (Figure 2). Severe infections may herald new HIV infection or be secondary to topical immunosuppressants such as calcineurin inhibitors or, more commonly, steroids. KOH examination sampling should be taken from the leading edge. The differential diagnosis includes pityriasis rosea, impetigo, inflammatory dermatoses such as psoriasis and seborrheic dermatitis, and syphilis.

#### Tinea Cruris

More common in men and when humidity is high, “jock itch” or “crotch itch” involves the upper thigh, intertriginous area, and peripheral spread into the perineum and perianal areas. The scrotum is rarely involved. The usually well-defined border may display scale, papules, or pustules.

The differential diagnosis includes a bacterial infection, erythrasma, candidiasis, intertrigo, psoriasis, and dermatitis. Morphology of the rash and expected involvement of other cutaneous sites is useful to eliminate these possible diagnoses. The origin of the infection is believed to be autoinoculation from tinea pedis or onychomycosis.

#### Tinea Manuum and Pedis

A classic finding of “one hand and two feet” involvement is useful to lead one to consider tinea manuum (Figure 3). The organism involved in the infection determines the amount of resultant inflammation. Whereas *Trichophyton rubrum* produces a dry

Figure 2 Tinea corporis.

Figure 3 Tinea manuum.

scale with erythema of the hands and feet (moccasin-type), *Trichophyton interdigitale* (previously known as *Trichophyton mentagrophytes*) often leads to a painful, itchy, blistering eruption of the feet. Other signs of *T. interdigitale* include interdigital maceration and superficial infection of the toenails with a distinct white appearance (white superficial onychomycosis). Toe-web infection with gram-negative bacteria may be consequential. Hyperhidrosis is often a precursor to this type of infection. An idiopathic reaction “dermatophytid” is a fairly common pruritic rash of small blisters involving the palms and sometimes the sides of the feet.

### Onychomycosis

Fungal infections of the nail are caused by dermatophytes (tinea unguium), yeasts, and nondermatophytic molds. It is common in the general population, accounting for 50% of skin fungal infections. Risk factors include advanced age, diabetes, circulatory disorders, and family history. There are three major subtypes of onychomycosis: *distal lateral subungual onychomycosis*, *white superficial onychomycosis*, and *proximal subungual onychomycosis*. Distal lateral subungual onychomycosis is the most common subtype and is caused by the anthropophilic dermatophytic fungus, *T. rubrum*. Symptoms include an initial discoloration of

the distal corner of the nail that may be white, gray, or brown caused by accumulation of keratinous debris under the nail that eventually spreads to involve the entire nail. Other common features are onycholysis, or splitting of the nail from the bed, nail thickening, and impaired nail growth. The diagnosis typically involves KOH, mycologic laboratory confirmation (culture), and biopsy. Yeast onychomycosis is most commonly caused by *Candida albicans* and typically involves fingernails of hands frequently exposed to moisture. Nondermatophytic molds primarily involve toenails. Though not life-threatening, onychomycosis can significantly impair an individual’s quality of life with concerns such as issues cutting the nails and cosmetic disfigurement.

### Pityriasis Versicolor

This superficial fungal infection of the skin is caused by the *Malassezia* species, a dimorphic lipophilic fungus that is part of the physiologic skin flora. Certain environmental, genetic, and immunologic factors can predispose the fungus to convert to its pathogenic hyphal form and development of disease. It grows best in warm, humid climates; thus there has been a higher prevalence reported in tropical climates. Furthermore, potential hormonal changes during adolescence can increase sebum production and allow for *Malassezia* to thrive, and the prevalence is even further increased in active adolescents. The pathophysiology may also be related to an impaired immune system.

The diagnosis is usually made clinically, but the presentation may vary; it classically consists of a well-demarcated rash with fine scale and thin plaques. The rash may be hyperpigmented, hypopigmented, or erythematous. Typically, the rash appears on the torso but may become widespread. The lesions may be mildly pruritic or asymptomatic. If KOH is performed on skin scrapings, numerous spores and hyphae can be visualized (“spaghetti-and-meatball” appearance). Treatment options include topical antifungals, including azoles and terbinafine,<sup>1</sup> selenium sulfide (antidandruff), and zinc pyrithione (Vanicream Z-Bar, DHS Body Wash). Topical retinoids may have a role in recalcitrant cases (Cosio et al., 2021). Oral azole antifungals also can be used, however systemic treatment is not first-line therapy because of side effects.

### Candidiasis

A dimorphic commensal fungus inhabiting the skin, mouth, and reproductive tract, candidiasis is found in up to 70% of healthy individuals. *Candida* infection of the skin usually involves moist or occluded areas such as the groin, axillae, and diaper area in the young. Candidal intertrigo classically presents as erythematous and macerated plaques with peripheral scaling. Satellite lesions help differentiate candidal lesions from other conditions. Skin lesions are typically nontender but may develop central pallor or become hemorrhagic in patients with thrombocytopenia. Primary treatment consists of topical azole and polyene (nystatin) antifungals that are well tolerated. Adjunct therapy with low-dose topical corticosteroids may be used for associated pruritus and pain. Systemic antifungal therapy is rarely used but may be used for refractory disease.

### Treatment

#### Tinea Capitis

First-line treatment for tinea capitis is systemic griseofulvin, but terbinafine may also be considered. Terbinafine may be more effective than griseofulvin in treating *T. tonsurans*, whereas griseofulvin may be more effective against *Microsporum*. Fluconazole and itraconazole are additional options that have demonstrated less evidence-based efficacy.

#### Pediatric Dosages (≥2 years)

##### Griseofulvin

- Microsize ([Grifulvin V, generic] 500-mg tablets): 20 to 25 mg/kg/day × 6 to 12 weeks (daily max 1000 mg/day)

<sup>1</sup>Not FDA approved for this indication.

- Ultramicrosized ([Gris-PEG, generic] 125 mg, 250-mg tablets): 10 to 15 mg/kg/day × 6 to 12 weeks (daily max 750 mg/day)
- Griseofulvin microsize suspension ([Grifulvin V, generic] 125 mg/5 mL): 15 to 25 mg/kg/day × 2 to 12 weeks

#### Terbinafine ([Lamisil, generic] 250-mg tablets)<sup>1</sup>

- 10 to 20 kg: 62.5 mg/day × 4 to 6 weeks
- 20 to 40 kg: 125 mg/day × 4 to 6 weeks
- >40 kg: 250 mg/day × 4 to 6 weeks

#### Terbinafine (Lamisil granules)<sup>2</sup>

- <25 kg: 125 mg/day × 4 to 6 weeks
- 25 to 35 kg: 165.5 mg/day × 4 to 6 weeks
- >35 kg: 250 mg/day × 4 to 6 weeks

#### Fluconazole oral suspension ([Diflucan, generic]<sup>1</sup> 10 mg/mL, 40 mg/mL)

- Continuous: 6 mg/kg/day × 20 days (daily max 400 mg)
- Pulse: 6 mg/kg/day, once per week × 6 to 12 weeks

#### Itraconazole (Sporanox)<sup>1</sup>

- Continuous:
- Oral suspension (10 mg/mL): 5 mg/kg/day × 4 weeks
- Pulses (three pulses)
- Oral suspension: 3 mg/kg/day, 1 week/month × 2 to 3 months
- Capsules (100 mg): 5 mg/kg/day, 1 week/month × 2 to 3 months

#### Adult Dosages

##### Terbinafine (Lamisil)<sup>1</sup>

- 250 mg/day × 4 to 6 weeks

##### Fluconazole (Diflucan)<sup>1</sup>

- 50 mg/day × 4 to 7 weeks

OR

- 150 mg/week × 4 weeks

##### Itraconazole (Sporanox)<sup>1</sup>

- 100 to 200 mg/day × 4 weeks

Topical therapies can also be helpful when used twice-weekly in conjunction with systemic treatment. These include antifungal shampoos like selenium sulfide (antidandruff), ciclopirox (Loprox), and zinc pyrithione (Head & Shoulders).

#### Tinea Corporis, Tinea Cruris, Tinea Pedis, Tinea Mannum, Tinea Faciei, and Tinea Barbae

Topical treatments should be used for 2 to 6 weeks once or twice daily. Options include terbinafine (Lamisil), butenafine (Lotrimin-Ultra), naftifine (Naftin), clotrimazole (Lotrimin), econazole (Ecoza), ketoconazole (Nizoral), sertaconazole (Ertaczo), luliconazole (Luzu), and eberconazole (Ebernet).<sup>2</sup> (The use of aforementioned topical products in tinea manuum is off-label). Begin therapy with topical treatment and reserve systemic treatment for widespread, resistant, or severe disease. If necessary:

#### Pediatric Dosages (all are off-label and not FDA approved)

##### Terbinafine (tablets)<sup>1</sup>

- <20 kg: 62.5 mg/day × 2 weeks
- 20 to 40 kg: 125 mg/day × 2 weeks
- >40 kg: 250 mg/day × 2 weeks

##### Itraconazole<sup>1</sup>

- 5 mg/kg/day divided qd-BID × 2 weeks (max 200 mg/day)

##### Griseofulvin (dosages listed are for age >2 to adolescent)

- Microsize: 10 to 20 mg/kg/day × 2 to 8 weeks
- Ultramicrosized: 5 to 15 mg/kg/day divided qd-BID
- Max: 750 mg/day

#### Adult Dosages (all are off-label and not FDA approved)

##### Terbinafine<sup>1</sup>

- 250 mg/day × 2 to 4 weeks

##### Itraconazole<sup>1</sup>

- 200 mg/day × 1 week

##### Fluconazole<sup>1</sup>

- 150 to 300 mg/week × 2 to 4 weeks (pulse dosing)

##### Griseofulvin

- Microsize: 500 to 1000 mg/day × 2 to 4 weeks
- Ultramicrosized: 375 to 500 mg/day × 2 to 4 weeks

##### Terbinafine

- 250 mg plus itraconazole 200 mg × 3 weeks (resistant cases)<sup>1</sup>

#### Tinea Unguium

Children may respond completely to antifungal topical lacquer or solutions without systemic therapy. Lacquers, such as amorolfine (Curanail, Loceryl, Locetar, Odenil)<sup>2</sup> are debrided and reapplied daily. Hydrolacquers, such as ciclopirox (Penlac) may also be used and are removable with washing and reapplied daily. Topical solutions, like efinaconazole (Jublia) and tavaborole (Kerydin), are used for 48 to 60 weeks. Topical retinoids may have a role in recalcitrant cases (Cosio et al., 2021).

If systemic therapy is required—and in all adult cases—first-line treatment is terbinafine. Systemic treatment in conjunction with lacquers has been associated with higher cure rates. Additionally, conventional oral therapy followed by topical therapy for maintenance may help prevent recurrence.

If there is no response to treatment or the patient cannot tolerate the medication, itraconazole may be used. Fluconazole<sup>1</sup> has not been shown to be as effective and requires a long duration of treatment (up to 6 months); therefore it is not a preferred treatment. Griseofulvin is not recommended. Lasers and photodynamic therapy if available are considered third-line options. Surgical options include chemical (40% to 50% urea compound) or surgical nail avulsion.

#### Pediatric Dosages

##### Terbinafine (≥2 years)

- <20 kg: 62.5 mg/day
- 20 to 40 kg: 125 mg/day
- >40 kg: 250 mg/day × 6 weeks for fingernails, × 12 weeks for toenails

##### Itraconazole

Daily for 1 week/month (2 months for fingernails, 3 months for toenails)

- <20 kg: 5 mg/kg/day
- 20 to 40 kg: 100 mg/day
- 40 to 50 kg: 200 mg/day
- >50 kg: 200 mg 2x/day

#### Adult Dosages

##### Terbinafine

- Continuous: 250 mg/day × 6 weeks for fingernails, × 12 weeks for toenails
- Pulse (for toenails): 250 mg BID × 4 weeks, no treatment × 4 weeks, 250 mg BID × 4 weeks (12 weeks total)

##### Itraconazole

- Continuous: 200 mg/day × 6 weeks for fingernails, × 12 weeks for toenails
- Pulse: 200 mg BID 1 week/month × 2 months for fingernails, × 3 months for toenails

#### Additional Comments

Before beginning systemic antifungal therapy, a baseline complete blood count and liver function tests must be obtained. Laboratory tests are repeated if therapy lasts longer than 6 weeks.

Griseofulvin is contraindicated in pregnancy, and there are restrictions for becoming pregnant or fathering after a medication course is complete. Patients should avoid alcohol during treatment. Griseofulvin is more effectively absorbed with fatty foods like peanut butter, yogurt, and ice cream. (Therapeutic failures have been noted as a result of lack of absorption.) Itraconazole has negative inotropic effects and can lead to QT prolongation. Ketoconazole<sup>1</sup> has risks of fatal liver damage and adrenal insufficiency and is generally not recommended.

<sup>1</sup>Not FDA approved for this indication.

## KELOIDS

Method of

Leslie A. Greenberg, MD

### CURRENT DIAGNOSIS

- Clinical characteristics: firm, raised, papular, plaque-like, nodular, and tumorous scar tissue that extends beyond the initial wound borders. May be painful or pruritic and disfiguring.
- Location: more commonly found on the ears, upper back and chest, and upper arms.
- Cause: results from an abnormal healing process after skin trauma or inflammation.
- Histologic characteristics: abnormally functioning dermal fibroblasts and overproduction of extracellular matrix result in markedly thickened bundles of hyalinized collagen arranged in a haphazard fashion.

### CURRENT THERAPY

#### Medical Therapies

- Intralesional corticosteroids (triamcinolone acetonide [Kenalog])
- Interferon alfa (IFN-alfa2b [Intron A])<sup>1</sup>
- Intralesional fluorouracil (5-FU, Aducil)<sup>1</sup>

#### Surgical Therapies

- Cryotherapy
- Primary excision

#### Physical Modalities

- Pressure therapy
- Radiation therapy
- Laser therapy

#### Miscellaneous Therapies

- Silicone gel sheeting or gel

<sup>1</sup>Not FDA approved for this indication.

Keloids are common, benign fibroproliferative lesions resulting from altered wound healing caused by abnormalities of fibroblast function and extracellular matrix overproduction. Lesions may be painful and severely disfiguring—at times, limiting range of motion. Histologically, keloids are foci of brightly eosinophilic staining collagen bundles laid haphazardly.

Keloids may be papular, plaque-like, nodular, or tumorous. The term *keloid* is derived from the Greek word meaning “tumorlike.” A keloid extends beyond the site of injury. Keloids tend to shrink over time but rarely resolve.

## Epidemiology

Keloids occur more commonly in people of African and Asian descent. There may be a familial or genetic contribution to keloid as an autosomal dominant inheritance with incomplete penetrance. Keloids may be intentionally induced for cosmetic purposes. For example, the ancient Olmec of Mexico in pre-Columbian times are one ethnic group that has used keloid scarification as an intentional means of decoration.

## Pathophysiology

Unlike scars, keloids are made up of markedly thickened bundles of collagen that are arranged in a haphazard fashion. Normal scar tissue formation, in contrast, consists of fibrillary bundles of collagen that are aligned parallel to the skin surface.

The pathogenesis of keloid formation is unknown. Fibroblast proliferation and increased collagen synthesis are caused by overexpression of growth factors. Growth factor production fails to self-regulate and does not turn off once the wound is well healed. Alteration of programmed fibroblast apoptosis has been implicated. It has been suggested that keloid fibroblasts fail to undergo physiologically programmed cell death and thereby produce extra connective tissue. Genetic factors are likely involved, and studies have identified four susceptibility loci.

Keloids represent the end stage of an inflammatory process that starts after a traumatic disruption of skin integrity. Over a period of weeks, abnormally functioning fibroblasts replace the granulation tissue associated with the early stages of healing. At that point, a distinctive morphologic scar or keloid may be noticeable. After a keloid is fully formed, it may look the same for years, or it may enlarge over time.

## Risk Factors

Certain populations are at higher risk for developing keloids. Dark-skinned individuals, such as those of Asian, African, and Hispanic descent, have a 15-fold increased risk for developing keloids compared with light-skinned individuals. Skin insults such as lacerations, secondarily infected skin lesions, surgery, or ear piercings challenge the body's healing process and may result in keloids, although keloids may also form without an inciting trauma. Keloids are more commonly found on the ears, upper back and chest, and upper arms. Ongoing tension or movement across the wound healing site may predispose to keloid formation. Genetics is a factor, and reports of familial cases with varied modes of inheritance indicate multiple genetic disorders that may influence keloid formation. Patients with specific rare inherited conditions like Goeminne syndrome and Rubinstein-Taybi syndrome are at increased risk for developing keloid formation. Age affects the propensity to form a keloid, with the highest incidence in individuals 10 to 20 years of age. Keloids are rarely found in newborns or older adults.

## Prevention

The best treatment is prevention of unnecessary trauma or surgery, including ear piercing and elective cosmetic surgery. Early treatment of acne helps decrease inflamed pustules and papule formation, which, when located at the posterior neck, may become acne keloidalis nuchae. Patients with acne keloidalis nuchae should avoid shaving the neck region and instead should use scissors to trim hair no shorter than one-eighth of an inch. Consider varicella vaccination (Varivax)<sup>1</sup> to decrease the keloid

<sup>1</sup>Not FDA approved for this indication.

risk of chickenpox lesions. Lack of ultraviolet (UV) B light may increase the risk of keloid formation. In fact, using UV A1 phototherapy may be a promising treatment of keloids. Other environmental preventive measures are to keep the wound moist and to avoid sun exposure and tension on the wound.

### Clinical Manifestations

Keloids are firm, rubbery, raised, papular, plaque-like, nodular, and tumorous scar tissue that extends beyond the initial wound borders. Lesions may develop as early as 1 month after injury or may begin to form 1 year after an inflammatory incident. Frequently, lesions are pruritic, are tender to palpation, and may be the source of sharp, shooting pains. Location is more often on the ears, jaw, neck, shoulders, upper back, and presternal chest. Keloids may be disfiguring and in rare instances may impair function (e.g., location over a joint). Keloids do not spontaneously regress.

### Diagnosis

The clinical diagnosis of a keloid is usually apparent. Rarely is histologic confirmation necessary. Lesions may continue to grow for weeks to months. Keloids on the ears, neck, and abdomen tend to be pedunculated, whereas those on the central chest and extremities are usually raised with a flat surface. Most keloids are round, oval, or oblong, with regular margins; however, some have a clawlike configuration with irregular borders.

### Differential Diagnosis

Hypertrophic scars appear different from keloids because the wound healing is linear, stays within the boundaries of the original wound site, and may be transiently indurated or tender to palpation. Hypertrophic scars are as prevalent in light- and dark-skinned individuals and as a rule tend to flatten significantly over time without treatment.

Giant cell fibroblastoma is a low-grade sarcoma considered a juvenile form of dermatofibrosarcoma protuberans. It is uncommon and locally aggressive. Histology shows multinucleated cells with hyperchromatic nuclei and infiltrating sheets of spindle shaped fibroblasts.

Lobomycosis is a chronic fungal infection occurring in tropical areas of Latin America. It appears as localized slow-growing nodules in exposed skin.

Dermatofibrosarcoma protuberans is an uncommon, locally aggressive cutaneous soft tissue sarcoma that may present as a plaque-like area of cutaneous thickening that can be violet-red or blue at the margins. Rarely, this may arise within a preexisting scar or tattoo. Definitive diagnosis usually requires a core needle biopsy or incisional biopsy.

### Treatment

Goals of therapy should be discussed with the patient. Often goals are cosmetic and functional improvement, reduction of scar volume, and relief of pain and itching at the site. Consider taking pretreatment photographs for comparison purposes.

### Intralesional Corticosteroid

Injections of intralesional corticosteroids are considered first-line therapy for keloids. A systematic review showed that up to 70% of cases respond with flattening of lesions, though the recurrence rate is up to 50% at 5 years. For local anesthesia, apply liquid nitrogen for 10 to 15 seconds or lidocaine-prilocaine cream (EMLA) under occlusion for 1.5 hours before injection. Do not use liquid nitrogen for more than 30 seconds, or permanent hypopigmentation may result. Use triamcinolone acetonide (Kenalog) 10 mg/mL. Space injections approximately 0.5 to 1.0 cm apart. Use a ½-inch, 30-gauge LuerLok (twist-on) needle with the bevel directed upward toward the skin and a tuberculin syringe to allow injection under pressure. Wear a face shield to avoid contact with back-pressure spray. Inject within the bulk of the lesion with enough triamcinolone to make the keloid blanch, usually 0.1 to 0.5 mL. Multiple injections may be needed. Injections may be given monthly until the desired degree of involution and/or symptomatic relief is achieved. If no change occurs after one injection with triamcinolone acetonide 10 mg/mL, increase the strength to 40 mg/mL (Figure 1). If no

**Figure 1** A, A keloid on the back. B, The scar after four intralesional injections of corticosteroid 10 mg/mL at 4 weeks apart. Note the side effects of skin atrophy and hypopigmentation. From Manuskiatti W: Current management of hypertrophic scars and keloids, *Siriraj Hosp Gaz* 55:249–258, 2003.

change occurs after three or four injections, consider referral to a plastic surgeon or dermatologist for surgical excision.

### Surgical Excision

Surgical excision of a keloid may help esthetically and symptomatically, though lesions tend to recur and may result in more extensive scarring. After excision, immediately inject the base of the surgical site in multiple sites with triamcinolone acetonide 20 mg/mL. Use a 30-gauge needle, and then occlude the excision site with a pressure dressing such as Elastoplast. Corticosteroid injections should then be repeated at 2-week intervals over a course of 3 to 4 months.

### Silicone Gel Sheeting

The use of silicone sheeting may be effective for the treatment of symptoms such as pain and itching for established keloids. It may also be used early in wound healing to prevent keloids at the site of new injuries. In some trials, silicone sheeting was effective in 70% to 80% of cases to avoid keloid formation. Sheeting is placed on top of the keloid, taped into place, and left on for 12 to 24 hours per day. The sheet is washed daily and replaced every 10 to 14 days. Consider effectiveness after 2 to 6 months of therapy. Over-the-counter and prescription self-drying silicone gel formulations are an alternative for exposed or larger areas.

### Cryotherapy

Cryotherapy can be used in conjunction with intralesional corticosteroids. This is widely available, is effective, and has an excellent safety profile. A 10- to 30-second freeze-thaw cycle can be repeated up to three times per treatment session and repeated every 4 to 6 weeks until a response occurs. One major permanent side effect is hypopigmentation, which may be most apparent in dark-skinned patients.

### Pressure Therapy

When pressure (to an area of possible keloid formation) is applied early in the healing process, it may decrease keloid formation. This is thought to be caused by decreases in oxygen tension of the

**Figure 2** A, A scar developing after cesarean section. B, The scar after two pulsed dye laser treatments 8 weeks apart.

wound by occluding small blood vessels and decreasing fibroblast proliferation. The optimal pressure should be 20 to 30 mm Hg for 12 to 24 hours per day for 6 to 12 months. Zimmer splints are inexpensive, molded earring-like pressure therapy that may be an effective treatment for keloids following ear piercing.

### Intralesional 5-Fluorouracil

Intralesional 5-fluorouracil (5-FU) has been used for scars that do not respond to intralesional corticosteroids. Schedule intralesional injections of 5-FU (Acrucil)<sup>1</sup> 50 mg/mL with a volume of 0.5 to 2.0 mL per session every 4 weeks for up to 12 weeks. Intralesional 5-FU has been shown to improve keloids by 50% and is considered to work best on small keloids. Injections may be painful and may cause hyperpigmentation. 5-FU can be mixed with triamcinolone acetonide for keloids resistant to triamcinolone alone: 0.1 mL of triamcinolone acetonide 40 mg/mL can be mixed with 0.9 mL of 5-FU 50 mg/mL and injected weekly for 8 weeks. A pulsed dye laser has been used in combination with intralesional injection of a mixture of 5-FU and steroid with cumulative beneficial effect (Figure 2).

### Surgical Excision

Surgical excision of keloids may be indicated if conservative therapies alone are unsuccessful. Excision is associated with keloid recurrence of up to 100%.

### Postoperative Radiation Therapy

Low-dose radiation therapy may be highly effective in reducing keloid recurrence if done immediately after surgical excision. However, there is no universally accepted radiation dose or modality for the postoperative treatment of keloids.

### Monitoring

Surveillance of scars during wound healing is important to alert the provider that keloids may be forming. Appropriate, focused, and timed treatment can then be performed. In a patient with keloid history, using prophylactic therapy may be instituted when a new wound is incurred. Close follow-up monitoring is vital during immediate and aggressive treatment.

## Complications

Patients should be advised that keloids can be recalcitrant to all types of therapy. If a keloid recurs (especially if ablative methods such as electrocautery are used), it may be more disfiguring than the original lesion. Trauma to the keloid may predispose the lesion to erosion and localized bacterial infection.

## MELANOMA

Method of

Geoffrey Gibney, MD; and Vesna M. Petronic-Rosic, MD, MSc, MBA

### CURRENT DIAGNOSIS

- ABCDEs:
  - Asymmetry of lesion.
  - Border irregularity, bleeding, or crusting.
  - Color change or variegation.
  - Diameter larger than 6mm or growing lesion.
  - Evolving: Surface changes or symptomatic.
- The “ugly duckling” sign: A mole that looks or feels different compared to surrounding moles.
- Total-body photography and dermoscopy.
- Excisional biopsy with narrow margins.
- Interpretation by physician experienced in the microscopic diagnosis of pigmented lesions.
- Molecular analyses (rarely).
- Appropriate staging workup.
- Genetic testing when appropriate (rarely).

### CURRENT THERAPY

- Early diagnosis and appropriate surgical therapy is the gold standard.
- Complete excision must be achieved with appropriate margins based on tumor thickness.
- Sentinel lymph node biopsy may be offered to patients with melanoma 0.8 to 4 mm thick, or any melanoma thickness if ulceration is present, with clinically unaffected regional nodes and without distant metastases.
- Dissection of the lymph node basin is not routinely offered to patients with micronodal metastases, although it can be offered in select patients.
- Dissection of the lymph node basin is offered to patients with macronodal metastases.
- Adjuvant therapy is offered for resected stage III and IV disease.
- Stage IV treatment depends on location and extent of metastatic disease and may include surgical resection, radiation therapy, and/or systemic therapy.

<sup>1</sup>Not FDA approved for this indication.

Melanoma is a malignancy of pigment-producing cells (melanocytes). Melanocytes are located predominantly in the skin but are also found in the eyes, ears, gastrointestinal tract, leptomeninges, and oral and genital mucous membranes.

### Epidemiology

Even though melanoma accounts for less than 5% of skin cancer cases, it causes the most skin cancer deaths. The American Cancer Society's most recent estimates for melanoma in the United States for 2020 are 100,350 new cases, with 6,850 deaths. The prevalence of melanoma in the United States doubled over three decades from 1982 to 2011, from 11.2 per 100,000 population to 22.7 per 100,000. The overall melanoma incidence rate has continued to increase, but may be starting to decrease in recent birth cohorts. The lifetime risk for developing melanoma is about 1 in 28 for males and 1 in 41 for females. More notable, the melanoma mortality rates dropped by 7% and 5% to 6%, respectively, annually in men and women aged 20 to 64 years and aged 65 years and older from 2013 to 2017. Mortality rates remain higher in blacks compared to all races combined.

### Risk Factors

A large number of nevi is the strongest risk factor for melanoma in persons of European ancestry. Atypical mole syndrome is another risk factor. Exposure to ultraviolet light is a major risk factor, especially in persons who have fair hair and skin, who have solar damage, who had sunburns and short, sharp bursts of sun exposure in childhood, and who used tanning beds. Tanning beds appear more detrimental when used before the age of 20 years. The International Agency for Research on Cancer has classified indoor tanning devices as "carcinogenic to humans" based on extensive review of scientific evidence. Familial risk factors include mutations in *CDKN2A* (*p16INK4a*), which are associated with increased risks for both melanoma and pancreatic cancer; they are transmitted in an autosomal dominant fashion and account for approximately 20% to 50% of familial melanoma cases. In recent years, mutations in *BRCA1*-associated protein 1 (*BAP1*), shelterin complex, microphthalmia-associated transcription factor (*MITF*), and phosphatase and tensin homolog (*PTEN*) have also been associated with melanoma and internal organ cancers. Organ transplant recipients have an increased risk for melanoma. Genodermatoses with a defect in DNA repair (such as xeroderma pigmentosum) increase risk for melanoma.

### Pathophysiology

Transformation of normal melanocytes into melanoma cells likely involves a multistep process of progressive genetic mutations that alter cell proliferation, differentiation, and death and affect susceptibility to the carcinogenic effects of ultraviolet radiation. Primary cutaneous melanoma can develop in preexisting melanocytic nevi, but more than 60% of cases likely appear de novo.

Melanomas arising in skin that is chronically sun damaged show molecular features that distinguish them from melanomas arising in skin that is not sun damaged. In particular, the tumor mutational burden is highest in melanoma arising from sun exposed areas, which is associated with response to immunotherapies. In addition, activating somatic mutations in the *BRAF* gene are seen in 40% to 60% of cutaneous melanoma, leading to constitutive activation of the MAPK pathway. Additional common mutations include *NRAS* (28%), *P53* (15%), *NF1* (14%), *CDKN2A* (13%), and *PTEN* (9%). The genetic makeup of non-sun exposed acral melanoma differs from cutaneous melanoma, with a lower frequency of *BRAF* mutations and the presence of *KIT* mutations in up to 12% of patients. Genetic studies have shown that 50% of familial melanomas and 25% of sporadic melanomas may be associated with mutations in the tumor suppressor gene p16. Linkage studies have identified chromosome 9p21 as the site of the familial melanoma gene.

### Prevention

Early detection of thin cutaneous melanoma is the best means of reducing mortality. Patients with a history of melanoma

should be educated regarding sun-protective clothing and sunscreens, skin self-examinations for new primary melanoma, possible recurrence within the surgical scar, and screening of first-degree relatives, particularly if they have a history of atypical moles.

### Clinical Manifestations

Early signs of melanoma include the ABCDEs:

- Asymmetry of lesion
- Border irregularity, bleeding, or crusting
- Color change or variegation
- Diameter larger than 6 mm or growing lesion
- Evolving: Surface changes or symptomatic

The "ugly duckling" sign is also useful to recognize lesions that look or feel different compared to surrounding moles.

Lentigo maligna (melanoma in situ) begins as an irregular tan brown macule that slowly expands on sun-damaged skin of elderly persons. Long-term cumulative sun exposure confers the greatest risk. Progression to invasive lentigo maligna melanoma is estimated to be 30% to 50%.

Superficial spreading melanoma, the most common type in light skin, represents approximately 70% of all melanomas. Peak incidence is in the fourth and fifth decade. Superficial spreading melanoma can arise in a preexisting melanocytic nevus that slowly changes over several years; it most commonly affects intermittently sun-exposed areas with the greatest nevus density (upper backs of men and women and lower legs of women). Pigment varies from black and blue-gray to pink or gray-white, and the borders are irregular. Absence of pigmentation often represents regression.

Nodular melanoma represents 15% of all melanomas. The median age at onset is 53 years. Clinically, a uniform blue-black, blue-red, or red nodule usually begins de novo and grows rapidly. About 5% are amelanotic. The most common sites are the trunk, head, and neck.

Acral lentiginous melanoma accounts for 10% of melanomas overall but is the most common type among Japanese, African Americans, Latin Americans, and Native Americans. The median age is 65 years, with equal gender distribution. It occurs on the palms or soles or under the nails and is on average 3 cm in diameter at diagnosis. Clinically, the lesion is a tan, brown-to-black, flat macule with color variegation and irregular borders. It does not appear to be linked to sun exposure.

### Diagnosis

Excisional biopsy with narrow margins is recommended for diagnosis. Incisional biopsy is acceptable when suspicion for melanoma is low, the lesion is large, or it is impractical to perform a complete excision. It is believed not to be detrimental if subsequent therapeutic surgery is performed within 4 to 6 weeks. Dermoscopy and total body photography are adjunctive noninvasive diagnostic techniques. Routine laboratory tests and imaging studies are not required for asymptomatic patients with primary cutaneous melanoma 4 mm or less in thickness for initial staging or routine follow-up. Indications for such studies are directed by a thorough medical history and complete physical examination.

Histologic interpretation should be performed by a physician experienced in the microscopic diagnosis of pigmented lesions. Molecular analyses for evidence of gene mutations, DNA copy-number abnormalities, or changed protein expression are useful adjunctive tools in the assessment of histologically ambiguous primary melanocytic tumors. It is now known that melanomas from sun-damaged skin, non-sun-damaged skin, or mucosal or acral surfaces harbor distinct molecular phenotypes.

The new revised American Joint Committee on Cancer (AJCC) staging system was published in 2017. Key changes in the eighth edition of the AJCC Cancer Staging Manual include:

1. tumor thickness measurements to be recorded to the nearest 0.1 mm, not 0.01 mm;

2. definitions of T1a and T1b are revised (T1a, <0.8 mm without ulceration; T1b, 0.8-1.0 mm with or without ulceration or <0.8 mm with ulceration), with mitotic rate no longer a T category criterion;
3. pathological (but not clinical) stage IA is revised to include T1bN0M0 (formerly pathological stage IB);
4. the N category descriptors “microscopic” and “macroscopic” for regional node metastasis are redefined as “clinically occult” and “clinically apparent”;
5. prognostic stage III groupings are based on N category criteria and T category criteria (i.e., primary tumor thickness and ulceration) and increased from three to four subgroups (stages IIIA-IIID);
6. definitions of N subcategories are revised, with the presence of microsattellites, satellites, or in-transit metastases now categorized as N1c, N2c, or N3c based on the number of tumor-involved regional lymph nodes, if any;
7. descriptors are added to each M1 subcategory designation for lactate dehydrogenase (LDH) level (LDH elevation no longer upstages to M1c);
8. a new M1d designation is added for central nervous system metastases.

This evidence-based revision of the AJCC melanoma staging system will guide patient treatment, provide better prognostic estimates, and refine stratification of patients entering clinical trials.

Five-year and ten-year survival rates based on the TNM classification range from 99% and 98% for patients with stage IA melanomas to 82% and 75%, respectively, for patients with stage IIC melanomas based on the AJCC 8<sup>th</sup> edition (Table 1). This dataset included patients dating as far back as 1998, which likely underrepresents the current melanoma-specific survival given the development of highly effective targeted and immune checkpoint therapies in the past decade.

### Differential Diagnosis

The differential diagnosis includes melanocytic nevus, angioma, pigmented basal cell carcinoma, pyogenic granuloma, seborrheic keratosis, Kaposi's sarcoma, and hematoma (especially for acral lentiginous melanoma).

### Treatment

Early diagnosis combined with appropriate surgical therapy is curative in most patients. For melanoma in situ, wide excision with 0.5 to 1.0 cm margins is recommended; lentigo maligna histologic subtype may require >0.5 cm margins to achieve histologically negative margins because of characteristically broad subclinical extension. Surgical margins for invasive melanoma should be at least 1 cm and up to 2 cm clinically measured around the primary tumor; clinically measured surgical margins do not need to correlate with histologically negative margins. Margins may be modified to accommodate individual anatomic or functional considerations. The recommended margins are:

Tumor Thickness	Clinically Measured Surgical Margin	Strength of Recommendation	Level of Evidence
In situ	0.5–1.0 cm	C	III
≤1.0mm	1 cm	A	I
1.01–2.0mm	1–2 cm	A	I
≥2.0mm	2 cm	B	I, II, III

Strength of Recommendations: A, B, C Level of Evidence: I, II, III (<https://www.aad.org/practicecenter/quality/clinical-guidelines/melanoma/surgical-management>, accessed 07.01.2019)

The recommended deep margin is muscle fascia. Wider margins and Mohs' micrographic surgery can reduce the risk of contiguous subclinical spread for the desmoplastic variant of melanoma.

Sentinel lymph node biopsy (SLNB) provides accurate staging information for patients with clinically unaffected regional nodes and without distant metastases. The status of SLN is the most important prognostic indicator for disease-specific survival in patients with primary cutaneous melanoma; however, the SLNB has not demonstrated an improvement in overall survival (MSLT1 study). Candidates for SLNB include patients with newly diagnosed primary cutaneous melanoma with a depth of at least 0.8 mm or presence of ulceration and who are clinically node-negative and have no clinical evidence of metastatic disease. In cases of positive SLNB, completion lymph node dissection has not demonstrated a survival advantage over observation and nodal surveillance in two large randomized prospective studies (DeCOG-SLT and MSLT2 studies). This has been practice-changing in that most melanoma patients with positive SLNB are now managed by observation/nodal surveillance, although completion lymph node dissection may be offered to select patients and remains an option within the NCCN guidelines. In patients with clinically detected regional nodal metastases (palpable and positive cytology or histopathology), therapeutic lymph node dissection of the involved basin is indicated in the absence of distant metastases.

For resectable local or in-transit recurrences, excision with a clear margin is recommended. For numerous or unresectable in-transit metastases, isolated limb perfusion or infusion with melphalan, intralesional injection with the oncolytic viral therapy talimogene laherparepvec (TVEC), or systemic targeted or immune checkpoint therapy are generally considered.

Radiotherapy is indicated in select patients with lentigo maligna melanoma, as an adjuvant in patients where re-resection of positive margins/recurrence is not feasible, for management of solitary/oligometastatic metastases (especially for brain metastases), and for palliation of symptomatic tumor sites.

Numerous adjuvant therapies have been investigated for the treatment of locoregional cutaneous melanoma following complete surgical removal. The current US Food and Drug Administration (FDA) approved agents include interferon alfa-2b (Intron A high dose and pegylated formulations [Peg-Intron]), anti-cytotoxic T-lymphocyte antigen-4 (CTLA-4) therapy (ipilimumab [Yervoy]), anti-programmed cell death 1 (PD-1) therapy (nivolumab [Opdivo] and pembrolizumab [Keytruda]), and *BRAF* targeted therapy (dabrafenib [Tafinlar] plus trametinib [Mekinist] in *BRAF* V600 mutant melanoma only). Interferon and ipilimumab are now seldom used since the more recent approval of the anti-PD-1 and *BRAF* targeted therapies, which are generally well tolerated and reduce relapse rates by 43% to 53% in patients with resected stage III melanoma. Of note, nivolumab is also approved as adjuvant therapy for resected stage IV melanoma.

Metastatic melanoma is an aggressive, immunogenic, and molecularly heterogeneous disease. In the last decade, treatment of melanoma took a dramatic turn with the discovery of targeted therapy aimed at the *BRAF* mutations in the mitogen-activated protein kinase (MAPK) pathway and immune checkpoint inhibitors. In 2011, the FDA approved ipilimumab, an anti-CTLA-4 antibody for metastatic melanoma therapy. Since then, novel monoclonal antibody agents that inhibit PD-1—pembrolizumab and nivolumab—were approved in 2014, followed by the nivolumab plus ipilimumab combination therapy in 2015. An additional class

**TABLE 1** Melanoma Specific Survival by AJCC 8<sup>th</sup> Edition.

STAGE	5 YEAR SURVIVAL	10 YEAR SURVIVAL
Stage I		
IA	99%	98%
IB	97%	94%
Stage II		
IIA	94%	88%
IIB	87%	82%
IIC	82%	75%
Stage III		
IIIA	93%	88%
IIIB	83%	77%
IIIC	69%	60%
IIID	32%	24%

of immunotherapy, the intralesional oncolytic viral therapy T-VEC (talimogene laherparepvec, Imlygic), received approval in 2015. Its use is limited to patients with palpable unresectable metastatic melanoma. The selective *BRAF* inhibitor vemurafenib (Zelboraf) was also approved in 2011 for the treatment of patients with advanced *BRAF* V600 mutant melanoma. Additional *BRAF* targeted regimens were subsequently approved, with the combination *BRAF* plus MEK inhibitors now the standard approach based on improvement in survival over monotherapy. The three approved *BRAF* plus MEK inhibitor regimens include dabrafenib [Tafinlar] plus trametinib [Mekinist], vemurafenib [Zelboraf] plus cobimetinib [Cotellic], and encorafenib [Braftovi] plus binimetinib [Mektovi]. Long-term survival of patients has dramatically improved with the new classes of *BRAF* targeted and anti-PD-1 therapies. Historically, approximately 10% of patients with advanced unresectable melanoma were alive at 5 years. The most recent prospective studies with dabrafenib plus trametinib, pembrolizumab, nivolumab, and nivolumab plus ipilimumab have shown 5-year survival rates of 34%, 43%, 44%, and 52%, respectively.

Although melanoma has traditionally been regarded as a near uniformly fatal malignancy, personalized treatment of this cancer relies on the recognition of its genetic heterogeneity and our ability to pharmacologically target these specific and recurrent changes. Recent advances in the treatment of melanoma have come from the understanding that melanoma is a large family of molecularly distinct diseases. Emerging evidence suggests that different melanoma subtypes may each be driven by diverse mechanisms of progression, associated with differing mechanisms of tumor escape and specific immunosuppression, innate immune cell activation, and altered T-cell trafficking into tumor sites that in turn modulate response to immunotherapies.

## Monitoring

Most metastases occur in the first 1 to 3 years after treatment of the primary tumor, and an estimated 4% to 8% of patients with a history of melanoma develop another primary melanoma, usually within the first 3 to 5 years following diagnosis. The risk of new primary melanoma increases in the presence of multiple dysplastic nevi and family history of melanoma. Consider cancer genetics consultation in patients with three or more melanomas in aggregate in first-degree or second-degree relatives on the same side of the family, families with three or more cases of melanoma or pancreatic cancer on the same side of the family, and (in low-incidence countries) patients with three or more primary melanomas.

The frequency of dermatologic monitoring is as follows:

- For patients with stage IA to IIA: every 6 to 12 months for 5 years, then every year as needed.
- For patients with stage IIB to IIC: every 3 to 6 months for 2 years, then every 3 to 12 months for 3 years, then every year as needed.

Follow-up visits for all patients should include a thorough medical history, review of systems, complete skin examination, and examination of lymph nodes. In patients at high risk for metastatic disease or with an abnormal examination, appropriate imaging studies, laboratory studies, or biopsies may be indicated. Evidence to support the use of routine imaging and laboratory studies in asymptomatic resected stage I to II melanoma patients with a normal physical examination remains controversial and is left to the discretion of the physician.

## Complications

Metastasis may occur locally in the regional lymph node basins, or it can occur distally in the skin (away from the melanoma scar), the remote lymph node(s), the viscera, and skeletal and central nervous system sites.

## NEVI

Method of

Jane M. Grant-Kels, MD; and Michael Murphy, MD

## CURRENT DIAGNOSIS

### Benign Melanocytic Lesions

- Symmetrical
- Sharply demarcated border
- Uniform color
- Diameter usually 6 mm or less and stable

### Malignant Melanocytic Lesions

- Asymmetrical
- Poorly circumscribed border
- Variegated in color
- Diameter often >6 mm and increasing (changing or evolving)

## CURRENT THERAPY

- Acquired melanocytic nevus: No treatment is required unless the lesion is asymmetrical or has an irregular border, change or variegation in color, or change in diameter. Symptomatic lesions should be biopsied.
- Recurrent melanocytic nevus: No treatment required if the original biopsy was benign.
- Halo melanocytic nevus: No treatment, but excision is recommended if atypical clinical features are identified.
- Congenital melanocytic nevus: Removal based on melanoma risk, cosmetics, and functional outcome. If not excised, routine follow-up with the use of photography, dermoscopy, and computer assistance is recommended.
- Blue nevus: No treatment, but excision is recommended if atypical clinical features are identified.
- Spitz nevus: If clinically unusual, a complete excisional biopsy is recommended.
- Dysplastic nevus: If only one lesion is present, excision may be considered. Patients with many dysplastic nevi require close surveillance, with removal of any lesion suspicious for melanoma.

Melanocytic nevi, or moles, are benign neoplasms composed of melanocytes. Melanocytic nevus cells are derived from melanocytes. Compared with melanocytes, nevus cells are not dendritic, are larger, and contain more abundant cytoplasm, often with coarse melanin granules. Nevus cells tend to aggregate into groups or nests. Melanocytic nevi are extremely common and can be found on almost everyone, anywhere on the cutaneous surface. This article discusses the most common types of melanocytic nevi: acquired melanocytic nevi, recurrent melanocytic nevi, halo melanocytic nevi, congenital melanocytic nevi (CMN), blue nevi, Spitz nevi, and dysplastic melanocytic nevi.

Most melanocytic nevi show activation of the mitogen-activated protein kinase (MAPK) pathway. A single initiating “driver” oncogenic event results in limited clonal proliferation of melanocytes that leads to nevus formation while uncontrolled growth is inhibited by additional cellular mechanisms. Specific initiating alterations are known to correlate with nevus phenotypes. *BRAF* and *NRAS* gene mutations are characteristic of conventional and large congenital nevi, respectively; *HRAS* mutations and tyrosine/serine-threonine kinase gene rearrangements are associated with Spitz nevi and pigmented spindle cell nevi; and *GNAQ* and *GNA11* mutations are seen in blue nevi.

An intermediate subset of melanocytic lesions, now classified as “melanocytomas,” are known to harbor two oncogenic events – an alteration in the MAPK pathway (similar to nevi) and an additional change involving a separate pathway. Examples of melanocytomas (with their characteristic secondary alterations) include deep penetrating nevus (*CTNNB1* or *APC* mutation), pigmented epithelioid melanocytoma (inactivation of *PRKARIA*), *BAP1*-inactivated melanocytic tumor (*BAP1* inactivation), and proliferative nodule arising in a congenital nevus (gains and losses of entire chromosomes). Most melanocytomas show indolent biologic behavior but may be associated with higher risk of transformation to melanoma compared with nevi.

Melanomas that arise within nevi (or de novo) demonstrate additional genetic/epigenetic alterations leading to uncontrolled cellular proliferation. These can include inactivation of *CDKN2A*, *PTEN*, *TP53* or *NF1* genes, *TERT* promoter mutations, and activation of *RAC1*, *ERBB2*, *MAP2K1*, *EGFR*, or *MET* oncogenes.

The majority of melanocytic tumors can be readily classified as nevus (or melanoma) based on histopathologic examination and immunohistochemistry findings. The latter includes PRAME immunostaining (most nevi are negative). However, there exists a small subset of melanocytic tumors that cannot be definitively classified as benign or malignant using light microscopy. A number of molecular tests have been developed to help refine diagnosis and determine biologic potential of histologically ambiguous melanocytic tumors. These tests include gene expression profiling and assessment of DNA copy number alterations (CNAs). Most melanomas demonstrate unstable genomes with numerous CNAs, while nevi lack or have a limited number of CNAs.

### Acquired Melanocytic Nevi

Acquired melanocytic nevi are subdivided into junctional, compound, and intradermal types based on the location of the nevus cells. By definition, these lesions are not present at birth but can begin to appear in early childhood, usually after 6 to 12 months of age. Peak ages of appearance of melanocytic nevi are 2 to 3 years of age in children and 11 to 18 years in adolescents. Although nevi can appear at any age, it is relatively unusual for new melanocytic nevi to develop in middle-aged or older adults. With time, nevi can spontaneously regress. Consequently, patients in their ninth decade of life usually demonstrate few melanocytic nevi. An average white adult has 10 to 40 melanocytic nevi, but African Americans have far fewer, averaging only 2 to 8.

The number and location of melanocytic nevi have been shown to be associated with sun exposure, immunologic factors, and genetics. Consequently, melanocytic nevi are most numerous on the sun-exposed skin of the head, neck, trunk, and extremities, but they are only rarely found on covered areas such as the buttocks, female breasts, and scalp. Evidence suggests that patients with an increased number of melanocytic nevi (>50) might have an increased risk of melanoma.

Melanocytic nevi appear in a sequential fashion. Junctional melanocytic nevi arise during childhood as flat, dark macules. Histologically, an increase in single or nested melanocytes is located at the dermoepidermal junction. With time, some of the junctional nests of melanocytes migrate into the dermis (compound melanocytic nevi). Clinically, compound melanocytic nevi are elevated and less heavily pigmented than junctional melanocytic nevi. Ultimately, all of the nevus cells migrate into the dermis (intradermal melanocytic nevi), resulting in the development of a tan or skin-colored dome-shaped papule. Melanocytic nevi can be flat or elevated and even polypoid, papillomatous, or verrucous, and can demonstrate a range of color from skin-tone to black, but they are characteristically uniform in color, symmetrical, well marginated, and usually smaller than 6 mm in diameter.

All melanocytic lesions of clinical concern should be examined with a dermatoscope—a handheld instrument with a magnified lens and a light source similar to an ophthalmoscope. This instrument allows evaluation of colors and microstructures not visible to the naked eye, helps determine whether pigmented lesions are melanocytic or nonmelanocytic, and aids in distinguishing whether melanocytic pigmented lesions are likely to be malignant. Used by an experienced physician with proper training, the dermatoscope improves diagnostic accuracy by 20% to 30%. Another useful technology is reflectance confocal microscopy (RCM), as it safely offers noninvasive imaging of skin lesions at cellular-level magnification and is reported to reduce unnecessary biopsies by 50% to 60%. RCM utilizes a low-energy laser light that focuses on a specific area of tissue; the magnitude of back-scattering of light depends on the differences in refractive indices of various structures in the skin. The horizontal images of the skin afford review of a lesion up to 8 mm × 8 mm in diameter and extend 200 to 300 μm into the skin.

It is unnecessary to surgically remove all melanocytic nevi because they are benign neoplasms of melanocytes. However, indications for removal include ABCDE (*asymmetry, irregular border, variegation or change in color, change in diameter, or evolving*), symptoms (e.g., pruritus), evidence of inflammation or irritation, cosmetic issues, and patient anxiety. Melanocytic nevi on acral, genital, or scalp skin that appear benign do not require surgical removal. Shave biopsies are appropriate therapy for lesions considered clinically benign. However, if a lesion is being removed because of concern regarding the possibility of malignancy, an excisional biopsy (biopsy of choice) or incisional biopsy (including a deep scoop) that extends to the subcutaneous tissue is indicated. All melanocytic lesions should be submitted to a dermatopathologist for histologic review. A history of recent sun exposure or trauma should be conveyed to the dermatopathologist because such external trauma can induce reactive atypical histologic findings.

### Recurrent Melanocytic Nevi

Recurrent melanocytic nevi are melanocytic nevi that have previously been incompletely removed (either iatrogenically or traumatically) and have recurred weeks to months later. Irregular brown pigmentation is clinically noted within the scar site. If the original biopsy demonstrated a benign melanocytic nevus, re-treatment is unnecessary unless the aforementioned indications are present. However, these nevi can demonstrate pseudomelanomatous histologic features. Therefore if the repigmented area is excised, the dermatopathologist should be notified of the clinical history and, if possible, the slides from the original biopsy should be obtained and reviewed to ensure that the lesion is not histologically misdiagnosed.

### Halo (Melanocytic) Nevi

Halo (melanocytic) nevi are melanocytic nevi in which a white rim or halo has developed. This phenomenon most commonly occurs around compound or intradermal nevi and is histologically associated with a dense, bandlike inflammatory infiltrate. The white halo area is histologically characterized by diminished or absent melanocytes and melanin. Approximately 20% of patients with halo nevi also exhibit vitiligo.

Although a halo can develop around many lesions in the skin, the most important differential diagnosis is between a halo nevus

and melanoma with a halo. The halo and the central melanocytic proliferation of halo nevi are symmetrical, round or oval, and sharply demarcated. Halo nevi most commonly occur in adolescence as an isolated event, but approximately 25% to 50% of affected persons have two or more.

The clinical course of halo nevi is variable. With time, the halo can repigment while the central nevus persists. Alternatively, the melanocytic nevus can regress completely and leave a depigmented macule that can persist or repigment over months or years.

Halo nevi do not require surgical excision unless atypical clinical features suggest the possibility of an atypical melanocytic lesion. It is advisable (particularly in adults, in whom halo nevi are less common) to perform a complete cutaneous examination with and without the aid of a Wood's lamp to rule out any associated atypical pigmented or regressed lesions. All patients should be advised to use sunscreens or protective clothing because of the increased risk of sunburn in the depigmented halo region.

### Congenital Melanocytic Nevi

By definition, CMN are present at birth. Arbitrarily, they have been classified into small (<1.5 cm), medium (1.5 to 20 cm), and large (>20 cm) lesions. Terms such as *bathing trunk* or *garment-type* nevi refer to CMN that cover a significant portion of the cutaneous surface.

The approximate incidence of small congenital nevi is 1% of all live births. Large congenital nevi are rare and reported in only 1 in 20,000 births. Histologically, some congenital nevi have distinguishing histologic features (melanocytic nevus cells that extend into the deeper dermis as well as the subcutis and melanocytic nevus cells arranged periadnexally, angiocentrically, within nerves, and interposed between collagen bundles). However, these features have been identified in some acquired melanocytic nevi and are absent in some congenital nevi (especially small ones). In addition, the history obtained from the patient or their parents is often inaccurate. Consequently, it can be very difficult in some cases to distinguish a small congenital nevus from an acquired nevus.

Congenital nevi can give rise to dermal or subcutaneous nodular melanocytic proliferations. The vast majority of these lesions, particularly in the neonatal period, are biologically benign, despite a worrisome clinical presentation and atypical histologic features. Genetic analysis has shown that benign melanocytic proliferations within congenital nevi harbor aberrations qualitatively and quantitatively different from those seen in melanoma.

Patients with multiple CMN (two or more, of any site or size) are at risk for extracutaneous (i.e., endocrine, metabolic, neurological) manifestations, termed *CMN syndrome*. The primary significance of congenital nevi is related to the potential risk for progression to melanoma. Essentially, the larger the nevus, particularly if accompanied by multiple small CMN, the greater the risk of progression to melanoma. Historically, even small nevi were estimated to exhibit a lifetime melanoma risk of 5%. However, recent prospective studies suggest that small and medium congenital nevi are associated with a low risk that may approximate the risk of acquired nevi. Conversely, large congenital nevi have a lifetime risk of melanomatous progression of approximately 6.3%. Up to two-thirds of melanomas that arise within these giant congenital nevi have a nonepidermal origin (arising mainly in the deep dermis and subcutis with high Breslow thickness on presentation), thus making clinical observation for malignant change difficult. Approximately 50% of these melanomas occur in the first 5 years of life, 60% in the first decade, and 70% before 20 years of age. Patients with large congenital nevi, especially those that involve posterior axial locations (head, neck, back, or buttocks) and are associated with satellite congenital nevi, are at increased risk for neurocutaneous melanosis (melanosis of the leptomeninges) and primary central nervous system (CNS) melanoma. Recent data suggest that in up to one-third of these patients, the primary melanoma develops within the CNS rather than the skin. The risk of melanoma appears to be higher in those with congenital abnormalities of the CNS (12% vs. 1% to 2% without CNS changes).

For large congenital nevi that involve a posterior axial location, screening magnetic resonance imaging (MRI) is indicated

to characterize congenital disease, if any, and act as a baseline should the child present with new neurological symptoms at a later stage. If clinical symptoms or MRI indicate neurocutaneous melanosis, excision of the large nevus should be postponed until 2 years of age (the median age of neurologic symptoms). Patients with neurocutaneous melanosis have a greater than 50% mortality rate within 3 years. The risk and morbidity of multiple, staged excisions of a large CMN is not appropriate in patients with symptomatic neurocutaneous melanosis. All other large CMN are candidates for excision as soon as general anesthesia is considered a relatively safe risk. Other issues that need to be considered before undertaking staged excisions include cosmetic issues, functional outcome, and psychosocial issues. The staged excisions are usually started after 6 months of age for nevi on the trunk and extremities and later for those on the scalp to allow closure of the fontanelle. If removal is not undertaken, follow-up with monthly self-examination, photography, dermoscopy, confocal laser microscopy, and computer assistance are recommended.

For small congenital nevi, routine excision is not always recommended because the risk of melanoma is lower, and if it occurs, it usually arises within the epidermis after puberty. If the lesions are not excised, follow-up by alternating visits to a dermatologist and primary care physician along with serial photography are indicated. Inasmuch as small congenital nevi typically enlarge with the growth of the child and can change in appearance with time, educating families on benign, predictable changes in contradistinction to potentially alarming changes is extremely important. If a lesion enlarges or changes suddenly or if parental anxiety or cosmetic issues arise, excision should then be contemplated for even small congenital nevi. Elective excision is best done when the patient is approximately 8 years old. With the use of topical anesthetic cream EMLA (eutectic mixture of local anesthetics: 2.5% lidocaine plus 2.5% prilocaine) or topical 4% lidocaine (ELA-Max), children of this age are usually cooperative and unscathed by the procedure.

### Blue Nevi

Blue nevi occur primarily on the face and scalp, in addition to the dorsal surfaces of the hands and feet, as well-circumscribed, slightly raised or dome-shaped bluish papules that are usually less than 1 cm in diameter. Although these lesions are usually acquired in childhood and adolescence, rare congenital lesions have been reported. Histologically, blue nevi demonstrate a combination of intradermal spindle or dendritic melanin-pigmented melanocytes and melanophages with dermal fibrosis. The blue appearance of these lesions is a function of both the depth of the melanin in the dermis and the Tyndall phenomenon: longer wavelengths of light penetrate the deep dermis and are absorbed by the lesional melanin, and shorter wavelengths (e.g., blue) are reflected back. Blue nevi that are clinically stable and that do not demonstrate atypical features do not require removal.

### Spitz Nevi

Nevi of large spindle and epithelioid cells (Spitz nevi) are relatively uncommon. In Australia, an annual incidence of 1.4 per 100,000 people has been recorded. Most Spitz nevi are noted in children and adolescents: One-third occur before the age of 10 years, one-third between the ages 10 to 20 years, and one-third past the age of 20 years. Rarely, lesions can occur in patients older than 40 years. Seven percent of Spitz nevi have been reported as congenital.

Four clinical types of Spitz nevi are recognized: light-colored soft Spitz nevi that can resemble a pyogenic granuloma; light-colored hard Spitz nevi that can resemble a dermatofibroma; dark Spitz nevi that must be distinguished from other melanocytic lesions, including melanoma; and disseminated or agminated Spitz nevi. Spitz nevi are typically smaller than 6 mm in diameter and dome shaped, with a smooth pink or tan surface and sharp borders. Although they can occur anywhere on the cutaneous surface except mucosal or palmoplantar areas, they are most commonly seen on the face (especially in children) and legs (especially in women). Spitz nevi in adults are usually more heavily melanized than those in children.

Dermatoscopy or epiluminescent microscopy (examination of lesions with enhanced light and a dermatoscope) helps magnify the

images in vivo and can assist in establishing the clinical diagnosis of some Spitz nevi. Histologically, the lesion can demonstrate features similar to those of melanoma, which earned the lesion its original designation by Sophie Spitz as a melanoma of childhood. Because Spitz nevi can be histologically difficult to distinguish from melanoma, if a biopsy is performed on a lesion because of parental, cosmetic, or transitional concern, complete excision with clear margins is recommended. Spitz nevi show fundamental genomic differences compared with melanoma, consistent with the generally benign behavior of these lesions. Spitz nevi typically demonstrate no or only a very restricted set of chromosomal aberrations (i.e., 11p gain in a subset of Spitz nevi). A distinct subset of atypical Spitz tumors is characterized by BRAF mutation and loss of BAP1 expression.

### Dysplastic Melanocytic Nevi

Dysplastic melanocytic nevi, or Clark's nevi, or nevi with architectural disorder and cytologic atypia, can occur sporadically as an isolated lesion or lesions or as part of a familial autosomal dominant syndrome. When such lesions occur sporadically, they are considered a marker for a patient who is at increased risk of melanoma (6% risk vs. an approximate 0.6% risk in the normal white population in the United States). In association with a family history or personal past medical history of melanoma, patients with dysplastic melanocytic nevi should be considered to have a significant risk of melanoma. One first-degree family member with melanoma is associated with a lifetime risk of melanoma of 15% for the patient with dysplastic melanocytic nevi. Two or more first-degree family members with melanoma place a patient with dysplastic melanocytic nevi at a lifetime risk of developing melanoma that approaches 100%. Less commonly, dysplastic melanocytic nevi can progress to melanoma. Such progression has been documented by serial photography. However, these data are confounded by the fact that clinically and histologically dysplastic melanocytic nevi may be difficult to distinguish from an early melanoma.

Dysplastic melanocytic nevi are clinically distinguished from common acquired melanocytic nevi by a diameter usually larger than 6 mm, an irregular border, asymmetry, and variable color with possible shades of brown, red, pink, and black; dysplastic melanocytic nevi can be flat, with or without a raised center (fried egg appearance). The lesions begin to appear in mid-childhood and early adolescence. New lesions can appear throughout the patient's life. In addition to the back and extremities, these lesions can occur on sun-protected areas, including the scalp, buttocks, and female breasts. Dysplastic melanocytic nevi can be few or numerous, with hundreds of lesions.

Histologically, dysplastic melanocytic nevi show both architectural disorder: extension of the junctional component beyond the dermal component (shouldering); bridging of nests between adjacent rete ridges; papillary dermal concentric and lamellar fibroplasia; and a variable lymphocytic infiltrate with vascular ectasias. They also show cytologic atypia of melanocytes: increased nuclear size, hyperchromasia, dispersion, or variation of nuclear chromatin patterns, and the presence of nucleoli. Although there is some discordance in the histologic grading of dysplastic melanocytic nevi among expert dermatopathologists, there is some evidence to support the use in clinical practice of a two-tier grading system: Grade A are dysplastic melanocytic nevi with mild or moderate cytologic atypia, and grade B are dysplastic melanocytic nevi with severe cytologic atypia. The probability of having a personal history of melanoma in any given patient with dysplastic melanocytic nevi correlates with the grade of cytologic atypia in melanocytic nevi cells. In addition, the presence of severe cytologic atypia in dysplastic melanocytic nevi correlates with a significantly greater risk of melanoma development (19.7%) compared with moderate (8.1%) or mild (5.7%) cytologic atypia.

Management of these patients is difficult. Dysplastic melanocytic nevi are not uncommon. Reportedly, as many as 4.6 million people in the United States have one or more sporadic dysplastic melanocytic nevi. Familial dysplastic melanocytic nevi are estimated to involve 50,000 patients in the United States. The risk of melanoma for these patients is probably on a continuum and correlated with their family history of melanoma or dysplastic melanocytic nevi, personal history of melanoma, number of acquired

and dysplastic melanocytic lesions, and history of sun exposure. Removal of all dysplastic melanocytic nevi is inappropriate inasmuch as the chance of any single lesion becoming malignant is small and, in addition, the melanoma can arise de novo.

In cases of mild and moderate dysplastic nevi with microscopically positive margins and no concerning residual clinical lesion, observation, rather than reexcision, is a reasonable management option. All severely dysplastic nevi should be reexcised. Partial biopsy of any pigmented lesion that is suspicious for melanoma can lead to delayed melanoma diagnosis and is discouraged.

Management includes patient education and total body photography for comparison at future skin examinations. Patients should avoid the sun and use sunscreens and protective clothing. These patients should have regular biannual or quarterly examinations of the entire integument, including the oral, genital, and perianal mucosa, the scalp, and an ophthalmologic examination. Comparison with the previous total body photographs and use of the dermatoscope can be helpful. Any lesions that are suspicious for melanoma should be excised. Examination of first-degree family members (parents, siblings, and children) of patients with melanoma or dysplastic melanocytic nevi is recommended to identify other persons at high risk.

## NONMELANOMA CANCER OF THE SKIN

Method of

Jake Lazaroff, MD; and Diana Bolotin, MD, PhD

### CURRENT DIAGNOSIS

- Skin cancers are polymorphous in appearance, ranging from small papules and plaques to nodules and tumors of different colors, sizes, and consistencies.
- The surface may be smooth, scaly, ulcerated, or crusted.
- A common feature is that all of these skin neoplasms grow continuously and relapse when superficially treated.
- The distinction between skin cancers and benign neoplasms or inflammatory dermatoses may be difficult for the nondermatologist to make.

## CURRENT THERAPY

- For the majority of nonmelanoma skin cancers, localized treatments are sufficient and include cryotherapy, immunotherapy, topical chemotherapy, and photodynamic therapy.
- Surgical techniques include electrodesiccation and curettage, simple excision, and Mohs micrographic surgery, which offers intraoperative confirmation of complete tumor removal and maximal cure rates.
- The Mohs procedure is indicated for more aggressive tumors, for tumors in certain anatomic locations, and in immunosuppressed patients.
- Rarely, sentinel lymph node dissection and adjuvant therapies, such as radiotherapy and chemotherapy, are warranted.

Nonmelanoma skin cancer (NMSC) is a heterogeneous group of skin malignancies that includes basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). These are the most common skin cancers, and NMSC in the stricter sense of the definition (Figure 1). The more-inclusive use of the term NMSC also includes malignant neoplasms of adnexal, fibrohistiocytic, and vascular origin as well as Merkel cell carcinoma and metastatic tumors. The vast majority of NMSCs are slowly growing and locally invasive neoplasms that are often diagnosed and treated by dermatologists. Management of the more aggressive tumors often requires a team approach to diagnosis, treatment, and clinical follow-up (Table 1).

### Basal Cell Carcinoma

BCC accounts for the majority of NMSCs in the United States and is increasingly diagnosed in younger patients. Light skin complexion and history of ultraviolet (UV) light exposure are the predominant risk factors for BCC in the majority of the population. Intermittent intense UV light exposures early in life, but not cumulative UV light exposure, pose the highest risk factor for developing BCC later in life. Other risk factors for BCC include exposure to ionizing radiation, psoralen photochemotherapy, arsenic, and smoking. A history of BCC also increases one's risk for developing a subsequent BCC. Immunosuppression, especially in recipients of solid-organ transplants, presents a significant risk factor for BCC. Inherited genodermatoses such as Gorlin, Bazex, and Rombo syndromes; xeroderma pigmentosum; and some forms of albinism are predisposing factors for BCC as well. Mutations in *PTCH1* that are found in Gorlin syndrome have been shown to be an early event underlying BCC pathogenesis.

Clinically, BCC is most commonly found on the head and neck region, though any part of the body can develop this tumor. The presentation varies depending on the histologic subtype of the tumor. Although many histologic variants of BCC exist, the most common subtypes are superficial, nodular and micronodular, morpheaform, and metatypic. The histologic heterogeneity results in variable clinical findings. Superficial BCC typically forms an erythematous scaly patch or plaque. Nodular BCC is the more classic-appearing lesion, a pink pearly nodule with or without central crust or ulcer. Unlike these subtypes, morpheaform BCC clinically resembles an ill-defined scar; it is the most histologically aggressive variant with a tendency for deep local invasion. Metatypic BCC is also known as *basosquamous carcinoma* because it has histologic features of both BCC and SCC, though it is distinguished from the latter by molecular markers. This subtype also has a tendency for more aggressive growth.

Although it is potentially locally destructive, BCC rarely metastasizes. Successful treatment of this tumor involves its local eradication. A number of treatment options exist and depend on the histologic subtype of the tumor. For small, superficial tumors, a

nonsurgical approach can suffice, though nonsurgical treatment often carries a higher risk of recurrence than surgical treatment. Nonsurgical options include topical 5-fluorouracil (Efudex 5%), topical imiquimod (Aldara), liquid nitrogen cryotherapy, photodynamic therapy, and local radiation therapy.

Electrodesiccation and curettage (ED&C) is an option that has a high cure rate for small and superficial tumors (95% to 98%). Standard excision with adequate margins is an appropriate surgical treatment providing good cure rates, especially for tumors with nonaggressive histologic pattern. Mohs micrographic surgery (MMS) offers the advantage of precise margin examination during excision and therefore carries the lowest overall rate of recurrence. This tissue-sparing procedure is also advantageous in terms of reconstruction on cosmetically sensitive regions. MMS is indicated to treat recurrent tumors, those in immunosuppressed patients, aggressive histologic variants, and BCCs located on certain areas of the face known to carry a higher risk of recurrence.

Although locally advanced and metastatic BCCs are uncommon, treatment with targeted molecules such as vismodegib (Erdvedge) have demonstrated clinical efficacy.

### Squamous Cell Carcinoma

Cutaneous squamous cell carcinoma (SCC) is the second most common skin malignancy. Its incidence is increasing among both men and women in the United States. Development of SCC is intimately linked to the cumulative UV radiation exposure of the patient via a mechanism that combines DNA damage with immunosuppression. History of ionizing radiation exposure is a risk factor as well. Similar to BCC, occupational exposures such as arsenic can also predispose one to SCC. Patients with xeroderma pigmentosum or oculocutaneous albinism also are at higher risk for SCC.

Chronic inflammation or injury can predispose to epidermal malignant transformation. Examples of this phenomenon are SCC developing within scars from burns, in chronic ulcers and skin overlying osteomyelitis, and in persistent lichen sclerosus or lichen planus. These tumors have a more aggressive behavior and higher rates of metastasis.

Human papilloma virus (HPV) predisposes to SCC. Verrucous carcinoma, a well-differentiated subtype of SCC, has a well-documented association with HPV types 6 and 11.

Transplant patients are at high risk for SCC that correlates with the degree of immunosuppression. In fact, SCC development is up to 250 times greater in immunosuppressed individuals compared with the general population, whereas BCC increases to a lesser extent with immunocompromise. A more common association between HPV and SCC has been noted in the immunocompromised population and might account for the disproportional increase of SCC over BCC in this population.

As with BCC, history of previous SCC has been found to be a risk factor for developing a subsequent SCC. This risk appears especially pronounced in smokers.

Unlike BCC, SCC often has a precursor lesion: actinic keratosis. Histologically, actinic keratosis demonstrates partial-thickness atypia of the epidermis, and patients often describe it as waxing and waning. Full-thickness histologic atypia is seen in SCC in situ (Bowen's disease), whereas invasive SCC penetrates the basement membrane to invade the underlying dermis. Histologically, the degree of differentiation of SCC tends to correlate with its clinical behavior. Well-differentiated lesions tend toward local invasion, as opposed to poorly differentiated SCC, which more commonly is infiltrative.

The typical clinical presentation of SCC is that of a hyperkeratotic pink plaque. More advanced lesions may be nodular and can ulcerate. In most cases, SCC shows only local invasion; however, perineural invasion and rarely metastasis are more likely with SCC than with BCC. The central face, temples, and scalp present high-risk zones for recurrence and metastasis.

Treatment of SCC involves modalities similar to those used for BCC. Cryotherapy is the mainstay of treatment for actinic

**Figure 1** Clinical images of skin cancers. A, Squamous cell carcinoma in sun-exposed skin of a 102-year-old African American woman. B, Depressed scarlike appearance of a morpheaform basal cell carcinoma on the nose. C, This firm tumor on the abdomen is a dermatofibrosarcoma protuberans. D, Violaceous plaques on the instep in an elderly Greek man typical for endemic Kaposi's sarcoma.

**TABLE 1** Overview of Therapeutic Modalities for the Management of Skin Cancers

THERAPEUTIC MODALITY	NEOPLASM	COMMENT
Cryotherapy	AK, SCC in situ Superficial BCC Kaposi's sarcoma	Versatile, but operator dependent
Topical 5-fluorouracil (Efudex)	AK, SCC in situ <sup>1</sup> Superficial BCC	Will treat preclinical AK
Topical imiquimod (Aldara)	AK Superficial BCC	Flulike adverse effects can occur
Photodynamic therapy	AK, SCC in situ Superficial BCC	SCC and BCC are off-label uses
Electrodesiccation and curettage	AK, SCC BCC	
Excision	All	
Mohs micrographic surgery	BCC, SCC MAC, sebaceous carcinoma DFSP, AFX Angiosarcoma EMPD, MCC	Preferred for certain types of invasive tumors (e.g., morpheaform BCC), on high-risk regions (e.g., nose, lip), and settings (e.g., recurrence, immunosuppressed patient)
Radiation therapy	BCC, SCC Kaposi's sarcoma, angiosarcoma MCC Inoperable tumors	Careful risk-to-benefit evaluation

AFX, Atypical fibroxanthoma; AK, actinic keratosis; BCC, basal cell carcinoma; DFSP, dermatofibrosarcoma protuberans; EMPD, extramammary Paget's disease; MAC, microcystic adnexal carcinoma; MCC, Merkel cell carcinoma; SCC, squamous cell carcinoma.

<sup>1</sup>Not FDA approved for this indication.

keratosis. Topical treatment with 5-fluorouracil (Carac 0.5%, Fluoroplex 1%, Fluorouracil 2 or 5%, or Efudex 5%)<sup>1</sup> alone or in combination with calcipotriol (Dovonex),<sup>1</sup> imiquimod (Aldara or Zyclara),<sup>1</sup> tirbanibulin (Klisyri),<sup>1</sup> or photodynamic therapy is often used as field therapy to depopulate large regions of the skin of actinic keratosis lesions. Continued sun protection has been shown to be of benefit to prevent progression from actinic keratosis to

SCC, especially in the immunocompromised population. Systemic retinoids, such as acitretin (Soriatane)<sup>1</sup> and nicotinamide<sup>7</sup> have also been used for the prevention and reduction of NMSC, particularly in high-risk populations. SCC in situ may be treated with ED&C. Excision with a clear surgical margin is often used in the treatment of SCC on the trunk or extremities, but MMS yields the highest cure rates, especially in high-risk areas such as the face and scalp.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

Adjuvant radiotherapy, surgical excision, and targeted approaches with anti-PD-1 monoclonal antibodies may be used alone or combination for more aggressive tumors. Overall, the prognosis for a patient with cutaneous SCC depends heavily on location, degree of histologic differentiation, invasion, and metastasis.

### Neoplasms of Adnexal Origin

The adnexal structures of the skin include the pilosebaceous unit as well as apocrine and eccrine glands and ducts. A great number of benign and malignant tumors of adnexal origin occur in the skin. Most of the adnexal malignancies are rare. Sebaceous carcinoma and microcystic adnexal carcinoma (MAC) are two of the more common adnexal carcinomas that have an aggressive nature and may be subtle at presentation.

### Sebaceous Carcinoma

Sebaceous carcinoma is an aggressive malignancy that is most commonly found on the head and neck region. More specifically, it is one of the more common tumors of the eyelid and periorcular area. Because of its nonspecific clinical presentation, it is often treated as chalazion before biopsy and diagnosis. Population-based risk factors associated with development of sebaceous carcinoma include older age and European ethnicity. History of irradiation and immunosuppression predisposes to sebaceous carcinoma development, similar to BCC and SCC. Sebaceous carcinoma is one of the cutaneous neoplasms characteristic of Muir-Torre syndrome, which results from mutations in DNA mismatch repair genes and is associated with multiple sebaceous neoplasms and internal malignancy.

Clinical diagnosis of sebaceous carcinoma is difficult, therefore progressive or nonresolving eyelid lesions require biopsy. Treatment of sebaceous carcinoma is primarily surgical. Wide local excision with 5- to 6-mm margins or MMS is indicated. A lower rate of recurrence with MMS (11.1%) has been shown compared with local excision (32%). Close follow-up is indicated to monitor for recurrence and metastasis.

### Microcystic Adnexal Carcinoma

MAC is another adnexal malignancy with predilection for the head and neck. In the United States, it is most prevalent in the white population and on the left side of the body, suggesting UV irradiation as a risk factor. Although it can be seen in a wide age range of patients, older adult patients have a higher risk of developing MAC. The low incidence of this tumor makes it difficult to evaluate other risk factors, though cases have been reported in immunosuppressed patients and those with a history of radiation therapy.

Clinically, MAC occurs as a slowly growing, pink- to flesh-colored ill-defined plaque. Paresthesia and/or numbness are common complaints and have been attributed to the high degree of perineural invasion by this tumor. MAC is a locally aggressive tumor with an unpredictable pattern of infiltrative growth. Histologically, MAC exhibits both pilar and sweat duct differentiation, deep invasion with a desmoplastic stromal response, and perineural invasion.

Surgical excision is the standard of care treatment for MAC, and radiation as an adjunct therapy is reported in a few cases. Because this tumor can extend for centimeters subclinically, MMS is favored as the first-line surgical treatment because it allows complete examination of the surgical margins intraoperatively and has been reported to have a lower recurrence rate than standard excision.

### Fibrohistiocytic Malignancies

Fibrohistiocytic tumors of the skin are derived from the mesenchymal tissue and range from those of intermediate malignant potential to aggressive pleomorphic sarcomas. Of these overall rare malignancies, dermatofibrosarcoma protuberans (DFSP) and atypical fibroxanthoma are more frequently encountered.

### Dermatofibrosarcoma Protuberans

DFSP is the most common fibrohistiocytic malignancy of the skin. It occurs at various ages ranging from infancy to older adulthood. The pathogenesis of DFSP involves a translocation between chromosomes

17 and 22 that fuses the collagen type 1  $\alpha_1$  gene (*COL1A1*) with the platelet-derived growth factor B-chain gene (*PDGFB*). This fusion gene results in overexpression of PDGFB, which acts as a potent growth stimulant for mesenchymal cells. In general, slowly growing DFSPs are locally invasive and infiltrative rather than metastatic. Therefore treatment of this tumor is primarily surgical.

A high recurrence rate has been noted in a number of studies and is attributed to the infiltrative growth of the tumor. MMS reduces recurrence rates and is often recommended. DFSP is thought to be a radiosensitive tumor, and adjunctive radiation therapy has been successfully used both preoperatively and postoperatively. The discovery of the *COL1A1-PDGFB* fusion gene has led to trials of imatinib (Gleevec) therapy as an adjunct to surgery for DFSP and is currently approved for use in unresectable, recurrent, or metastatic disease.

### Atypical Fibroxanthoma

Atypical fibroxanthoma is a low-grade sarcoma of the skin. This locally invasive tumor favors sun-damaged skin of the head and neck region in older adults. Patients with xeroderma pigmentosum have a higher risk for developing atypical fibroxanthoma. It has a nonspecific clinical presentation, and a biopsy with histopathology is needed for diagnosis. Histologically, this tumor often exhibits marked pleomorphism and frequent mitoses. Often immunohistochemical staining is necessary for definitive diagnosis. Surgery is the treatment of choice for atypical fibroxanthoma. Either wide local excision or MMS may be used, though lower recurrence rates have been reported with MMS. Despite the pleomorphic microscopic appearance, this tumor rarely metastasizes, and the prognosis with appropriate treatment is favorable.

### Vascular Malignancies

Vascular neoplasms of the skin are rare. Kaposi's sarcoma (KS) and angiosarcoma, both increasingly encountered in healthy older adults as well as in immunosuppressed patients, are discussed here.

### Kaposi's Sarcoma

Controversy exists regarding the nature of cell proliferation seen in KS. Some regard it as a true malignancy, and others view it as a reactive proliferation. Four types of KS exist: KS of older adult men of Jewish and Mediterranean origin, African-endemic KS, immunosuppression-associated KS, and AIDS-associated KS. Infection with human herpesvirus 8 (HHV-8) is involved in the pathogenesis of all types of KS. Clinical findings include nonblanching purpuric patches and plaques that can progress to nodules with ulceration. KS can be isolated to the skin or can become disseminated to the lymph nodes and viscera. Diagnosis is established with histopathology and immunostaining. Management of KS is complex because of the varied clinical course of the four subtypes. In cases of localized lesions, surgery, cryotherapy, or laser treatment may be useful. Radiotherapy can also be used for localized disease. Patients with disseminated KS are generally treated with chemotherapy. In AIDS-associated KS, institution of HIV medications has been shown to effect resolution of KS.

### Angiosarcoma

Angiosarcoma is a rarer but more aggressive vascular cutaneous malignancy that tends to metastasize and carries a poor prognosis. Clinically, angiosarcoma favors the head and neck area of older adult men; it can also arise within sites of previous radiation therapy or chronic lymphedema. No association between angiosarcoma and HHV-8 has been found. Patients present with an asymptomatic enlarging purpuric plaque that can eventually develop a nodular component. Angiosarcoma may have multifocal involvement that is often not appreciated clinically. The treatment for angiosarcoma involves wide local excision and postoperative radiotherapy. The overall prognosis is poor, and distant metastasis-free 5-year survival rates range between 20% and 37%.

### Other Nonmelanoma Skin Cancers

#### Merkel Cell Carcinoma

Merkel cell carcinoma (MCC) is a rare but often fatal NMSC that derives from cutaneous neuroendocrine cells. Fair skin and a history

of exposure to UV light are risk factors for developing MCC. Like many other NMSCs, MCC favors the head and neck and is much more common in older adults. Immunosuppression appears to be a risk factor for MCC development because its incidence is significantly increased in patients with AIDS and recipients of organ transplants. Polyomavirus has been implicated in the pathogenesis of MCC.

This malignancy is often metastatic upon presentation. Clinically, it occurs as a nonspecific, red asymptomatic papule or nodule. A biopsy with immunohistochemical analysis is diagnostic. The therapy for MCC involves surgery with wide local excision or MMS. Sentinel lymph node biopsy can be performed for staging purposes but should be considered on a case-by-case basis. MCC is sensitive to radiotherapy, which is a recommended adjuvant treatment for patients with lymph node involvement. Palliative chemotherapy often produces a response; however, recurrence is common. Preliminary data indicate a promising signal with checkpoint immunotherapy in patients with advanced disease, though prognosis remains poor for metastatic disease or lymph node involvement.

### Paget's Disease

Paget's disease refers to intraepidermal spread of adenocarcinoma. Two types are seen in the skin: mammary Paget's disease and extramammary Paget's disease (EMPD). Mammary Paget's disease is most commonly seen in women and has a strict association with adenocarcinoma of the breast. The lesions are usually unilateral scaly red plaques that favor the nipple. Often the underlying tumor is not clinically present but is detected through imaging. Other dermatoses of the nipple can resemble mammary Paget's disease, therefore definitive diagnosis requires biopsy and immunohistochemistry. Surgical excision along with appropriate treatment of the breast cancer is the recommended treatment. Prognosis depends on the extent of breast cancer at diagnosis, though it appears to be poorer for breast cancer patients with mammary Paget's disease than those without.

EMPD consists of two types of disease: type I disease is associated with distant adenocarcinoma, and type II disease is a primary cutaneous EMPD. Both are very rare, but, like mammary Paget's disease, they have a female predominance. Most commonly extramammary Paget's disease is found in the genital or perianal region; however, other areas of the skin can be affected less frequently. Clinically, EMPD manifests as a well-demarcated red plaque that can become erosive. Long-standing disease can spread from the groin to the trunk, mimicking an inflammatory dermatosis. Definitive diagnosis is based on biopsy findings, and further workup includes extensive screening for associated internal malignancy. Treatment relies on surgical excision with wide margins. MMS can be used to examine margins intraoperatively. The prognosis for type I EMPD depends on the extent of underlying tumor, but the prognosis for type II is favorable.

### Cutaneous Metastases

Metastasis to the skin often heralds the systemic spread of an internal malignancy. Primary malignancy underlying the skin metastasis tends to differ by sex and age. In men, lung cancer is the most common source of skin metastasis, whereas breast cancer is the more common primary tumor in women. The head and neck are favored as sites of skin metastasis in men, but the trunk is favored in women.

The clinical presentation of skin metastasis is varied and often nonspecific. A new, asymptomatic cutaneous or subcutaneous nodule may be the reason for a biopsy that reveals metastasis of an unknown primary tumor. Diagnosis is made by histopathology and appropriate molecular staining. Specific clinical patterns of metastasis may be encountered. Inflammatory carcinoma can be seen with cutaneous breast cancer metastases. Occasionally, neoplastic infiltration leads to localized areas of alopecia. Zosteriform distribution of skin metastasis has been reported with breast cancer, colon cancer, or SCC.

Leukemia cutis refers to skin involvement with acute myelogenous leukemia, chronic myelogenous leukemia, myelodysplastic syndromes, chronic lymphocytic leukemia, or adult T-cell lymphoproliferative diseases. In rare cases, skin involvement precedes

bone marrow disease and is termed *aleukemic leukemia cutis*. In chronic leukemias, skin involvement tends to predict disease progression into the acute phase. Children appear to have a higher incidence of leukemia cutis compared with adults but have a more favorable overall prognosis.

Metastatic skin tumors are distinguished from primary cutaneous malignancies histologically. Treatment is always geared toward the primary malignancy. Regardless of the type of neoplasm or site of metastasis, spread of an internal malignancy to the skin carries a poor prognosis.

## PAPULOSQUAMOUS ERUPTIONS

Method of

Tam T. Nguyen, MD

### CURRENT DIAGNOSIS

- Psoriasis can be clinically described as erythematous plaques with silvery white scales.
- Severity is rated as mild (< 5% body surface area [BSA]), moderate (5%–10% BSA), or severe (>10% BSA).
- Most cases are mild chronic plaques involving the extensor surfaces.
- Involvement of scalp and palmar and plantar surfaces is classified as severe.
- Psoriasis is commonly comorbid with several conditions, including cardiovascular disease, depression, and metabolic disorders.

### CURRENT THERAPY

- Class I/II (super-potent) topical steroid is the mainstream treatment of mild to moderate psoriasis.
- For moderate to severe cases, systemic treatment with methotrexate is the gold standard.
- Narrowband ultraviolet B (UVB) remains a safe treatment option for all patients including children and pregnant women.
- Several immunomodulators or biologicals including etanercept (Enbrel) have been proved very effective therapy. Biologicals can be given as monotherapy or in combination with other modalities for very recalcitrant cases.
- Treatment of comorbid conditions is paramount.

### Epidemiology

Psoriasis, a common chronic idiopathic inflammatory disorder, affects 2% to 3% of Americans. The number of persons affected by this condition has more than doubled from 1970 to 2000. It is a chronic disorder that can involve many organ systems including skin, mucosa, the gastrointestinal tract, and joints. Although the onset of psoriasis can occur at any age, there is a bimodal distribution peaking in young adults in their early 20s and again in persons in their 50s. There is an equal prevalence among male and female patients, but the incidence is higher in men among younger adult populations.

### Risk Factors

There is a strong family history and association with HLA-Cw6, HLA-B13, and HLA-B27. Psoriatic genes appear to be located on four key genes called pSOR1-4, which show an autosomal dominant pattern. There are about 36 gene loci associated with psoriasis. The genome-wide association study (GWAS) showed that the genes STAT3 and STAT5 regulate the cytokines associated with psoriasis. In addition to the genetic etiology, environmental triggers, such as drugs, infection, and stress, also have a role in the pathogenesis of the psoriasis. Psychogenic stress from home and school is especially common in pediatric cases. Lithium and  $\beta$ -blockers are two well-known triggers of psoriasis. Certain conditions, such as Crohn's disease and multiple sclerosis, predispose patients to developing psoriasis.

### Pathophysiology

Even though the exact mechanism is unknown, psoriasis is a disease of T cells that leads to abnormal epidermal differentiation and hyperproliferation. Normal skin has epidermal turnover of about 21 to 28 days, but psoriatic skin turns over every 3 to 4

days. Several cytokines, including IL-12 and IL-23, are part of the immune-mediated disease.

### Diagnosis

Although most psoriatic lesions have characteristic scaly and silvery plaques, the lesions can be misleading. Refer to [Box 1](#) for the differential diagnosis. Psoriasis has several subtypes including erythrodermic, pustular, and vulgaris. Psoriasis vulgaris has several subtypes including chronic plaque, guttate ([Figure 1](#)), and inverse psoriasis. More than 80% to 90% of psoriasis cases are the chronic plaque psoriasis. Therefore this chapter focuses on this subtype.

Severity of psoriasis is classified based on the body surface area (BSA) involved. There are several severity instruments, such as Koo-Menter Psoriasis, for assessing the severity. One of the best validated tools is the Psoriasis Area Severity Index (PASI). These instruments are used to classify the condition according to coverage of body surface area (BSA) as either mild (< 5% of BSA), moderate (5%–10% of BSA), or severe (>10% of BSA). BSA can be estimated using the rule of 9s. Each upper extremity and the head is 9%, and the chest, back, and each lower extremity are 18%. For children, similar rules apply, except that each lower extremity is 13.5%. When the lesions involve difficult regions such as hands, feet, face, scalp, and genitalia, they are treated as severe regardless of the amount of BSA they cover.

Fortunately, more than 70% to 75% of cases are classified as mild to moderate, and there is no need for blood work. However, when psoriasis is associated with comorbidities, such as depression and heart disease, or when systemic medications cause serious side effects, it may be reasonable to get basic laboratory tests such as a complete blood count with platelet (CBC), chemistry, liver function tests (LFTs), cholesterol panel, hepatitis B and C, uric acid, and erythrocyte sedimentation rate (ESR). For patients at high risk, consider HIV testing. Also, consider evaluating for tuberculosis with a PPD test. These laboratory tests are even more crucial when considering treating with immunosuppressants like methotrexate (Trexall) and biological agents. Liver biopsy should be done if methotrexate is used at a cumulative dose of 3.5 to 4g. Equally important, patients' quality of life needs to be assessed, which can be done with an instrument called the Dermatology Life Quality Index (DLQI).

### Differential Diagnosis

The differential diagnosis of psoriasis is lengthy and can be tricky. [Box 1](#) lists the differential diagnosis of psoriasis.

### Clinical Manifestations

Most presentations of psoriasis are asymptomatic. When symptomatic, the most common clinical manifestation is pruritus. Other possible symptoms include fever and malaise, especially for more extensive disease. When psoriasis involves the joints, patients can have pain and stiffness in the involved joints; many of these cases involve the distal interphalangeal joints. On physical examination, the lesions are well-circumscribed dark pink to red plaques with silvery to white scales ([Figures 2 and 3](#)). Scales can be absent in certain locations, such as the intertriginous area (gluteal folds) ([Figures 4 and 5](#)). The margins are sharp and distinct, especially over extensor surfaces such as the elbows and knees (see [Figure 2](#)). Lesions also can involve the sacral area, nails, scalp, and the genitalia. If psoriasis forms under a nail, onycholysis (lifting of the nail plate) can occur with pitting and subungual keratosis.

When the scales are removed, several distinctive minute blood droplets appear, called the Auspitz sign. Use caution when removing the scales because it can be painful. When new lesions form at a site of trauma, it is called the Koebner phenomenon. Diagnosis can be made clinically. However, when in doubt, biopsy the lesion, which will show a thickened epidermis with an absent granular cell layer. The stratum corneum is hyperkeratotic, with classic infiltration of neutrophils.

## BOX 1 Differential Diagnosis of Psoriasis

### Plaque-like

Eczema  
Fungal infection  
Squamous cell carcinoma  
Subacute cutaneous lupus erythematosus

### Guttate

Secondary syphilis  
Pityriasis rosea

### Erythrodermic

Pityriasis rubra pilaris  
Drug eruptions

### Pustular

Candidiasis  
Acute generalized exanthematic pustulosis

### Inverse

Intertrigo  
Cutaneous T-cell lymphoma

**Figure 1** Guttate psoriasis with droplike, discrete papules and small plaques with scales.

If this inflammatory process affects the joints, psoriatic arthritis ensues. Although this article does not discuss psoriatic arthritis, it is important to recognize when it occurs. Unlike rheumatoid arthritis, the distal interphalangeal (DIP) joints are regularly involved, but it can affect any joints. Psoriatic arthritis only occurs in 4% to 42% of patients with psoriasis. Diagnosis can be made with the CASPAR criteria, which evaluates five possible presentations, including having psoriasis, nail dystrophy, negative rheumatoid factor, dactylitis, and radiographic evidence.

### Treatment

Corticosteroids remain the mainstay for psoriasis therapy; they reduce inflammation, decrease mitosis, and reduce erythema. Because most cases are mild to moderate, the first-line therapy to consider is topical corticosteroids. Even for severe cases that require systemic treatment, topical steroids should still be considered as a first-line adjuvant therapy. Because psoriatic lesions are thickened, it is critical to go directly to super-potent steroids (class I), such as clobetasol (Clobex) (refer to [Box 2](#) for steroid potency). When the localized lesions are lichenified and do not respond to potent topical corticosteroids, using steroid-impregnated tapes (flurandrenolide tape [Cordran]), which function as an occlusive wrap, can help. However, for areas of thinner skin, such as mucosa and lesions on the face, use less-potent topical steroids. Use caution when using class 1 steroids owing to all the potential side effects, including skin atrophy, hypopigmenta

**Figure 2** Chronic plaque psoriasis on the extensor surfaces.

**Figure 3** Chronic plaque psoriasis with classic silvery scales.

**Figure 4** Chronic plaque psoriasis with limited scales.

**Figure 5** Chronic plaque psoriasis without scales.

tion, telangiectasis, striae, and potential systemic absorption. In addition to the possible side effects, tachyphylaxis (reduced efficacy with prolonged use) can occur. Therefore it is crucial to limit the use of potent topical steroids to less than 12 weeks.

One way to reduce the use of topical steroids is by using the vitamin D<sub>3</sub> analogue class, such as calcipotriene (Dovonex). This class of drugs inhibits epidermal proliferation and stimulates cellular differentiation. It is considered as effective as medium-potency corticosteroids, without the side effects. However, one drawback is that it takes about 8 weeks to be effective. Therefore it should not be used for acute psoriatic eruptions. More often it is used in combination with topical steroids, since topical calcipotriene in combination with high dose topical steroids like betamethasone (Enstilar) works better than either alone. It is generally well tolerated topically, but about 10% of patients experience burning and itching or hypercalcemia.

Other topical applications include tazarotene (Tazorac) and anthralin (Dritho-Crème HP 1%, Dritho-Scalp 0.5%). Tazarotene is an acetylenic retinoid and can be as effective as high-potency topical corticosteroids. However, its use is limited owing to the side effects of erythema, burning, pruritus, and peeling. Therefore it is best to combine it with corticosteroids to reduce the irritation. In addition, tazarotene can stain clothing, and it is less popular owing to the side effects (redness and irritation on skin as well as staining) and the feel and smell of the solutions. However, it is a good alternative to topical corticosteroids.

For a limited number of thickened lesions, consider intralesional steroid injections, such as a single intralesional injection of a mid-potency steroid (e.g., triamcinolone acetonide or Kenalog-10, 5–10 mg/mL). Most injected plaques clear completely and remain in remission for months. However, as with other steroid injections, side effects of skin atrophy and telangiectasis can occur. Therefore the face and intertriginous areas should not be injected because of the increased risk of side effects.

For severe and recalcitrant cases, systematic medications are needed. One of the gold standards in the United States and many other countries is methotrexate (Trexall) because it is available as a generic. Its exact mechanism is unknown; initially it was believed to inhibit proliferation, but more-recent studies describe an

**BOX 2** Classification of Topical Steroids, With a Few Samples From Each Class

**Class 1: Super Potent**

Clobex lotion 0.05%, clobetasol propionate  
Cormax cream or solution, 0.05%, clobetasol propionate  
Diprolene gel or ointment, 0.05%, bethamethasone dipropionate  
Olux foam, 0.05%, clobetasol propionate

**Class 2: Potent**

Elocon ointment, 0.1%, mometasone furoate  
Florone ointment, 0.05%, diflorasone diacetate  
Halog ointment/cream, 0.1%, halcinonide  
Lidex cream, gel, ointment, 0.05%, fluocinonide

**Class 3: Upper Mid-Strength**

Cutivate ointment, 0.005%, fluticasone propionate  
Cyclocort cream/lotion, 0.1%, amcinonide  
Lidex-E cream, 0.05%, fluocinonide  
Maxivate cream/lotion, 0.05%, betamethasone dipropionate  
Valisone ointment, 0.1%, betamethasone valerate

**Class 4: Mid-Strength**

Aristocort cream, 0.1%, triamcinolone acetonide  
Cordran ointment, 0.05%, flurandrenolide  
Elocon cream, 0.1%, mometasone furoate  
Kenalog cream, ointment, spray, 0.1%, triamcinolone acetonide

**Class 5: Lower Mid-Strength**

DesOwen ointment, 0.05%, desonide  
Diprosone lotion, 0.1%, betamethasone dipropionate  
Kenalog lotion, 0.1%, triamcinolone acetonide  
Synalar cream, 0.025%, fluocinolone acetonide

**Class 6: Mild**

Derma-Smoothe/FS Oil, 0.01%, fluocinolone acetonide  
DesOwen cream, 0.05%, desonide  
Synalar cream/solution, 0.01%, fluocinolone acetonide  
Tridesilon cream, 0.05%, desonide

**Class 7: Least Potent**

Topicals with hydrocortisone, dexamethasone<sup>6</sup>, methylprednisolone<sup>6</sup>, and prednisolone<sup>6</sup>

<sup>6</sup>May be compounded by pharmacists.

antiinflammatory property. The most common serious side effect of this drug is hepatotoxicity (as many as 33% of patients show some liver disease). Therefore it is crucial to screen for alcohol dependency, liver disease, and obesity. Standard practice is to check baseline CBC and liver function enzymes, and then repeat these laboratory tests after 1 month of therapy. Methotrexate is highly teratogenic; hence it is absolutely contraindicated in pregnancy. After stopping the medication, men should wait at least 3 months and women should wait one ovulatory cycle before attempting to conceive.

There are two methods for initiating methotrexate. Most patients start at an initial dose of 7.5mg (3 tabs of 2.5mg) weekly; in pediatric cases dosage<sup>1</sup> is 0.2 to 0.7 mg/kg weekly. Others start at a higher dosage of 0.4 to 0.5 mg/kg weekly. Unfortunately, there is no current study to compare the two methods. With either dosing regimen, do not exceed 30 mg per week. Methotrexate depletes the body's storage of folic acid, so it is important to supplement folic acid 1mg daily except the day when methotrexate is taken. The methotrexate can be titrated upward every 2 to 4 weeks.

Unlike methotrexate, which can take several weeks before it becomes effective, cyclosporine (Neoral), a calcineurin inhibitor, is rapidly effective for severe cases. It is dosed at a low dose of 2 to 5 mg/kg/day divided into two doses and increased slowly every

<sup>1</sup>Not FDA approved for this indication.

**BOX 3** Other Treatment Modalities for Moderate to Severe Psoriasis

Fumaric acid esters<sup>2</sup>: First-line therapy in a couple of European countries  
 Hydroxyurea (Hydrea)<sup>1</sup>: A good option because there is no liver or kidney toxicity; however, be cautious of bone marrow suppression  
 Leflunomide (Arava)<sup>1</sup>  
 Mycophenolate mofetil (Cellcept)<sup>1</sup>: good choice for HIV patients and patients with immunobullous disorders  
 Retinoic acid metabolism–blocking agents: liarozole<sup>2</sup> and talarozole (Rombozale)<sup>5</sup>  
 Alitretinoin topical (Panretin)<sup>1</sup>  
 Sulfasalazine (Azulfidine)<sup>1</sup>  
 Tacrolimus (Prograf)<sup>1</sup>  
 6 thioguanine (Tabloid)<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.<sup>2</sup>Not available in the United States.<sup>5</sup>Investigational drug in the United States.

2 to 4 weeks. Maintenance dosage is about 3 to 5 mg/kg/day. A main concern for this drug is nephrotoxicity. As long as the use of cyclosporine is limited to 1 year, it is generally safe. However, kidney function still needs to be monitored regularly. Cyclosporine has been associated with an increased risk of squamous cell carcinoma, especially when the patient has a history of psoralen plus ultraviolet A (PUVA) therapy.

Although not FDA-approved, azathioprine (Imuran) has been a successful systemic medication for psoriasis. Generally, it is initially dosed at 0.5 mg/kg. If there is cytopenia, then the dosage can be increased by 0.5 mg/kg/day every 4 to 6 weeks as needed. Another dosing method is based on thiopurine methyltransferase (TPMT) levels. If the TPMT is less than 5.0 U, do not use azathioprine. If the level is between 5 and 13.7 U, the maximum daily dose should be 0.5 mg/kg/daily. If the TPMT level is between 13.7 and 19.0 U, then the maximum daily dose may be increased to 1.5 mg/kg. There is only one FDA-approved phosphodiesterase type-4 inhibitor (PDE4), apremilast (Otezla). Taken orally twice a day, this drug inhibits PDE4 leading to increased intracellular cAMP levels.

Acitretin (Soriatane) and isotretinoin (Claravis)<sup>1</sup> are retinoids, which are vitamin A derivatives. Although acitretin is more commonly used, either may be used and requires a period of 3 to 6 months to achieve results. However, these retinoids are generally less effective than methotrexate and cyclosporine. Though they are less effective and a longer time is required for this class of agents to work, their main benefits include no malignancy potential and no immunosuppression. Therefore these drugs are safe in patients with HIV and other immunosuppressive conditions. Unfortunately, acitretin and isotretinoin are highly teratogenic. Both male and female patients need to be drug free for 1 year for isotretinoin and 3 years for acitretin before they conceive. For other possible treatment agents, refer to [Box 3](#).

In recent years, immunomodulators or biologicals have revolutionized the treatment course of psoriasis. Generally, criteria for this class of therapy are PASI greater than 10 and failure of other therapies or a contraindication to other therapies such as methotrexate. Most agents are limited to 1 to 2 years of use because most studies have not been evaluated beyond 2 years. Tuberculosis should be evaluated (PPD and possibly chest x-ray) before starting these biologicals. All the medications in this class should be avoided in pregnancy. Alefacept (Amevive)<sup>2</sup> and efalizumab (Raptiva) are T-cell inhibitors. Efalizumab (Raptiva) was withdrawn from the market in 2009 owing to reported cases of progressive multifocal leukoencephalopathy. Another class is tumor necrosis factor (TNF).

<sup>1</sup>Not FDA approved for this indication.<sup>2</sup>Not available in the United States.

Etanercept (Enbrel), one of the first TNF inhibitors, should not be used in patients with multiple sclerosis. Four monoclonal antibodies include infliximab (Remicade), adalimumab (Humira), certolizumab (Cimzia), and golimumab (Simponi)<sup>1</sup>, and all are TNF inhibitors. In recent years, a new class of biologics that inhibit interleukin (IL)-12 and IL-23 has shown promising results. Ustekinumab (Stelara) was first approved within this class, followed by guselkumab (Tremfya), tildrakizumab (Ilumya), and risankizumab (Skyrizi) in 2019 and mirikizumab in 2020. Secukinumab (Cosentyx), a new biological for plaque psoriasis is a recombinant, high-affinity, fully humanized IgG monoclonal antibody that selectively binds and neutralizes interleukin-17A (IL-17A). Additional three IL-17A inhibitors, ixekizumab bimekizumab, (Taltz) bimekizumab, and brodalumab (Siliq), have been approved for use. Currently, bimekizumab and mirikizumab are investigational drugs in the US.

Etanercept (Enbrel) blocks TNF- $\alpha$ . It is generally dosed at 50mg SC twice weekly for 12 weeks and then 50mg weekly. Patients can self-administer the drug; laboratory monitoring is not required. There are limited data beyond 2 years. Etanercept is the preferred drug for children. Infliximab (Remicade) blocks both soluble and bound TNF- $\alpha$ . Its dosage is 3 to 5 mg/kg IV on weeks 0, 2, and 6, and then every 6 to 8 weeks. Medication generally is infused over 2 hours. It is approved for 1 year. In a comparative study, infliximab was found to be superior to methotrexate. TNF does not appear to increase the risk of herpes zoster but could be associated with an increase in melanoma.

Adalimumab (Humira) blocks both soluble and bound TNF- $\alpha$ . Initiate the dose at 40mg SC every 2 weeks, although some patients require dosing every 7 to 10 days. Alternatively, the initial dose may be 80mg followed by 40mg. Patients may self-administer the injections. As with infliximab, before initiating treatment, obtain a PPD (and consider chest x-ray as well). Antibodies can develop within the first 28 weeks, which will decrease the efficacy of the drug. Both infliximab, which has been in use for many years, and adalimumab have limited long-term safety data beyond 1 year. Some data suggest an increase in cancer risk beyond 1 year. Adalimumab is FDA approved for psoriatic arthritis.

Alefacept (Amevive)<sup>2</sup>, a T-cell inhibitor, is dosed at 15mg IM or IV once a week for 12 weeks. Its efficacy follows the rule of thirds: It works well in about one-third of cases, does not work at all in one-third of cases, and the rest fall in between. After a cycle of 12 weeks, the courses may be repeated as needed. However, it is crucial initially to monitor T-cell counts biweekly. A newer agent, ustekinumab (Stelara), has been shown to improve lesions in 66% to 76% of cases. It is initially dosed at 45 to 90mg SC at weeks 0 and 4, depending on body weight. Maintenance is every 12 weeks. Besides ustekinumab, another IL-12/IL-23 inhibitor, guselkumab (Tremfya), was approved in 2017 and is dosed at 100 mg/mL SC in weeks 0 and 4, then every 8 weeks.

When these therapies are contraindicated, one alternative is phototherapy. This is the reason many patients report decreased symptom severity during the summer months due to the natural UV light. Phototherapy started with photochemotherapy with oral or topical psoralens combined with UVA light (PUVA). Although phototherapy is very effective for psoriasis, even in very thick lesions, recent studies have shown an increased risk of skin cancer. Therefore PUVA has become less popular since the advent of UVB radiation treatment, especially with narrow-band UVB (NB-UVB). NB-UVB is equally effective as PUVA and does not have the risk of skin cancer. The exact mechanism is unknown, but it is believed to affect DNA and to suppress IL-17 and IL-23, creating photoproducts that interfere with cell cycle progression. NB-UVB is first-line course of therapy for pregnant and pediatric patients. There are two methods for initiating NB-UVB phototherapy: the skin type protocol, which is easier to execute; and the minimum erythema dose (MED), which is more detailed but more accurate. Refer to [Table 1](#) for treatment protocols. Both protocols generally require 30 to 35 treatments with the optimal frequency of three times a week.

<sup>1</sup>Not FDA approved for this indication.<sup>2</sup>Not available in the United States.

**TABLE 1** Methods for Initiating Narrow-Band Ultraviolet B (NB-UVB) Therapy and Subsequent Dosing of Phototherapy

THERAPY	MED NB-UVB PROTOCOL						MED NB-UVB PROTOCOL
	TYPE 1	TYPE 2	TYPE 3	TYPE 4	TYPE 5	TYPE 6	
Initial dose	130 mJ/cm <sup>2</sup>	220 mJ/cm <sup>2</sup>	260 mJ/cm <sup>2</sup>	330 mJ/cm <sup>2</sup>	350 mJ/cm <sup>2</sup>	400 mJ/cm <sup>2</sup>	Start with 50%–70% MED The starting dose should be based on the provider's comfort and the patient's history of response to light; e.g., start closer to 70% if the patient has a history of tanning and start closer to 50% if the patient has a history of burning; most centers start at 70%
<b>SUBSEQUENT DOSES</b>							
Severe erythema	No treatment. When burn resolves, decrease by 50% of last dose and then increase dose by 10%						
Mild erythema	Same dose	Same dose	Same dose	Same dose	Same dose	Same dose	Decrease dose by 20%
Barely perceptible erythema	—	—	—	—	—	—	Same (erythmogenic) or slight decrease (suberythmogenic)
No erythema: increase dose by	15 mJ/cm <sup>2</sup>	25 mJ/cm <sup>2</sup>	40 mJ/cm <sup>2</sup>	45 mJ/cm <sup>2</sup>	60 mJ/cm <sup>2</sup>	65 mJ/cm <sup>2</sup>	20%
<b>DOSING SCHEDULE</b>							
Optimal schedule	3 ×/wk (M, W, F) is the optimal schedule because less is not as effective and more does not improve the resolution. Subsequent treatments should not be less than 24 hours from the last treatment. For the treatment of eczema, no clear guideline to the frequency. Some use 5 ×/wk.						
<b>DOSE ADJUSTMENTS FOR MISSED DAYS</b>							
	MISSED DAYS			DOSE ADJUSTMENT			
1–7				Increase doses per skin type			
8–11				Same dose			
12–14				Decrease by 2 treatments' worth			
15–20				Decrease by 25%			
21–27				Decrease by 50%			
28 +				Start over			

Given all the treatment options (refer to [Box 4](#)), the choice of the treatment regimen depends on several factors. First, the severity of the psoriasis must be determined as well as the social and emotional impact of the condition. Another consideration is financial, including the insurance coverage, copayment, and deductibles. The lowest-cost treatment is methotrexate, and alefacept is the highest. The patient's conveniences and preferences should be discussed. If the severity is only mild to moderate without much emotional impact, topical steroid and vitamin D analogue should be considered the first options. Other topicals include tar (Balnetar, Psoriasis, Scytera), anthralin (Dritho-Crème HP, Dritho-Scalp), and tretinoin (Retin-A)<sup>1</sup>. If the degree is severe and/or the patient has emotional impact, systemic medications should be used. Most insurance plans will probably require that the patient try at least one oral medication before employing the biologicals. If systemic therapy is used, consider combining it with phototherapy (if possible). If there is no improvement within 2 to 4 months, the regimen should be changed to biologicals. Other combinations may be employed for better resolution.

For healthy patients, any of these therapies may be tried. Unfortunately, there are limitations with children, pregnant women, and patients trying to conceive. For pediatric patients, topical agents should be tried first, followed by UVB monotherapy. If the plaques are still recalcitrant, add either methotrexate (Trexall) or phototherapy. If phototherapy is not available and topical agents have failed, consider using methotrexate or cyclosporine (Neoral). Other options for pediatric patients include adalimumab (Humira) and etanercept (Enbrel). For pregnant women and patients trying to conceive, first try topical agents followed by UVB (ideally narrowband). This combination remains the safest option. If stronger options are needed, the only class B drugs are systemic steroids, adalimumab (Humira), alefacept (Amevive)<sup>2</sup>, infliximab (Remicade), and ustekinumab (Stelara). An absolute contraindication in this population is the retinoid class, such as isotretinoin (Claravis)<sup>1</sup> and acitretin (Soriatane).

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

**Complications**

Patients suffering from psoriasis cope with the physical appearance of their lesions as well as the associated mental anguish associated with many other chronic ailments. Furthermore, psoriasis is associated with other chronic diseases, such as abdominal obesity, metabolic syndrome, and atherogenic dyslipidemia. Weight loss can improve the appearance of psoriatic plaques. Patients with psoriasis are more likely to have coronary artery disease, elevated blood pressure, obesity, and insulin resistance. Treating psoriasis decreases the cardiovascular risks. There is an increased risk of malignancy, such as lymphoma. Substance abuse and smoking are common among these patients as well.

**PARASITIC DISEASES OF THE SKIN**
*Method of*

Andreas Katsambas, MD, PhD; and Clio Dessinioti, MD, MSc, PhD

**CURRENT DIAGNOSIS**
**Cutaneous Amebiasis**

- Purulent, foul-smelling nodules, ulcers, cysts, sinuses
- Microscopic identification of *Entamoeba histolytica* in stool or biopsy samples
- Molecular methods

**Cutaneous Leishmaniasis**

- Ulcerated nodule (i.e., volcano sign)
- Identification of *Leishmania* parasites by direct examination or culture from the lesion aspirate or biopsy
- Montenegro skin test
- In vitro lymphocyte proliferation assay
- Polymerase chain reaction

**Trypanosomiasis**
**Chagas' Disease**

- Chagoma: painful erythematous nodule
- Regional adenopathy
- Cardiomyopathy, megaesophagus, megacolon
- Microscopic examination of *Trypanosoma cruzi* in blood, lymph node biopsy, or skin biopsy or culture

**African Sleeping Sickness**

- Trypanosome chancre: painful, inflammatory nodule
- Regional adenopathy
- Fever, generalized pruritic eruption with erythematous annular plaques
- Central nervous system involvement
- Microscopic identification of *Trypanosoma brucei* in chancre fluid, lymph node aspirates, blood, bone marrow, cerebrospinal fluid

**Cutaneous Toxoplasmosis**

- Roseola, urticaria, prurigo-like nodules
- Isolation of *Toxoplasma gondii* in the skin

**Ascariasis**

- Urticaria
- Identification of adult worm or eggs in stool

**Cutaneous Larva Migrans**

- Creeping eruption
- Intense pruritus

**Cysticercosis**

- Subcutaneous nodules
- Isolation of *Taenia solium* in skin lesion
- Serologic tests

### Dracunculiasis

- Ruptured blister with prolapsing worm

### Filariasis

#### Lymphatic Filariasis

- Fever with lymphangitis and lymphadenitis
- Chronic pulmonary infection
- Progressive lymphedema leading to massive tissue thickening, especially of the legs and scrotum (i.e., elephantiasis)
- Microscopic identification of microfilariae in blood

#### Onchocerciasis (River Blindness)

- Subcutaneous nodules, dermatitis, "leopard skin," "lizard skin," lymphedema
- Identification of microfilariae in skin snips
- Blindness

#### Loiasis (Calabar Swellings)

- Pruritus, localized subcutaneous swellings
- Serpiginous lesion on the conjunctivae
- Microscopic identification of microfilariae in blood

#### Schistosomiasis (Snail Fever)

- Pruritic papules, edema
- Fever, lymphadenopathy, diarrhea
- Bilharziasis cutanea tarda: pruritic, grouped papules
- Identification of the eggs in stool, urine, biopsy of affected tissues
- Enzyme-linked immunosorbent assay (ELISA) tests

#### Cercarial Dermatitis (Swimmer's Itch)

- Extremely pruritic erythematous macules, papules, vesicles on body areas exposed to infested water

#### Human Scabies

- Pruritus worsening at night
- Papules, excoriations, nodules, burrows on genitals, interdigital spaces, axillae, wrists
- Microscopic identification of mites or eggs or feces from burrows or papules

#### Pediculosis

##### Pediculosis Capitis

- Intense pruritus of the scalp
- Nape dermatitis
- Identification of lice and nits on the hair

##### Pediculosis Corporis (Vagabond's Itch)

- Intense pruritus, erythema, urticarial lesions, papules, nodules, and excoriations
- Identification of lice and nits on clothing

##### Pediculosis Pubis

- Pruritus
- Blue macules
- Identification of lice and nits on pubic hair

## CURRENT THERAPY

#### Cutaneous Amebiasis

- Metronidazole (Flagyl) 750 mg PO three times daily for 7 to 10 days, or
- Tinidazole (Tindamax) 2 g once PO daily for 5 days, followed by iodoquinol (Aloquin) 650 mg PO three times daily for 20 days or paromomycin (Humatin) 25 to 35 mg/kg/day PO in three doses for 7 days

#### Cutaneous Leishmaniasis

- Preparations of pentavalent antimony are sodium stibogluconate (Pentostam)<sup>10</sup> or
- Meglumine antimoniate (Glucantime).<sup>2</sup> Dose of pentavalent antimonium: 20 mg/kg/day IV or IM for 20 days, or

- Miltefosine (Impavido) (FDA-approved), for persons 12 years of age and older who weigh at least 45 kg: 150 mg/day for 28 days, or
- Topical paromomycin<sup>2</sup> applied twice daily for 10 days or
- Cryotherapy, topical 5-ALA PDT, intralesional antimonial regimens

#### Trypanosomiasis

##### Chagas' Disease (American Trypanosomiasis)

- Nifurtimox (Lampit)<sup>10</sup> 8 to 10 mg/kg/day PO in three doses for 60 days, or
- Benznidazole (Radanil, Rochagan)<sup>10</sup> 5 to 7 mg/kg/day PO in two doses for 60 days

##### East African Sleeping Sickness

- Suramin (Germanin)<sup>10</sup> 4 to 5 mg/kg (day 0) (test dose) IV, then 20 mg/kg IV (max 1 gm/injection) on days 1, 3, 7, 14, 21
- For second stage, melarsoprol (Mel-B)<sup>10</sup> 2.2 mg/kg/day (max 180–200 mg/day) IV for 10 days.

##### West African Sleeping Sickness

- Pentamidine<sup>1</sup> 4 mg/kg/day IM or IV for 7 days
- For second stage *T. b. gambiense*, NECT combination therapy: For adults, Nifurtimox<sup>1,10</sup> 15 mg/kg/day orally in 3 doses for 10 days, and eflornithine<sup>2</sup> 400 mg/kg/day IV in 2 infusions for 7 days

#### Cutaneous Toxoplasmosis

- Self-limited disease; treatment not needed in healthy, non-pregnant persons

#### Ascariasis

- Albendazole (Albenza)<sup>1</sup> 400 mg PO once, or
- Mebendazole (Vermox) 100 mg PO twice daily for 3 days or 500 mg once, or
- Ivermectin (Stromectol)<sup>1</sup> 150 to 200 µg/kg PO once

#### Cutaneous Larva Migrans

- Self-limiting skin disease. Albendazole or ivermectin may be used off-label, if needed.

#### Filariasis

##### Lymphatic Filariasis

- Diethylcarbamazine (DEC, Hetrazan)<sup>10</sup> 6 mg/kg/day PO as a 1 day or 12 day treatment course. DEC is contraindicated in some patients, and consultation with a tropical medicine specialist is recommended.

##### Onchocerciasis

- Ivermectin (Stromectol) 150 µg/kg PO once for 6 months
- Patients with Loa loa co-infections should not be treated for onchocerciasis without consulting an expert on loiasis.

#### Schistosomiasis

- Praziquantel (Biltricide) 40 mg/kg/day in two divided doses for 1 day (*S. haematobium* and *S. mansoni*) and 60 mg/kg/day in three divided doses for 1 day (*S. japonicum*, *S. mekongi*)

#### Human Scabies

- Permethrin (Acticin, Elimite) 5% cream rinse, applied for 10 hours head to toe; a second application 7 to 10 days later, or
- Benzyl benzoate<sup>1,6</sup> 10% to 25% solution<sup>6</sup> applied once daily at night on 2 consecutive days with re-application at 7 days. or
- Sulfur<sup>1,6</sup> 6% to 30% ointment in petrolatum,<sup>6</sup> or as cream or lotion, applied on three successive days.
- Ivermectin (Stromectol)<sup>1</sup> 200 µg/kg PO as 2 doses taken 1 week apart.

#### Pediculosis

##### Pediculosis Capitis

- Malathion (Ovide) 0.5% lotion, applied for 8 to 12 hours before being washed off; approved for children older than 6 years, or

- Permethrin (Nix) 1% lotion, applied to shampooed hair and washed off after 10 minutes; second application 7 to 10 days later; approved for children older than 2 years
- Pyrethrins with piperidyl butoxide (RID) applied for 10 minutes
- Benzyl benzoate 25% solution<sup>1,6</sup>
- Lindane shampoo: for recalcitrant disease, associated with serious reactions not to be used in children
- Ivermectin 0.5% lotion (Sklice), apply to dry hair and scalp then rinse off after 10 minutes

#### **Pediculosis Corporis**

- Disinfection of clothes

#### **Pediculosis Pubis**

- Same treatment as pediculosis capitis: three times daily

<sup>b</sup>All doses are recommended for adults unless otherwise indicated. Note that contraindications of treatments may apply for children and for women during pregnancy and lactation.

<sup>1</sup>Not available in the United States.

<sup>2</sup>Not available in the United States.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>6</sup>May be compounded by pharmacists

<sup>10</sup>Available in the United States from the Centers for Disease Control and Prevention.

Parasitic diseases are a common cause of morbidity and mortality, particularly in tropical and developing countries. They may be caused by protozoa, helminths, or arthropods. Because of the immigration of persons from tropical and subtropical countries worldwide and the travel of people from industrialized to tropical regions, parasitic diseases may be found in temperate climates. Skin lesions may provide important diagnostic clues for parasitic infections, and they are reviewed in the following sections, along with updated treatment guidelines.

## **Diseases Caused by Protozoa**

### **Cutaneous Amebiasis**

Intestinal amebiasis is caused by *Entamoeba histolytica*, which may rarely invade the skin and cause cutaneous amebiasis. The disease is transmitted by ingestion of food or water contaminated with cyst forms of the parasite and through fecal exposure during sexual contact.

Cutaneous amebiasis develops at the site of the invasion of the parasites into the skin from an underlying amebic abscess, usually at the perianal area or the abdominal wall. Cutaneous findings include purulent, foul-smelling nodules, cysts, and sinuses, which are associated with regional adenopathy and dysentery. Skin lesions grow rapidly and may lead to death if left untreated.

Diagnosis of cutaneous amebiasis is confirmed by microscopic identification of *E. histolytica* in the stool and in aspirates or biopsy samples obtained during colonoscopy, during surgery, or from the border of an ulcer. Treatment of choice for extraintestinal amebiasis is oral metronidazole (Flagyl) 750 mg PO three times daily for 7 to 10 days or tinidazole (Tindamax). Tinidazole was FDA approved in 2004 for the treatment of intestinal amebiasis in adults (2 g/day for 3 days) and children older than 3 years, and it appears to be as effective as, and better tolerated than, metronidazole. Either treatment should be followed by iodoquinol (Aloquin) 650 mg PO three times daily for 20 days or paromomycin 25 to 35 mg/kg/day PO divided in three doses for 7 days.

### **Leishmaniasis**

Leishmaniasis results from the infection with intracellular protozoan parasites belonging to the genus *Leishmania*. Leishmania parasites are transmitted to humans and other mammalian hosts (e.g., dogs, rodents) during feeding by infected female phlebotomine sandflies that serve as vectors. The parasites exist as promastigotes in the midgut of sandflies and as amastigotes (i.e., Leishman-Donovan bodies) within macrophages of humans and other mammals. Based on the extent and the severity of involvement in the human host, leishmaniasis may be clinically classified

as cutaneous leishmaniasis, diffuse cutaneous leishmaniasis, mucocutaneous leishmaniasis, and visceral leishmaniasis.

Cutaneous leishmaniasis (New World or Old World form) begins as a small erythematous papule at the site of the bite of the sandfly, which evolves into an ulcerated nodule with a raised and indurated border (i.e., volcano sign) (Figure 1). The lesions gradually heal with a depressed scar. Diffuse cutaneous leishmaniasis is characterized by widespread cutaneous involvement without visceralization. Mucocutaneous leishmaniasis (known as espundia in South America) affects the skin, the mucosa, and the cartilages of the upper respiratory tract (especially the nose and the larynx) and may result in severe disfigurement. Visceral leishmaniasis results from the involvement of the bone marrow, spleen, and the liver, and it may lead to death if left untreated. It manifests with fever, splenomegaly, pancytopenia, and wasting. Post-kala azar dermal leishmaniasis may appear within a year after visceral disease independent of treatment, and it is characterized by macules, papules, and nodules, which are usually hypopigmented.

Diagnosis of leishmaniasis is based on finding the parasites in the skin from the lesion aspirate or biopsy by direct examination or culture. The leishmanin (Montenegro) skin test shows past and current infections, and it detects the inflammatory response in the skin after injection of phenol-killed parasites into the dermis. A past or current infection is also documented by an in vitro lymphocyte proliferation assay that requires a drop of blood from a finger prick. Polymerase chain reaction (PCR) techniques may be used to identify different *Leishmania* species. Circulating antibody levels are not considered a useful diagnostic sign.

Cutaneous leishmaniasis is usually self-limited and may not require treatment. Treatment of cutaneous leishmaniasis is indicated in case of numerous lesions or when lesions affect the face to avoid scarring. Therapies include the preparations of pentavalent antimony, such as sodium stibogluconate (Pentostam)<sup>10</sup> 20 mg/kg/day IV or IM for 20 days. Meglumine antimoniate (Glucantime)<sup>2</sup> 20 mg/kg/day IV or IM for 20 days or miltefosine (Impavido) for 28 days may be used. In 2014, FDA approved oral miltefosine for the treatment of cutaneous leishmaniasis caused by *L. braziliensis*, *L. paramensis*, and *L. guyanensis* in adults and adolescents who are not pregnant or breastfeeding. The FDA-approved treatment regimen for persons 12 years of age and older who weigh from 30 to 44 kg is one 50-mg oral capsule of miltefosine twice a day (total of 100 mg per day) for 28 consecutive days. The approved regimen for persons 12 years of age and older who weigh at least 45 kg (99 pounds) is one 50-mg capsule three times a day (total of 150 mg per day) for 28 consecutive days. Miltefosine is contraindicated in pregnant women during treatment and for 5 months thereafter. Alternatively, intralesional injections of antimonials, cryotherapy, local heat, oral ketoconazole (Nizoral)<sup>1</sup>, topical amphotericin B<sup>2</sup>, pentamidine (Pentam)<sup>1</sup> IM or IV, 5-aminolevulinic acid<sup>1</sup> photodynamic therapy (PDT), or topical paromomycin<sup>2</sup> (applied twice daily for 10–20 days) have been used.

The production of antileishmanial antibodies does not correlate with resolution of the disease. Infection and recovery are associated with lifelong immunity to reinfection by the same species of *Leishmania*, although interspecies immunity may also exist.

### **Trypanosomiasis**

There are three types of trypanosomiasis:

- American trypanosomiasis or Chagas' diseases, caused by *Trypanosoma cruzi*
- East African sleeping sickness, caused by *Trypanosoma brucei rhodesiense*
- West African sleeping sickness, caused by *Trypanosoma brucei gambiense*

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>10</sup>Available in the United States from the Centers for Disease Control and Prevention.

**Figure 1** Cutaneous leishmaniasis is characterized by an ulcerated nodule with a raised and indurated border (i.e., volcano sign).

American trypanosomiasis (i.e., Chagas' disease) is caused by the parasite *T. cruzi*, and it is endemic in Central and South America. The disease is transmitted by the bite of infected "cone-nosed" insects, by transfusion of infected blood, by organ transplantation, and across the placenta. During the acute stage, Chagas' disease manifests with a painful erythematous nodule, known as chagoma, which is associated with regional adenopathy. The chronic stage manifests with cardiomyopathy, megaesophagus, and megacolon. Diagnosis is confirmed by microscopic identification of the parasite in fresh anticoagulated blood, in blood smears, by lymph node biopsy or skin biopsy, or by culture. Antiparasitic treatment is indicated for all cases of acute or reactivated Chagas' disease and for chronic *T. cruzi* infection in children up to age 18. Physicians should consider factors such as the patient's age, clinical status, and health. Treatment recommended by CDC includes benznidazole (Radanil, Rochagan)<sup>10</sup> 5 to 7 mg/kg/day PO in two doses for 60 days or nifurtimox (Lampit)<sup>10</sup> 8 to 10 mg/kg/day PO in three doses for 60 days.

African trypanosomiasis (i.e., East and West African sleeping sickness) occurs in Africa and is transmitted by the bite of infected male and female tsetse flies. It manifests with a highly inflammatory, painful, red or violaceous, indurated nodule surrounded by an erythematous halo, called trypanosome chancre, at the site of the inoculation of the parasites. There is regional adenopathy. Later, the chancre resolves spontaneously, and the patient has fever, malaise, a generalized pruritic eruption with erythematous annular plaques or urticarial lesions, and central nervous system (CNS) involvement with personality changes, apathy, somnolence, coma, and death. Diagnosis is based on the identification of trypanosomes by microscopic examination in chancre fluid, affected lymph node aspirates, blood, bone marrow, or in the late stages of infection, cerebrospinal fluid.

Treatment of East African sleeping sickness in adults consists of suramin (naphthylamine sulfonic acid, Germanin)<sup>10</sup> 4 to 5 mg/kg (test dose) IV and then 20 mg/kg (max 1 g/injection) IV on days 1, 3, 7, 14, and 21. For second stage disease (*T. b. rhodesiense*), melarsoprol B (a trivalent organic arsenical, Mel-B)<sup>10</sup> is used 2.2 mg/kg/day (max 180–200 mg/day) IV for 10 days. For West African sleeping sickness, pentamidine is the recommended drug for first stage *T. b. gambiense* infection, 4 mg/kg/day IM or IV for 7 days. For second stage *T. b. gambiense*, CDC recommends NECT: Nifurtimox<sup>1,10</sup> 15 mg/kg orally in three doses for 10 days, then eflornithine<sup>2</sup> 400 mg/kg/day IV in two infusions for 7 days (adult doses).

#### Cutaneous Toxoplasmosis

Systemic toxoplasmosis (congenital or acquired) is caused by the parasite *Toxoplasma gondii*, and it usually is transmitted from

contact with infected cats. The disease may also be acquired by eating raw or undercooked meats from infected animals. Cutaneous involvement is rare. It manifests with punctate macules or ecchymoses in the congenital form, and the acquired form manifests with roseola and erythema multiforme lesions, urticaria, prurigo-like nodules, and maculopapular lesions. Diagnosis of cutaneous toxoplasmosis is confirmed by isolation of the parasite in the skin. Treatment is not needed for healthy nonpregnant patients because symptoms resolve in a few weeks. For pregnant women, the choice of drug is based on gestational age at diagnosis and may include pyrimethamine-sulfadiazine.<sup>1</sup>

#### Diseases Caused by Helminths

##### Ascariasis

Ascariasis is caused by *Ascaris* species, mainly *Ascaris lumbricoides*. It is transmitted by the ingestion of eggs in soil contaminated with human feces. Skin involvement of ascariasis manifests with urticaria. Diagnosis is based on finding the adult worm or eggs in the feces. Treatment includes albendazole (Albenza)<sup>1</sup> 400 mg PO once or mebendazole (Vermox) 100 mg PO twice daily for 3 days (or 500 mg once) or ivermectin (Stromectol)<sup>1</sup> 150 to 200 µg/kg PO once.

##### Cutaneous Larva Migrans

Cutaneous larva migrans is also known as creeping eruption, with the first term describing a syndrome and the second a clinical sign found in various conditions. The syndrome cutaneous larva migrans is caused when various nematode larvae (i.e., hookworms, such as *Ancylostoma braziliense*, *Ancylostoma caninum*, *Bunostomum phlebotomum*) of dogs, cats, and other mammals penetrate and migrate through the skin. Cutaneous larva migrans is transmitted by skin contact to soil contaminated with animal feces. In humans, larvae are unable to reach internal organs and eventually die. Cutaneous larva migrans manifests with intensely pruritic, papular lesions, which evolve as the larvae migrate to a characteristic linear, minimally elevated, serpiginous tract that moves forward in an irregular pattern. Diagnosis is easily made clinically and is supported by a travel history or by possible exposure in an endemic area.

Cutaneous larva migrans is self-limiting. Treatment includes off-label use of albendazole<sup>1</sup> and ivermectin.<sup>1</sup> Symptomatic treatment may be advised for severe itching.

##### Filariasis

Filariasis is caused by nematodes (i.e., roundworms) that inhabit the lymphatics and subcutaneous tissues. The most common filarial infections include lymphatic filariasis, onchocerciasis, and loiasis.

Lymphatic filariasis is caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and it is transmitted by mosquitoes. Adult worms result in a chronic inflammatory cell infiltrate around lymphatic vessels, causing their dilatation, hypertrophy, and obstruction. Many patients are asymptomatic, but some may develop fever with lymphangitis and lymphadenitis, chronic pulmonary infection, and progressive lymphedema leading to massive tissue thickening, especially of the legs and scrotum (i.e., elephantiasis). The overlying skin is thickened. Diagnosis is based on microscopic identification of the microfilariae in the blood and affected tissues.

Diethylcarbamazine citrate (DEC)<sup>10</sup> is the recommended treatment by the CDC for adults at a dose of 6 mg/kg/day, as a 1 day or 12 day treatment course. However, DEC is contraindicated in some patients and consultation with a tropical medicine specialist is recommended.

##### Onchocerciasis

Onchocerciasis (i.e., blinding filariasis) is caused by the filarial nematode *Onchocerca volvulus*, which is transmitted by the

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>10</sup>Available in the United States from the CDC.

<sup>1</sup>Not FDA approved for this indication

<sup>10</sup>Available in the United States from the Centers for Disease Control and Prevention.

blackflies *Simulium*. It may manifest with subcutaneous onchocercid nodules, acute or chronic dermatitis, depigmentation (i.e., leopard skin), and skin atrophy (i.e., lizard skin), and in later stages, it may manifest with lymphadenopathy and lymphedema. The microfilariae have a predilection for the eyes, and the infection can lead to blindness (i.e., river blindness). Diagnosis is based on identification of microfilariae in skin snips.

Treatment in adults consists of ivermectin (Stromectol) 150 µg/kg in one dose PO every 6 months. DEC is contraindicated as it may lead to blindness. To kill microfilariae, CDC recommends doxycycline<sup>1</sup> 100 to 200 mg orally daily for 6 weeks. Patients with *Loa loa* co-infection should not be treated for onchocerciasis without consulting an expert on loiasis.

### Loiasis

Loiasis (i.e., Calabar swellings) is caused by the parasite *Loa loa*, which is transmitted by deerflies (*Chrysops*). Cutaneous manifestations include pruritus, urticaria, and Calabar swellings, which are erythematous, warm, subcutaneous swellings associated with the migration of the worm through the subcutaneous tissues. Occasionally, there is subconjunctival migration of the adult worm, producing a migrating serpiginous lesion on the conjunctivae. Diagnosis is confirmed by identification of microfilariae in the blood by microscopic examination.

### Schistosomiasis

Schistosomiasis (i.e., snail fever) in humans is caused mainly by the trematodes *Schistosoma haematobium*, *Schistosoma japonicum*, and *Schistosoma mansoni*. All trematodes have a life cycle that involves the snail as an intermediate host. The infective cercariae leave the snail, swim, and penetrate the human skin, causing a pruritic papular dermatosis. The disease is transmitted by exposure to contaminated water with live cercariae or by drinking infested water. Skin findings of acute schistosomiasis include pruritic schistosomal dermatitis due to a hypersensitivity response to the cercariae and edema of the face, extremities, genitals, and trunk. Schistosomal fever (i.e., Katayama fever), lymphadenopathy, and diarrhea may also develop. Late skin findings (i.e., bilharziasis cutanea tarda) appear in patients with visceral disease and include firm, pruritic, grouped papules. Secondary infection, ulceration, and development of squamous cell carcinoma may follow. Diagnosis is confirmed by identification of the eggs in the urine or stool, by biopsy of affected tissues, or by enzyme-linked immunosorbent assay (ELISA).

Treatment includes praziquantel (Biltricide) 40 mg/kg/day in two divided doses for 1 day (for *S. haematobium* and *S. mansoni*) or 60 mg/kg/day in three divided doses for 1 day (for *S. japonicum*).

### Cercarial Dermatitis

Cercarial dermatitis (i.e., swimmer's itch) is caused by cercariae (i.e., larvae) of nonhuman schistosomes that penetrate the skin and die without invading other tissues. It is transmitted by contact with fresh or salt water contaminated with cercariae. It manifests with extremely pruritic, erythematous macules of sudden onset, which evolve into papules, vesicles, and urticarial lesions located on parts of the body directly exposed to the water, while sparing clothed areas. Cercarial dermatitis is a self-limited disease, and treatment is symptomatic with topical steroids and oral antihistamines.

## Diseases Caused by Arthropoda

### Human Scabies

Scabies is a common skin infestation caused by the mite *Sarcoptes scabiei*, which is an obligate human parasite. Scabies is transmitted by direct contact with an infested individual or by contact with bedding and clothing. The incubation period for scabies is about 3 weeks, and reinfestation results in symptoms within 1 to 3 days. Scabies is characterized by pruritus that usually worsens at night. Papules, nodules, excoriations, and burrows may be found. Lesions are usually located on interdigital spaces, wrists, ankles,

axillae, waist, and genitals. Scabies manifests as red-brown nodules that represent a hypersensitivity response. In adults, the head is usually spared, whereas the involvement of the scalp, palms, and soles is common in infants.

Cruled or Norwegian scabies manifests with hyperkeratotic papules or plaques of the hands and feet (often with nail involvement) and an erythematous scaly eruption on the face, neck, scalp, and trunk. Because pruritus is often absent, this disease can be misdiagnosed as psoriasis, eczema, or an adverse drug reaction. Lesions contain thousands of mites and are highly contagious. Cruled scabies mainly affects immunocompromised patients (e.g., patients with human immunodeficiency virus infection), mentally retarded persons, or debilitated patients.

Diagnosis is based on the microscopic identification of mites or their eggs or feces from burrows or papules. Treatment should be applied from the neck down in adults, and in infants, application should include the scalp and face (avoiding the eyes and mouth).

Treatment includes 5% permethrin (Elimite) applied head to toe for 10 hours and repeated after 1 week. Benzyl benzoate solution<sup>1,6</sup> 10% to 25% applied once daily at night on 2 consecutive days with re-application at 7 days, is also a recommended treatment. Sulfur ointments in petrolatum<sup>1,6</sup> or as cream or lotion, at concentrations of 6% to 30% may be used with application on 3 successive days. Ivermectin (Stromectol)<sup>1</sup> 200 µg/kg/dose (taken with food) as two doses 1 week apart, can be used. Regarding treatment of scabies in special situations, the European guidelines 2017 mention that permethrin is safe in pregnancy (grade B recommendation) and lactation and is licensed for use in children from age 2 months onwards. Benzyl benzoate and sulphur are considered safe in pregnancy (grade B recommendation) by the European guideline. Ivermectin should not be used during pregnancy or in children weighing less than 15 kg. Aggressive treatment with ivermectin at a single dose of 200 µg/kg, repeated after 2 weeks with or without topical 5% permethrin cream (two applications, 1 week apart) and keratolytics (5% salicylic acid ointment<sup>1</sup> applied twice daily) is the treatment of choice for crusted scabies. All sexual and close personal and household contacts within the preceding 6 weeks should be treated simultaneously. Bedding and clothing should be decontaminated (i.e., machine washed and dried using the hot cycle or dry cleaned) or removed from body contact for at least 3 days, because the mite dies when separated from the human host. Post-treatment itch should be treated with repeated application of emollients. Oral antihistamines and mild topical corticosteroids may also be useful.

### Pediculosis

Pediculosis (i.e., lice) is a contagious dermatosis, caused by lice, which are blood-sucking, wingless insects and are obligate human parasites. Two species of lice infest humans causing three clinical forms of infestation: *Pediculus humanus capitis* (i.e., head louse), *Pediculus humanus corporis* (i.e., body louse), and *Phthirus pubis* (i.e., pubic louse). The body louse is the only louse that can carry human disease, including rickettsioses and epidemic typhus.

### Pediculosis Capitis

*Pediculosis capitis* is caused by *P. humanus capitis*, and it is transmitted by close contact or by fomites with combs, brushes, towels, and hats. It manifests with pruritus (due to the saliva of the louse), excoriations, nape dermatitis, secondary bacterial infection, and cervical and suboccipital lymphadenopathy. Diagnosis is based on identification of lice and eggs or nits on the hair and on fluorescence of nits with Wood's light. Visible nits are deposited on the hair shaft, close to the scalp. After adequate treatment, nits found at 1.0 to 1.5 cm from the scalp are not alive.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

Topical pediculicides should be applied according to the package instructions. Treatment includes malathion (Ovide) 0.5% lotion applied for 8 to 12 hours or permethrin (Nix) 1% cream rinse applied to shampooed hair for 10 minutes. A second application with permethrin is recommended 1 week later to kill hatching progeny. Alternatively, pyrethrins with piperidyl butoxide (RID) can be applied and washed off after 10 minutes. Benzyl benzoate 25% solution<sup>6</sup> is mainly a scabicide, but it may also be used as a pediculicide. Ivermectin lotion 0.5% (Sklice) was approved by the FDA in 2012 for treatment of head lice in persons 6 months of age and older, using a fine-toothed comb. Bedding, clothing, and headgear should be decontaminated (as for scabies) or removed from body contact for 2 weeks. The nits must be removed from the hair by combing.

### Pediculosis Corporis

*Pediculosis corporis* (i.e., vagabond's itch) is caused by *P. humanus corporis*, which lives and reproduces in the lining of clothes and leaves the clothing only for feeding from the skin. This disease is usually found among vagabonds. Transmission occurs mainly through contact with contaminated clothing or bedding. Clinical manifestations include pruritus, excoriations, and small, red macules that usually occur on the back. Clothes should be examined carefully for lice.

Treatment is the same as for pediculosis capitis and is applied on the affected body area. Dry heat or washing in hot water followed by ironing is effective in killing the lice and their ova in clothing. Items that cannot be washed should be removed from body contact for 2 weeks.

### Pediculosis Pubis

*Pediculosis pubis* is caused by *P. pubis* and affects the pubic hair. However, if left untreated, it may also affect very hairy regions of the chest, abdomen, axillary region, and especially in children, the eyelashes, edge of the scalp, and eyebrows. Patients present with pruritus. Useful diagnostic signs include small, blue-gray macules on the trunk, thighs, and axillae (i.e., taches bleuâtres or maculae ceruleae) due to conversion of bilirubin to biliverdin by the saliva of the louse and a brown "dust" found on underclothing due to the excreta of the insects. Nits and/or lice attached to hairs are visible with the naked eye or using a dermatoscope. *P. pubis* is transmitted mainly by sexual contact, but it also may be transmitted by clothing or from parents to children.

Patients with pubic lice should be evaluated for other sexually transmitted diseases. Treatment of pediculosis pubis is the same as for pediculosis capitis and is applied on the affected areas. Bedding and clothing should be decontaminated (as for scabies) or removed from body contact for 2 weeks. Attention should be paid to treating sexual partners within the previous month because they are a common cause of reinfestation. For infested eyelashes and eyebrows, ophthalmic-grade petrolatum ointment may be used two to four times daily for 10 days, and lice and nits should be carefully removed from the eyelashes with forceps.

<sup>6</sup>May be compounded by pharmacists.

## PIGMENTARY DISORDERS

Method of

Rebat M. Halder, MD; and Ahmad Reza Hossani-Madani, MD, MS

### CURRENT DIAGNOSIS

#### Hyperpigmentation

- Ephelides: Multiple, small (1–4 mm), light- to dark-brown macules with poorly defined margins that occur on sun-exposed areas of the body.
- Solar lentigines: Light-brown to dark-brown macular hyperpigmented lesions that are induced by natural or artificial sources of radiation and that can coalesce; they are located on face, neck, forearms, and hands.
- Melasma: Arcuate or polycyclic light- to dark-brown macules that coalesce into patches on face, neck, or forearms.
- Postinflammatory hyperpigmentation: Dark patches or macules with indistinct margins at the location of an inciting inflammatory event.

#### Hypopigmentation

- Pityriasis alba: Round, well-defined, pale macules with fine overlying powdery white scales, ranging in size from 0.5 to 5 cm in diameter, that transition to smooth, hypopigmented macules.
- Vitiligo: Sharply demarcated, depigmented, milky-white macules in a localized or generalized distribution.
- Idiopathic guttate hypomelanosis: Multiple circular, smooth, small macules that are porcelain white, with occasional black dots, found on sun-exposed areas of upper and lower extremities.
- Postinflammatory hypopigmentation: Off-white or tan macules with ill-defined borders at the site of an inciting inflammatory event.

## CURRENT THERAPY

### Hyperpigmentation

- Ephelides: Hydroquinone 4% (Blanche, Melpaque HP, Skin Bleaching-Sunscreen) plus maximum UVA-blocking sunscreen in the morning and tretinoin 0.025% cream (Retin-A)<sup>1</sup> in the evening
- Solar lentiginos: Hydroquinone 4% plus tretinoin 0.025% cream (Retin-A)<sup>1</sup> in the evening; cryotherapy; laser therapy.
- Melasma: Monotherapy with hydroquinone 4% twice daily or tretinoin 0.025%<sup>1</sup> in the evening; double therapy with hydroquinone 4% twice daily plus tretinoin 0.025%<sup>1</sup> in the evening; triple therapy with fluocinolone acetonide 0.01% plus hydroquinone 4% plus tretinoin 0.05% (Tri-Luma Cream) in the evening; cysteamine cream (Cyspera)<sup>2</sup> once daily.
- Postinflammatory hyperpigmentation: Treat inciting event; hydroquinone 4% alone or in combination with low-potency topical steroid; cysteamine cream (Cyspera)<sup>2</sup> once daily.

### Hypopigmentation

- Pityriasis alba: Emollients, lubricants, sunscreen; tacrolimus 0.1% ointment (Protopic)<sup>1</sup> twice daily or low-potency non-halogenated steroid for face and medium-potency steroid for body; phototherapy (UVB) for extensive disease.
- Vitiligo: In patients with less than 20% body surface area (BSA) involvement, treat with cover-up cosmetics, topical (potent or very potent steroid or calcineurin inhibitor trial for less than 2 months), phototherapy (UVB), or excimer laser. If local treatment fails, a surgical grafting approach may be used if the patient has less than 20% BSA involvement. For patients with more than 20% BSA involvement, phototherapy (UVB) is preferred. For patients with more than 50% BSA or disfiguring facial involvement, depigment with monobenzyli ether of hydroquinone (monobenzone 20% [Benoquin]), 4-methoxyphenol, or Q-switched ruby laser (694 nm).
- Idiopathic guttate hypomelanosis: Cryotherapy; dermabrasion; surgical minigrafting; intralesional steroids.
- Postinflammatory hypopigmentation: Cosmetics; topical corticosteroids; topical PUVA.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Available through dispensing clinics or online.

### Definition

The word *chromophore* is defined as elements that impart color to the skin. Hyperchromias describe abnormally darker skin, and hypochromias describe abnormally lighter skin. Pigmentation refers to melanotic causes of skin color change, differentiating it from skin color changes as a result of blood, carotene, bilirubin, or other causes. Hyperpigmentation refers to an increase in melanin production, melanocyte number, or both in the skin. Hypopigmentation refers to decrease of melanin, melanocytes, or both in the skin. Depigmentation refers to the absence of both melanin and melanocytes. Deposition of melanin in the epidermal layers visibly appears as a yellow to brownish hue. Dermal deposition appears as blue or blue-gray, with mixed epidermal and dermal melanin deposition appearing gray or blue-brown.

### Evaluation

A thorough history and visual inspection of the pigmentary disorder can provide useful clues to the diagnosis, particularly recognition of pigmentary patterns (diffuse, circumscribed, linear, or reticulated). Further examination may be achieved by using the Wood's lamp to differentiate epidermal from dermal melanin.

### General Recommendations for All Pigmentary Disorders

Broad-spectrum sunscreen with an SPF of 30 is recommended, in addition to wearing protective clothing. Avoiding prolonged sun exposure is also desired.

## Hyperpigmentation

### Ephelides

#### Description

Ephelides (freckles) are multiple, small (1–4 mm), light- to dark-brown macules with poorly defined margins that occur on sun-exposed areas of the body (face, upper back, arms). They are more commonly found in children (fading with age), fair-skinned persons, and those with red or blonde hair (especially those of Celtic ancestry). A relationship has been shown between painful sunburns in youth and development of ephelides, and the macules become darker with greater UV exposure. They are thought to be genetic in origin, following an autosomal dominant pattern, and are strongly associated with variants in the melanocortin-1-receptor (MC1R). Ephelides are significant because they are associated with an increased risk of melanoma and nonmelanoma skin cancer, perhaps serving as a marker for sun susceptibility.

#### Treatment

Although treatment is not necessary, modalities include either hydroquinone 4% (Blanche, Melpaque HP, Skin Bleaching-Sunscreen) plus maximum ultraviolet A (UVA)-blocking sunscreen in the morning and tretinoin 0.1% cream (Retin-A)<sup>1</sup> in the evening. Other therapies have included cryotherapy, lasers, and chemical peels.

### Solar Lentigo (Lentigo Senilis Et Actinicus)

#### Description

Solar lentiginos are pigmented spots that share morphologic similarities with ephelides, making differentiation difficult. They are defined as light-brown to dark-brown macular hyperpigmented lesions induced by natural or artificial sources of radiation, which can coalesce. The incidence increases with age, and more than 90% of white persons older than 50 years demonstrate lesions. They appear most often on the face, neck, forearms, and hands. They can occur in nonclassic locations in those receiving phototherapy (such as the penis). Histologically, they differ from ephelides by the presence of epidermal hyperplasia, increased melanocyte number, and elongation of the rete ridges.

#### Treatment

Although treatment is not necessary, two different modalities have been used: physical therapies and topical therapies. Physical therapies include cryotherapy and lasers, and topical treatments include retinoids or combinations of agents. Liquid nitrogen may be used with a cotton swab for 5 to 10 seconds to induce lightening. Recurrence rates may be as high as 55% at 6 months. Side effects include atrophy with longer cryoprobe application, postinflammatory hyper- or hypopigmentation, and pain. The Q-switched Nd:YAG (1064 nm) laser, among others, has been used with success.

### Melasma

#### Description

Melasma is a hypermelanosis of the face, neck, and forearms that occurs with a higher incidence in women of African American, Latin American, and Asian descent. It appears on sun-exposed areas as arcuate or polycyclic macules that coalesce into patches. Epidermal melanin deposition causes a brownish appearance, and dermal melanin appears bluish. Combined epidermal and dermal melanin deposition appears gray. It is distributed in a central facial (65%), malar (20%), or mandibular (15%) pattern. More commonly seen in women and those with darker skin, it can also be found in men. Contributing factors include a genetic predisposition, pregnancy, oral contraceptive use, endocrine dysfunction, hormonal treatment, UV light exposure, cosmetics, and phototoxic drugs.

#### Treatment

First-line treatment for melasma consists of broad-spectrum sunscreen with greater than SPF 30 coverage in addition to monotherapy with hydroquinone 4% twice daily or tretinoin 0.025% (Retin

<sup>1</sup>Not FDA approved for this indication.

A)<sup>1</sup> nightly. Double therapy with hydroquinone 4% twice daily plus tretinoin 0.025%<sup>1</sup> nightly may prove efficacious after an unsuccessful trial of monotherapy. If that fails, triple therapy may be attempted, with fluocinonide acetone 0.01%, hydroquinone 4%, and tretinoin 0.05% (Tri-Luma) once daily being effective. Side effects of triple therapy include erythema, desquamation, burning, dryness, and pruritus at the site of application; telangiectasia; perioral dermatitis; acne breakouts; and hyperpigmentation. Cysteamine cream (Cyspera)<sup>2</sup> once a day can be used as an alternative to hydroquinone. Chemical peels, superficial and medium depth, and Q-switched 1064 nm Nd:YAG laser or intense pulsed light (IPL) may also be used for patients whose topical treatments have failed.

### Postinflammatory Hyperpigmentation

#### Description

Postinflammatory hyperpigmentation is a very common condition that occurs as a result of a previous or ongoing inflammatory process, most commonly acne vulgaris, atopic dermatitis, infections, and phototoxic reactions, and as a result of treatment with topical medications, chemical peels, and lasers. Postinflammatory hyperpigmentation occurs more commonly in persons with darker skin pigmentation and appears as dark patches or macules with indistinct margins at the location of the inciting inflammatory event.

#### Treatment

Primary treatment is aimed at treating the inciting cause of the hyperpigmentation. Additional effective therapies include 4% hydroquinone alone or in combination with a topical steroid. Broad-spectrum sunscreen should also be employed. Cysteamine cream (Cyspera)<sup>2</sup> can be used as an alternative to hydroquinone.

### Hypopigmentation or Depigmentation

#### Pityriasis Alba

##### Description

Pityriasis alba is a childhood or adolescent condition that affects all races. It begins as an erythematous macule with ill-defined borders. The erythema fades after a few weeks, leaving two or three round, well-defined, paler macules with overlying fine powdery white scale, ranging in size from 0.5 cm to 5 cm in diameter. These eventually transition to smooth, hypopigmented lesions, which are generally located on the face. The pathogenesis of this disorder is unknown.

#### Treatment

Pityriasis alba is thought to be a self-limited skin disease. However, general treatment guidelines include use of emollients and lubricant, use of sunscreen, and decreasing sun exposure. Lesions limited to the face may be treated with hydrocortisone 1%<sup>1</sup> or other mild, nonfluorinated steroid. More potent steroids may be used for lesions on the body, including hydrocortisone valerate 0.2% (Westcort)<sup>1</sup> or alclometasone dipropionate 0.05% (Aclovate).<sup>1</sup> However, these can lead to atrophy if used over an extended period. Newer, nonsteroidal, effective alternatives include tacrolimus 0.1% ointment (Protopic)<sup>1</sup> twice daily. Side effects include a burning sensation that fades over time. Extensive disease that is not amenable to topical therapy might benefit from phototherapy (UVB).

### Vitiligo

#### Description

Persons with vitiligo acquire sharply demarcated, depigmented macules in a localized or generalized distribution. These macules appear milky white compared with the surrounding normally pigmented skin. Lesions can increase in size. There is no predilection for race or sex, and three-quarters of patients generally present before the age of 30 years.

#### Treatment

General recommendations include the use of sunscreen, avoidance of the sun, and use of protective clothing. Treatments for localized vitiligo (<20% of body surface area) include cover-up cosmetics, a 2-month trial of topical treatment (potent or very potent corticosteroid or calcineurin inhibitor), excimer laser, or topical PUVA. Adults who have failed treatments for localized vitiligo may be considered for narrow-band UVB or surgical treatment, which includes split-skin grafting, transfer of suction blisters, or autologous epidermal suspensions added to derm-abraded skin. Surgical candidates should have localized, limited involvement and should not demonstrate lesion enlargement or Koebner phenomenon for 12 months prior to treatment. Patients with more than 20% body involvement may be considered for narrow-band UVB (311 nm). Those with greater than 50% body involvement or disfiguring facial involvement may be considered for complete depigmentation with monobenzyl ether of hydroquinone 20% (monobenzene 20% [Benoquin]). Children are generally not offered surgical treatment.

### Idiopathic Guttate Hypomelanosis

#### Description

This is an acquired, asymptomatic leukoderma with multiple, circular, smooth, small macules that have a porcelain-white color. Brown dots are occasionally observed within the macules. The macules increase in number with age, but they generally do not increase in size. They are most commonly located on sun-exposed areas of the upper and lower extremities.

#### Treatment

Treatments have included cryotherapy, dermabrasion, surgical minigrafting, and intralesional steroids; however, none of these have shown consistent acceptable results. Phototherapy has not been shown to be effective.

### Postinflammatory Hypopigmentation

#### Description

Postinflammatory hypopigmentation is the result of an inciting inflammatory event leading to lesions that are off-white or tan, with ill-defined borders. This entity is noticed more commonly in those with darker skin.

#### Treatment

Hypopigmentation resolves with treatment of the underlying condition. Cosmetic cover-ups may be useful. Topical corticosteroids, tacrolimus 0.1% ointment (Protopic),<sup>1</sup> and phototherapy may also be used in patients who have lesions in cosmetically distressing areas.

<sup>1</sup>Not FDA approved for this indication.

## PREMALIGNANT SKIN LESIONS

Method of

Daniel Stulberg, MD; and Katarzyna Wilamowska, MD, PhD

### CURRENT DIAGNOSIS

#### Actinic Keratoses

- Scaly white or flesh-colored lesions often with palpably rough surface
- Individuals with light skin and hair color are at high risk
- Most common on face, hands, and sun-exposed skin

#### Actinic Cheilitis

- Scale, thickening or fissures on the lips
- Lower lip more commonly involved than upper lip

#### Porokeratoses

- Macular lesions with slight scale or rice-paper appearance and hyperkeratotic border
- Disseminated superficial actinic porokeratoses (DSAP) predominant type—autosomal dominant transmission

#### Human Papillomavirus Disease

- Verrucous or papular flesh-colored lesions
- Genital, perineal, perirectal, or oral locations are at risk of malignancy

#### Atypical Nevi

- Multiple irregularly pigmented nevi in the familial atypical mole and melanoma syndrome
- Numerous, often raised nevi, especially with shades of red, brown, and black

### CURRENT THERAPY

#### Actinic Keratoses or Cheilitis

- Cryosurgery first line if limited number of lesions
- Topical medications for extensive actinic change with multiple lesions
- 5-fluorouracil (Carac, Efudex) typically 2–3 weeks, although multiple protocols/variations
- Diclofenac sodium (Solaraze) longer protocol, less effective
- Imiquimod (Aldara, Zyclara) longer protocol, less effective
- Ingenol mebutate (Picato) 3-day course limited by maximum of 25-cm<sup>2</sup> treatment area and expense of medication
- Less commonly, laser, curettage, retinoids, photosensitizing medications followed by light therapy

#### Porokeratoses

- See treatment options for actinic keratoses

Actinic keratoses are the most common precancerous skin lesions seen in usual practice. If untreated, it is estimated that from 0.1% to 10% of these lesions will progress to squamous cell carcinoma that requires significantly more aggressive treatment. Fortunately, effective treatment is available, although it can cause significant discomfort. Risk factors for developing actinic keratoses are similar to those of developing basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and, to a certain extent, melanoma skin cancer. These risk factors include lighter skin colors, family history of actinic keratoses or nonmelanoma skin cancer, exposure to sunlight, ultraviolet radiation, use of tanning beds, and immunosuppression from disease, or immunosuppressant medications to prevent organ transplant rejection.

There are several other conditions or situations that can increase risk of precancerous and cancerous skin lesions. The

first is arsenic. This is rare in developed countries and, other than avoiding arsenic exposures, is treated as outlined below for actinic keratoses. The human papilloma virus (HPV) can lead to papillomatous lesions and genital and oropharyngeal. Individuals with the familial atypical mole and melanoma syndrome (FAMMS), previously called atypical nevus syndrome, have multiple abnormal-appearing nevi and a family history of melanoma. Patients with atypical nevi and more than one first-degree relative with melanoma have a risk of melanoma approaching 100%.

Actinic keratoses should be treated to reduce the risk of progression to squamous cell carcinoma unless the patient has a limited life expectancy and the clinician determines that, based on the condition of the patient and their comorbidities, the discomfort of treatment would outweigh the benefits for the patient. Avoiding sun exposure and using broad-brimmed hats, sunscreen, and protective clothing while outdoors can reduce the risk of additional lesions. Unfortunately, because of the long lead time between sun exposure and onset of disease, most patients will continue to develop more actinic keratoses due to the underlying skin damage. Patients should be counseled regarding the occurrence of additional precancerous and cancerous skin lesions and should be examined every 6 to 12 months, or even more frequently depending on the amount of disease burden, their individual risk factors, and clinical judgment.

There are several rare inherited genetic disorders that predispose patients to precancerous and cancerous cutaneous lesions, grouped under genodermatoses. Xeroderma pigmentosum (XP) is an autosomal recessive disorder where homozygotes have severe sun sensitivity due to inability to repair sun-damaged DNA, leading to development of BCCs, SCCs, and melanomas in early childhood. Basal cell nevus syndrome, another autosomal dominant disorder, is characterized by developmental anomalies and tumors, especially BCCs, starting in the fourth decade of life. Oculocutaneous albinism results from a group of autosomal recessive disorders of melanin biosynthesis. This deficiency leads to reduced or absent pigmentation of skin, hair, and eyes, leading to early photodamage.

Nevus sebaceous presents as a waxy yellow or brown congenital plaque or plaques. Around the time of puberty the plaque can thicken and develop into benign or, less commonly, malignant tumors. In addition to these specific disorders, patients with chronic ulceration, burn scars, radiation therapy fields, and inflammatory conditions including discoid lupus, lichen planus, lichen sclerosis, and lymphedema are at risk of developing skin cancers in affected areas.

### Actinic Keratoses and Actinic Cheilitis

#### Clinical Manifestations

Actinic keratoses (AKs) are an abnormal proliferation of keratinocytes and a precursor of squamous cell carcinoma. Over time, 0.1% to 10% of the lesions will progress to squamous cell carcinoma. AKs present as rough or scaly white or flesh-colored lesions, often with a slightly erythematous base (Figure 1). A combination of visual inspection of the skin and tactile examination is useful to diagnose these lesions. Often they are easier to identify by gently palpating the patient's skin for their characteristic rough surface on sun-exposed areas. If there is significant underlying erythematous thickened tissue, the clinician should consider whether the lesion has already progressed to squamous cell carcinoma, and potentially proceed with biopsy (Figure 2). Patients frequently note that they have scratched off a lesion but it returns over time, and many patients who have had multiple AKs become very adept at pointing them out to their clinician.

Actinic cheilitis is the same precancerous process when it occurs on the lips. It is more common on the lower lip, which catches the sun's rays more directly. The lip becomes rough, or the patient notes that it is always chapped. Dyshidrotic chapped lips can be in the differential diagnosis. A trial of topical lip balm may be initiated, and if the rough surface does not resolve, actinic cheilitis is the likely diagnosis. If there is ulceration or significant thickening of the lip, biopsy should be performed because of the possibility of squamous cell carcinoma of the lip.

**Figure 1** Early onset of actinic keratoses in young man with high-risk skin type.

**Figure 3** Treating multiple actinic keratoses with cryosurgery.

**Figure 2** Sun-damaged skin with multiple actinic keratoses and squamous cell carcinoma in situ, a.k.a. Bowens disease.

### Treatment

For patients with a limited number of lesions, destruction with cryosurgery is a quick and effective treatment with success rates generally above 95%. Cryosurgery can be performed using a variety of tools. Liquid nitrogen spray devices provide the coldest temperatures and fastest treatment in clinical practice. Other useful options include nitrous oxide spray devices, evaporative refrigerant liquids, mechanically cooled metal probes via refrigerant technology or compressed nitrous oxide or carbon dioxide devices or using a swab dipped in liquid nitrogen. Treatment protocols vary based on the instrument. For liquid nitrogen spray,

there are multiple sized apertures available and freezing protocols based on clinician preference and lesion size. One protocol is to hold the spray tip 1 to 2cm from the AK, spray until the lesion is frozen and keep frozen for 6 seconds, allow the lesion to thaw, and repeat the cycle. For clinical efficiency it is useful to treat several lesions in succession to allow the earlier lesions to thaw before repeating the freeze (Figure 3). Counsel the patient that the cold spray does cause discomfort and even feels like a burning or stinging sensation. After treatment, the lesions typically become erythematous, have slight swelling, and sometimes will blister. If they blister, topical petrolatum and an adhesive bandage may be used to protect the healing wound. If lesions do not resolve after adequate cryosurgery, consider biopsy for possible squamous cell carcinoma, which will require more aggressive treatment. Patient discomfort of cryosurgery varies. Most individuals will tolerate up to 15 lesions, although some patients will only tolerate cryosurgery of a few lesions, and some will tolerate treatment of dozens of lesions. Patients can return for additional cryosurgery on subsequent visits, or, if they have a very high density of lesions, topical agents may be more efficient to treat large areas with multiple lesions. The lips can be treated with cryosurgery or topical agents for actinic cheilitis. Because of the risk of swelling and discomfort, a lighter freeze protocol may be useful for the lips.

Topical chemotherapy with 5-fluorouracil (Carac, Efudex) has been used to treat AKs successfully for decades. It is particularly useful for field or blanket therapy in patients with multiple lesions and is very effective in clearing more than 90% of the lesions in treated areas. There are multiple variations in treatment protocols, and it is manufactured in 0.5% and 5% topical creams and 2% and 5% topical solutions. One option is to apply 5% 5-fluorouracil to the affected areas twice daily for 2 weeks until there is significant inflammation, often erosions and exudate (Figures 4 and 5). If there has been no reaction, the treatment can be extended out to 3 weeks. There is significant discomfort with this treatment protocol, which can be lessened by not treating the patient's entire affected areas all at once. Starting with treatment of one forearm and allowing that to heal before proceeding to the next forearm can be a useful way of starting and allowing the patient to get some familiarity with its use before starting it on a portion of their face or scalp. Treating the entire face or scalp can be very uncomfortable, so treating only one portion at a time and waiting until that heals before treating another area may be helpful. Because of photo sensitivity and increased risk of sunburn, it is preferable to perform treatment during the winter months or use strict sun avoidance. The 0.5% 5-fluorouracil formulation may be better tolerated on the lips for actinic cheilitis. Patients should be counseled to expect significant inflammation. It may

**Figure 4** BID 5- fluorouracil at 3 weeks.

**Figure 5** Daily 5-fluorouracil at 5 weeks.

also be useful to advise them that as a topical chemotherapy, this medication targets the lesions and typically does not cause inflammation of unaffected skin.

Because of the amount of inflammation with 5-fluorouracil, other topical treatments have been developed. They cause less inflammation but unfortunately also have lower efficacy rates. These other treatments include topical imiquimod (Aldara, Zylara), diclofenac (Solaraze), and tirbanibulin 1% (Klisyri). Imiquimod is used at bedtime twice a week for 16 weeks. Diclofenac is used twice daily for 8 to 12 weeks and is typically better tolerated. Both of these are less effective than topical 5-fluorouracil. Tirbanibulin is used once daily for 5 days. Tirbanibulin use is limited by its high cost and only being approved to use for 25 square cm, approximately a 2" × 2" area, which is extremely small compared with the large amount of skin usually affected by AKs and an efficacy of 44% to 54% for complete clearance.

**Figure 6** Porokeratosis with rice-paper appearance and peripheral ridge a.k.a. cornoid lamella.

Outside of typical primary care practices, several other options exist. Photodynamic therapy can be used after a sensitizing application of aminolevulinic acid (Levulan) or methyl aminolevulinate (Metvixia). Nonselective chemical peels, dermabrasion, and ablative lasers can be used for field therapy to an entire area, treating both lesions and unaffected skin in the treatment field. Individual lesions may be treated with laser, trichloroacetic acid (Tri-Chlor),<sup>1</sup> or curettage.

Nicotinamide<sup>4,7</sup> 500mg orally BID has been shown to reduce the rate of developing additional lesions in patients already affected by actinic keratoses. The medication needs to be continued to maintain its effect.

## Porokeratoses

### Clinical Manifestations

Although much less common than actinic keratoses, porokeratoses also have malignant potential. Disseminated superficial actinic porokeratoses, like AKs, present on sun-exposed areas. They usually present as atrophic or rice-paper-appearing lesions surrounded by a slightly raised border (Figure 6). The plaque form (i.e., Mibelli's porokeratosis) is large and progressive, and the linear type may be generalized or segmental. Both of these types often manifest very early in life. Malignant transformation occurs mostly commonly in the linear type, followed by the Mibelli type. It is rare in the disseminated type and has not been reported in the punctate type.

### Treatment

Disseminated superficial porokeratosis can be treated with locally destructive methods as outlined above for actinic keratoses and surgical excision.

### Management of Complications

Treatment with cryosurgery is expected to cause local inflammation including possible vesicles and erosions. Topical petrolatum under an adhesive dressing or applied multiple times per day if used without a dressing can facilitate moist wound healing. Cryosurgery can cause hypopigmentation, which can be cosmetically distressing for patients with darker skin types and can

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

predispose to sunburn in any skin type. Inflammation from topical medications for actinic keratoses can be soothed by application of petrolatum. Secondary infections, impetigo, and cellulitis are uncommon but possible after cryosurgery or inflammation associated with topical products. Antibiotics to cover methicillin-resistant *Staphylococcus aureus* and *Streptococcus spp.*, should be prescribed if needed. Reactivation of herpes labialis can occur when treating the lips. Prophylactic antiviral therapy may reduce the risk of an outbreak in patients with history of herpes labialis.

## PRESSURE INJURY

Method of

Rebecca M. Wester, MD

### CURRENT DIAGNOSIS

- The National Pressure Injury Advisory Panel redefined the definition: pressure injury replaces the terms “pressure ulcer,” “decubitus ulcer,” and “bed sores.”
- Pressure injury develops from pathologic changes in combination with localized skin and underlying soft tissue damage, typically over a bony prominence or associated with a medical device. Skin can be intact or have an open ulcer. Pressure injury can occur with shearing.

### CURRENT THERAPY

- Treatment is based on the stage and characteristics of the pressure injury.
- Nutrition and pressure relief are important interventions.
- Host-specific factors have profound effects on the healing process and have a greater influence than what is put on the wound.
- Utilize interdisciplinary approach (physical and occupational therapy, and dietary consultation) for optimal outcomes.

## Epidemiology

Most pressure injuries develop during acute hospitalizations, in spite of the adoption of national pressure ulcer prevention guidelines. Prevalence rates for pressure injuries have changed little over the

past two decades. Hospitalized patients in intensive care or undergoing cardiovascular or hip surgery have higher rates. Hospitalized individuals with COVID-19 and acute respiratory distress syndrome (ARDS) requiring mechanical ventilation have demonstrated increased risk for pressure injury related to prone positioning.

End-stage skin failure occurs when hypoperfusion occurs at the end of life. The prevalence of pressure injuries is 11% to 18% for palliative care patients, nearly double in comparison with hospital rates. Pressure injuries impose a significant burden, not only on the patient but also on the entire health care system. To put it into perspective, the cost of treating 10 pressure injuries is equivalent to 5 knee replacements, 6 hip replacements, 9 pacemakers, or 5 bypass operations.

## Risk Factors

External factors that lead to the development of pressure injuries include pressure, shearing forces, friction, and moisture. Interaction of these external factors with host-specific factors such as immobility, sensory loss, incontinence, reduced perfusion, and compromised nutritional status culminates in tissue damage. Decreased skin perfusion resulting from hypotension, anemia, shock, or peripheral artery disease is increasingly recognized as an important cause of pressure ulcers. Hypercoagulation and microvascular occlusion associated with COVID-19 infection affect the skin and cause increased risk of skin discoloration and breakdown. Other risk factors are cerebrovascular disease, cardiovascular disease, recent lower extremity fractures, medications, and diabetes.

**Pressure ulcer risk assessment.** The Braden and Norton scales are commonly used for pressure risk assessment. These scales assess risk factors such as physical and mental condition, mobility, moisture, continence, and nutrition. However, they are weak predictors of risk of ulcers and may be no better at reducing risk than clinical judgment.

## Pathophysiology

Pressure alone is not sufficient to cause an ulcer; it's the addition of the confounding host-specific factors that ultimately leads to tissue damage. Superficial lesions are primarily the result of moisture and friction. Exposure to moisture in the form of perspiration, urine, or feces can lead to skin maceration. Friction occurs when patients are dragged across an external surface. This results in an abrasion with damage to the most superficial layer of skin. Friction contributes mostly to stage 2 pressure injuries, with limited contributions to stage 3 to 4 pressure injuries because it does not cause the necrotic changes associated with deep tissue injury. Pressure injuries are greatest over bony prominences where weight-bearing points come in contact with external surfaces and immobilization devices. Pressure over a bony prominence tends to result in a cone-shaped distribution, with the most affected tissues located deep, adjacent to the bone–muscle interface. Thus the extent of injury to deep tissues is often much greater than perceived from the visible ulcer on the skin surface. Typically, stage 3 to 4 pressure injuries start as a deep tissue injury that may then progress to the surface. There is little evidence to suggest that a stage 4 pressure injury develops as a gradual progression from stage 1 to stage 4.

## Differential Diagnosis

Besides pressure injuries, other chronic skin ulcers are arterial ulcers, venous stasis ulcers, and diabetic ulcers: arterial ulcers occur in distal digits or over bony prominences, venous stasis ulcers occur on the lateral aspect of the lower leg in the setting of chronic edema, and diabetic ulcers occur in regions of callous formations. Traumatic injuries such as abrasions, skin tears, or burns are not pressure injuries; nor are surgical incision sites. COVID-19-related skin changes should be considered for purple discoloration found on non-pressure loaded skin surfaces. These areas have been found to lack pressure-shear etiology and should not be classified as a pressure injury. Only pressure injuries are staged; never stage a wound that arises from a different etiology.

## Diagnosis

Staging is done according to the National Pressure Ulcer Advisory Panel Pressure Injury Staging System:

**Stage 1:** Nonblanchable erythema of intact skin. May appear differently in darkly pigmented skin. Color changes do not include purple or maroon discoloration; this indicates deep tissue injury. Changes in skin temperature, sensation, and firmness may be present prior to visual changes in skin color.

**Stage 2:** Partial-thickness skin loss with exposed dermis. The wound bed is viable, pink or red, and moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. This stage should not be used to describe moisture-associated skin damage (MASD) including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARS), or traumatic wounds (skin tears, burns, abrasions).

**Stage 3:** Full-thickness skin loss. Adipose (fat) is visible in the ulcer and granulation tissue and rolled skin edges are often present. Slough or eschar may be visible. The depth of tissue damage varies by anatomic location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and bone are not exposed. If slough or eschar obscures the extent of tissue loss, then it is an unstageable pressure injury.

**Stage 4:** Full-thickness skin and tissue loss. Exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone is in the ulcer. Slough or eschar may be visible. Rolled edges, undermining, and tunneling often occur. Depth varies by anatomic location. If slough or eschar obscures the extent of tissue loss, then it is an unstageable pressure injury.

**Unstageable:** Obscured full-thickness skin and tissue loss. The extent of tissue damage within the ulcer cannot be determined because it is obscured by slough or eschar. If slough or eschar is removed, a stage 3 or 4 pressure injury will be revealed. Stable eschar (dry, adherent, intact, without erythema or fluctuance) on the heel or ischemic limb should not be softened or removed.

**Deep tissue injury:** Persistent, nonblanchable, deep red, maroon, or purple discoloration. May appear as a dark wound bed or blood-filled blister. Pain and temperature skin changes often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. The wound may evolve rapidly from intense or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structure is visible, then it is a full-thickness pressure injury (unstageable or stage 3 or 4). Do not use deep tissue injury to describe vascular, traumatic, neuropathic, diabetic, or dermatologic conditions.

**Medical device-related pressure injury:** Results from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device. The injury should be staged using the staging system.

**Mucosal membrane pressure injury:** Found on mucous membranes in patients with a history of a medical device in use at the location of the injury. Owing to the anatomy of the tissue, these ulcers cannot be staged.

## Therapy

**Pressure relief.** Position the patient frequently at fixed intervals to relieve pressure over compromised areas. There is no evidence to suggest an optimal interval at which to reposition patients, although every 2 hours is recommended based on expert opinion. Advanced static support surfaces (mattress overlays and foam, gel, or air mattresses) rather than standardized hospital mattresses should be used to prevent pressure injuries in high-risk patients. Check the pressure-relieving devices for “bottoming out” by inserting your hand (palm up) between the device and the bed under the patient’s sacral area. The device is considered

**TABLE 1** Débridement Methods

<b>Mechanical:</b> Wet-to-dry dressings; removes both devitalized and viable tissues; causes pain. Cleansing wound with each dressing change is considered mechanical débridement and is beneficial in reducing biofilm and bacteria in wound bed.
<b>Surgical (sharp):</b> Scalpel, scissors, or forceps to remove devitalized tissue; quick and effective by skilled clinician; should be used when infection is suspected; causes pain
<b>Enzymatic:</b> Topical débriding agent to dissolve the necrotic tissue; appropriate when there are no signs or symptoms of local infection
<b>Autolytic:</b> Synthetic dressing to allow the devitalized tissue to self-digest from the enzymes found in the ulcer fluids; recommended for those who cannot tolerate débridement; may take a long time to be effective; commonly used with palliative wounds
<b>Biosurgery:</b> Larvae to digest devitalized tissue; quick and effective; good option for those who cannot tolerate surgical débridement; limited by access to larvae

ineffective if you are unable to slide your hand freely. For immobile individuals, offload the heels by “floating the heels” with pillows under the patient’s legs.

**Pain.** Dressing changes hurt. Use individualized pain management. Assess pain frequently using a valid and reliable tool when possible. Attention should also be paid to visual cues and signs of pain when determining pain levels, specifically for those patients who are unable to provide pain rating or description. Both pharmacologic and nonpharmacologic interventions should be considered. Physical and occupational therapy consult may be beneficial as E-stim, diathermy, and ultrasound have demonstrated effectiveness in reducing pain associated with pressure injury. Additionally, consider premedication prior to wound dressing changes or other procedures.

**Assessment of nutrition/hydration.** Pressure injuries occur in sicker individuals in whom overall intake may be reduced by coexisting illness. If adequate dietary intake is compromised, supplemental vitamins/minerals at the recommended daily allowance (RDA) should be considered. Protein supplementation may improve outcomes in the treatment of pressure ulcers, as per current guidelines. However, a 2014 Cochrane review concluded that there is no clear evidence that nutritional interventions (i.e., dietary supplementation) reduce the number of people who develop pressure injuries or help the healing of existing pressure injuries. There is no evidence to support the use of vitamin C or zinc to treat pressure injuries in patients who are not deficient in these nutrients. There is no difference in healing rates associated with supratherapeutic doses of vitamin C or zinc. Adequate nutrition and hydration are essential for wound healing. Current guidelines recommend dietary referral for comprehensive nutritional assessment. This includes documentation of food and fluid intake, BMI and weight history, and nutrition focused physical assessments to assess for muscle wasting. Serum protein, serum albumin, prealbumin, and other laboratory values are no longer recommended as they are affected by inflammation, renal function, and other factors and do not correlate well with clinical observation of nutritional status. Protein supplements have demonstrated effectiveness in promoting wound healing and maintaining weight in individuals with pressure injury. Artificial nutrition is considered an option for those patients who cannot meet their nutritional requirements via normal oral intake. The decision to use tube feeding must consider the patient’s wishes, overall goal of care, and complications of tube feeding. Recent studies surprisingly observed that the use of tube feedings increased the incidence of pressure injuries and was associated with poorer healing. Tube feeding is associated with agitation, increased use of physical and chemical restraints and worsening of ulcers in individuals with severe dementia.

**Removal (débridement) of necrotic tissue.** Débridement by any of several methods (Table 1) may improve the time to a clean wound bed, but the effect of débridement on the time to healing remains to be determined.

**Promotion of healing (reepithelialization).** Pressure injuries should be cleansed with wound cleanser, saline, or tap water in combination with gauze to remove biofilm, slough, or necrotic debris that can be

**TABLE 2** Pressure Injury Dressing Types

DRESSING	RECOMMENDATIONS
Hydrocolloid	Light to moderate exudate ulcers
	Clean stage 2 or shallow (noninfected) stage 3 ulcers
	Consider using filler dressing beneath in deep ulcers to fill dead space
	Consider for autolytic débridement
Transparent film	Partial thickness with minimal exudate ulcers or closed wounds
	Consider as secondary dressing with alginate or other wound filler that will likely remain in the ulcer for an extended time (3–5 days)
	Do not use on moderately to heavily exudative ulcers
	Do not use as cover dressing over enzymatic débriding agents
Hydrogel	Full thickness with minimal or no exudate (stage 3 or 4) ulcers
	Consider use on shallow, minimally exudate ulcer
	Consider amorphous hydrogel for granulating noninfected ulcers
Alginate	Full thickness with moderate to heavy exudate ulcers with cavities (stage 3 or 4)
	Consider in clinically infected ulcer with concurrent treatment for the infection
	Consider for dry ulcer beds
Foams	Exudate stage 2 and shallow stage 3 ulcers
	Avoid using single small piece pf foam in exudate ulcer with cavities
	Consider gelling foam in heavily exuding ulcers
Silver impregnated	Clinically infected or heavily colonized Avoid prolonged use; discontinue when wound infection is controlled

easily removed with each dressing change (see [Table 1](#)). The choice of a particular dressing depends on the wound characteristics, such as amount of exudate, dead space, or wound infection. A hydrocolloid, foam, or other nonadherent dressing that promotes a moist wound environment should be used ([Table 2](#)). Follow manufacturer recommendations regarding frequency of dressing changes. Negative pressure wound therapy (NPWT), skin grafting, and surgical closure are advanced options for closure of pressure injuries and are effective at reducing infection and heal time. This can greatly improve quality of life for patients with pressure injuries. Consider referral to wound specialist or surgeon for evaluation of these options.

### Monitoring

**Measurement.** After staging the pressure injury, measure the length, width, and depth of ulcers. Document the presence of exudate, necrotic tissue, eschar, slough, undermining, and tunneling. Presence of healing tissue (pink granulation or epithelialization) should be recorded as well. Measurement frequency depends on the patient's care location, whether it's the hospital, a long-term care facility, or home care.

**Infection.** All pressure ulcers are colonized with bacteria. Never swab a chronic ulcer. The presence of bacteria alone does not indicate active infection, only colonization. Edema, odor, and purulent discharge are nonspecific. Worsening pain, erythema at

wound edges, and warmth are signs of advancing cellulitis. Fever or delirium may be the only signs of infection. Systemic rather than topical antibiotics should be used to treat an infected pressure ulcer. Consider osteomyelitis when bone is exposed.

## PRURITUS ANI AND VULVAE

Method of

Muhammad Ahmad Ghazi, MD

### CURRENT DIAGNOSIS

- Anogenital pruritus is primarily idiopathic; most secondary etiologies can be divided into dermatologic, anogenital conditions, and systemic causes.
- Good history and physical examination are important for accurate diagnosis.
- Laboratory tests and procedures to diagnose the cause of pruritus ani and vulvae should be tailored to individual patients based on their presentation.

### CURRENT THERAPY

- Initial treatment is usually conservative, and clinicians should focus on reassurance, education about hygienic practices, regular bowel movements, avoidance of moisture and irritants, and a trial of topical corticosteroids.
- Anogenital conditions such as hemorrhoids, fissures, skin tags, and fistulas—if present—must be treated first.
- Pruritus vulvae secondary to lichen planus, lichen sclerosus, and lichen simplex chronicus usually require superpotent topical steroid treatment.
- Refractory cases of pruritus ani may benefit from injectable treatments of methylene blue.<sup>1</sup>
- Suspicious lesions of vulva and perineum that are resistant to initial treatment must be biopsied to rule out malignancy.

<sup>1</sup>Not FDA approved for this indication.

Pruritus ani and vulvae is not a disease per se; rather, it is a symptom or manifestation of an underlying disease or the result of poor

personal hygienic practices. Pruritus is derived from the Latin *prurire*, which means “to itch.” Pruritus ani is literally an unpleasant sensation leading to scratching the skin around the anal opening. Anogenital pruritus is a commonly ignored skin condition. Symptoms range from mild to severe and can be complicated by sleep disturbances, anxiety, depression, and social embarrassment. Pruritus ani and vulvae can be primary, in which case there is no identifiable cause, or be secondary to an underlying condition. Most of the secondary causes are anorectal, including hemorrhoids, fistulas, and fissures. Psoriasis, lichen sclerosus, and lichen simplex chronicus are common secondary dermatological causes of pruritus in the vulvar region.

### Epidemiology

Pruritus ani is a common condition with an estimated prevalence of 1% to 5% of the population. It affects all ages and both genders. Male to female prevalence of pruritus ani is about 4:1. Symptoms are worse at night and in warm, moist climates. Pruritus vulvae is seen in women of all ages. Young females usually present with an infectious etiology while the primary disease is more common in postmenopausal women. Genital pruritus in men is rare and usually presents with balanitis.

### Risk Factors

Poor personal hygiene, chronic diarrhea, obesity, high-risk sexual behaviors, and immunodeficiency states predispose a person to pruritus in the anogenital area. Heat, sweating, and tight undergarments may exacerbate the condition. A proposed list of causative factors is included in [Boxes 1 and 2](#).

### Pathophysiology

The itching sensations of pruritus ani and vulvae are mediated by unmyelinated C fibers, which are distributed densely in the perineal region at the dermal-epidermal junction of the skin. Irritants in

#### BOX 1 Common Causes of Pruritus Ani

Acute	Chronic
Idiopathic up to 25% of cases	Dermatoses:
Fecal contamination:	Allergic or contact dermatitis,
Poor hygiene	psoriasis, lichen planus,
Fecal incontinence	lichen simplex chronicus,
Anal sphincter dysfunction	lichen sclerosis, Hailey-Hailey disease
Anorectal pathology: 10% to 50% of cases	Inflammatory:
Hemorrhoids, perianal fissures, pilonidal sinus, perianal abscess, rectal prolapse, polyps, and papilloma	Inflammatory bowel disease (ulcerative colitis and Crohn's disease)
Mechanical factors:	Malignant:
Excessive washing, rubbing, synthetic undergarments	Anal squamous cell cancer
Infectious:	Extramammary Paget's disease
Erythrasma (corynebacterium infection), Candida, dermatophytosis, herpes simplex, human papilloma virus, HIV, syphilis	Lymphoma/leukemia
Parasitic:	Metabolic:
Scabies, pinworm	Diabetes mellitus, chronic liver disease and chronic kidney disease, celiac disease, iron deficiency anemia, hypovitaminosis A, B, D, E
Dermatoses:	Miscellaneous:
Allergic or contact dermatitis, psoriasis, drug eruptions	Hyperhidrosis
Dietary factors:	Neuropathic pruritus
Tomatoes, chilis, coffee, beer, soda, dairy, chocolate, tea, citrus fruits	Psychogenic (anxiety related)

#### BOX 2 Common Causes of Pruritus Vulvae in Women

PREPUBERTAL AGE	REPRODUCTIVE AGE	POSTMENOPAUSAL AGE
Poor hygiene	Vaginitis	Urinary or fecal incontinence
Sensitization of vulvar skin: soaps, deodorants	Trichomonas	Menopause: Lack of estrogen leads to loss of skin elasticity and makes it prone to itching
Contact dermatitis	Bacterial vaginosis	Atrophic vaginitis
Parasitic infestations: Pinworms (Enterobius vermicularis), pediculosis, scabies	Candidiasis	Lichen sclerosis
Bacterial infections (Group A beta hemolytic infections and Escherichia coli)	Rarely tinea cruris	Paget's disease of vulvae
Vaginal candidiasis (rare in this age group)	Herpes simplex type II	Vaginal malignancy (squamous cell cancer)
Lichen sclerosis	HIV, syphilis	
Suspected child sexual abuse (based on evidence of genital trauma)	Dermatitis	
	Atopic dermatitis	
	Contact dermatitis	
	Psoriasis	
	Lichen planus	
	Lichen simplex chronicus	
	Lichen sclerosis	
	Seborrheic dermatitis	
	Pregnancy	
	Vulvar itching is worsened because of vulvar engorgement; pregnancy also predisposes women to vaginal discharge and candidiasis	
	Systemic diseases: Diabetes, renal and liver diseases	
	Miscellaneous	
	Vulvar intraepithelial neoplasia (HPV)	
	Mechanical trauma	
	Idiopathic	

stool (exotoxins, intestinal lysosymes, endopeptidase, trypsin) and increased alkalinity of certain foods such as tomatoes, chocolate, and caffeine contribute to the perianal itching that precedes scratching. The itch-scratch cycle is mediated by several mechanical and inflammatory mediators, including histamine, kallikrein, bradykinin, trypsin, serotonin, and neuropeptides. The resulting nerve impulse is carried via spinothalamic tract to the thalamus, where the itching sensation is perceived. Intestinal transit time and altered anal sphincter pressure are influenced by certain foods that predispose people to perianal seepage and pruritus.

Pruritus vulvae is the result of increased permeability of the dermis resulting from a structurally thin stratum corneum as compared to the rest of the vulvar skin. Factors aggravating the pruritus include constant friction, rubbing, anatomic location, occlusion, moistness, fear of uncleanliness in women, and excessive washing. The most common cause of pruritus vulvae is vulvar dermatitis or eczema, which affects one-third to half of all women presenting with this complaint. Dermatitis or eczema can be endogenous and the result of familial disposition, and it manifests as atopic dermatitis. Exogenous dermatitis such as contact dermatitis can be allergic, given that a trigger (allergen) might induce an immune response or contact irritant dermatitis. Common irritants include soaps, shampoos, vaginal creams, alcohol, tea tree oil,<sup>7</sup> douches, vaginal hygiene products,

<sup>7</sup>Available as dietary supplement.

vaginal contraceptives, sanitary pads, nylon underwear, and toilet paper. Chemical allergens contributing to contact dermatitis in the genital area include benzocaine, neomycin, ethylenediamide, propylene glycol, latex dyes, nickels, semen, lanolin, perfumes, and tampons.

### Clinical Manifestations

Perianal and vulvar itching, erythema, excoriations, fissures, hemorrhoids, pinworms, and fecal incontinence may be noticed on inspection of the perineal area. In the acute phase, skin redness of varying degrees is visible. Excoriations from the skin from itching may be present. Fissures in the labial folds may be present. Superinfection with yeast or bacteria may complicate the presentation.

Chronic anogenital dermatitis usually presents as erythema of varying degrees, and papillae appear in the labial folds. Hypo- or hyperpigmentation of the skin or thickening of the labial skin might develop over time, causing “lichenification,” which leads to lichen simplex chronicus.

### Diagnosis of Pruritus Ani and Vulvae

A detailed history of bowel habits and personal hygiene (including products used, such as perfumes); dietary habits (e.g., caffeine consumption); and previous medical, psychiatric, and surgical history help elucidate the cause of pruritus ani. The patient should be asked about personal or family history of hives, asthma, conjunctivitis, or atopy when allergic dermatitis is suspected. Other relevant questions of history include recent use of antibiotics, clothing preferences, family history of cancers, other family members with similar symptoms (pinworms and scabies), rectal bleeding, change in bowel habits, or sexual preference (anal receptive intercourse). For pruritus vulvae, the patient should be asked about any history of itching, burning sensation, vaginal discharge, postcoital bleeding, or dysperunia. Rarely, elderly patients with lumbosacral radiculopathy may experience perianal itching as a result of neurological deficits.

### Physical Examination

Inspection with a bright light and a chaperone is recommended. Palpation includes a digital rectal exam and a female pelvic examination in case of pruritus vulvae. Wet preparation of vaginal secretions for *Candida*, bacterial vaginosis, potassium hydroxide testing, and cultures for *Neisseria gonorrhoeae* and chlamydia are recommended. Microscopic examination of scrapings will help to differentiate the parasitic and fungal infections.

### Laboratory Tests

Laboratory tests should not be done routinely in all cases and should be tailored to the patient’s history and physical examination. Below is a list of laboratory tests that should be considered when diagnosing possible causes of anogenital pruritus:

1. CBC (complete blood count) helps to differentiate between parasitic and infectious cases and diagnoses anemia (a possible cause of chronic pruritus ani)
2. Chemistry profile (to identify systemic causes such as hepatic and kidney diseases)
3. Urinalysis to screen for infection and systemic diseases such as diabetes
4. DNA polymerase chain reaction probe for gonorrhea and chlamydia
5. Cellophane tape test to look for pinworms
6. Stool for ova and parasites
7. Test for diabetes mellitus and HIV if suspected
8. Anal Pap smear for HPV is indicated if there is a history of anal receptive intercourse

### Procedures

Anoscopy and proctoscopy are indicated to diagnose hemorrhoids and perianal fistulae. Colposcopic examination of the perineum may provide a detailed view of local pathology.

Colonoscopy is indicated for patients over 40 with a family history of colon cancers. Patch testing should be performed to diagnose allergic contact dermatitis. A skin biopsy is indicated in case of ulcerated skin lesions, refractory cases, and suspicious lesions to rule out malignancy. A 3 to 6 mm punch biopsy is recommended.

### Differential Diagnosis

A broad range of clinical problems can be enumerated in the differential diagnosis, including (but not limited to) allergic skin reactions, infections, parasitic infestations, chronic liver disease, diabetes, and neoplasms; chronic conditions such as psoriasis or dermatitis; infections such as condylomata accuminata; and skin cancers such as Bowen’s disease, squamous cell cancer, Paget’s disease, or melanoma.

### Prevention and Treatment

#### General Principles of Treatment

The goal of treatment should be the resolution of symptoms, restoration of skin anatomy, and prevention of recurrence. The most important step in the management of pruritus ani and vulvae is reassurance and patient education (Figure 1). An informed and educated patient tends to deal with symptom-related anxiety better. To identify and treat the cause, it should be understood that pruritus ani and vulvae are commonly idiopathic, and conservative measures are usually sufficient to treat the condition. However, secondary causes need to be identified and treated.

Anorectal conditions such as hemorrhoids, fistulas, and fissures may require surgical treatment and consultation. Antidiarrheals should be used in cases of loose stool. A high-fiber diet should be started.

Women presenting with vulvar pruritus should be screened and treated for vaginal infection (e.g., one dose of oral fluconazole [Diflucan] 150 mg for vulvovaginal candidiasis; metronidazole [Flagyl] 500 mg oral twice daily for 7 days for bacterial vaginosis). Dermatological conditions such as psoriasis and dermatitis are treated with topical steroids. Hormone replacement therapy can be used in cases of menopause. Topical estrogen creams are better alternatives for symptomatic relief.

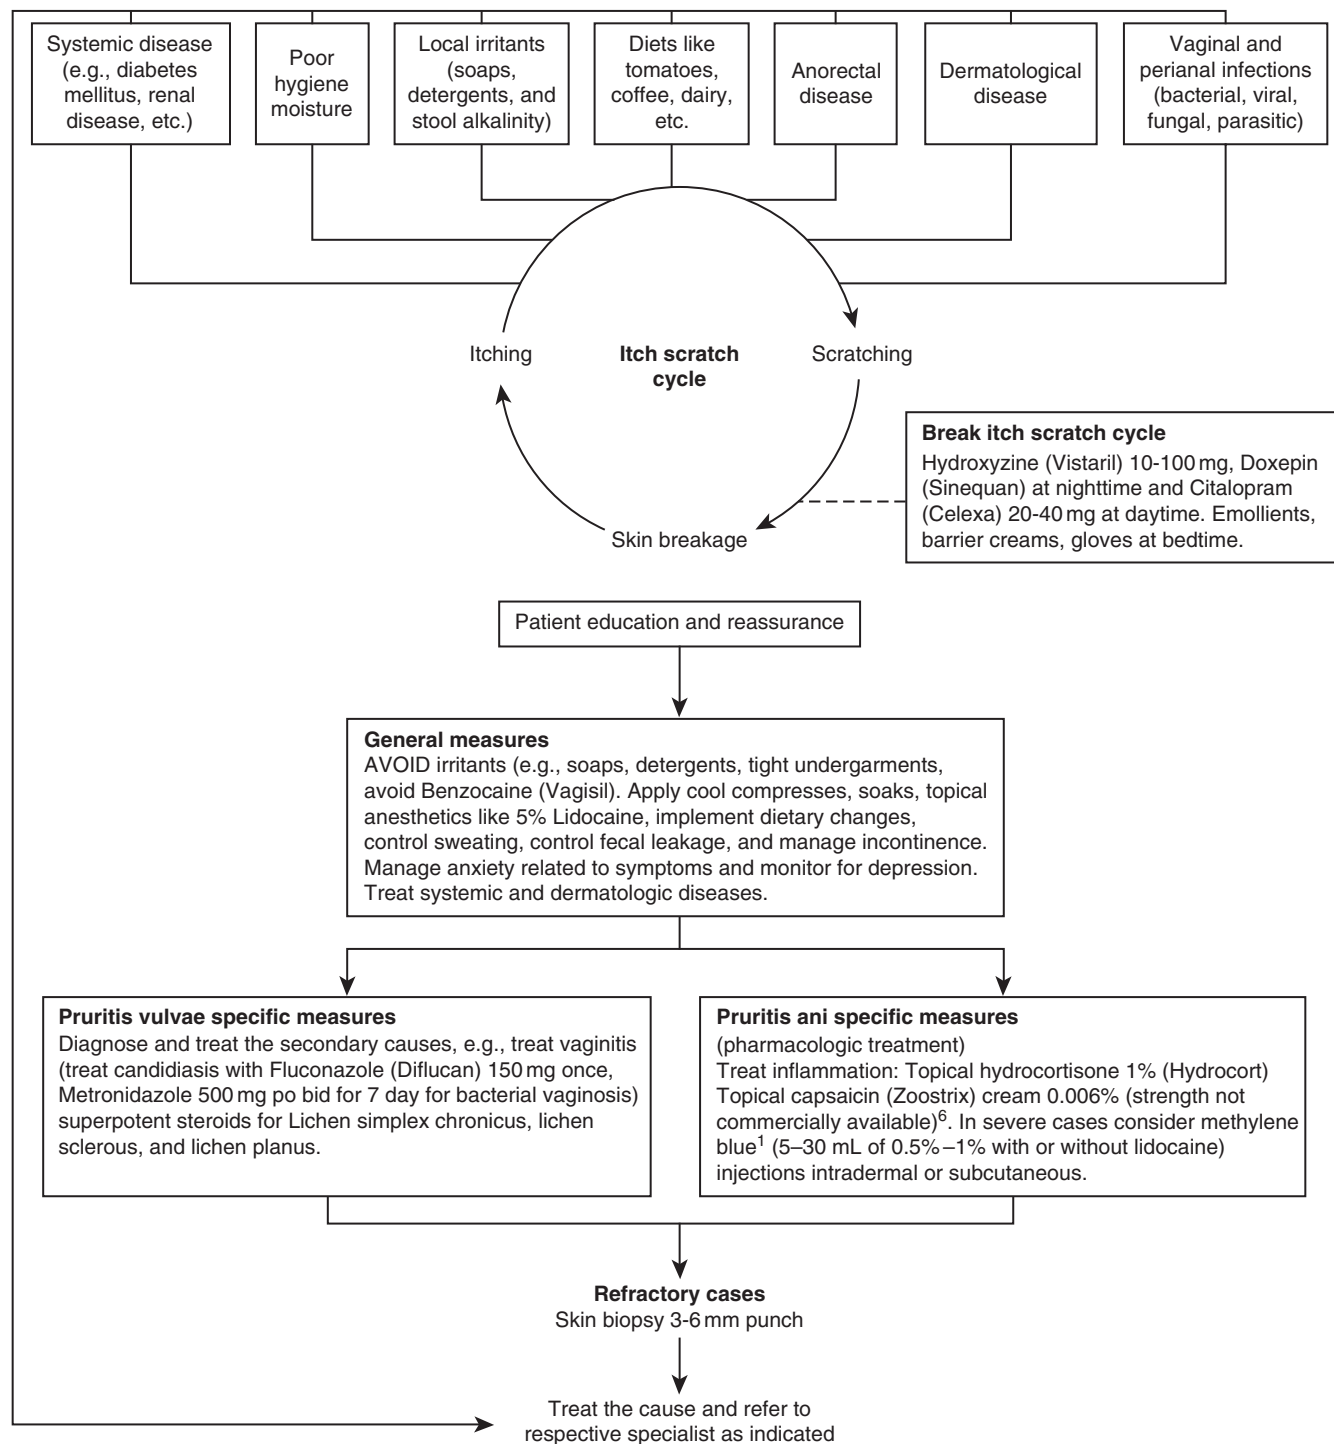

Patients should be instructed to gently cleanse the perianal area twice daily and after each bowel movement. Sitz baths with plain warm water are recommended for perianal pruritus. The perianal area should be patted dry after washing. Patients with vulvar pruritus should avoid tight undergarments, jeans, and panty hose. The use of laundry detergents, bubble baths, feminine douches, or sprays containing protease should be discouraged. Women with a predisposition to vulvar dermatitis should wear loose pants. Panty liners should be avoided and replaced with tampons or cotton cloth. Vulvae should be washed gently; women should avoid vigorous rubbing or cleaning. Patients with vulvar pruritus should use a bland moisturizer as a soap substitute to avoid irritation resulting from chemicals. The vulva should be dried before wearing underwear, and excessive perspiration should be controlled with talcum powder. Patients should be encouraged to manage incontinence and maintain an ideal body weight. Cornstarch should be avoided, as it can lead to bacterial colonization and exacerbation of symptoms.

Dietary modifications (for anal pruritus) are imperative, including limitations on the consumption of chocolate, tea, coffee, citrus fruits, and alcoholic beverages. Eating yogurt is recommended, especially while on antibiotics, to prevent diarrhea and worsening of perianal seepage.

Emollients such as aqueous creams or petrolatum or emulsifying ointments treat itching and dry skin, which can prevent erosion and ulcer formation. These agents can be used irrespective of the etiology of pruritus. Zinc oxide (Desitin) cream is used topically to prevent excoriations in cases of perianal and vulvar pruritus. Combination products such as zinc oxide/bacitracin (rash relief antibacterial), zinc oxide/menthol (Calmoseptine), and zinc oxide/miconazole (Vusion) are available and can be used for symptomatic relief. Topical anesthetics (lidocaine 5% [L-M-X5 Anorectal, Topicalaine 5]) may be used twice a day to help with acute symptoms. Topical benzocaine (Vagisil Anti-Itch Creme) should be avoided, as it is a strong irritant and allergen. Cool compresses and gel packs can help. Ice should not be used, as it can cause frostbite.

Antihistamines should be used to improve sleep, and patients should wear cotton gloves at night to prevent itching while asleep. Nails should be cut short, and nail varnish should be avoided. Sedating antihistamines might help (e.g., hydroxyzine [Vistaril] 50 mg PO at bedtime; doxepin [Sinequan]<sup>1</sup> 10 to 100 mg at bedtime; citalopram

<sup>1</sup>Not FDA approved for this indication.

**Figure 1** Pathogenesis and management of pruritus ani and vulvae. <sup>1</sup>Not FDA approved for this indication. <sup>6</sup>May be compounded by pharmacists.

[Celexa]<sup>1</sup> 20 to 40 mg during the daytime). Citalopram can also help with underlying anxiety symptoms, but caution is advised in the elderly and patients at risk of arrhythmias, because citalopram can cause QT interval prolongation. Any suspicious lesions of the vulvae and perineum should be biopsied to rule out underlying malignancy.

#### Pharmacologic Treatments

For mild pruritus ani, 1% to 2.5% hydrocortisone (Hydrocort) topical ointment is effective. Pramoxine (Prax, Senna Sensitive) can also be used alone or in combination with topical hydrocortisone cream (Analpram-HC, Pramosone). 1% Hydrocortisone/1% iodoquinol (Vytone) can be used as an antiinflammatory treatment for external use in the anal and vulvar area. Topical capsaicin cream 0.006%<sup>6</sup> has been used in cases of refractory

itching and can be combined with topical hydrocortisone cream to avoid hypersensitivity. This strength of capsaicin cream is not commercially available.<sup>6</sup> Mild topical corticosteroid ointments are sufficient to treat the perianal pruritus, and superpotent steroids should be avoided, as the skin is thin and there is a risk of ulcer formation. Methylene blue<sup>1</sup> injections are reserved for long-standing, intractable pruritus ani. Methylene blue 0.5% to 1% 5 to 30 mL mixed with normal saline and local anesthetics is injected intradermally, subcutaneously, and intracutaneously in the perianal skin to produce hypoesthesia. This treatment may be repeated, and studies report a success rate of 80% to 90%. Possible complications associated with methylene blue injections include cellulitis, transient urinary incontinence, urinary retention, skin abscess and skin necrosis. Long term effectiveness of these injections need further prospective studies.

<sup>6</sup>May be compounded by pharmacists.

For moderate vulvar disease, 0.1% triamcinolone (Kenalog) ointment is recommended. For severe cases and thickened skin, the superpotent steroid topical clobetasol (Temovate) or halobetasol (Ultravate) 0.05% ointments can be used. The use of these superpotent steroid creams should be limited and reserved for the resistant cases of pruritus vulvae, lichen simplex chronicus, lichen sclerosus, or resistant lichen planus. Vulvar lichen and lichen planus should be treated over the long term with superpotent steroids for adequate response and treatment. A very thin layer of steroid cream should be used, and patients should be educated about the side effects of the medication before starting the treatment. For vulvar lichen planus and lichen sclerosus, superpotent steroids are used topically once or twice daily for 2 to 3 months; three times a week for 1 month; then once or twice per week for the long term. For lichen simplex chronicus, treatment is twice daily for 2 weeks and then once daily for 2 weeks. It then moves to three times per week.

Topical calcineurin inhibitors 1% pimecrolimus cream (Elidel)<sup>1</sup> or 0.03% to 1% tacrolimus ointment (Protopic)<sup>1</sup> may be used for refractory cases as steroid-sparing agents. A common side effect of these agents is a burning sensation, so their use is controversial in cases of lichen sclerosus and lichen planus. Lichen sclerosus has 2-5% increased risk of developing squamous cell cancer, therefore clinical monitoring is recommended every 6-12 months and suspicious lesions must be biopsied.

In cases of neuropathic pruritus ani and vulvae, amitriptyline (Elavil)<sup>1</sup> 10 to 150 mg at bedtime is suggested. Other options are gabapentin (Neurontin)<sup>1</sup> 300 to 3600 mg up to three times a day (maximum daily dose is 3600 mg); pregabalin (Lyrica)<sup>1</sup> 75 to 400 mg/day; and mirtazapine (Remeron)<sup>1</sup> 7.5 to 15 mg at bedtime. In resistant and rare cases in which none of the above mentioned treatments is effective, radiation treatment may be indicated to destroy nerve endings. Naltrexone<sup>1</sup>, an opioid antagonist has shown effectiveness in reducing itching episodes after one week of treatment in a case study. Case reports suggest treatment of perianal atopic dermatitis resistant to other treatments may respond to dupilumab (Dupixent)<sup>1</sup>, which is a monoclonal antibody. Treatment should be reserved for biopsy confirmed cases of atopic dermatitis in consultation with dermatologist. Several experimental treatments, such as laser phototherapy, alcohol injection therapy, radiation, and surgery, have not been studied and are not recommended routinely.

### Complications

Pruritus ani and vulvae can lead to myriad complications, including lichenification, skin excoriations, ulcers, secondary bacterial infections, and abscess formation.

### Referral

For undiagnosed and resistant skin conditions, patients should be referred to a dermatologist. Persistent anal itching, a change in bowel habits, and rectal bleeding should prompt a referral to a gastroenterologist and colorectal specialist. Pruritus vulvae with vaginal bleeding and weight loss are indications for referral to a gynecologist.

### Monitoring and Prognosis

Most cases of pruritus ani and vulvae are treated with general measures that lead to a full recovery. Long-term use of corticosteroids should be discouraged, and periodic monitoring for side effects, including skin erosions and bleeding, is advisable based on reported symptoms. The idiopathic disease usually persists and depicts a relapsing remitting course.

<sup>1</sup>Not FDA approved for this indication.

## PYODERMA GANGRENOSUM

Method of

Dominic J. Wu, MD; and Anand N. Rajpara, MD

### CURRENT DIAGNOSIS

- Pyoderma gangrenosum (PG) is a chronic inflammatory and ulcerative skin disease of uncertain etiology that is commonly mistaken for skin infection.
- Diagnosis of PG is typically a diagnosis of exclusion. Thorough workup to exclude other causes of ulcerative diseases (e.g., infection, malignancy, vascular) is paramount.
- There is no uniformly accepted diagnostic algorithm, and many have been proposed. A recent Delphi consensus set of diagnostic criteria is becoming more widely adopted.
- Recent diagnostic criteria require biopsy of the ulcer edge demonstrating neutrophilic infiltrate as the major criterion, while ruling out infection is no longer an absolute requirement.

### CURRENT THERAPY

- There is no established gold standard treatment regimen.
- Goals of therapy should include reducing inflammation, reducing pain, and controlling any contributing underlying diseases.
- Due to the nature of the disease and complex medical treatments, it is important to involve relevant consultants early on, such as dermatology, rheumatology, gastroenterology, rheumatology, ophthalmology, etc.
- For mild, localized disease, consider topical and/or intral-lesional corticosteroids.
- For moderate to severe cases, the first-line systemic agents are historically systemic corticosteroids and cyclosporine (Neoral, Sandimmune).<sup>1</sup>
- Alternative treatment options that have shown success include tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) inhibitors such as infliximab (Remicade)<sup>1</sup> and adalimumab (Humira),<sup>1</sup> mycophenolate mofetil (CellCept),<sup>1</sup> IVIG,<sup>1</sup> tetracyclines,<sup>1</sup> and more.
- Avoid debridement and surgical procedures due to risk of pathergy.
- Appropriate wound care is essential, including selection of appropriate dressings. Less exudative wounds can be treated with hydrogels and films. More exudative lesions should be managed with more absorptive dressings such as hydrocolloids and alginates. Consider involvement of wound care specialists.

<sup>1</sup>Not FDA approved for this indication.

## Pathophysiology and Epidemiology

Pyoderma gangrenosum (PG) is a chronic ulcerative inflammatory neutrophilic dermatosis of uncertain etiology that is often misdiagnosed as severe skin infection. It is a relatively rare condition with incidence estimated at approximately 3 to 10 cases per million people per year, but it is not uncommonly encountered in dermatology clinic. It most frequently presents in young to middle-aged female adults between 20 to 50 years of age. Although its exact etiology is unknown and 25% to 50% of patients have idiopathic disease, it is frequently associated with numerous systemic diseases including inflammatory bowel disease (ulcerative colitis, Crohn disease), malignancy, granulomatosis with polyangiitis, Behçet disease, and more. This association suggests a possible underlying immunologic abnormality. PG is also a component of multiple genetic conditions including PAPA (pyogenic arthritis, PG, acne), PASH (PG, acne, hidradenitis suppurativa), and PAPASH (pyogenic arthritis, PG, acne, hidradenitis suppurativa) syndromes. Pathergy, even from minor trauma, may result in initiation and aggravation of PG lesions.

## Clinical Manifestations

The clinical appearance of PG can often mimic other skin diseases, especially ulcerative infectious skin diseases, vascular diseases, and malignancies. The classic most characteristic clinical subtype is ulcerative PG. In addition, there are three other main clinical subtypes including pustular, bullous, and vegetative. The initial lesion of classic PG (ulcerative) typically begins as a painful solitary nodule or pustule that ruptures and undergoes necrosis, resulting in the formation of an ulcer. The most frequent location of PG is on the lower extremities (especially the pretibial region); however, it can appear anywhere including mucous membranes. The center of the classic PG ulcer is frequently coated with purulent material and granulation tissue. The edge of the ulcer is characteristically dusky to violaceous, irregular, undermined, and overhanging (Figure 1). Pustular PG is more commonly seen in patients with underlying inflammatory bowel disease and presents with multiple pustules with surrounding erythema to violaceous rim. These pustules may or may not rupture to form a more classic-appearing PG ulcer. Bullous, or atypical PG, is most commonly seen in patients with underlying lymphoproliferative disorders such as leukemia or multiple myeloma. Lastly, vegetative PG presents with more superficial ulcerations without significant purulence and undermined borders.

Although the ulcer of PG is not infectious in itself, it may become secondarily infected, resulting in increased purulence and malodor.

## Diagnosis

The clinical, laboratory, and histologic findings in PG are rather nonspecific; thus a diagnosis of PG is typically a diagnosis of exclusion. A detailed history of the lesion including evolution, pain, pathergy, and any associated underlying conditions are critical. General approach to workup includes biopsy of ulcer edge demonstrating neutrophilic infiltrate, and broad workup should be considered to exclude other causes including complete blood count (CBC; underlying hematologic disorder), bacterial and fungal cultures, herpes simplex virus (HSV)/varicella zoster virus (VZV) PCR, antinuclear antibody (ANA) (underlying autoimmune conditions—systemic lupus erythematosus, collagen vascular disorders), antineutrophil cytoplasmic antibodies (ANCA; granulomatous vasculitis), hypercoagulability studies (vascular etiology), rheumatoid factor, urinalysis, serum and/or urine protein electrophoresis, chest imaging, and colonoscopy (evaluate for inflammatory bowel disease [IBD]). Other laboratories including comprehensive metabolic profile, hepatitis panel (which can also be helpful in evaluating for cryoglobulinemia), and tuberculosis screening are also helpful in preparation of potential treatment with immunosuppressive agents. Individual clinicians may choose varying levels of workup, depending on clinical suspicion and patient history.

Numerous diagnostic criteria and algorithms have been proposed, although they have not been uniformly accepted. Previously, diagnostic criteria required excluding all other diagnoses including infection, which is challenging and often results in delayed treatment. A recent Delphi consensus of international experts proposed and validated a set of diagnostic criteria as below:

**Figure 1** Classic ulcer of pyoderma gangrenosum with dusky to violaceous, irregular, undermined border. From James WD, et al: *Andrews' Diseases of the Skin*. Philadelphia: Elsevier; 2019.

Major criterion:

- Biopsy of ulcer edge demonstrating a neutrophilic infiltrate

Minor criteria:

- Exclusion of infection
- History of pathergy
- Personal history of IBD or inflammatory arthritis
- History of papule, pustule, or vesicle that rapidly ulcerated
- Peripheral erythema, undermining border, and tenderness at site of ulceration
- Multiple ulcerations (at least one occurring on an anterior lower leg)
- Cribriform or “wrinkled paper” scar(s) at sites of healed ulcers
- Decrease in ulcer size within 1 month of initiating immunosuppressive medication(s)

Diagnosis of PG requires the major criterion and four or more minor criteria. These criteria are becoming more widely adopted in academic institutions.

## Differential Diagnosis

It is important to consider and exclude alternative diagnoses when evaluating a patient with possible PG. PG can mimic ulcerative infections such as herpes simplex virus, ecthyma gangrenosum, chancroid, deep fungal infections, sporotrichosis, atypical mycobacterial infection, necrotizing fasciitis, syphilis, and Buruli ulcer. Vascular disorders to consider include venous or arterial ulcerations, vasculitides including granulomatosis with polyangiitis, polyarteritis nodosa, cryoglobulinemia, and so on.

## Therapy

There is no one-size-fits-all treatment for PG, and the goal of therapy is primarily to reduce the inflammatory process, promote healing, reduce pain, and treat any contributing underlying medical conditions. Debridement and surgical therapy should be avoided if possible due to pathergy and potential for worsening disease. Surgical therapy in other areas of the body should also be avoided if possible due to risk of developing similar lesions at other sites. It is important to involve relevant consultants as soon as possible based on the patient's case, including dermatology, ophthalmology, rheumatology, oncology, gastroenterology, and so on.

First-line therapy includes local high-potency topical corticosteroids such as clobetasol propionate 0.05% (Clobex, Temovate) twice a day and/or systemic corticosteroids such as prednisone 0.5 to 1 mg/kg/day divided in two to three doses, with slow taper over weeks to months. Colchicine<sup>1</sup> 0.6 mg PO three times a day has shown success as monotherapy or used in conjunction with corticosteroids. Cyclosporine (Neoral, Sandimmune)<sup>1</sup> 2.5 to 5 mg/kg/day divided twice a day has been demonstrated to lead to rapid improvement in pain and improvement in ulceration. Combination therapy with systemic corticosteroids and cyclosporine has also demonstrated success. Milder localized disease can be treated with intralesional corticosteroid injections such as with triamcinolone acetonide (Kenalog) 10 mg/mL into the ulcer edge or high-potency topical corticosteroids.

Alternative therapies utilized with success for moderate to severe disease include infliximab (Remicade)<sup>1</sup> 5 mg/kg IV at weeks 0, 2, and 6; adalimumab (Humira)<sup>1</sup> 80 mg SC loading dose, followed by 40 mg SC weekly or every other week; mycophenolate mofetil (Cellcept)<sup>1</sup> 750 mg to 1.5 g PO twice a day; dapsone<sup>1</sup> 50 to 150 mg daily; sulfasalazine (Azulfidine) 0.5 to 6 g PO daily divided in 3 to 4 doses, methotrexate<sup>1</sup> 2.5 to 25 mg PO, SC, or IM weekly, and more. The authors have also seen success with intravenous immunoglobulin (IVIG)<sup>1</sup> 1.5 to 3 g/kg IV monthly given over 2 to 5 days, although this can be incredibly expensive and is generally used as adjuvant therapy. IVIG is also an option for treatment if there is secondary infection and immunosuppressive therapies with TNF- $\alpha$  inhibitors are contraindicated.

Tetracycline antibiotics such as minocycline (Minocin)<sup>1</sup> 200 to 300 mg/day divided in 2 doses have also been reported to show success in treatment of PG, thought to be related to their anti-inflammatory properties by reducing chemotaxis of neutrophils.

Appropriate wound care for PG ulcers is essential, depending on the clinical appearance of the lesion. Wound care specialists should be utilized if possible. Occlusive dressings are often utilized to increase the rate of healing by promoting angiogenesis, promoting collagen synthesis, and acting as a barrier against secondary infection. Hydrogels and films such as Tegaderm may be used in lesions with minimal exudate. In more exudative lesions, more absorptive dressings such as hydrocolloids, foams, and alginates would be more appropriate. Examples of these dressings that are frequently utilized for ulcer management include DuoDERM and SeaSorb. It is important to note that these dressings, especially alginates, may be associated with foul odor due to their reaction with healing tissue and may not actually be an indicator of secondary infection. Avoid wet-to-dry dressings, as this debridement may incite pathergy and cause aggravation of the wound.

## Monitoring

PG tends to be a chronic and recurrent disease. Ulcers may take many months to heal, and it is essential to monitor for any signs of developing infection. Patients and clinicians should monitor for increased pain, increased purulence, fevers, increased erythema and/or streaking—all of which can be indicators for secondary infection. Topical and oral antimicrobials may be helpful; however, this may lead to antibiotic resistance and should be utilized only if secondary infection is confirmed.

Adequate control of any contributing underlying conditions is essential, and patients should be advised that trauma and elective surgical procedures may trigger the development of future PG lesions.

Many of the treatments utilized in the management of PG also have their large range of adverse side effects, and it is important to monitor patients closely when they are taking these medications. For example, systemic corticosteroids are the most commonly employed agents in PG. More severe or resistant lesions may require prolonged therapy and at higher doses, which can lead to increased adverse side effects. These patients should be closely monitored, and consider recommending supplemental calcium, vitamin D, proton pump inhibitors if indicated, and even bisphosphonates. The duration of treatment is case-dependent and should be determined based on clinical response and any concerning side effects.

<sup>1</sup>Not FDA approved for this indication.

## ROSACEA

Method of

Lisa M. Johnson, MD; and Daniel J. Van Durme, MD, MPH

### CURRENT DIAGNOSIS

- Rosacea is a chronic inflammatory disease of the skin that predominantly affects the convexities of the central face (cheeks, chin, nose, and central part of forehead). It most commonly occurs in adults aged 30 to 50 years.
- Rosacea is a clinical diagnosis.
- Transition to a phenotype-based approach to the diagnosis, classification, and management of rosacea from the traditional subtype-based approach is occurring, allowing more individualized management of symptoms that most concern a patient.
- Two cutaneous phenotypes may be considered independently diagnostic of rosacea: (1) fixed centrofacial erythema in a characteristic pattern that may periodically intensify, or (2) phymatous changes.
- The presence of two or more major phenotypes (flushing, telangiectasia, inflammatory lesions, and ocular manifestations) may be considered diagnostic of rosacea.
- Common exacerbating factors that intensify signs and symptoms include alcohol, heat, spicy foods, and sunlight.

### CURRENT THERAPY

- Therapy is best chosen based on severity and predominant manifestation(s).
- Avoidance of known triggers is key for all types.
- Brimonidine tartrate 0.33% gel (Mirvaso, Onreltea) and oxymetazoline hydrochloride 1% cream (Rhofade) are useful for facial flushing. Ivermectin cream (Soolantra) and metronidazole gel (Metrogel, Rosadan) can be effective for papules and pustules. Isotretinoin (Accutane, Claravis)<sup>1</sup> can be effective in treating very severe and refractory rosacea.
- Ocular rosacea can be treated with increased eyelid hygiene, adding topical or oral antibiotics if needed.
- Rhinophyma (sebaceous gland hypertrophy and fibrosis) needs surgical management.

<sup>1</sup>Not FDA approved for this indication.

Rosacea is well established as a chronic cutaneous syndrome, encompassing various combinations of potential signs and symptoms that manifest primarily on the convexities of the central face (cheeks, chin,

nose, and central part of forehead). Signs and symptoms are often characterized by repeated remissions and exacerbations. Rosacea is commonly diagnosed in certain demographic groups, and in epidemiologic studies of Whites, its prevalence has been 10% or higher. Although it has been most frequently observed in patients with fair skin, rosacea has also been diagnosed in Asians, Latin Americans, African Americans, and Africans. The disorder is identified more often in women than in men, and although it may occur at any age, the onset typically occurs at any time after age 30.

### Diagnosis

The classification of rosacea was updated in 2016 and modified in 2019 by the global ROSacea COnsensus panel (ROSCO). This panel recommended transitioning to an individualized phenotype-based approach to the diagnosis, classification and management of rosacea rather than the traditional subtype-based approach. By focusing on individual lesions rather than a group of dermatologic characteristics constituting a subtype, treatment can be tailored to the signs and symptoms that most concern an individual patient.

### Diagnostic Phenotypes

The panel identified two phenotypes as independently diagnostic of rosacea: (1) centropalpebral erythema associated with periodic intensification, and (2) phymatous changes. Phymatous changes include patulous follicles, skin thickening or fibrosis, glandular hyperplasia, and a bulbous appearance of the nose. Rhinophyma is the most common form, but other phymas may occur.

### Major Phenotypes

Flushing transient erythema, telangiectasia, inflammatory lesions, and ocular manifestations were major phenotypes commonly identified in patients with rosacea but were not considered individually diagnostic. In the absence of one of the two diagnostic phenotypes, the presence of two or more of these major phenotypes may be considered diagnostic.

### Secondary Phenotypes

Secondary signs and symptoms of rosacea may appear with one or more diagnostic or major phenotypes and include burning or stinging, edema, and a dry appearance.

### Ocular Rosacea

Ocular rosacea can occur in the context of mild, moderate, or severe dermatologic disease and may also appear in the absence of diagnostic skin manifestations. Ocular signs strongly suggestive of ocular rosacea include lid margin telangiectases, interpalpebral conjunctival injection, spade-shaped infiltrates in the cornea, and scleritis and sclerokeratitis.

### Treatment

One key aspect of management is to have the patient maintain a careful diary for the purpose of determining and then avoiding his or her own triggers. Common triggers include alcohol, heat, certain foods, sunlight, stress, and menstruation, among others. Broad-spectrum sunblock (UVA and UVB) should be used daily, along with application of moisturizers for dry skin and drying applications for oily skin, and gentle cleansing of the whole face. Cosmetics with a red-neutralizing green pigment can help appearance.

Brimonidine tartrate 0.33% gel (Mirvaso, Onreltea) is a selective alpha<sup>2</sup>-adrenergic receptor agonist with vasoconstrictive activity and has been approved for the treatment of persistent (nontransient) facial erythema in adults 18 years and older with rosacea, along with oxymetazoline hydrochloride 1% cream ([Rhofade] an alpha<sub>1A</sub>-adrenoreceptor agonist that also activates alpha<sup>2</sup>-receptors at higher concentration).

Patients with mild to moderate papules and pustules benefit from topical 1% ivermectin cream (Soolantra), which is applied to the face once daily, and topical antibiotics such as metronidazole 0.75% to 1% cream, lotion, or gel (MetroCream 0.75%, Noritate 1% cream, MetroLotion 0.75%, Rosadan 0.75% gel, Metrogel 1% or azelaic acid 20% cream [Azelex]<sup>1</sup> or 15% gel

[Finacea]) applied once or twice daily. Persistent telangiectasias can be effectively treated with laser therapy and intravascular aethoxysklerol ([Asclera] 0.5%–1%)<sup>1</sup> injections.

Patients affected by mild phymata benefit from tetracycline<sup>1</sup> therapy. Standard therapies for advanced phymata are ablative (destructive) laser and dermatologic surgery. Low-dose isotretinoin (Accutane, Claravis)<sup>1</sup> appears to reduce phymata by its anti-inflammatory capacity and by lessening the number of sebaceous glands and inhibiting their proliferation.

There is no US Food and Drug Administration (FDA)-approved therapy for facial edema. Immunomodulators such as isotretinoin<sup>1</sup> and dapsone (oral or topical [Aczone gel])<sup>1</sup> or combination therapies with doxycycline (Oracea)/prednisolone have been tried, but the therapeutic value is unclear.

Both prescribers and patients must register with the iPledge program to prescribe and to receive the prescriptions for isotretinoin. See [www.ipledgeprogram.com](http://www.ipledgeprogram.com).

Ocular rosacea can often be controlled with increased eyelid hygiene, washing with warm water and baby (no-tears) shampoo twice a day along with artificial tears. Long-term consumption of omega-3 fatty acids<sup>7</sup> may improve meibomian-gland dysfunction. Topical ophthalmic cyclosporine drops (Restasis)<sup>1</sup> applied as one drop to the eye twice daily (12 hours apart) demonstrate statistically significant improvement in common signs and symptoms compared with artificial tears. If severe, it can be treated with systemic tetracycline.<sup>1</sup> If it persists, ophthalmology referral is necessary.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

## STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Method of

Scott Worswick, MD

### CURRENT DIAGNOSIS

- A diagnosis of toxic epidermal necrolysis (TEN) can be rendered when the body surface area (BSA) involved contains more than 30% denuded skin.
- A diagnosis of Stevens-Johnson Syndrome (SJS) can be rendered when less than 10% of the BSA involves denuded skin.
- SJS-TEN overlap is diagnosed when the involved BSA is between 10% and 30% BSA.
- Patients with SJS, SJS-TEN overlap, and TEN should have involvement of not only the cutaneous surface but also at least one mucosal region (most commonly the oral mucosa). Cases do exist with no mucosal involvement but this is rare and should prompt consideration of an alternate diagnosis.
- A thorough drug history and skin biopsy (ideally using the fresh-frozen technique) are essential when considering a diagnosis of SJS or TEN.

## CURRENT THERAPY

- Conservative therapy is a cornerstone of therapy for all patients. This includes appropriate wound care, monitoring for fluid loss and electrolyte imbalance, thorough daily skin exams, and monitoring of vital signs to rule out concurrent infection.
- A dermatologist should be involved in the care of all hospitalized patients with Stevens-Johnson Syndrome and toxic epidermal necrolysis. In the appropriate clinical context, ophthalmology and OBGYN should also be involved. Depending on hospital resources, ICU and/or plastic surgery and the burn unit should be involved early in the care of these patients.
- Classically, systemic corticosteroids and intravenous immunoglobulin (IVIG)<sup>1</sup> were utilized in the management of these patients. New data suggest either cyclosporine (Neoral, Sandimmune)<sup>1</sup> or etanercept (Embrel)<sup>1</sup> may improve overall outcomes.

<sup>1</sup>Not FDA approved for this indication.

## Epidemiology

Toxic epidermal necrolysis (TEN) is a rare diagnosis, only afflicting approximately one patient per million per year (most studies cite this incidence rate, though one study from the United States did cite an incidence rate as high as 12.7 per year). Stevens-Johnson Syndrome (SJS) and SJS-TEN overlap affect approximately five per million patients per year. The overall mortality varies greatly among different studies but is currently estimated to be ~25% for TEN. It can affect patients of any age, and most data regarding therapy are stratified by age into pediatric and adult cohorts. There are some experts who feel there may be a viral trigger or co-factor for the disease because prevalence increases in the spring.

## Risk Factors

Common implicated agents include sulfonamide antibiotics as well as more recently described penicillin and cephalosporin antibiotics, aromatic anticonvulsants, allopurinol (Zyloprim), and nonsteroidal antiinflammatory drugs (NSAIDs). Numerous other medications have been reported to trigger the disease and some other common offending agents include the anti-programmed death-1 and anti-cytotoxic T-lymphocyte-associated protein 4 chemotherapeutic agents, dapsone and nevirapine (Viramune). The most important intervention is to determine and remove the offending agent as some studies cite an increase in mortality of 34% per day if the offending agent is not removed from the patient's regimen.

Certain tests can be performed after hospitalization in selected cases to determine the most likely offending agent if unknown. For example, patch testing can be done, and in the case of carbamazepine-induced SJS-TEN, has a sensitivity greater than 70%. Likewise, if multiple drugs are suspected as potential inciting agents, it may be worth checking the patient's human leukocyte antigen (HLA) types and correlating this with his/her ethnicity to make an educated guess about likely agent (if a patient has three potential inciting agents including allopurinol, the patient is of Asian descent, and HLA-typing reveals positive HLA-B5801, it could be concluded with a higher level of certainty that allopurinol is the most likely agent).

Less common triggers include vaccines such as MMR and less commonly the meningococcal, varicella and influenza vaccines, herpes, and ultraviolet light. These are more likely to be implicated in patients with target lesions or low body surface area (BSA) involvement and are exceedingly rare in patients diagnosed with full-blown TEN. An important trigger to consider in the work-up is mycoplasma, which can be responsible for causing mycoplasma-induced rash and mucositis (MIRM). MIRM is a clinical mimicker common in pediatric patients, which is characterized by lower BSA but worse mucosal involvement (typically involving two sites and usually including the ocular mucosa in dramatic fashion).

In addition to the causes of SJS and TEN described previously, there are risk factors that seem to predispose patients to the disease. These include: HIV (some studies cite a thousand-times increased chance of developing TEN among HIV-positive patients, even when controlled for the number and type of medications these patients were exposed to), lupus, female gender, Asian or African ethnicity, patients undergoing brain cancer treatment with corticosteroids and radiation, and certain HLA types. For example, one recent meta-analysis found that certain HLA-B subtypes predispose Asian patients to the development of carbamazepine-induced TEN, including HLA-B1502, HLA-B4001, HLA-B4601, and HLA-B5801. Other studies have identified HLA-B1502 as a risk factor for aromatic anticonvulsant-induced TEN among various Asian populations, HLA-B5801 as a risk factor for allopurinol-induced TEN among Asians, HLA-C0401 for nevirapine-induced TEN among patients in Malawi, and HLA type B3802, A29, B12, and DR7 as a risk factor among Europeans for sulfonamide-induced TEN.

## Pathophysiology

As described previously, an immunologic basis for the development SJS and TEN is hypothesized given the fact that certain HLA types among certain groups predispose them to development of the disease. There currently exist four theories to explain how small drugs might interact with HLA and T-cell receptors (TCRs) to initiate a chain of events leading to SJS/TEN.

In the hapten theory (which has been validated in the case of penicillin-induced drug reactions), it is presumed that the drug molecule combines with an endogenous peptide and this is presented to the HLA molecule and recognized by the TCR. In the p-i model (pharmacologic interaction with the immune receptors), which has been validated in carbamazepine-HLA-B1502 interactions, the drug itself binds directly, reversibly, and noncovalently to HLA and/or TCR. In the altered peptide repertoire model, it is proposed that the drug binds to the peptide-binding groove of the HLA molecule thereby altering the overall binding ability of the HLA molecule. Lastly, in the altered TCR repertoire model, it is suggested that some drugs (such as sulfamethoxazole) can bind directly to the TCR (but not with the HLA molecule) and thereby alter the conformation of the TCR giving them the ability to bind to self-HLA.

Regardless of the type of interaction that allows a drug to alter the way HLA and TCR react to self, patients with TEN exhibit increased activity of natural killer (NK) cells and specific T lymphocytes (NK T-cells and CD<sup>+</sup> + cytotoxic T-cells). These cells mediate keratinocyte cell death via a cascade of events including Fas-FasL binding and procaspase-8 activation, increased tumor necrosis factor- $\alpha$  and interferon- $\gamma$  levels, and activation of the perforin-granzyme-granulysin apoptosis pathway.

## Differential Diagnosis

Patients with SJS and TEN typically complain of skin pain before the eruption begins. A prodrome consisting of low-grade fever, malaise, and/or flu-like symptoms is not uncommon. Within days some degree of mucosal involvement (which can take the form of dusky erythema, bullae/vesicles, denuded mucosal surface(s), dysuria, ocular erythema, pain with defecation, or pain with swallowing) is almost universal, while the extent of cutaneous involvement can vary dramatically but should include either a dusky erythema with eventual vesicles, bullae, or denuded skin, or less commonly targetoid lesions. The majority of patients with SJS and TEN present with painful red-purple (dusky) patches or macules that progress over the span of a few days. Areas that began with dusky erythema develop superimposed bullae, vesicles, or denuded skin.

Most patients with SJS and TEN do not present with typical targets on cutaneous exam. Such lesions are characterized by a small red central papule surrounded by a white ring and finally most peripherally by another ring of erythema. These lesions characterize erythema multiforme, which is much more commonly the result of herpes rather than drug allergy. However, there are rare reported cases of SJS and TEN that do include or are even dominated by cutaneous typical or atypical targets.

The main differential diagnosis for patients with classic dusky erythema, mucosal involvement, and skin pain includes acute graft-versus-host disease (GVHD), bullous lupus, generalized fixed drug eruption (FDE), cutaneous burns, paraneoplastic pemphigus (PNP), in pediatric patients MIRM, and in infants infection with the Chikungunya virus. The majority of these entities can be ruled out by clinical history alone, as patients with acute GVHD should have had a recent transplant and patients with PNP a concurrent malignancy. Dramatic mucosal involvement, in any age group, should prompt work-up for mycoplasma; when MIRM is suspected it should be treated with empiric antibiotics and in severe cases IVIG<sup>1</sup>. Patients with a known malignancy (particularly chronic lymphocytic leukemia [CLL], lymphoma, Castleman disease, sarcoma, or thymoma) and/or of older age and with significant mucosal disease should have, in addition to a biopsy, a direct immunofluorescence (DIF) performed and serum drawn for indirect immunofluorescence and ELISA performed to rule out PNP. It is important to check a DIF as well in any patients with joint pain or other symptoms suggestive of systemic lupus erythematosus (SLE), as well as antinuclear antibody (ANA), anti-Sjogren's syndrome-related antigen (SSA), and anti-Sjogren's Syndrome Type B (SSB), anti-dsDNA and anti-Smith. Likewise, if you are evaluating an infant who has no medication exposure and is from an endemic area, it is important to check serum titers for the Chikungunya virus.

### Diagnosis

Determining the inciting agent is as important as making a quick diagnosis of TEN. A thorough drug history is essential including prn medication usage (frequently patients do not report their NSAID use or a recent antibiotic exposure). If SJS or TEN is suspected and the inciting agent is known, it is important to immediately inform the patient and his/her family of the suspected allergy and add it to the patient's medication allergy list. Dermatology should be consulted and when possible/necessary will ideally perform a skin biopsy to be processed emergently using the fresh-frozen technique (results can be ready within 30 minutes). Hematoxylin and eosin staining will also be done on permanent sections (and these results are available 1 to 3 days later depending on the site/lab).

After making a diagnosis of SJS or TEN, a practitioner can employ a scoring system called SCORTEN to estimate the patient's mortality. In this system a patient receives one point if he/she is aged above 40 years, BSA greater than 10%, history of concurrent malignancy within 2 years, serum blood urea nitrogen greater than 28 mg/dL, glucose greater than 252 mg/dL, bicarbonate level less than 20 mEq/L, and heart rate more than 120 beats per minute during the first 24 hours. With each increasing point, mortality increases such that a score of 2 confers an expected mortality of 12%; a score of 3 equates to a 35% mortality; a score of 4 with a 58% mortality; and a score of 5 or higher with an expected 90% chance of mortality.

### Therapy

#### Medical Therapy

Classic therapy for SJS and TEN was with systemic corticosteroids but this has fallen out of favor in the United States due to recent meta-analyses suggesting no improvement in outcomes. Likewise, IVIG<sup>1</sup> was a mainstay of therapy in the early 21st century, but a large review from Europe found a worsened mortality in patients given IVIG compared with those given steroids or supportive care alone. Other data are conflicting with some studies suggesting that a 4-day dose of daily 1 g/kg IV<sup>1</sup> provides a mortality benefit, with other studies finding no improvement.

More recent success seems to have come from the utilization of etanercept (Enbrel)<sup>1</sup> or cyclosporine (Neoral, Sandimmune)<sup>1</sup> in the treatment of this disease. In 2014 a group from Italy treated 10 patients with one 50 mg subcutaneous dose and found not only a 0% mortality despite an expected mortality of 47%, but also decreased time to re-epithelialization. Likewise, in 2018 a

Taiwanese group found an improved mortality benefit of etanercept over corticosteroids among 96 patients.

Similarly, data emerging in the last decade have suggested that cyclosporine also confers a mortality benefit. In 2010 a British case series found a 0% mortality in patients receiving 3 mg/kg per day orally despite a predicated ~30% mortality based on SCORTEN. Another study cites a significantly decreased time to re-epithelialization (3.67 days) among patients who survived after receiving cyclosporine at a dose of 3 to 4 mg/kg per day.

#### Adjuvant Mucosal Therapies

Patients with SJS/TEN can suffer from long-term skin/hair/nail complications including post-inflammatory hyperpigmentation, photosensitivity (70% of patients according to one study), chronic pruritus, eruptive nevi, nail changes, hypertrophic scars, and telogen effluvium. They also have a significant morbidity when their mucosal surfaces are severely involved with disease. Ocular complications can include ectropion, trichiasis, ankyloblepharon, corneal scarring, and even blindness. To some extent these complications are minimized by a choice of systemic therapy to mediate disease (i.e., either etanercept or cyclosporine). However, other measures can also be employed including amniotic membrane grafting by ophthalmology (which has been shown in a randomized controlled trial to improve multiple ocular outcome measures), topical steroid application, oxygen therapy, and bronchodilators. Likewise, urogenital sequelae occur in about one in four patients and can include adhesions leading to dyspareunia or even total vaginal fusion. Therefore involvement of gynecology or urology in the care of any patient with genital SJS/TEN is essential.

#### Monitoring

It is important to remember that the cutaneous examination of a patient with TEN differs greatly depending on the time of exam relative to the onset of eruption. With onset it is possible the patient will only complain of pain and have no skin lesions whatsoever. Within days a typical exam would include florid oral mucosal involvement with areas of skin showing dusky erythematous macules or patches. Over the next few days, most of the cutaneous lesions will evolve and become vesicles, bullae, or entire surfaces will denude. Monitoring for efficacy of chosen therapy means being aware of what is expected in terms of progression (that some or all areas that were dusky will denude), and ensuring that no new dusky areas develop.

The most common cause of death in patients with TEN is infection, so checking daily white blood cell counts and following vitals every 2 to 4 hours if not more frequently is essential. Fevers can occur simply as the result of the disease process itself, but any fever should prompt blood, urine, and sputum cultures. Prophylactic antibiotics have not been shown to improve outcomes but when an infection is suspected it must be treated immediately.

<sup>1</sup>Not FDA approved for this indication.

## SUNBURN

Method of

Kamille S. Sherman, MD

### CURRENT DIAGNOSIS

- Typically a first-degree or second-degree burn occurring on sun-exposed or ultraviolet (UV)-exposed (e.g., tanning bed) skin within 4 hours to 2 days of exposure
- May be demarcated from unaffected skin by an obvious boundary where protective clothing prevented the sun or UV exposure, with the burned area having a consistent, continuous appearance

### CURRENT THERAPY

- Over the counter nonsteroidal antiinflammatory drugs (NSAIDs) or acetaminophen at doses as directed by the manufacturer on the packaging can relieve pain and decrease inflammation but will not change long-term damage to the skin. Some experts recommend a short-term course of oral steroids if a large area of skin is sunburned.
- Cool the skin, either with a cool bath/shower or apply a cool, damp towel or wear cool, damp flannel clothing over the affected area.
- Drink plenty of water to prevent dehydration or rehydrate if mildly dehydrated.
- Do not break any blisters on the skin.
- Do not apply benzocaine or other “-caine” types of products, as they can irritate the skin, cause allergic reactions, or precipitate methemoglobinemia.
- Apply a soothing moisturizer, such as aloe vera<sup>7</sup> or calamine, PRN. This may be in lotion or gel form.
- As skin heals, apply hydrating moisturizers.
- As healing occurs, avoid reinjury/reexposure of affected skin to sun or UV light.
- Assess for secondary infection and treat if necessary.
- Review patient medication list, as some over-the-counter and prescription drugs and herbal remedies increase sensitivity to UV light.

<sup>7</sup>Available as dietary supplement.

### Epidemiology

In a study of 31,162 US adults, using the 2015 National Health Interview Survey (NHIS) Cancer Control Supplement, a total of 34.2% of adults experienced sunburn in 2015. Of those experiencing sunburn, 16.3% experienced one sunburn, 9.9% experienced two sunburns, 3.4% experienced three sunburns, and 4.6% experienced four or more sunburns. There is epidemiologic evidence suggesting that the harmful effects of UV radiation exposure from typical doses of sunlight vary over the course of the life span, with some evidence of a window of biologic vulnerability in childhood that translates into increased skin cancer risk later in life.

### Risk Factors

“Sun sensitivity” was assessed using two questions in the 2015 NHIS Cancer Control study. One question asked what would happen to the respondent’s skin if, after several months of not being in the sun, the individual went out in the sun for an hour without sunscreen, a hat, or protective clothing (short exposure). The second question asked the individual what would happen if he or she were out in the sun repeatedly, such as every day for 2 weeks, without sunscreen, a hat, or protective clothing (i.e.,

repeated exposure). About half of individuals who described themselves as “sun sensitive” indicated they would experience sunburn (50.2%).

Non-Hispanic white individuals are more likely to experience sunburn than other racial/ethnic groups. Adults who self-reported skin that tended to burn after repeated sun exposure were more likely to become sunburned as compared with individuals who easily develop tans. Behaviors associated with sunburn include use of self-applied tanning products, aerobic activity, binge drinking in the past 30 days, and overweight or obesity. An increase in the number of sunburns an individual experiences is directly related to an increase in the risk of skin cancer.

Approximately 50.2% of adults aged 18 to 29 years reported having experienced sunburn, as did 14.8% of adults aged 66 years or older.

The level of UV protection afforded by clothing can vary widely based on color, material, and weave of the fabric. The US Preventive Services Task Force (USPSTF) reports that indoor tanning before age 35 years, or more than 10 tanning sessions over a lifetime and for longer than 1 year, have been linked to increased skin cancer risk.

### Pathophysiology

UV radiation (both A and B) from both solar and artificial sources has been classified as a human carcinogen by national and international organizations. UVA damage is associated with “aging,” whereas UVB is associated with “burning.” UVB rays are responsible for directly damaging skin cell DNA by inducing the formation of thymine-thymine cyclobutane dimers. As the body generates a DNA repair response to these dimers, inflammatory markers lead to vasodilation, edema, and pain, which manifest as classic-appearing sunburn. UVB light also activates peripheral nociceptors by causing an increase in chemokines.

### Prevention

The most frequently used sun protection behaviors among US adults include staying in the shade (37.1%) and using sunscreen (31.5%). About one-fourth of those engaging in sun-protective behaviors wear long clothing to the ankles (28.4%). Less frequent behaviors include regular use of long-sleeved shirts (12.3%) and wide-brimmed hats (14.2%). Women are more likely to use shade (41.3%) and sunscreen (40.2%) as protective behaviors, whereas men are more likely to wear long clothing to the ankles (34.3%) and to use shade (30.7%).

The sun protection factor (SPF) is a relative measure of the fraction of sunburn-producing UV rays that reach the skin. Assuming correct application, “SPF 20” means that one-twentieth of the burning radiation will reach the skin. The effectiveness of a sunscreen can be calculated by multiplying the SPF by the length of time it takes a user to suffer a burn without sunscreen. For example, if a person develops a sunburn in 20 minutes when not wearing a sunscreen, using an SPF 30 sunscreen would protect the individual for about 10 hours. Because the intensity and wavelength distribution of UVB rays varies throughout the day and by latitude, the effectiveness of sunscreen also varies. Direct exposure to the sun should be avoided between the hours of 10 A.M. and 4 P.M. A broad-spectrum sunscreen with SPF of at least 30 should be applied 30 minutes before sun exposure and every 90 minutes thereafter, even if the product is labeled “water resistant.”

There are many suggestions regarding the appropriate use of sunscreen, although the NHIS found that sunscreen users were actually more likely to experience sunburn. This probably happens because sunscreen users are out in the sun more frequently than those who do not use sunscreen regularly.

Along with recommending staying in the shade, the American Cancer Society uses a slogan popularized in Australia as one of that country’s skin cancer prevention strategies: “Slip! Slop! Slap! ... and Wrap!” The phrase is a way to remind individuals to slip on a shirt, slop on sunscreen, slap on a hat, and wrap on sunglasses to protect eyes and sensitive skin from the sun’s harmful rays.

## Clinical Manifestations

Sunburn appears most often as a first-degree burn—an injury affecting the epidermis and associated with erythema, pain, and mild swelling followed by skin peeling. More severe sunburn may lead to second-degree burns, in which blisters accompany the erythema and swelling. Second-degree sunburns hurt more significantly and affect both the epidermis and dermis. These burns can take several weeks to heal.

## Diagnosis

The diagnosis is based largely on the history of sun exposure coupled with the classic appearance and distribution of sunburn.

## Differential Diagnosis

The differential diagnosis of sunburn includes autoimmune diseases such as systemic lupus erythematosus and dermatomyositis; bacterial infections such as staphylococcal scalded skin syndrome, cellulitis, and erysipelas; and dermatologic diseases such as rosacea, acne, stasis dermatitis, and seborrheic dermatitis. There are also congenital ichthyotic conditions. Other solar reactions caused by the sun's rays include solar urticaria, photoallergic type IV sensitivity reactions, and phototoxic reactions.

## Treatment

Treatment for sunburn is largely supportive. Oral analgesics, such as nonsteroidal antiinflammatory drugs and/or acetaminophen, provide some relief. Cool bathing, cool towels, and flannel clothing moistened with cool water can provide some comfort. Moisturizing topical products such as aloe vera or calamine may provide comfort. Some experts recommend steroid usage, either topical or orally, although consensus on their use is mixed and steroids are usually reserved for patients with extensive areas of sunburn. Treatment of secondary skin infections, especially if broken blisters are infected, includes antibiotic usage for common skin pathogens. The avoidance of local anesthetic creams and sprays containing “-caine” derivatives is standard advice. “Caines” can irritate the skin, cause allergic reactions, and precipitate methemoglobinemia. Opioids for pain associated with sunburn should be avoided except in the most unusual circumstances. Adequate water intake to prevent or reverse dehydration is encouraged. In the rare case of extensive sunburn with large areas of blistering accompanied by massive fluid loss and electrolyte imbalances, intravenous rehydration may be considered as well as transfer to a burn unit. Avoiding another sunburn, especially before the first one appears “healed,” is important. The DNA damage caused by sunburn is not reversible. There are no topical or systemic agents that are FDA approved to reverse UV damage to the skin.

## Monitoring and Complications

Most sunburns are self-limited and will heal over a number of days to weeks, at least appearing “healed” to casual inspection. Patients who suffer severe sunburn should be warned to watch for the development of secondary infections. The underlying DNA changes in the skin are linked to the development of skin cancers, including melanoma. The USPSTF recommends “counseling young adults, adolescents, children, and parents of young children about minimizing exposure to UV radiation for persons aged 6 months to 24 years with fair skin types to reduce their risk of skin cancer.”

The USPSTF concludes that current evidence is insufficient to assess the balance of benefits and harms of counseling adults about skin self-examination. Evaluation of suspicious skin lesions should be undertaken by physicians, with monitoring and/or removal of suspicious lesions.

Skin cancer is the most common type of cancer in the United States. Although invasive melanoma accounts for 2% of skin cancer types, it is responsible for 80% of skin cancer deaths. Basal and squamous cell carcinoma, the two predominant types of nonmelanoma skin cancer, represent the vast majority of skin cancers. About 5.4 million basal and squamous cell skin cancers are diagnosed in the United States each year; they occur in an estimated 3.3 million Americans, as some people have more than one. About 8 out of 10 of these are basal cell cancers. About 2000 people die from basal or squamous cell skin cancers in the United

States annually. There will be an estimated 100,350 new cases of melanoma skin cancer in 2020. The 5-year survival rate for melanoma, according to the American Cancer Society, is 92%. Treatment for skin cancer can include surgery and radiation therapy, as well as some newer forms of nonsurgical treatment such as novel topical drugs, photodynamic therapy, and laser surgery.

## URTICARIA AND ANGIOEDEMA

Method of

Joyce M.C. Teng, MD, PhD

### CURRENT DIAGNOSIS

- Acute and chronic urticaria have the same features, including erythematous, edematous papules or wheals with central pallor that last less than 24 to 48 hours.
- Laboratory assessments are not recommended for acute urticaria in the absence of evidence suggesting underlying systemic illness.
- Limited laboratory studies are indicated for chronic urticaria only if there are signs of systemic disease.
- Serum measurements of C4 and C1-esterase inhibitor are the recommended initial tests if hereditary or acquired angioedema are suspected.
- Skin biopsy should be considered to rule out urticarial vasculitis if an individual lesion is painful and persists for more than 2 to 3 days with accompanying ecchymosis or petechiae.

### CURRENT THERAPY

- Primary treatment of urticaria and angioedema is removal of triggering factors and initiation of therapy for symptomatic relief.
- Oral antihistamines are the cornerstones of therapy. The application of first-generation H<sub>1</sub>-antihistamines may be limited by central nervous system and anticholinergic side effects.
- Nonsedating second generation antihistamine are often used as first line therapy. Higher dose can be used when symptoms are not controlled.
- Anti-IgE therapy, omalizumab (Xolair), has been approved for patients over 12 years of age with chronic idiopathic urticaria. Systemic corticosteroids and immunosuppressive therapy, especially cyclosporine (Neoral),<sup>1</sup> have been used successfully in cases that are refractory to the maximum dose of antihistamines.
- Fresh-frozen plasma infusions along with standard airway precautions have been recommended for angioedema patients with laryngeal edema.
- A subcutaneous C1 esterase inhibitor injection (Haegarda) has been used successfully to prevent attack in hereditary angioedema.

<sup>1</sup>Not FDA approved for this indication.

Urticaria, or hives, is a common cutaneous eruption that occurs in up to 25% of the general population sometime during their lives (Bailey, 2008). It is characterized by transient, circumscribed, pruritic, erythematous papules or plaques, often with central pallor. Individual lesions often coalesce into large wheals on the trunk and extremities that may resolve over a few hours without leaving any residual skin changes. The process is mediated by mast cells in the superficial dermis, and skin changes often resolve within 30 min to 24 hr.

Angioedema is a similar process occurring in deep dermis or subcutaneous tissue. Angioedema may occur independently, accompanied by urticaria, or as a component of anaphylaxis. It is characterized by localized swelling that develops over minutes to hours and resolution may take up to 72 hours. Common locations of angioedema include the mucosa and areas with loose connective tissue, such as the face, eyes, lips, tongue, and genitalia. Patients usually do not have pruritus, but they may have pain and a sensation of warmth. Angioedema is usually a benign process that resolves without sequelae unless it involves the larynx. African Americans are disproportionately affected, representing up to 40% of the hospital admissions for angioedema.

### Classification

Urticaria can be classified as acute or chronic, depending on the duration. Acute urticaria usually lasts for less than 6 weeks and can be spontaneous or triggered by infection, medication, insect bite, and food (Table 1). The chronic form, lasting more than 6 weeks, accounts for approximately 30% of cases of urticaria, and no clear causes can be identified in more than 80% of these cases. Stress however has been identified as a trigger in some of the cases. Depending on the triggers, chronic urticaria can be classified as cold, heat, solar, delayed pressure, vibratory, cholinergic, contact, or aquagenic urticaria. A significant number of patients with chronic urticaria may have persistent symptoms for more than 10 years. Approximately 40% of patients with chronic urticaria have associated angioedema, although the incidence of laryngeal edema is low.

### Diagnosis

Urticaria is diagnosed clinically in most cases. A detailed history, physical examination, and complete review of systems are essential for diagnosing patients with urticaria and angioedema. The history should include the distribution and characteristics of lesions (e.g., pain, pruritus), duration of skin eruption, accompanying angioedema, airway involvement and other associated systemic symptoms (e.g., fever, arthralgia, swelling joints, refusal to walk by children). Patients should also be questioned

about changes in dietary habits, stress, recent exposures, infection, and newly administered medications, including antibiotics, over-the-counter analgesia, and hormones. Patients who suffer from recurrent angioedema should be asked about their use of angiotensin-converting enzyme (ACE) inhibitor medications.

Laboratory assessment is usually not helpful in diagnosing patients with acute urticaria who lack any history or clinical findings to suggest an underlying disease process. A limited number of diagnostic tests are indicated in the evaluation of patients with chronic urticaria when there is sign of systemic disease associated, such as a complete blood cell count with differential white blood cell count, an erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) determination, a thyroid-stimulating hormone (TSH) level, antithyroglobulin and antimicrosomal antibodies, antinuclear antibodies (ANA), folate, B12, ferritin, liver function test, and hepatitis B and C serologies. A detailed review of systems may help to narrow the focus of the screening test.

A skin biopsy of an early lesion should be performed to rule out urticarial vasculitis if the affected individual has skin lesions that are painful and last for more than 2 to 3 days with residual ecchymosis or petechiae. In patients with angioedema, prominent edema of the interstitial tissue may be demonstrated by biopsy. It is associated with antibodies against C1q, which leads to persistent complement activation and low serum C3, C4. Serum measurements of C4 and C1-esterase inhibitor are recommended initial tests if hereditary or acquired angioedema is suspected. Hereditary angioedema is caused by deficiency (type I) or dysfunction (type II) of C1-esterase inhibitor protein. A C1q level should be obtained to screen for the acquired form of angioedema if the affected individual is middle-aged. Additional constitutional symptoms and extracutaneous manifestations are often present in patients with autoinflammatory syndromes such as Schnitzler's syndrome, cryopyrin-associated periodic syndrome (CAPS), Muckle-Wells syndrome (MWS), neonatal-onset multisystem inflammatory disease (NOMID) and, rarely, hyper-IgD syndrome (HIDS) and tumor necrosis factor receptor alpha-associated periodic syndrome (TRAPS).

### Treatment

More than two thirds of cases of urticaria are self-limited. Spontaneous remission of chronic urticaria and angioedema is also common. The primary objective of management is to identify and discontinue the offending trigger. A patient presenting with angioedema must first be assessed for signs of airway compromise. Medical therapy is indicated for those who are symptomatic.

Antihistamines remain the first-line therapy for most patients with urticaria, because the primary complaint of pruritus is predominantly mediated by histamine released from mast cells. First-generation antihistamines such as hydroxyzine (Atarax or Vistaril 1 mg/kg (max 25 mg/dose) for children and 25–50 mg every 6 hours in adults), diphenhydramine (Benadryl 25–50 mg every 6 hours), cyproheptadine (Periactin 4 mg three times daily), and chlorpheniramine<sup>1</sup> (Chlor-Trimeton 4 mg every 6 hours) are potent and have the quickest onset of action. However, the treatments are often limited by their sedating and anticholinergic side effects. Many first-generation antihistamines are available over the counter, providing accessible first-line therapy for patients. Patients with urticaria that lasts for several days should be considered for treatment using second-generation antihistamines such as loratadine (Claritin<sup>1</sup> 10 mg twice daily<sup>3</sup>), desloratadine<sup>1</sup> (Clarinex 5 mg twice daily<sup>3</sup>), cetirizine<sup>1</sup> (Zyrtec 10 mg twice daily<sup>3</sup>), levocetirizine<sup>1</sup> (Xyzal 5 mg daily), and fexofenadine<sup>1</sup> (Allegra 180 mg twice daily<sup>3</sup>). If urticaria is not adequately controlled, the second generation antihistamine dosage can be at least doubled. Doxepin (Sinequan),<sup>1</sup> an H<sub>1</sub>- and H<sub>2</sub>-receptor antagonist, is seven times more potent than hydroxyzine in suppression of wheal and flare responses. Because of its central nervous system side effects, combined use of doxepin with a first-generation antihistamine should be restricted. Topical 5% doxepin cream (Zonalon)<sup>1</sup> may help to suppress pruritus in patients with localized urticaria. Anti-IgE

**TABLE 1** Mechanisms in Urticaria and Angioedema

DISORDER	CAUSES
Immunoglobulin-mediated urticaria	Ig-E mediated: food, medication, insect bites, contact allergen, aeroallergens, other causes Urticaria associated with autoimmunity: antinuclear antibodies (ANAs), thyroid autoantibodies, other causes
Direct activation of mast cell degranulation	Physical stimuli: exercise, heat, cold, pressure, aquagenic, solar radiation, etc. Other agents: opiates, antibiotics (e.g., vancomycin [Vancocin]), radiocontrast, ACTH (Cortrosyn), muscle relaxants
Complement-mediated	Viral infections, parasites, blood transfusion
C1-esterase inhibitor deficiency	Genetic and acquired angioedema, paraproteinemia
Reduced kinin metabolism	Angiotensin-converting enzyme (ACE) inhibitors
Reduced arachidonic acid metabolism	Aspirin

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

treatment using omalizumab (150–300 mg per month) for chronic urticaria refractory to high-dose antihistamine therapy has been approved by the FDA for patients over 12 years of age in US. While the treatment is highly effective, safe, and suitable for long-term use, it has a high cost.

Systemic prednisone at 30 to 40 mg in a single morning dose is sufficient to suppress acute urticaria in adults. Tapering should be gradual over a 3- to 4-week period by decreasing the dosage 5 mg every 3 to 5 days to minimize rebound. Alternate-morning dosing when reaching 20 mg daily may help to minimize the steroid side effects. Methylprednisolone (Solu-Medrol 40 mg) should be given intravenously as initial therapy to patients with angioedema. This may be followed by a tapering oral course. Chronic therapy with systemic steroids is to be avoided. Three months of off-label treatment with cyclosporine (Neoral)<sup>1</sup> at 3 to 5 mg/kg can be given safely to patients who are refractory to corticosteroid or omalizumab therapy. Close monitoring for hypertension and renal insufficiency is necessary during the treatment.

Leukotriene inhibitors such as zileuton (Zyflo<sup>1</sup> 600 mg four times daily), zafirlukast (Accolate<sup>1</sup> 20 mg twice daily), and montelukast (Singulair<sup>1</sup> 10 mg once daily) may be effective for patients with autoimmune urticaria.

Proper management of underlying autoimmune thyroid disease or autoimmune collagen vascular diseases has been beneficial for patients with associated urticaria. Life-threatening angioedema triggered by angiotensin-converting enzyme (ACE) inhibitors has been successfully treated with infusion of fresh-frozen plasma. Hereditary angioedema can be prevented with tranexamic acid<sup>1</sup> or modified androgens. Intravenous C1-esterase inhibitor (Cinryze) or icatibant (Firazyr), a bradykinin B2 antagonist, can be administered to prevent acute attacks. Subcutaneous injection of C1-esterase inhibitor (Haegarda) has been approved by FDA in 2017 to prevent hereditary angioedema attacks. Treatments with methotrexate<sup>1</sup>, warfarin (Coumadin),<sup>1</sup> plasmapheresis, colchicine,<sup>1</sup> hydroxychloroquine (Plaquenil),<sup>1</sup> anti-TNF-alpha,<sup>1</sup> interferon,<sup>1</sup> and intravenous immunoglobulin (Baygam)<sup>1</sup> have been reported for severe, refractory<sup>1</sup> urticaria. Vitamin D<sup>1</sup> supplementation can also be beneficial in reducing symptoms in patients with a deficiency. These treatments are administered only by specialists on an individual basis. Non-pharmacotherapeutic means such as frequent use of skin emollients, avoidance of hot shower, scrubbing, and excessive sun exposure should also be recommended as part of management plans.

<sup>1</sup>Not FDA approved for this indication.

## VENOUS ULCERS

Method of

Jose A. Jaller, MD; and Robert S. Kirsner, MD, PhD

### CURRENT DIAGNOSIS

- Venous ulcers are the most common cause of lower-extremity ulceration.
- Valvular incompetence, vein distention, muscular weakness, and/or a decrease in the range of motion of the ankle may lead to venous insufficiency.
- The mechanism of cutaneous ulceration resulting from venous insufficiency remains unclear.
- The typical location for a venous ulcer is on the medial malleolus.
- Complications of chronic venous ulcers are cellulitis and less often squamous cell carcinoma.
- Compression is the gold standard of treatment of venous disease.

### CURRENT THERAPY

- Compression therapy is used to deliver a graded compression of 30–40 mm Hg at the ankle. Arterial disease should be excluded prior to full compression.
- Systemic medications as adjuvant therapy to compression bandages include aspirin<sup>1</sup>, pentoxifylline (Trental), or micro-nized purified flavonoid fraction (Daflon 500 mg)<sup>2</sup>.
- Other treatments, along with compression, include engineered skin, placental and skin grafts, electrical stimulation, locally derived growth factors, and venous surgery.
- The lifelong use of elastic compression stockings (30–40 mm Hg) is the mainstay of prevention.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

Ulcers resulting from venous insufficiency are the most common cause of leg ulceration. The Wound Healing Society classifies wounds as *acute* if they sustain restoration of anatomic and functional integrity in an orderly and timely process and *chronic* if they do not. Venous leg ulcers (VLUs) are more frequently seen in the elderly population; however, about 1 in 5 primary VLUs occur in patients under 40 years of age. Personal or family history of venous disease, obesity, smoking, advanced age, female sex, hypertension, and leg injuries are strong risk factors to the development of VLUs.

### Epidemiology

Venous insufficiency affects approximately 5% of the world's population and about 2% of the American population. VLUs affect 1% to 2% of adults in the United States, accounting for over 2 million lost workdays annually. The associated pain, inability to perform daily activities, and social stigma due to the appearance and odor of the wounds drastically diminish patients' quality of life. Moreover, the high cost of treatment, time off work, and hospital admissions forge a massive economic burden in the healthcare system. Seventy percent of all leg ulcers result solely from venous disease, and an additional 20% of patients have mixed arterial and venous disease. A recent report that used claims data from 2013 private and governmental insurance companies revealed that wounds and ulcers had the highest direct US healthcare cost of all skin diseases (\$12 billion) and caused approximately 21% of all deaths related to skin condition, second only to cutaneous cancers.

## Pathophysiology

In the lower extremities, the venous system comprises the deep and superficial veins. Blood flows from the superficial to the deep veins through the communicating or perforating veins to ultimately reach the heart. Veins contain unidirectional valves that prevent blood return or reflux. During calf muscle relaxation, the pressure difference (high pressure in the superficial veins) allows blood flow from the superficial to deep veins. When a healthy individual contracts the calf muscles, a high pressure develops in the deep vein system, allowing blood to flow from the deep veins to the heart. If the calf muscle contraction is restricted or the one-way valves are deficient, the system fails to adequately return venous blood to the heart, leading to venous hypertension (also known as sustained ambulatory high pressure).

The pathway to developing an ulcer due to venous insufficiency is unclear, albeit several hypotheses have been considered since the beginning of the 20th century. Patients with chronic venous disease can develop ulcers in their lower extremities for a different reason (e.g., trauma), but given their venous disease and suboptimal wound healing capacity, these lesions can develop into VLUs. In the early 1980s, Browse and Burnard suggested that venous hypertension could lead to endothelial distention, causing extravasation of fibrinogen into the interstitial fluid, which results in “pericapillary fibrin cuff” formation around the capillary vessels. Fibrin cuffs act as a barrier to diffusion of oxygen and nutrients, causing ischemia and ulcer formation. A few years later, Coleridge-Smith and colleagues suggested that venous hypertension could lead to decreased capillary perfusion, resulting in leukocyte trapping. The trapped leukocytes release proteolytic enzymes, which result in free radical formation and capillary damage. The increased capillary permeability causes extravasation of fibrinogen and other metabolites, which leads to the formation of a fibrin cuff around the capillaries and ultimately ischemia.

Further studies supported the presence of increased levels of monocyte aggregation. Claudy and colleagues showed that leukocyte activation caused release of tumor necrosis factor alpha (TNF- $\alpha$ ), ultimately leading to pericapillary fibrin cuff formation. In 1993, Falanga and Eaglstein observed that fibrin cuffs were discontinuous around capillaries and therefore did not form a barrier to oxygen and nutrients causing ischemia. They also postulated the “trap” hypothesis, which suggests that venous hypertension causes endothelial cell distention leading to extravasation of macromolecules (i.e.,  $\alpha_2$ -macroglobulin and fibrinogen) into the dermis. Moreover,  $\alpha_2$ -macroglobulin can bind to growth factors, such as TNF- $\alpha$  and transforming growth factor beta (TGF- $\beta$ ), making them unavailable for wound repair. Patients with venous disease may have other factors that contribute to venous ulcer formation, such as systemic alteration in fibrinolysis and arteriovenous shunting. Despite all previously conducted studies and hypotheses, further research is needed to explain the mechanism of cutaneous ulceration resulting from venous insufficiency.

## Evaluation and Diagnosis

VLUs are diagnosed clinically; however, blood flow imaging, pathology, and microbiologic cultures can aid to rule out other conditions. Clinical signs, such as wound location, associated venous disease, and past personal history of venous ulcers, are paramount for the diagnosis. VLUs are typically located on the lower leg, particularly in the medial lower leg or medial malleolus. The ulcer usually begins as a blister or erosion on the skin that hinders healing and develops into a full-thickness lesion, or ulcer. Ulcer borders are irregular and usually smooth. The base of the ulcer may be covered with granulation tissue, yellow slough, or both. Venous ulcers are associated with the presence of pigmentation, erythema, dermatitis, edema, and induration (i.e., lipodermatosclerosis) of the surrounding skin and with varicose veins in the lower leg. Hemorrhoid deposition resulting from red blood cell extravasation and iron-related stimulation of melanocytes cause the surrounding hyperpigmentation.

Lipodermatosclerosis is caused by sclerosis of the dermis and subcutaneous tissue. The presence of lipodermatosclerosis has

been associated with a greater impairment of fibrinolysis in patients with venous ulcers and may be a poor prognostic factor for restriction of leg movement. Other known prognostic factors are duration and size of the ulcer and history of venous surgery. Ulcers present for longer than 6 months and larger than 5 cm in diameter tend to be more refractory to therapy.

A diagnosis of venous ulcers may be based on clinical presentation. The findings of a lower leg ulcer associated with lipodermatosclerosis or varicose veins, or both, suggest a venous ulcer. Other common findings include atrophie blanche (i.e., porcelain white scars with telangiectasia and dyspigmentation) and dermatitis. Venous dermatitis is associated with erythema, eczema, pruritus, and scaling of the skin. Contact dermatitis surrounding the ulcer may result from the use of topical agents.

Even though venous insufficiency can be confirmed with a variety of techniques, including duplex ultrasound or plethysmography, the presence or absence of arterial disease is a more important factor dictating treatment and prognosis. Compression should be used with caution in patients with peripheral arterial disease (PAD). Also, sharp debridements should be avoided as much as possible in patients with PAD. These patients might need evaluation by a vascular surgeon for possible revascularization of the affected vessel.

A simple, noninvasive measurement to assess peripheral arterial disease is the ankle brachial index (ABI). This value is calculated by dividing the systolic pressure in the ankle by the systolic pressure in the arm. An ABI of less than 0.9 indicates peripheral vascular disease and represents an independent risk factor for vascular disease in other vascular beds, such as the coronary arteries. Care must be taken with diabetic or elderly patients who may have a falsely negative ABI value. All patients with an abnormal ABI value should be further evaluated. Consider a vascular consultation, magnetic resonance angiography (MRA), angioplasty, and stent bypass.

To aid in the exclusion of any underlying disease (e.g., hematologic disease, diabetes), initial laboratory tests should include complete blood cell (CBC) count with a differential count, chemistry panel, hemoglobin A1C, prealbumin and albumin determinations, liver function tests, and levels of homocysteine, proteins C and S, antithrombin III, and factor V Leiden.

Several vascular studies help in the diagnosis and severity of venous disease. Color duplex ultrasound is usually the initial study done to assess venous reflux in the lower extremities. Continuous-wave Doppler studies may yield false-negative results because it may be difficult to differentiate between the superficial and deep venous system. Air plethysmography and photoplethysmography are helpful in evaluating venous reflux and calf muscle dysfunction. Invasive venography is the gold standard to assess venous reflux, but it is used only as a last resort because of its invasive properties.

The CEAP classification was developed in 1994 by the American Venous Forum (AVF) to standardize the diagnosis and treatment of venous disease. It was based on clinical manifestations (C), etiologic factors (E), anatomic distribution of disease (A), and underlying pathophysiologic findings (P).

## Complications

Main complications of long-term or chronic venous ulcers are cellulitis, osteomyelitis, and squamous cell carcinoma. A finding of exposed tendon or bone, in addition to suggesting an underlying osteomyelitis, suggests an ulcer with a nonvenous cause.

Radiographs and biopsy for histology and culture are appropriate first steps in evaluation. Consult an orthopedic surgeon for further analysis and treatment, which may include a bone biopsy and bone débridement.

## Treatment

Compression is the gold standard of treatment of venous disease. After arterial disease has been excluded, reversal of the effects of venous hypertension through compression bandages and leg elevation is the cornerstone of therapy.

The goal of compression therapy is to deliver sustained graded compression with 30 to 40 mm Hg at the ankle. These bandages are applied circumferentially from the toes to the knees (involving the heel) with the foot dorsiflexed. The optimal method to deliver this pressure is through multilayered elastic compression dressings. Elastic compression dressings deliver compression during ambulation (i.e., walking) and at rest, accommodate to reduction in edema, and are superior to single-layered dressings. Inelastic compression (short-stretch compression) may deliver similar results but appear to require greater sophistication by those applying them to accomplish this. Inelastic bandages, which do not deliver compression at rest, may be advantageous<sup>1</sup> in patients with arterial disease or patients who do not tolerate full compression (e.g., elderly). Highly pressured compression stockings are as effective as compression wrappings; however, patients' compliance is a significant limitation. Additionally, studies have reported that any leg exercise or physical activity, in addition to compression therapy, may lead to increased VLU healing outcomes.

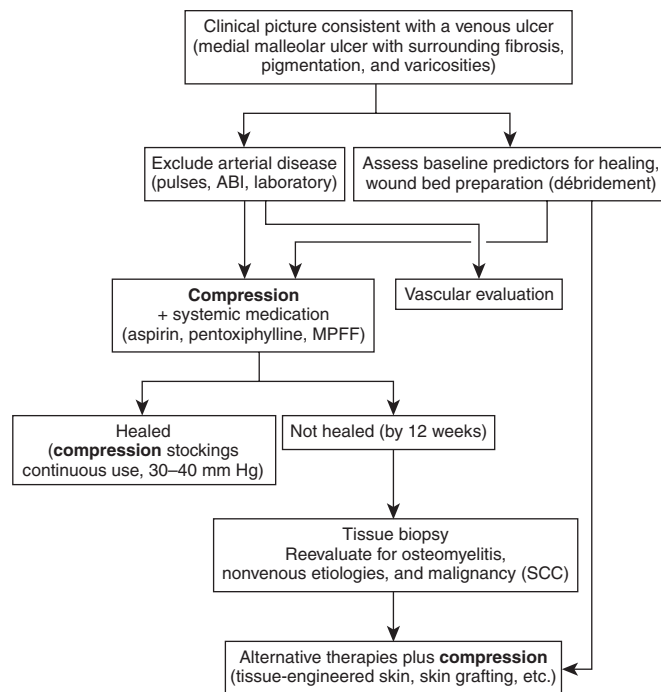

Systemic medication as adjuvant therapy to compression bandages, such as pentoxifylline<sup>1</sup> (Trental 400 to 800 mg three times daily<sup>3</sup>), aspirin<sup>1</sup>, or micronized purified flavonoid fraction (MPFF, Daflon 500 mg<sup>2</sup> [diosmin<sup>7</sup> 90% and hesperidin<sup>7</sup> 10%]) have shown to be superior to compression bandages alone with regard to the rate of healing. The use of pentoxifylline as adjuvant therapy to compression in venous ulcers has been shown to be very beneficial.

Wound bed preparation was proposed as a way to help the healing process. It is a multistep process that improves the wound bed by removing necrotic and fibrinous wound tissue, increasing the amount of granulation tissue, and decreasing edema, chronic wound fluid (i.e., exudate), and bacterial burden.

The decision of which wound dressing to use will depend on the amount of wound drainage. Occlusive dressings should be used for dry to mildly exudative wounds, providing a moist environment for healing. A variety of types of occlusions may be used, and the choice depends on several factors, including the location of the wound and the amount of fibrinous slough and exudate present. Foam, gel, and calcium alginate dressings are highly absorbent dressings and should be used for moderate-to-severe exuding wounds. Sharp wound debridement should be performed to remove any devitalized tissue. Fear of excessive infection with the use of occlusive dressings is unfounded. Topical antiseptics and cleansing agents should be used with caution because they may increase the time required for healing. Topical agents such as cadexomer iodine (Iodosorb), silver-impregnated dressings, and topical anesthetics are alternatives that do not prolong healing. These topical agents should be considered when the wound appears contaminated, but not infected. Wound infections should be treated like cellulitis, with systemic antibiotics.

Up to 50% of venous ulcers may be refractory to compression therapy alone. This refractory subset may be predicted by baseline characteristics (size and duration) and by a decrease in size with 2 to 4 weeks of treatment (Figure 1). Other available treatments include tissue-engineered skin, autologous skin, electrical stimulation, treatment with locally delivered growth factors, and venous surgery. Three categories exist for skin grafts: autologous, allogeneic (cultured), and artificial (tissue-engineered skin). Three different techniques have been used for autologous skin grafts: epidermal skin graft (only epidermis and no dermis), split-thickness skin graft (all the epidermis and a portion of the dermis), and full-thickness skin graft (complete dermis and epidermis). The use of artificial, or bioengineered grafts, has risen in the past decades.

Apligraf is a bilayered engineered living skin composed of keratinocytes and fibroblasts from neonatal foreskin that is approved by the US Food and Drug Administration for treatment of venous leg and diabetic neuropathic foot ulcers. Likewise, other synthetic

**Figure 1** Simplified algorithm for the diagnosis and treatment of patients with venous ulcers. *ABI*, Ankle-brachial index; *MPFF*, micronized purified flavonoid fraction; *SCC*, squamous cell carcinoma.

skin grafts have used animal tissue to generate this sophisticated dressing. Surgical treatment of incompetent superficial and perforator veins along with standard of care (i.e., compression) reduce the risk of recurrence.

After healing occurs, patients with venous insufficiency are at risk for recurrence. The lifelong use of elastic compression stockings (30 to 40 mm Hg) is the mainstay of therapy, but early intervention after recurrence is critical. Health professionals need to understand the importance of further research to ultimately minimize the psychological, physical, and socioeconomic impact that ulcers caused by venous insufficiency have on patients and society.

## VIRAL DISEASES OF THE SKIN

Method of

Cheryl A. Armstrong, MD; and Sylvia L. Brice, MD

### CURRENT DIAGNOSIS

#### Herpes Simplex Viruses 1 and 2

- Clinical: Grouped vesicles or erosions, especially in perioral or anogenital location
- Laboratory: Tzanck smear, viral culture, antigen detection, PCR, gG-based type-specific serology

#### Varicella-Zoster Virus

- Clinical: Papules, pustules, vesicles in diffuse (varicella) or dermatomal (herpes zoster) distribution
- Laboratory: Tzanck smear, antigen detection, viral culture, PCR

#### Hand-Foot-and-Mouth Disease

- Clinical: Papulovesicles on oral mucosa, hands, feet following fever, constitutional symptoms
- Laboratory: PCR

#### Parvovirus B19

- Clinical: "Slapped cheeks" reticular erythema on trunk or extremities following fever, constitutional symptoms; arthralgias, arthritis, purpuric eruptions; transient aplastic crisis, fetal hydrops
- Laboratory: B19 specific IgM serology, PCR

#### Molluscum Contagiosum

- Clinical: Few to multiple 1- to 4-mm umbilicated flesh-colored papules
- Laboratory: Histopathology if clinical appearance atypical

#### Orf

- Clinical: One to several solid to vesicular nodules on hands, forearms; history of exposure to sheep, goats, cattle
- Laboratory: Histopathology if clinical appearance atypical; PCR

Abbreviation: NSAID = nonsteroidal antiinflammatory drug.

### CURRENT THERAPY

#### Herpes Simplex Viruses 1 and 2

- Acyclovir (Zovirax), valacyclovir (Valtrex), famciclovir (Famvir)
- For acyclovir resistance: foscarnet (Foscavir),<sup>1</sup> cidofovir (Vistide)<sup>1</sup>

#### Varicella-Zoster Virus

- Acyclovir, valacyclovir, famciclovir
- For acyclovir resistance: foscarnet,<sup>1</sup> cidofovir<sup>1</sup>

#### Hand-Foot-and-Mouth Disease

- Supportive care

#### Parvovirus B19

- Supportive care, IVIg (Gammagard)<sup>1</sup>

#### Molluscum Contagiosum

- Surgical or chemical methods of destruction
- Immunomodulators (imiquimod [Aldara],<sup>1</sup> cimetidine [Tagamet]<sup>1</sup>)

#### Orf

- Self-limited

<sup>1</sup>Not FDA approved for this indication.

Abbreviation: HSV = herpes simplex virus; IVIg = intravenous immunoglobulin.

## Herpes Simplex Viruses 1 and 2

Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are the most closely related members of the human herpesvirus family, and the skin lesions they produce are clinically indistinguishable. Clusters of tense blisters on an erythematous base often quickly evolve into erosions or ulcerations with associated crusting. Lesions can develop at any mucocutaneous site but are typically found in the perioral or anogenital regions. Both HSV-1 and HSV-2 are transmitted by direct mucocutaneous contact with an infected host. Following viral replication in the skin or mucosa, intact viral nucleocapsids travel via sensory neurons to the corresponding dorsal root ganglia to establish latency. Later, a variety of stimuli can trigger reactivation. The virus travels back along the sensory neurons to the mucocutaneous surface to replicate and induce active or subclinical infection. In the case of subclinical infection, no active skin lesions are evident, but infectious particles are present, a state known as asymptomatic shedding. Although the viral titer is much lower than during clinically active disease, asymptomatic shedding of the virus in oral and genital secretions is thought to be responsible for the majority of cases of HSV transmission.

Primary, initial nonprimary (also known as first episode), and recurrent are terms used to further define the nature of the HSV infection. A *primary* infection refers to a patient's first infection with either type of HSV at any site. These patients are seronegative initially but subsequently develop HSV type-specific antibodies. A patient who is already infected with one HSV type and then develops an infection with the alternate type experiences an *initial nonprimary* or first-episode infection (e.g., the first episode of genital herpes in a patient with a prior history of orofacial herpes). These patients are seropositive for one type-specific HSV antibody (e.g., HSV-1) and later develop antibodies specific for the alternate HSV type (e.g., HSV-2). A *recurrent* infection is one that occurs at a site of prior infection. These patients are seropositive for HSV-1 or HSV-2, or both. Because most primary infections, whether oral or genital, are asymptomatic, the first evidence of disease often represents a recurrent or initial nonprimary infection.

### Orofacial Herpes Simplex Virus Infection

Orofacial HSV, also known as herpes labialis, fever blisters, or cold sores, is commonly acquired during childhood or adolescence. Symptomatic primary disease usually takes the form of gingivostomatitis with or without additional lesions on the cutaneous perioral surfaces. Fever, malaise, and tender lymphadenopathy may also be present. In recurrent episodes, clusters of blisters erupt along the vermilion border of the lips, and subsequent erosions and crusting persist for several days up to 2 weeks. Lesions can develop anywhere in the perioral area, especially on the cheeks. In men, a viral folliculitis of the beard area (herpetic sycosis) may be mistaken for a bacterial process because it is often pustular. The presence of a prodrome and recurrence in the same site are clues to the correct diagnosis. Although recurrent intraoral lesions of HSV can occur, they are uncommon in immunocompetent persons. Exposure to ultraviolet light is a common trigger factor for herpes labialis, as is fever or intercurrent infection.

### Genital Herpes Simplex Virus Infection

When symptomatic, primary genital herpes often involves bilaterally distributed lesions in the anogenital area with associated fever, inguinal adenopathy, and dysuria or urinary retention. Aseptic meningitis can also occur. The lesions often persist for 2 to 3 weeks or longer. Nonprimary infections are usually less severe and have fewer constitutional symptoms. Recurrent episodes tend to be milder and shorter in duration. Often, there is a prodrome of tingling or burning followed by the development of localized vesicles that can quickly rupture, leaving nonspecific erosions or ulcerations. The lesions may be anywhere within the anogenital region but tend to recur close to the same area in subsequent episodes. The time between exposure and development of primary disease is

estimated to be from 3 to 14 days. However, more often the first clinical indication of disease is a recurrence, which can occur weeks to years after the initial infection. Prior infection with HSV-1 provides some protection against acquisition of HSV-2.

Based on seroepidemiologic evidence, it is estimated that approximately 17% of the United States population aged 14 to 49 years are infected with HSV-2. In most of these persons, this disease has not been officially diagnosed and they are unaware that they are infected. Nevertheless, they experience asymptomatic shedding and unknowingly transmit the disease to sexual partners. Interrupting this cycle of transmission has become a major focus among health care providers who work with these patients. A combination of patient education and appropriate use of systemic antiviral agents may be gradually having some impact on this epidemic. Recommendations for patients with genital herpes include avoiding sex with uninfected partners when active lesions or prodromal symptoms are present and routinely using latex condoms to minimize transmission during periods of asymptomatic shedding. Chronic suppressive doses of oral antiviral agents (Table 1), including acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir), significantly reduce the frequency of clinical recurrences as well as the rate of asymptomatic shedding and may be recommended together with these other practices to reduce the risk of transmission.

Although HSV-2 is the etiologic agent in a majority of cases of genital herpes infections, an increasing number of genital herpes infections are caused by HSV-1. Symptomatic recurrences and asymptomatic shedding are less frequent with genital HSV-1 infection than with genital HSV-2 infection, and this distinction becomes important for patient counseling and prognosis.

#### Other Mucocutaneous Herpes Simplex Virus Infections

Eczema herpeticum, also known as Kaposi's varicelliform eruption, represents a cutaneous dissemination of HSV usually seen in patients with atopic dermatitis or other underlying skin disease. Herpetic vesicles develop over an extensive mucocutaneous surface, most often the face, neck, and upper trunk, presumably spreading from a recurrent oral HSV infection or asymptomatic shedding from the oral mucosa. Eczema herpeticum can also develop in the presence of genital HSV. As with other HSV infections, eczema herpeticum may be recurrent. In addition, patients can develop localized, recurrent HSV in previously involved areas. Because of the extensive and inflammatory nature of the process and the possible secondary bacterial infection, the underlying viral etiology may be obscured. A history of eczema and recurrent HSV in the patient and careful observation for the grouped vesicles or erosions can be key to the correct diagnosis.

Herpetic whitlow refers to HSV infection of the hand, usually one or more distal digits. Previously thought to be limited to health care professionals with exposure to oral secretions of their patients, it is now recognized that autoinoculation from orolabial or genital HSV contributes to a significant number of cases.

Herpes gladiatorum is a problem seen most commonly in athletes who participate in close contact sports such as wrestling. Typically transmitted from active herpes labialis or asymptomatic shedding in oral secretions of an infected opponent, herpes gladiatorum often affects the head, neck, or shoulders and may be recurrent. In the wrestler with frequent outbreaks, chronic suppressive therapy may be recommended.

#### Diagnosis

Viral culture remains a common and acceptable method for diagnosing HSV infection. This method is sensitive when specimens are obtained from lesions that have not yet become too dry or crusted, usually during the first 2 to 3 days after onset. An adequate sample, obtained by unroofing the blister and swabbing the base, increases the likelihood of an accurate result. Antigen detection tests can remain positive even after lesions have dried, as long as the specimen includes epithelial cells and not just debris. For this method, a scraping from the lesion is usually smeared on a glass slide to be sent to the laboratory. Not all antigen detection methods are designed to distinguish HSV-1 from HSV-2.

**TABLE 1** Recommendations for Systemic Antiviral Treatment of Mucocutaneous Herpes Simplex Virus Infection

EPISODE	DRUG	DOSAGE
<b>Genital Herpes Simplex Virus</b>		
Primary or first episode	Acyclovir	Mild to moderate: 400 mg PO tid <sup>3</sup> or 200 mg PO 5 ×/d × 7–10 d Severe: 5 mg/kg IV q8h × 5 d
	Valacyclovir	1 g PO bid × 7–10 d
	Famciclovir <sup>1</sup>	250 mg PO tid × 10 d
Recurrent episode (start at prodrome)	Acyclovir	400 mg PO tid × 5 d <sup>3</sup> or 800 mg PO bid × 5 d <sup>3</sup> or 800 mg PO tid × 2 d <sup>3</sup>
	Valacyclovir	500 mg PO bid × 3 d or 1 g daily × 5 d
Chronic suppression	Famciclovir	1 g PO bid × 1 d or 125 mg PO bid × 5 d
	Acyclovir	>6 outbreaks per year: 400 mg PO bid or 200 mg PO tid Adjust up or down according to response
	Valacyclovir	6–10 outbreaks per year: 500 mg PO qd ≥10 outbreaks/year: 1 g PO qd
	Famciclovir	≥6 outbreaks/year: 250 mg PO bid
<b>Orofacial Herpes Simplex Virus</b>		
Primary or first episode	Acyclovir <sup>1</sup>	15 mg/kg 5 ×/d × 7 d
	Valacyclovir <sup>1</sup>	1 g bid × 7 d
	Famciclovir <sup>1</sup>	500 mg bid × 7 d
Recurrent episode (start at prodrome)	Acyclovir <sup>1</sup>	400 mg PO 5 ×/d × 5 d
	Valacyclovir	2 g PO bid × 1 d
	Famciclovir	1500 mg in 1 dose
Chronic suppression	Acyclovir <sup>1</sup>	400 mg PO bid-tid
	Valacyclovir <sup>1</sup>	500 mg–1 g PO qd
<b>Orolabial or Genital Herpes Simplex Virus in Immunosuppressed Patients</b>		
Recurrent or suppressive	Acyclovir <sup>1</sup>	400 mg PO tid or 5–10 mg/kg IV q8h
	Valacyclovir	500 mg–1 g PO bid
	Famciclovir	500 mg PO bid

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

Polymerase chain reaction (PCR) is highly sensitive and has become routinely available for diagnosis of mucocutaneous HSV infections. PCR may also be useful for detection of asymptomatic shedding.

The Tzanck smear (cytologic detection) is both insensitive and nonspecific but may be of use in some clinical settings. It does not differentiate HSV types or HSV from varicella-zoster virus (VZV). Immunohistochemical staining of biopsy specimens can help differentiate between VZV and HSV within 1 to 2 days in laboratories with these techniques available.

Serologic testing for HSV was previously of limited use because it could not reliably differentiate HSV-1 from HSV-2. Because

they share significant genetic homology, HSV-1 and HSV-2 code for a number of common proteins that are not antigenically distinct. However, they also code for type-specific proteins that can be used to differentiate them. Current tests based on detecting type-specific viral glycoprotein G (gG-based, type-specific assays) are accurate and should be requested for this purpose. A positive HSV-2 serology may be useful in confirming the diagnosis of genital herpes in a patient with a negative viral culture or with unrecognized or asymptomatic disease. Alternatively, a negative serology can help exclude the diagnosis of HSV in a patient with chronic, nonspecific oral or genital symptoms.

### Varicella Zoster Virus

VZV, another member of the human herpesvirus family, produces two specific patterns of disease in the skin. The primary infection results in varicella, also known as chickenpox, a widespread vesicular eruption usually seen in the pediatric population. Since the attenuated chickenpox vaccine was introduced in 1995, there has been a progressive decline in this disease. Following the primary infection, VZV establishes latency in the dorsal root ganglia until some later point, when reactivation can occur. The ensuing unilateral dermatomal distribution of blisters, often preceded by neuralgic pain, is known as herpes zoster or shingles. Herpes zoster is especially common in patients older than 50 years, but it may be seen at any age. It is also seen more commonly in immunocompromised patients, such as organ transplant recipients or patients infected with HIV. Herpes zoster is no longer considered a marker for underlying cancer, and evaluation for occult malignancy in an otherwise asymptomatic patient is not indicated. A single recurrence of herpes zoster, usually in the same dermatome, may occur, but this is uncommon in immunocompetent individuals. Additional recurrences, however, suggest a dermatomal form of HSV, and laboratory assessment for this possibility may be indicated.

The most common dermatomes involved with herpes zoster are in the thoracolumbar (T3-L2) and trigeminal (V1) regions. Skin lesions typically evolve from papules to vesicles and pustules, and then to crusted erosions, before healing approximately 2 to 4 weeks after onset. The associated neuropathic pain commonly persists after the lesions have healed. Pain that continues for more than 3 months after the skin lesions resolve is referred to as postherpetic neuralgia, one of the most common and debilitating complications of this infection.

Several clinical presentations of herpes zoster deserve additional attention. Ophthalmic zoster, with lesions along the tip, side, or base of the nose indicating involvement of the nasociliary branch of the trigeminal nerve (Hutchinson's sign), may be associated with increased risk for ocular complications. Prompt initiation of a systemic antiviral agent (Table 2) and evaluation by an ophthalmologist are recommended. Disseminated zoster, with more than a few lesions outside the primary and immediately adjacent dermatomes, can indicate visceral involvement and its associated complications. The term *zoster sine herpette* describes patients with neuropathic pain resembling zoster but without any skin lesions. The diagnosis can be supported by demonstration of increased IgG antibody titers between the acute and convalescent phases. Chronic zoster is seen predominantly in HIV-infected

persons. Single or multiple warty growths can persist for weeks or months in areas of skin previously involved by typical lesions of varicella or herpes zoster. Chronic zoster is often resistant to acyclovir. Tissue biopsy and viral cultures, with further testing for antiviral resistance, may aid in assessment.

### Herpes Zoster

#### Diagnosis

Diagnosis of herpes zoster is often made on clinical grounds alone. A Tzanck smear can provide additional support of the viral etiology. With atypical presentations, however, the diagnosis is best confirmed by real time PCR. An antigen detection method can be used if active blisters are present. Both are rapid and differentiate VZV from HSV. Viral cultures is insensitive but may be required if there is a need to assess possible antiviral resistance. Basic VZV serology is rarely useful for diagnosis.

#### Treatment

There are three systemic antiviral agents routinely used for the treatment of HSV and VZV infections: acyclovir, valacyclovir, and famciclovir. All three are highly effective and generally well tolerated. Because they inhibit only actively replicating viral DNA, they have no impact on latent infection. Recommendations for antiviral treatment of mucocutaneous HSV infections and herpes zoster, localized topical measures, and available formulations are outlined in Tables 1 to 5. Optimal antiviral dosage schedules for less-common HSV infections, such as herpetic whitlow, have not been determined. The doses outlined in Table 1 for either episodic or chronic suppressive therapy can be used as a guideline in these cases.

Acyclovir became available more than 25 years ago and continues to be widely used. Inside an infected host cell, acyclovir must be phosphorylated—first by a virally encoded enzyme (thymidine kinase) and then by host-cell enzymes—to the active form of the drug, acyclovir triphosphate. As a nucleotide analogue, acyclovir triphosphate is incorporated into replicating viral DNA, abruptly terminating further synthesis of that viral DNA chain. Acyclovir triphosphate also interferes with viral DNA replication by directly inhibiting viral DNA polymerase. Valacyclovir is an oral prodrug of acyclovir and has a much higher bioavailability. After ingestion, valacyclovir is rapidly metabolized to acyclovir, and the subsequent mechanism of action is as just described. Famciclovir is an oral prodrug of penciclovir (Denavir), designed for greater bioavailability. Similar to acyclovir, penciclovir must first be phosphorylated by viral thymidine kinase and then by cellular enzymes to penciclovir triphosphate. In this active form, penciclovir triphosphate interferes with viral DNA synthesis and replication by inhibiting viral DNA polymerase. Famciclovir has greater bioavailability and a longer intracellular half-life than acyclovir. For all three agents, the required activation by viral thymidine kinase and the preferential inhibition of viral DNA synthesis contribute to the highly specific antiviral activity.

If taken as recommended, acyclovir, valacyclovir, and famciclovir are generally comparable in their safety and effectiveness. Valacyclovir and famciclovir offer the convenience of less-frequent dosing. Dosing for all three should be adjusted in the presence of renal insufficiency (see Table 5).

**TABLE 2** Recommendations for Systemic Antiviral Treatment of Herpes Zoster

DRUG	DOSAGE	
	IMMUNO-COMPETENT PATIENTS	IMMUNO-SUPPRESSED PATIENTS
Acyclovir	800 mg PO 5 × per d × 7–10 d	800 mg PO 5 × per d × 10 d* 10 mg/kg/dose IV q8h × 7–10 d*
Valacyclovir	1 g PO tid × 7 d	1 g PO tid × 10 d*
Famciclovir	500 mg PO tid × 7 d	500 mg PO tid × 10 d*

\*Continue until there are no new lesions for 48 h.

**TABLE 3** Topical Treatment Options for Mucocutaneous Herpes Simplex Virus and Varicella Zoster Virus Infections

TREATMENT	COMMENT
Cool, moist compresses using tap water or aluminum acetate 1:20 to 1:40 (Burow's solution, Domeboro, Bluboro)	Good for moist, oozing lesions to accelerate drying Apply wet dressing to involved skin and cover with a dry cloth to allow evaporation
Calamine lotion or similar shake lotion containing alcohol, menthol, and/or phenol; Aveeno colloidal oatmeal	Useful as drying and antipruritic agent May be applied after wet dressing
Bacitracin, <sup>1</sup> Polysporin, mupirocin <sup>1</sup> (Bactroban)	Use if there is concern for localized secondary bacterial infection
2% Viscous lidocaine, compounded suspensions <sup>4,6</sup> (e.g., Kaopectate <sup>1</sup> or Maalox, <sup>1</sup> diphenhydramine, <sup>1</sup> lidocaine)	Useful for temporary pain relief of oral or genital mucosal involvement
Acyclovir ointment	Used together with systemic antiviral agents, may be of benefit to immunocompromised individuals for localized HSV
Penciclovir (Denavir) cream	Can decrease the duration of lesions in herpes labialis by half a day if applied every 2 h while awake for 4 days beginning at the first sign of disease
Acyclovir buccal tablet (Sitavig) 50 mg	Can decrease the duration of herpes labialis by 0.8 days if single tablet is applied within 1 hour of prodromal symptom

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

Abbreviation: HSV = herpes simplex virus.

**TABLE 4** Formulations of Acyclovir, Valacyclovir, and Famciclovir

DRUG	ORAL	TOPICAL	INTRAVENOUS
Acyclovir	200, 400, 800 mg 50 mg buccal tablet	5% Ointment (5g, 15g, 30g) 5% cream (5g)	Yes
Valacyclovir	500 mg, 1 g	No	No
Famciclovir	125, 250, 500 mg	No	No
Penciclovir (Denavir)	No	1% cream (1.5 g, 5 g)	No

**TABLE 5** Recommended Antiviral Dose Modification in Patients with Impaired Renal Function

CREATININE CLEAR- ANCE (ML/MIN)	GENITAL HERPES SIMPLEX VIRUS			HERPES ZOSTER	HERPES LABIALIS
	INITIAL	RECURRENT	SUPPRESSION		
<b>Acyclovir (Zovirax)</b>					
>25	200 mg 5 ×/d	200 mg 5 ×/d	400 mg q12h	800 mg 5×/d	
10–24	200 mg 5 ×/d	200 mg 5 ×/d	400 mg q12h	800 mg q8h	
<10	200 mg q12h	200 mg q12h	200 mg q12h	800 mg q12h	
<b>Valacyclovir (Valtrex)</b>					
>50	1 g q12h	500 mg q12h	500 mg-1 g q24h	1 g q8h	2 g PO bid for 1 d
30–49	1 g q12h	500 mg q12h	500 mg-1 g q24h	1 g q12h	1 g PO bid for 1 d
10–29	1 g q24h	500 mg q24h	500 mg q24-48h	1 g q24h	500 mg bid for 1 d
<10	500 mg q24h	500 mg q24h	500 mg q24-48h	500 mg q24h	500 mg single dose
<b>Famciclovir (Famvir)</b>					
>60		125 mg q12h	250 mg q12h	500 mg q8h	
40–59		125 mg q12h	250 mg q12h	500 mg q12h	
20–39		125 mg q24h	125 mg q12h	500 mg q24h	
<20		125 mg q24h	125 mg q24h	250 mg q24h	
>60		1 g bid × 1 d			1500 mg single dose
40–59		500 mg bid × 1 d			750 mg single dose
20–39		500 mg single dose			500 mg single dose
<20		250 mg single dose			250 mg single dose

Although antiviral therapy does not decrease the incidence of postherpetic neuralgia, all three agents decrease the time for lesion healing and shorten the overall duration of pain if initiated within 48 to 72 hours after the onset of herpes zoster. Valacyclovir and famciclovir appear to be more effective than acyclovir for this purpose, presumably because of easier dosing. An otherwise healthy person younger than 50 years who has discrete involvement on the trunk and mild to moderate pain might benefit minimally or not at all from this intervention, especially if it is initiated after 72 hours of lesion onset. However, patients who are older than 50 years, are immunosuppressed, have involvement in the ophthalmic distribution, or have more-extensive lesions or severe pain should receive systemic antiviral therapy, even if the 72-hour deadline has expired. Adequate pain control, often requiring opiates, is also important.

The addition of systemic corticosteroids to the antiviral regimen is not recommended for uncomplicated herpes zoster. Corticosteroids may be of benefit in herpes zoster complicated by facial paralysis, cranial polyneuropathy, or acute retinal necrosis. Corticosteroids should not be used without concomitant systemic antiviral therapy.

Vaccination with a herpes zoster vaccine substantially reduces the incidence of both herpes zoster and postherpetic neuralgia. There are two herpes zoster vaccines available. The live attenuated vaccine (ZVL/Zostavax) has been in use since 2006 and is given as a single intramuscular injection. The Zoster Vaccine Recombinant, Adjuvanted (RZV/Shingrix) received FDA approval in October 2017, for immunocompetent adults 50 years and older. RZV is a non-live recombinant glycoprotein E vaccine and requires 2 doses given intramuscularly 2–6 months apart. The U.S. Advisory Committee on Immunization Practices (ACIP) currently recommends the use of RZV for immunocompetent adults aged 50 years or older for the prevention of herpes zoster and related complications. The ACIP also recommends RZV for adults aged 50 years or older who previously received the live-attenuated herpes zoster vaccine (ZVL/Zostavax) and either RZV or ZVL for adults aged 60 years or older (RZV is preferred).

Despite widespread use of these antiviral agents, antiviral resistance is rarely a problem in the immunocompetent population. However, it does arise in the setting of immunosuppression. The basis for the resistance is most commonly a mutation in the gene coding for thymidine kinase. Less often there is a mutation in the viral DNA polymerase. In either case, all three standard drugs become ineffective. Alternative antiviral agents available for treatment of acyclovir-resistant HSV and VZV infections include foscarnet (Foscavir)<sup>1</sup> and cidofovir (Vistide).<sup>1</sup>

### Hand-Foot-and-Mouth Disease

Hand-foot-and-mouth disease is typically a disease of childhood. The most common etiologic agent is a nonpolio enterovirus, Coxsackie A16, and transmission is via the oral–oral or fecal–oral route. It is highly contagious. Several days after exposure, a prodrome of low-grade fever, malaise, abdominal pain, or respiratory symptoms can develop, followed by the appearance of papulovesicles on the palate, tongue, or buccal mucosa. Similar lesions can subsequently develop on the feet and hands. The eruption persists for 7 to 10 days and then resolves. Treatment is symptomatic. Nail dystrophies including onychomadesis (separation of the proximal portion of the nail plate from the nail bed) and Beau's lines (horizontal grooves in the nail plate) may be seen 2–4 weeks later.

Since 1997, outbreaks of hand-foot-and-mouth disease caused by enterovirus 71 have been reported in Asia and Australia. Although hand-foot-and-mouth disease associated with Coxsackie A16 infection is typically a mild illness, hand-foot-and-mouth disease caused by enterovirus 71 has shown a higher incidence of neurologic involvement, including fatal cases of encephalitis.

An atypical hand-foot-and-mouth disease with more widespread cutaneous involvement has been reported as associated

with Coxsackievirus A6. There is a predilection for areas commonly involved in atopic dermatitis, such as the antecubital and popliteal fossae and this presentation may be confused with eczema herpeticum or VZV infection. Diagnosis of these more atypical cases may require laboratory assessment. This could include antigen detection or PCR to exclude HSV and VZV. Reverse Transcription PCR (RT-PCR) of vesicle fluid, oropharyngeal swab or stool specimen may be used to confirm the enterovirus infection.

### Parvovirus B19

Cutaneous manifestations of parvovirus B19 infection include the childhood exanthem known as erythema infectiosum (fifth disease) and, less commonly, petechial or purpuric eruptions. The virus is transmitted primarily via respiratory secretions and, to a much lesser extent, through blood or blood products. The host cells for viral replication are erythroid progenitor cells, which subsequently undergo cell lysis.

A child with erythema infectiosum typically develops a low-grade fever and nonspecific upper respiratory symptoms approximately 2 days before the onset of rash. The rash has been described as having a slapped-cheeks appearance, with prominent redness over the malar eminences. This is followed by a pink-to-red lacy or reticular eruption over the trunk and extensor surfaces of the arms and legs. The rash usually lasts a week to 10 days but can transiently recur over months in response to precipitating factors such as sunlight, exercise, and bathing. Diagnosis of erythema infectiosum is usually made on clinical grounds, and treatment is symptomatic. By the time the rash appears and the diagnosis has been made, the child is no longer infectious. Much less commonly parvovirus B19 infection may manifest as a papular-purpuric eruption with edema, erythema, and patechiae in a “gloves and socks” distribution on the hands and feet.

Infection with parvovirus B19 in older adolescents and adults often manifests with arthralgias or arthritis rather than a rash. In certain patient populations, parvovirus B19 infections may be associated with complications including transient aplastic crisis, chronic anemia, and hydrops fetalis. In these less-typical presentations, serology (anti-B19 IgM or documented seroconversion) may be needed for diagnosis. Intravenous immunoglobulin (IVIg [Gamimune N]<sup>1</sup>) is used successfully for treatment of chronic or persistent infection in immunosuppressed patients.

### Molluscum Contagiosum

Molluscum contagiosum are benign umbilicated papules caused by infection with the *Molluscipoxvirus*, a member of the poxvirus family. Lesions are limited to the mucocutaneous surface and typically appear in clusters on the face, trunk, and skin fold areas in children and on thighs, lower abdomen, and suprapubic areas in sexually active adults. Large numbers of lesions in an extensive distribution may be seen in the immunosuppressed population.

Transmission routinely occurs by skin-to-skin contact with an infected host, but transmission from contaminated fomites has been reported. Autoinoculation commonly occurs. Diagnosis is usually based on clinical examination, but histopathology of atypical lesions may be used for confirmation.

Because molluscum contagiosum tends to be self-limited, treatment is not always recommended, but it can reduce the risk of autoinoculation and transmission to others. Treatment modalities are primarily aimed at destroying the lesions, similar to those used for verruca vulgaris (Table 6). In the case of sexual transmission, evaluation for other sexually transmitted diseases may be indicated.

### Orf and Milker's Nodules

Orf (also known as ecthyma contagiosum) and milker's nodules are caused by the closely related *Parapoxvirus*, a member of the poxvirus family. The virus responsible for orf is widespread in

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 6** Treatment Options for Molluscum Contagiosum

TREATMENT	COMMENT
Cryotherapy (liquid nitrogen)	Freeze individual lesions for 5–10 sec Repeat PRN in 2–3 wk
Curettage	Entire lesion may be removed using a curette; this results in bleeding Removal of central core with toothpick or other pointed instrument is also effective
Cantharidin (Cantharone) <sup>1</sup>	Blister-inducing agent: Apply to lesion with toothpick, air dry Cover with tape or adhesive bandage Patient to wash area after 24 h (or sooner if significant pain)
Podophyllin (25% in tincture of benzoin) <sup>1</sup>	Cytotoxic agent: Apply to lesion with toothpick Patient to wash off after 4–6 h Contraindicated in pregnancy
Podoflox (Condylox 0.5% gel or solution) <sup>1</sup>	Done by patient: Apply bid for 3 consecutive d/wk × 2–4 wk Contraindicated in pregnancy
Salicylic acid/lactic acid (Occlusal, Duofilm) <sup>1</sup>	Done by patient: Apply daily
Imiquimod (Aldara) 5% cream <sup>1</sup>	Done by patient: Apply daily 5 consecutive d/wk Leave on overnight Continue for 8–12 wk
Cimetidine (Tagamet) <sup>1</sup>	30 mg/kg/d PO × 6–12 wk Can boost cell-mediated immunity
<i>Candida</i> antigen (Candin) <sup>1</sup>	Intralesional injection 0.3 mL <sup>3</sup>

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

sheep and goats, whereas the virus causing milker's nodules is found in cattle. Transmission to humans is by direct contact with infected animals or recently vaccinated animals and is usually seen several days and up to 2 weeks after exposure. Preexisting skin trauma or other disruption of the normal cutaneous barrier enhances the risk of transmission. Barrier precautions and proper hand hygiene are important preventive measures.

Orf and milker's nodules most commonly appear as one to several nodules on the dorsal aspect of the hands or forearms. Lesions evolve through several clinical stages over a period of 3 to 5 weeks, ranging from solid red nodules to vesicular, exudative, or wartlike tumors. As with other poxvirus infections, lesions of orf often demonstrate central umbilication. Regional lymphadenopathy and lymphangitis are commonly seen.

Diagnosis is based on a history of exposure and clinical examination. Tissue biopsy for histopathology or electron microscopy may also be used. Orf virus infection can resemble skin lesions associated with potentially life-threatening zoonotic infections such as tularemia, cutaneous anthrax, and erysipeloid. Should this be a concern, definitive diagnostic testing using PCR is available through the Centers for Disease Control and Prevention (CDC).

In general, the lesions of orf are self-limited, resolving within 4 to 6 weeks, and treatment is not routinely required. However, immunocompromised persons can develop more progressive and destructive lesions requiring therapeutic intervention such as topical cidofovir<sup>1,6</sup> or imiquimod (Aldara).<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

## WARTS (VERRUCAE)

Method of

M. Chantel Long, MD

### CURRENT DIAGNOSIS

- Common warts: rough, hyperkeratotic, firm papules usually found on the extremities.
- Flat warts: small, flat, pink or flesh-colored papules on the face, arms, or legs.
- Plantar and palmar warts: callus-like lesions that disrupt skin lines on the soles or palms.
- Mosaic warts: large clusters of warts.
- Filiform warts: small, finger-like lesions on the face.
- Genital warts: flesh to brown colored, flat or exophytic, found in the anogenital region.
- Differential diagnoses: seborrheic keratoses, molluscum contagiosum, keratoacanthoma, squamous cell carcinoma, acrochordon, amelanocytic melanoma, calluses, and corns.

### CURRENT THERAPY

- Approximately 20% of warts spontaneously resolve within 3 months and 60% within 2 years in a healthy person.
- Salicylic acid and dimethyl ether.
- Cryotherapy.
- Cantharidin (Cantharone).<sup>1,6</sup>
- Surgical removal.
- Pulsed-dye laser.
- Immunotherapy: topical imiquimod (Aldara),<sup>1</sup> intralesional *Candida* antigen (Candin).<sup>1</sup>
- Photodynamic therapy.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

Note: Cantharidin and Candin are not FDA approved. Aldara is approved for genital and perianal warts only.

Verrucae, commonly known as cutaneous warts, are benign skin growths caused by the human papillomavirus (HPV). Cutaneous warts are divided into common warts, plantar warts, flat warts, and genital warts. Common warts account for 70% of all cutaneous warts. Two-thirds of untreated common warts spontaneously regress within 2 years, but previously infected individuals have a higher rate of developing new warts than those who were never infected.

## Epidemiology

It is estimated that 10% of the general population has cutaneous warts, and warts are one of the most common reasons for dermatologic visits. Transmission occurs through direct contact with an infected person. As a result, warts are seen with greater frequency among groups of people in close contact, such as schoolchildren. Thus, warts are more common in adolescents with a frequency estimated as high as 20%. Since the extent of infection is determined by the immune response, warts are also more common in immunocompromised patients. Autoinoculation is possible by scratching the lesions, often leading to a linear pattern.

## Pathophysiology

Warts are caused by HPV. More than 200 genotypes of HPV have been identified, and the virus is prevalent. HPV causes both clinical and subclinical infections and plays a role in certain cutaneous malignancies, including squamous cell carcinoma. It is found in the basal layer of the epidermis but replicates in the superficial, well-differentiated layer of the skin. The cellular proliferation gives rise to thick, hyperkeratotic lesions generally known as warts. The warts can occur anywhere on the skin or mucous membranes.

## Clinical Manifestations

Most warts are asymptomatic, though patients often present with complaints of a “bump.” Usually, the warts appear flesh-colored, brown, or gray and can be flat to exophytic, giving them the classic “cauliflower” appearance. The lesions may be single or multiple and may range in size from minuscule to several centimeters in diameter. Localized irritation, pruritus, pain, or bleeding may occur. Symptoms vary based on the location and size of the lesions.

Several types of warts occur with variations in appearance, site of infection, and the specific type of HPV involved. Common warts (*verrucae vulgaris*) are white to flesh-colored, rough, hyperkeratotic, raised, and firm, usually found on the extremities. They disrupt normal skin lines on the fingers and toes and are most associated with HPV types 1, 2, and 4. Flat warts (*verrucae plana*) are caused by HPV types 3, 10, or 28 and are tan to flesh colored. They are small, 1 to 3 mm in diameter, flat, sharply demarcated growths that appear in large numbers on the face, arms, or legs. They usually occur in a linear arrangement related to local trauma, such as shaving. Butcher warts are associated with HPV type 7 and have a thick, raised, exophytic appearance. They are most common in workers who regularly handle raw meat or fish. Plantar and palmar warts (*verrucae plantaris* and *verrucae palmaris*) are hard, thickened, callus-like lesions that disrupt skin lines on the soles or palms. They are associated with HPV types 1, 2, 4, 27, and 57. They are usually flesh colored, covered with callus, and can be painful, especially when located on pressure points. If warts coalesce into a plaque, this is termed a *mosaic* wart. Filiform warts are slender, finger-like growths most commonly seen on the face, especially around the eyelids, nose, and mouth. Periungual warts are common warts impinging on and growing under toenails or fingernails. Genital warts (*condyloma acuminatum*) are flesh colored to brown, flat or exophytic lesions, occurring in anogenital regions. Mucosal papillomas are warts that occur on mucous membranes, usually in the mouth or vagina, and tend to be white in color.

Epidermodysplasia verruciformis is a rare, autosomal recessive disorder that leads to widespread reddish brown, flat papules on the trunk, hands, face, and extremities. These warts have malignant potential, especially on sun-exposed areas. It is estimated that one-third may become malignant. These patients present in childhood. Chronically infected with multiple types of HPV, including types 3, 5, 8, 9, 12, 14, 15, 17, 19 to 25, 36 to 38, 47, 49, and 50, the warts have lifelong persistence. Another related disease is verrucous carcinoma. This is a slow-growing variant of squamous cell carcinoma that occurs in the oral mucosa, anogenital region, or plantar surface. These warts are associated with HPV types 6 and 11.

## Risk Factors

Risk factors most associated with verrucae include immunosuppression and close contact. Due to their decreased immune response, immunocompromised hosts are at increased risk not only for infection, but also for malignant transformation of the warts. Pregnancy, previous wart infection, and handling raw meat or fish are also known risk factors.

## Differential Diagnosis

The differential diagnosis of warts includes seborrheic keratoses, molluscum contagiosum, keratoacanthoma, squamous cell carcinoma, acrochordon, amelanocytic melanoma, porokeratosis, calluses, corns, and cutaneous malignancy.

Diagnosis is based on clinical findings. When the clinical appearance of the lesion is typical, no other confirmatory tests are usually necessary. Paring down the stratum corneum, or outer layer of skin, may reveal black dots, which are thrombosed or bleeding capillaries, and helps confirm the diagnosis. If needed, tissue biopsy can provide histopathologic confirmation. In immunocompromised patients, biopsy is recommended to rule out squamous cell carcinoma in any suspicious lesions, which includes large or rapidly growing, pigmented, atypical, friable, bleeding, or ulcerated lesions.

## Treatment

Approximately 20% of warts spontaneously resolve within 3 months and 60% within 2 years in a healthy person. Therefore, treatment is not always necessary. Current treatments do not eradicate the virus and do not guarantee resolution. Most patients seek treatment because of the physical appearance, discomfort, or interference with daily and social functioning, especially if located on the palms, digits, or soles. The American Academy of Dermatology established reasoning for wart treatment, including the desire of the patient; for symptoms of pain, bleeding, itching, or burning; for disabling or disfiguring lesions; for large numbers or large size of lesions; for a desire to prevent spread to unblemished skin; and because of a concomitant immunocompromised condition. Immunosuppressed patients are at higher risk for developing numerous warts and require treatment to prevent progression to squamous cell carcinoma. It is often more difficult to eradicate warts in an immunosuppressed host.

Many therapeutic modalities are available for the treatment of warts. No single therapy is universally effective. Warts can resolve, recur, shrink, or grow despite therapy. It is likely that all wart therapies work by triggering an immune response to the presence of papillomavirus in the skin. Treatment of warts must be individualized and often more than one modality is needed to achieve resolution. Conservative, less painful, and less expensive treatments are preferred.

Treatment methods are divided into the categories of home remedies, over-the-counter treatments, and office-based therapies. Office-based treatments include destructive methods, surgical or laser procedures, immunologic intervention, and combination therapy.

## Home Remedies

Home remedies include applications of tea tree oil,<sup>7</sup> garlic extract,<sup>7</sup> duct tape,<sup>1</sup> and hyperthermic therapy. One study comparing cryotherapy with duct tape occlusion of common warts showed resolution in 85% of the children treated by occlusion, compared with 60% in the liquid nitrogen group. Proper protocol involves covering the wart with duct tape, which is left in place for 6 days. Then the site should be soaked, pared down with an emery board, and left uncovered overnight. This is repeated for a total of eight cycles. Another common home remedy is hyperthermic therapy. This involves immersing the affected area in a 45°C water bath for 30 minutes three times per week. It is a safe and inexpensive option.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

### Over-the-Counter Treatment

The most common over-the-counter option used by patients is one of the salicylic acid products, such as Compound W, Duo-film, WartStick, and Mediplast. These keratolytic products are offered as a solution, gel, cream, or pad in concentrations from 10% to 60%. They can be quite successful when used consistently and as directed in motivated patients. Repeated application, with pumice stone or callus file use, results in cure rates of 60% to 80%, but takes several weeks to work.

More recently, several over-the-counter wart-freezing therapies have become available. One such option is dimethyl ether, marketed as Compound W Freeze Off or Dr. Scholl's Freeze Away. These are available in aerosol form for wart treatment, which can be repeated every 2 weeks. Dimethyl ether achieves a temperature of  $-57^{\circ}\text{C}$ , which is markedly higher than the  $-196^{\circ}\text{C}$  temperature obtained with liquid nitrogen. This results in a more shallow depth of destruction. Because salicylic acid and dimethyl ether treatments destroy the infected epidermis and cause an immune reaction, they can be irritating and tedious, prompting many patients to seek medical care.

### Office-based Treatment

Office-based treatments are largely destructive, immunomodulating, or both. Destructive treatments include cryosurgery, surgical excision, laser therapy, or repeated application of topical chemotherapy agents, such as salicylic acid, cantharidin (Cantharone),<sup>1,6</sup> podophyllin (Podocon),<sup>1</sup> or 5-fluorouracil (Efudex).<sup>1</sup> The most commonly used physician office-based treatment is cryotherapy with liquid nitrogen. It can be applied by a cotton-tipped applicator or cryogun. The wart and a 1 to 2mm margin are frozen for 10 to 30 seconds. The freeze should be repeated once after a thaw of 20 seconds. If the warts are thick, they can initially be pared down. The patient is told that a blister will result and should be left intact if possible. Treatment should be repeated every 3 to 4 weeks until normal skin markings return. Cryotherapy has demonstrated a 60% to 80% cure rate. If warts persist beyond 3 months of therapy, another method of treatment should be selected.

Another option is cantharidin (Cantharone) in a 0.7% colloidal solution. It is a chemical derived from blister beetles that is painless on application and well tolerated by children. It causes epidermal necrosis with blistering after application and occlusion for 8 hours. It is applied in the office and repeated every 4 weeks. Although not Food and Drug Administration (FDA) approved, it is a commonly used technique and can be compounded by a pharmacist. It is useful for treatment of common, periungual, and plantar warts in children, and the cure rate approaches 80%. Unfortunately, an occasional "donut wart," a ring of new warts surrounding the cleared original site, occurs.

Surgery is used for large, solitary warts, and is more direct. Large common warts of the hands or extremities are more easily treated if they are debulked surgically. This method is not recommended for plantar warts because of scarring. Surgical removal followed by electrodesiccation and curettage is effective but requires local anesthesia and can result in scarring.

Other destructive methods of wart removal usually are reserved for resistant, multiple lesions, or recalcitrant warts in immunosuppressed patients. This often requires specialty referral. Acids, including bichloroacetic and trichloroacetic acid (Tri-Chlor),<sup>1</sup> should be applied by a skilled practitioner because they are known to cause pain on application, ulceration, and even scarring. Laser therapy, most often with a pulsed-dye laser (PDL) or carbon dioxide (CO<sub>2</sub>) laser, provides selective photothermolysis of blood vessels within the wart, which compromises blood supply and results in necrosis. The PDL method is less aggressive and less painful than CO<sub>2</sub> vaporization. These treatments cause minimal damage to normal skin. Overall, both therapies are generally well tolerated, but local anesthesia may be necessary. Although more expensive, these methods have cure rates ranging from 45% to 90%. Photodynamic therapy (PDT) is useful for patients with

multiple recalcitrant warts, especially patients who are immunosuppressed. PDT involves a topical photosensitizer applied by a trained provider. It is activated by visible light, resulting in tissue destruction. Studies of this method have been promising.

Immune modulation alone or in combination with destructive methods is helpful in treating resistant warts. The self-applied immunomodulator imiquimod (Aldara) was initially approved for treatment of genital warts. It is also used anecdotally to treat flat and common warts<sup>1</sup> by inducing cytokines, including interferon production, at the site of application. A thin coat is applied at bedtime and then washed off after 6 to 10 hours. It is usually applied three times weekly and combined with cryotherapy or salicylic acid.

Intralesional immunotherapy, which includes *Candida* antigen (Candin),<sup>1</sup> interferon alfa-2b (Intron A),<sup>1</sup> bleomycin,<sup>1</sup> and MMR vaccine,<sup>1</sup> is an effective option for treatment in some patients. *Candida* antigen injection (Candin) is considered a first-line therapy in children with large or multiple warts and a second-line therapy for patients with resistant warts. It is well tolerated. *Candida* antigen is commercially available as a 1:1000 dilution. Using a 30-gauge needle and tuberculin syringe, one can inject 0.2 to 0.3mL directly into the wart and repeat every 3 weeks. Pretesting is unnecessary, side effects are minimal, and more than 75% of patients treated with a series of three injections have clearing of the injected and distant warts. Intralesional interferon alfa-2b (Intron A) has been used successfully to treat genital warts and warts that have not responded to conventional therapies. The clearance rate varies from 36% to 62%, but it requires multiple injections in a physician's office, is expensive, and can cause systemic adverse effects such as flu-like symptoms. Intralesional bleomycin is effective but expensive and causes severe pain. The MMR vaccine is used off-label for intralesional injection and often combined with lidocaine for comfort.

Other topical immunomodulators, such as squaric acid dibutylester (SADBE)<sup>1,6</sup> or diphencyprone,<sup>1,7</sup> are contact sensitizers that induce an allergic dermatitis through type IV hypersensitivity reactions. Although time consuming, treatment with SADBE is well tolerated and a good choice for recalcitrant warts in children. Other topical products available for off-label treatment include retinoids, formaldehyde compounds, and 5-fluorouracil (Efudex).<sup>1</sup> These agents interfere with epidermal proliferation, effect a nonspecific antiviral action, or inhibit mitosis, leading to keratinocyte and viral death. All of these choices usually require specialty referral.

Oral immunomodulation with high-dose cimetidine (Tagamet)<sup>1</sup> has been proposed. It is postulated to enhance cell-mediated immune response. Evidence has been anecdotal. Daily doses of 30 to 40mg/kg have been used divided twice a day to four times a day for 8 to 12 weeks.

To ensure resolution and no recurrence of warts, the patient and practitioner must often make compromises in regard to convenience, discomfort, and scarring. The factors to consider when deciding on treatment include wart location and size, patient tolerance and preference, cost, convenience, and clinician preference. Patient-applied options allow the patient greater control; however, this requires good compliance and the warts must be accessible by the patient or caregiver. Provider-applied treatments are good choices for large treatment areas. Data regarding the efficacy of using more than one modality at a time are lacking. It is common practice for health care providers to combine treatment modalities. Table 1 outlines current therapy regimens.

### Patient Education

Counseling of patients regarding the goal and length of treatment is necessary. Patients should be educated that current treatments do not eradicate HPV, and therefore the objective of therapy is elimination of symptoms. They also need to understand that a repeated course of therapy is often required and it may take weeks to months to achieve desired results. Each treatment should be reviewed in detail, including risks and benefits. Subsequently, the management should be tailored depending on the wart, patient, and practitioner.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

**TABLE 1** Treatment Regimens

DRUG	AVAILABLE AS	MECHANISM OF ACTION	DISADVANTAGES	INSTRUCTIONS
<b>Patient Applied</b>				
Salicylic acid (Compound W, Duofilm, or Mediplast)	Solution, gel, lotion, cream, plaster, pad 10%–60% concentration	Keratolytic that destroys the infected epidermis while irritation stimulates an immune response	Local irritation Requires multiple applications Requires compliance Wart may need to be pared down to increase penetration	Apply nightly until clear, usually for weeks to months
Dimethyl ether (Compound W, Freeze Off, Dr. Scholl's Freeze Away)	OTC in spray canister	As above	Local irritation Requires compliance Blistering may occur	May treat every 2 weeks Total of four treatments per wart advised
Retinoids (Accutane, Retin-A, Soriatane) <sup>1</sup>	Soriatane (10 and 25 mg tabs), Accutane (10, 20, and 40 mg tabs), Retin-A cream/gel	Antimitotic that interferes with epidermal proliferation	Systemic with mucocutaneous dryness, elevated triglycerides, abnormal liver enzymes Avoid use in pregnancy Local irritation and dryness	Take PO daily If topical form, apply nightly
Imiquimod (Aldara) <sup>1</sup>	Cream 5%	Immunomodulator that mediates cytokines	Irritation, erythema, pruritus, scarring, hyperpigmentation	Apply 3 times/wk on mucosal skin Apply daily on keratinized skin
Cimetidine (Tagamet) <sup>1</sup>	Tablets (200, 300, 400 mg) Liquid (300 mg/5 mL)	Immunomodulator that may enhance immune response	Unclear efficacy Diarrhea Many drug-drug interactions	30–40 mg/kg daily, divided bid–qid for 8–12 weeks
<b>Provider Applied</b>				
Cryotherapy	Cryogun or cotton-tip application	Destroys infected dermis, induces inflammation, and leads to stimulated immune response	Pain, erythema, blistering, hypopigmentation, scarring Onychodystrophy if not careful with periungual warts	Freeze for 10–30 seconds with a 1–2 mm border, allow to thaw, then repeat May offer/need local anesthesia May repeat every 3–4 weeks
<i>Candida</i> antigen injections (Candin) <sup>1</sup>	1:1000 dilution	Immunomodulator	Discomfort	Intralesional injection of 0.2–0.3 mL
Trichloroacetic acid (TCA) <sup>1</sup>	Solution, up to 80%	Destroys infected epidermis; best for mucosal surfaces	Pain	Apply sparingly with cotton tip, air dry Repeat weekly to every other week Do not allow to “run” on normal skin  Neutralize with soap or sodium bicarbonate
Cantharidin (Cantharone) <sup>1</sup>	Colloidal solution 0.7%, compounded	Destroys epidermis, leads to blister formation Is painless, good for kids	Avoid on face Blistering will occur	Apply with fine applicator to wart only and have patient wash off after 6–8 hr
Surgery		Surgical removal	Avoid if bleeding disorder Often requires anesthesia Scarring	Surgical excision followed by curettage and cauterization
Interferon alpha-2b (Intron A) <sup>1</sup> injections		Immunomodulator	Expensive Flu-like side effects	Multiple intralesional injections several times a week Often requires specialty referral
Laser vaporization		Destroys epidermis	Expensive Requires local anesthesia	Requires specialty referral

<sup>1</sup>Not FDA approved for this indication.

Abbreviations: bid=twice a day; OTC=over-the-counter; PO=orally; qid=four times a day.

## ACUTE KIDNEY INJURY

Method of

Sarah Burns, DO, MS

### CURRENT DIAGNOSIS

- Acute kidney injury (AKI) is a common diagnosis seen in the outpatient setting, in the emergency department, and in hospitalized patients.
- AKI is defined by increase in serum creatinine by  $\geq 0.3$  mg/dL within 48 hours, increase  $\geq 1.5$  times the baseline creatinine within 7 days, or oliguria.
- Identify the underlying cause of AKI, denoted by pathophysiologic etiology (prerenal, intrinsic, and postrenal) to determine therapy.

### CURRENT THERAPY

- Treat any reversible causes identified.
- Ensure hemodynamic stability.
- Correct any imbalances in electrolytes or in acid-base standing.
- Avoid nephrotoxins and renally dose all medications if glomerular filtration rate (GFR) is decreased.
- Prompt consultation to specialists to determine whether renal replacement treatment is appropriate.

### Background/Definitions

Acute kidney injury (AKI) is a diverse syndrome defined by a sudden decrease in kidney function shown by a rise in serum creatinine and/or decrease in urine output. This sudden decrease in renal function affects fluid balance, electrolyte balance, acid-base balance, and waste elimination. The older term *acute renal failure* has been supplanted by AKI. The term AKI reflects a lack of strict separation between normal renal function and complete failure of the kidneys.

Previously there was no standard definition for diagnosing AKI, and there were more than 30 different definitions in the literature. In 2004 Risk, Injury, Failure, Loss, and End Stage Kidney Disease (RIFLE) criteria were proposed, evolving into the AKI Network (AKIN) criteria in 2007. In 2012 these validated criteria were adapted into international clinical practice guidelines released by Kidney Disease: Improving Global Outcomes (KDIGO). Although KDIGO criteria are widely used in research, there are parts of the definition that have not been validated. However, most experts endorse the use of KDIGO criteria for the diagnosis and management of AKI.

KDIGO criteria denote AKI when there is an increase in serum creatinine greater than or equal to 0.3 mg/dL within 48 hours, or an increase greater than or equal to 1.5 times the baseline creatinine within 7 days, or a decrease in urine volume to less than 0.5 mL/kg/h over 6 hours. To further describe the severity of

AKI, there are stages (Table 1) describing the amount of change in serum creatinine from baseline. Multiple studies have demonstrated that increasing severity of AKI is associated with increased mortality and worse kidney function in the future.

### Epidemiology

AKI is commonly found in hospitalized patients, and the incidence appears to be increasing over time in the United States. A 2013 meta-analysis for all hospitalized patients worldwide showed an overall incidence of AKI in 21.6% of patients. With the KDIGO definition, this study showed that 1 in 5 adults and 1 in 3 children worldwide experience AKI during a hospital stay. A 2015 multinational cross-sectional study of AKI in intensive care unit (ICU) patients showed AKI occurred in 57.3% of ICU patients. Additionally, it has been observed that rises in serum creatinine are associated with adverse patient outcomes, increased mortality, longer length of hospital stay, and higher healthcare costs. AKI also has been shown to be an independent risk factor for mortality.

There are multiple factors, based on several observational studies, that may affect the chance of developing AKI. These factors vary between individuals, and it is not clear why one factor would cause an individual to develop an AKI and another not to. As delineated by KDIGO clinical practice guidelines, the following increase the risk of AKI: critical illness, sepsis, shock, burns, trauma, major surgery including cardiac surgery, nephrotoxic drugs, iodinated radiocontrast agents, and poisonous animals and plants. KDIGO clinical practice guidelines indicate that certain patient populations are susceptible to AKI, and they include the following: volume depletion, older age, female sex, black race, chronic kidney disease (CKD), other chronic diseases (including heart, lung, and liver), diabetes mellitus, cancer, and anemia.

### Etiology

The causes of AKI can be broadly divided by the pathophysiologic etiology, specifically prerenal, intrinsic, and postrenal causes (Box 1). Prerenal AKI from renal hypoperfusion is the most common cause of AKI in the community setting. Acute tubular necrosis (ATN; an intrinsic etiology) is the most common cause of hospital-acquired AKI. Although the cause of AKI is traditionally classified by the portion of the kidney affected, it should be noted that diseases may cross these pathophysiologic boundaries. Therefore AKI may be multifactorial.

### Prerenal

Prerenal AKI is caused by renal hypoperfusion caused by a decrease in the arterial volume. Recall that autoregulation will help maintain the kidney's glomerular filtration rate (GFR) by blunting changes in blood flow by various mechanisms. Ultimately, autoregulation can only compensate for a degree in decreased renal perfusion. For example, in those with CKD, these autoregulatory mechanisms are diminished which increases the susceptibility of developing an AKI on CKD. Decreased arterial volume occurs in renal vasoconstriction, which is caused by sepsis (early in course), hepatorenal syndrome, iodinated contrast, medications such as norepinephrine or vasopressin, nonsteroidal antiinflammatory drugs, and angiotensin-converting enzyme inhibitors. Intravascular

**TABLE 1** Staging of Acute Kidney Injury (Based on Kidney Disease: Improving Global Outcomes).

STAGE	SERUM CREATININE	URINE OUTPUT
1	≥0.3 mg/dL increase OR 1.5–1.9 times baseline	<0.5 mL/kg/h for 6–12 h
2	2–2.9 times baseline	<0.5 mL/kg/h for ≥12 h
3	3 times baseline OR Increase in creatinine to ≥4 mg/dL OR Starting renal replacement therapy	<0.3 mL/kg/h for ≥24 h OR Anuria for ≥12 h

volume depletion reduces the arterial volume to the kidneys and is caused by gastrointestinal losses, hemorrhage, diuretic use, cirrhosis, nephrotic syndrome, and burns. Renal hypoperfusion is also caused by reduction in cardiac output, which is seen in shock, pericardial disease, heart failure, pulmonary embolism, pulmonary hypertension, and sepsis. Systemic vasodilation is another cause of renal hypoperfusion and is caused by sepsis, cirrhosis, anaphylaxis, and drugs. Increased abdominal pressure as seen in abdominal compartment syndrome can be another cause of prerenal AKI.

The clinical presentation of prerenal AKI is variable and dependent on the cause. The cause should be investigated first with an excellent history and physical examination. Prerenal causes may be suspected in patients with dehydration, gastrointestinal losses such as vomiting or diarrhea, sweating, other insensible losses, increased ostomy output, bleeding, dizziness, or syncope. Prerenal causes should be suspected in patients with chronic medical conditions, such as heart failure or cirrhosis. All medications (current, recently used, prescribed, over the counter) should be investigated in every patient suspected to have an AKI from any cause. Further work-up is discussed below. Prerenal AKI may improve rapidly if the underlying cause is treated, if the volume status is improved, and/or if the offending medication is removed.

### Intrinsic

Intrinsic AKI can be divided into the component of the kidney that is affected, which includes diseases of the vasculature, the glomeruli, the tubules, and the interstitium. Vascular causes are uncommon and include those that affect the small vessels and those that affect the large vessels. Small vessels are affected by vasculitides, scleroderma, and malignant hypertension. Large vessels are affected by aneurysms, infarct from aortic dissection, venothrombosis, and atheroembolism especially in the setting of recent vascular surgery or arterial catheterization.

Glomerular diseases originate from inflammation of the vessels and the glomeruli and may be a manifestation of an infection, of a vasculitis, or of a rheumatologic disorder. Glomerular diseases are divided into nephritic and nephrotic diseases, determined by less than 3 g of proteinuria per day or more than 3 g of proteinuria per day, respectively. Rapid progressive glomerulonephritis (RPGN) is an acute cause of AKI that may be seen in the hospital and always presents with a nephritic pattern. Nephrotic patterns of AKI are rarely encountered in hospitalized patients.

Tubular and interstitial diseases commonly cause AKI specifically from damage caused by ischemia, endogenous or exogenous nephrotoxins, medications, or infections. Tubulointerstitial diseases include ATN, acute interstitial necrosis, cast nephropathy, acute urate nephropathy, crystalline nephropathy, and acute phosphate nephropathy. The most common AKI in hospitalized patients is caused by ATN. ATN occurs from prolonged renal hypoperfusion and tissue ischemia or from endogenous or exogenous nephrotoxic exposure. Common endogenous nephrotoxins include hemolysis, rhabdomyolysis,

tumor lysis syndrome, and multiple myeloma. Common exogenous nephrotoxins include radiocontrast, aminoglycosides, ethylene glycol, cisplatin, and methotrexate. Common nephrotoxins associated with AKI are listed in [Box 2](#). Cast nephropathy is attributable to excess immunoglobulin light chains in multiple myeloma. Excess cellular contents released into circulation after chemotherapy can cause acute urate nephropathy in tumor lysis syndrome, less common nowadays with the prophylactic use of allopurinol (Zyloprim) or rasburicase (Elitek) prior to chemotherapy administration. Intravenous acyclovir (Zovirax) causes crystalline nephropathy. Oral sodium phosphate solution (Fleet) given for a bowel preparation for colonoscopy can cause acute phosphate nephropathy through an unclear mechanism.

The clinical presentation of intrinsic AKI is variable and dependent on the cause. The cause should be investigated first with an excellent history and physical examination. Vascular causes of intrinsic AKI should be suspected in recent vascular surgery, recent arterial catheterization, anticoagulation, atheroembolic disease, flank pain, or trauma. Glomerular causes of intrinsic AKI should be suspected in patients with systemic lupus erythematosus, systemic sclerosis, rash, arthritis, HIV infection, hepatitis C viral infection, cough, sinusitis, hematuria, hemoptysis, or weight loss. ATN should be suspected in patients with exposure to nephrotoxins, hypotension, trauma, or exposure to radiocontrast agents. AIN should be suspected in medication use or if there is a rash, fever, infection, or arthralgias. Further work-up is described in the following. Management and prognosis are variable and depend on the underlying cause.

### Postrenal

Postrenal AKI is caused by obstruction of any cause in the urinary tract, within the kidney itself or from the ureter, bladder, bladder neck, or urethra. The most common cause is caused by obstruction of the bladder neck, either structural or functional, such as seen in benign prostatic hyperplasia. Other causes include extrinsic compression from metastatic cancer, neurogenic bladder, or retroperitoneal fibrosis, or intrinsic obstruction from calculi, crystals, or blood clots.

The clinical presentation of postrenal causes of AKI with variable urine output from anuria to polyuria, hematuria (if clots are present or malignancy is suspected), dysuria, urgency, increased frequency, weak stream, nocturia, spinal cord injuries, or long-standing poorly controlled diabetes. An excellent history and physical examination will start the investigation of the cause. It is important to diagnosis and treat postrenal causes promptly to avoid long-term damage and improve the chance for recovery.

### Approach to Diagnosis

The cause of AKI should always be approached in a patient-centered manner. The diagnostic work-up will depend on clinical context, severity, and duration of AKI in addition to comorbid conditions. For patients in the outpatient setting with new onset or rapidly worsening GFR, close follow-up is warranted, and these patients should likely be hospitalized for daily monitoring

**Prerenal Causes**

- Hypovolemia caused by true or effective intravascular volume depletion  
Hemorrhage of any cause, gastrointestinal (GI) losses (diarrhea, vomiting), diuretics, burns, cirrhosis, nephrotic syndrome
- Diminished cardiac output or pump failure  
Shock, pericardial disease, heart failure, pulmonary embolism, pulmonary hypertension, and sepsis
- Systemic vasodilation  
Sepsis, cirrhosis, anaphylaxis, and drugs
- Vasoconstriction of renal vessels  
Sepsis (initially), hepatorenal syndrome, iodinated contrast, medications such as norepinephrine (Levophed) and vasopressin, nonsteroidal antiinflammatory drugs, and angiotensin-converting enzyme inhibitors
- Increased abdominal pressure  
Abdominal compartment syndrome

**Intrinsic Causes**

- Intrinsic renal vascular disease  
Small: vasculitides, thrombotic thrombocytopenic purpura, scleroderma, atheroembolic disease, and malignant hypertension  
Large: infarct from aortic dissection, systemic thromboembolism, renal artery aneurysm, and renal vein thrombosis
- Intrinsic renal glomerular disease  
Nephritic: proliferative glomerulonephritis (e.g., rapidly progressive glomerulonephritis)

- Nephrotic: nonproliferative glomerulonephritis
- Intrinsic tubular and interstitial disease  
Acute tubular necrosis  
Angiotensin-converting enzyme inhibitors/angiotensin II receptor blockers plus nonsteroidal antiinflammatory drugs, radiocontrast or other nephrotoxins, after cardiac surgery, sepsis/shock or prerenal state, and rhabdomyolysis
- Acute interstitial nephritis  
Nonsteroidal antiinflammatory drugs, aspirin, omeprazole (Prilosec), thiazide diuretics, furosemide, allopurinol (Zyloprim), penicillin, vancomycin, and cephalosporins
- Cast nephropathy  
Multiple myeloma
- Acute urate nephropathy  
Tumor lysis syndrome
- Crystalline nephropathy
- IV acyclovir (Zovirax)
- Acute phosphate nephropathy after phosphate bowel prep

**Postrenal Causes**

- Extrinsic  
Benign prostatic hyperplasia  
Metastatic cancer  
Retroperitoneal fibrosis  
Neurogenic bladder
- Intrinsic  
Calculi  
Crystals  
Blood clots

**BOX 2** Common Nephrotoxic Medications Associated With Acute Kidney Injury

- Vancomycin
- Aminoglycosides
- Penicillin
- Piperacillin and tazobactam (Zosyn)
- Cephalosporins
- Heme pigments
- Cisplatin
- Radiocontrast
- Pentamidine (Pentam)
- Foscarnet (Foscavir)
- Cidofovir (Vistide)
- Tenofovir (Viread)
- IV immunoglobulin
- Mannitol
- Synthetic cannabinoids
- Nonsteroidal antiinflammatory drugs
- Angiotensin-converting enzyme inhibitors
- Aspirin
- Omeprazole (Prilosec)
- Thiazide diuretics
- Furosemide (Lasix)
- Allopurinol (Zyloprim)

of laboratory studies and clinical status, especially if urgent or emergent treatment is warranted.

Careful review of the medical record can aid in determining trends in serum creatinine, assisting in the determination of an

acute, acute on chronic, or chronic process. Once an acute process is identified, the evaluation of AKI should be categorized into prerenal, intrinsic, or postrenal cause to determine further work-up and ultimately treatment. At minimum, the clinician should obtain urinalysis, urine microscopy, laboratory studies including complete blood count, and metabolic panel with creatinine and electrolytes. Prerenal causes are more suggestive when blood urea nitrogen (BUN):creatinine ratio is greater than 20, when urine specific gravity is elevated, or when urine sodium is low. A renal ultrasound may be useful to obtain to assess for postrenal causes including obstruction, and can specifically give information on cortical thickness, differences in densities in cortex and medulla, integrity of the collecting system, and kidney size. Postvoid residual may be considered and placement of urinary catheter if obstruction is suspected. Although a patient's urine output is an important clinical indicator, it is not necessarily kidney specific. Urine output may increase, decrease, or maintain irrespective of the insult affecting the kidneys. Trends in urine output can be useful when determining possible causes of AKI.

Measurements of fractional excretion of sodium (FeNa) or urea (FeUr) have not consistently been shown to have clear clinical correlations. FeNa is defined by the following formula:

$$\text{FeNa} = \frac{100 \times (\text{urinary sodium} \times \text{serum creatinine})}{(\text{serum sodium} \times \text{urinary creatinine})}$$

FeNa less than 1% suggests prerenal and FeNa greater than 2% suggests ATN. Despite the claims that a FeNa calculation can determine prerenal AKI versus ATN, there is no absolute FeNa value that is always diagnostic of prerenal disease. There are many limitations in using FeNa, including that there are other causes of AKI that have a calculated FeNa of less than 1% (including some occasions of ATN). Additionally, single measurements of creatinine may be

misleading, given that serum creatinine can vary even in a given day. Patients with CKD have impaired sodium handling and in the setting of prerenal disease, will have a FeNa that is greater than 1%. However, this FeNa value should not preclude the clinician from addressing the underlying issue (for example, hypovolemia causing prerenal AKI in a patient with known CKD) solely based on a FeNa percentage. FeNa is not sensitive or specific enough in the inpatient population and therefore is not generalizable to the average hospitalized patient. The entirety of a patient's presentation should allow the clinician to determine the cause of AKI.

### Approach to Treatment

The cause of AKI will determine the treatment. If history and examination are pointing toward prerenal volume depletion as the mechanism of AKI, then intravenous fluids should be administered. This does not apply to prerenal AKI from heart failure or cirrhosis. Hypovolemia and hypotension should be addressed with balanced crystalloid solutions (for example, lactated Ringer's), which will reduce the risk of severe hyperchloremic metabolic acidosis that can occur with saline solutions. The optimal rate of infusion of fluids depends on the clinical status of the patient and comorbidities with expert recommendation to consider 1 to 3 L of fluid to start and to avoid volume overload. Concern for sepsis or infection should be treated appropriately including cultures as indicated, intravenous fluid resuscitation, and antibiotics. Urinary obstruction should be treated and depending on the site of obstruction, a patient may need placement of a urinary catheter or percutaneous nephrostomy tube. Depending on the patient's GFR, any medication given should be renally dosed. All nephrotoxic insults should be avoided. Diuretics should be used in the setting of volume overload, such as in acute decompensated heart failure causing AKI, and it should be noted that diuretics do not specifically affect AKI recovery or have a survival benefit. If there are life-threatening abnormalities or imbalances caused by AKI including volume overload, hyperkalemia, acidemia, or uremia, then prompt consultation is warranted to a nephrologist and likely to a critical care specialist. In these cases, renal replacement therapy or another hemodialysis modality will likely be considered. The ideal timing to starting dialysis in patients with AKI is unknown, and the mortality benefit to early initiation of dialysis also is unclear. As already mentioned, in patients with acute decompensated heart failure, diuretics are used and inotropes may also be necessary to achieve improvement in renal perfusion in the setting of decreased cardiac output. In patients with liver disease and concomitant AKI, hepatorenal syndrome may be considered as the underlying cause of AKI; however, it is a diagnosis of exclusion and is treated in the ICU with norepinephrine (Levophed)<sup>1</sup> or on the general medical floor with midodrine (Proamatine)<sup>1</sup>, octreotide (Sandostatina)<sup>1</sup>, and albumin<sup>1</sup>. Acute interstitial nephritis should be treated with the withdrawal of the inciting medication or agent, and if there is no improvement in some days, patients may benefit from glucocorticoids. ATN has no one specific treatment, as it is dependent on the underlying cause (ischemia or nephrotoxins).

### Prognosis and Outcomes

AKI is associated with adverse patient outcomes, increased mortality, longer length of hospital stay, and higher healthcare costs. The duration of AKI tends to vary between 7 and 21 days. Some patients with AKI recover kidney function within days and some require dialysis for months. After an episode of AKI, patients are at increased risk for CKD and end-stage renal disease (ESRD). Patients with CKD who experience AKI are more likely to advance to ESRD. Some patients may never return to their baseline kidney function. Irreparable decline in kidney function is more likely in patients of advanced age, those with CKD, and those with heart failure. Mortality rates range from 16% to 50% according to stage of AKI and also depend on cause of

AKI, concurrent comorbid conditions such as sepsis, lung or liver failure, and cerebrovascular events. Patients who are discharged after a hospitalization during which AKI occurred warrant close follow-up. The KDIGO clinical practice guideline, in their expert opinion, recommended that clinicians evaluate patients 3 months after AKI for resolution of AKI or new onset CKD or worsening of preexisting CKD.

### Developing Issues—Biomarkers

The aim of AKI biomarkers is to excel in early diagnosis, to assess risk accurately, to assess treatment response, and to evaluate prognosis. There are over 20 biomarkers available to date that can be divided into functional biomarkers, tubular enzymes, damage biomarkers, and preinjury phase biomarkers in the evaluation of AKI. Nearly all biomarkers can be affected by at least one factor. The urine biomarker NephroCheck (insulin-like growth factor-binding protein [IGFBP7] and tissue-inhibitor of metalloproteinases 2 [TIMP2]) is FDA approved and commercially available. Despite validation in the prediction of onset of severe AKI in the critical care setting, this test has limitations including that it can commonly lead to false positive results (especially if used in patients that are low risk for AKI) and cannot be used in the outpatient setting. Given the heterogeneity of AKI, it is evident that no one biomarker is entirely specific for AKI. Biomarkers are but one factor in risk assessment in AKI, and there are newer developments related to monitoring and evaluating AKI risk progression. These include electronic alert systems, machine learning algorithms and artificial intelligence, in addition to models based on renal angina index, furosemide stress test, or biomarkers. Additional study is needed to validate and to standardize risk models to better intervene upon AKI to improve outcomes.

## CHRONIC KIDNEY DISEASE

Method of

Catherine Do, MD; and Mark Unruh, MD

### CURRENT DIAGNOSIS

- The estimated glomerular filtration rate (eGFR) is the generally accepted, best index of kidney function. Normal eGFR varies according to age, sex, and body size; in young adults, it is approximately 125 mL/min per 1.73 m<sup>2</sup> and declines with age.
- Chronic kidney disease (CKD) is defined as GFR <60 mL/min/1.73 m<sup>2</sup> as well as elevated markers of kidney damage. The most common marker of kidney damage is urine albumin.
- The most common method to assess GFR is serum creatinine combined with the CKD-EPI equation. The Task Force on Reassessing the Inclusion of Race in Diagnosing Kidney Diseases, a joint effort by both the National Kidney Foundation and American Society of Nephrology, advised the removal of the race adjustment in GFR equations in 2021 because its inclusion led to higher GFR estimations in individuals identified as Black and led to delays in CKD diagnosis and kidney care (2). The Task Force also recommended more widespread use of serum cystatin C for CKD confirmation. If possible, one can determine the underlying cause of CKD and consider referral to a nephrologist for management if GFR <30 mL/min/1.73 m<sup>2</sup>.

### CURRENT THERAPY

- Initiate treatment to delay or prevent disease progression, including an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin receptor blocker (ARB) to reduce blood pressure to <130/80 mm Hg and urine total protein excretion to as low as possible, but at least <1 g/day.
- Prevent or treat biochemical or clinical abnormalities including serum potassium, calcium, bicarbonate, calcium, phosphorus, parathyroid hormone (PTH), and hemoglobin.
- Evaluate for the presence of comorbid conditions such as hypertension, diabetes, and cardiovascular disease (CVD).

*Chronic kidney disease* (CKD) is the term used to describe patients with decreased glomerular filtration rate (GFR) or with kidney damage such as albuminuria; there are different levels of CKD. CKD has been classified by cause, kidney function, and severity of albuminuria. *Kidney damage* is defined as structural or functional abnormalities of the kidney, initially without decreased GFR, which over time can lead to decreased kidney function. Markers of kidney damage include abnormalities in the composition of the blood or urine or structural abnormalities in imaging tests. *End-stage renal disease* (ESRD) or *kidney failure* is the term used to describe patients who have advanced renal failure requiring renal replacement therapy (i.e., either hemodialysis/peritoneal dialysis or transplantation). CKD has been associated with higher costs of care and risk of death.

Most CKD demonstrates an inexorable progression. The rate of decline could be estimated as much as 7 to 10 mL/min/year in those with an untreated diabetic nephropathy. Electrolyte homeostasis, causes of progressive decline in function, and manifestations of kidney failure are similar enough across the different pathologies that we can think of common underlying routes to progression, symptoms, and hopefully amelioration of CKD. These interventions often do not reverse kidney disease; rather,

**TABLE 1** Risk Factors for the Development or Progression of Chronic Kidney Disease

Albuminuria
Hypertension
Episodes of acute kidney injury
Underlying cause of kidney disease (e.g., diabetic nephropathy)
Obesity

Smoking
High-protein diet
Metabolic acidosis
Hyperphosphatemia
Hyperuricemia
Hyperglycemia

they slow the progression of kidney disease. Therefore, earlier diagnosis and treatment may delay kidney death so a patient can avoid undergoing dialysis, transplantation, and the complication of kidney failure.

### Prevalence of Chronic Kidney Disease

Estimates are that there are 30 times as many subjects with CKD compared with ESRD. Approximately 14.7% of the U.S. adult population is thought to have some form of CKD. Of note, the majority of those with stage 1 and 2 kidney disease may not even be aware of their kidney disease. Furthermore, more than 75 million are thought to have an increased risk of developing CKD. Only a fraction of patients understand that they have CKD, so it is crucial that to convey this to them so they can take steps to slow the progression.

### Risk Factors for Chronic Kidney Disease

Nonmodifiable risk factors are important for risk stratification by screening and for understanding the pathophysiology of CKD progression (Table 1). These risk factors include age and ethnicity, which are risk factors for many kidney diseases. For example, African-American patients with diabetes have a twofold to threefold higher risk of developing kidney failure compared with white patients. Modifiable risk factors are important for both understanding disease progression and as a possible option for prevention or therapy. For example, heavy consumption of analgesics has been associated with the development of kidney failure. The number of patients who develop kidney disease and are at risk for developing kidney disease will increase with the aging population and the increasing prevalence of diabetes.

### Approach to the Diagnosis of Chronic Kidney Disease

In clinical practice, the serum creatinine and blood urea nitrogen (BUN) concentrations are commonly used as indicators of GFR. The laboratory measurement of creatinine and urea is accurate and reliable, although normal values may vary slightly among laboratories. Creatinine production varies with muscle mass, therefore changes in lean body weight influence the serum creatinine level. For example, a male body builder may have an elevated creatinine but normal renal function and vice versa for a cachectic female older adult with muscle atrophy. When using plasma creatinine to assess GFR, it is also important to keep in mind the semilogarithmic relationship between the serum creatinine concentration and GFR. The Kidney Disease International Global Outcomes (KDIGO) Guideline on Chronic Kidney Disease currently recommends using the Chronic Kidney Disease Epidemiology (CKD-EPI) 2009 creatinine equation: This equation is currently the most accurate way to estimate GFR from serum creatinine. The CKD-EPI creatinine equation is as follows:

$$GFR = 141 \times \min(S_{cr}/\kappa, 1)^\alpha \times \max(S_{cr}/\kappa, 1)_{-1.209} \times 0.993^{Age} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if black]},$$

where: *Scr* is serum creatinine in mg/dL,  $\kappa$  is 0.7 for females and 0.9 for males,  $\alpha$  is  $-0.329$  for females and  $-0.411$  for males, *min* indicates the minimum of *Scr*/ $\kappa$  or 1, and *max* indicates the maximum of *Scr*/ $\kappa$  or 1.

Formulas derived from studies of large groups of patients—such as those by Cockcroft and Gault and the Modification of Diet in Renal Disease (MDRD) in which GFR was correlated with other factors (e.g., body weight, age, and serum albumin)—are sufficiently accurate to use for clinical purposes. In recent years, the inclusion of a race adjustment in creatinine-based GFR equations has been questioned because race is a social construct and not a biological variable, therefore its inclusion in GFR calculations is nonscientific. The Task Force on Reassessing the Inclusion of Race in Diagnosing Kidney Diseases, a joint effort by both the National Kidney Foundation and American Society of Nephrology, advised the removal of the race adjustment in GFR equations in 2021 because its inclusion led to higher GFR estimations in individuals identified as Black and led to delays in CKD diagnosis and kidney care. The task force also recommended more widespread use of serum cystatin C for CKD confirmation in addition to use of creatinine-based equations.

The recent classification of CKD includes a measure of albuminuria. A spot albumin-to-creatinine ratio serves as a very

important biomarker. Higher levels of albuminuria are linked to CKD progression, higher frequency of acute kidney injury, higher rates of dialysis, and higher risk of death.

There are novel estimating equations that use a range of new biomarkers to estimate kidney function. The most widely used is cystatin C, which can be used to estimate GFR in patients with extremes of age or body habitus. Cystatin C is a low-molecular-weight cysteine protease inhibitor produced in all nucleated cells. It has a constant level of production but increases with poor renal function, hence cystatin C may serve to improve the estimates of GFR in a number of settings. However, thyroid disease and inflammation can affect cystatin C levels, so providers should interpret this biomarker with caution in these settings.

### Management of Chronic Kidney Disease

#### Staging

The purpose of CKD staging is to guide management, including stratification of risk for progression and complications of CKD. Staging of CKD should be done according to [Figure 1](#) and [Table 2](#) and based on the following:

- Cause of disease
- Six categories of eGFR (G stages)
- Three levels of albuminuria (A stages)

The GFR is the generally accepted best index of kidney function. CKD is defined as GFR less than 60 mL/min per 1.73 m<sup>2</sup> as well as markers of kidney damage. In the United States, the most common marker of kidney damage is urine albumin. Other

**Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012**

				Persistent albuminuria categories		
				Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (ml/min/ 1.73 m <sup>2</sup> ) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60-89			
	G3a	Mildly to moderately decreased	45-59			
	G3b	Moderately to severely decreased	30-44			
	G4	Severely decreased	15-29			
	G5	Kidney failure	<15			

**Very dark gray (G1/G2 and A1): low risk (if no other markers of kidney disease, no CKD); Light gray (G3a and A1; G1/G2 and A2): moderately increased risk; Medium gray (G3b and A1; G3a and A2; G1/G2 and A3): high risk; Medium dark gray (G4/G5 and A1; G3b/G4/G5 and A2; G3a/G3b/G4/G5 and A3): very high risk.**

Figure 1 Prognosis of chronic kidney disease by glomerular filtration rate and albuminuria.

markers are kidney cysts or pathologic changes in the kidney. The severity of CKD is also determined by the level of GFR.

### CKD Stage 3 (Moderately Decreased GFR)

Stage 3 CKD (GFR 30 to 59 mL/min per 1.73 m<sup>2</sup>) has been subdivided into GFR stage 3a (G3a is GFR 45 to 59 mL/min per 1.73 m<sup>2</sup>) and stage 3b (G3b is GFR 30 to 44 mL/min per 1.73 m<sup>2</sup>) to more accurately reflect the continuous association between lower GFR and risk for mortality and adverse kidney outcomes.

**TABLE 2** Chronic Kidney Disease Classification Based on Glomerular Filtration Rate and Albuminuria

GFR STAGES	eGFR (mL/min/1.73 m <sup>2</sup> )	TERMS
G1	>90	Normal or high
G2	60–89	Mildly decreased
G3a	45–59	Mildly to moderately decreased
G3b	30–44	Moderately to severely decreased
G4	15–29	Severely decreased
G5	<15	Kidney failure (add D if treated by dialysis)

ALBUMINURIA STAGES	ALBUMIN-TO-CREATININE RATIO (mg/g)	TERMS
A1	<30	Normal to mildly increased
A2	30–300	Moderately increased
A3	>300	Severely increased

\*Chronic kidney disease is defined as either GFR  $\leq$ 60 mL/min/1.73 m<sup>2</sup> for  $\geq$ 3 months or structural or functional abnormalities manifested by the presence of markers of kidney damage in blood, urine, or imaging studies.

†Uremic symptoms include nausea, vomiting, anorexia, metallic taste, pericarditis, peripheral neuropathy, central nervous system changes including difficulty with concentration, and seizures.

eGFR, Estimated glomerular filtration rate; GFR, glomerular filtration rate.

### CKD Stage 4 (Severely Decreased GFR)

Stage 4 CKD is GFR 15 to 29 mL/min per 1.73 m<sup>2</sup>.

### CKD Stage 5 (Kidney Failure)

Stage 5 CKD is GFR <15 mL/min per 1.73 m<sup>2</sup> or treatment by dialysis.

Referral to a nephrologist is recommended when the eGFR <30 mL/min per 1.73m<sup>2</sup> and/or the urine albumin-to-creatinine ratio is >300 mg/g, with earlier referral recommended in specific cases. Early referral to a nephrologist is associated with improved outcomes once patients initiate dialysis.

### General Approach to Treatment of Chronic Kidney Disease

Treatment of CKD is divided according to modalities that are specific to the underlying disorder and those that are used to treat all patients with CKD.

The physician treating the patient with CKD has two goals: preventing or delaying CKD progression and alleviating the electrolyte and hormonal abnormalities that can lead to symptoms or complications. The provider can use the CKD classification system shown in Figure 1 to educate patients and highlight the need for adhering to strategies to slow the rate of CKD progression.

### Strategies to Slow Chronic Kidney Disease Progression

Because we have a better understanding of the progression of kidney disease, we can effectively slow progression. Rather than losing 10 mL/min/year of kidney function as an untreated type 1 diabetic, those with adequate disease control can forestall the need for dialysis by slowing the rate of progression anywhere from 2 to 6 mL/min/year. Providers can treat the underlying cause by identifying reversible factors such as volume depletion, uncontrolled hypertension, obstructive uropathy, and nephrotoxins. This makes a dramatic difference to the individual and to society in terms of quality of life and costs to the health care system.

### Blood Pressure Management

In addition to the use of an angiotensin-converting enzyme inhibitor (ACE-I) or angiotensin receptor blocker (ARB), management of hypertension in CKD first entails salt-depleting therapy with a salt-restricted diet and diuretic therapy (Table 3). Patients frequently require additional therapy to combat the enhanced vasoconstriction and to attempt to slow the rate of CKD progression. The KDIGO blood pressure guidelines have recommended a target blood pressure of <130/80 for those with advanced kidney

**TABLE 3** Recommendations for the Treatment of Patients with Chronic Kidney Disease

BLOOD PRESSURE CONTROL IN CKD	MAINTAIN BLOOD PRESSURE <130/80 mm Hg OR <140/90 mm Hg FOR DIABETIC CKD
Reduce proteinuria by administering ACEIs or ARBs	Decrease urine protein excretion as low as possible, at least to <1 g/day
Control phosphate concentration with phosphate binders, using non-calcium-containing binders when possible	Maintain serum phosphate toward the normal range in CKD
Maintain vitamin D level by administration of vitamin D analogues	Maintain 1,25(OH)2D <sub>3</sub> levels at 30 ng/mL by administration of cholecalciferol (D <sub>3</sub> ) or ergocalciferol (D <sub>2</sub> )
Prevent hyperparathyroidism with vitamin D analogues or calcimimetics	Maintain parathyroid levels between 150 and 600
Correct anemia with erythropoiesis-stimulating agents and iron replacement as needed	Maintain hemoglobin between 10 and 11 mg/dL. Keep iron saturation (iron/TIBC) >20%
Administer diuretics to control hypertension and volume overload	Maintain euvolemia when possible
Control serum potassium with dietary restriction, diuretics, and/or potassium exchange resin as necessary	Maintain serum potassium <5.0 mEq/L
Prevent malnutrition with adequate calories and protein intake	Maintain protein intake between 0.6 and 1 g/kg in CKD and between 1 and 1.3 g/kg on dialysis
Control metabolic acidosis with administration of sodium bicarbonate or sodium citrate	Maintain serum bicarbonate >22 mEq/L but <26 mEq/L

1,25(OH)2D<sub>3</sub>, 1,25(OH)2-vitamin D<sub>3</sub>; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CKD, chronic kidney disease; TIBC, total iron-binding capacity.

disease. Among patients with diabetes and CKD, these guidelines recommended a blood pressure target <140/90 based largely on results from the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study. Lastly, there is a real opportunity to improve care because of gaps in awareness, treatment, and control of blood pressure among patients with CKD. Although blood pressure treatment has been shown to slow CKD progression, a substantial number of CKD patients have poor blood pressure control. Around 30% of CKD patients are not aware of their blood pressure. Of those who are aware, substantial portions are untreated. Few of those that are treated are controlled. Only one-fifth of patients with CKD stages 3 to 4 have awareness, treatment, and control of blood pressure.

**Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers**

ACEIs and ARBs are the preferred antihypertensive agents for the treatment of blood pressure among patients with CKD, particularly patients with albuminuria. Angiotensin II (Ang II) plays a key role in the progression of glomerulosclerosis, and there is a large amount of experimental data in both animals and humans that blocking Ang II mitigates progression. This is thought to be caused by a reduction in the glomerular capillary hypertension, reduction in proteinuria, and a diminution of the Ang II fibrosing effects. ACEIs and ARBs both are likely to delay progression of kidney disease and have cardiovascular benefits. Some studies have examined the possibility of using both together in treatment of CKD, with results suggesting more harm than benefit because of higher rates of hyperkalemia and acute kidney injury among patients receiving dual therapy. The ACEIs and ARBs substantially delay progression of kidney failure. There does not appear to be a point where ACEI/ARB medications should be discontinued unless there is a significant increase in creatinine after starting these medicines. When an ACEI or ARB causes an increase in creatinine >30%, the agent should be held to investigate potential renal artery stenosis or volume depletion.

**Dietary Protein Restriction**

The role of dietary protein restriction in renoprotective strategies for CKD patients remains controversial. KDIGO guidelines suggest daily restriction in protein intake to 0.8 g/kg for CKD patients, although a very-low-protein diet has been associated with increased mortality over the long term. One study showed a benefit with intake of nuts and other healthy protein foods in reducing the progression and mortality from CKD.

Although there were inconclusive results in the Modified Diet in Renal Disease (MDRD) study, the largest controlled clinical trial performed to investigate protein restriction in CKD, a benefit of moderate protein restriction was suggested by long-term follow-up analysis. Several prior and subsequent studies and meta-analyses appear to support the role of low protein in slowing CKD progression and delaying initiation of maintenance dialysis therapy.

Overall, most experts believe that despite the absence of observed benefit in the MDRD trial, systematic reviews suggest that protein restriction may be beneficial, and the balance of evidence suggests a benefit of moderate dietary protein restriction. Limiting protein intake is also associated with favorable laboratory and metabolic effects, including reduction of BUN levels, uremic toxins, and acid load, in addition to reduced phosphorus load with better control of metabolic bone disorders. Protein restriction may be particularly effective in diseases characterized by hyperfiltration, such as diabetes and certain glomerulopathies.

In patients with CKD, a balanced and individualized dietary approach based on a low-protein diet should be carefully monitored, with periodic follow-up for adequate caloric intake and surveillance to optimize protein malnutrition with body weight as well as serum albumin.

**Avoiding Nephrotoxic Medications**

Note that patients must avoid nephrotoxins and both prescription and over-the-counter medications can have deleterious kidney effects. The most concerning nephrotoxins are nonsteroidal antiinflammatory drugs, antacids, proton pump inhibitors, and a number of herbal medications (licorice, cat’s claw). Several prescription medications can be deleterious to the kidney. Noteworthy are the calcineurin inhibitors such as cyclosporine (Sandimmune) and tacrolimus (Prograf), which cause progressive renal insufficiency. We know this because solid-organ transplants have a high rate of kidney failure. Other medications such as aminoglycosides and amphotericin (Fungizone) or the use of intravenous contrast have detrimental effects on the hospitalized patient.

**Clinical Manifestations of Kidney Failure**

P.A. Pirry coined the word *urémie* in 1847 to indicate problems caused by “contaminating the blood with urine.” The basic abnormality is the presence of waste products that are not being eliminated by the kidney. In current use, the term *uremia* reflects a clinical syndrome associated with loss of kidney function. Uremic symptoms in advanced CKD result both from kidney excretory failure (e.g., retention of urea, certain hormones, polyamines, trace elements, serum proteases, so-called “middle molecules,” pyridine derivatives, B<sub>2</sub>-microglobulin) and from the loss of metabolic and endocrine functions normally performed by the kidney. Uremia is thought to be in part caused by protein intake because a low-protein diet mitigates some of the symptoms. Although we know that some of the uremic toxins are partially dialyzable, the exact etiology of uremia remains unknown.

**TABLE 4** Signs and Symptoms of Kidney Failure

CARDIOVASCULAR COMPLICATIONS	ENDOCRINE DISORDERS
Hypertension	Secondary hyperparathyroidism
Ischemic cardiac disease	Glucose intolerance (uremic diabetes)
Pericardial disease	Hyperlipidemia
Congestive heart failure	Sexual dysfunction/infertility
HEMATOLOGIC ABNORMALITIES	IMMUNOLOGIC DEFECTS
Anemia	Lymphocytopenia, leukopenia
Bleeding tendency	Decreased antibody responses
	Decreased cell-mediated response
	Increased susceptibility to infection
NEUROPSYCHIATRIC ABNORMALITIES	DERMATOLOGIC ABNORMALITIES
Peripheral neuropathy	Pruritus, uremic pigmentation,
Central nervous system disturbances	uremic frost, calciphylaxis, nail changes
Seizures	
Sleep disorders	
MUSCULOSKELETAL ABNORMALITIES	GASTROINTESTINAL ABNORMALITIES
Bone disease	Anorexia, nausea, vomiting
Myopathies	Upper tract disease: gastritis, duodenitis
Carpal tunnel syndrome	

Uremia also relates a loss of metabolic and endocrine functions normally performed by the intact kidney. Hence, kidney failure is a multisystem disorder (Table 4). The measurement of kidney function can be variable, and this degree of variability makes it difficult to use as the only factor in clinical decision making. Therefore as CKD progresses, clinicians tend to regularly assess the subjective symptoms associated with uremia. In particular, uremia has been described in the following systems: neurologic (sleep, memory), gastrointestinal (appetite, nausea, dysgeusia), and dermatologic (itching). If the severity of these symptoms cannot be managed by symptomatic therapy, this would be an indication for starting dialysis. Furthermore, if a dialysis patient has these symptoms, it may reflect inadequate treatment, and the dialysis dose will need to be increased. Of note, the usual physical signs of kidney failure can be rapidly assessed during an examination: blood pressure, pericardial rub, edema, and crackles on lung examination.

### Measures Designed to Treat Comorbidity in Kidney Disease Anemia

Anemia (Table 5) may be managed in patients with CKD by first ruling out other causes of anemia such as gastrointestinal bleeding and iron deficiency. Iron deficiency is common in patients with CKD and may be evaluated with a total iron saturation (TSAT) and ferritin. Low ferritin (<100 ng/mL) and TSAT (<20%) in patients with moderate to advanced CKD indicate an absolute iron deficiency. Iron deficiency may be treated using the oral or intravenous route. After iron stores are restored, if the anemia persists and other causes are ruled out, then an erythropoiesis-stimulating agent (ESA) such as erythropoietin (Procrit, Epogen) may be used. For CKD patients, the use of ESAs has been shown to reduce the need for blood transfusions and modestly improve quality of life. The risks associated with ESA use include an increase in cardiovascular events, hypertension, and cancer progression. For CKD patients, the recommendations are to initiate therapy if Hgb is <10 g/dL with an individualized decision for a target based on risks and benefits. In many cases, providers target a hemoglobin between 10 and 11 mg/dL and avoid exceeding levels >12 mg/dL.

### Metabolic Acidosis

Metabolic acidosis develops in CKD when the eGFR decreases below 30 mL/min. Recent studies have linked metabolic acidosis in CKD to protein wasting, loss of bone, and sympathetic activation. Observational studies have also linked metabolic acidosis to a higher rate of CKD progression and increased risk of death. There are a large number of ongoing studies testing whether oral sodium bicarbonate supplementation in CKD preserves renal function, and bicarbonate supplementation has been widely adopted for metabolic acidosis in CKD. A standard dose used

in clinical trials for CKD patients has been sodium bicarbonate 0.5–1 mEq/kg/day. The supplemental bicarbonate may be titrated up or down depending on serum bicarbonate and symptoms. If bicarbonate is not tolerated by patients, then clinicians could try Shohl's solution (citric acid/sodium citrate), as citrate is converted to bicarbonate by the liver. Currently, a reasonable target serum bicarbonate for patients with moderate to advanced CKD would be >22mEq/L and <26mEq/L.

### Divalent Ion Metabolism

CKD is associated with abnormalities of divalent ions (Ca<sup>++</sup>, P) and of the hormones that regulate the concentration of these minerals in body fluids. The dysregulation of these divalent ions has also attracted attention as a possible source of CVD because individuals with CKD are found to have calcium deposition and a calcification of heart valves. Lastly, failed management of divalent ions may lead to calcific uremic arteriolopathy or to calciphylaxis. Calciphylaxis is a rare syndrome characterized by the development of painful nodules in the soft tissue that indurate and ulcerate. This disorder has no uniformly effective treatment and has a high mortality rate. Serum phosphorus is controlled by administration of phosphate binders, usually starting with calcium citrate (Citracal)<sup>1</sup> or acetate (PhosLo). If these are not successful or if patients have elevated serum calcium levels, then sevelamer (Renagel) or lanthanum (Fosrenol) can be used alone or in combination with calcium binders. Physicians should aim to maintain serum phosphorus levels between 2.7 and 4.6 mg/dL in CKD stages 3 and 4 and between 3.5 and 5.5 mg/dL in CKD stage 5. Defining the target PTH level in the setting of CKD remains a challenge because of end-organ resistance to PTH. PTH levels should be maintained between 150 and 600 pg/mL (2 to 9 × normal) in patients with ESRD and those on dialysis. Suppression of PTH secretion can be achieved by administration of various vitamin D analogues in combination with calcimimetic agents such as cinacalcet (Sensipar) and etelcalcetide (Parsabiv). Serum calcium levels should be monitored closely. Low 1,25(OH)<sub>2</sub>-vitamin D<sub>3</sub> [1,25(OH)<sub>2</sub>D<sub>3</sub>] levels have been documented in many individuals both with and without renal failure. In patients with renal impairment, this can contribute to the abnormal 1,25(OH)<sub>2</sub>D<sub>3</sub> levels. Measurement of 1,25(OH)<sub>2</sub>D<sub>3</sub> levels should be obtained in all patients with CKD and estimated GFR less than 60 mL/min/1.73 m<sup>2</sup>. If levels are below 30 ng/mL, ergocalciferol (D<sub>2</sub>) or cholecalciferol (D<sub>3</sub>) should be given at sufficient doses to maintain it above this level.

### Hyperkalemia

The clinical consequence of hyperkalemia includes cardiac toxicity, muscle weakness, and death. The target potassium concentration for patients with CKD should remain in the normal range, and patients should be monitored during treatment with ACEIs or ARBs. Management of high serum potassium in patients with CKD should include a low-potassium diet. If there is a sudden increase, it may be caused by the use of salt substitutes, large amounts of juice, or eating high-potassium foods. It may be helpful to obtain a nutrition consult to help the patient maintain a low-potassium diet and have a nutritionist be aware of differences in diverse foods because both noni and coconut juice are high in potassium. In addition, it is recommended to review medications for those associated with hyperkalemia and consider decreasing the dose of the ACEI or ARB. Diuretics also may be used to decrease serum potassium levels in CKD, with loop diuretics the most widely used for patients with an eGFR <30 mL/min. Lastly, potassium-binding agents may be used to control serum potassium levels in patients with advanced CKD. The potassium exchange resin, sodium polystyrene sulfonate (Kayexalate), or one of the newer exchange resins, patiromer (Veltassa) or sodium-zirconium cyclosilicate (Lokelma), will decrease serum potassium levels.

**TABLE 5** Factors to Consider in the Management of Patients with Chronic Kidney Disease

#### Contributors to the Loss of Kidney Function

- Hypertension
- Diabetes mellitus
- Dietary salt intake
- Proteinuria
- Metabolic acidosis

#### Complications of Chronic Kidney Disease

- Anemia
- Platelet dysfunction
- Abnormal bone and mineral metabolism (e.g., secondary hyperparathyroidism)
- Lipid abnormalities (elevated cholesterol and triglycerides)
- Metabolic acidosis
- Volume overload
- Electrolyte disturbances (e.g., hyperkalemia)
- Cardiovascular disease

<sup>1</sup>Not FDA approved for this indication.

### Volume Overload

Sodium retention contributes to hypertension and edema among patients with CKD. To adequately address volume overload, both the intake and sodium excretion may need to be addressed in patients with CKD. Patients should adhere to a low-sodium diet, which is often complicated by other dietary restrictions (low-potassium, low-phosphate, American Diabetes Association diet). Given the complexity of diet in CKD, use of a nutritionist with expertise in kidney-related diets can help both volume overload and the other complications of CKD. In addition to sodium restriction, patients may need to use a diuretic for blood pressure and volume management. In the setting of an eGFR <30 mL/min, loop diuretics are often used to address volume overload. The loop diuretics such as furosemide (Lasix) should be dosed frequently enough to maintain a negative sodium balance. If the loop diuretic at higher doses is not adequately addressing volume overload, then an additional distal tubule diuretic such as metolazone (Zaroxolyn) may be used to increase urinary sodium excretion. It should be noted that increasing sodium excretion may cause acute kidney injury in CKD patients, particularly in the setting of ACEIs/ARBs and other diuretics. In this case, patients will often respond to reducing the diuretic dose with close monitoring.

### Chronic Kidney Disease–Mineral Bone Disorder

Chronic kidney disease–mineral bone disorder (CKD-MBD) is a systemic disorder of mineral and bone metabolism. CKD-MBD is associated with CKD and results from hyperphosphatemia caused by diminished kidney phosphorus excretion and hypocalcemia caused by impaired kidney production of active 1,25(OH)<sub>2</sub>D<sub>3</sub>, which leads to secondary hyperparathyroidism. Elevations in serum fibroblast growth factor 23 (FGF23), metabolic bone disease, soft tissue calcifications, and other metabolic derangements are associated with morbidity and mortality in CKD. The management of CKD-MBD is complex because of the influence of the homeostatic system and the availability of multiple treatment options without definitive randomized trials. The ideal strategy should be normalizing serum calcium, phosphate, PTH, and metabolic acidosis while minimizing the risks associated with the therapies. The various treatment options for hyperphosphatemia and secondary hyperparathyroidism include dietary phosphorus restriction, phosphate binders, calcitriol (Rocaltrol) or other active vitamin D analogues, calcimimetic agents, adequate hemodialysis, and parathyroidectomy. The optimal PTH level in the setting of CKD remains a challenge and has not been prospectively determined. KDIGO guidelines recommend that PTH be kept between two to nine times the upper limit of normal for the assay.

### Cardiovascular Disease

Although >10 million American adults are estimated to have a GFR <60 mL/min (i.e., CKD 3 or worse), far fewer are on dialysis or have received a transplant. Why is there a disparity between the number receiving renal replacement therapies and the number with CKD? Most patients with CKD die from CVD before requiring dialysis or transplantation. On dialysis, the risk of death from CVD remains 10 to 100 times higher than in the general population. A 25-year-old male patient on hemodialysis has approximately the same risk of dying from heart disease as an 80-year-old patient without CKD. Traditional risk factors account for only a portion of the CVD risk associated with CKD. Traditional risk factors include age, diabetes, lipids, hypertension, and smoking, among others. Many nontraditional risk factors are believed to play a role in increasing CVD risk in patients with CKD. Some of these risk factors are anemia, volume overload, hyperparathyroidism, calcium/phosphate disturbances, uremia, and malnutrition/inflammation often associated with CKD. The exact role these nontraditional risk factors play is an actively researched area. In general, one should consider patients with CKD high-risk patients for CVD, and CKD is considered by some

to be a coronary equivalent. Data indicate that patients with a lower GFR (<45 mL/min) and microalbuminuria/proteinuria carry a very high CVD risk (approximately equivalent to a prior history of coronary disease). This is important when assessing a patient in the emergency department for chest pain or evaluating a patient preoperatively for surgery, and so on. Treatment focuses on optimizing management of known CVD risk factors and being alert for harbingers of active CVD. Those caring for CKD patients must address CVD risk management. Primary prevention focuses on blood pressure, exercise, +/- aspirin, +/- statins. The data available for cardiovascular risk management are limited in part because of the exclusion of patients with significant CKD in many large studies. Hence the utility of aspirin and statins (if any) in this setting is not well established. CKD patients often present with atypical symptoms of CVD; therefore a high index of suspicion is important.

### The Effect of Sodium-Glucose Cotransporter-2 Inhibitors on Chronic Kidney Disease

Novel oral hypoglycemic agents such as sodium-glucose cotransporter-2 (SGLT-2) inhibitors have expanded pharmacotherapeutic options for the treatment of type 2 diabetes mellitus (DM). SGLT-2 receptor expression is limited to the renal proximal tubule. These receptors reabsorb filtered urinary glucose, contributing to hyperglycemia. SGLT-2 inhibitors lower serum glucose by preventing renal reuptake of glucose, producing an osmotic diuresis, thus lowering blood glucose. The hypoglycemic effects of urinary glucose enrichment depend on renal function and thus are limited in those with advanced CKD with an eGFR below 30 mL/min/m<sup>2</sup>. SGLT-2 inhibitors include canagliflozin (Invokana), empagliflozin (Jardiance), and dapagliflozin (Farxiga), among many. These agents have pleiotropic effects such as protective cardiovascular and renal benefits in addition to their hypoglycemic effects. Studies of SGLT-2 inhibitors including CREDENCE, EMPA-REG, and CANVAS have shown cardiovascular benefits of these agents, leading to their preference as second-line medications for the treatment of type 2 diabetes mellitus in those with established CVD. The renal protective benefits as seen with canagliflozin include reduction in loss of renal function as well as reduction in albuminuria, both important in the treatment of diabetic nephropathy. These agents are thought to prevent hyperfiltration observed in diabetic nephropathy. In addition, blood pressure lowering was also observed with SGLT-2 inhibitor treatment with the mechanism ascribed to osmotic diuresis. Whether all SGLT-2 inhibitors confer renal protective effects remains to be seen. A small reduction in GFR can occur after starting an SGLT-2 inhibitor. This is common and should be followed. It is not a reason to discontinue the drug. For now, these novel medications are welcome additions to the classic renin-angiotensin-aldosterone blockers commonly used to treat and slow the progression of diabetic nephropathy.

## MALIGNANT TUMORS OF THE UROGENITAL TRACT

Method of

Danica May, MD; and Moben Mirza, MD

### CURRENT DIAGNOSIS

#### Prostate cancer

- Prostate cancer is the most common cancer diagnosis for men in the United States.
- Screening with prostate-specific antigen (PSA) and digital rectal exam (DRE) should be offered starting at age 55 and ending at age 70 for the average risk patient. For higher risk patients (African American patients or strong family history of prostate cancer), screening should be discussed starting at age 40.
- Prostate cancer risk factors include African ancestry, family history, as well as Lynch syndrome and other genetic mutations.
- Transrectal ultrasound (TRUS)-guided biopsy is the diagnostic test for prostate cancer and may be indicated for patients with elevated PSA or abnormal DRE.
- Staging involves cross-sectional abdominal and pelvic imaging as well as bone scan for patients with high risk cancer.

#### Benign and malignant renal tumors

- Most patients with renal cell carcinoma (RCC) are diagnosed incidentally on imaging work-up for other symptoms or complaints. The classic triad of a palpable mass, hematuria, and flank pain is a relatively rare presentation.

- Risk factors for RCC are smoking, obesity, hypertension, and genetic syndromes such as von Hippel-Lindau disease, Birt-Hogg-Dube syndrome, and tuberous sclerosis complex.
- Most malignant renal masses are renal cell carcinoma, but lymphoma, metastases from other malignancies, and other renal malignancies should be considered in the differential as treatment options will vary.
- Benign masses include oncocytoma, angiomyolipoma (AML), renal cysts, and adenomas among others.
- Staging of renal masses involves abdominal imaging with CT scan or MRI. Chest imaging should be obtained. Laboratory analysis should include a CBC, CMP, and urinalysis. CT-guided core renal mass biopsy may be obtained after urologic consultation.

#### Urothelial cell carcinoma

- Urothelial cell carcinoma can affect the renal pelvis, ureter, bladder, or urethra, though most cases occur in the bladder.
- The average patient is older than age 60 and may have significant medical comorbidities.
- Risk factors include smoking, radiation, certain chemical exposures, and Lynch syndrome.
- Microscopic or gross hematuria is the most common presentation. Patients may also present with urgency, frequency, dysuria, flank pain, or have hydronephrosis discovered on imaging.
- Work-up involves a CT urogram for patients with adequate renal function and cystoscopy.
- Tumors discovered in the bladder should be resected endoscopically for diagnosis and staging. Tumors in the renal pelvis or ureters can be biopsied ureteroscopically.

#### Primary carcinoma of the prostate and urethra

- Primary urethral malignancies typically consist of urethral or squamous cell carcinoma.
- Patients often present with hematuria, and overall survival remains poor.
- Studies are lacking on this rare disease state, but treatment depends on stage, disease location, and histology.

#### Penile cancer

- Penile cancer is a rare malignancy with poor prognosis for men with advanced stage disease.
- Presentation often involves an ulceration or palpable mass, and biopsy is the key to diagnosis.
- The vast majority of penile lesions are squamous cell carcinomas.
- Risk factors for penile cancer involve chronic inflammation, tobacco use, lack of neonatal circumcision, STDs, HPV infection specifically with subtypes 6, 16, and 18, and phimosis.
- Staging scans involve chest, abdomen, and pelvis imaging with attention paid to the inguinal lymph nodes.

#### Testicular cancer

- Testicular cancer is diagnosed in men with a median age of 33 years and has excellent outcomes at 5 years.
- Risk factors for testicular cancer include undescended testis and a personal or family history of testicular cancer.
- The majority of testicular cancers are germ cell tumors, which include seminoma and non-seminoma.
- Germ cell tumors can also present in extra-testicular locations such as the retroperitoneum or mediastinum.
- Men with a testicular mass should undergo an ultrasound and intratesticular masses that are concerning for malignancy should be removed via radical orchiectomy. Sperm banking should be offered.
- Serum tumor markers include beta-hCG, AFP, and LDH. Staging, pathology, and tumor markers dictate next management steps.

## CURRENT THERAPY

### Prostate cancer

- Treatment options depend on PSA, Gleason grade, clinical stage, and the patient's overall health and life expectancy. Men with limited life expectancy may be good candidates for watchful waiting. Active surveillance is an option for men with low-risk and some men with favorable intermediate risk prostate cancer.
- Treatment options for clinically localized prostate cancer include radical (typically robotic) prostatectomy and radiation therapy in the form of external beam or brachytherapy with or without androgen deprivation therapy.
- The cornerstone of treatment for men with nodal or metastatic disease involves androgen deprivation therapy.
- Other treatment options include chemotherapy, immunotherapy, or newer secondary hormone therapies.
- Following definitive therapy, follow up for men treated for prostate cancer involves regular PSA monitoring every few months for 5 years and then yearly after that.

### Benign and malignant renal tumors

- Surgery remains a mainstay of treatment for localized renal cell carcinoma. Partial or radical nephrectomy can be performed taking into consideration the clinical stage, tumor location, patient's overall health, renal function, presence or absence of a contralateral kidney, and genetic syndromes predisposing the patient to future malignancies.
- Ablative therapy and active surveillance are options for small renal masses.
- Simple renal cysts do not require treatment. Complex or enhancing cysts should be treated based on their risk of malignancy.
- Follow up for patients treated for renal cell carcinoma involves periodic laboratory analysis as well as cross-sectional abdominal and chest imaging.
- Systemic therapy options for patients with metastatic renal cell carcinoma have increased drastically with the newest treatments including immune checkpoint inhibitors.
- The treatment of angiomyolipomas (AMLs) is often based on size and is directed toward prevention of the complication of retroperitoneal hemorrhage. Embolization or surgical removal has traditionally been proposed at a 4-cm size, although larger AMLs can be safely observed.

### Urothelial cell carcinoma

- Treatment options depend on stage, grade, and tumor location.
- Superficial low-grade bladder tumors can be managed with resection and periodic surveillance cystoscopy.
- Patients with superficial high-grade cancer or cancers invasive into the lamina propria (T1) diagnosed on initial resection may be offered a repeat resection. Treatment following this often involves induction and maintenance intravesical Bacillus Calmette-Guérin (BCG) therapy. Patients with high-grade T1 bladder cancer should be counseled and offered radical cystectomy. These patients should have periodic cystoscopy and upper tract imaging as indicated.
- The standard of care for patients with muscle invasive (T2) bladder cancer is cisplatin-based neoadjuvant chemotherapy followed by radical cystectomy. Patients ineligible for cisplatin-based chemotherapy should undergo immediate radical cystectomy.
- For patients who are unwilling or unfit for radical cystectomy, chemoradiation therapy can be offered.
- Upper tract tumors of the renal pelvis or ureter are managed by grade as well as clinical stage. The pathologic stage may not be accurately established prior to definitive treatment.

- Nephroureterectomy should be offered for patients with upper tract urothelial cell carcinoma. Other options can include endoscopic management with tumor ablation or partial resection of the ureter if tumor location is amenable. Cisplatin-based neoadjuvant or adjuvant chemotherapy should be considered.

### Primary urothelial carcinoma of the prostate and urethra

- Superficial urothelial tumors (Tis, Ta, T1) of the urethra can be resected or biopsied followed by intravesical BCG therapy.
- The surgical treatment for men with T2 proximal urethral cancer involves removal of the bladder and prostate with urethrectomy. More distal disease involving the pendulous urethra can be managed with a distal urethrectomy or partial penectomy.
- Women are often treated with cystectomy and urethrectomy.
- Patients with higher stage urethral cancer may be offered neoadjuvant or adjuvant chemotherapy or radiation therapy.

### Penile cancer

- Organ sparing approaches include topical therapy, laser therapy, Mohs surgery, glansctomy, radiation therapy, or wide local excision and are most utilized in patients with superficial or properly selected penile cancer patient with T1 disease.
- More aggressive tumors should be treated with partial or total penectomy.
- Higher risk patients need to undergo inguinal node dissection and pelvic node dissection should be considered for highly selected patients.
- Neoadjuvant chemotherapy should be considered for bulky, bilateral, or fixed inguinal lymphadenopathy.

### Testicular cancer

- Following radical orchiectomy, imaging of the chest, abdomen, and pelvis is key for staging. Repeat tumor markers should also be collected as persistent tumor marker elevation after orchiectomy changes treatment.
- Patients with localized seminoma with normal tumor markers can undergo surveillance, chemotherapy, or radiation therapy.
- For patients with more advanced disease, treatment options should include chemotherapy or radiation therapy.
- In patients with pure seminoma and a residual retroperitoneal mass, further work-up with a PET/CT scan can aid in characterization of residual disease.
- Radiation therapy is not a standard treatment for men with non-seminoma testicular cancer.
- Patients with localized non-seminoma with normal tumor markers can undergo observation, chemotherapy, or retroperitoneal lymph node dissection (RPLND).
- For patients with more advanced disease, treatment options should include chemotherapy and/or surgical resection.
- Residual retroperitoneal masses in the patient treated for non-seminoma testicular cancer should be removed via RPLND.
- Follow up for all patients with testicular cancer includes surveillance with chest, abdominal, and pelvic imaging as well as periodic tumor markers.

## Prostate Cancer

### Background

Prostate cancer is the most common cancer diagnosis among men in the United States. It accounts for over 191,000 new cases in 2020 and is the third most common overall malignancy after breast and lung/bronchus cancers. It is a relatively indolent cancer with 97.8% 5-year relative survival. Family history of prostate cancer, particularly among first-degree relatives, is a well-known risk factor for developing prostate cancer. Known genetic alterations include both germline as well as somatic mutations. Common mutations include

BRCA1/2, ATM, MLH1, MSH2, MSH6, and PMS2, among many others. Syndromes linked to prostate cancer include Lynch syndrome and hereditary breast and ovarian cancer (HBOC) syndrome. Other risk factors for development of prostate cancer include increasing age, African American ancestry, smoking, and Ashkenazi Jewish heritage.

### Diagnosis

Prostate cancer is most often diagnosed in a localized and asymptomatic state via screening. Rarely, prostate cancer is detected at a locally advanced state with symptoms of pelvic pain, urinary retention, or ureteral obstruction with hydronephrosis. The minority of men are diagnosed in the metastatic state, with the most frequent complaint being bone pain from metastases. The utilization of prostate-specific antigen (PSA) blood testing has drastically changed the diagnosis of prostate cancer from a historically predominantly metastatic state to a localized and potentially curable state in the current era. In 2012, the US Preventive Services Task Force released a grade D recommendation against the use of PSA-based screening for any man. This recommendation was modified in 2018 to allow for informed decision making for prostate cancer screening in men aged 55 to 69. The American Urological Association recommends individualized prostate cancer screening for men aged 40 to 54 who are at higher risk, shared decision-making for men aged 55 to 69, and cessation of screening for men aged 70 or older or those men with life expectancy less than 10 to 15 years. Screening of prostate cancer with PSA should not be dismissed with the assumption that prostate cancer is an indolent cancer. Screening can lead to diagnosis and appropriate risk stratification.

The basis of prostate cancer screening is serum PSA as well as digital rectal exam (DRE). While PSA is only produced by the prostate, it is not specific to malignant versus benign cells, and there are a variety of causes of elevated PSA. Benign causes of elevated PSA include benign prostate hypertrophy, prostatitis, instrumentation of the urethra such as catheterization or utilization of cystoscopy, and urinary tract infections. One of the difficulties of PSA utilization is that there is no cutoff normal level. In fact, 6.6% of men with a PSA of 0.5 ng/mL or less were found to have prostate cancer with rates increasing to 26.9% in men with PSA of 3.1 to 4.0 ng/mL. In general, PSA increases with age. Some men may have an abnormal DRE, which can prompt further work-up. Worrisome findings including induration or nodules palpable within the prostate.

Following screening with PSA and DRE, further work-up includes a prostate biopsy. The vast majority of prostate biopsies are performed with transrectal ultrasound (TRUS) to help with volumetric and anatomical surveys. The majority of prostate cancer is detected in the peripheral zone, so the standard 12-core biopsy template targets this area in a systematic fashion. Prostatic volume as well as anatomy such as large intravesical lobes should be noted as this information can be helpful in surgical planning.

Prostate MRI is an increasingly utilized tool in men with various clinical situations including elevated PSA with a prior negative biopsy, performance of active surveillance (AS; further discussed below), staging, and surgical planning, as well as in men whose pathology appears discordant with their rectal examination or PSA level. Multiparametric MRI gives not only detailed anatomic information, but also functional assessment of various tumor regions. This information can then be used for an MRI-guided biopsy or more commonly fusion biopsy via platforms that fuse concerning MRI findings with real-time TRUS biopsy for improved lesion targeting.

The vast majority of prostate cancers are adenocarcinomas. Prostate biopsy pathology is based on Gleason grading system 1 to 5, with 5 reflecting poorly differentiated and most aggressive cells. The grading system is translated into a score that adds the most common and second most common grading pattern to yield a score between 2 and 10. Further classification into a Gleason group between 1 and 5 informs appropriate risk classification. In general, low-risk prostate cancer consists of Gleason 6 prostate cancer (Gleason group 1), while intermediate risk prostate

cancer consists of Gleason 7 prostate cancer (Gleason group 2 and 3). High-risk prostate cancer includes Gleason sums 8, 9, and 10 prostate cancer (Gleason groups 4 and 5). Risk groups also take into account clinical stage, PSA levels, and biopsy core positivity. TNM staging is used for prostate cancer. Prostate cancer diagnosed either surgically via a transurethral resection of the prostate or via TRUS biopsy is stage T1. T2 is organ-confined prostate cancer, while T3 is defined as extra-prostatic extension. Finally, T4 involves invasion of surrounding structures including the bladder, pelvic floor or sidewall, or rectum (Table 1). Grade, stage, and risk group are instrumental in treatment decisions.

Current recommendations include germline testing for patients with positive family history of prostate cancer; high-risk, regional, or metastatic prostate cancer; Ashkenazi Jewish ancestry; or intraductal histology. Various genetic alterations necessitate genetic counseling as well as change some treatment options. Staging imaging should be carried out for certain men diagnosed with prostate cancer. Current recommendations include pelvic imaging with or without abdominal imaging via CT or MRI as well as a radionuclide bone scan in men with unfavorable intermediate, high risk, and very high-risk disease.

### Treatment

Treatment decisions for men diagnosed with prostate cancer depend on a series of factors including risk group, staging, and clinical node status on imaging, as well as the patient's overall health and life expectancy. In patients with limited life expectancy, observation may be utilized. Observation of known prostate cancer involves monitoring the patient with eventual initiation of palliative androgen deprivation therapy (ADT) for symptomatic or imminently symptomatic disease. On the other hand, AS may be utilized for patients with very low risk or low risk disease, and the properly selected favorable intermediate risk disease patient with adequate life expectancy. AS involves periodic assessment of PSA, DRE, and surveillance biopsies. Prostate MRI may also be utilized in an AS algorithm. AS aims to allow for early disease reclassification with ability to perform definitive treatment at that point. Approximately two-thirds of men on AS will be able to avoid treatment and the associated side effects. Another effect of AS is less overtreatment of small, indolent prostate cancers.

The preferred treatment for very low risk and low risk prostate cancer patients with adequate life expectancy is AS. Other options in the properly selected patient population include external beam radiation therapy (EBRT) or brachytherapy, radical prostatectomy (RP), or observation. As previously mentioned, AS remains an option for patients diagnosed with favorable intermediate risk prostate cancer. This cohort of men may also be treated with EBRT or brachytherapy as well as RP. Treatment recommendations for men with unfavorable intermediate risk prostate cancer include RP, EBRT combined with ADT, or EBRT and brachytherapy boost with ADT. For men with high risk or very high risk prostate cancer, treatment recommendations include EBRT and ADT with or without docetaxel (Taxotere) chemotherapy, EBRT with brachytherapy and ADT, or RP. In men with regional lymphadenopathy, the cornerstone of treatment is ADT. This may be combined with EBRT or abiraterone (Zytiga).

Following definitive treatment, patients should be monitored with PSA and DRE every 3 to 6 months. Following RP, PSA should be undetectable as all prostate and prostate cancer tissue has theoretically been surgically removed. Men treated with EBRT or brachytherapy should have a decline in PSA to a low, steady level. In men with detectable or rising PSA after RP, repeat imaging including bone imaging, CT, MRI, C-11 choline, F-18 fluciclovine PET/CT, or PET/MRI may be utilized to assess for sites of disease recurrence. If no metastases are detected, observation or EBRT with or without ADT are treatment options. When metastases are detected, ADT combined with apalutamide (Erleada), docetaxel (Taxotere), abiraterone (Zytiga), enzalutamide (Xtandi), or EBRT to the primary tumor in the setting of low volume metastases are treatment options. Most men with metastatic prostate cancer initially have castration-naïve prostate

**TABLE 1** Risk Stratification and Staging Workup

NCCN RISK GROUP	CLINICAL/PATHOLOGIC FEATURES	IMAGING
Very low	T1c AND Gleason score $\leq 6$ /grade group 1 AND PSA $< 10$ ng/mL AND Fewer than 3 prostate biopsy fragments/cores positive, $\leq 50\%$ cancer in each fragment/core AND PSA density $< 0.15$ ng/mL/g	Not indicated
Low	T1–T2a AND Gleason score $\leq 6$ /grade group 1 AND PSA $< 10$ ng/mL	Not indicated
Favorable intermediate	T2b–T2c OR Gleason score $3 + 4 = 7$ /grade group 2 OR PSA 10–20 ng/mL AND Percentage of positive biopsy cores $< 50\%$	Bone imaging: not recommended for staging Pelvic $\pm$ abdominal imaging: recommended if nomogram predicts $> 10\%$ probability of pelvic lymph node involvement
Unfavorable intermediate	T2b–T2c OR Gleason score $3 + 4 = 7$ /grade group 2 or Gleason score $4 + 3 = 7$ /grade group 3 OR PSA 10–20 ng/mL	Bone imaging: recommended if T2 and PSA $> 10$ ng/mL Pelvic $\pm$ abdominal imaging: recommended if nomogram predicts $> 10\%$ probability of pelvic lymph node involvement
High	T3a OR Gleason score 8/grade group 4 or Gleason score $4 + 5 = 9$ /grade group 5 OR PSA $> 20$ ng/mL	Bone imaging: recommended Pelvic $\pm$ abdominal imaging: recommended if nomogram predicts $> 10\%$ probability of pelvic lymph node involvement
Very high	T3b–T4 OR Primary Gleason pattern 5 OR $> 4$ cores with Gleason score 8–10/grade group 4 or 5	Bone imaging: recommended Pelvic $\pm$ abdominal imaging: recommended if nomogram predicts $> 10\%$ probability of pelvic lymph node involvement

From Partin AW: *Campbell-Walsh-Wein Urology*, ed 12, Elsevier, 2021.

cancer and respond to medical or surgical (orchiectomy) castration. A rising PSA in the setting of castrate level testosterone indicates the advent of castration-resistant prostate cancer (CRPC), and ADT should be continued indefinitely. Once castration resistance has been identified, bone health should be prioritized with utilization of denosumab (Xgeva) or zoledronic acid (Zometa) in the setting of bone metastases. Therapy options include abiraterone (Zytiga), docetaxel (Taxotere), enzalutamide (Xtandi), sipuleucel-T (Provenge), radium Ra 223 dichloride (Xofigo) for symptomatic bone metastases, or mitoxantrone (Novantrone) for palliation in men who cannot tolerate other therapies. Painful bony metastases can be palliated with EBRT.

## Benign and Malignant Renal Tumors

### Background

Kidney and renal pelvis cancers account for 4.1% of all new cancer cases at more than 73,000 cases in the United States in 2020 leading to 14,830 deaths. The 5-year relative survival from 2010 to 2016 is approximately 75%. The majority of kidney masses are detected incidentally on cross-sectional imaging for other chief complaints, and the median age at diagnosis is 64 years. These tumors can be primary renal cell carcinoma (RCC), metastases from second primaries such as breast, lung, ovarian, or melanoma as well as lymphoma deposits, or benign renal tumors such as oncocytoma, angiomyolipoma (AML), renal cysts, leiomyoma, and adenomas. RCC subtypes include clear cell, chromophobe, papillary, collecting duct, translocation, and medullary carcinoma. The majority of tumors are clear cell RCC, which comprise 70% of RCC subtypes.

Hereditary syndromes predisposing patients to RCC include von Hippel-Lindau (VHL) disease, hereditary papillary renal carcinoma (HPRC), hereditary leiomyomatosis and renal cell carcinoma (HLRCC), tuberous sclerosis complex (TSC), and Birt-Hogg-Dube (BHD) syndrome, among others. Other risk factors include smoking, obesity, and hypertension.

### Diagnosis

Rarely patients with RCC present with a triad of symptoms including hematuria, a flank mass, and flank pain. More

commonly, patients are found to have a renal mass on imaging performed for other indications and the frequency of incidental detection has increased with widespread abdominal imaging. In the patient with a renal mass, laboratory analysis should include a CBC, CMP, and urinalysis. Cross-sectional abdominal imaging with CT or MRI with contrast should be obtained if not already performed. A chest x-ray is required to complete staging but chest CT, bone scan, brain MRI, and core-needle biopsy may also be obtained. Patients who present with multiple renal masses or young age ( $< 46$  years old) may be referred for genetic evaluation. Core-needle biopsy of renal masses may be indicated in patients with unclear etiology of their renal mass such as concern for an infiltrating mass like lymphoma, AS guidance, or in combination with ablation strategies.

TNM stage and histologic grade are important for prognosis and treatment guidance in the patient with RCC. Stage T1 tumors are tumors  $\leq 7$  cm in greatest dimension and are limited to the kidney. T2 tumors are greater than 7 cm but  $\leq 10$  cm and are limited to the kidney. T3 disease involves invasion into major veins including the renal vein or vena cava or invasion into perinephric tissue, while T4 disease is invasion beyond Gerota's fascia. Histologic grade is graded as G1 through G4 with increasing dedifferentiation.

Renal cysts are a very common benign finding and are graded via Bosniak classification with scores ranging from I to IV. Simple cysts are defined as thin-walled cysts without septa, calcifications, or solid component and lack enhancement. As the Bosniak score increases, so does the complexity and malignancy risk of the cyst with Bosniak IV cysts defined as cysts with enhancing soft tissue components and thick or irregular walls or septa. Oncocytomas are the most common benign, enhancing mass and are associated with BHD syndrome. They are often diagnosed on pathology as diagnosis via imaging characteristics can include hypervascularity with a central scar but are not definitive findings. AMLs are common manifestations in patients with TSC but are often easily diagnosed on CT or MRI due to the presence of macroscopic fat, which has negative Hounsfield units. While benign, AMLs are the leading cause of spontaneous retroperitoneal hemorrhage and intervention

is targeted toward prevention of this outcome. A cutoff size of 4 cm has been suggested, at which point treatment via surgery or embolization may be offered and discussed. Treatment should be tailored to patient circumstances. Patients with TSC and multiple or enlarging AMLs may be offered everolimus (Afinitor), an mTOR inhibitor for size reduction. While other benign renal lesions do occur, they are relatively rare and beyond the scope of this chapter.

### Treatment

Surgery remains a mainstay of treatment for localized RCC. Surgical options include removal of the whole kidney via radical nephrectomy or removal of the mass with preservation of the remaining healthy parenchyma via partial nephrectomy. In general, partial nephrectomy is the approach of choice for stage T1 tumors, especially if tumors are less than 4 cm with a favorable location within the kidney. Radical nephrectomy may be indicated based on tumor size, clinical stage, and anatomy but can be associated with decreased renal function. Concomitant lymph node dissection has not been shown to improve oncologic outcomes. The adrenal gland should be removed for large upper pole tumors or abnormal appearance on staging imaging. Other treatment options include AS or ablative techniques. AS is preferable for elderly patients with comorbidities and small renal masses or in patients who prefer to avoid intervention. Periodic imaging is performed with intervention for enlarging masses. Ablative techniques involve microwave, cryoablation, or thermal ablation and are again most utilized in small renal masses less than 3 cm. Advanced RCC can extend into the renal vein, vena cava, or even the right atrium. Depending on the level of tumor thrombus, cardiothoracic surgery may need to be involved with resection to allow for utilization of vascular bypass. Follow up for patients is dependent on stage but involves periodic laboratory analyses as well as chest and abdominal imaging.

Some patients who present with metastatic disease may ultimately undergo a cytoreductive nephrectomy with resection of the primary tumor followed by systemic therapy. In general, this is offered to patients with lung-only metastases, good performance status, and good prognostic features. Patients who do not fit these criteria should undergo a biopsy and be evaluated for systemic therapy. In addition, some patients with localized disease treated with a partial or radical nephrectomy will develop systemic disease and should also consider systemic therapy. Tumor histology determines treatment options with clear cell being the most common histology. Systemic therapy for RCC is rapidly evolving with a shift from the cytokine era to targeted therapies consisting of tyrosine kinase inhibitors (TKIs), mammalian target of rapamycin inhibitors (mTORs), and immune checkpoint inhibitors. Systemic therapy for favorable risk patients with clear cell histology includes axitinib (Inlyta) with pembrolizumab (Keytruda), pazopanib (Votrient), or sunitinib (Sutent), while poor or intermediate risk patients with clear cell histology should be offered ipilimumab (Yervoy) with nivolumab (Opdivo), axitinib (Inlyta) with pembrolizumab (Keytruda), or cabozantinib (Cabometyx). Patients with non-clear cell histology should be offered enrollment into a clinical trial or sunitinib (Sutent).

## Urothelial Cell Carcinoma

### Background

Urothelial cell carcinoma is a malignancy that can affect the renal pelvis, ureter, bladder, and urethra, although the majority of cases are bladder cancer. In 2020, in the United States an estimated 81,400 new cases of bladder cancer will be diagnosed with nearly 18,000 deaths. Urothelial cell cancer is a male predominant disease and affects the elderly with a median age of diagnosis of 73 with many patients having significant medical comorbidities. Modifiable risk factors include smoking, pelvic radiation, chemical exposure, obesity, and diabetes mellitus. Lynch syndrome is associated with upper tract urothelial cell carcinomas.

### Diagnosis

The most common presenting sign of urothelial cell carcinoma is microscopic or gross hematuria but can also include lower

urinary tract complaints, hydronephrosis on imaging, or flank pain. Work-up for hematuria involves upper tract imaging frequently with a CT urogram, a CT of the abdomen and pelvis with pre-contrast, post-contrast, and delayed images, as well as cystoscopy. If tumors are found in the bladder and cross-sectional imaging has not been performed, a CT or MRI of the abdomen and pelvis should be obtained. Next steps involve endoscopic resection of the tumors for pathological analysis and staging. Upper tract, which includes renal pelvis or ureteral tumors, may be visualized during ureteroscopy with biopsy allowing for differentiation of low versus high grade tumor cells as well as identification of location and volume of tumor for future treatment guidance. Chest imaging as well as laboratory tests complete staging.

Stage and grade are key to guide treatment decisions for patients with urothelial cell carcinoma with grade designated as low or high. TNM staging of bladder cancer is broken up into Ta, Tis, T1, T2, T3, and T4. Ta is noninvasive while Tis is urothelial carcinoma in situ. T1 involves invasion into lamina propria, T2 invades muscularis propria, T3 invades perivesical tissue, and T4 invades prostatic stroma, uterus, vagina, pelvic wall, abdominal wall, or seminal vesicles. TNM staging is similar for the renal pelvis and ureter with T3 defined as invasion into peripelvic fat, renal parenchyma, or periureteral fat and T4 defined as invasion into adjacent organs or through the kidney into perinephric fat.

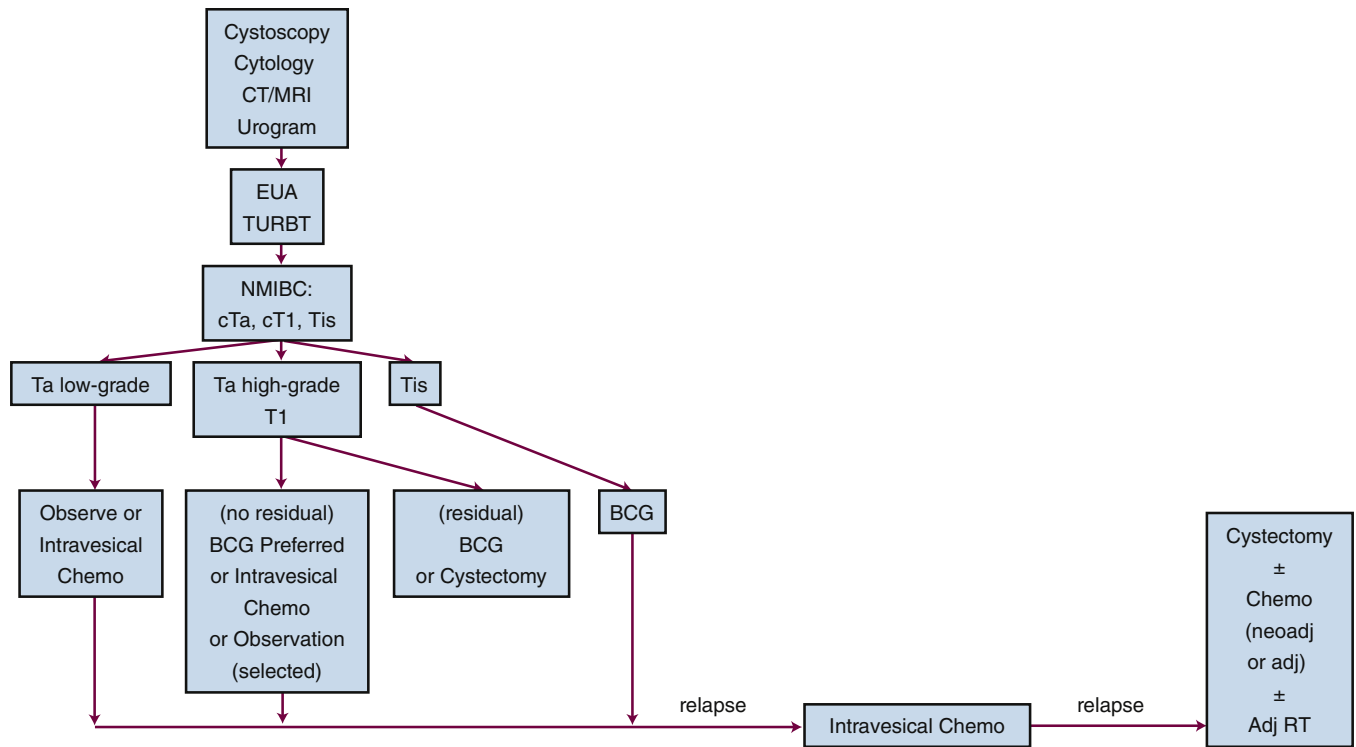

Most bladder, ureter, and renal pelvis tumors are urothelial cell carcinomas. Subtypes also known as variant histology include nested, microcystic, micropapillary, plasmacytoid, clear cell, sarcomatoid, squamous, and lymphoepithelioma-like. Distinct and more rare types of genitourinary tract malignancies of the urothelium include squamous cell, adenocarcinoma, and small cell carcinoma.

### Treatment

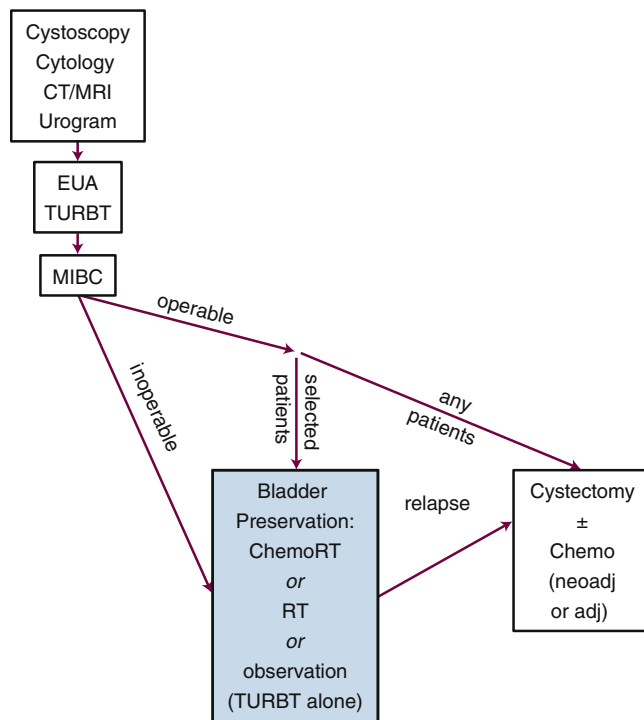

#### Bladder

Once bladder cancer has been diagnosed, appropriate pathologic and radiologic staging should be completed. Pathology determines need for repeat transurethral resection of bladder tumor (TURBT) with recommendations for second resection for Ta high-grade tumors and any T1 tumors. Patients with Ta low-grade tumors may be observed. For patients with high-grade T1 disease, a radical cystectomy should be offered. Patients with Tis, Ta high-grade, and T1 disease should be offered intravesical therapy usually with Bacillus Calmette-Guérin (TICE BCG) or BCG therapy (Figure 1). Treatment options for muscle invasive or T2 disease are quite different and the gold standard is platinum-based neoadjuvant chemotherapy followed by radical cystectomy (Figure 2). Prior to treatment for muscle invasive bladder cancer (MIBC), a CBC, CMP, and chest imaging should be obtained. A bone scan is indicated if concern for bony metastases exists. A radical cystectomy involves removal of the bladder, prostate, and seminal vesicles for men. A radical cystectomy in females involves removal of the bladder often with concomitant removal of the uterus, ovaries, anterior vagina, and urethra. A urinary diversion is then formed with the majority of patients receiving an ileal conduit with abdominal stoma. Continent diversions are also options. Cisplatin-based neoadjuvant chemotherapy with dose dense methotrexate<sup>1</sup>, vinblastine<sup>1</sup>, doxorubicin (Adriamycin), and cisplatin (ddMVAC) or gemcitabine (Gemzar)<sup>1</sup> with cisplatin (GC) are the current recommendations. If patients are unable to tolerate chemotherapy, immediate radical cystectomy should be performed. Adjuvant chemotherapy is recommended for adverse pathologic features including stage T3-T4 or node positive disease if not given in a neoadjuvant fashion. Finally, chemoradiotherapy with bladder preservation may be selected by some patients. Ideal candidates should not have hydronephrosis or extensive carcinoma in situ. Concurrent radiation therapy with radio sensitizing chemotherapy such as cisplatin and 5-FU (fluorouracil)<sup>1</sup> are administered. The patient's bladder should be reassessed after 2 to 3 months with surgical consolidation as a consideration for residual muscle invasive disease. In patients who

<sup>1</sup>Not FDA approved for this indication.

present with concern for nodal involvement or metastases, options include neoadjuvant therapy followed by consolidative cystectomy or systemic therapy alone. In the locally advanced or metastatic patient population who are cisplatin ineligible, gemcitabine (Gemzar)<sup>1</sup> with carboplatin (Paraplatin)<sup>1</sup>, atezolizumab (Tecentriq)<sup>1</sup>, or pembrolizumab (Keytruda)<sup>1</sup> are the preferred regimens.

**Upper Tract Urothelial Cell Carcinoma**

The treatment of upper tract urothelial cell carcinoma follows the same basic principles as treatment of bladder cancer. As previously mentioned, ureteroscopy with biopsy of tumor allows for grade determination though is much less likely to accurately diagnose stage due to the limited ability to obtain specimens via a ureteroscope. The gold standard for nonmetastatic upper tract disease involves a radical nephroureterectomy with bladder cuff removal. Platinum-based neoadjuvant chemotherapy should be considered for patients with lymphadenopathy, large high-grade tumors, sessile tumors, or concern for parenchymal invasion. For some small, papillary, unifocal, low-grade tumors, management may involve endoscopic management with laser ablation of tumor and periodic surveillance ureteroscopy or cross-sectional imaging. Distal ureteral tumors can at times be managed with a distal ureterectomy with ureteral reimplant.

**Primary Carcinoma of the Prostate and Urethra**

**Background**

Primary carcinoma of the prostate or urethra is quite rare. Prostatic urethral histology is most often urothelial in origin while the remaining urethral primary malignancies are predominantly squamous cell carcinoma. Overall survival is relatively poor at 42% at 5 years. Due to the low incidence, a lack of data and studies of ideal management for these patients are lacking. Stage, disease location, histology, and tumor size remain important prognostic factors.

## Diagnosis

Initial work-up involves DRE in men with cystoscopy and transurethral or transvaginal resection or biopsy of the tumor. Cross-sectional imaging with MRI or CT of the pelvis assists with tumor staging as well as assesses for concomitant lymphadenopathy, while chest imaging assesses for metastases.

## Treatment

As with urothelial malignancies of the bladder, Tis, Ta, or T1 urothelial cell carcinoma of the male prostate or urethra and female urethra should be followed by a repeat resection and subsequent BCG treatment<sup>1</sup>. In men, proximal urethral disease (prostatic or bulbar urethra) stage T2 or higher is ideally managed with a urethrectomy with cystoprostatectomy. T2 urothelial disease of the pendulous urethra can be managed with a distal urethrectomy or partial penectomy. Adverse pathology or positive margins may be further managed with chemotherapy or chemoradiotherapy. In women, T2 urethral urothelial malignancies should be managed with chemoradiotherapy, urethrectomy with cystectomy, or distal urethrectomy if tumor location is amenable. In more advanced disease stages including T3–T4 or palpable inguinal lymphadenopathy, systemic therapy with or without concomitant radiation followed by consolidative surgery are guideline recommendations.

## Penile Cancer

### Background

Penile cancer remains a rare disease in North America and Europe, with approximately 2200 cases diagnosed and 440 deaths in 2020 in the United States. It remains a highly lethal disease if not caught at a very early stage. Once disease has spread to pelvic lymph nodes, 5-year survival rates are 0%. As with prostate and bladder malignancies, increasing age is a risk factor for penile cancer with a median age of diagnosis of 68 years in the United States. Other risk factors include phimosis, which also limits examination and early detection as well as tobacco use, chronic inflammation, balanitis, lichen sclerosis, poor hygiene, STDs (specifically HIV and HPV), and lack of neonatal circumcision. Key HPV types include 6, 16, and 18. Histology of penile cancer is overwhelmingly squamous cell carcinoma with subtypes including verrucous, papillary squamous, warty, and basaloid. Verrucous histology carries the most favorable prognosis with more aggressive variants including sarcomatoid and adenosquamous. Tumor grade is designated as grade 1 to 4 with 1 being well differentiated and grade 4 being poorly or undifferentiated.

### Diagnosis

A careful physical examination is key for men who present with penile lesions, while care should be taken to observe lesion characteristics including location, size, and consistency, as well as perform an inguinal lymph node examination to assess for lymphadenopathy. Staging utilizes the TNM staging system with Tis defined as carcinoma in situ, Ta as non-invasive squamous cell carcinoma, T1 as superficial invasion substratified based on lymphovascular/perineural invasion and high versus low grade, T2 with corpus spongiosum or urethral invasion, T3 with corpora cavernosa invasion, and T4 as invasion into surrounding structures such as the bony pelvis, prostate, or scrotum. Tissue should be obtained for pathologic analysis. MRI or ultrasound can assess with anatomic characterization of the tumor.

### Treatment

Organ sparing approaches for management of penile cancer include topical therapy, laser therapy, Mohs surgery, glanslectomy, and wide local excision. Topical therapies include imiquimod (Aldara)<sup>1</sup> and 5-FU (Efudex)<sup>1</sup>. Organ sparing approaches can be primary treatment options for patients with Tis, Ta or the properly selected patient with

T1 penile cancer. Low-grade T1 tumors can also be treated with radiation therapy. If location or size preclude less aggressive therapies, partial penectomy may be necessary. Higher-grade T1 tumors often necessitate partial or total penectomy with intraoperative frozen sections to ensure negative margins. T2 tumors or greater should be treated aggressively with partial or total penectomy, although radiotherapy or chemoradiotherapy are also options. Patients with low risk pathology, Tis-T1a penile cancer, should undergo inguinal lymph node surveillance while higher risk pathology, T1b or greater penile cancer, necessitates cross-sectional imaging of the chest, abdomen, and pelvis with inguinal lymph node dissection or dynamic sentinel node biopsy. In low risk patients with palpable lymphadenopathy, biopsy should be performed with node dissection performed for positive nodes with or without neoadjuvant chemotherapy. For palpable inguinal lymphadenopathy larger than 4 cm, fixed lymph nodes smaller than 4 cm, or bilateral lymphadenopathy, patients should receive neoadjuvant chemotherapy if medically suitable followed by inguinal lymphadenectomy with or without pelvic lymphadenectomy. Other treatment options include radiation therapy or chemoradiotherapy. Adjuvant chemotherapy should be offered for patients with multiple positive nodes or extranodal extension. Finally, adjuvant radiation therapy should be offered to the patient with positive pelvic nodes. For patients who present with metastases, systemic chemotherapy, radiation therapy, or chemoradiotherapy are options. The preferred chemotherapy regimen is TIP with paclitaxel (Taxol)<sup>1</sup>, ifosfamide (Ifex)<sup>1</sup>, and cisplatin (Platinol)<sup>1</sup>. Patients with recurrence should be referred for a clinical trial or treatment with pembrolizumab (Keytruda)<sup>1</sup>.

## Testicular Cancer

### Background

Testicular cancer is predominantly a disease of younger men with median age at diagnosis of 33 years of age. An estimated 9,610 new cases will be detected in 2020 with 440 deaths. Testicular cancer has a high 5-year survival rate of 95%. Risk factors include a family history of testicular cancer, personal history of testicular cancer, or undescended testicle. The majority of testicular tumors are germ cell tumors consisting of seminoma and nonseminoma. Seminomas are the more common subtype and carry a more favorable prognosis. Nonseminoma can be comprised of choriocarcinoma, embryonal carcinoma, yolk sac tumors, and teratoma. Germ cell tumors that originate outside the testicle may be located in the retroperitoneum or mediastinum and follow similar treatment recommendations.

### Diagnosis

Men with testicular cancer often present with painless testicular enlargement or a mass. They may at times experience pain, which can be confused with epididymitis or orchitis. Ultrasound examination is the next step with findings of an intratesticular mass necessitating collection of serum tumor markers including AFP, beta-hCG, and LDH.

Staging follows the TNM classification. Tis tumors are germ cell neoplasia in situ, T1 tumors are limited to the testis without lymphovascular invasion (LVI), T2 tumors are limited to the testis with LVI or invade hilar soft tissues or epididymis, T4 tumors invade the spermatic cord, and T4 tumors involve scrotal invasion. Nodal metastases are classified based on size, and metastases are divided into non-retroperitoneal nodal disease/pulmonary metastases or non-pulmonary metastases. Finally, the S stage is based on post-orchietomy tumor markers.

### Treatment

Once an intratesticular mass is identified on physical exam or trans-scrotal ultrasound, radical inguinal orchietomy is the next step (Figure 3). Sperm banking should be offered to any patient who wishes to preserve future fertility before radical orchietomy and certainly prior to any systemic therapy or

<sup>1</sup>Not FDA approved for this indication.

**Figure 3** Management algorithm for suspicious testicular mass.

retroperitoneal lymph node dissection. Following orchiectomy, chest imaging and a CT scan of the abdomen and pelvis should be obtained with repeat post-operative tumor markers. For patients with T1 to T4 localized pure seminoma with normal tumor markers, treatment following orchiectomy can include surveillance (which is preferred), carboplatin (Paraplatin)<sup>1</sup>, or radiation therapy. For patients with pure seminoma and retroperitoneal lymphadenopathy less than 5 cm in maximum dimension, options include chemotherapy with a regimen of bleomycin, etoposide (Toposar), and cisplatin (Platinol) or etoposide (Toposar) with cisplatin, as well as radiation therapy to the retroperitoneum. For patients with bulkier retroperitoneal lymphadenopathy, non-regional lymphadenopathy, or metastases, chemotherapy is recommended. PET/CT scans may be obtained in the patient with residual post-chemotherapy masses with resection if PET positive.

Non-seminomatous testicular cancer is managed differently than seminoma, and radiation therapy is not indicated. For patients without lymphadenopathy and normal tumor markers, options include surveillance, chemotherapy regimens as previously described for pure seminoma, and RPLND. For patients with enlarged lymph nodes in the retroperitoneum, treatment options include chemotherapy or RPLND. Treatment should be focused on chemotherapy for patients with bulky retroperitoneal lymphadenopathy, non-retroperitoneal lymphadenopathy, or metastases. Patients who undergo chemotherapy with residual masses larger than one centimeter on follow up CT scans should undergo surgical resection. Follow up for patients treated for testicular cancer can include periodic tumor markers, CT scan of the abdomen and pelvis, and chest x-ray.

Early urologic consultation should be considered for several common clinical conditions to prevent delayed diagnosis. Patients with elevated PSA or hematuria may frequently be treated with antibiotics for presumptive prostatitis or urinary tract infections. These patients should instead be promptly referred to a urologist to prevent delayed diagnosis of prostate cancer or urologic malignancy. In addition, patients with testicular masses may not seek work-up and treatment in a timely fashion. Upon presentation, a prompt ultrasound should be obtained. Initial empiric treatment with antibiotics for presumed orchitis or epididymitis can be avoided for intratesticular masses seen on ultrasound to allow for expedient orchiectomy.

<sup>1</sup>Not FDA approved for this indication.

## NEPHROLITHIASIS

Method of

William J. Somers, MD

### CURRENT DIAGNOSIS

- Renal calculi can present acutely or more often as an incidental finding on an unrelated radiologic study.
- Ureteral calculi present with either an acute onset of excruciating flank pain or a gradual onset preceded by generalized abdominal discomfort.
- Renal colic pain can radiate from ipsilateral flank pain to the lower abdomen, often mimicking pain from cholecystitis, appendicitis, or ovarian conditions such as torsion or ruptured ovarian cysts.
- Physical examination will reveal an anxious patient experiencing sharp, excruciating costovertebral pain. Pain commonly occurs in waves. Percussion of the flank reveals exquisite tenderness. The patient cannot find a comfortable resting position.
- Computed tomography without intravenous contrast (CT stone protocol) is the definitive diagnostic study. Abdominal plain film radiography and renal ultrasonography are not as accurate as CT.
- Urinalysis may demonstrate either microscopic or gross hematuria. Pyuria in the absence of bacteriuria is common and does not always indicate infection.
- Nausea, vomiting, and low-grade fever are common. Temperature over 101°F suggests infection and is an acute urologic emergency.

### CURRENT THERAPY

- Asymptomatic renal stones can be managed electively with observation or surgical intervention.
- Once the acute episode is controlled with intravenous analgesics and the patient is discharged from the emergency department, ureteral obstruction can be managed with oral analgesics, liberal oral fluid intake, and expectant observation if the patient is afebrile and the stone is 5 mm or less in size.
- A follow-up renal ultrasound examination should be obtained 2 weeks after the first presentation of symptoms. If hydronephrosis persists but the patient is asymptomatic and urine is not infected, a repeat CT should be ordered in 4 to 6 weeks. If at that time the stone has not passed or hydronephrosis persists, refer the patient to a urologist.
- Fever and/or leukocytosis, regardless of a clean urine, indicates possible pyonephrosis, a surgical emergency. The patient should be hospitalized for definitive treatment.

### Prevention

One recommended diet plan is as follows:

1. Low sodium diet <2g daily
2. Low protein/animal fat diet <8 oz. daily
3. Normal calcium diet 1000 mg daily (1200 mg for postmenopausal women)

#### 4. Daily fluid intake of 100 oz. daily

- Patients who are recurrent calcium stone formers should be offered thiazide diuretics in addition to maintaining the dietary measures to limit stone formation. Because excess sodium intake can block the action of thiazides and increase urinary calcium excretion to 50 mg daily, patients must be encouraged to maintain a low-sodium diet.
- Patients who form uric acid stones should be encouraged to maintain a liberal oral intake of fluids (100 oz daily) and consider alkalinizing the urine with a potassium citrate (Urocit-K) supplement.
- There is no standard definition of a low-oxalate diet, so patients should be encouraged to follow the aforementioned dietary guidelines.
- Dietary factors that increase the risk of stone formation are as follows:
  - Sugar sweetened colas
  - Sugar sweetened non-cola beverages, punch, and so on.
- Dietary factors that decrease the risk of stone formation:
  - Coffee, tea, wine, beer, orange juice.
  - Adding lemon to water, or drinking lemonade has not been shown to conclusively lower the risk of stone formation. It does encourage fluid intake, which is the major goal of prevention.
- One recent study showed that only one-third of patients will follow dietary guidelines for stone prevention.

### Pathophysiology

Urine exists in four states: **undersaturated**, a state in which no crystals will form; **metastable**, a state in which salt concentration is high but urine inhibitors prevent supersaturation; **saturated**, a state in which addition of salts will not dissolve; and **supersaturated**, which is an unstable solution, and crystals can form spontaneously. Urine is generally in a supersaturated state.

The generally accepted theory describing stone formation begins with spontaneous crystallization in a supersaturated urine. This tiny crystal nucleus then attaches to a cell membrane in the collecting tubule. This nidus then attracts other crystals and cell debris, forming a tiny calcification that gradually grows larger as these particles continue to adhere to the mass. Some of these calcifications break off and proceed to the collecting system or remain in the renal tubules indefinitely.

Another theory suggests that spontaneous crystallization occurs at damaged sites along the nephron. Crystals attach to the damaged cell wall, remain fixed in place, and attract further crystal accumulation. Initial cell damage is believed to occur from high calcium oxalate levels based on studies that implicate oxalate as the sole cause for renal tubule cell damage. Pak 1976 showed that the calcium oxalate concentration is four times higher in urine than its solubility in water. This higher concentration may have an adverse effect on the cells, an interesting but as yet unproved theory.

Historically, Randall plaques were believed to provide a base for crystal nucleation in the collecting system. These plaques are located in the loop of Henle just below the urothelium in the renal papillae. As they grow, they erode through the urothelium, forming a nidus for crystal attachment and growth.

Because a supersaturated salt solution will spontaneously generate crystal formation, there must be some inherent factors that inhibit crystal formation. Citrate, magnesium, and pyrophosphates are the major stone inhibitors naturally found in urine. Citrate is the major inhibitor. Citrate complexes with calcium, reducing its availability and thus preventing spontaneous precipitation of calcium oxalate as well as inhibiting the calcium crystal nucleation. Magnesium binds to oxalate, also reducing its availability to bind with calcium.

### Calcium Stones

Calcium stones are the most common type of stone in the United States. The incidence is estimated to be 2% per 100,000 individuals and 11% in previous stone formers. Hypercalciuria is the first step in stone formation. Thirty percent to 40% of calcium is absorbed in the small intestine, and about 10% is absorbed from the colon. The kidney filters 270 mmol of calcium daily and absorbs all except for approximately 4 mmol. The active form of vitamin D is the most potent stimulator of intestinal calcium absorption. Calcium transport is regulated at three sites: intestine, bone, and kidney. Low calcium intake stimulates increased calcium absorption, which stimulates parathyroid hormone (PTH). PTH regulates the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D or calcitriol. PTH also stimulates the mobilization of calcium from bone through the action of osteoclasts and increases the absorption of calcium from renal tubules.

The classic model for hypercalciuria describes three types:

1. Absorptive hypercalciuria, the most common form, occurs in 55% of stone formers and is caused by increase in intestinal absorption of calcium. Absorptive hypercalciuria can be categorized as type 1, in which urinary calcium remains high despite a low calcium diet, and type 2, in which urinary calcium is normalized on a low-calcium diet.
2. Resorptive hypercalciuria, identified in approximately 5% of stone formers, is usually seen in patients with hyperparathyroidism. Excessive PTH secretion causes increased production of calcitriol (1,25-dihydroxyvitamin D), which causes increased intestinal absorption of calcium. These patients present with hypercalciuria, hypercalcemia, and reduced phosphatemia. Patients with serum calcium levels above 10 should be evaluated for hyperparathyroidism.
3. Renal hypercalciuria, commonly referred to as *renal leak hypercalciuria*, is caused by a defect in calcium reabsorption in the proximal tubule. It is characterized by high fasting urine calcium levels, normal serum calcium levels, and elevated PTH.

Other causes for hypercalcemia include sarcoidosis, granulomatous diseases, malignancy, and glucocorticoid use. Malignancy is the most common cause for hypercalcemia in hospitalized patients. Of the malignancies, lung and breast malignancies are most common. It is believed that the tumors produce cytokines and other factors that cause bone destruction through the action of osteoclasts, resulting in bone destruction and subsequent hypercalcemia. Glucocorticoids stimulate the release of PTH. Nephrolithiasis is common in patients with Cushing syndrome.

### Vitamin D Supplements

If a patient develops de novo kidney stones while taking calcium and vitamin D supplements, a 24-hour urine collection for calcium, phosphorus, uric acid, and citrate should be ordered. If this demonstrates hypercalciuria, the patient is referred to a nutritionist for dietary guidance. Let patients know that dietary calcium is a more natural way of increasing calcium levels, whereas calcium supplements could increase the risk. I would also question the need for taking both supplements.

### Oxalate

Oxalates cause increased urinary saturation of calcium oxalate, which in turn can cause calcium oxalate stone formation. Primary hyperoxaluria is an autosomal recessive disorder responsible for end-stage renal failure before 15 years of age in 50% of young patients.

Enteric hyperoxaluria is the most common cause of acquired hyperoxaluria. It is associated with chronic diarrheal conditions, loss of large segments of small bowel, and intrinsic bowel disease. Loss of fat absorption in these patients results in increased oxalate absorption. Oxalate readily binds to calcium, which can ultimately initiate stone formation.

### Renal Tubular Acidosis

Renal tubular acidosis (RTA) describes a defect in urinary acidification resulting in a metabolic acidosis. Hypokalemia, elevated

urine pH, hypocitraturia, and hypercalciuria can lead to stone formation. There are three common types of RTA. Type 1 (distal) RTA patients are at high risk for stone formation. Calcium phosphate stones are associated with type 1 patients, which should prompt further diagnostic testing. Treatment can decrease the rate of stone formation. Type 2 (proximal) RTA is not associated with nephrolithiasis. Type 4 RTA is not commonly associated with stones, but can occasionally occur.

### Uric Acid Stones

Uric acid stones are unique in that they can be dissolved medically. Uric acid is the end product of purine metabolism. Humans lack the enzyme uricase, which is the final step in the metabolism of uric acid to allantoin. Uric acid is not readily soluble in normally acidic urine. Hyperuricosuria is found in patients with gout, type 2 diabetes, and Lesch-Nyan syndrome. Alkalinizing urine is the primary treatment for asymptomatic uric acid renal stones.

### Prevention

The time-honored key to prevention for all stones is increased water intake. Multiple studies have shown increasing oral intake of fluids to produce a 2- to 2.5-L daily urine output is the most efficient and least expensive way to prevent most stones. Additional measures include a low-salt diet and limiting animal protein.

When available, the stone should be analyzed to provide a diagnosis and a specific plan tailored to the type of stone and underlying pathologic cause if present. A complete medical history should be obtained that can identify an underlying cause such as hyperparathyroidism, Cushing syndrome, type 2 diabetes, antiviral medication, and so on. The American Urological Association has published guidelines for prevention and management of nephrolithiasis.

Common misconceptions about the type of fluid patients should be drinking include avoiding alcohol, coffee, colas, wine, and beer. In general, there is no definite consensus on avoidance of certain fluids or the selection of certain fluids to help prevent recurrent calcium oxalate stones. Neither water hardness nor grapefruit juice is associated with stone formation. Vitamin D replacement does not appear to be a risk factor for stone formation.

Contrary to popular belief, a low-calcium diet is associated with an increase in calcium oxalate stones. It is believed that low calcium intake results in increased oxalate absorption from the gut and higher levels of urinary oxalate. A low-sodium diet has been shown to decrease urinary calcium excretion, but compliance with a low-sodium diet is generally difficult. There are conflicting reports about calcium supplements and increased stone risk in older women. If a patient is taking supplements, baseline 24-hour urine collections should be obtained to monitor urinary calcium levels and make dietary adjustments as needed. Because urinary citrate is a stone inhibitor, patients should be encouraged to add fruits and vegetables to their diet. There is no hard evidence that drinking lemonade or adding lemon to tap water prevents recurrent stone formation. Animal protein intake contributes to an acidic urine, which promotes stone formation. Patients should limit their weekly intake of meats, cheese, eggs, and fish.

There are no definitive studies demonstrating a beneficial effect of reducing a high purine diet with lower uric acid stone formation. But in general, patients with recurrent calcium or uric acid stones and a diet high in purines may benefit from reducing their intake of high purine foods. These include various seafoods, shellfish, water fowl, organ meats, game meats, pork, and poultry. Simply restricting red meats without limiting other high-purine foods is not beneficial. For patients who have failed dietary measures or those who continue to form stones after altering their diets, medical therapy is indicated.

Thiazide diuretics are the gold standard for treatment of recurrent calcium oxalate stones. Chlorthalidone<sup>1</sup> 25 mg daily,

hydrochlorothiazide<sup>1</sup> 50 mg daily, and indapamide<sup>1</sup> 2.5 mg daily are all well tolerated. (Patients should be monitored for hypokalemia.) Potassium citrate (Urocit-K) 10 to 20 mEq daily can be prescribed for patients with recurrent calcium oxalate stones, uric acid stones, and cystine stones. Sodium citrate is an alternate choice but risks creating a higher urinary calcium load. A baseline 24-hour urinary citrate level and follow-up study 6 months later will determine if therapy is effectively increasing urinary citrate levels. Uric acid stones can be dissolved with aggressive urinary alkalization using potassium citrate. Patients with hyperuricosuria and recurrent calcium oxalate or uric acid stones should be offered allopurinol (Zyloprim) 300 mg daily. Patients with cystine stones should be managed with high fluid intake, urinary alkalization with potassium citrate, and reduction in sodium and protein intake. Thiol drugs should be prescribed if dietary measures fail. Alpha-mercaptopyrionyl glycine (tiopronin, Thiola) 800 mg daily in three divided doses is the standard treatment. An alternative preparation, D-penicillamine (Cuprimine), is associated with more severe side effects and should be a second-line choice.

Struvite stones occur in the presence of chronic urinary infection. Treatment of the stone with sterilization of the urinary tract is the best option. If surgery is not an option, suppressive antibiotic therapy may help.

### Diagnosis

A CT examination without intravenous contrast is the most accurate way of diagnosing renal and ureteral stones. It is the first choice for suspected renal or ureteral stones. Abdominal plain film radiography is an unreliable and inaccurate diagnostic tool. It should never be ordered in an acute situation. Small 1- to 2-mm stones are difficult to see on plain film radiographs. Uric acid stones, cystine stones, and triamterene stones are radiolucent and seldom visible on plain films. Renal ultrasonography is a good tool to identify and follow hydronephrosis, but it does not accurately identify renal stones and cannot be used to follow ureteral stones. A CT stone protocol is readily available in medical centers and outpatient facilities. It can be performed in less than 15 minutes, and no preparation is required. Diagnosis is instantaneous and accurate. MRI has been used to diagnose ureteral stones in pregnant patients, but interpretation is dependent on the radiologist's experience and familiarity with the technique. It is not frequently used for this purpose.

### Differential Diagnosis

Asymptomatic nephrolithiasis is usually discovered as an incidental finding on an unrelated radiologic study. Intense renal shadowing on abdominal ultrasonography is suggestive of a renal stone. A calcification overlying the renal shadow on an abdominal plain film can suggest a renal stone, but the differential diagnosis includes arterial calcifications, stomach or intestinal contents, calcified lymph nodes, renal cell tumors, cholelithiasis, and so on. Pelvic calcifications seen on plain films can be ascribed to phleboliths, ovarian calcifications, prostate calcifications, appendololiths, vascular calcifications, bladder stones, and so on. Needless to say, plain films should not be expected to provide an accurate diagnosis. Unless the renal stone is obstructing the renal pelvis, it does not cause pain. Patients who present with back pain and nonobstructing renal stones should not be treated for renal colic. Further diagnostic evaluation is indicated.

In contrast with asymptomatic renal stones, ureteral stones almost always present with a dramatic onset of excruciating pain. The diagnosis is almost instantaneous. Renal colic is localized to either costovertebral area. Nausea and vomiting are common. Changing position does not relieve pain. As the stone progresses distally, the pain can mimic multiple acute abdominal conditions. The differential diagnosis of right lower-quadrant abdominal pain includes the following:

- Acute appendicitis
- Ovarian conditions (e.g., cyst rupture, ectopic pregnancy, torsion)

<sup>1</sup>Not FDA approved for this indication.

- Incarcerated inguinal hernia
- Cholecystitis
- Testicular torsion
- Diverticulitis (rare)

The differential diagnosis for left lower-quadrant pain is the same as for right lower-quadrant pain, with the exception of appendicitis and cholecystitis, for obvious reasons. Diverticulitis is more commonly seen in the descending colon than in the ascending colon.

## Treatment

### Renal Stones

Asymptomatic renal stones pose a dilemma about whether or not to treat the patient. One of the largest retrospective studies evaluated the natural history of these stones based on location and size of the stone. In more than 3 years of active observation, the study found that 60% of stones remained asymptomatic, 7% passed spontaneously, and 20% were operated on for pain. Less than 30% of the stones caused renal colic. Most studies determined that lower-pole stones did not pass spontaneously but grew faster in size than stones in the upper collecting system. These upper-pole stones also passed more spontaneously. Patients should be offered treatment of renal stones if larger than 5 mm and in the upper pole of the kidney. Lower pole stones can be followed if the patient is not anxious to have treatment or if the stone has been present for years without a change in size or location. Stones 10 mm or larger should be treated regardless of position. These stones could pass spontaneously and will require emergency surgery. All staghorn calculi should be treated unless comorbidities prevent surgical intervention. Autonephrectomy is the ultimate outcome for untreated staghorn calculi.

Once a decision is made to treat a renal stone, the next step is to decide which method is best for the patient. Factors to consider are size of the stone, stone composition, location, number of stones, and body habitus.

Rigid and flexible ureteroscopy with holmium laser disintegration of stones is rapidly replacing electrocorporeal shockwave lithotripsy (ESWL) for both ureteral and renal calculi. The success rate for stone destruction and removal is higher than for ESWL. ESWL is indicated for renal and ureteral stones less than 20 mm. However, the clearance rate after ESWL is only 60%.

Percutaneous nephrostolithotomy (PNL) is the best choice for these larger stones. All staghorn and partial staghorn calculi should be treated by PNL.

Medical dissolution treatment should be offered to patients with uric acid or cystine stones. Unfortunately, compliance with a medical and dietary regimen is dismal, and most patients will need surgical intervention.

### Ureteral Stones

It is generally accepted that stones less than 5 mm will pass spontaneously over 3 months. Most stones pass sooner than that. The following is a general guide for treatment of the acute episode:

- CT stone protocol to identify the number, size, and location of the stone(s)
- Intravenous narcotic and antiemetic if necessary
- Urinalysis to evaluate for bacteria. Pyuria and hematuria are common and not signs of infection. If bacteria are present, obtain a culture and begin empiric antibiotics.
- Abdominal plain film radiograph. If the stone is visible, this will provide a way to follow the stone.
- CBC, electrolytes
- Hydronephrosis will be present but does not dictate treatment.

Once pain is controlled, the patient is able to tolerate fluids by mouth, and laboratory tests are acceptable, the patient can be discharged with oral narcotics and possibly an alpha blocker. Oxycodone 5 mg PO every 4 to 6 hours is a good choice for pain control. Tamsulosin (Flomax)<sup>1</sup> 0.4 mg PO daily has been shown in many studies to assist in spontaneous stone passage, but

recent research showed a higher rate of stone passage for larger upper ureteral stones than for smaller distal stones. Nonetheless, an alpha blocker should be offered to most patients with ureteral stones.

Urologic dogma holds that stones less than 5 mm have spontaneous passage rates of higher than 90%. Stones in the distal ureter have a 98% passage rate. I believe most urologists doubt 9-mm stones will pass with or without the concomitant use of tamsulosin unless the patient has passed these large stones previously. Surgical intervention, either ureteroscopy or ESWL, is usually the preferred treatment option.

A 4- to 6-week course of tamsulosin is reasonable. A stone strainer should be given to the patient. A repeat stone protocol CT should be obtained in 4 to 6 weeks if the stone has not passed. If the stone has not passed by then, a urological consult is recommended.

Patients with any of the following signs and/or symptoms should be admitted and urologic consultation obtained as soon as possible:

- Fever and leukocytosis, or signs of sepsis
- Solitary kidney
- Uncontrolled pain or vomiting
- Bilateral ureteral stone

Once the patient collects the stone, it should be sent for analysis. A follow-up renal sonogram should be obtained 6 to 8 weeks after passage to identify any residual silent hydronephrosis. If hydronephrosis is present, urologic consultation should be obtained.

### Complications

The most serious complication of nephrolithiasis is pyonephrosis. This is a urologic emergency requiring immediate drainage of the obstructed kidney. A percutaneous nephrostomy is the quickest way to achieve drainage.

Stones can become lodged in the ureter and remain asymptomatic. They eventually become impacted. The urothelium surrounds and covers the stone, trapping it in place over time. Silent hydronephrosis continues until the kidney eventually becomes atrophic and nonfunctioning. To avoid this complication, either a CT or renal sonogram must be obtained 6 to 8 weeks after the patient passes a stone or is no longer symptomatic.

### Monitoring

Stone patients should have yearly radiologic studies for at least the first 5 years after they present with a stone. There is a 50% chance they will develop another stone during that time. CT is the most accurate, but abdominal plain film radiography is useful if the stone(s) are visible. There is no place for renal ultrasonography for monitoring patients long-term. If the stone burden increases over time, urologic consultation should be obtained.

If a 24-hour urine collection is obtained and dietary or medical treatment is recommended, the metabolic evaluation should be repeated 6 months later to determine if the plan is effective. Not surprisingly, most patients will not comply with the recommendations. Periodic 24-hour metabolic evaluations every few years is a good way to remind patients to self-monitor their fluid intake and modify their diets if necessary.

## PRIMARY GLOMERULAR DISEASE

Method of

Saeed Kamran Shaffi, MD, MS

### CURRENT DIAGNOSIS

- Hematuria, proteinuria, hypoalbuminemia, hyperlipidemia, and elevated blood urea nitrogen and creatinine levels are the main laboratory abnormalities seen in patients with primary glomerular diseases.
- Our ability to diagnose some of the glomerular diseases and to monitor their disease-activity has improved with the recent discovery of disease-specific serum and kidney biopsy markers.

### CURRENT THERAPY

- The goals of management of a primary glomerular disease patient are:
  - To diagnose the glomerular abnormality
  - To slow the progression of chronic kidney disease and subsequent development of end-stage kidney disease
  - To manage and ameliorate the glomerular disease symptoms
  - To prevent complications of primary glomerular diseases and the therapies used for their management, such as infection, thrombosis, coronary vascular disease, osteoporosis, and trace metal deficiencies

### Clinical Presentation

The clinical presentation of the primary glomerular diseases can be grouped into syndromes, which are listed in [Box 1](#).

**Nephrotic syndrome:** The disease-defining symptoms of the nephrotic syndrome are  $>3.5$  g/day of proteinuria in adults, serum albumin of  $<3$  g/L, and edema. Hyperlipidemia and thrombophilia are often present.

**Sub-nephrotic proteinuria:** These patients have proteinuria of  $<3.5$  g/day without hypoalbuminemia, edema, and hyperlipidemia.

**Acute nephritic syndrome:** Nephritic syndrome presents as microscopic hematuria, which is defined as  $>3$  red blood cells (RBC) per high-power field (HPF). Patients with the nephritic syndrome also have a varying amount of proteinuria and may have an elevated creatinine level indicating a decline in the glomerular filtration rate (GFR).

**Asymptomatic microhematuria:** Hematuria is seen on urine analyses; however, these patients do not develop progressive kidney dysfunction.

**Rapidly progressive glomerulonephritis (RPGN):** Rapidly progressive glomerulonephritis is a syndrome associated with a rapid decline in renal function over the course of a few days, weeks, or months. On the kidney biopsy, RPGN presents as glomerular crescents which form due to the disruption of the glomerular basement membrane with fluid spillage in the Bowman's space resulting in extracapillary cellular proliferation and crescent formation.

**Slowly progressive nephritic syndrome:** Some of the glomerular diseases have a smoldering course with persistent hematuria and proteinuria that may eventually lead to CKD and end-stage kidney disease.

Causes of primary glomerular diseases: [Table 1](#) lists the causes of primary glomerular diseases.

### BOX 1 Clinical Presentation of Glomerular Diseases

Nephrotic syndrome  
Sub-nephrotic proteinuria  
Acute nephritic syndrome  
Asymptomatic microhematuria  
Rapidly progressive glomerulonephritis  
Slowly progressive chronic nephritis

**TABLE 1** Causes and Clinical Presentation of the Primary Glomerular Diseases

CAUSES OF PRIMARY GLOMERULAR DISEASE	PRESENTATION
Minimal change disease	Nephrotic syndrome
Primary focal segmental glomerulosclerosis	Usually nephrotic syndrome, rarely nephritic syndrome
Primary membranous glomerulonephritis	Nephrotic syndrome
IgA nephropathy	Usually nephritic syndrome, sometimes microscopic hematuria or gross hematuria
Postinfectious glomerulonephritis	Nephritic syndrome
Membranoproliferative glomerulonephritis due to alternate complement pathway abnormalities (dense deposit disease and C3 glomerulonephritis)	Nephritic syndrome
Fibrillary glomerulonephritis	Nephritic or nephrotic syndrome
Thin basement membrane disease	Asymptomatic microscopic hematuria

### BOX 2 Signs of Glomerular Hematuria.

$>22\%$  dysmorphic\* RBCs on optical and  $>40\%$  on phase contrast microscopy

In the setting of hematuria and dysmorphic RBCs, an immunoreactive albumin excretion of  $>0.59$  mg/mg total protein excretion is strongly suggestive of glomerular hematuria

The newer generation of the urine analysis machines (sediMAX) automate the phase-contrast microscopy detection of dysmorphic RBCs without loss of precision

\*Red blood cells in the glomerular hematuria develop membrane abnormalities when they pass through the inflamed glomerular membranes and are called dysmorphic. A certain type of dysmorphic RBC, with characteristic membrane blebs called acanthocytes, are strongly correlated with glomerular hematuria.

### Diagnosis of the Primary Glomerular Diseases

Glomerular disease is suspected when a clinician notices hematuria, proteinuria, or an abnormal blood urea nitrogen or creatinine level. It is paramount to rule out other conditions which can present with similar abnormalities.

**Hematuria:** It is imperative to differentiate between the glomerular and nonglomerular hematuria ([Box 2](#) and [Figure 1](#)).

**Proteinuria:** Proteinuria is often seen in primary glomerular diseases. Urinary protein and albumin excretion in an adult

**Figure 1** A and B. Acanthocytes: phase contrast microscopy, unstained; C. Acanthocytes: brightfield microscopy, unstained; D. RBC cast: brightfield microscopy, unstained. (Courtesy of Jay R. Seltzer, M.D. Chief of Nephrology - Missouri Baptist Medical Center - St. Louis Missouri.)

should not exceed 150 mg/day, and 30 mg/g, respectively. Reduction in proteinuria—especially when sustained longitudinally—is associated with better clinical outcomes. In clinical practice, a spot urine protein to creatinine (P/C) ratio or albumin to creatinine ratio is often used for the assessment of the proteinuria; however, the concordance between the spot and the 24-hour urine collection is poor. On the other hand, 24-hour urine collection is cumbersome, is not feasible in children, and is associated with significant under- and overcollection even in highly motivated patients. Therefore, a morning first void spot urine (P/C) ratio is adequate for proteinuria surveillance; however, a 24-hour urine collection for proteinuria assessment should be considered when the use of therapeutic agents that can cause significant morbidity is being contemplated for proteinuria reduction.

**GFR assessment:** The best method to estimate GFR in patients with glomerular diseases is not known. Assessment of the longitudinal trends in the estimated GFR (eGFR) in this population may provide the clinicians with a better guide of renal status than a single value in isolation.

**Kidney biopsy:** Apart from a few situations such as serum anti-phospholipase A 2 receptor positivity in a high biopsy risk patient and steroid responsive nephrotic syndrome in children, which is almost always due to minimal change nephropathy, a kidney biopsy is essential for the diagnosis of primary glomerular diseases. Kidney biopsy not only provides a definitive diagnosis of the primary glomerular abnormality in most of the patients but also informs the clinician of the prognosis by quantifying the degree of the irreversible changes such as glomerulosclerosis, interstitial fibrosis, and tubular atrophy.

## General Management of Primary Glomerular Diseases

Primary glomerular diseases may manifest as signs and symptoms (Box 3) which can be debilitating.

### Treatment of Primary Glomerulonephritis

**Edema:** Dietary sodium restriction (1.5 to 2 g or 60 to 80 mmol/day) is the first step for edema management due to nephrotic syndromes. Oral loop diuretics (Table 2) should be used if the sodium restriction does not ameliorate the symptoms. Use of diuretics with better oral bioavailability and longer half-life may be more effective in edema management (see Table 2). Gut wall edema in patients with severe nephrotic syndrome may preclude effective diuresis with orally administered diuretics in which case intravenous loop diuretics alone or combined with a thiazide diuretic (e.g., metolazone [Zaroxolyn]) may be tried. Use of loop diuretics with intravenous albumin (Albuminar)<sup>1</sup> to maximize diuresis is controversial with some reports showing beneficial while others showing equivocal results; this strategy can be considered in patients with severe diuretic resistance.

**Hypertension:** Optimal control of hypertension in patients with a glomerular disease may decrease cardiovascular morbidity and mortality, and slow CKD progression. There is limited evidence for sodium restriction and angiotensin-converting enzyme inhibitors (ACEi) or angiotensin receptor blockers (ARBs) use to achieve a goal BP target of <125/75 mm Hg in patients with >1g/day of proteinuria.

**Hyperlipidemia:** Patients with primary glomerular diseases are at a higher risk of developing hyperlipidemia and cardiovascular

<sup>1</sup>Not FDA approved for this indication.

events. Hyperlipidemia should be treated aggressively to the same targets as the general population.

**Hypercoagulable states:** Patients with glomerular diseases are at significant risk of thromboembolism due to the alterations in the pro-coagulant and anticoagulant factors. The incidence of thromboembolism has been reported as high as 8% to 44%, and 5% to 62% in nephrotic syndrome and membranous glomerulonephritis, respectively. Anticoagulation should be considered in patients with a low serum albumin (below 2 to 2.5 g/dL) along with one of the following: >10 g/d of proteinuria; BMI of >35 kg/m<sup>2</sup>; family history and genetic disposition of thromboembolism; New York Heart Association Class III or IV congestive heart failure; recent abdominal or orthopedic surgery; prolonged immobilization. The Chapel Hill group has devised an online calculator (<https://www.med.unc.edu/gntools/>) to aid the clinicians in deciding about the use of anticoagulation in patients with membranous glomerulonephritis.

Case-reports have described aspirin<sup>1</sup>, warfarin (Coumadin)<sup>1</sup>, low-molecular-weight heparin,<sup>1</sup> or direct-acting oral anticoagulant (DOAC) use for thromboembolism prevention in patients with nephrotic syndrome. Expert opinion suggests starting anticoagulation with low-dose, low-molecular-weight heparin, followed by introduction of warfarin. When therapeutic INR is achieved, stop heparin. Alternatively, low-molecular-weight heparin with aspirin has been suggested for a period of 3 months before introducing warfarin if proteinuria does not resolve.

**Chronic kidney disease:** Studies have shown that complete remission of proteinuria is associated with preservation of renal function and end-stage kidney disease. Disease-modifying therapies, which will be described later, should be used to prevent the development of renal fibrosis which is irreversible.

**Trace metal deficiency:** Patients with primary glomerular diseases who have nephrotic syndrome may have deficiencies of iron, copper, zinc, and selenium. Twenty-five hydroxyvitamin D [25-(OH)D] deficiency, which is extremely common in patients with nephrotic syndrome, is due to urinary loss of 25(OH)D, and is often difficult to treat unless the patient achieves complete remission. Treatment of 25(OH)D deficiency is outlined in **Box 4** and is similar to that in the general population.

**Endocrine abnormalities:** Loss of hormone-binding proteins and albumin in patients with proteinuric glomerular diseases

leads to various endocrine abnormalities. Low T4 levels are seen in approximately 50% of nephrotic syndrome patients with preserved renal function due to urinary loss of thyroid-binding globulin; however, these patients are usually euthyroid due to their preserved ability to convert T4 to T3. On the other hand, glomerular disease patients with low GFRs have a diminished T3 level due to diminished conversion of T4 to T3; however, unlike other chronic illnesses, the conversion of T4 to metabolically inactive reverse T3 (rT3) is not enhanced.

**Risk of infections:** Chronic kidney disease, nephrotic syndrome, and use of the immunosuppressive medications are some of the risk factors that increase the propensity to develop infections in patients with primary glomerular diseases. Patients should be up to date on their vaccinations to mitigate infection risk (**Box 5**).

*Pneumocystis jirovecii* prophylaxis should be administered to patients who are on >20 mg of prednisone and/or on immunosuppressive medications that affect the T cells such as corticosteroids and cyclophosphamide (Cytoxan).

## Therapy of Specific Glomerular Diseases

### Minimal-Change Disease

Minimal-change disease is the most common cause of nephrotic syndrome in children (90%) and is rare adults (10%). No abnormality is detected on light microscopic evaluation of the kidney; however, the electron microscopy shows diffuse foot process effacement. A child presenting with nephrotic syndrome is assumed to have a minimal-change disease and does not require a kidney biopsy. In adults, minimal-change disease is a rare occurrence and is usually diagnosed with a kidney biopsy. Most cases of minimal-change disease are idiopathic, although secondary causes such as drugs (nonsteroidal antiinflammatory drugs [NSAIDs]), hematological malignancies, and thymoma are associated with this condition. Therapy of minimal-change disease is shown in **Box 6**.

### Primary Focal Segmental Glomerulosclerosis

Primary focal segmental glomerulosclerosis is a pathological term denoting patchy glomerulosclerosis and is thought to be due to

#### BOX 3 Abnormalities Seen in the Primary Glomerular Diseases

- Edema
- Hypertension
- Hyperlipidemia
- Hypercoagulable state
- Chronic kidney disease
- Trace metal and vitamin deficiencies
- Endocrine hormonal abnormalities
- Infection risk

#### BOX 4 Treatment of Vitamin D Deficiency in Primary Glomerular Diseases

25(OH)D level less than 12 ng/mL: treat with 50,000 international units (IU) of vitamin D2 (ergocalciferol)<sup>1</sup> or vitamin D3 (cholecalciferol)<sup>1</sup> orally once a week for 6 to 8 weeks followed by 800–1000 IU/day of vitamin D3 for maintenance therapy. Higher doses of daily vitamin D3 may be necessary if the levels remain low (<30 ng/mL) 3 months after therapy initiation.

25(OH)D levels between 12 and 20 ng/mL: treat with 800–1000 IU/day of vitamin D3. Repeat levels in 3 months. Higher vitamin D3 doses may be necessary if the levels are below the normal range (30–50 ng/mL).

25(OH)D level between 20 and 30 ng/mL: treat with 600–800 IU of vitamin D3 daily.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Pharmacokinetics of Loop Diuretics

NAME	RELATIVE POTENCY	ORAL BIOAVAILABILITY	HALF-LIFE (HOURS)	ELIMINATION ROUTE	COMMENTS
Furosemide (Lasix)	1	~60%	~1.5	~65% renal, 25% metabolism	Renal disease prolongs half-life
Bumetanide (Bumex)	40	~80	~0.8	~62% renal, 38% metabolism	Liver disease prolongs half-life
Torsemide (Demadex)	20	~80%	~3.5	~20% renal, 80% metabolism	Liver disease prolongs half-life

an unknown permeability factor which causes proteinuria, hypertension, and kidney dysfunction. This condition should be differentiated from the secondary glomerulosclerosis (focal or global) which is a sequela of kidney injury. Reduction in proteinuria is associated with better renal survival and is the goal of therapy. **Box 7** shows the therapies used for the management of primary focal segmental glomerulosclerosis.

### Primary Membranous Glomerulonephritis

Idiopathic membranous glomerulonephritis is the second most common cause of nephrotic syndrome in the US adults. This condition is characterized by diffuse subepithelial deposits seen on kidney biopsy. Our understanding of the pathophysiology of the idiopathic membranous glomerulonephritis was revolutionized in 2009 with the discovery of elevated M-type phospholipase-A(2) receptor [PLA2R], an antigen expressed in the human podocytes, antibody in the serum and the immune deposits in the glomeruli of the vast majority of patients. Antibodies against thrombospondin type 1 domain-containing 7A (THSD7A) have been found in PLA2R negative idiopathic membranous patients (2% to 4%). Serum anti-PLA2R and THSD7A antibody levels are measured by commercial laboratories and are used to monitor idiopathic membranous glomerulonephritis disease activity—a rise in titer is associated with relapse while a fall is associated with remission. **Box 8** details the treatment strategies used for the management of primary membranous glomerulonephritis.

### IgA Nephropathy

IgA nephropathy is the leading cause of glomerulonephritis worldwide. A multi-hit hypothesis has been proposed in the pathogenesis of IgA nephropathy, with mistracking of the poorly

O-glycosylated galactose deficient IgA1 (Gd-IgA1) into the circulation, thought to be derived from the mucosal B-cells, production of IgG and IgA antibodies against Gd-IgA1, formation and deposition of mesangial immune complexes, and activation of the complement system resulting in immune-mediated injury leads to kidney damage. The antigen-antibody complexes deposit in the kidneys and cause a mesangial (M) and endocapillary (E) proliferative glomerulonephritis which can lead to glomerulosclerosis (S) and tubular atrophy (T). At times, IgA nephropathy can also present as crescentic glomerulonephritis (C). The MEST-C classification of the kidney biopsy provides useful information regarding disease prognostication. The secondary cause of IgA nephropathy such as HIV and cirrhosis should be ruled out. IgA nephropathy often has a smoldering course presenting as a nephritic syndrome with progressive loss of kidney function that may lead to end-stage kidney disease. Recently, it has been shown that decreasing proteinuria to <1 g/day results in better renal survival and has become one of the goals of therapy. **Box 9** shows the therapeutic options for IgA nephropathy.

Many new therapeutic options are being developed for the management of IgA nephropathy. A phase 3 clinical trial to study the effects of a molecule that inhibits the lectin-binding pathway of the complement system is currently being conducted. Another trial studied the effects of oral budesonide (Entocort

#### BOX 5 Recommended Immunization in Patients With Glomerular Diseases

Hepatitis A vaccine (Havrix, VAQTA)  
 Hepatitis B vaccine (Engerix-B, Recombivax HB)  
*Haemophilus influenzae* type B conjugate vaccine (Hib [ActHIB, Hiberix])  
 Annual trivalent inactivated influenza vaccine  
 1 dose thirteen-valent pneumococcal conjugate vaccine (PCV13 [Pneumovax 13]) followed in 8 weeks by a 23-valent pneumococcal polysaccharide vaccine (PPSV23 [Pneumovax 23]), then repeat PPSV23 in 5 years since the last dose; at age 65 years or older, administer 1 dose PPSV23 at least 5 years after the most recent PPSV23  
 Meningococcal Vaccine against sero-group (A, C, W and Y; Menactra, Menveo)<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

#### BOX 6 Minimal-Change Disease Therapy

Prednisone 1 mg/kg (maximum 80 mg) or alternate-day single dose of 2 mg/kg (maximum 120 mg) for 4–16 weeks. Taper slowly in 6 months if complete remission (proteinuria <300 mg/g) is achieved in 4 weeks.

Most patients respond to corticosteroids but 25% of treated patients have frequent relapses and 30% become steroid dependent (two relapses during or within 2 weeks of completing steroid therapy). No response to steroids in 8–16 weeks should be considered steroid resistance.

Second-line agents are calcineurin inhibitors, oral cyclophosphamide (Cytoxan), or rituximab (Rituxan)<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

#### BOX 7 Primary Focal Segmental Glomerulosclerosis Therapy

First line: Prednisone 1 mg/kg q day or 2 mg/kg every alternate day. Continue high-dose steroids for 4–16 weeks until complete remission is achieved, followed by a taper in 6 months.

Second line: Calcineurin inhibitors for patients who cannot tolerate prednisone.

Third line: Patients with frequently relapsing primary FSGS may respond to rituximab (Rituxan)<sup>1</sup>

Fourth line: Mycophenolate mofetil (MMF [CellCept]).<sup>1</sup>

Adrenocorticotropic hormone (ACTH) gel (Corticotropin [HP Acthar]).<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

#### BOX 8 Primary Membranous Glomerulonephritis Therapy

Watchful waiting for 6 months with maximization of ACEi or ARB. Factors associated with low likelihood of achieving spontaneous remission are persistence of >4 g/day of proteinuria with no response to antihypertensive/antiproteinuric therapy in 6 months; presence of life threatening nephrotic syndrome; greater than 30% increase in serum creatinine; and a high anti-PLA2R antibody titer.

Oral cyclophosphamide<sup>1</sup> and prednisone with or without intravenous methylprednisolone (Solumedrol) pulses in alternate months for 6 months. Some centers use cyclophosphamide and prednisone together for 3 months, while others eliminate prednisone altogether.

Calcineurin inhibitors are as effective as cyclophosphamide in inducing remission; however, the risk of relapse after medication discontinuation is high.

Rituximab<sup>1</sup> has similar rates of complete remission as cyclophosphamide, however, the complete remission rate is lower. Furthermore, rituximab-treated patients are less likely to develop adverse events than cyclophosphamide-treated groups.

<sup>1</sup>Not FDA approved for this indication.

ACEi, Angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blockers.

**BOX 9** IgA Nephropathy Therapy

Maximum ACEi/ARB therapy to bring the proteinuria to <1 g/day. If eligible, patients should be provided information about the currently ongoing clinical trials for IgA nephropathy.

Patients who continue to have >1 g/day of proteinuria, despite maximum ACEi/ARB inhibition for >6 months with a BP of <125/75 mm Hg, should receive a 6-month course of corticosteroids if their eGFR is >50 mL/min/1.73 m<sup>2</sup>. Recent data show that patients with eGFR <50 mL/min/1.73 m<sup>2</sup> may benefit from corticosteroid therapy; however, they may experience higher serious adverse events.

Patients with IgA nephropathy in whom >50% glomeruli show crescents should be treated with corticosteroids and cyclophosphamide.<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

ACEi, Angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blockers; eGFR, estimated GFR.

EC)<sup>1</sup> in patients with IgA nephropathy and showed that this agent reduced proteinuria significantly compared to placebo and a phase 3 study is currently being planned.

**Postinfectious Glomerulonephritis**

Acute postinfectious glomerulonephritis presents as nephritic syndrome, acute kidney injury, and low serum complement levels and is more common in children and young adults. This condition was classically described in the convalescence of scarlet fever, but other bacteria, viruses, and protozoa can also cause this condition. Kidney biopsy shows diffuse proliferative glomerulonephritis with prominent mesangial and subepithelial deposits that on immunofluorescence microscopy show positivity for C3 and IgG. It can also present as crescentic glomerulonephritis which portends a poor prognosis. The treatment of renal failure due to postinfectious glomerulonephritis is symptomatic. The primary infection that caused postinfectious glomerulonephritis should be treated appropriately if present at the time of diagnosis. Children have an excellent prognosis with the recovery of kidney function in the vast majority of the patients. However, adults with this condition have a poor renal prognosis with 30% of the patients developing CKD. The outcomes are particularly worse for patients with severe proteinuria with two out of three patients developing progressive kidney dysfunction.

**Membranoproliferative Glomerulonephritis due to Alternate Complement Pathway Abnormalities**

Membranoproliferative glomerulonephritis (MPGN) is a pathological phenotype seen on kidney biopsy characterized by endocapillary proliferative glomerulonephritis, increased mesangial matrix, and thickening of the glomerular basement membranes. Various infectious, autoimmune, vascular, and neoplastic processes can lead to this type of glomerular injury. MPGN is now classified on the basis of disease mechanism rather than the histological findings with an emphasis of staining intensity of C3 and IgG on immunofluorescence microscopy. Presence of both C3 and IgG point toward an immune-complex-mediated process. Predominant C3 staining on immunofluorescence with minimal IgG staining indicates abnormalities in the alternate complement pathway that cause dense deposit disease (DDD) and C3 glomerulonephritis (C3GN). These are rare conditions affecting children and young adults and present as nephritic syndrome, renal function abnormalities, and hypertension. Laboratory data abnormalities include low C3 levels with normal C4 levels (alternate complement pathway abnormality), presence of antibodies (C3 nephritic factor, anti-factors H, B, or I), gene mutations of the alternate complement pathway proteins (complement factor H and I-related protein gene mutations), diminished serum factors that regulate the alternate complement

<sup>1</sup>Not FDA approved for this indication.

**BOX 10** Dense Deposit Disease (DDD) and C3 Glomerulonephritis (C3GN) Therapy

Patients with >500–1000 mg/g of proteinuria should receive ACEi/ARB therapy.

Patients with severe disease and a known autoantibody have been treated with plasma exchange, rituximab<sup>1</sup>, and eculizumab (Soliris)<sup>1</sup>.

Patients with a genetic defect have been treated with plasma exchange with fresh frozen plasma.

Patients with rapidly progressive glomerulonephritis should be treated with plasma exchange, corticosteroids, and cyclophosphamide<sup>1</sup> or mycophenolate mofetil<sup>1</sup>.

<sup>1</sup>Not FDA approved for this indication.

ACEi, Angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blockers.

pathway (serum factor H, B, I, and serum membrane cofactor protein [MCP]), and elevated terminal complement pathway constituents (C5b-9). Treatment options for DDD and C3GN are listed in **Box 10**.

**Fibrillary Glomerulonephritis**

Fibrillary glomerulonephritis is an uncommon condition primarily affecting adults. Kidney biopsy shows amyloid-like deposits; however, they are Congo-Red negative and thus are not truly amyloid. Electron-microscopy shows characteristic findings of randomly organized fibrils sized 10 to 30 nm. One-third of the patients with fibrillary glomerulonephritis have another disorder such as autoimmune disease, malignancy, and monoclonal gammopathy. Recently, our understanding of the pathophysiology of idiopathic fibrillary glomerulonephritis improved significantly with the identification of DnaJ homolog subfamily B member 9 (DNAJB9)—a member of the molecular chaperone gene family—in fibrillary deposits. Almost all the patients with fibrillary glomerulonephritis showed positive immunohistochemistry to DNAJB9 while all the patients with amyloidosis were negative. The disease usually presents as nephritic syndrome. The prognosis is generally poor with most of the patients developing end-stage kidney disease. Antiproteinuric therapy with ACEi/ARB and immunosuppression have been tried with variable results with the patients with milder disease (non-nephrotic range proteinuria and preserved eGFR) more likely to achieve complete remission.

## PYELONEPHRITIS

Method of

Mark Wirtz, MD; Julia R. Lubsen, MD; and Melissa Stiles, MD

### CURRENT DIAGNOSIS

- Clinical manifestations of pyelonephritis include systemic signs and symptoms (fever, chills, sweats, malaise), urinary symptoms (frequency, urgency, dysuria), flank pain, costovertebral angle (CVA) tenderness, nausea, and vomiting.
- Up to 20% of patients do not have urinary symptoms.
- Signs and symptoms such as malaise and altered mental status may be atypical in older adults and immunocompromised patients.
- Urinalysis shows pyuria, bacteriuria, or both. A urine culture growing >10,000 colony-forming units (CFU) of uropathogenic bacteria confirms pyelonephritis in the appropriate clinical context.
- Computed tomography (CT) of the abdomen/pelvis should be considered in patients who have known or suspected nephrolithiasis, acute kidney injury, or concern for complicated pyelonephritis.
- Imaging and repeat urine culture and blood cultures should be considered in patients who worsen or do not improve after 24 to 48 hours of appropriate antibiotic therapy.

### CURRENT THERAPY

- Evaluate the risk for antimicrobial resistance based on local antibiograms and patient risk factors.
- Empiric outpatient treatment
  - Fluoroquinolones or trimethoprim-sulfamethoxazole (TMP-SMX [Bactrim]) are reasonable oral antibiotics.
  - Strongly consider a single dose of a long-lasting empiric intravenous antibiotic such as ceftriaxone (Rocephin) or gentamicin in addition to starting an oral agent.
- Empiric inpatient treatment
  - Ceftriaxone is recommended as empiric coverage.
  - Cefepime (Maxipime), a carbapenem, or an aminoglycoside can be considered if there is concern for ceftriaxone resistance.

### Epidemiology

Pyelonephritis is a common, severe urinary tract infection (UTI) with an annual incidence in the United States of 459,000 to 1,138,00 cases. Pyelonephritis is more common in women than in men, and women are five times more likely to be hospitalized. The highest-risk group for hospitalization are adults older than 65 years of age. In the United States, costs related to pyelonephritis (direct and indirect) are around \$2 billion per year. Recurrent pyelonephritis is uncommon (<10%) and should prompt evaluation for predisposing conditions.

### Pathophysiology and Microbial Etiology

Pyelonephritis is usually caused by an ascending enteric bacterial infection from the bladder but can also be caused by direct seeding via bacteremia. The result is inflammation of the renal pelvis and kidney. Uropathogenic *Escherichia coli* (UPEC) strains account for as much as 80% of all outpatient pyelonephritis in women. Other bacteria implicated include other *Enterobacteriaceae* (*Klebsiella pneumoniae*, *Proteus mirabilis*), *Staphylococcus saprophyticus*, *Candida* species, *Pseudomonas aeruginosa*, *Enterococcus* species, and *Ureaplasma* species. The likelihood of these pathogens increases with male sex, increasing age,

hospitalization, and complicated infections, although UPEC still predominates.

### Risk Factors

Risk factors for pyelonephritis include the following:

- Risk factors for cystitis (personal or maternal history of cystitis, spermicide exposure, new sexual partner, recent sexual intercourse)
- Urinary tract obstruction
- Incontinence in women older than 30 years of age
- Diabetes mellitus
- Genetic predisposition (low *CXCR1* expression resulting in altered immunity)
- Pregnancy

### Clinical Manifestations

Clinical manifestations of pyelonephritis can include systemic signs and symptoms such as fever, chills, sweats, and malaise. Typical urinary symptoms (e.g., urinary frequency, urgency, and dysuria) may be present, but up to 20% of patients do not have any bladder-related symptoms. Other symptoms can include flank pain, CVA tenderness, nausea, and vomiting. Depending on disease severity, signs and symptoms of sepsis may be present. It is important to note that certain groups (older adults, immunocompromised patients) may not have typical systemic or urinary symptoms and can present with only vague symptoms (e.g., malaise) and/or mental status changes.

### Diagnosis

Pyelonephritis should be suspected in patients with flank pain or tenderness and a urinalysis that shows pyuria (2 to 5 white blood cells per high-power field), bacteriuria, or both. As discussed earlier, presenting signs and symptoms may be atypical, especially in older adults and immunocompromised patients. The differential diagnosis of acute pyelonephritis is listed in [Table 1](#).

In the correct clinical context, the diagnosis is confirmed by a urine culture that grows  $\geq 10,000$  CFU of a uropathogenic bacteria. A urine culture should be ordered in all patients suspected of having pyelonephritis. Blood cultures are not recommended for uncomplicated pyelonephritis. Although bacteremia is common, pathogens isolated from blood cultures are usually concordant with pathogens isolated from urine cultures, and blood culture results rarely change management. Blood cultures should be considered in patients with complicated pyelonephritis (see the “Complications” section later in this chapter) and in all patients presenting with severe sepsis and septic shock.

Abdominal imaging is not always needed to diagnose pyelonephritis, but it can identify complications such as urinary tract obstruction, renal or perinephric abscess, and emphysematous pyelonephritis. Initial imaging should be considered in patients who have known or suspected nephrolithiasis, significant acute kidney injury, or concern for complicated pyelonephritis. Imaging and repeat urine culture and blood cultures should be considered in patients who worsen or do not improve after 24 to 48 hours of appropriate antibiotic therapy. In most cases, the preferred imaging test is CT of the abdomen/pelvis with and without contrast

**TABLE 1** Differential Diagnosis of Acute Pyelonephritis

- |   |   |
|---|---|
| • Appendicitis  | • Pancreatitis                            |
| • Cholangitis   | • Perforated viscus                       |
| • Cholecystitis   | • Pelvic inflammatory disease             |
| • Cystitis  | • Pneumonia                               |
| • Diverticulitis  | • Prostatitis                             |
| • Gastroenteritis   | • Renal vein thrombosis, renal infarction |
| • Herpes zoster   | • Nephrolithiasis                         |
| • Musculoskeletal pain  |   |
| • Ovarian cysts, ovarian torsion, ovarian tumors, ectopic pregnancy |   |

enhancement. Renal ultrasonography is more sensitive than CT for diagnosing hydronephrosis and urinary tract obstruction. Noncontrast CT of the abdomen/pelvis is preferred for detecting nephrolithiasis. A CT of the abdomen/pelvis with contrast is best for detecting abscesses and emphysematous pyelonephritis, but contrast may be contraindicated in patients with acute kidney injury.

### Treatment Considerations

The most appropriate empiric treatment and disposition of a patient with pyelonephritis requires consideration of several factors including antimicrobial resistance, ability for close-interval follow-up, host vulnerability, and severity of illness.

Antimicrobial resistance is a significant concern that drives decisions regarding treatment and disposition. Fluoroquinolone resistance (ciprofloxacin, 5.1% to 39.8%) is now as common as TMP-SMX resistance (14.6% to 37.1%) in developed countries. Local antimicrobial resistance may not be known, and hospital antibiograms may not accurately reflect the setting in which the clinician practices. Patient markers for antimicrobial resistance include prior history of a resistant infection or same antibiotic class use in the past year, older age, long-term care or hospitalization, diabetes, and recurrent pyelonephritis. If an appropriate oral antibiotic is not available, hospital admission is warranted until culture data are available.

The ability of close interval follow-up is crucial in the management of pyelonephritis, especially if the outpatient setting is being considered. It is not uncommon for symptoms such as fever, flank pain, and nausea to persist for the first few days of appropriate antibiotic treatment. Hence a patient with stable housing, reliable transportation, and a supportive psychosocial environment would be best suited for outpatient management.

Several risk factors related to host vulnerability can increase morbidity and mortality. Anatomic risk factors include stones, neoplasms, and anomalies that may impair drainage of the urinary tract. Interventional factors can be related to bladder catheters, nephrostomy tubes, or recent instrumentation. Immunologic risks include immunosuppression, older age, and diabetes. Pyelonephritis in pregnancy is dangerous to both the mother and fetus, and it should be treated in an inpatient setting with intravenous antibiotics.

Hospitalization should be considered for patients who have severe pain, intractable nausea and vomiting, and hypovolemia. Patients with complicated pyelonephritis, severe sepsis, or septic shock would warrant hospital admission.

### Outpatient Management

Supportive care is important for all patients. Antiemetics, antipyretics, and analgesics should be given for symptom relief. Patients with hypovolemia, nausea, and vomiting may require intravenous fluid resuscitation.

Antibiotics should be administered quickly, cover the organisms of concern, and have activity in the urine, kidneys, and bloodstream (Table 2). Earlier practice guidelines, including those from the Infectious Diseases Society of America (IDSA), strongly favored fluoroquinolones. However, increasing rates of resistance and the significant adverse effects of fluoroquinolones have led to subsequent guidelines recommending either a fluoroquinolone or TMP-SMX. Additionally, most guidelines also recommend using clinical judgment in escalating therapy beyond a single oral agent to include a supplemental parenteral, long-lasting antibiotic at time of diagnosis if resistance of an organism to the proposed oral antibiotic chosen is greater than a threshold of 10%. Prompt follow-up should be arranged to reevaluate the patient's response and review culture data. Oral beta-lactams (including amoxicillin-clavulanate [Augmentin], cefdinir [Omnicef]<sup>1</sup>, and cefpodoxime [Vantin])<sup>1</sup> have inferior efficacy compared with the fluoroquinolones and TMP-SMX. Their use should be restricted

**TABLE 2** Antimicrobial Therapy for Acute Pyelonephritis

#### Oral

- Ciprofloxacin (Cipro) 500 mg twice daily for 5–7 days
- Ciprofloxacin extended-release (Cipro XR) 1000 mg daily for 5–7 days
- Levofloxacin (Levaquin) 750 mg daily for 5–7 days
- Trimethoprim-sulfamethoxazole DS (Bactrim DS) 160/800 mg twice daily for 10–14 days
- Amoxicillin-clavulanate (Augmentin) 875–125 mg twice daily for 10–14 days
- Cefixime (Suprax) 400 mg daily for 10–14 days
- Cefpodoxime (Vantin)<sup>1</sup> 200 mg twice daily for 10–14 days

#### Intravenous

- Ceftriaxone (Rocephin) 1 g IV/IM every 24 hours
- Cefepime (Maxipime) 1–2 g IV every 8–12 hours
- Piperacillin-tazobactam 3.375 g IV every 6 hours
- Ertapenem (Invanz) 1 g IV every 24 hours
- Meropenem (Merrem)<sup>1</sup> 1 g IV every 8 hours
- Gentamicin 5 mg/kg of body weight IV every 24 hours

Switch to appropriate oral regimen once symptoms improve based on culture and susceptibility results. Total duration of therapy ranges from 5 to 14 days depending on clinical response and oral antibiotic chosen.

to situations in which sensitivities are known and clear contraindications to fluoroquinolones and TMP-SMX exist.

### Inpatient Management

Intravenous antibiotics should be administered promptly for hospitalized patients. Ceftriaxone (Rocephin) is an acceptable option for empiric coverage of uncomplicated pyelonephritis (see Table 2). Other antibiotics such as cefepime (Maxipime), piperacillin-tazobactam (Zosyn), a carbapenem, or an aminoglycoside can be considered if there are risk factors for ceftriaxone resistance or if there is worsening or no improvement after 24 to 48 hours of empiric therapy with ceftriaxone. Multidrug-resistant organisms need special consideration and may warrant consultation with infectious disease. Antibiotic therapy should be tailored based on urine culture and susceptibilities. If the patient is clinically improving, antibiotics can be switched from intravenous to oral administration if there is an acceptable oral option.

### Complications

The treatment of pyelonephritis may be complicated by urinary tract obstruction, renal abscess, emphysematous pyelonephritis, renal failure, and septic shock. Obstruction usually requires drainage for source control, either percutaneous drainage, ureteral stent placement, or Foley catheter placement depending on the location. Urinary tract obstruction can be associated with significant renal failure. Renal abscess formation is often associated with obstruction and may also require drainage. Emphysematous pyelonephritis is a rare, life-threatening, gas-producing, necrotizing kidney infection often associated with diabetes (95% of cases). Emphysematous pyelonephritis is initially managed with antibiotics, glycemic control, and percutaneous drainage, and some cases may require partial or total nephrectomy. Severe pyelonephritis can lead to septic shock and death. Treating these complications may involve consultations with urology, nephrology, interventional radiology, surgery, and critical care.

<sup>1</sup>Not FDA approved for this indication.

## Prevention

At this time, there are no specific preventive measures for pyelonephritis above those for prevention of recurrent cystitis. Of note, long-term studies of antimicrobial prophylaxis demonstrated that breakthrough urinary tract infections were resistant to the prophylactic antibiotic utilized, which should inform treatment of pyelonephritis in this setting. In pregnant patients, treatment of asymptomatic bacteriuria significantly lowers the risk of pyelonephritis.

## TRAUMA TO THE GENITOURINARY TRACT

Method of

Anna Faris, MD; and Yooni Yi, MD

The genitourinary tract is involved in about 10% of trauma cases. The kidney, followed by the bladder and urethra, are the most commonly involved genitourinary organs. In most cases, injury to the genitourinary tract is not isolated, and the initial evaluation of urologic injuries should consider the context of the patient's associated injuries and triage more pressing or life-threatening issues. Still, early involvement of the urologist is prudent to help plan further interventions. The spectrum of genitourinary injuries is widespread, and management can range from immediate repair to temporization with delayed reconstruction. The goal of a urologist in the trauma setting is to establish urinary drainage in order to optimize kidney function, minimize hemorrhage, and control urinary extravasation to reduce associated complications such as infection or ileus.

### Renal Trauma

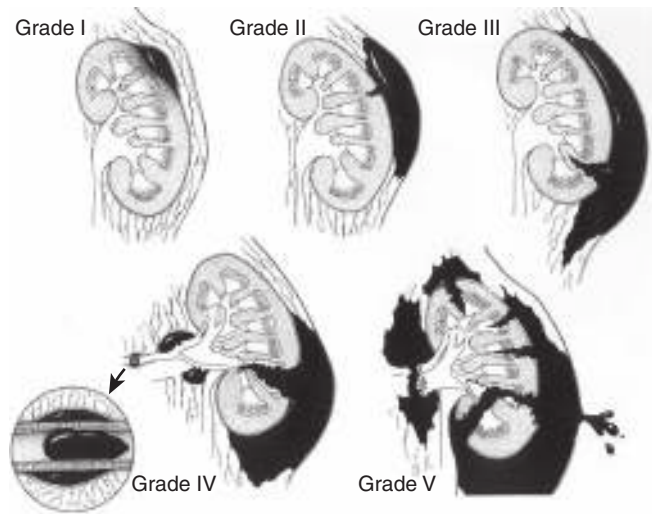

Renal injury occurs in 1% to 5% of all trauma cases. Blunt impact accounts for the majority of renal injuries (82% to 95%) and causes damage secondary to direct organ injury or disruption of the kidney from its attachments (e.g., renal hilum and ureteropelvic junction). Penetrating trauma most commonly is caused by stabbing or gunshot wounds. The damage from penetrating injury can be limited to the tract of the stab wound, or it can be more extensive secondary to necrosis from energy transfer and the blast effect of high-velocity bullets. The history is crucial in the diagnosis of renal injury and should include the mechanism of trauma as well as any preexisting kidney disease or condition that might contribute to worsening renal function. Hematuria has a very poor correlation with degree of injury because disruption of the ureteropelvic junction, arterial disruption or thrombosis, and other severe injuries can exist in a setting with no hematuria.

The American Association for the Surgery of Trauma (AAST) classifies renal injuries into five grades (Figs. 1 and 2):

- Grade 1: Nonexpanding subcapsular hematoma/contusion with absence of parenchymal injury

**Figure 1** Computed tomography scan demonstrating large right perirenal hematoma and thrombosed posterior segmental artery. This was classified as a grade IV renal injury.

**Figure 2** American Association for the Surgery of Trauma grading system for traumatic renal injuries: grade I, renal contusion and subcapsular hematoma; grade II, cortical laceration and perirenal hematoma; grade III, laceration into medulla or segmental renal artery thrombosis without a parenchymal injury; grade IV, laceration involving the collecting system, with or without a devascularized segment and contained vascular injury; grade V, renal artery thrombosis, avulsion of the renal pedicle, and shattered kidney. (From McAninch JW [ed]: *Traumatic and Reconstructive Urology*. Philadelphia, WB Saunders, 1996.)

- Grade 2: Less than 1 cm laceration into the renal cortex, not extending into the collecting system, with a nonexpanding hematoma confined to the perirenal fascia
- Grade 3: Greater than 1 cm laceration, extending through the renal cortex and medulla but not the collecting system
- Grade 4: Laceration extending to the collecting system with urinary extravasation or a segmental vascular injury with contained hematoma; renal artery thrombosis
- Grade 5: Shattered kidney or renal pedicle avulsion

With evolving imaging technology and endovascular management techniques, one group attempted to simplify injury severity grades 4 and 5 as follows:

- Grade 4: Parenchymal laceration involving the collecting system, lacerations of the collecting system with urinary extravasation, renal pelvis laceration and/or complete ureteral pelvic disruption; vascular segmental injuries
- Grade 5: Vascular compromise of the main renal arteries or veins such as laceration, avulsion, or thrombosis

Renal injury should be suspected in any trauma patient who has a penetrating injury with flank ecchymosis, broken ribs, gross or microscopic hematuria ( $\geq 3$  red blood cells per high-power field), a blunt injury with gross hematuria, or a blunt injury with microscopic hematuria and shock (systolic blood pressure  $< 90$  mm Hg). In addition, imaging of the urinary tract should be obtained in children who have more than 50 red blood cells per high-power field even in the absence of hypotension.

In a stable patient, radiographic evaluation should consist of computed tomographic (CT) scanning with intravenous contrast and delayed images showing opacification of the collecting system and ureters (CT urogram). In the absence of a CT scan in a patient who is transported directly to the operating room for exploration, an intraoperative single-film intravenous pyelogram can be performed to confirm that two functioning kidneys are present; however, the poor quality of the images makes them unreliable for staging purposes.

Kidney exploration is indicated for the patient who is hemodynamically unstable despite resuscitation in whom renal injury is thought to be the reason for a life-threatening and persistent hemorrhage. If there are findings of a large perirenal hematoma ( $> 4$  cm) and/or notable vascular contrast extravasation in the setting of a Grade 3–5 injury and hemodynamic instability, intervention should be performed. Another absolute indication for renal exploration and revascularization is renal artery hilar avulsion or renal artery thrombosis when bilateral or in a solitary kidney. In patients undergoing exploratory laparotomy for associated injuries, renal exploration should be performed only in the presence of an expanding or pulsatile hematoma. Exploration of a nonexpanding, nonpulsatile hematoma is associated with a higher rate of nephrectomy and should be avoided. Almost all other injuries can be managed conservatively or with minimally invasive methods. Patients with bleeding specifically limited to segmental renal vessels and who are stable can be taken for angioembolization. This minimally invasive procedure is only appropriate at institutions with skilled and available interventional radiologists.

Increasing rates of conservative management have greatly decreased rates of nephrectomy, with current practice revealing 80% of high-grade injuries managed conservatively. The factors most predictive of nephrectomy are grade of injury and penetrating injury.

Nonoperative management consists of supportive care with intravenous hydration, antibiotics, bedrest, and serial measurements of hemoglobin and hematocrit. Patients can ambulate after they are clinically stable, gross hematuria has resolved, and the hemoglobin and hematocrit have been relatively constant over 24 hours.

Routine early follow-up imaging for grades 1 to 3 blunt renal injury is unnecessary. Any imaging should be motivated by a change in the patient's clinical situation or laboratory values. Follow-up imaging is indicated within 48 hours of initial injury for patients with grade 4 or 5 injuries. Imaging is also prudent in cases with concern for worsening urinoma or hematoma that might require further intervention. Clinical signs such as worsening flank or abdominal pain, abdominal distension, fevers, and/or continued drop in blood counts can alert clinicians to such complications. Additionally, there should be periodic monitoring of blood pressure following renal trauma.

### Ureteral Trauma

Trauma to the ureter is rare (1% of all genitourinary trauma). This is most likely because of its position in the retroperitoneum and bony pelvis protection, its relatively small caliber, and its mobility. The etiology of ureteric trauma is mostly iatrogenic occurring secondary to gynecologic, general surgery, and urologic procedures. Ureteral injury should be suspected in all cases of penetrating trauma to the abdomen, especially with high-velocity projectiles, because of the blast effect.

The AAST has classified ureteric injuries into five grades of severity:

- Grade 1: Hematoma only
- Grade 2: Injury involving less than 50% of the circumference of the ureter

- Grade 3: Injury involving greater than or equal to 50% of the circumference of the ureter
- Grade 4: Complete transection with less than 2 cm of devascularization
- Grade 5: Complete transection with more than 2 cm of devascularization

The diagnosis usually is made intraoperatively if a high suspicion of ureteric injury is present or postoperatively by imaging obtained for investigation of fistula formation or clinical signs of upper tract obstruction. Hematuria is not a sensitive marker for ureteral injury; therefore, lack of hematuria does not portend a lack of ureteral injury. For non-iatrogenic injuries, imaging should be obtained in patients who had rapid deceleration or penetrating injuries to the flank. Imaging modalities used are usually intravenous pyelography, CT scanning with intravenous contrast and delayed images (CT Urogram), and retrograde pyelography. Findings indicative of ureteral injury include contrast extravasation, ureteral narrowing, and delayed peristalsis (Fig. 3). Alternatively, the ureters may be interrogated intraoperatively by using direct inspection, injection of intravenous methylene blue<sup>1</sup>, or by passing a ureteral catheter (if it passes easily, an injury is unlikely).

Grade 1 and 2 injuries can be managed initially by placement of a ureteral stent. If grade 2 or 3 injuries are identified immediately during exploration for a suspected ureteric injury, they can be managed by primary closure of the ureteric injury over an internal stent and placement of an abdominal drain as long as there is no associated thermal injury or necrosis. Grade 3 through 5 injuries usually require debridement of nonviable ends with re-anastomosis over an internal ureteral stent or more complicated surgical procedures involving mobilization of the bladder and reimplantation of the ureter into the bladder. In an unstable patient, ureteral repair may be managed with temporary urinary drainage and a definitive repair in a delayed fashion. If internal ureteral stent placement is not possible, percutaneous nephrostomy tubes can be placed. An additional drain may be required if the urine leak is not contained by nephrostomy tubes alone. The type of ureteral repair depends on the amount

<sup>1</sup>Not FDA-approved for this indication.

**Figure 3** Intravenous pyelogram demonstrating extravasation of urine from right mid-ureter.

of devitalized tissue and the location of the injury (proximal, mid, or distal ureter). Ureteroureterostomy, transureteroureterostomy, ureterocalicostomy, renal autotransplantation, uretero-neocystostomy with or without Boari flap or psoas hitch, and bowel interposition are all treatment options for various degrees of ureteral injuries.

### Bladder Trauma

Blunt trauma accounts for 51% to 86% of bladder injuries resulting from external trauma, and approximately 70% (35% to 90%) of those patients have associated pelvic fractures. The most common cause of blunt trauma is motor vehicle crashes. Penetrating trauma accounts for 14% to 49% of traumatic bladder injuries. The incidence of iatrogenic injury varies by procedure but is highest for hysterectomy and other obstetric and gynecologic procedures. In cases of blunt trauma, injury should be suspected in patients who have pelvic fractures, suprapubic pain, inability to void, ileus or abdominal distention. For iatrogenic injuries, urine in the field, visible laceration of the bladder, or gas distention of the urinary drainage bag in laparoscopic surgery warrants further investigation. It is important to delineate whether a bladder injury involves intraperitoneal or extraperitoneal rupture. Intraperitoneal rupture often occurs at the level of the bladder dome, where the muscular support is weakest (Figs. 4 and 5).

The diagnostic test of choice is a cystogram, in which the bladder is filled with contrast to capacity (350 to 400 mL instilled by gravity). Passive filling of the bladder by clamping of the catheter is associated with unacceptably high rates of false-negative tests. With cystography, it is important to obtain scout imaging prior to fill and post-drainage films (if obtaining plain film cystography, may consider oblique views). Before placement of a foley catheter, retrograde urethrography should be performed if there is a suspicion of urethral injury

Most extraperitoneal bladder ruptures can be managed with Foley catheter drainage for 7 to 10 days. Bladder neck involvement, concomitant vaginal or rectal injuries, presence of bone fragments in the bladder, or bladder wall entrapment necessitate

surgical intervention. Intraperitoneal ruptures should be managed with surgical exploration because of the associated ileus and peritonitis caused by urine leak. It is recommended that penetrating bladder injuries are explored and repaired because of the risk of necrosis. Bladder repair is performed with a multiple-layer closure and catheter drainage for 7 to 10 days.

### Urethral Trauma

Traumatic injury to the urethra occurs in 1.5% to 10% of patients who sustain a pelvic fracture. Female urethral injuries are very rare. The male urethra is anatomically divided into a posterior portion (prostatic and membranous urethra) and an anterior portion (bulbous urethra, penile/pendulous urethra, and fossa navicularis). Injury to the anterior urethra occurs mostly from blunt trauma, penetrating injuries, or instrumentation. Posterior urethral injuries are usually associated with pelvic fractures but can occur secondary to blunt, penetrating, or iatrogenic injury.

Classic signs of urethral injury include blood at the meatus, a high-riding prostate on rectal examination, inability to void, or perineal or scrotal ecchymosis. Imaging is indicated with any of these signs. The imaging study of choice is a retrograde urethrogram, and it should be performed before placement of a urethral catheter is attempted. In the absence of any signs, the diagnosis is most frequently made when retrograde urethrography is performed to investigate difficulty with urethral catheter placement (Fig. 6).

The AAST grading system does not distinguish between anterior or posterior injury but classifies urethral injuries as follows:

- Grade 1: Contusion and blood at the meatus with normal urethrogram
- Grade 2: Stretch injury with no extravasation of contrast
- Grade 3: Partial disruption with contrast extravasating at the injury site but still reaching the bladder

**Figure 4** Intraperitoneal bladder rupture. Note contrast extravasating from the dome of the bladder and outlining the small intestine as well as the left colon.

**Figure 5** Extraperitoneal bladder rupture seen on computed tomographic cystogram.

**Figure 6** Retrograde urethrogram diagnostic of partial bulbar urethral transection resulting from straddle injury.

- Grade 4: Complete disruption with contrast not reaching the bladder; urethral defect of less than 2 cm
- Grade 5: Complete disruption with urethral defect greater than 2 cm or complex injury involving the bladder neck, prostate, rectum, or vagina

Grade 1 and 2 injuries can be managed conservatively by the placement of a urethral catheter. Management of grade 3 urethral injury should initially emphasize stabilization of the patient because extensive bleeding could be present in cases of severe injury to the pelvis. Placement of a catheter may be attempted even if there is a suspicion of partial urethral injury. If this is met with difficulty, a suprapubic tube may be placed.

In cases of complete disruption, prompt urinary drainage should be established by placement of a suprapubic tube catheter. This can help facilitate a primary realignment or repair with delayed urethroplasty. Primary realignment involves endoscopic passage of a guidewire across the defect and placement of a catheter over the guidewire. Immediate open repair is rarely indicated unless complex injury extends into the bladder neck, rectum, or vagina. Immediate exploration is recommended for anterior urethral injuries associated with penetrating trauma or penile fractures. Female urethral injuries are optimally treated at initial presentation to decrease the risk of incontinence. Physicians should continue to follow patients for at least 1 year, monitoring for complications such as incontinence, erectile dysfunction, and stricture formation.

### Trauma to the External Genitalia

Injury to the scrotum is most frequently secondary to blunt trauma and can cause a hematoma, ecchymosis, or testicular injury. Scrotal swelling and patient discomfort can make separation of testicular injury from extratesticular scrotal trauma difficult on physical examination. In the case of blunt scrotal injuries, a scrotal ultrasound should be performed in most patients with suspicion of testicular rupture. A heterogeneous echo pattern in the testicular parenchyma on ultrasonography suggests testicular injury (Fig. 7). Visualization of a tear in the tunica albuginea is less accurate. Ultrasound studies with Doppler additionally provide information about any compromise in testicular blood flow. In the setting of penetrating scrotal injury, surgical exploration is recommended.

Scrotal exploration should be performed whenever testicular injury is suspected. If the tunica is ruptured and there is extrusion of seminiferous tubules, the extruded tubules should be debrided, hemorrhage controlled, and the tunica closed. Testicular salvage rates are highest when the scrotum is explored acutely compared to delayed exploration. Another possible

**Figure 7** Testis ultrasound image demonstrating heterogeneous architecture characteristic of testicular rupture.

indication for scrotal exploration is a large hematoma; evacuation of the hematoma can decrease the morbidity associated with protracted recovery and resolution of the hematoma and can occasionally identify a manageable source of bleeding. Scrotal exploration should also be performed in cases of inconclusive ultrasound findings or whenever the clinical suspicion for testicular injury is high.

Trauma to the penis can range in severity from a contusion to complete amputation. In cases of penile amputation, stabilization of the patient is important, and the need for transfusion should be addressed. Immediate microreplantation is the management technique of choice if available. The severed penile segment should be immediately placed in a normal saline bag over ice to help preserve the fragment for reimplantation.

A penile fracture occurs after blunt injury to the erect penis rupturing the tunica albuginea. Such injuries are usually incurred during sexual intercourse and patients often report a “crack” or a “pop” followed by pain and detumescence. The hematoma is usually limited to the penis, unless the injury also involves Buck fascia, causing ecchymosis and bruising that involves the scrotum as well. Surgical exploration, closure of the fascial defect, and repair of any associated urethral injury should be done acutely. In cases of unclear history or physical examination, the provider may consider penile ultrasound or penile MRI for more conclusive evidence of a penile fracture. It is also important to rule out associated urethral injury, which occurs in 10% to 22% of the cases.

In females, blunt trauma to the vulva is rare. Injuries to genitalia can be associated with sexual assault and must be evaluated in that context. Consequently, vaginal smears should be taken, and the vagina should be thoroughly inspected under anesthesia with a speculum.

Trauma resulting in skin loss, such as burns, large abrasions, and avulsions, should be explored and debrided in an effort to stage the injury and decrease the risk of complications such as Fournier gangrene. Delayed reconstruction can be performed after stabilization and proper delineation of viable versus nonviable tissues. The reconstructive options include mobilization of local flaps or skin grafts.

### Conclusion

Critical considerations when treating urogenital trauma include patient stability, mechanism of injury, and maintaining broad differentials for organ involvement. Appropriate imaging in the hemodynamically stable patient is crucial to avoid missing injuries that can risk severe complications such as uncontrolled bleeding, urine leaks, and infections. Guidelines have migrated towards more conservative treatments demonstrating success in select cases such as decreased nephrectomy rates and improved urethral healing without strictures. Early involvement of a urologist to guide proper workup and management can help optimize recovery outcomes.

## URETHRAL STRICTURE DISEASE

Method of

Hadley Wyre, MD; and Sable Shew, MD

### CURRENT DIAGNOSIS

- Perform a thorough history and physical examination, delineating past trauma, instrumentation, and sexual history, as well as a complete genitourinary examination.
- Patients with urethral stricture will commonly present with obstructive symptoms of weak urinary stream, straining to urinate, and even frank urinary retention.
- In-office testing consists of urinalysis and urine culture for evaluation of infection, as well as uroflowmetry and postvoid residual bladder ultrasound to evaluate urine flow rate and emptying ability.
- Retrograde urethrogram remains the gold standard for diagnosis of urethral stricture disease.

### CURRENT THERAPY

- In the acute setting of urinary retention, the ideal management would be placement of a suprapubic tube to avoid manipulation of the stricture; however, dilation and catheter placement may be appropriate or necessary in some patients.
- Depending on the patient, goals of care should be delineated regarding treatment of stricture disease; that is, definitive therapy versus chronic management of stricture symptoms.
- Endoscopic treatments are available and include urethral dilation and direct visualization internal urethrotomy; however, repeat attempts at these approaches have a low long-term success rate.
- Surgical management includes both anastomotic and augmentation urethroplasty—both of which are more invasive than endoscopic approaches but are known to have improved long-term patency rates.

Urethral stricture disease affects 0.6% of the male population and can be classified in multiple ways: anterior versus posterior, benign versus malignant, extrinsic versus intrinsic, and congenital versus acquired. The urethra is a conduit for urine from the bladder to outside of the body. In males, the anterior urethra (region encircled by corpus spongiosum) begins at the meatus and includes the fossa navicularis, penile urethra, and bulbar urethra—strictures here are the result of scarring of the urethral epithelium and surrounding spongy tissue, termed spongiofibrosis. As this scarring narrows the urethral lumen, symptoms become noticeable. Typically, the urethral lumen must narrow to less than 14 French for this scarring to be the cause of any voiding symptoms. Anterior urethral stricture can be secondary to iatrogenic injury, infections, penile/perineal trauma, pelvic fractures, and self-instrumentation. In the posterior urethra, including the membranous urethra, prostatic urethra, and bladder neck, narrowing is termed contracture or stenosis and is the result of a distraction injury sustained during pelvic trauma or prior surgical procedures of the prostate (Figure 1).

### Diagnosis

Often patients with strictures will present with obstructive voiding symptoms including weak or intermittent stream, postvoid dribbling, straining to urinate, or overt urinary retention. Nonobstructive symptoms include postvoid fullness, urinary tract infections, and pelvic pain. A thorough history, including a detailed social/sexual history, and physical examination should be done,

**Figure 1** Anatomy of male urethra. (A) Penile urethra. (B) Bulbar urethra. (C) Prostatic urethra. White arrow by A=fossa navicularis; white arrow between B and C=membranous urethra.

and any prior trauma to or instrumentation of the genitourinary tract noted. The physical examination should be comprehensive, with the genital examination examining for palpable strictures in the anterior urethra.

Laboratory workup should include urinalysis and urine culture for evaluation of infection, as well as a basic metabolic panel to evaluate for any renal function compromise. It is possible to perform an assessment of voiding symptoms in a clinic setting with the use of postvoid ultrasound and uroflowmetry. Once the patient has voided to completion, an ultrasound measurement of postvoid residual urine volume can objectively estimate the patient's ability to evacuate and alert the provider to overt retention. Uroflowmetry is the measurement of flow rate of urine—findings that suggest significant stricture include an elongated voiding time and a low maximal flow rate, essentially flattening the flow curve to a plateau appearance.

The gold standard in urethral stricture diagnosis remains the retrograde urethrogram. Radiocontrast is administered via catheter in a retrograde fashion, filling the urethra and opacifying it—this study is especially helpful for evaluating the length, location, and severity of strictures in the anterior urethra. Additionally, an antegrade study, or voiding cystourethrogram, can be performed to allow for visualization of the bladder neck, prostatic urethra, and membranous urethra. In addition to cystoscopic evaluation for direct visualization of the stricture, ultrasound of the penis/perineum can be used to further delineate characteristics of the stricture. Biopsy is occasionally performed to rule out malignancy as a cause of the stricture (Figure 2).

### Acute Treatment

Acutely, the main complication from a urethral stricture is frank urinary retention, which may be associated with a decline in renal function. Typically a urethral catheter cannot be placed because of obstruction from the stricture. In the setting of overt urinary retention, a suprapubic tube is often placed at the bedside or in the operating room to allow for rapid decompression of the urinary system without manipulating the stricture. There are times where suprapubic tube placement may not be possible, and it is therefore reasonable to dilate the stricture and place a urethral catheter to drain the urine. However, manipulation of the stricture can lead to an increase in the length of the stricture and complexity of the eventual repair.

### Long-Term Treatment

Multiple modalities exist for the treatment of urethral stricture disease, with varying success rates and complication rates. A thorough discussion between the patient and provider, considering the patient's goals for either cure or symptom management, life expectancy, and stricture qualities, is vital to

**Figure 2** Bulbar urethral stricture visualized on retrograde urethrogram.

ensuring that an appropriate care plan is developed. Prior to proceeding with any treatment, it is essential to evaluate the urethra proximal to and distal to the stricture with the modalities mentioned earlier; this is to ensure removal of all affected tissue and prevent recurrence.

Conservative management with urethral dilation is appropriate as a first attempt at treatment of a short stricture with minimal spongiofibrosis, with the ultimate goal of stretching rather than tearing tissue to open the lumen without increasing the scarring present. Direct visualization internal urethrotomy (DVIU) is opening of a stricture—by laser, cold knife, or hot knife—to release the scar and allow the urethra to heal at a larger diameter over a catheter. Long-term success rates for DVIU have been reported at 20% to 30% for short strictures with minimal spongiofibrosis. It is important to note that the success rate of repeat DVIU is close to 0%, and after failure, the patient should be referred for definitive surgical repair.

Surgical management includes operations to excise the scar and perform urethral anastomosis, and tissue transfer reconstruction with harvesting of distant tissue—typically oral mucosa—for urethral augmentation. Anastomotic urethroplasty is best for short strictures, 1 to 2 cm in length, while augmentation urethroplasty can be utilized for much longer defects. For any type of urethral reconstruction, resticture is the most common complication, as well as sexual dysfunction and ejaculatory dysfunction. Other treatment options include long-term suprapubic tube drainage, perineal urethrostomy, and urinary diversion, depending on each patient's individual case and discussion with the patient's surgeon. Regardless of modality, clinicians should monitor patients for symptomatic recurrence of strictures.

## URINARY INCONTINENCE

Method of

Simon Patton, MD; and Renee M. Bassaly, DO

### CURRENT DIAGNOSIS

- Urinary incontinence is broadly categorized as stress urinary incontinence or urgency urinary incontinence.
- The diagnosis can often be determined by a careful history and physical examination but can be aided with noninvasive methods such as a bladder diary.
- It is important to rule out any other potential causes of incontinence including urinary tract infection, urinary retention, or medication side effect.

### CURRENT THERAPY

- Modest weight loss has been shown to help both forms of incontinence and is an important first-line therapy.
- Urgency urinary incontinence can initially be managed with lifestyle modifications including timed voiding and avoidance of bladder irritants, as well as physical therapy. Further options include medications (anticholinergics or B<sub>3</sub> agonists).
- Third-line therapy for urgency urinary incontinence includes sacral neuromodulation, botulinum toxin injections, and tibial nerve stimulation.
- Stress urinary incontinence can be managed conservatively with home Kegel exercises or formal pelvic floor training with physical therapy. Mechanical urethral support using a disposable tampon-like device or incontinence pessary is another non-invasive option.
- Surgical management of stress urinary incontinence is midurethral slings, principally using synthetic mesh. I would include Burch and autologous sling.

## Epidemiology

Urinary incontinence is a very common problem particularly in the female population, with incidence roughly twice that of male patients (30% vs. 17%). The exact incidence may be difficult to know, however, because this is a sensitive subject that patients may not volunteer unless solicited. The annual cost of treating incontinence is estimated to be \$24 billion, and annually 260,000 women undergo surgery for stress incontinence.

## Risk Factors

Risk factors vary between genders. Women are at greater risk due to anatomic differences, principally a shorter urethral length. Other risk factors include increased age, parity, obesity, diabetes, smoking, and pelvic radiation. In male patients a history of prostate surgery or an enlarged prostate are potential risk factors. Urinary tract symptoms including incontinence may represent manifestations of neurologic disorders including history of stroke, multiple sclerosis, or spinal cord injury.

## Pathophysiology

The bladder consists of a smooth muscular reservoir (the detrusor muscle), two inlets (the ureters), and an outlet (the urethra). Urine from the kidneys enters the bladder via the ureters and exits via the urethra, which is itself a muscular tube consisting of smooth and striated muscle. Bladder function has two phases: storage and emptying. During the storage phase, the bladder collects urine; this phase involves relaxation of the detrusor muscle and contraction of the urethral muscle, all of which is under sympathetic and voluntary control. The emptying phase involves relaxation

of the urethral muscles and contraction of the detrusor, which is mediated by the parasympathetic system. Under normal circumstances, emptying is voluntarily initiated in the adult.

In women, the bladder and urethra are supported by the anterior vaginal wall, which, in turn, is suspended by connective tissue attachments from the pelvic floor muscles. Continence is maintained when the urethral closure pressure exceeds the detrusor pressure. Adequate support from the anterior vaginal wall is required to maintain this relationship during periods of increased intraabdominal pressure. Consequently, urinary continence depends on the relative relaxation of the detrusor, the contraction of urethral muscles, and the support of the anterior vaginal wall. Incontinence can ensue when these relationships are disrupted.

### Prevention

The pelvic floor musculature plays an important role in the maintenance of continence, and as such, pelvic floor physical therapy directed at these muscles has been shown to improve continence in both postmenopausal women and younger postpartum women, at least in the short term. Physical therapy in the male population has not been studied as a prevention strategy. One modifiable risk factor for incontinence is obesity, and even a modest weight loss of 10% has been shown to help improve continence status.

### Clinical Manifestation

Urinary incontinence can be a sign, symptom, as well as a diagnosis. Urinary incontinence falls into two broad categories: stress incontinence and urge incontinence. Stress urinary incontinence occurs when urethral closure pressure cannot increase sufficiently to compensate for a sudden increase in intraabdominal pressure, as from laugh, cough, or Valsalva maneuver. Urgency urinary incontinence occurs when an unintended bladder contraction creates an insuppressible urge to void, leading to urinary leakage. When patients have signs or symptoms of both stress and urge incontinence, it is referred to as *mixed urinary incontinence*.

### Diagnosis

Diagnosis rests principally on a careful history and physical examination. A thorough history is important to solicit what causes a patient to leak. Leakage with laughing, coughing, sneezing, exercise, or similar exertion would likely be stress urinary incontinence. Leakage associated with an urge that is difficult to defer is likely urgency urinary incontinence. If patients have both symptoms, then they likely have mixed urinary incontinence. If a patient complains of symptoms of mixed incontinence, a careful history to determine which is most bothersome is important. If the patient has difficulty knowing what has caused their leakage, a 3-day bladder diary recording liquid consumed, times and amounts voided, and leakage events with associated symptoms can help with diagnosis and treatment.

Other pertinent components to a thorough history include surgery to the spinal cord, bladder neck, or pelvic floor, which may lead to obstruction; neurologic disease (e.g., multiple sclerosis or a spinal cord lesion); or psychiatric disease (e.g., dementia, which may limit the ability to recognize a need to void). Musculoskeletal function, with emphasis on mobility, should be reviewed. A detailed medication history will identify any medications that may affect urine output or bladder function. It is important to also elicit any other symptoms that may coexist with incontinence and signal pelvic floor dysfunction, including nocturia, fecal incontinence, or constipation.

After a thorough history, a detailed physical examination is necessary. A focused genitourinary examination includes inspection of the external genitalia. Eliciting reflexes from the S2-S4 nerve roots will help determine whether there is any neurologic component. In female patients, perform a pelvic examination and look for any prolapse or pelvic masses and note whether any atrophy is present. Palpation of the urethra allows for evaluation of any urethral masses or possible diverticula. Lastly, assessment of pelvic floor musculature is important, evaluating for any pain or discomfort in the levator ani muscles and assessing the patient's

ability to perform a proper Kegel exercise. In males, performance of a digital rectal examination is recommended to evaluate for any prostatic masses or hypertrophy.

The physical examination provides an opportunity for diagnosis as well; asking the patient to cough or perform a Valsalva maneuver allows for the direct visualization of stress incontinence if present. Additionally, this provides an opportunity in female patients to evaluate for prolapse and assess urethral mobility. Historically, this was done by placing a cotton swab in the urethra to observe for hypermobility seen with >30 degrees of mobility on strain from baseline. However, because of patient discomfort, this test is not routinely performed. After completing the physical examination, one must perform a urinalysis to rule out any infectious etiology and at times perform a post-void residual (either with a bladder scan or with catheterization) to evaluate for any possible voiding dysfunction. If the patient has a more complex history because of prior urologic surgery, neurologic disease, or is difficult to diagnose on history and physical alone, then complex urodynamic testing may be indicated.

### Differential Diagnosis

The differential diagnosis for urinary incontinence includes stress urinary incontinence, urgency urinary incontinence, and a mixture of the two as mentioned above. Other causes of undesired leakage of urine include overflow (due to urinary retention), functional (due to impaired mobility or mental capacity), as well as a fistula or diverticulum. A patient with a fistula most commonly presents with the complaint of constant persistent urinary leakage. In the industrialized world these generally form after genitourinary surgery, whereas in developing countries trauma from childbirth is the primary cause. A diverticulum may present with a painful anterior vaginal wall mass as well as irritative voiding symptoms such as urinary frequency, urgency, dysuria, and postvoid dribbling. Other causes of lower urinary tract symptoms such as urgency, frequency, and dysuria include urinary tract infection, uncontrolled diabetes, or urinary tract malignancy.

### Therapy

#### Stress Urinary Incontinence

Nonsurgical options for treatment of stress urinary incontinence include strengthening of the pelvic musculature through Kegel exercises and mechanical support of the urethra. Kegel exercises may be performed by the patient at home, although some patients may have difficulty identifying the muscles to perform them properly. Formal training with a pelvic floor physical therapist can help the patients learn to identify the muscles (sometimes using biofeedback devices) and contract them appropriately. Proper contraction of the levator ani muscles provides improved support for the bladder and urethra and helps decrease leakage.

Mechanical support of the urethra and bladder neck can be accomplished using an incontinence pessary or a disposable incontinence tampon. Pessaries are ring-shaped silicone devices with a knob that is meant to sit under the urethra. Patients are fitted for the correct size in the office. Patients must be followed up for at 3 to 6 month intervals to ensure the pessary has not caused any erosions or excoriations. This can be avoided by teaching patients how to insert and remove the pessary themselves or prescribing a vaginal estrogen cream in postmenopausal patients. A disposable option is available over the counter as well. It comes in three sizes, and the patients can fit themselves at home with the starter pack. Once they find the correct size, it can be placed when the patient desires and may be kept in place for up to 8 hours. Some patients choose this option if they only have stress incontinence during certain times (i.e., exercise).

If conservative therapies do not adequately address their complaints, surgical options are available. The general principle of restoring support to the urethra is the same as in conservative therapies. This can be accomplished by placing a sling under the urethra. The sling material can be lightweight polypropylene mesh or fascia (either autologous or cadaveric). The most commonly used type is the synthetic mesh and it is placed either

retropubically or through the obturator membrane. Both methods have been shown to have a high rate of satisfaction with a low complication rate.

Stress incontinence in men is much less common but can also be treated with slings placed at the bulbar urethra. Artificial urinary sphincters can also be implanted that compress the urethra and can be controlled by the patient.

### Urgency Urinary Incontinence

Lifestyle modifications are a good first-line therapy for patients with urgency urinary incontinence. Drinking an appropriate amount of fluids and avoiding foods and beverages that are known to irritate the bladder can provide significant relief. Additionally, performing timed voiding can help retrain the bladder. Formal training with a pelvic floor physical therapist has also been shown to significantly decrease incontinence episodes. It is important to note, however, that just performing Kegel exercises is often not adequate in these patients and can in fact worsen their symptoms if they already have tightly held, nonrelaxing pelvic floor musculature.

Pharmacologic therapy consists of anticholinergic medications or beta 3 agonists. Anticholinergic medications target the muscarinic receptors on the bladder; however, they are not specific and can cause significant dry mouth, dry eyes, and constipation, side effects that lead to a high discontinuation rate. Patients are unable to take this class of medication if they have closed-angle glaucoma. Additionally, there have recently been some concerns raised about long-term use leading to cognitive decline. The beta 3 agonists also work to slow down detrusor contractions but do so by targeting a different receptor. They have been shown to raise blood pressure and so are precluded in patients with uncontrolled severe hypertension; all patients should routinely check their blood pressure after starting one of these medications.

Third-line therapies for urgency urinary incontinence include sacral neuromodulation, tibial nerve stimulation, and intradetrusor injection of botulinum toxin A. Sacral neuromodulation has been approved by the Food and Drug Administration for this indication, as well as fecal incontinence and voiding dysfunction. It consists of a lead placed in the S3 foramen and connected to a pacemaker-like device that is implanted in the adipose of the buttocks. Patients are then able to control some of the settings (including program and amplitude) from an external device. The sacral nerve roots can also be stimulated via the tibial nerve. Treatments involve a small, acupuncture-sized needle placed in the tibial nerve followed by 30 minutes of stimulation. These are carried out at weekly treatments for 12 weeks followed by monthly maintenance therapy.

Botulinum toxin A, a neurotoxin that works by decreasing the pre-synaptic release of acetylcholine, can be injected directly into the detrusor muscle. A risk of this treatment is urinary retention, which requires that patients be able to perform self-catheterization.

### Mixed Urinary Incontinence

If a patient presents with components of both stress and urgency, eliciting first which symptom is the most bothersome allows for appropriate tailoring of treatment. It is important to remind patients that even a modest weight loss of 10% can help reduce bothersome urinary symptoms by up to 60%. As noted above, physical therapy can help address both type of incontinence as a valuable first-line therapy.

### Overflow Incontinence

If a patient is diagnosed with overflow incontinence, then management is directed at maintaining an empty bladder through self-catheterization. In male patients, if the retention is due to prostatic hypertrophy, then pharmacologic therapy with  $\alpha$ -agonists or 5 $\alpha$  reductase inhibitors may be warranted. If medication fails to improve their symptoms, then surgical treatment with ablation (microwave or radiofrequency) or resection is indicated.

### Complications

Urinary incontinence can cause significant morbidity in terms of financial as well as psychological burdens on patients. In addition to causing rashes and skin breakdown, incontinence also leads to depression, isolation, anxiety, depression, and increased risk of falls. Incontinence is one of the leading causes of institutionalization in the elderly. As the population ages, the incidence of incontinence will continue to increase, making its diagnosis and treatment increasingly important.

## BENIGN PROSTATIC HYPERPLASIA

Method of

Judd W. Moul, MD

### CURRENT DIAGNOSIS

- Benign prostatic hyperplasia (BPH) is an extremely common condition in aging men, characterized by prostate gland growth that can obstruct the flow of urine and cause urinary symptoms.
- Diagnosis of BPH is usually based on symptoms of weak urine stream, hesitancy, intermittent stream, nocturia, and dribbling. These symptoms are generally called *lower urinary tract symptoms* (LUTS).
- Additional diagnostic aids include digital rectal examination (DRE), urinary flow rates and post void residual (PVR) measurements, PSA blood test, cystoscopy, and sometimes urodynamic testing.

### CURRENT THERAPY

- Medical therapies include alpha blocker agents (most commonly tamsulosin) and five-alpha reductase inhibitors (finasteride or dutasteride), sometimes used individually or together.
- Surgical therapy includes transurethral resection of the prostate (TURP) using electrocautery or laser devices, and open or robotic simple prostatectomy for men with very large gland size.
- More recent minimally-invasive surgical approaches include Uro-Lift, REZUM, prostate artery embolization (PAE), and various laser techniques such as laser enucleation procedures (such as HOLEP).
- Therapy is individualized based on degree of urinary symptoms, patient bother, and the size of the prostate.

Benign prostatic hyperplasia (BPH) is a disease process characterized by the increased growth of prostatic cells within the prostate gland, which sits at the base of the bladder and surrounds and fuses with the urethra. These glandular changes may result in changes in urinary flow, collectively known as lower urinary tract symptoms (LUTS). The presence of LUTS such as weak stream, increased frequency and urgency of urination, nocturia, and the feeling of incomplete bladder emptying occurring secondary to prostate enlargement are more accurately characterized as benign prostatic obstruction (BPO); however, most clinicians routinely and acceptably apply the BPH diagnosis. Although many other disease processes (i.e., congestive heart failure, poorly controlled diabetes, renal failure, and many others) can contribute to LUTS in males, BPH is a leading contributor to urinary dysfunction in older males and is known to significantly affect quality of life.

### Epidemiology

BPH is generally considered a disease of the aging male, with associated symptoms uncommon before the age of 40 years. By ages 60 and 85 years, the histologic prevalence of BPH at autopsy is 50% and 90%, respectively. Likewise, the associated LUTS increase with age. At age 70 years, about 40% of men report LUTS; by age 75 years, the incidence of LUTS increases to 50%.

### Pathophysiology

Although BPH is common, we know very little about its true pathophysiology. Current thought attributes BPH to an “awakening” of senescent epithelial and smooth muscle cells of the prostatic transition zone. Before the 1980s, BPH was generally thought of as a static condition of a gradually growing prostate gland causing progressive bladder outlet obstruction, following the “donut hole” analogy that the prostate is like a donut surrounding the bladder neck and outlet. With aging and prostate growth, the donut hole gets smaller, causing progressive obstruction. In the era when surgical treatment via transurethral resection of the prostate (TURP) was the only effective treatment, this simple static explanation was sufficient. We now know that BPH has both a static obstructive and a dynamic component under neural control. In addition, the contribution of the bladder to LUTS has been well recognized as a key contributor to the dynamic component of BPH and LUTS.

Specifically, the static growth and proliferation of the periurethral tissue in BPH is thought to be driven by androgens, as men castrated before puberty do not develop BPH. Testosterone, the main male hormone, is converted to the more active metabolite dihydrotestosterone (DHT) by the enzyme  $5\alpha$ -reductase in the prostatic stromal and epithelial cells.  $5\alpha$ -Reductase occurs in two forms, types 1 and 2. However, only type 2 is present in the prostate and genitalia. This is critical for understanding one of the two main classes of medical therapy for BPH—the  $5\alpha$ -reductase inhibitors (5-ARIs), medications that block the conversion of testosterone to DHT.

The dynamic component of BPH and LUTS is attributed to autonomic input to the smooth muscles in the lower urinary tract, including the bladder, prostate, and urethra. These areas have a large concentration of  $\alpha_1$ -adrenergic receptors that, when stimulated, cause increased smooth muscle tone. This physiology then leads to increased urethral resistance and contributes to the obstructive symptoms of BPH, leading to the basis for the other main class of drugs to treat BPH—the  $\alpha_1$ -adrenergic blockers.

### Symptoms

LUTS include urinary frequency, decreased force and caliber of the urinary stream, hesitancy, straining to void, urgency, and nocturia. The degree of impact may range from minimal “bother” to frank urinary retention with renal failure. Most urologists now use a standardized self-administered questionnaire, such as the International Prostate Symptom Score (IPSS) (Figure 1), designed to elicit symptoms and bother in a typical male population with suboptimal health-seeking behavior.

It is now very common for men to be referred to urology for a collection of age-related issues including elevated prostate-specific antigen (PSA), LUTS, BPH, and erectile dysfunction (ED). Commonly, the PSA or ED brings the patient to the attention of the healthcare system for the first time in years and may be the first opportunity to influence men on healthy living and health maintenance as they enter

## International Prostate Symptom Score (I-PSS)

Patient Name: \_\_\_\_\_ Date of birth: \_\_\_\_\_ Date completed \_\_\_\_\_

In the past month:	Not at all	Less than 1 in 5 times	Less than half the time	About half the time	More than half the time	Almost always	Your score
<b>1. Incomplete emptying</b> How often have you had the sensation of not emptying your bladder?	0	1	2	3	4	5	
<b>2. Frequency</b> How often have you had to urinate less than every two hours?	0	1	2	3	4	5	
<b>3. Intermittency</b> How often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
<b>4. Urgency</b> How often have you found it difficult to postpone urination?	0	1	2	3	4	5	
<b>5. Weak stream</b> How often have you had a weak urinary stream?	0	1	2	3	4	5	
<b>6. Straining</b> How often have you had to strain to start urination?	0	1	2	3	4	5	
	<b>None</b>	<b>1 Time</b>	<b>2 Times</b>	<b>3 Times</b>	<b>4 Times</b>	<b>5 Times</b>	
<b>7. Nocturia</b> How many times did you typically get up at night to urinate?	0	1	2	3	4	5	
<b>Total I-PSS score</b>							
<b>Score</b>	1–7: <i>Mild</i>		8–19: <i>Moderate</i>		20–35: <i>Severe</i>		

Quality of life due to urinary symptoms	Delighted	Pleased	Mostly satisfied	Mixed	Mostly dissatisfied	Unhappy	Terrible
If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that?	0	1	2	3	4	5	6

**Figure 1** The International Prostate Symptom Score (IPSS) questionnaire. Available from the Urological Sciences Research Foundation at: [http://www.usrf.org/questionnaires/AUA\\_SymptomScore.html](http://www.usrf.org/questionnaires/AUA_SymptomScore.html). Accessed April 18, 2020.

their middle or older age. Recognizing this, all healthcare providers should keep this in mind and try to perform a broader men's health assessment while the patient is available.

### Diagnosis

The diagnosis of BPH is generally made based on symptoms or the IPSS standardized questionnaire, self-administered by the patient, combined with a digital rectal examination, PSA blood test, urinalysis, and, in some cases, a transrectal ultrasound or cystoscopy. The differential diagnosis can include urinary tract infection (UTI), prostatitis, urinary stones in the lower urinary tract, urethral stricture disease, neurogenic or overactive bladder, prostate or bladder cancer, and even congestive heart failure. Some common medications, such as over-the-counter cold medicines containing  $\alpha$ -adrenergic agents, can exacerbate LUTS and can even put a man into acute urinary retention if he has underlying BPH.

A properly performed digital rectal examination is critical to master in the diagnosis of BPH. Because the posterior prostate gland is

located adjacent to the rectum and about 3 to 5 cm internal to the anus, the experienced clinician can gain valuable information from this examination. We prefer the patient to bend over the examining table with toes pointed slightly inward, the knees bent slightly forward and the forehead and arms/elbows resting on the table. The examiner uses a liberally lubricated gloved index finger to palpate the posterior side of the prostate for size estimate and for any induration or nodularity that might indicate the presence of prostate cancer. In such a case, referral to a urologist would be mandatory.

The size of the prostate is measured either by estimating the weight in grams or the volume in cubic centimeters. Models have been developed to teach clinicians how to gauge size and consistency. In general, a normal-size prostate is 20 to 25 g (or  $\text{cm}^3$ ) in middle-aged men. A size of 25 to 30, 30 to 50, and greater than 50 g (or  $\text{cm}^3$ ) is a general guide to mild, moderate, and severe BPH. However, size does not necessarily correlate with symptoms, and both symptom score and size estimate should be reported. The size gauges the histologic condition and the symptoms indicate the LUTS and the bother index, which are both important for individualized treatment.

The laboratory assessment should include a urinalysis to rule out hematuria. Like an abnormal digital rectal examination, a urinalysis that shows persistent red blood cells should prompt referral to a urologist for cystoscopic and upper urinary tract assessment. A urinalysis suggesting UTI should be followed up with a urine culture. If the patient presents in acute or chronic urinary retention and especially if there is a high postvoid or postcatheter residual bladder volume, a serum creatinine and blood urea nitrogen should be obtained. Severe BPH sometimes causes hydronephrosis and renal insufficiency; rarely, it causes renal failure. In-office bladder ultrasound scanners are very useful to quickly assess residual urine.

Contemporary diagnosis of BPH involves obtaining a PSA result. The latest guidelines from the American Urological Association (<https://www.auanet.org>) regarding the use of PSA testing are very helpful. Although the traditional upper limit of normal for PSA testing has been 4.0 ng/mL, recent guidelines are based more on changes in PSA levels over time, considering that most men with BPH will have prior PSA results. In the specific setting of using PSA to help manage BPH, the best data come from the Proscar Long-Term Efficacy and Safety Study (PLESS), where a PSA of 0 to 1.3 ng/mL, 1.4 to 3.2 ng/mL, and greater than 3.2 ng/mL was associated with small, medium, and large prostate glands (assuming that prostate cancer has been ruled out) and predicted therapeutic response to finasteride (Proscar) (see later).

## Treatment

Treatment of BPH is always individualized to the patient and involves evaluation of symptoms and both along with objective findings from examination and laboratory results. Current treatments range from periodic monitoring with a surveillance-only approach to the treatment of extreme cases with open or robotic enucleation surgery.

### Active Surveillance and Watchful Waiting

For many men, especially those with lower symptom scores and little bother, annual monitoring with digital rectal examination, PSA, urinalysis, and symptom assessment are all that is required. Many men are happy to be reassured that they do not have clinically significant prostate cancer and are glad to hear that no immediate treatment is necessary.

### Complementary and Alternative Medicine

The use of complementary and alternative medicine supplements is very common and physicians should ask patients about their use, just as they ask about prescription medications. There are now many “prostate” and “men’s health” supplements containing a variety of chemicals, including zinc, saw palmetto,<sup>7</sup> vitamin E,<sup>1</sup> vitamin D<sup>1</sup>, and selenium,<sup>7</sup> among others. Aside from a few European clinical trials of saw palmetto, the use of supplements to help BPH is speculative. One challenge is quality assurance of dose and ingredients of these agents, which are not regulated by the US Food and Drug Administration (FDA). Although it was not done to investigate BPH, the NIH-funded Selenium and Vitamin E Cancer Prevention Trial (SELECT) to determine whether vitamin E or selenium, or both, would prevent prostate cancer is illustrative. Neither supplement had any effect on prostate cancer (or BPH to our knowledge). With the lack of robust trial data for the plethora of supplements, the answer from evidence-based medicine is clear.

## Medical Therapy

### $\alpha$ -Blocker Medications

The use of oral  $\alpha$ -adrenergic blocking agents to treat BPH has been commonplace since the 1980s. These agents are directed at the dynamic component of BPH and LUTS by relaxing the smooth muscle tissue in the bladder neck and prostate. In simple terms, they relax the bladder outlet, resulting in better urinary flow.

Initial agents, such as prazosin (Minipress),<sup>1</sup> were not selective blockers and were also used to treat hypertension. Furthermore,

these early agents were not long acting and had to be taken multiple times per day, which severely limited their practical clinical utility. The next generation in the class were doxazosin (Cardura) and terazosin (Hytrin), which were longer-acting agents dosed only once a day. However, they were not selective and also lowered blood pressure, so titration was necessary. The third- and current-generation agents are selective blockers that treat BPH but do not lower blood pressure when used at recommended doses. The three in this class are tamsulosin (Flomax), alfuzosin (Uroxatral), and silodosin (Rapaflo).

In general, clinicians use  $\alpha$ -blockers in men with smaller prostate glands ( $\leq 30$ – $35$  g or  $\text{cm}^3$ ), in younger men, and in patients where rapid effect is needed. Side effects of this class can include headache, dizziness, asthenia, drowsiness, and retrograde ejaculation, with alfuzosin reported to have the lowest rate of retrograde ejaculation among these drugs. The  $\alpha$ -blockers are also now frequently used to relieve the dysfunctional voiding, which is believed to contribute significantly to some cases of prostatitis.

### 5 $\alpha$ -Reductase Inhibitors

The 5 $\alpha$ -reductase inhibitors have been available since the early 1990s. Finasteride (Proscar) was the first agent in this class (5 mg/day) and is a type 2 inhibitor. Dutasteride (Avodart; 0.5 mg/day) is a type 1 and type 2 inhibitor that was approved in 2002. Both drugs prevent the conversion of testosterone to the more active metabolite DHT in the prostate. This inhibition results in involution of BPH tissue and prostatic shrinkage. On average, most men achieve a reduction of 20% to 40% in prostate size after at least 6 months of use. In general these agents are most effective in men with prostate glands more than 30 g (or  $\text{cm}^3$ ) in size. Both drugs are expected to result in lower PSA levels by about 50% after 6 months of use. It is critical to take this into account when a patient is being screened for prostate cancer. If the PSA level does not fall by about half and the patient has been compliant with medication, he should be referred for urologic evaluation. In following up on men taking finasteride or dutasteride, PSA is generally doubled in assessing risk for prostate cancer. However, the PSA velocity or doubling time and other prostate cancer screening tools are still valid as long as the effect on PSA is appreciated.

Two key clinical trials are important. The Medical Therapy of Prostate Symptoms (MTOPS) trial showed that the combination of an  $\alpha$ -blocker (doxazosin) and a 5 $\alpha$ -reductase inhibitor (finasteride) was more effective than either alone or than placebo in treating BPH and LUTS. The Prostate Cancer Prevention Trial (PCPT), in a large 7-year study, showed that finasteride lowered the rate of prostate cancer by 25% over placebo. The Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial confirmed the prostate chemoprevention benefit of this class of drugs, showing that dutasteride also lowered the rate of prostate cancer by 23% over placebo. In 2010, the FDA ruled that dutasteride would not be approved for prostate cancer prevention, citing safety concerns in this prevention setting. In 2013, the long-term follow-up of the PCPT showed that there was no excess mortality associated with long-term finasteride use compared with placebo, proving the long-term safety of this therapy.

Urologists frequently use 5 $\alpha$ -reductase inhibitors to treat chronic hematuria due to an enlarged prostate after exclusion of more worrisome etiologies such as renal or bladder cancer; they may also prescribe these agents before prostate surgeries or procedures for BPH to lessen surgical bleeding.

### Minimally Invasive Procedures

In the past 35 years, a series of minimally invasive procedures have appeared in practice with the goals of reducing prostatic obstruction while preserving sexual function with normal erections and ejaculation. Balloon dilation, transurethral microwave therapy (TUMT), and transurethral needle ablation (TUNA) have all fallen from favor due to lack of durable effect in improving LUTS. Two newer minimally invasive procedures have, however, shown durability in multiyear randomized clinical trials. The prostatic urethral lift procedure (UroLift) utilizes small,

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

permanently implanted anchors placed cystoscopically that physically retract and compress the obstructing lobes of the prostate and can provide almost immediate improvement in flow rates and symptom scores. Alternatively, water vapor thermal therapy (Rezüm) utilizes radiofrequency-generated water vapor (103°C) injected cystoscopically into the prostate tissue, resulting in gradual resorption of the treated tissue and significant improvements in flow rates and symptom scores over the course of weeks following the procedure. Both procedures carry the benefits of very low rates of ED and retrograde ejaculation; however, whether either procedure will provide long-lasting relief of LUTS similar to more invasive surgical procedures remains unknown. Prostatic artery embolization (PAE) has shown promise in several studies as a minimally invasive therapy for BPH; however, the 2018 American Urologic Association guidelines have recommended against PAE as therapy for bothersome LUTS outside of a clinical trial setting. High-intensity focused ultrasound was granted FDA approval in 2015 for ablation of prostate tissue but has not gained wide use for BPH management and is more frequently utilized in the treatment of prostate cancer.

### Surgical Therapy

TURP remains the gold standard treatment for men who have failed to improve on medical therapy, who dislike or are intolerant of medication side effects, or who have developed urinary retention, renal failure secondary to BPH, or large bladder calculi. TURP is associated with relatively low rates of incontinence and ED; however, retrograde ejaculation is an expected and permanent outcome for most men undergoing this surgery. Evolutions of the traditional TURP procedure now utilize saline irrigation, thereby reducing the risk of hyponatremia during the procedure. Several laser technologies (Greenlight, Holmium, or Thulium) utilized for the enucleation or vaporization of prostate tissue have resulted in reduced hospital stays, transfusion rates, and duration of catheterization compared with TURP and are recommended treatment options for medically complex cases calling for anti-coagulant therapy. Aquablation utilizes a transurethral water jet to ablate prostate tissue under ultrasound guidance. Finally, for men with severe BPH and very large glands (>150 g), simple prostatectomy performed robotically or via a small suprapubic incision remains a valuable and highly effective surgical treatment. As with radical prostatectomy used for the treatment of prostate cancer, open or robotic prostatectomy for BPH should be performed by urologic surgeons who are highly experienced in this area.

### Summary

With the widespread acceptance of medical therapies for BPH in the 1980s and 1990s, treatment paradigms rapidly shifted away from surgical treatment for bothersome voiding symptoms. A growing number of studies have suggested an association between medical therapies for LUTS and the development of dementia. These studies are controversial and preliminary; however, it is common in our practice to encounter elderly men who are using two or three medications for the management of symptoms. With increasing awareness of the risks of polypharmacy and with the advent of new minimally based procedures for BPH, many of which can be performed in office, the pendulum seems to be swinging back toward the earlier consideration of surgical treatment for BPH.

## EPIDIDYMITIS AND ORCHITIS

Method of

Robin A. Walker, MD

### CURRENT DIAGNOSIS

- Subacute or gradual onset of scrotal pain and swelling that occasionally radiates to the lower abdomen. Typically unilateral; however, inflammation can spread to the opposite testicle.
- Fever and urinary tract symptoms (e.g., dysuria, frequency, urgency, hematuria) may be present.
- The testicle should be in normal position with the cremasteric reflex intact (rule out torsion).
- Pain is relieved by elevation of the testicle (Prehn sign).
- Ultrasonography with Doppler is readily available and has high sensitivity and specificity for ruling out testicular torsion; however, referral to urology should not be delayed if torsion is suspected.
- Urinalysis should be obtained, preferably on a first-void urine specimen.
- Urine is sent for culture, especially when sexually transmitted disease (STD) is not suspected.
- Urine is the preferred specimen for nucleic acid amplification assays for *Gonorrhea* and *Chlamydia*.

### CURRENT THERAPY

- Acute epididymitis most likely caused by chlamydia or gonorrhea: ceftriaxone (Rocephin)<sup>1</sup> 500 mg IM once PLUS doxycycline (Vibramycin)<sup>1</sup> 100 mg twice daily for 10 days. Use 1 g of ceftriaxone if patient weights  $\geq$ 150 kg.
- Acute epididymitis mostly likely caused by chlamydia, gonorrhea, or enteric organisms (men who practice insertive anal intercourse): ceftriaxone (Rocephin)<sup>1</sup> 500 mg IM once PLUS levofloxacin (Levaquin)<sup>1</sup> 500 mg once daily  $\times$  10 days. Use 1 g of ceftriaxone if patient weights  $\geq$ 150 kg.
- Acute epididymitis most likely caused by enteric organisms alone: levofloxacin (Levaquin)<sup>1</sup> 500 mg once daily  $\times$  10 days
- Oral cephalosporins and fluoroquinolones are no longer recommended for gonococcal infections.
- Cultures, if obtained, should be followed and treatment adjusted accordingly.
- Patients should follow up in 2 to 3 days. Pain should improve in 1 to 3 days with treatment. Failure to improve should elicit reevaluation of the diagnosis and therapy, and consideration should be given to other causes such as a testicular tumor/cancer, abscess, infarction, and tuberculosis (TB) or fungal pathogens.
- Sexual partners should be referred for evaluation and treatment if there was intercourse in the preceding 60 days from onset of symptoms.
- Education should occur regarding prevention of STDs.

<sup>1</sup>Not FDA approved for this indication.

## Epidemiology

Epididymitis is most common in males 18 to 35 years of age, but it can occur in all ages.

In men 35 years of age or younger who are sexually active, the most common pathogens are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In those older than 35 years of age, the cause is most likely urinary tract pathogens such as *Escherichia coli*. In men who perform insertive anal intercourse, coliform bacteria are common causative agents. Other less common pathogens include TB, fungal infections, and viruses. Cytomegalovirus has been identified as a cause in HIV patients.

In boys 2 to 13 years of age, the incidence is approximately 1.2 per 1000 individuals and is most commonly a postinfectious inflammatory reaction to pathogens such as enteroviruses, adenoviruses, and mycoplasma pneumonia. If a bacterial pathogen is isolated, a urologic workup for any anatomic abnormalities is warranted.

Other uncommon noninfectious causes of epididymitis include vasculitides and medications such as amiodarone (Pacerone).

Orchitis is less common than epididymitis and is most often associated with concurrent epididymitis, occurring in approximately 60% of men with epididymitis. In prepubertal boys, orchitis is usually a sequela of mumps infection. Between 20% and 30% of men with mumps develop orchitis.

## Risk Factors

The predominant risk factor for epididymitis is unprotected sexual intercourse. Additionally, trauma from strenuous physical activity, bicycle or motorcycle riding, and prolonged sitting can predispose to epididymitis. Risk factors in prepubertal boys and men older than 35 years of age are related to anatomic abnormalities (e.g., prostatic obstruction, posterior urethral valves, meatal stenosis), recent instrumentation, or urogenital tract surgery (e.g., vasectomy). In prepubertal boys, recent infections can predispose to a postinfectious inflammatory reaction in the epididymis.

## Pathophysiology

Infective epididymitis is usually caused by retrograde ascent of pathogens, most commonly bacterial. Noninfectious epididymitis can be autoimmune or can be associated with known syndromes (e.g., Behçet disease) or a side effect of medications, most notably amiodarone (Pacerone). If symptoms last longer than 3 months, the patient meets the diagnostic criteria for chronic epididymitis.

## Clinical Manifestations

The typical presentation is subacute onset of unilateral scrotal pain. Any acute onset of pain requires careful consideration of possible testicular torsion. The pain in epididymitis can radiate to the lower abdomen. Fever and urinary tract symptoms such as increased frequency, dysuria, and hematuria are frequently present. The cremasteric reflex is preserved and the testicle should be in its normal anatomic position. The epididymis is tender, swollen, and often indurated. Pain is relieved on testicular elevation (Prehn sign). Over time, scrotal wall erythema and a reactive hydrocele may appear, and infection can spread from the epididymis to the testicle (orchitis) as well as to the opposite testicle.

Epididymitis secondary to noninfectious causes tends to have a more gradual onset of symptoms.

Viral orchitis from mumps is characterized by abrupt onset of unilateral testicular pain with swelling that typically occurs 4 to 7 days after the development of parotitis. About 75% of patients with orchitis will also have fever, and one-third will complain of dysuria.

## Diagnosis

Diagnosis can be made by a careful history and physical examination; however, laboratory testing can help confirm epididymitis.

All suspected cases should undergo point-of-care evaluation for urethral inflammation by one of three tests. (1) Gram, methylene blue, or gentian violet stain of urethral secretions demonstrating  $\geq 2$  white blood cells (WBCs) per oil immersion field; (2) positive leukocyte esterase on first-void urine; (3) Microscopic examination of sediment spun from first-void urine demonstrating  $\geq 10$

WBCs per high-power field. The presence of inflammation helps differentiate it from testicular torsion.

Nucleic acid amplification tests for *N. gonorrhoeae* and *C. trachomatis* should be run on all sexually active men, and urine is the preferred specimen. Gonococcal infection is established by the presence of WBCs containing intracellular gram-negative diplococci. Urine should be obtained for analysis and culture, preferably from a first-void sample. All men with acute epididymitis should be tested for HIV and syphilis.

Color Doppler ultrasonography is a readily availability study with a sensitivity and specificity for testicular torsion ranging between 89% and 100%. However, imaging should not delay immediate referral to a specialist if torsion is clinically suspected.

## Differential Diagnosis

- Testicular torsion: duration less than 6 hours, absence of cremasteric reflex, diffuse testicular tenderness. Elevation of the testis usually exacerbates discomfort.
- Orchitis: testicular tenderness and swelling, normal cremasteric reflex.

## Therapy/Treatment

In sexually active men 14 to 35 years of age, empiric treatment should be started for suspected epididymitis before laboratory results are available. The current recommended regimen is ceftriaxone (Rocephin)<sup>1</sup> 500 mg IM once plus doxycycline (Vibramycin)<sup>1</sup> 100 mg orally twice daily for 10 days. For sexually active men who practice insertive anal intercourse, the recommended treatment is ceftriaxone (Rocephin)<sup>1</sup> 500 mg IM once plus levofloxacin (Levaquin)<sup>1</sup> 500 mg orally once daily for 10 days. The dose of ceftriaxone (Rocephin) should be increased to 1 g IM for patients who weigh  $\geq 150$  kg. The Centers for Disease Control and Prevention (CDC) no longer recommends fluoroquinolones or oral cephalosporins for the treatment of gonococcal infections.

When enteric pathogens alone are suspected, treatment consists of levofloxacin (Levaquin)<sup>1</sup> 500 mg orally for 10 days.

Most patients can be treated in the outpatient setting. Inpatient treatment is recommended for suspicion of abscess, intractable pain, signs of sepsis, or failure of outpatient care. Symptomatic care consists of pain control with supportive garments, nonsteroidal antiinflammatory drugs (NSAIDs), rest, and cold packs.

Men whose epididymitis was confirmed or suspected to be caused by gonorrhea or chlamydia should be instructed to refer all sexual partners over the previous 60 days from the onset of symptoms for evaluation and treatment. Patients and their partners should be advised to abstain from sexual intercourse until they have been treated and symptoms have resolved.

Orchitis, when not associated with epididymitis infection, is typically treated in a supportive manner with hot or cold packs, rest, NSAIDs, and scrotal elevation. Symptoms from viral associated orchitis typically resolve in 3 to 10 days.

## Complications

Complications include sepsis, abscess, formation, extension of infection, and infertility.

<sup>1</sup>Not FDA approved for this indication.

## ERECTILE DYSFUNCTION

Method of

Aleksandr Belakovskiy, MD; Joel J. Heidelbaugh, MD; and Karl T. Rev, MD

### CURRENT DIAGNOSIS

- Questionnaire
- Sexual Health Inventory for Men (SHIM) [also called International Index of Erectile Function (IIEF-5)] [https://www.baus.org.uk/\\_userfiles/pages/files/Patients/Leaflets/SHIM.pdf](https://www.baus.org.uk/_userfiles/pages/files/Patients/Leaflets/SHIM.pdf)
- Assessment of risk factors
- Tobacco use
- Diabetes
- Hypertension
- Hyperlipidemia
- Obesity
- Iatrogenic causes
- Psychogenic causes
- Physical exam including vitals, body mass index (BMI), genital exam, and assessment for secondary sex characteristics
- Relationship between erectile dysfunction, endothelial dysfunction, and coronary heart disease

### CURRENT THERAPY

- Lifestyle modifications including tobacco cessation, weight loss, increased exercise
- Sexual health counseling
- Medication modification if taking medications known to contribute to erectile dysfunction
- Pharmacotherapy (Table 1)
- Oral phosphodiesterase type 5 (PDE-5) inhibitors: avanafil (Stendra), sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra, Staxyn)
- Prostaglandin: alprostadil; either by intracavernosal injection (Caverject, Edex) or as an intraurethral suppository (Muse)
- Requires a test dose in the office and instruction on technique for proper administration
- Vacuum erectile devices
- Penile implants

Erectile dysfunction is the inability to attain or maintain a penile erection sufficient for sexual satisfaction.

### Epidemiology

Numerous studies have investigated the prevalence of erectile dysfunction in men of various ages. Based on the most recent studies, worldwide prevalence increases with age. For men under age 40 the prevalence is 1% to 10%; for ages 40 to 49 it is 2% to 15%; for men ages 50 to 59 it is mixed, ranging from 15% to 40%; for ages 60 to 69 it is 20% to 40%; and for men 70 and older it is 50% to 100%. Among men in the United States the prevalence is 22% overall. This is higher than the 16% prevalence for seven other countries found in a study comparing the United States to Brazil, Mexico, United Kingdom, Germany, France, Italy, and Spain. Accurate diagnosis of erectile dysfunction has varied over time, with current literature favoring the use of validated questionnaires such as the Sexual Health Inventory for Men (SHIM); [https://www.baus.org.uk/\\_userfiles/pages/files/Patients/Leaflets/SHIM.pdf](https://www.baus.org.uk/_userfiles/pages/files/Patients/Leaflets/SHIM.pdf).

### Risk Factors

A number of medical conditions can predispose to erectile dysfunction. Numerous studies have demonstrated the correlation between cardiovascular disease and the incidence of erectile dysfunction. Risk factors that predispose to cardiovascular disease also play similar roles in erectile dysfunction, including increasing age, diabetes, hypertension, hyperlipidemia, tobacco use, and obesity.

Certain classes of medications can contribute to the development of erectile dysfunction. One of the most common is the antidepressants, specifically selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs). Common antihypertensive medications can also contribute to or exacerbate erectile dysfunction, including beta blockers, alpha blockers, calcium channel blockers, and thiazides. Other medication classes that should be considered in patients with erectile dysfunction include opiates, first-generation antihistamines, and benzodiazepines.

Risk factors for psychogenic erectile dysfunction should also be evaluated. Psychogenic erectile dysfunction can occur at any age, but it is frequently seen in men under age 40, and it often occurs in men with anxiety, stress, depression, or a history of sexual abuse. Assess for healthy sexual partnerships by asking about performance anxiety and sexual desire discrepancy, both of which are common contributors to erectile dysfunction. Clues that erectile dysfunction may have a psychogenic component include the ability to have normal erections with masturbation, and the continued presence of nocturnal erections. If needed for evaluation, nocturnal tumescence testing can be performed.

Tobacco, alcohol, opioids, and substances such as marijuana and cocaine can cause erectile dysfunction. All substance use should be assessed. Many other health issues can contribute to erectile dysfunction, including a history of prostate or pelvic surgery, radiation therapy, or trauma; gonadal, thyroid, or other diseases that affect hormone levels; testicular pain; and chronic diseases that affect general health and well-being.

### Pathophysiology

The pathophysiology of erectile dysfunction depends on the etiology of the condition. Many men have multiple potential causes. Psychogenic erectile dysfunction is due to nonorganic causes, while individuals with risk factors for cardiovascular disease primarily have etiologies stemming from vascular disease. Iatrogenic erectile dysfunction due to medication use or prior surgery may be caused by inhibition of the parasympathetic nervous system or other mechanisms of action.

Erectile dysfunction can be a warning sign of silent cardiovascular disease. The relationship between erectile dysfunction and the risk factors for coronary heart disease was noted in the Massachusetts Male Aging Study. The endothelial dysfunction that can precede the clinical stage of atherosclerotic disease is recognized as an additional risk factor for erectile dysfunction in men without symptoms of cardiovascular disease. Endothelial function is mediated by nitric oxide, which is also the mechanism responsible for the vascular dilatation required to obtain and maintain an erection. A man with erectile dysfunction should be considered at risk for cardiovascular disease until proven otherwise.

### Prevention

Erectile dysfunction prevention is centered around treating modifiable risk factors. Treatment of overweight and obesity with dietary changes and increased aerobic exercise can aid in the prevention of erectile dysfunction. For tobacco users, cessation should be strongly encouraged. Bupropion (Zyban) and varenicline (Chantix) can be used for smoking cessation with limited risk of exacerbating erectile dysfunction. Nicotine replacement therapy can be used as a bridge to help with tobacco cessation. Appropriate treatment of comorbid diseases, including diabetes, hypertension, and hyperlipidemia can also aid in prevention. Sexual health counseling that focuses on good partner communication and healthy relationship dynamics can help prevent psychogenic erectile dysfunction.

## Clinical Manifestations

Many men are uncomfortable mentioning problems of sexual function. Some men will report erectile dysfunction without providing information on the specifics of their concern. It is important for physicians to proactively ask about sexual function, and to clarify if a patient's concern is with achieving or maintaining an erection, or if it may be related to ejaculation or low libido. Low libido can be secondary to stress, mood disorders, hypogonadism, or other causes. The evaluation and potential treatments will differ based on the specific concern. Questionnaires such as the SHIM ([https://www.baus.org.uk/\\_userfiles/pages/files/Patient s/Leaflets/SHIM.pdf](https://www.baus.org.uk/_userfiles/pages/files/Patient%20Leaflets/SHIM.pdf)) can provide additional information to help distinguish the specific clinical manifestation.

## Diagnosis

The history provides the majority of information needed for the diagnostic evaluation, including a review of known medical and surgical history, use of medications and substances, an assessment of current relationship satisfaction, and a questionnaire such as the SHIM. The history should include risk factor evaluation, assessment for any history of cardiovascular disease, diabetes, hypertension, hyperlipidemia, or mood disorders, as well as a review of medications that might contribute to erectile dysfunction. A physical exam should also be performed, including evaluation of blood pressure, body mass index, secondary sex characteristics, and a genital exam.

The role of laboratory studies is limited. In individuals who lack secondary sex characteristics, as well as those with refractory symptoms despite PDE-5 inhibitor use, check a morning total testosterone to assess for hypogonadism. Limited evidence supports obtaining a morning total testosterone in all men with erectile dysfunction. If the initial morning total testosterone is low, it should be repeated at least once in several months to confirm the diagnosis. If morning testosterone levels are normal in a patient with high likelihood of hypogonadism, a free testosterone or bioavailable testosterone can be checked to help account for the effects of sex hormone-binding globulin. If evidence of hypogonadism is found, additional testing to distinguish primary versus secondary hypogonadism should be done. Hemoglobin A1c and a lipid panel may be helpful if there is a suspicion for underlying diabetes, hyperlipidemia, or cardiovascular disease contributing to erectile dysfunction. If a review of symptoms elicits a suspicion for hypothyroidism, checking a thyroid stimulating hormone level may be indicated. Consultation with a urologist, endocrinologist, or men's health specialist may be helpful when the etiology is unclear.

## Differential Diagnosis

In men presenting with concern for erectile dysfunction, the differential diagnosis is geared toward deciphering the underlying cause. As previously mentioned, there are numerous potential contributing factors to erectile dysfunction. It is important to assess for both organic and psychogenic causes. The history should include asking about nocturnal tumescence, as well as the ability to achieve and maintain an erection with and without a partner. If erectile dysfunction occurs regardless of situation, this is more likely to indicate an organic etiology. If it occurs primarily with a partner, further evaluation of the relationship is indicated. As mentioned above, numerous factors can predispose to erectile dysfunction, and related diagnoses may include cardiovascular disease, tobacco use, diabetes, hypertension, hyperlipidemia, obesity, and metabolic syndrome. Medications should also be reviewed, because they can cause iatrogenic erectile dysfunction in some patients.

## Therapy (or Treatment)

Lifestyle modifications play an important role in both the prevention and treatment of erectile dysfunction. Weight reduction for overweight or obese men (BMI >25 kg/m<sup>2</sup>) and increased exercise for all men can improve SHIM scores. Underlying illnesses such as hyperlipidemia, hypertension, and diabetes should be adequately controlled in order to decrease their potential impact on erectile dysfunction. Another important consideration is tobacco cessation;

current or former smoking increases the risk of erectile dysfunction. Sexual health counseling is often helpful for individuals and couples dealing with erectile dysfunction, no matter what the etiology is. Referral to a mental health professional or sexuality expert may be beneficial.

Pharmacologic treatment begins with oral PDE-5 inhibitors. They prevent the breakdown of cyclic guanosine monophosphate (cGMP) and allow increased nitric oxide levels, causing smooth muscle relaxation of the corpora cavernosa, and helping to sustain an erection. This requires a functional libido as well as intact vasculature in order to achieve an erection. There are four PDE-5 inhibitors currently approved in the United States for treatment of erectile dysfunction: avanafil (Stendra), sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra, Staxyn) (see [Table 1](#)). There are no significant differences in safety or benefit among these medications. Tadalafil has a longer duration of action than the others.

PDE-5 inhibitors are usually taken on an as-needed basis, with onset of effects typically within about 1 hour of ingestion. The lowest effective dose should be used to reduce the risk of adverse reactions. Higher doses do not lead to a linear increase in beneficial effect, but can increase the risk of adverse reactions. Tadalafil, because of its longer duration of action, can be taken daily at a lower dose with similar efficacy to as-needed dosing. The duration of adverse effects may be longer with daily use.

The most common adverse reactions to PDE-5 inhibitors include headache, flushing, dyspepsia, dizziness, nasal congestion, visual disturbance, and myalgias. Overall, these adverse reactions tend to be mild to moderate in nature and are similar across all four medications. Special consideration should be given to individuals who take nitrate-containing medications; the combination of a PDE-5 inhibitor with nitrates can cause severe hypotension that may be life threatening.

Testosterone is not an effective monotherapy for erectile dysfunction. However, for men with confirmed hypogonadism, the combination of a PDE-5 inhibitor with testosterone replacement may be effective.

If patients do not have adequate symptom relief with lifestyle modification, sexual health counseling, and oral PDE-5 inhibitor use, the prostaglandin alprostadil (Caverject, Edex, Muse) can be considered. Alprostadil works by relaxing arterial smooth muscle and is available in intraurethral and injectable preparations (see [Table 1](#)). The intraurethral formulation (Muse) is a dissolvable suppository placed in the urethra with an applicator. The injectable form (Caverject, Edex) is injected directly into one side of the corpora cavernosa. Alprostadil can be used as a single agent or in combination with a PDE-5 inhibitor. If the patient is amenable to a trial of alprostadil, an in-office test dose should be administered to find the lowest effective dose and to teach proper administration technique. Some patients may not be suitable candidates if they are not comfortable with injections or intraurethral insertion. Alprostadil should be avoided in patients who have sickle cell anemia or other risk factors for priapism.

If pharmacological therapies are ineffective or contraindicated, patients may elect to use a vacuum erectile device. These prescription devices are placed over the penis and a vacuum pump removes air from inside the device, creating an influx of blood into the penis and leading to an erection. A ring is then slid from the base of the vacuum tube onto the penis to constrict the outflow of blood and maintain the erection. To avoid ischemic injury, the ring should only be used for up to 30 minutes. Adverse effects of vacuum erectile devices may include the erect penis feeling cool or cold to the touch due to the restricted blood flow, and bending at the base of the penis due to the application of the constricting ring. Overall, these devices have a fairly high satisfaction rate. Caution should be used when considering a vacuum erectile device for patients who are taking anticoagulants or have bleeding disorders.

For patients with erectile dysfunction refractory to the above treatments, surgical implantation of a penile prosthesis can be offered. Penile prostheses come in several forms, including inflatable devices and persistently semirigid implants. Patients and

**TABLE 1** Pharmacotherapy for Erectile Dysfunction

GENERIC NAMES	BRAND NAMES	SIZES	TYPICAL DOSING	COMMENTS
<b>Oral Phosphodiesterase Type 5 (PDE-5) Inhibitors</b>				
avanafil	Stendra	50-, 100-, 200-mg tablet	50–200 mg by mouth once daily as needed, 1 h before sexual activity	Use lowest effective dose. Contraindicated with nitrates.
sildenafil	Viagra	25-, 50-, 100-mg tablet	25–100 mg by mouth once daily as needed, 1 h before sexual activity	Use lowest effective dose. Contraindicated with nitrates.
tadalafil	Cialis	2.5-, 5-, 10-, 20-mg tablet	5–20 mg by mouth once daily as needed, 1 h before sexual activity OR 2.5–5 mg by mouth once daily without regard to sexual activity	Use lowest effective dose. Contraindicated with nitrates. Has a longer duration of action than other PDE-5 inhibitors.
vardeafil	Levitra Staxyn	5-, 10-, 20-mg tablet 10-mg oral dissolving tablet	5–20 mg by mouth once daily as needed, 1 h before sexual activity	Use lowest effective dose. Contraindicated with nitrates. Available as a 10 mg oral dissolving tablet (Staxyn)
<b>Prostaglandin</b>				
alprostadil injectable	Caverject 20 mcg/mL, 40 mcg/mL vials	Caverject Impulse 10 mcg/0.5 mL, 20 mcg/0.5 mL prefilled syringes Edex 10 mcg/mL, 20 mcg/mL, 40 mcg/mL cartridges	Initiate dose at 1.25 or 2.5 mcg intracavernosally and titrate does with no more than 2 doses per 24 hours (maximum dose: 40 mcg [Edex], 60 mcg [Caverject]). Self administration: maximum 3 times/week with 24 hours between doses	Provide an in-office test dose and instruction in proper technique for administration. Use lowest effective dose.
alprostadil intraurethral	Muse	125-, 250-, 500-, 1000-mcg urethral suppositories	Initiate dose at 125 or 250 mcg intraurethral and titrate dose on separate occasions in physician's office. Maximum 2 suppositories per 24 hours for self-administration	Provide an in-office test dose and instruction in proper technique for administration. Use lowest effective dose.

their partners should be counseled regarding risks and benefits to ensure realistic postsurgical expectations. Risks include scarring, penile shortening, recurrent infections, and mechanical failure requiring removal.

### Monitoring

A validated questionnaire such as the SHIM ([https://www.baus.org.uk/\\_userfiles/pages/files/Patients/Leaflets/SHIM.pdf](https://www.baus.org.uk/_userfiles/pages/files/Patients/Leaflets/SHIM.pdf)) is a simple and reliable tool for monitoring ongoing symptoms. A periodic clinical evaluation, including a review of all supplements and medications, can be helpful to identify potential causes of symptoms and any adverse reactions.

### Management of Complications

The majority of adverse reactions with PDE-5 inhibitors are mild to moderate in nature and can be limited by using the lowest effective dose. PDE-5 inhibitors are contraindicated in patients taking nitrates because of the significant risk of life-threatening hypotension. If accidentally ingested, the patient should be monitored by healthcare professionals. The risk also depends on which specific agent was ingested, as the duration of action differs between medications. While the risk of prolonged erection (priapism) is low with PDE-5 inhibitors, men with erections lasting greater than 4 hours should seek emergency attention.

The major potential complication of alprostadil is a prolonged erection lasting greater than 4 hours, which will require emergent urological treatment. Penile fibrosis is also a risk that has been reported in 4.9% of patients using alprostadil at 4 years.

Treatment with exogenous testosterone impairs spermatogenesis and should be avoided in men who are trying to conceive or are interested in future fertility.

The major complication of vacuum erectile devices is ischemic injury, generally when the constricting ring is left in place for greater than 30 minutes at a time. Any suspicion for ischemic injury should also prompt emergent urologic intervention.

Patients with penile implants are prone to recurrent infections or mechanical failure, potentially requiring removal of the device.

## PROSTATE CANCER

Method of

William G. Nelson, MD, PhD

### CURRENT DIAGNOSIS

- Serum prostate-specific antigen (PSA) testing, with or without digital rectal examination (DRE), can be used for prostate cancer screening for men beginning at 50 years of age until 70 years of age.
- Prostate cancer screening carries significant risks of overdiagnosis and overtreatment of clinically insignificant prostate cancers.
- The diagnosis of prostate cancer is usually made via ultrasound-guided transrectal core needle biopsies that sample the prostate; magnetic resonance imaging (MRI) is increasingly used to direct core biopsies to regions of the prostate suspicious for harboring aggressive prostate cancers.
- Histologic grade (Gleason score) and anatomic stage provide the prognosis needed for treatment decision making. Several different tumor-based molecular biomarker tests can add further prognostic information.
- Metastatic prostate cancer can be evaluated using  $^{99m}\text{Tc}$ -methylene diphosphonate (MDP) or  $^{18}\text{F}$ -sodium fluoride (NaF) bone scans, abdominopelvic computed tomography (CT) or MRI scan, and  $^{11}\text{C}$ -choline,  $^{18}\text{F}$ -fluciclovine,  $^{68}\text{Ga}$ -PSMA, or  $^{18}\text{F}$ -piflufolastat positron emission tomography (PET) studies.
- Germline genetic testing for DNA repair gene variants along with tumor testing for DNA repair gene defects tends to accompany diagnosis of high-risk localized, locoregionally advanced, and metastatic prostate cancer.

### CURRENT THERAPY

- Options for management of localized prostate cancer include active surveillance, radical prostatectomy, external-beam radiotherapy (EBRT), brachytherapy, and proton-beam radiotherapy.
- Androgen-deprivation therapy (ADT) using gonadotrophic hormone-releasing hormone analogues is a mainstay of systemic prostate cancer treatment.
- CYP17 inhibitors and androgen receptor antagonists can be added to further ablate androgen signaling.
- CYP17 inhibitors, androgen receptor antagonists, and taxane chemotherapy can improve survival when given along with ADT for hormone-sensitive metastatic prostate cancer or upon progression to castration-resistant prostate cancer (CRPC).
- Stereotactic bone radiation therapy (SBRT) can be directed at metastatic lesions in the setting of oligometastatic disease progression to prolong progression-free survival.
- The  $\alpha$ -particle-emitting calcium mimetic  $^{223}\text{Ra}$  can palliate painful bony metastases.
- Poly(ADP-ribose) polymerase (PARP) inhibitors may be effective in up to 20% of men with CRPC who carry germline and/or somatic mutations in homologous recombination repair genes (*BRCA1*, *BRCA2*, *ATM*, and others).
- Immune checkpoint blockade may be of benefit for patients with mismatch repair-deficient prostate cancer.
- Platinum-based chemotherapy can be used to treat small cell/neuroendocrine prostate cancer.

Prostate cancer comprises the most commonly diagnosed cancer among men in the United States, with an estimated 268,490 new cases and 34,500 deaths expected for 2022. At some point

during life, 1 in 8 men can expect to be diagnosed with prostate cancer, though the risk of dying from the disease is only about 1 in 41. African-American men suffer disproportionately with the disease, exhibiting more than twice the age-adjusted mortality as Caucasians.

The prostate gland itself is a male sex accessory gland located adjacent to the rectum in the pelvis and surrounding the urethra to supply secretions to the ejaculate. Why it should spawn so many cancers has proven enigmatic. The prostate can be divided into three zones: a *peripheral zone*, where most prostate cancers arise; a *transition zone* near the urethra that is prone to benign enlargement (benign prostatic hyperplasia/hypertrophy [BPH]); and a *central zone*. Under the influence of the male androgenic hormones testosterone (T) and dihydrotestosterone (DHT), normal epithelial cells produce the serine protease prostate-specific antigen (PSA; encoded by the *KLK3* gene). The appearance of PSA in the bloodstream tends to indicate epithelial barrier dysfunction within the prostate gland, attributable to three highly prevalent conditions in aging men in the United States: inflammation (prostatitis), BPH, or prostate cancer. Blood testing for PSA has emerged as a common screening tactic for prostate cancer, necessarily confounded by the near-ubiquitous coexistence of prostatitis and BPH.

Most patients present with prostate cancer apparently confined to the prostate gland, often detected by PSA screening. Though usually indolent, when aggressive, prostate cancer tends to spread to bony sites, causing pain by undermining bone architecture through stimulating osteoblastic activity, a phenomenon readily evident via NaF bone scanning. Patients dying of prostate cancer also manifest metastasis to lymph nodes, liver, the dura, and elsewhere.

Patients who are diagnosed with prostate cancer today confront a large and often confusing array of treatment options. The typical patient diagnosed with the disease is at least 65 years of age or older; the risks and benefits associated with different treatment choices in this age range are relevant not only for prostate cancer specialty care, but for general medical care as well. The 5-year survival for a man with localized prostate cancer is >95%, underscoring the need for balancing prostate cancer treatment selection with other health priorities.

### Epidemiology

Heredity plays as significant a role in prostate cancer development as for any other common cancer. Analyses of concordance for prostate cancer between monozygotic (identical) versus dizygotic (fraternal) twins have consistently found excess prostate cancers among the identical twins despite similar environmental exposures, leading to the estimate that as many as 42% of prostate cancer cases may be attributable to inheritance. Two sets of inherited susceptibility genes merit special attention for prostate cancer treatment. Germline defects in DNA double-strand break repair genes, such as *BRCA1*, *BRCA2*, *ATM*, *PALB2*, *FANCA*, *RAD51D*, and *CHEK2*, or in DNA mismatch repair genes, such as *MSH2*, *MLH1*, *MSH6*, and *PMS2*, may increase the risk of developing prostate cancer or of exhibiting metastatic prostate cancer progression. Defective DNA repair in prostate cells has important treatment implications. When germline DNA repair gene defects are accompanied by somatic alterations at the remaining allele, crippling of DNA double-strand break repair can serve as an indication for treatment with poly(ADP-ribose) polymerase (PARP) inhibitors, while loss of DNA mismatch repair constitutes an indication for treatment with immune checkpoint inhibitors. With a growing role in prostate cancer treatment decision making, both germline testing and tumor tissue testing for DNA repair gene defects has become increasingly common for patients with the disease. Of course, the detection of defective DNA repair genes in the germline of a patient with prostate cancer should also alert his physician to consider cascade genetic testing of relatives as abnormal repair gene carriers could be at risk for breast, ovarian, colorectal, or other cancers.
